1.01 A History of Ideas in Evolutionary Neuroscience

G F Striedter, University of California, Irvine, CA, USA

Glossary

allometry	The notion that changes in the size of an object (e.g., the body or the brain) entail predictable changes in the proportional sizes of its components. In contrast, isometric scaling involves no changes in an object's proportions.
convergence	The independent evolution of similar structures or functions from non-homologous ancestral precursors.
developmental constraint	The notion that the mechanisms of development bias the production of phenotypic variants that natural selection can act on.
encephalization	Brain size relative to what one would expect in an organism of the same type (i.e., species or other taxonomic group) and body size. Synonym: relative brain size.
heterochrony	Phylogenetic changes in the relative timing of developmental events or in the relative rates of developmental processes.
homology	The relationship between two or more characters that were continuously present since their origin in a shared ancestor. For a more detailed definition, especially for neural characters, see Striedter (1999).
mosaic evolution	The notion that, as brains evolve, individual brain regions may change in size independently of one another. In contrast, concerted evolution indicates that brain regions must change their size in concert with one another.

The field of evolutionary neuroscience is more than 100 years old, and it has deep pre-evolutionary roots. Because that illustrious history has been reviewed repeatedly (Northcutt, 2001; Striedter, 2005) and is treated piecemeal in several articles of this book, I shall not review it fully. Instead, I will discuss a selection of the field's historically most important ideas and how they fit into the larger context of evolutionary theory. I also emphasize ideas that are, or were, controversial. Specifically, I present the field's central ideas in contrast pairs, such as 'common plan versus diversity' and 'natural selection versus constraints'. This approach scrambles the chronology of theoretical developments but helps to disentangle the diverse strands of thought that currently characterize evolutionary neuroscience. It also helps to clarify which future directions are likely to be most fruitful for the field.

1.01.1 Common Plan versus Diversity

One of the most famous battles of ideas in comparative biology was that between Etienne Geoffroy St. Hilaire and George Cuvier over the existence, or not, of a common plan of construction (or Bauplan) for animals (Appel, 1987). Geoffroy was of the opinion, previously developed by Buffon (1753), that all animals are built according to a single plan or archetype, but Cuvier, France's most illustrious morphologist, recognized at least four different types. Their disagreement erupted into the public sphere when Geoffroy in 1830 endorsed the view that the ventral nerve cord of invertebrates is directly comparable (today we say 'homologous') to the spinal cord of vertebrates. Cuvier responded that Geoffroy was speculating far beyond the available data, and he reasserted publicly that the major types of animals could not be linked by intermediate forms or topological transformations. This Cuvier–Geoffroy debate was followed closely by comparative biologists all across Europe, who

were already flirting with the idea of biological evolution or, as they called it, the transmutation of species. If Cuvier was right, then evolution was impossible. On the other hand, some of Geoffroy's hypotheses (e.g., his proposal that insect legs correspond to vertebrate ribs) did seem a trifle fanciful. Thus, the Cuvier–Geoffroy debate embodied much of the ambivalence surrounding evolution in the first half of the nineteenth century.

After Darwin offered a plausible mechanism for the transmutation of species, namely, natural selection (Darwin, 1859), the idea of biological evolution took hold and, by extension, Geoffroy's ideas gained currency. Innumerable homologies were sought and, frequently, revealed (Russel, 1916). Most impressive was the discovery of extensive molecular homologies between species that span the metazoan family tree (Schmidt-Rhaesa, 2003). It was striking, for example, to discover that many of the genes critical for early brain development are homologous between insects and vertebrates (Sprecher and Reichert, 2003). Indeed, the invertebrate and vertebrate genes are sometimes functionally interchangeable (Halder *et al*., 1995; deRobertis and Sasai, 1996). Those discoveries supported Geoffroy's view that all animals were built according to a common plan, which could now be understood to be a common genetic blueprint or 'program' (Gehring, 1996). Indeed, many biologists proceeded to search for molecular genetic homologies that could reveal previously unimagined morphological homologies (Janies and DeSalle, 1999). Geoffroy would have been thrilled. There are, however, problems with the view that animals are all alike.

The most serious problem, in my view, is that homologous genes may sometimes be involved in the development of adult structures that are clearly not homologous (Striedter and Northcutt, 1991). For example, insect wings and vertebrate nervous systems both depend on *hedgehog* function for normal development, but this does not make neural tubes and insect wings homologous (Baguña and Garcia-Fernandez, 2003). Instead, findings such as this suggest that evolution tends to work with highly conserved 'master genes' (Gehring, 1996) or, more accurately, tightly knit assemblies of crucial genes (Nilsson, 2004), which it occasionally reshuffles by altering their upstream regulatory elements and/or downstream targets. Evolution is a terrific tinkerer that manages to create novelty from conserved elements. This conclusion echoes Geoffroy's arguments insofar as it acknowledges that "Nature works constantly with the same materials" (Geoffroy, 1807), but it does not mesh with the view that evolution built all animals according to a single plan. What we have, then, is at least a partial rapprochement of the positions held by Cuvier and Geoffroy: adult organisms do conform to several different body plans, but they are built by shuffling repeatedly a highly conserved set of genes (Raff, 1996). Therefore, a crucial question for research is how evolutionary changes in networks of developmentally important genes influence adult structure and function.

Implicit in the preceding discussion has been the idea that adult species differences arise because of evolutionary changes in development (Garstang, 1922). This idea is commonly accepted now, but, back in the nineteenth century, Haeckel (1889) used to promote its polar opposite, namely, the notion that phylogeny creates ontogeny (see Gould, 1977). Haeckel also promoted the idea that all vertebrates pass through a highly conserved phylotypic stage of embryonic development (Slack *et al*., 1993). Studies have, however, challenged the phylotypic stage idea by showing that the major groups of vertebrates can be distinguished at all stages of embryogenesis (Richardson *et al*., 1997). An intriguing aspect of that early embryonic variability is that it consists mainly of differences in the timing of developmental processes (Richardson, 1999). Little is known about the genes that generate those changes in developmental timing (also known as heterochrony), but some of them, at least, are likely to be fairly well conserved across species (Pasquinelli and Ruvkun, 2002). More importantly, the notion that adult diversity is based on evolution changing the temporal relationships of conserved processes represents another reconciliation of Cuvier's insistence on adult diversity with Geoffroy's belief in a common plan. Thus, the field of evolutionary developmental biology (evo-devo for short) has overcome the once so prominent dichotomy between conservation and diversity. Its major challenge now is to discover the mechanistic details of how conserved genes and processes are able to produce such diverse adult animals.

Evo-devo thinking has also invaded neuroscience, but evo-devo neurobiology still emphasizes conservation over diversity. For example, we now have extensive evidence that all vertebrate brains are amazingly similar at very early stages of development (Puelles *et al*., 2000; Puelles and Rubenstein, 2003). However, we still know very little about how and why brain development diverges in the various vertebrate groups after that early, highly conserved stage or period. Looking beyond vertebrates, we find that insect brain development involves at least some genes that are homologous to genes with similar functions in vertebrates (Sprecher and Reichert, 2003). This is

remarkable but does not prove that insects and vertebrates are built according to a common plan – if by that we mean that the various parts of adult insect brains all have vertebrate homologues. For example, the finding that several conserved genes, notably *Pax6*, are critical to eye development in both invertebrates and vertebrates, does not indicate that all those eyes are built according to a common plan. The crucial question, which we are just beginning to explore, is how the conserved genes are tinkered with (reshuffled, co-opted, or redeployed) to produce very different adult eyes (Zuber *et al*., 2003; Nilsson, 2004). This, then, seems to be the future of evo-devo neurobiology: to discover how highly conserved developmental genes and processes are used to different ends in different species. As I have discussed, this research program has ancient roots, but it is just now becoming clear.

1.01.2 *Scala Naturae* versus Phylogenetic Bush

The idea of evolution proceeding along some kind of scale from simple to complex also has pre-evolutionary roots. Aristotle, for example, ordered animals according to the degree of perfection of their eggs (see Gould, 1977). Later religious thinkers then described an elaborate scale of nature, or *scala naturae*, with inanimate materials on its bottom rung and archangels and God at the other extreme. The early evolutionists, such as Lamarck, transformed this static concept of a *scala naturae* into a dynamic phylogenetic scale that organisms ascended as they evolved. Darwin himself had doubts about arranging species on a scale, but most of his followers had no such qualms (Bowler, 1988). Even today, the phylogenetic scale is taught in many schools and it persists in medicine and academia. For example, the National Institutes of Health's (NIH) guide for institutional animal care and use still recommends that researchers, whenever possible, should work with "species lower on the phylogenetic scale" (Pitts, 2002, p. 97). On the other hand, most contemporary evolutionists have pronounced as dead both the *scala naturae* and its postevolutionary cousin, the phylogenetic scale (Hodos and Campbell, 1969). What do those modern evolutionists cite as the scales' cause of death?

One fatal flaw in the idea that species evolve along a single scale is that, as we now know, evolution made at least some species simpler than their ancestors. Salamanders, for example, are much simpler, especially in brain anatomy (Roth *et al*., 1993), than one would expect from their phylogenetic position. Even more dramatically, the simplest of all animals, the placozoans, are now thought to have evolved from far more complicated ancestors (Collins, 1998). As more and more molecular data are used to reconstruct phylogenies, it is becoming apparent that such secondary simplification of entire animals has occurred far more frequently than scientists had previously believed (Jenner, 2004) – perhaps because they were so enamored of the phylogenetic scale. A second major problem with *scala naturae* thinking is that the order of species within the scale depends on which organismal features we consider. For example, many fishes would rank higher than mammals if we based our scale on skull complexity, which was reduced dramatically as early mammals evolved (Sidor, 2001). Similarly, dolphins rank high if we look only at brain size, but relatively low if we consider neocortical complexity, which was reduced as the toothed whales evolved (Morgane and Jacobs, 1972). Most people tacitly agree that 'higher animals' are warm-blooded, social, curious, and generally like us, but once we try to be more objective, the single 'chain of being' (Lovejoy, 1936) fractionates into a multitude of different chains, none of which has any special claim to being true.

This multiple-chains idea becomes self-evident once we have grasped that species phylogenies are just like human family trees; they are neither ladders, nor trees with just a single trunk, but bushes or tumbleweeds (Striedter, 2004) with branches growing in divergent directions. Within a given branch, or lineage, complexity may have increased at some points in time and decreased at others, but even if complexity increased more frequently than it decreased, the overall phylogeny would fail to yield a single scale, because complexity tends to increase divergently in different lineages. For example, bats, honeybees, and hummingbirds are all incredibly complex, compared to their last common ancestor, but they are each complex in different ways. Of course, we can pick one parameter and build a scale for that – we can, for instance, compare the ability of bats, honeybees, and hummingbirds to see ultraviolet (UV) radiation – but different parameters might well yield different scales. Simply put, changes that occurred divergently in different lineages will not, in general, produce a single overarching scale. This insight is old hat to evolutionary biologists, but news to many neuroscientists (Hodos and Campbell, 1969). In part, therefore, the persistence of *scala naturae* thinking in the neurosciences reflects a lack of proper training in contemporary evolutionary theory. In addition, I suspect that human minds possess a natural tendency for ordering disparate items linearly. Such a bias would be useful in many contexts, but it would make it

difficult to comprehend (without training) the divergent nature of phylogeny.

Although *scala naturae* thinking persists in neuroscience generally, evolutionary neuroscientists have labored to expunge its ghost. For example, a consortium of 28 comparative neurobiologists revised the nomenclature of avian brains to replace the terms *neo*striatum, *archi*striatum, and *paleo*striatum – which suggested that brains evolved by the sequential addition of new brain regions – with terms devoid of *scala naturae* overtones (Reiner *et al.*, 2004a, 2004b; Jarvis *et al.*, 2005). Some of the replacement names are terms that were already used for brain regions in other vertebrates; they reflect our current understanding of homologies. However, some of the new terms – e.g., nidipallium and arcopallium – are novel and intended to apply exclusively to birds. These novel names were coined because bird brains, particularly bird forebrains, have diverged so much from those of other vertebrates (including reptiles) that strict one-to-one homologies are difficult, if not impossible, to draw for several regions (Striedter, 1998, 1999). Thus, the revised terminology reflects a new consensus view that avian brains did not evolve by the sequential addition of new brain areas, yet also reminds us that bird brains are full of features that evolved quite independently of those that feature in mammalian phylogeny. In other words, the new terminology avoids *scala naturae* overtones and, instead, combines the notion of a common plan with that of divergent complexity.

As comparative neurobiologists reject the notion of a *scala naturae*, they stand to lose a central part of their traditional justification for working on nonhuman brains. No longer can they argue that research on other brains must be useful because nonhuman brains are always simpler, and therefore easier to comprehend, than human brains. Instead, they must admit that some nonhuman brains are stunningly complex and, more importantly, that their phylogenetic paths toward complexity diverged from the primate trajectory. That is, complex bird, fish, or insect brains are not mere steps along the path to human brains, but the outcome of divergent phylogenies (see Evolution of the Nervous System in Fishes, Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?, Evolution of Color Vision and Visual Pigments in Invertebrates). Does this suggest that research on nonhuman brains should cease to be funded? I do not think so, but the justification for working on nonhuman brains ought to be tweaked.

One obvious alternative justification is that all brains are likely to share some features, especially if they come from close relatives. Another good justification for research on nonhuman brains is that, compared to human brains, the former are much more amenable to physiological and anatomical research. This line of justification assumes that the model differs from the target system only in those respects that make the model easier to study, and not in the respects that are modeled – an assumption that sometimes fails. It now appears, for example, that the auditory system of owls, which was generally regarded as an ideal model for sound localization in vertebrates, exhibits some highly specialized features (McAlpine and Grothe, 2003). This finding, at first glance, suggests that research on bird brains is wasteful, but this is a simplistic view. Research on the owl's auditory system has taught us much about how neurons compute behaviorally relevant information and it serves as an invaluable reference against which we can compare sound processing in other species, including humans. Furthermore, some differences between a model and its target can lead to surprising discoveries. Much might be gained, for example, from studying why some nonhuman brains are far more capable than primate brains of repairing themselves (Kirsche and Kirsche, 1964). Thus, model systems research can be useful even if the model is imprecise. A third, less frequently discussed, justification for examining the brains of diverse species is that comparative research can bring to light convergent similarities, which in turn might reveal some principles of brain design. For example, the discovery that olfactory systems in both vertebrates and many different invertebrates exhibit distinctive glomeruli strongly suggests that those glomeruli are needed for some critical aspects of odorant detection and analysis (Strausfeld and Hildebrand, 1999).

Therefore, research on nonhuman brains need not be justified in terms of a presumed phylogenetic scale. Instead, comparative neurobiology is valuable because (1) all brains are likely to share some features, (2) nonhuman brains are more amenable to some types of research, and (3) the study of diverse nonhuman brains can lead to the discovery of design rules for brains. Historically, only the first of these alternatives has been widely discussed, but all are logically sound, and none depend on the existence of a *scala naturae*.

1.01.3 Relative Size versus Absolute Size

The most obvious difference between species is that they differ enormously in size. Because life began with tiny organisms, evolutionary increases in body size must have outnumbered or outpaced the decreases. This is true of organisms generally, but it

also holds for several individual lineages, including mammals and, within mammals, primates (Stanley, 1973; Alroy, 1998). The most fascinating aspect of those changes in body size is that they involved much more than the isometric scaling up or down of the ancestral condition; they involved allometric changes in the proportions of body parts and physiologic processes. For example, skeletal mass increases disproportionately with increasing body size, whereas heart rate decreases. Countless studies – on both vertebrates and invertebrates – have documented these allometries and explored their functional implications (Calder, 1984; Schmidt-Nielsen, 1984).

Much less is known about the causes of allometry. Studies on allometry in insects showed that some scaling relationships are readily modifiable by natural or artificial selection (see Emlen and Nijhout, 2000; Frankino *et al*., 2005). This finding suggests that even tight scaling laws are not immutable, which would explain why many traits scale differently (e.g., with different exponents) in different taxonomic groups (Pagel and Harvey, 1989). A very different, more theoretical line of research has shown that numerous allometries, specifically those with power law exponents that are multiples of 1/4, may have evolved because the optimal means of delivering metabolic energy to cells is through an hierarchically branching, fractal network of vessels whose termini (e.g., capillaries) are body size-invariant (West *et al*., 1997; Savage *et al*., 2004; West and Brown, 2005). This theory is mathematically complex and still controversial (Kozlowski and Konarzewski, 2004; Brown *et al*., 2005; Hoppeler and Weibel, 2005), but it is elegant. Furthermore, because the theory of West *et al*. is based in part on the assumption that natural selection optimizes phenotypes, it is consistent with the aforementioned finding that allometries are modifiable by selection. However, West *et al*.'s (1997) theory cannot explain (or does not yet explain) why some organs, such as the brain, scale with exponents that are not multiples of 1/4. Nor can it easily explain taxonomic differences in scaling exponents. Thus, the causal – physiological and/or developmental – bases of allometry are coming into focus but remain, for now, mysterious.

Brain scaling, in particular, remains quite poorly understood (see Principles of Brain Scaling, Scaling the Brain and Its Connections, How to Build a Bigger Brain; Cellular Scaling Rules for Rodent Brains). The discovery that brains become proportionately smaller with increasing body size dates back to the late eighteenth century (Haller, 1762; Cuvier, 1805–1845). Since then, numerous studies have documented brain allometry in all the major groups of vertebrates (Deacon, 1990a; van Dongen, 1998) and even some invertebrates (Julian and Gronenberg, 2002; Mares *et al*., 2005). Generally speaking, those studies confirmed that in double logarithmic plots of brain size versus body size, the data points for different species within a given lineage tend to form a reasonably straight line, indicating the existence of a simple power law. The slope of those best-fit lines are almost always less than 1, which reflects the aforementioned fact that brains generally become proportionately smaller with increasing body size. The large body of work on brain–body scaling further revealed that data points for different taxonomic groups often form lines with similar slopes but different y intercepts. These differences in y intercepts are known as differences in relative brain size or encephalization. They seriously complicate efforts to draw a single allometric line for any large taxonomic group (Pagel and Harvey, 1989), but they allow us to identify evolutionary changes in relative brain size among some smaller taxonomic groups. For example, they allow us to determine that relative brain size increased with the origin of mammals, with the origin of primates, several times within primates, with the origin of the genus *Homo*, and, last but not least, with the emergence of *Homo sapiens* (see Primate Brain Evolution in Phylogenetic Context, The Hominin Fossil Record and the Emergence of the Modern Human Central Nervous System, The Evolution of Human Brain and Body Growth Patterns). Overall, such phylogenetic analyses suggest that, among vertebrates, relative brain size increased more frequently than it decreased (Striedter, 2005).

Enormous effort has gone into determining the functional significance of evolutionary changes in brain–body scaling. Darwin, for example, had argued that relative brain size is related to "higher cognitive powers" (Darwin, 1871), but defining those powers and comparing them across species has proven difficult (Macphail, 1982). Consequently, most subsequent investigators shied away from the notion of general intelligence, or 'biological intelligence' (Jerison, 1973), and focused instead on more specific forms of higher cognition. Parker and Gibson (1977), for example, proposed that a species' degree of encephalization is related to its capacity for extracting nutritious fruits and nuts from their protective shells. Several authors have stressed correlations between brain size and 'social intelligence' (Byrne and Whiten, 1988; Dunbar, 1998; Reader and Laland, 2002). Collectively, these studies reinforced the sense that relative brain size is, somehow, related to some forms of intelligence. However, relative brain size also correlates with several other attributes, such as longevity, home-range size, diet, and metabolic rate (for a review, see van Dongen, 1998). The latter correlations, with diet and metabolism, have received

particularly lavish attention (Martin, 1981; McNab, 1989; Aiello and Wheeler, 1995). Paradoxically, the discovery of so many correlations has led some evolutionary neuroscientists to despair: there are too many correlates of relative brain size, and many of them come and go, depending on which taxonomic group is being examined and which statistical methods are used for the analyses (e.g., Bennet and Harvey, 1985; Iwaniuk *et al.*, 1999; Deaner *et al.*, 2000; Beauchamp and Fernández-Juricic, 2004; Jones and MacLarnon, 2004; Martin *et al.*, 2005). Too many contested hypotheses, too little certitude.

There is not much clarity on why brains scale so predictably with body size. Early workers argued that brains generally scale against body size with a power law exponent close to 2/3 because the brain's sensory and motor functions were related to the body's surface area, which presumably scales with that same exponent (Snell, 1891; Jerison, 1973). According to this view, brain sizes in excess of that predicted by the 2/3 power law are due to increases in the brain's nonsomatic, cognitive regions. This would explain the correlations between relative brain size and some forms of intelligence. Unfortunately, there are two major problems with this view. First, brain–body scaling exponents often differ substantially from 2/3 (van Dongen, 1998; Nealen and Ricklefs, 2001). The second problem is that the brain's more cognitive regions also scale predictably with body size (Fox and Wilczynski, 1986), undermining the assumption that brains are divisible into regions that scale with body size and regions that do not. Therefore, the excess neuron hypothesis (Striedter, 2005) is dead. In searching for an alternative, some have suggested that brain–body allometry is linked to the scaling of metabolic rates. This hypothesis is based on the observation that, in at least some taxonomic groups, brain size and basal metabolic rate scale against body size with similar exponents (Martin, 1981; Mink *et al.*, 1981). However, other studies have shown that the correlation between brain size and metabolism is not tight, once the mutual correlation with body size is factored out (McNab, 1989). This correlational slack presumably arises because species differ in how much of the body's total energy supply they deliver to the brain (Aiello and Wheeler, 1995; Kaufman, 2003), but this just underscores that relative brain size is not so tightly linked to metabolic rate.

Overall, the lack of clarity on what causes brains to scale predictably with body size, and how to interpret deviations from the scaling trends, has caused interest in relative brain size to fade. Increasingly, evolutionary neuroscientists have turned away from relative brain size and asked, instead, how the size of individual brain regions correlates with various behavioral parameters (Harvey and Krebs, 1990; see Brain Size in Primates as a Function of Behavioral Innovation, Mosaic Evolution of Brain Structure in Mammals). This shift in research strategy makes sense, because, after all, the brain is functionally heterogeneous. However, even studies that focus on correlations between single brain areas and specific behaviors – some refer to them as neuroecological studies – are controversial because: (1) the behavioral parameters are difficult to quantify and/or define (Bolhuis and Macphail, 2001), (2) neuronal structure–function relationships are complex and often poorly understood, (3) it is difficult to decide *a priori* whether one should correlate behavioral parameters against a region's absolute size, its proportional size, or its size relative to expectations (Striedter, 2005), and (4) the methods for establishing statistically significant correlations in phylogenetic data remain debatable (Felsenstein, 1985; Garland *et al.*, 1992; Smith, 1994; Martin *et al.*, 2005). Brave neuroscientists are continuing to tackle those problems, but the larger problem of how to deal with relative brain size – how to find its causes and its functional significance – is fading from view. Perhaps we need a new approach to understanding relative brain size – perhaps one that is linked more directly to the physiological and geometric properties of brains (West and Brown, 2005) – but this novel direction is not yet apparent.

As interest in relative brain size waned, interest in absolute brain size waxed, mainly because many of the brain's internal structural and functional features turn out to scale predictably with absolute brain size. Best studied is the phenomenon of size-related shifts in brain region proportions (Sacher, 1970; Finlay and Darlington, 1995). In mammals, for example, the neocortex becomes disproportionately large as absolute brain size increases, whereas most other regions become disproportionately small. A second interesting scaling law is that a brain's degree of structural complexity tends to increase with absolute brain size. Within the neocortex, for example, the number of distinct areas increases predictably with neocortex size (Changizi and Shimojo, 2005). A third fascinating aspect of brain scaling is that the amount of white matter within mammalian brains scales allometrically with absolute brain size (Ringo, 1991; Zhang and Sejnowski, 2000). This connectional allometry, taken together with the fact that synapse size and density are relatively size-invariant, indicates that brains become less densely interconnected, on average, as they increase in size (Stevens, 1989; Deacon, 1990a, 1990b; Striedter, 2005; see Scaling the Brain and Its Connections). All of this signifies that brains change structurally in many ways as they vary in absolute size. Many of those changes have clear functional

implications. For example, it has been suggested that, as hominid brains increased in size, the axons interconnecting the two cerebral hemispheres became so sparse and long that the hemispheres became less capable of interacting functionally, which led to an increase in functional asymmetry (Ringo *et al*., 1994; see Cortical Commissural Connections in Primates, The Evolution of Hemispheric Specializations of the Human Brain). Considerations such as these suggest that absolute brain size is a much better predictor of brain function than relative brain size, at least among close relatives (Striedter, 2005).

In retrospect, we can say that evolutionary neuroscientists historically have overemphasized relative brain size. As Dunbar (2006) put it, comparative neurobiologists have too long been "dragooned into worrying about relativizing brain size by a very peculiar view that body size must be the default determinant of brain volume." Can we explain this undue emphasis? Partly, evolutionary neuroscientists may have worried that focusing on absolute brain size and linking it to higher cognitive powers would force us to conclude that whales and elephants, with their enormous brains, are smarter than humans (see Cetacean Brain Evolution, Evolution of the Elephant Brain: A Paradox between Brain Size and Cognitive Behavior). This is a valid concern, for few would doubt that humans are – or at least can be – the most intelligent creatures on earth. However, whales and elephants are behaviorally complex, and humans may well be special because they are unique in possessing symbolic language (Macphail, 1982). Furthermore, it seems to me that large whales, with large brains, are more intelligent (both socially and in their hunting strategies) than dolphins or small whales. This hypothesis remains to be tested, but it points to a strategy for reconciling absolute and relative brain size: among close relatives, comparisons of absolute brain size are most informative, but in comparisons of distant relatives (e.g., whales and humans), relative brain size is a more potent variable (Striedter, 2005). This view is consistent with the finding that, among primates, social group size correlates more strongly with absolute brain size than with relative brain size (Kudo and Dunbar, 2001; Striedter, 2005). It also serves as a productive counterweight to the field's traditional, almost exclusive emphasis on relative brain size.

1.01.4 Natural Selection versus Developmental Constraints

Darwin's theory of natural selection entails two main components, namely, that (1) organisms produce offspring with at least some heritable variation and (2) that organisms generally produce more offspring than their environment is able to sustain. Given those two components, some variants are bound to be fitter than others in the sense that their offspring are more likely to survive and produce offspring. This difference, in turn, will cause the heritable traits of the fitter variants to spread in the population. Given this, Darwin's most "dangerous idea" (Dennett, 1995), one can explain an organism's attributes in terms of the selective pressures that promoted their spread and, hence, their current existence. An enormous number of such adaptational explanations have been proposed. Many stress that natural selection optimized features for specific functions; others emphasize that natural selection tends to produce optimal compromises between competing functions and/or costs (Maynard Smith, 1982). Generally speaking, the explanatory power of these adaptational explanations derives solely from natural selection's second step, the sorting of offspring. Generation of the variants that are sorted is usually assumed to be random and, hence, irrelevant to explanations of the phenotype. This 'adaptationist paradigm' (Gould and Lewontin, 1979) has dominated evolutionary theory for most of its history.

In the 1970s and 1980s, however, the adaptationist paradigm was challenged by authors who stressed that the variants available to natural selection may not really be random (Gould and Lewontin, 1979; Alberch, 1982; Maynard Smith *et al*., 1985). Central to those challenges was the idea that, even if mutations are random at the genetic level, those random genetic mutations are channeled, or filtered, through mechanisms of development that favor the emergence of some phenotypes. Some structures may be impossible for embryos to develop; others are likely to emerge (Alberch, 1982). If this is true, then natural selection chooses not among a random selection of phenotypes but from a structured set that is determined, or at least biased, by the mechanisms of development. This idea is important, because it suggests that development constrains the power of natural selection to set the course of evolutionary change. It threatens natural selection's widely assumed omnipotence. Some authors carried this threat so far as to exhort biologists to halt their search for adaptive scenarios and to research, instead, the 'generative' mechanisms of development (Goodwin, 1984). Fortunately, most evolutionary biologists today seek a more balanced rapprochement of embryology and evolutionary biology (Gilbert *et al*., 1996; Wagner and Laubichler, 2004).

Specifically, evo-devo biologists today tend to accept the concept that natural selection is the most prominent determinant of who thrives and

who dies, no matter how constrained development might be. They also tend to stress that development itself is subject to descent with modification – i.e., evolution – which means that even fairly tight constraints can change. Therefore, explanations couched in terms of natural selection are not antithetical to those involving developmental constraints, but complementary (Striedter, 2005). Still, the synthesis of natural selection and developmental constraints remains uncertain in one key respect: what if the mechanisms of development were shaped by natural selection to produce variants that are much fitter than one would expect by chance? Then the distinction between the generative and selective components of natural selection (see above) would blur. The developmental production of variants would no longer be random with respect to a species' ecology. This hypothesis, which was pushed furthest by Riedl (1977), is interesting and potentially profound, but not yet supported by much evidence.

Brains were historically considered to be shaped by natural selection, unencumbered by developmental constraints. In general, the size and structure of both entire brains and individual brain regions were thought to be optimized. Jerison (1973, p. 8), made this idea explicit when he wrote that "the importance of a function in the life of each species will be reflected by the absolute amount of neural tissue of that function in each species." How development produced that fine-tuning was never specified. Presumably, the idea was that genetic mutations could vary the size and structure of individual brain regions freely, leading to steady improvements in fitness until an optimum was reached. Little thought was given to the possibility that brains might be constrained in how they could evolve. However, a few authors proposed that trophic dependencies between interconnected brain regions might cause entire circuits or systems to change size in unison rather than piecemeal (Katz and Lasek, 1978). Such 'epigenetic cascades' (Wilczynski, 1984) might channel evolution (Katz *et al*., 1981), but they would not constrain natural selection, because the cascades help to optimize functional brain systems by matching the size of interconnected neuronal populations. That is, epigenetic cascades act not against, but in conjunction with, the optimizing power of natural selection; they are not classical constraints, which may explain why they have rarely been discussed (Finlay *et al*., 1987).

The idea of brains evolving under a restrictive developmental rule was proclaimed forcefully by Finlay and Darlington (1995). Their argument was founded on the observation that the various major brain regions in mammals scale against absolute brain size with different allometric slopes (Sacher, 1970; Gould, 1975; Jerison, 1989). Although this finding was well established at the time, it had not been explained; it was a scaling rule without a cause. Finlay and Darlington's major contribution was to propose that the height of a region's allometric slope was related to the region's date of birth (i.e., the time at which the region's precursor cells cease to divide), with late-born regions tending to become disproportionately large with increasing brain size. Why does this relationship exist? Finlay and Darlington (1995) showed that their late-equals-large rule emerges naturally if neurogenetic schedules (i.e., the schedules of what regions are born when) are stretched as brains increase in size and compressed when they shrink. This insight, in turn, prompted Finlay and Darlington to hypothesize that brain evolution is constrained to stretch or compress neurogenetic schedules and cannot, in general, delay or advance the birth of individual regions. In other words, even if evolution 'wanted' to increase the size of only one brain region, it would be 'forced' to change also the size of many other brain regions. Thus, Finlay and Darlington argued that development constrains brains to evolve concertedly, rather than mosaically.

Finlay and Darlington's developmental constraint hypothesis has been challenged by various authors, who all pointed out that brains do sometimes evolve mosaically (Barton and Harvey, 2000; Clark *et al*., 2001; de Winter and Oxnard, 2001; Iwaniuk *et al*., 2004; Safi and Dechmann, 2005). In addition, Barton (2001) has argued that correlations between region size and absolute brain size are due to functional requirements, rather than developmental constraints. Specifically, Barton (2001, p. 281) reported that the sizes of interconnected brain regions in what he called a functional system exhibited "significantly correlated evolution after taking variation in a range of other structures and overall brain size into account." Finlay *et al*. (2001) countered that such system-specific evolution may indeed occur, particularly for the so-called limbic system (see also Barton *et al*., 2003), but that this does not negate the existence of developmental constraints. In a review of this debate, I concluded that most of it may be resolved by arguing that instances of mosaic (and/or system-specific) evolution occur against a background of concerted, developmentally constrained evolution (Striedter, 2005; see Mosaic Evolution of Brain Structure in Mammals). Both Finlay and Barton seem open to this kind of rapprochement (Finlay *et al*., 2001; Barton, 2006).

The debate on mosaic versus concerted evolution highlights how little we know about the evolution of

neural development or, for that matter, about the role that natural selection played in shaping brains. The developmental data used to support Finlay *et al.*'s (2001) hypothesis came from just 15 species and were collected by several different laboratories, using diverse methodologies. Moreover, the data are limited to dates of neurogenesis. We know virtually nothing about species differences (or similarities) in how large brain regions are prior to neurogenesis, how quickly the regions grow, or how much cell death they endure. Data on these other, relatively neglected aspects of brain development might reveal additional constraints, and they might clarify how regions can evolve mosaically even if neurogenetic schedules are conserved.

Similarly lacking are data on natural selection and the brain. Although several analyses have shown that the size of some brain regions (relative to absolute brain size) correlates with aspects of a species' behavior or ecology (e.g., Clark *et al.*, 2001; de Winter and Oxnard, 2001; Iwaniuk *et al.*, 2004), such correlations are only indirect evidence for natural selection. More direct data are difficult to gather, because direct demonstrations of natural selection at work require measurements of heritability and fitness functions. As it is, we know so little about how selection acts on brains that debates on its potency are bound to erupt. Clearly, more studies must be performed before we can reach firm conclusions about which aspects of brain development and evolution are tightly constrained and which are subject to specific selective pressures.

1.01.5 One Law, Many Laws, or None

Is human history explicable in terms of general principles or laws? This question has been debated extensively. Some scholars insist that history is based largely on a few major laws, playing out against a background of far less important noise. Others argue, instead, that history is so full of contingencies (or accidents) that general or universal laws are blown to bits. I am not competent to review this debate but find myself most sympathetic to the intermediate position taken by Hempel (1942) in his call for a nomological–deductive approach to history. Basically, Hempel argued that historical events can be explained only by reference to various general (deterministic or probabilistic) laws that causally link preceding events or conditions to the event being explained. For example, an account of why an automotive radiator cracked during a frost would involve both historical contingencies and general laws relating temperature to pressure (Hempel, 1942). Similarly, events in human history can be explained by "showing that the event in question was not 'a matter of chance', but was to be expected in view of certain antecedent or simultaneous conditions" (Hempel, 1942) and the operation of several, often implicitly assumed, general laws. This nomological–deductive methodology waxes and wanes in popularity (Kincaid, 1996; McIntyre, 1996), but it seems logical in principle. Naturally, one may debate whether human behavior is predictable enough to yield the kind of laws that are needed for nomological–deductive explanations (Beed and Beed, 2000).

Evolutionary biologists have likewise debated the role of general laws in explaining the past, which in their realm is phylogeny. Some have argued that natural selection is a universal law that can be used to explain the emergence of many, if not most, biological features. Others have countered that natural selection is a mathematical truth, rather than an empirically determined law (Sober, 2000). More importantly, many biologists have pointed out that the results of natural selection are not highly predictable. Gould (1989) made this argument when he declared that rewinding the tape of life on earth and playing it again would not lead to a repeat performance. Biological history is full of accidents, of happenstance. Therefore, Gould argued, evolutionary explanations must be crafted one event at a time, without recourse to general laws. On the other hand, Gould did grant that evolution is constrained by diverse physical principles, by rules of construction and good design, and by some scaling rules (Gould, 1986, 1989). In his view, "the question of questions boils down to the placement of the boundary between predictability under invariant law and the multifarious possibilities of historical contingency" (Gould, 1989, p. 290). Gould placed this boundary "so high that almost every interesting event of life's history falls into the realm of contingency" (Gould, 1989, p. 290). This appears to be an extreme position, for many other evolutionary biologists place that same boundary lower. They tend to be far more impressed than Gould by the degree of convergent evolution in the history of life (Carroll, 2001; Willmer, 2003). They look, for example, at the convergent similarities of eyes in vertebrates and octopi and conclude that some design rules for eyes exist. In sum, disagreements persist about the placement of Gould's boundary between predictability and contingency, but most biologists accept that evolutionary explanations must involve at least some causal laws (Bock, 1999).

Given this context, it is not surprising that neuroscientists are conflicted about the importance of

general laws for explaining the evolutionary history of brains. Marsh (1886) had proposed that brains consistently increase in size over evolutionary time, but later authors vehemently disagreed (see Jerison, 1973; Buchholtz and Seyfarth, 1999). Personally, I think that Marsh did have a point, for brain and body size have both increased, at least on average, in several vertebrate lineages (see Striedter, 2005). Still, Marsh's laws were merely descriptions of phylogenetic trends, not causal laws. The first explicitly causal law of brain evolution was Ariëns Kappers' (1921) law of neurobiotaxis, which states that cell groups in evolution tend to move toward their principal inputs. Unfortunately for Ariëns Kappers, later studies showed that cell groups do not move quite so predictably and called into question some of the mechanisms that supposedly produced neurobiotaxis. The next major putative law of brain evolution was Ebbesson's (1980) parcellation principle, which states that brains become more complex by the division of ancestrally uniform cell groups into daughter aggregates that selectively lose some of their ancestral connections. This principle was strenuously criticized by most comparative neuroanatomists, mainly because its empirical foundation was shaky (see Ebbesson, 1984). Although a weak version of Ebbesson's theory, stating merely that brains become less densely connected as they increase in size, is probably defensible (Deacon, 1990a; Striedter, 2005), the strong version of Ebbesson's original idea has failed the test of time: plenty of data now show that brains evolve not only by the loss of connections, but also by creating novel projections.

Confronted with this abundance of failed brain evolution laws, most evolutionary neuroscientists have emphasized only a single, undisputed regularity of brain evolution, namely, that numerous aspects of brain structure and function are highly conserved across species. Specifically, they focused, á la Geoffroy St. Hilaire, on the existence of common plans of construction and highlighted molecular homologies between invertebrates and vertebrates (see above). This has been productive. It is important to note, however, that the principle of phylogenetic conservation predicts stability and does not deal explicitly with change. Is brain phylogeny subject to just a single law, which states that brains change little over time? Or are there also laws of evolutionary change in brains? I affirmed the second possibility (Striedter, 2005), but laws of evolutionary change in brains are no doubt difficult to find. C. J. Herrick, a founding father of evolutionary neuroscience, put it well:

> Most scientific research has been directed to the discovery of the uniformities of nature and the codification of these in a system of generalizations. This must be done before the changes can be interpreted. The time has come to devote more attention to the processes and mechanisms of these changes… but it is much more difficult to find and describe the mechanisms of … [the] apparently miraculous production of novelties than it is to discover the mechanical principles of those repetitive processes that yield uniform products (Herrick, 1956, p. 43).

The last few years have seen an uptick in the number of studies that address evolutionary change and novelty in brains (Aboitiz, 1995; Catania *et al*., 1999; Rosa and Tweedale, 2005), and modern research on brain scaling and developmental constraints (see above) has advanced our understanding of the regularities that lurk within brain variability. In addition, a rapidly increasing number of studies is beginning to reveal genomic changes that are probably linked to changes in brain size and/or structure (e.g., Dorus *et al*., 2004; Mekel-Bobrov *et al*., 2005). Therefore, the time Herrick discussed, when evolutionary change becomes a focus of analysis (see also Gans, 1969), is probably at hand.

Thus, I envision a future in which most evolutionary neuroscientists will embrace many different laws, some dealing with constancy and some with change. A few philosophers of science (e.g., Beatty, 1995) might decry such a vision, because they think that any natural law deserving of its name must apply universally, in all contexts and without room for other, countervailing laws. I have no training in philosophy, but think that all scientific laws apply only in specified domains and given assumptions (Striedter, 2005). In the real world, particularly in the complex world of biological systems, most laws or principles are sometimes excepted. This does not make them useless but, instead, prompts us to ask what causes the observed exceptional cases (West and Brown, 2005). If we understand the causal basis of our laws, then the exceptions should, with further work, become explicable. In other words, I think that evolutionary neuroscientists can fruitfully avail themselves of Hempel's nomological–deductive approach to history. To some extent, they always have.

1.01.6 Conclusions and Prospects

In summary, the history of evolutionary neuroscience features some serious missteps, such as the idea that brains evolved in a phylogenetic series and Ariëns Kappers' law of neurobiotaxis, but it also reveals considerable progress. The *scala naturae* has ceased to guide the research of evolutionary neuroscientists

and the idea of neurobiotaxis has quietly disappeared. The once stagnant field of brain allometry is showing signs of revival, largely because of new statistical techniques and a new emphasis on absolute brain size. The debate about concerted versus mosaic evolution persists, but directions for rapprochement are emerging. In general, the field has flirted with a broad variety of theoretical ideas and found some of them wanting and others promising. In terms of theory, the field is still quite young, but it is poised to mature now.

Predicting directions of growth for any science is problematic, but I believe that most future developments in evolutionary neuroscience will parallel developments in other, non-neural domains of evolutionary biology. After all, the history of evolutionary neuroscience is full of ideas that originated in non-neural areas of biology. For example, the methodology of phylogenetic reconstruction or cladistics (which I did not discuss in this article but have treated elsewhere; see Striedter, 2005) was originally developed by an entomologist (Hennig, 1950; see also Northcutt, 2001). Similarly, evolutionary developmental biology was burgeoning before it turned to brains (Hall, 1999). Therefore, I think it likely that the future of evolutionary neuroscience has already begun in some non-neural field. Maybe molecular genetics, with its new emphasis on evolutionary change (Dorus *et al*., 2004), will soon take center stage. Maybe the excitement about linking physiological allometries to metabolic parameters (West and Brown, 2005) will infect some mathematically inclined evolutionary neuroscientists. Or perhaps the next big thing in evolutionary neuroscience will be microevolutionary studies that integrate across the behavioral, physiological, and molecular levels (Lim *et al*., 2004). Maybe the future lies with computational studies that model *in silico* how changes in neuronal circuitry impact behavior (e.g., Treves, 2003). It is hoped that all of these new directions – and more – will bloom. If so, the field is headed for exciting times.

On the other hand, evolutionary neuroscientists are still struggling to make their findings relevant to other neuroscientists, other biologists, and other taxpayers (see Relevance of Understanding Brain Evolution). It may be interesting to contemplate the evolution of our brains, or even the brains of other animals, but can that knowledge be applied? Does understanding how or why a brain evolved help to decipher how that same brain works or, if it does not work, how it can be repaired? Are advances in evolutionary neuroscience likely to advance some general aspects of evolutionary theory? All of these questions remain underexplored (see Bullock, 1990).

Near the end of the nineteenth century, Jackson (1958) attempted to apply evolutionary ideas to clinical neurology, but his efforts failed. It has been pointed out that some species are far more capable than others at regenerating damaged brain regions (e.g., Kirsche and Kirsche, 1964) and that nonhuman apes tend not to suffer from neurodegenerative diseases such as Alzheimer's (Erwin, 2001). Such species differences in brain vulnerability and healing capacity might well help us elucidate some disease etiologies or lead to novel therapies. Unfortunately, this research strategy has not yet succeeded. Thus far, evolutionary neuroscience's most important contribution has been the discovery that human brains differ substantially from other brains, particularly nonprimate brains, which means that cross-species extrapolations must be conducted cautiously (Preuss, 1995). This is an important message, but it can be construed as negative in tone. Hopefully, the future holds more positive discoveries.

Work on justifying evolutionary science is especially important in the United States, where anti-evolutionary sentiment is on the rise. Many conservative Christians believe that evolution is a dangerous, insidious idea because it makes life meaningless (Dennett, 1995). Add to this fear the notion that our thoughts and feelings are mere products of our brains (e.g., Dennett, 1991) and evolutionary neuroscience seems like a serious threat to God's supremacy. Although this line of argument is well entrenched, Darwin and most of his immediate followers were hardly atheists (Young, 1985). Instead, they either distinguished clearly between God's words and God's works, as Francis Bacon put it, or argued that God's creative act was limited to setting up the laws that control history. Either way, God was seen as quite compatible with evolutionary theory. Moreover, Darwin's view of life need not produce a meaningless void. Instead, it helps to clarify our relationships with other humans, other species, and our environment. Those relationships, in turn, give meaning to our lives, just as linguistic relationships give meaning to our words. Thus, Darwin knew – and we would do well to recall – that evolutionary biology can be useful even if it yields no direct medical or technological applications. Even Huxley (1863), who was a very pragmatic Darwinian and coined the word 'agnostic', knew that the uniquely human quest to comprehend our place in nature is not driven by mere curiosity or technological imperatives, but by a profound need to understand ourselves, our purpose, our existence. Within that larger and enduring enterprise, evolutionary neuroscience will continue to play a crucial role.

1.02 Metazoan Phylogeny

R A Jenner, University of Bath, Bath, UK

Glossary

apomorphy An evolutionarily derived character or character state, an evolutionary novelty. An autapomorphy refers to a derived character or character state unique for a single taxon; a synapomorphy refers to a shared derived character or character state possessed by at least two taxa.

body plan Set of characters primitively shared by the members of a clade, irrespective of taxonomic level. These characters both include ancestrally inherited plesiomorphies and newly evolved apomorphies for that clade.

clade Monophyletic taxon, all descendants from a most recent common ancestor.

coelom Internal body cavity lined by a mesodermally derived epithelium.

crown group A clade of extant taxa, as distinct from a stem group (see also 'stem group').

eumetazoa Metazoa minus Porifera (traditionally Eumetazoa also excluded Placozoa, but new molecular findings indicate a less basal position of Placozoa).

grade A paraphyletic group of taxa.

homoplasy Independently evolved, nonhomologous features, such as convergences and independent losses.

Hox genes Important developmental regulatory genes involved in specifying positional information along animal body axes, including appendages.

monophyletic Having a single evolutionary origin. A monophyletic taxon includes an ancestor and all its descendants. See also 'paraphyletic'.

paraphyletic Having a single evolutionary origin, but differing from a monophyletic taxon by including an ancestor, but only a subset of its descendants.

phylum Highest Linnean category for classification of animals.

plesiomorphy Ancestral character or character state.

sister taxon The closest relative of a given taxon.

stem group A clade or grade of extinct taxa, as distinct from a crown group.

synapomorphy See 'apomorphy'.

1.02.1 Introduction to Metazoan Phylogeny

This article provides an outline of our current understanding of the phylogeny of the kingdom Metazoa, which comprises all multicellular animals (most authors equate Metazoa with Animalia, but a few apply the latter name to a more inclusive group of Metazoa plus Choanoflagellata, the most likely sister taxon of animals). Metazoan phylogenetics has a long pedigree. The first generation of evolutionary biologists in the period immediately following the publication of Charles Darwin's *On the Origin of Species* enthusiastically embarked upon the challenging task of reconstructing the genealogy of life (Bowler, 1996). The influential research program of evolutionary morphology that was established by Ernst Haeckel and Carl Gegenbaur at the University of Jena in Germany

had an especially prominent place at the cradle of metazoan phylogenetics as they and their followers brought both anatomical and developmental evidence to bear on the problems of animal phylogeny.

However, after a strong start in the last decades of the nineteenth century during which phylogenetic research virtually came to define evolutionary biology, interests in reconstructing the phylogeny of life diminished concomitant with a surge to embrace a more experimental approach to biological questions (see Relevance of Understanding Brain Evolution, Evolutionary Neuroethology – A Case Study: Origins and Evolution of Novel Forms of Locomotion in Hippid Sand Crabs (Malacostraca, Decapoda, Anomala).

Yet, although metazoan phylogenetics became a much less conspicuous discipline in biology at the beginning of the twentieth century, research into the deep history of the Metazoa certainly did not disappear altogether. Now, in the twenty-first century, the study of metazoan phylogeny has reached its zenith of popularity. Several factors are responsible for this situation. First, in the late 1980s and early 1990s the first analyses of metazoan phylogeny based on molecular sequence evidence were published, and these provided a huge stimulus for other workers to start analyzing metazoan phylogeny (Bergström, 1986; Field *et al.*, 1988; Lake, 1990). Importantly, the continued collection and analysis of new molecular evidence have now established a widely accepted so-called new view of animal evolution (Halanych, 2004).

Second, the early 1990s witnessed the first computerized cladistic analyses of morphological evidence (Schram, 1991; Eernisse *et al.*, 1992). The compilation and analysis of explicit morphological data matrices made the practice of morphological phylogenetics much more transparent than heretofore. Current phylogenetic analyses of the Metazoa habitually analyze both molecular and morphological data either separately or combined into a single large data matrix.

Third, the last quarter of the twentieth century also saw the gestation and birth of evolutionary developmental biology – evo-devo in short. The origins of this increasingly mature discipline similarly extend back to the evolutionary morphology of the late nineteenth century. Understanding the large-scale pattern of animal relationships is central to evo-devo because at the core of its research agenda is the desire to understand the evolution of animal body plans in terms of changes in developmental patterns and processes (Hall, 1999).

This article will outline our current understanding of metazoan phylogeny on the basis of available molecular and morphological evidence. The reader should note, however, that no definitive picture of animal relationships can be presented at this time. Metazoan phylogenetics is currently a highly active discipline characterized by a great flux of ideas. Many questions still remain unresolved, and the hope for an overarching consensus should at this time be tempered by the realization that different data sources and methods of analysis may yield conflicting phylogenies, as will be discussed below. Therefore the picture of metazoan phylogeny presented in this article is necessarily provisional. However, one should not underestimate the significant progress that has been made in our understanding of animal relationships in many different parts of the metazoan phylogeny in the last 15 years or so.

It should be noted that the subject area covered in this article is enormous, covering a huge literature. In view of space limitations and in the interest of readability I have included only a minimum of in-text citations, principally only a small sample of important recent and comprehensive works that are expressly focused on high-level metazoan phylogenetics, and review papers. These key references should help guide the interested reader into the vast literature on animal phylogeny. I especially recommend Halanych (2004) and selected chapters in Cracraft and Donoghue (2004) as optimal starting points for a more indepth study of metazoan phylogeny.

1.02.1.1 Data

This section will briefly introduce the different kinds of evidence used to reconstruct metazoan phylogeny, and review their respective strengths and weaknesses. Until about 15 years ago all metazoan phylogenies were strictly based upon morphological evidence, including information about embryology. With the advent of molecular phylogenetics this situation has changed dramatically, and many workers now prefer to infer phylogenies solely with molecular data, or in combination with morphological evidence. In contrast, information derived from fossils plays only a minor role in metazoan phylogenetics, with the exception of several taxa for which a relatively rich and detailed fossil record is available, notably the arthropods, echinoderms, priapulids, brachiopods, and chordates.

1.02.1.1.1 Molecules Our understanding of the tree of life on all levels is increasingly based upon molecular evidence. Although many zoologists still endorse the value of morphological evidence, the molecular hegemony is increasingly gaining strength in metazoan phylogenetics as well.

The foundation for the new view of metazoan phylogeny is firmly based upon analysis of the 18S rRNA, or nuclear small ribosomal subunit (SSU), gene (Eernisse and Peterson, 2004; Halanych, 2004). The SSU gene was one of the first genes that was sequenced for species belonging to different animal phyla. For most of the traditionally recognized animal phyla the SSU gene has now been sequenced for at least one species, and for increasing numbers of phyla multiple species have been sequenced. Consequently, the SSU gene is currently the most broadly sampled gene within the Metazoa. Its relatively slow mutation rate makes it an appropriate gene to study the deep divergences of the Metazoa, but the SSU gene has not resolved all high-level phylogenetic questions.

To complement and test the results based on the SSU gene, researchers are now investigating the phylogenetic utility of different molecular loci as well, including the 28S rRNA, or nuclear large ribosomal subunit (LSU) gene, the myosin heavy-chain type II gene, various mitochondrial genes, as well as mitochondrial gene order, Hox genes, and the genes for elongation factor-1α and elongation factor-2 (Giribet, 2002, 2003; Ruiz-Trillo *et al.*, 2002; Halanych, 2004).

In addition, the sequencing of the entire genomes of several model metazoans such as the nematode *Caenorhabditis elegans*, the fly *Drosophila melanogaster*, and the primate *Homo sapiens* has allowed for a different strategy of phylogenetic analysis. Instead of sampling many taxa for the same gene, several phylogenomic studies have recently been published that have attempted to reconstruct metazoan phylogeny by comparing large numbers of homologous sequences for just the small set of animals for which genome sequence data are available (Copley *et al.*, 2004; Wolf *et al.*, 2004; Dopazo and Dopazo, 2005; Philip *et al.*, 2005; Philippe *et al.*, 2005). Interestingly, the results of several of these studies do not support the findings of phylogenetic analyses based on fewer genes, but with larger samples of species. This apparent discrepancy focuses attention on two important issues.

First, these apparent phylogenetic conflicts indicate the importance of adequate taxon sampling. In order to represent properly phylogenetically important variation in gene sequences, and to prevent being misled by homoplasy, phylogeneticists should aim at a sufficiently large representation of metazoans in their phylogenies.

Second, recent research has shown that, for the same set of taxa, independent phylogenetic analyses based on only one or a few genes can be in significant conflict with each other (Rokas *et al.*, 2003b). However, in such cases the conflict may be resolved by combining all molecular evidence into a single phylogenetic analysis, which may then yield a single, well-supported phylogeny. This shows that it is crucial to study metazoan phylogeny with multiple molecular loci, and that one should be wary of accepting phylogenies based on just one or two loci.

As an illustration of the high pace of developments in the discipline, new studies published between submission and revision of this article show that the conflict between standard molecular phylogenetic analyses and phylogenomic studies is probably only apparent (Copley *et al.*, 2004; Philippe *et al.*, 2005). It is the probable result of long-branch attraction resulting from insufficient sampling in the first phylogenomic studies. The long-diverged gene sequences of the distantly related model organisms have accumulated so many mutations that chance similarities may cause them to be grouped together in a phylogenetic analysis. Increasing taxon sampling may break up such long branches, decreasing the conflict with the much-better-sampled analyses that focus on only one or a few genes.

Finally, molecular evidence has not only added greatly to our ability to reconstruct metazoan phylogeny, it has also allowed us for the first time to estimate the approximate divergence times of the major metazoan taxa, even when the fossil record is mostly mute about most of these divergence events (Smith and Peterson, 2002). This application of molecular evidence is among the most exciting, but also the most controversial of topics in evolutionary biology. Of particular interest are the problems of apparent discrepancies of divergence time estimates based on molecular and fossil evidence observed for many groups of organisms, ranging from vascular plants to birds, and the possibility that the major metazoan lineages diverged very rapidly, making it very difficult to reconstruct and precisely date the sequence of divergence events giving rise to modern crown groups (Smith and Peterson, 2002; Graur and Martin, 2004; Reisz and Müller, 2004; Rokas *et al.*, 2005; Ho and Larson, 2006). However, through an increasing understanding of the relative strengths and weaknesses of molecular and fossil divergence times estimates, recent studies have been able to bring molecular estimates of divergence times and the metazoan fossil record increasingly in closer agreement, although a period of cryptic evolution of the major metazoan lineages is still suggested, about which the fossil record is silent.

1.02.1.1.2 Morphology Morphological characters, obtained from the study of all stages of the life cycle, from zygote to adult organism, had been the sole source of phylogenetic information until the late 1980s. Even today morphological evidence is habitually used for phylogenetic analyses of the Metazoa, either alone, or in combination with molecular evidence (Ax, 1995–2001; Zrzavy *et al.*, 1998; Giribet *et al.*, 2000; Nielsen, 2001; Peterson and Eernisse, 2001; Glenner *et al.*, 2004; Jenner and Scholtz, 2005).

Certain types of morphological character have traditionally been imbued with great phylogenetic value. The most familiar major divisions in the animal kingdom reported in textbooks reflect many of these characters. For example, the possession of bilateral symmetry, with distinct anteroposterior, dorsoventral, and left–right axes has long been regarded as the principal synapomorphy of the Bilateria. The possession of a body composed of three germ layers, ectoderm, endoderm, and mesoderm, is reflected in the name Triploblastica, a synonym of Bilateria.

Within the Bilateria the clades Protostomia and Deuterostomia are typically diagnosed on the basis of different fates of the embryonic blastopore, which characteristically is said to give rise to the adult mouth in protostomes, and the anus in deuterostomes.

Great phylogenetic value has also been attached to the possession of characteristic cleavage patterns in the early embryo. For example, the widely recognized clade Spiralia is characterized by spiral cleavage, found in such phyla as the mollusks, annelids, and nemerteans.

The nature of body cavities has been of paramount importance in metazoan phylogenetics, and the bilaterian groups Coelomata, Pseudocoelomata, and Acoelomata have often been distinguished in textbooks, with the first possessing a coelom, and the latter two lacking a coelom.

In addition to these important characters, the organization of the central nervous system (brain structure and configuration of main nerve cords) and the nature of the life cycle (indirect development with larvae, or direct development from egg to adult without an intervening free-living larva) have also played important roles in generating phylogenetic hypotheses for the Metazoa. Currently available morphological data matrices may include hundreds of characters, and the largest published morphological data set for the Metazoa included more than 16 000 data entries (Zrzavy *et al.*, 1998).

Despite this wealth of morphological information and the publication of a significant number of morphological phylogenetic analyses of the Metazoa over the 15 years, no detailed consensus view of animal relationships has yet resulted on the basis of morphology alone. This is because the selection and interpretation of phylogenetic characters are fraught with difficulties, and different decisions feeding into data matrix constructions may lead to different phylogenies (Jenner and Schram, 1999; Jenner, 2001, 2003, 2004a). Even when a data set has been properly compiled, homoplasy of characters may mislead the phylogenetic analysis. Recent research increasingly shows that key phylogenetic characters once thought to have evolved only once may in fact be evolutionarily very labile.

1.02.1.1.3 Fossils Although fossils may be thought of as providing perhaps the most direct evidence of the course of evolution, fossils have nevertheless not played a leading role in establishing high-level metazoan phylogeny. So far the fossil record remains largely silent about the details of the origin of the animal phyla, but as the fossil record continues to be mined, new and valuable insights into metazoan evolution continue to accrue (Valentine, 2004).

The most important contribution of fossils to metazoan phylogeny is in supplying the information to reconstruct the stem taxa of modern or crown group taxa (Budd and Jensen, 2000). Of special relevance are various exceptionally preserved Cambrian faunas, such as the Burgess Shale fauna of British Columbia, the Sirius Passet fauna of northern Greenland, and the Chengjiang fauna of southwest China. Fossils collected at these and other localities have greatly informed the early evolution of groups such as the arthropods, priapulids, and chordates. However, the phylogenetic significance of many fossils remains elusive, in particular the highly problematic Ediacaran (Precambrian) fossils, which may be a diverse assemblage that contains genuine members of extant phyla, and real oddballs that cannot be placed inside the Metazoa.

The inclusion of fossils into phylogenetic analyses of living taxa can have a huge impact on tree topology (Wheeler *et al.*, 2004; Lee, 2005). Consequently, ignoring available fossil evidence cannot be easily justified, even when one is only interested in the phylogenetic relationships of living taxa.

1.02.1.2 Methods

All widely used phylogenetic methods have been used to reconstruct metazoan phylogeny, including distance methods, parsimony analysis, likelihood

analysis, and, most recently, Bayesian analysis. Currently, molecular sequence data have been analyzed with all these methods, and morphological evidence has been studied with both parsimony and Bayesian analysis.

1.02.2 Overview of Major Metazoan Clades and Grades

Comprehensive molecular and morphological phylogenetic analyses have generated abundant support for the monophyly of the Metazoa. Among the morphological features shared by most metazoans are the possession of an extracellular matrix, intercellular junctions such as septate junctions, spot desmosomes, and spermatozoa. On the molecular level the evolution of at least one Hox gene seemed to have accompanied the origin of the Metazoa. The multicellularity characteristic of plants and fungi has evolved independently of metazoan multicellularity.

Among the unicellular eukaryotes the choanoflagellates are likely the closest living relatives of the animals (Lang *et al.*, 2002). Morphological and functional similarities between choanoflagellate cells and the choanocytes found in sponges (Porifera) have long been interpreted as providing support for a close relationship between animals and choanoflagellates (Maldonado, 2004). Increasing research efforts are now under way to elucidate the genomic makeup of the choanoflagellates, which could yield insights into the nature of the first metazoan genomes.

Recent phylogenetic analyses of SSU and LSU sequences have suggested another protistan candidate as the closest relative of metazoans. These studies found the mesomycetozoans (also know as ichthyosporeans) to be the closest relative of either the Metazoa or the choanoflagellates. Nevertheless, because the mesomycetozoans are mostly specialized tissue parasites, the free-living choanoflagellates may better serve as less-modified models of the metazoan ancestor.

The remainder of this section presents a brief overview of the main branches on the metazoan phylogeny (Figure 1). This is followed by a more detailed overview of the precise composition and phylogenetic relationships within the main animal clades (Figures 2–8).

1.02.2.1 Nonbilaterians and Acoelomorpha

Although the Porifera (sponges), Placozoa (*Trichoplax adhaerens*), Cnidaria (e.g., jellyfish, sea anemones), and Ctenophora (comb jellies) are

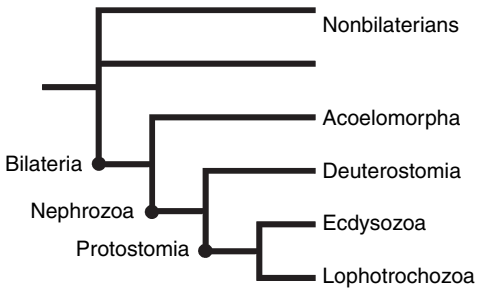

Figure 1 Concise phylogeny of the Metazoa, indicating the main grades and clades. A grade of nonbilaterians comprises Porifera, Placozoa, Cnidaria, Ctenophora, and Myxozoa. The Bilateria comprises the Acoelomorpha, which unites Acoela and Nemertodermatida. The remaining bilaterians are called Nephrozoa because of the widespread occurrence of nephridia. The three main clades are Deuterostomia, Ecdysozoa, and Lophotrochozoa. See text for further discussion.

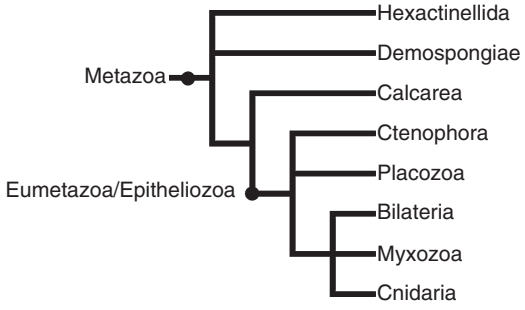

Figure 2 Basal metazoan relationships. The poriferans form a basal grade, with calcarean sponges more closely related to the other metazoans. The branching sequence of the nonbilaterians is not well understood. Cnidaria, and possibly Myxozoa, are probably most closely related to the Bilateria. See text for further discussion.

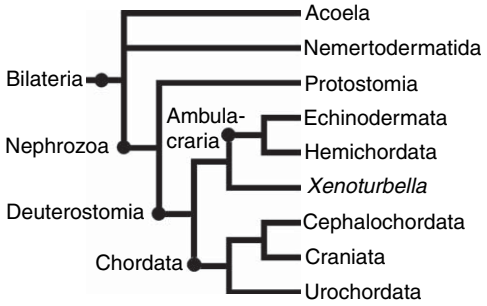

Figure 3 Overview phylogeny of the Bilateria, with an emphasis on deuterostome phylogeny. The acoels and nemertodermatids are the earliest diverging extant bilaterians. The Protostomia and Deuterostomia are likely sister taxa. Within the deuterostomes there are two sister clades. The clade Ambulacraria unites echinoderms and hemichordates, and probably *Xenoturbella*. The clade Chordata unites the urochordates, cephalochordates, and the craniates. See text for further discussion.

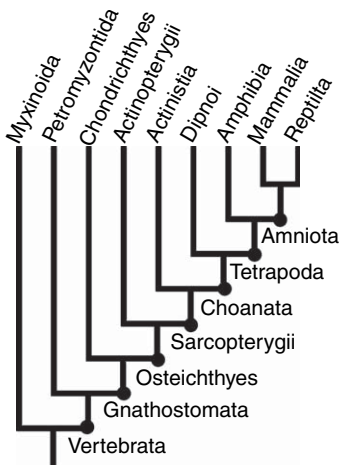

Figure 4 Craniate phylogeny. The extant agnathans (hagfish and lamprey) form two successive sister groups to the gnathostomes. Within the Gnathostomata there is a basal division between bony fishes (Osteichthyes) and cartilaginous fishes (Chondrichthyes). Within the clade of bony fishes there is a division between lobe-finned fishes (Sarcopterygii) and ray-finned fishes (Actinopterygii). Coelacanths (Actinistia) and lungfishes (Dipnoi) are successive sister taxa to the Tetrapoda, which include all terrestrial vertebrates. See text for further discussion.

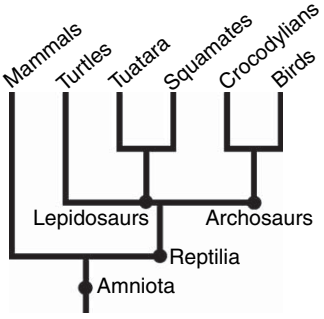

Figure 5 Phylogeny of extant amniotes, with emphasis on basic reptile relationships. Among living amniotes the mammals and reptiles are sister clades. Within the living reptiles, Lepidosauria and Archosauria are likely sister taxa. The tuataras and squamates (snakes and lizards) comprise the Lepidosauria, while birds and crocodilians comprise the Archosauria. The phylogenetic position of the turtles remains unresolved. See text for further discussion.

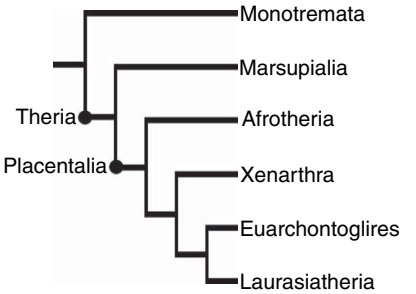

Figure 6 Phylogeny of extant mammals. The living monotremes (platypus and echidnas) and marsupials are successive sister taxa to the living placental mammals. Four major clades comprise Placentalia. The Afrotheria and Xenarthra have southern hemisphere origins, in Africa and South America, respectively. The clades Euarchontoglires and Laurasiatheria have northern hemisphere origins. Afrotheria includes elephants, manatees, golden moles, and aardvarks. Xenarthra comprises anteaters, sloths, and armadillos. Euarchontoglires includes primates and rodents. Laurasiatheria includes artiodactyls, perissodactyls, cetaceans, bats, and carnivores. The Afrotheria and Laurasiatheria comprise two independent parallel radiations of similar morphologies, ranging from mole-like forms to ant-eating forms. See text for further discussion.

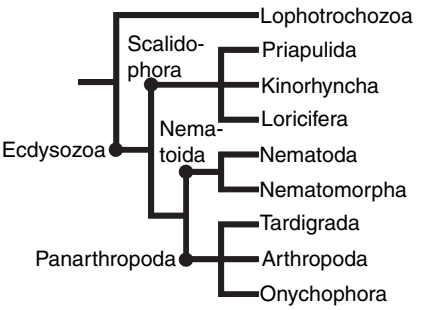

Figure 7 Protostome phylogeny with emphasis on ecdysozoan relationships. The three main ecdysozoan clades are Scalidophora, Nematoida, and Panarthropoda. The scalidophorans comprise the loriciferans, penis worms (priapulids), and mud dragons (kinorhynchs). Nematoida comprises the horsehair worms (nematomorphs), and roundworms (nematodes). Panarthropoda comprises the arthropods, water bears (tardigrades), and velvet worms (onychophorans). See text for further discussion.

often typified as diploblasts, these earliest diverging nonbilaterian metazoans (Figures 1 and 2) could hardly be said to be characterized by the possession of a common body plan, nor could they be considered as members of a monophyletic clade. I therefore prefer to refer to them simply as nonbilaterians. Although the precise evolutionary branching sequence of these groups is still contentious (Rokas *et al.*, 2003a), they likely form a grade of organization (paraphyletic group) basal to the Bilateria. The morphological disparity between these phyla spans an enormous range of body architectures, with the maximally simple placozoans at opposite extremes, with just four differentiated somatic cell types, and the cnidarians, of which some of the most complex forms, such as cubozoans, possess differentiated muscle and nervous systems, and some remarkably complex sensory organs. The elucidation of the precise sequence of divergences of these taxa is therefore vital to understanding the assembly of more complex body plans at the base of the Bilateria. However, all these groups are traditionally considered to lack bilateral symmetry.

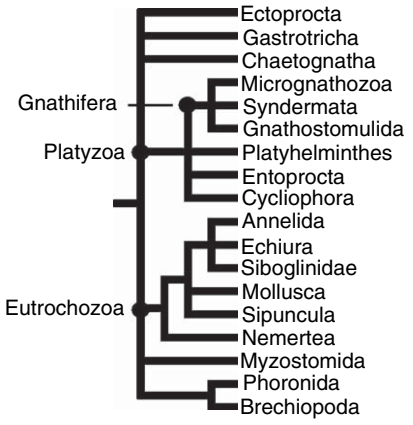

Figure 8 Phylogeny of the Lophotrochozoa. Only several clades can currently be recognized. Phoronids and brachiopods form a clade. The eutrochozoans form a clade characterized by a trochophore larva (also found in entoprocts). The Platyzoa is a putative clade of noncoelomate lophotrochozoans, and the clade Gnathifera is supported by characteristic features of their cuticularized jaws. The relationships of the remaining members of the Lophotrochozoa remain unresolved. See text for further discussion.

Surprisingly, recent investigations have added another group to the base of the Bilateria. The enigmatic, microscopical, and parasitic myxozoans were until very recently considered to be protozoans. However, recent advances in molecular phylogenetics and ultrastructural research have established their metazoan affinities, and their possible relationships to either the cnidarians or the Bilateria (Okamura and Canning, 2003; Zrzavy and Hypsa, 2003).

The earliest diverging unambiguously bilaterally symmetrical organisms appear to be the Acoelomorpha, comprising two taxa: Acoela and Nemertodermatida (Figures 1 and 3). Previously considered to be basal flatworms (Platyhelminthes), molecular data and a reinterpretation of available morphological evidence instead suggest that these relatively simple flatworm-like organisms are the most basally branching crown group bilaterians (Baguñà and Riutort, 2004). Consequently, the acoelomorphs are considered to be the sister group to the remaining bilaterians, the three main clades of which will be introduced below.

1.02.2.2 Deuterostomia

The deuterostomes are a well-circumscribed clade, comprising the Echinodermata (e.g., sea stars, sea lilies, sea urchins, sea cucumbers), Hemichordata (acorn worms and pterobranchs), and Chordata (sea squirts, lancelets, craniates plus vertebrates) (Figures 1 and 3–6). Traditionally, the membership of the Deuterostomia was considered to be wider, also including the three lophophorate phyla Brachiopoda (lamp shells), Phoronida, and Ectoprocta (moss animals), and frequently the Chaetognatha (arrow worms) as well. However, re-evaluation of morphological evidence (Lüter, 2000; Bartolomaeus, 2001; Gruhl *et al.*, 2005) is throwing serious doubt on the deuterostomian synapomorphies of brachiopods and phoronids, and accumulating molecular evidence now firmly places the lophophorates in the protostome clade Lophotrochozoa, while the phylogenetic position of the chaetognaths remains elusive. More recently, the enigmatic worm *Xenoturbella bocki* has been proposed to be a deuterostome as well.

Apart from clearly circumscribing the membership of the Deuterostomia, recent research has also reorganized the phylogenetic relationships within the deuterostomes on many levels (Blair and Hedges, 2005). In contrast to traditional ideas, the echinoderms and hemichordates are now united as sister groups in a clade Ambulacraria. Furthermore, within the chordates, the sister group relationship between the cephalochordates (lancelets) and the craniates (hagfish plus vertebrates) has been consolidated. However, the widely accepted position of the tunicates as the sister group to cephalochordates plus craniates has now come under fire from phylogenomic analyses that support instead an unexpected sister group relationship between tunicates and vertebrates, to the exclusion of the cephalochordates (Blair and Hedges, 2005; Delsuc *et al.*, 2006). Intriguingly, a recent morphological phylogenetic analysis yielded the same result (Ruppert, 2005).

A large amount of new phylogenetic research within the vertebrates on many taxonomic levels has in several instances generated an evolutionary picture that is significantly at odds with established views, for example relationships within the placental mammals (Figure 6; Murphy *et al.*, 2004; Springer *et al.*, 2004). Since invertebrates comprise the vast majority of animal diversity this article is chiefly concerned with invertebrate phylogeny. However, in view of the fact that vertebrates are disproportionately represented in research on nervous systems, a brief overview of our current understanding of vertebrate phylogeny will also be presented (see Section 1.02.3.3; Figures 4–6).

1.02.2.3 Ecdysozoa

The Ecdysozoa is the second major clade within the Bilateria (Figures 1 and 6), and it includes a subset of the animal phyla generally considered part of the

Protostomia. The key synapomorphy uniting the ecdysozoans is the possession of a cuticle that is periodically molted (a process named ecdysis). The ecdysozoan phyla are the arthropods (e.g., insects, crustaceans, myriapods, and chelicerates), onychophorans (velvet worms), tardigrades (water bears), nematodes (roundworms), nematomorphs (horsehair worms), priapulids, loriciferans, and kinorhynchs (mud dragons). Probably concomitant with the evolution of a cuticle that covers the entire body surface, the ecdysozoans lost the motile epidermal cilia that are widespread in other animal phyla. Moreover, in contrast to many other invertebrates, the life cycle of ecdysozoans does not include a free-living ciliated larval stage. They are therefore referred to as exhibiting direct development, instead of indirect development via a larval stage, which characterizes the life cycles of many marine invertebrates.

The discovery of the clade Ecdysozoa has generated a large amount of debate, principally by refuting the widely accepted Articulata hypothesis (Giribet, 2003; Jenner and Scholtz, 2005). Traditionally, the annelids and arthropods are considered to be closely related as articulatans on the basis of the shared possession of body segmentation. The striking morphological and developmental similarities between segmentation in these two groups were widely regarded as being among the most reliable homologies that could be identified between different animal phyla. By placing the arthropods in the Ecdysozoa, and relegating the annelids to the third major clade of bilaterians, the Lophotrochozoa, it had to be assumed that either segmentation evolved independently in annelids and arthropods, or if in fact homologous, segmentation must have been lost in many other animal phyla.

1.02.2.4 Lophotrochozoa

The third major clade within the Bilateria is Lophotrochozoa (Figures 1 and 8). This clade includes the largest number of traditionally recognized animal phyla, and it embodies the greatest amount of disparity among body plans found within the Metazoa. Lophotrochozoans span an enormous range of body architectures, life cycles, developmental modes, habitats, behaviors, and include both the smallest and the biggest living invertebrates, ranging from the tiny loriciferans that measure about a tenth of a millimeter, to the gigantic deep-sea squids with body lengths measuring in multiple meters. Consequently, without question the Lophotrochozoa represents the phylogenetically most challenging metazoan clade.

The name Lophotrochozoa derives from the fact that many members of this clade either possess ciliated feeding tentacles, called a lophophore, such as the brachiopods and phoronids, or they include a ciliated trochophore larva in their life cycles, such as the mollusks, annelids, echiurans (spoon worms), sipunculans (peanut worms), and the entoprocts. However, the Lophotrochozoa also includes the ectoprocts (moss animals), platyhelminths (flatworms), nemerteans (ribbon worms), gnathostomulids, rotifers, acanthocephalans, cycliophorans, micrognathozoans, and possibly the gastrotrichs and chaetognaths.

Traditionally, all nondeuterostome animals were united in a clade Protostomia, and indeed in several recent phylogenetic analyses the clades Lophotrochozoa and Ecdysozoa together form a clade Protostomia as sister group to the deuterostomes. However, molecular phylogenetic analyses have not yielded strong support for the monophyly of Protostomia. Moreover, the value of the morphological characters in support of a clade Protostomia is currently being reinterpreted, and it might turn out that the protostomes are a paraphyletic taxon, perhaps giving rise to the deuterostomes.

1.02.3 Phylogenetic Relationships Within the Major Clades and Grades

In this section a detailed description will be given of our current state of understanding of the phylogeny of the Metazoa. However, as explained in the introduction, the reader should realize that no fully resolved high-level metazoan phylogeny is yet available. As a result, the view of metazoan phylogeny presented here is a conservative estimate based on the synthesis of available molecular and morphological data. The metazoan phylogeny presented here does not represent the result of a single comprehensive phylogenetic analysis of all available evidence. Wherever it is relevant, congruence and conflict between data sources will be mentioned.

1.02.3.1 Nonbilaterians: Porifera, Placozoa, Ctenophora, Cnidaria, and Myxozoa

Porifera, Placozoa, Ctenophora, Cnidaria, and Myxozoa are the earliest diverging animal groups (Figures 1 and 2). Available evidence supports Porifera as the basal-most of these taxa. However, in contrast to traditional ideas, the sponges may not form a clade, and the interrelationships of the other basal metazoans are unclear at the present time (Rokas *et al.*, 2003a; Halanych, 2004).

Three main groups of living sponges are recognized: (1) Calcarea, or sponges with a skeleton of calcareous spicules; (2) Demospongiae (including most familiar sponges); and (3) Hexactinellida (the glass sponges, whose bodies are largely composed of syncytial tissues). Both demosponges and hexactinellids possess a skeleton of siliceous spicules.

The three groups of sponges share a unique adult body plan that is characterized by the possession of a water canal or aquiferous system, which consists of a complex of spaces inside the sponge body that are in open connection with the surrounding water. These spaces are lined by so-called collar units that are built from either single cells (choanocytes or collar cells) or syncytia (choanosome). These special cells bear a single flagellum that is encircled by a collar of microvilli. This microvillar collar assists in the capture of food particles from the water inflow created by the beating flagella. Sponges possess only a few general types of differentiated cell types, and the nerve cells, special sensory cells, and muscle cells that are characteristic of other metazoans are not developed in sponges (some hexactinellids do show the ability to conduct electrical impulses along their syncytia, and demosponges may possess contractile cells, sometimes referred to as myocytes).

Although traditionally considered to be a monophyletic group, recent molecular (SSU) phylogenetic analyses with a broad sampling of basal metazoans and nonmetazoan outgroups have instead found Porifera to be paraphyletic. Intriguingly, the calcareans were found to be the sister group to the remaining metazoans, which may be called Eumetazoa, with the demosponges and hexactinellids diverging earlier. The precise relationships of the demosponges and hexactinellids to each other and to the clade Calcarea plus Eumetazoa are not yet clear.

The paraphyly of the sponges (Figure 2) provides significant support for the hypothesis that the eumetazoan ancestor was sponge-like. Sponges have generally not been considered a fertile substratum for the evolution of eumetazoan diversity. Their morphological simplicity on the one hand (e.g., lacking true germ layers, muscles, nervous and sensory systems, and generally, epithelia with basement membranes), and their morphological and functional specialization as epibenthic, sessile, and semipermeable water filters on the other hand, have led sponges to be regarded as a specialized dead end in evolution. Now, possible sponge paraphyly forces us to consider them more seriously as a starting point from which to derive eumetazoan diversity. The recent description of the carnivorous sponge *Asbestopluma hypogea*, which has completely lost the characteristic poriferan aquiferous system with choanocytes, and thus its ability to filter-feed, exemplifies that in principle the poriferan body plan has the flexibility to transform into a fully functional macrophagous feeder, a transition that is thought to have taken place during the early evolution of the Metazoa (Vacelet and Duport, 2004).

Furthermore, molecular biological research has shown that the sponge genome contains a surprising array of genes that code for important structural and regulatory molecules present in more derived metazoans, such as the bilaterians (Müller, 2003). These molecules include a range of transmembrane receptor molecules, transcription factors, extracellular matrix proteins, and potential neurotransmitters and antibodies (neuronal-like receptors, homeobox genes, tyrosine kinases, and phosphatases, serotonin, crystallin, integrin, fibronectin, and immunoglobulin-like molecules). Extensive gene duplication is also indicated to have taken place before the divergence of the sponges and the remaining metazoans.

Only one species of placozoan has been described so far, *Trichoplax adhaerens*, and all placozoans known to date conform to the morphological description of *T. adhaerens*. However, new evidence from nuclear and mitochondrial markers in placozoans collected from different localities around the world shows a remarkable degree of genetic divergence, with genetic distances being equal to those between different families of other marine nonbilaterians (Voigt *et al.*, 2004). Placozoans are small (usually 1–2 mm long), flat, ciliated, creeping organisms, without any fixed body axis. The body is composed of just four differentiated somatic cell types, organized into a ventral and a dorsal epithelium, and an enclosed space with so-called fiber cells. The presence of true epithelia in placozoans, with cells connected by belt desmosomes and septate-like junctions has been interpreted as a synapomorphy with all animals excluding sponges, which are generally thought to lack these features. The clade of Placozoa plus all nonsponge animals is therefore sometimes named Epitheliozoa (Figure 2). However, evidence for true epithelia exists in sponges as well, although it is frequently overlooked.

However, the consensus based strictly on morphological evidence that placozoans are the sister group to the Eumetazoa is now contested by accumulating molecular evidence (SSU). Molecular evidence suggests that placozoans may be less basal metazoans than previously thought, diverging from the remaining animals after the

morphologically much more complex ctenophores or ctenophores plus cnidarians have branched off (Wallberg *et al.*, 2004). This would imply that placozoans have become morphologically extremely simplified, losing complex differentiated tissues and organs, including a nervous system, muscles, and sensory organs. Although there is some preliminary phylogenomic research that has indicated the possibility that Placozoa are in fact the sister group to all metazoans, including sponges, this finding has not yet been convincingly substantiated.

In addition, efforts are under way to sequence the whole genome of *Trichoplax*, and genetic studies as well as the first analyses of expression patterns of developmental regulatory genes have started to yield new insights into the biology of Placozoa, such as the presence of genetic signatures of the occurrence of sex in placozoans (placozoan sex has never been observed), and hints indicating that *Trichoplax* may exhibit a greater degree of histological differentiation than previously thought (Jakob *et al.*, 2004; Signorovitch *et al.*, 2005).

Living ctenophores are very delicate, transparent, mostly pelagic, biradial animals, and they exhibit a passing resemblance to cnidarian jellyfish (hence their vernacular name comb jellies). However, they can be clearly distinguished from medusae by the possession of eight rows of comb plates that run the length of the body. Comb plates consist of closely apposed cilia of several aligned cells. Ctenophores also possess a complex aboral apical organ that is the main sensory center of the animal. An additional unique feature found in many ctenophores is the colloblast, a specialized epidermal cell type located on the tentacles of tentaculate ctenophores that is used for catching prey. Ctenophores possess nerve cells organized in a nerve net at the base of the epidermis and in the mesodermal derivatives. They also possess subepidermal, nonepithelial muscle cells, which are also widespread in bilaterians, but are primitively absent from the other nonbilaterians, including cnidarians. In common with bilaterians, ctenophore muscles are derived from endomesoderm, although genuine epithelial germ layers are not formed during ctenophore development.

The possession of mesodermally derived nonepithelial muscles has been taken as the main character to indicate a sister group relationship between ctenophores and bilaterians. Several workers defend the union of ctenophores and cnidarians in a clade Coelenterata on the basis of similarities in the early embryonic development of these groups, but molecular evidence (SSU and LSU) does not support either this or the previous hypothesis. Instead, these data indicate that ctenophores are very basal metazoans, grouping either with calcarean sponges, or as a sister group to calcareans and the remaining metazoans. Yet, a recent comprehensively sampled phylogenetic analysis of SSU sequence data dismissed these results as being artifacts due to insufficient taxon sampling, and instead found strong support for a sister group relationship between ctenophores and (Cnidaria plus Bilateria) (Wallberg *et al.*, 2004).

The new basal phylogenetic position of ctenophores or their close juxtaposition to the much simpler calcarean sponges has interesting implications for our understanding of the course of character evolution if proved correct. It may imply that the morphological features shared between bilaterians, cnidarians, and ctenophores, including well-developed nervous systems, muscles, sensory organs, and digestive system, are either convergent on some level or have been lost altogether in calcarean sponges.

Cnidaria is a well-supported monophyletic group, comprising the Anthozoa (including sea anemones and corals), Hydrozoa (including the familiar laboratory animal *Hydra* and the colonial siphonophores), Scyphozoa (including most familiar jellyfishes), and Cubozoa (including the notorious sea-wasps). Cnidarians exhibit approximately the same morphological grade of organization as the ctenophores, including a nervous system in the form of a diffuse nerve net (localized nerve concentrations may be found, for example, around the mouth of polyps, and the bell of medusae), epithelio-muscle cells (nonepithelial muscle cells in certain groups are thought to have evolved convergently to those in ctenophores and bilaterians), and an alimentary canal.

Cnidarians are definitely more closely related to the bilaterians than the sponges, and although this is a tentative conclusion, they may represent the sister taxon to the bilaterians (Figure 2; Halanych, 2004; Wallberg *et al.*, 2004). This is supported by ribosomal gene sequences, information from Hox genes, and SSU secondary structure. However, their relationship to placozoans, ctenophores, and myxozoans remains contentious. Significantly, researchers are increasingly focusing on the cnidarians to understand the origin of evolutionary novelties at the base of the Bilateria, including the molecular genetic underpinnings of the establishment of the main body axes and bilateral symmetry, the mesodermal germ layer, and sensory organs. As mentioned above for sponges, the genome of cnidarians contains a set of genes involved in the elaboration of complex morphologies in

bilaterians, but without forming these complex structures themselves. Studying the functions of these genes in basal metazoans could yield precious insights into the origin of novelties during animal evolution. In contrast, cnidarian genomes also seem to have retained a set of genes from nonmetazoan ancestors, which have been lost in the bilaterians (Technau *et al.*, 2005). This hints at the role of gene loss in animal evolution and underscores the lack of correlation between phenotypic and genomic complexity in metazoans.

The last group of nonbilaterians to be discussed are the myxozoans. Until very recently they were considered to be parasitic protists. Previously invisible to most zoologists, this diverse group of obligate parasites of a host of invertebrates and vertebrates is of substantial economic importance because of the diseases they can cause in commercial fish hosts (Kent *et al.*, 2001). New morphological and molecular evidence has indicated their metazoan affinities. The myxozoan's polar capsules show striking morphological and functional similarities to cnidarian stinging capsules or nematocysts, and myxozoan spores are multicellular. It is currently unclear whether myxozoans are derived cnidarians, or basal bilaterians (Figure 2).

1.02.3.2 Acoelomorpha: Acoela and Nemertodermatida

One of the most surprising and significant advances in metazoan phylogenetics in the last few years has been our changing perception of the phylogenetic position of two groups of morphologically simple flatworm-like organisms: the Acoela and the Nemertodermatida (Figures 1 and 3). Acoels and nemertodermatids are small ciliated worms that were previously considered to be primitive members of the phylum Platyhelminthes. Chiefly based on similarities of their epidermal cilia, the two groups were united in the clade Acoelomorpha. In common with platyhelminths, acoelomorphs have a blind-ending gut that may or may not have a lumen. However, unlike most platyhelminths, acoelomorphs lack a continuous epidermal basement membrane, as well as protonephridia, and their nervous system is only weakly differentiated in the form of a nerve net with a weakly differentiated brain and several longitudinal cords. The brain in acoels has been described as commissural, rather than ganglionic, and it has been argued that a true ganglionic brain with a central neuropil evolved after the acoelomorphs diverged from the remaining bilaterians. The name Nephrozoa has been proposed for the clade of all nonacoelomorph bilaterians, based on the widespread presence of nephridia in these taxa (Jondelius *et al.*, 2002).

Currently, molecular evidence in the form of nucleotide sequences of SSU, LSU, and myosin II heavy chain, as well as amino acid sequences from several mitochondrial genes support the position of the acoelomorphs as the basal-most extant bilaterians. In addition, possession of a complement of Hox/ParaHox genes intermediate between those found in cnidarians and the remaining bilaterians appears to buttress the basal position of the acoelomorphs. However, molecular evidence has not yet provided unequivocal evidence for the monophyly of Acoelomorpha, and the acoels and nemertodermatids may be distinct taxa, branching off subsequent to each other at the base of the Bilateria.

The acoelomorphs can therefore serve the important function as a bridge to help close the architectural gap between bilaterians and the more basal metazoans. As the most basal-living bilaterians, the morphology and life cycle of the acoelomorphs is especially important for informing the primitive conditions for the Bilateria as a whole. Their lack of segmentation, coeloms, excretory organs, their relatively simple nervous systems, the absence of distinct larval stages in their life cycles, and their apparently limited set of Hox/ParaHox genes strengthen the inference that the most recent common ancestor of the Bilateria was a relatively simple, compact, direct-developing organism, with a sac-like gut (Baguñà and Riutort, 2004).

1.02.3.3 Deuterostomia

The three core phyla of the Deuterostomia are the echinoderms, the hemichordates (enteropneusts and pterobranchs), and the chordates (urochordates, cephalochordates, and craniates plus vertebrates; Figure 3). In addition, recent molecular phylogenetic research has added the enigmatic and rather simple worm *X. bocki* to the deuterostomes as well (Bourlat *et al.*, 2003). Of the three main bilaterian clades, the high-level phylogeny of the deuterostomes is currently best understood. This section will describe deuterostome phylogeny in detail, including an account of high-level vertebrate phylogeny.

1.02.3.3.1 Echinodermata, Hemichordata, and *Xenoturbella* Currently, a sister group relationship of the echinoderms and hemichordates in a clade Ambulacraria is robustly supported by both molecular and morphological evidence (Smith *et al.*, 2004; Figure 3). Previous hypotheses often considered Hemichordata not to be monophyletic, with

the enteropneusts being the sister group to the chordates, and the pterobranchs diverging more basally within the deuterostomes. Recent molecular and morphological phylogenetic analyses established the monophyly of the Hemichordata and its placement as a sister group to the Echinodermata (Cameron, 2005; Zeng and Swalla, 2005). A reinterpretation of morphological characters in these groups, as well as in the lophophorates that were previously considered to be deuterostomes, supports this hypothesis.

The exclusively marine echinoderms contain some of the most familiar invertebrates, such as sea stars and sea urchins. Their pentaradial symmetry, calcareous endoskeletal elements, and their elaborate coelomic water vascular system are diagnostic features of the phylum. Although the living species are classified into five well-demarcated groups (asteroids or sea stars, echinoids or sea urchins, ophiuroids or brittle stars, crinoids, feather stars or sea lilies, and holothuroids or sea cucumbers), the morphological diversity of extinct echinoderms yields a further 18 or so distinct echinoderm taxa.

The phylogeny of the extant echinoderms is far from established, but some provisional conclusions may be drawn on the basis of currently available morphological and molecular data sets. First, the crinoids are the sister group to the remaining taxa, which are grouped in a clade Eleutherozoa. Within the Eleutherozoa, the asteroids are the most likely sister group to a clade comprising the ophiuroids, echinoids, and holothuroids. Within this clade there is robust support for a sister group relationship between the echinoids and the holothuroids in a clade Echinozoa. In contrast, support for a sister group relationship between the clade Echinozoa and the ophiuroids is not very strong.

The Hemichordates comprise the enteropneusts, or acorn worms, and the pterobranchs. Enteropneusts and pterobranchs are very easily distinguishable. Enteropneusts are large (typically between 20 and 25 cm), free-living, bottom-dwelling worms equipped with a bulbous anterior proboscis (prosome) that is clearly separated from the long posterior trunk (metasome) by a collar (mesosome) at the anterior end of which the mouth opens. Pterobranchs, on the other hand, are tiny sessile, colonial animals that carry a prominent crown of ciliated tentacles. Like the enteropneusts the pterobranchs possess a tripartite body, with coelomic cavities in each of the three subdivisions of the body, with an anterior part called the oral shield (prosome that secretes the tubes in which they live), a short middle collar (mesosome bearing the tentacles), and a sac-like trunk (metasome).

In several early morphological phylogenetic analyses Hemichordata was assumed to be monophyletic, but this assumption was not confirmed by most morphological phylogenetic analyses that separated the enteropneusts and pterobranchs as individual taxa. Hemichordate monophyly is confirmed, however, by phylogenetic analyses of SSU and LSU sequences, and recent reinterpretation of hemichordate morphology confirms two potential hemichordate synapomorphies that had previously been hypothesized: possession of a stomochord (anterior dorsal extension of the pharynx wall into the prosome) and presence of mesocoelomic ducts that connect the coelomic cavities of the mesosome with the outside (Cameron, 2005; Ruppert, 2005).

The monophyly of the pterobranchs is not in doubt, as they share such unique features as the secretion of tubes, or coenecia, with their prosome, or cephalic shield, and the possession of tentacles on the mesosome. However, SSU and LSU evidence and phylogenetic analysis of combined molecular and morphological data suggest the possibility that the enteropneusts are paraphyletic with respect to the pterobranchs. Alternatively, pterobranchs may be the sister group to a monophyletic Enteropneusta. If pterobranchs have evolved from within the enteropneusts, this implies several rather drastic changes in body architecture probably associated with miniaturization. These changes would include simplification of the pterobranch gill skeleton, and simplification of the nervous system from possession of the well-developed dorsal nerve cord or tube in the collar of enteropneusts, to a simpler neural ganglion in the collar region of pterobranchs.

The Ambulacraria hypothesis, according to which echinoderms and hemichordates are sister taxa, has significant implications for understanding deuterostome evolution in general, and the origin of the chordate body plan in particular, because the origin of the chordate nervous system, the notochord, and pharyngeal gill slits has frequently been discussed with respect to either enteropneust anatomy or hemichordate and echinoderm larval morphology.

For example, the classic hypothesis proposed for the origin of the chordate nervous system is Walter Garstang's auricularia or dipleurula hypothesis, later amended and elaborated by other authors, most recently Thurston Lacalli. At the core of this hypothesis is the derivation of the chordate dorsal nerve tube from the fused ciliary bands of a dipleurula-type larva, as is commonly found in the life cycles of both echinoderms and enteropneusts. However, monophyly of the Ambulacraria implies that such a larval form is a possible synapomorphy

of the echinoderms and hemichordates, and is not a plesiomorphy for the chordates (Lacalli, 2005).

The recent addition of the small, morphologically simple worm *X. bocki* to the morphologically much more complex coelomate deuterostomes also has potentially important implications for understanding deuterostome character evolution. Molecular evidence indicates a possible phylogenetic position for *Xenoturbella* as the sister group to the Ambulacraria (Bourlat *et al.*, 2003; Figure 3). Since *Xenoturbella* lacks complex morphology shared by the other deuterostomes, including coelomic cavities and a gut with both mouth and anus (it has a blind-ending gut), it raises the interesting question of whether *Xenoturbella* may have become secondarily simplified, or whether it has retained its morphological simplicity from the root of the Bilateria, and as indicated by the acoelomorphs discussed above.

1.02.3.3.2 Chordata: Urochordata and Cephalochordata The monophyly of Chordata (Urochordata, Cephalochordata, and Craniata) is widely accepted (Figure 3). The urochordates, or tunicates, have long been considered to be the sister group of the clade Cephalochordata plus Craniata, with the latter two taxa also being sister groups. Chordate monophyly is principally supported by the presence of a notochord, or chorda, a dorsal neural tube, longitudinal muscles along the notochord, or its derivatives, the presence of an endostyle that secretes a mucus filter used in feeding, and the presence of special cerebral sensory organs in the form of optic and otic receptors. It should be noted that some of these features are only present in the tadpole larvae of the tunicates, not in the sessile adults (with the possible exception of the larvaceans, or appendicularians, which are likely derived from more typical ascidian ancestors). The body plan of adult tunicates is entirely different from those of the cephalochordates and craniates.

Interestingly, until recently, available molecular phylogenetic evidence did not yield any convincing support for the monophyly of the chordates. The precise placement of the urochordates turned out to be a particularly vexing issue. SSU and LSU sequences have variously suggested urochordates to be the sister group to a monophyletic clade of Cephalochordata plus Craniata, sister group to Ambulacraria, or sister group to all of the deuterostomes. More recent phylogenetic studies based on the simultaneous analysis of a larger number of different genes have instead started to provide tentative support for an unexpected sister group relationship between vertebrates and tunicates (Blair and Hedges, 2005; Delsuc *et al.*, 2006). If this turns out to be correct, it will have important consequences for understanding the origin of the vertebrates, for which cephalochordates are commonly interpreted as a stand-in of the last common vertebrate ancestor. However, straightforward comparisons between urochordates and vertebrates are very difficult, especially because of the strong modifications of the many forms that are sessile as adults.

The vast majority of tunicates are represented by the familiar sessile ascidians or sea squirts. The remaining species comprise the pelagic thaliaceans (salps, pyrosomids, and doliolids), and the appendicularians or larvaceans. A highly complex and unique cuticular exoskeleton known as the tunic, which includes free cells, has given the phylum its name, although it is not present in all tunicates. A large pharynx or branchial basket is another conspicuous organizational feature of urochordates. A similar pharynx can also be identified in the cephalochordates and the ammocoetes larva of lampreys. The characteristic tadpole larva with a bulbous body and slender muscular tail is also unique for urochordates. In fact, larvaceans look somewhat like urochordate tadpole larvae during their entire life cycle. It has been hypothesized that larvaceans have evolved by truncating development so that the original tadpole larva has now become the definitive adult (a phenomenon known as pedomorphosis). Recent phylogenetic evidence deriving both the pelagic larvaceans and thaliacians from within a paraphyletic clade of ascidians provides some support for this hypothesis (Zeng and Swalla, 2005).

The cephalochordates, or lancelets (also known as amphioxus), are widely accepted to be the sister group to the craniates. Lancelets are the most vertebrate-like of all invertebrates, and they resemble little fish in their morphology. The segmented nature of their body musculature can readily be distinguished, and shows a striking similarity to the segmentally arranged muscle blocks or myomeres found in vertebrates. These muscle blocks are derived from coelomic (somitic) pouches. Moreover, vertebrates and cephalochordates share the attainment of a certain degree of brain complexity reflected in both its ultrastructure and the expression of developmental regulatory genes, and the elaboration of special sense organs, principally an olfactory organ (corpuscles of Quatrefages in lancelets) marked by the expression of a developmental regulatory gene also expressed in craniate ectodermal placodes. However, the evolutionary significance of these features remains unclear when, as discussed

above, urochordates indeed prove to be more closely related to vertebrates.

1.02.3.3.3 Craniata and Vertebrata The last decade has witnessed remarkable progress in resolving the major phylogenetic relationships within the extant craniates and vertebrates (Rowe, 2004; Figures 4–6). Especially the application of molecular evidence from a variety of sources has contributed significantly to the emergence of the current consensus.

The basal-most extant groups within the Craniata are the hagfishes (Myxinoida) and lampreys (Petromyzontida), which together are referred to as Cyclostomata, representing the jawless agnathans. Whether Cyclostomata is monophyletic or paraphyletic with hagfishes as the sister group to the Vertebrata, including the lampreys, is currently unclear. Different analyses contradict each other. For the purpose of this article I accept cyclostomatan paraphyly as a working hypothesis, with lampreys as the sister group to the Gnathostomata, which comprises all living jawed vertebrates (Figure 4).

The basal-most split within Gnathostomata is between the sister groups Chondrichthyes (cartilaginous fishes including sharks and rays) and Osteichthyes (bony fishes and tetrapods). Within the Osteichthyes there is a basal split between the Actinopterygii (ray-finned fishes, comprising all living fishes except the coelacanths and lungfishes) and the Sarcopterygii (lobe-finned fishes: coelacanths, lungfishes, and tetrapods). Although it has commonly been thought that the coelacanths are the nearest relatives of the Tetrapoda, accumulating molecular evidence instead supports a basal split within the Sarcopterygii between the sister groups Actinistia (coelacanths) and Choanata (the lungfishes and tetrapods). The lungfishes (Dipnoi) are the sister group to the Tetrapoda, or terrestrial vertebrates (Figure 4).

An important caveat may obtain here. Although the basal vertebrate relationships described above are widely accepted, a recently published phylogenetic analysis of complete mitochondrial genomes and 18S and 28S ribosomal sequences instead suggested that a fish is a fish, and a tetrapod is a tetrapod; the tetrapods were a sister clade to a clade comprising all gnathostome fishes (Arnason *et al.*, 2004). This study provided suggestive evidence that the traditional phylogeny in which tetrapods evolve from within a paraphyletic group of fishes is an artifact of rooting the phylogeny within the gnathostomes, either with bony fishes or cartilaginous fishes. This procedure may already assume paraphyly of gnathostome fishes. Only when phylogenies are rooted instead with a non-gnathostome outgroup, such as hagfish or lamprey, can the hypothesis of the monophyly of gnathostome fishes be really tested. In this case a monophyletic clade of gnathostome fishes, including lungfishes and coelacanths, is recovered. Yet, nothing is ever unambiguous in phylogenetics, and this result was again contradicted by more recent studies published between first submission and revision of this article, which on the basis of phylogenetic analysis of a large number of nuclear protein-coding genes showed that gnathostome fishes are paraphyletic with respect to tetrapods (Blair and Hedges, 2005).

Extant tetrapods comprise three clades: Amphibia, Reptilia, and Mammalia (Figure 4). The amphibians (anurans, such as frogs; caudatans, such as salamanders; and caecilians) are the sister group to the Amniota, comprising the extant sister groups Reptilia and Mammalia (Figures 4 and 5). Although long considered to be a paraphyletic group, the reptiles are currently recognized as the monophyletic sister clade of the Synapsida, which includes the modern mammals plus extinct stem taxa. Reptilia comprises two major clades of extant reptiles: Archosauria and Lepidosauria (Lee *et al.*, 2004; Figure 5). Monophyly of Archosauria is well established, and the clade comprises the extant crocodilians and birds, as well as the extinct pterosaurs and dinosaurs.

Living lepidosaurs are the tuataras, lizards, and snakes. Lizards and snakes are grouped together in a clade Squamata, the monophyly of which is well supported, but the internal relationships of which remain uncertain (Lee, 2005; Vidal and Hedges, 2005). Monophyly of the Lepidosauria is generally believed to be well supported as well, but several recent molecular phylogenetic analyses of nuclear genes contradict morphological and mitochondrial sequence support for a monophyletic Lepidosauria, suggesting instead a paraphyletic Lepidosauria with squamates as sister group to all remaining extant reptiles.

The perennially problematic phylogenetic position of turtles has not yet been convincingly resolved (Figure 5). On the basis of morphological and paleontological evidence turtles were either allied with a group of extinct marine lepidosaurian reptiles, or were placed outside all other living reptiles. However, the application of molecular sequence data has yielded no support for any of these hypotheses. Instead, these data surprisingly suggest that turtles are closely related to archosaurian reptiles (Rest *et al.*, 2003; Lee *et al.*, 2004). So

far no anatomical support for this relationship has been recovered, and a recent morphological phylogenetic study places turtles as a sister group to Lepidosauria (Hill, 2005).

The congruence of diverse molecular evidence has recently generated a new consensus of mammalian phylogeny that is significantly at odds with traditional ideas established on the basis of morphological and paleontological evidence (Murphy *et al.*, 2004; Springer *et al.*, 2004). The basal divergences among the mammals are in agreement with traditional ideas. The Monotremata (duck-billed platypus, echidnas) and their fossil stem group are together called Protheria, and Protheria is the sister group to the marsupial and placental mammals and their stem groups. The marsupials and their stem group are called Metatheria, while the Placentalia and their stem group are called Eutheria. Metatheria and Eutheria are sister groups within a clade Theria.

The emerging molecular picture of placental mammal phylogeny is strikingly at odds with traditional ideas (Figure 6). Four main clades are recognized: Xenarthra, Afrotheria, Euarchontoglires, and Laurasiatheria. The latter three clades were not recognized previously. Euarchontoglires and Laurasiatheria are sister clades with northern hemisphere origins. Xenarthra is sister group to this superclade, and the divergence between Afrotheria and the remaining placental mammals represents the basal-most split. The xenarthrans and afrotherians had a southern hemisphere origin.

Afrotheria includes morphologically very disparate forms such as elephants, hyraxes, manatees, golden moles, elephant shrews, tenrecs, and aardvarks. Xenarthra includes sloths, armadillos, and anteaters. Euarchontoglires unites rodents, lagomorphs (rabbits, pikas) together with flying lemurs, tree shrews, and primates. Laurasiatheria includes bats, certartiodactyls (artiodactyls and cetaceans), perissodactyls, carnivores, pangolins, and insectivores such as moles, hedgehogs, and shrews. One of the most striking implications of the new placental mammal phylogeny is the extent of parallel morphological evolution between afrotherians and laurasiatherians. Both clades show independent radiations of similar adaptive forms, including mole-like animals (golden mole and mole), hedgehog-like animals (tenrec and hedgehog), shrew-like animals (elephant shrew and shrew), anteaters (aardvarks and pangolin), and fully aquatic forms (manatees and dolphins).

The implications of the new mammal phylogeny for understanding phenotypic evolution are enormous, and many received wisdoms need to be freshly scrutinized. Humans turn out to be more closely related to mice than to cows or dogs, ungulates or hoofed mammals do not form a clade, and the traditional order Insectivora is equally spread out across the mammalian tree.

The enormous range of morphological variation characterizing clades such as Afrotheria also poses a real challenge to those who wish to reconstruct their ancestral phenotype. For example, so far just a single morphological synapomorphy has been proposed for the clade Afrotheria (Carter *et al.*, 2006), a situation reminiscent of the difficulty of establishing morphological synapomorphies for the large invertebrate clade Lophotrochozoa (see below). Moreover, current evidence suggests that morphologically very distinct taxa, such as hyraxes, elephants, and sirenians, and which form a clade within Afrotheria, may have radiated very rapidly, establishing their distinctive body plans in a short amount of time (Nishihara *et al.*, 2005). Evidently, a satisfactory synthesis of the molecular phylogeny with morphology and fossil evidence is the daunting challenge still before us.

1.02.3.4 Ecdysozoa

Monophyly of the clade Ecdysozoa was one of the major surprises of the molecular phylogenetics of the Metazoa because it implied that the segmented arthropods and annelids were merely distant relatives, with the former a member of Ecdysozoa, and the latter a member of Lophotrochozoa. Ecdysozoa unites the arthropods (e.g., insects, crustaceans, myriapods, and chelicerates), onychophorans (velvet worms), tardigrades (water bears), nematodes (roundworms), nematomorphs (horsehair worms), priapulids, kinorhynchs (mud dragons), and loriciferans (in the absence of molecular sequence data, this latter taxon is included solely on the basis of morphological evidence; Figure 7). Molecular support for Ecdysozoa derives from an increasing number of sources, including SSU, LSU, elongation factor-1α, elongation factor-2, myosin heavy-chain type II, Hox genes, and sodium-potassium adenosine triphosphatase (ATPase) α-subunit. Additionally, proposed morphological synapomorphies of the ecdysozoans include the covering of the body with a cuticle, which is ultrastructurally similar across ecdysozoans, and which is periodically moulted (presumably under hormonal control, although that has so far only been investigated in any detail in the arthropods and nematodes), the loss of motile epidermal cilia, a terminal mouth, and the loss of intestinal cilia. Finally, the neural expression of horseradish peroxidase

immunoreactivity has also been proposed as an ecdysozoan apomorphy. The failure of various phylogenomic studies to confirm the monophyly of Ecdysozoa may be due to insufficient taxon sampling (limited to those taxa whose genomes have been sequenced), and the potentially highly modified nature of the genome of the nematode *C. elegans* (Copley *et al.*, 2004; Philippe *et al.*, 2005).

With the conspicuous exception of the arthropods and nematodes, not many molecular sequences have so far been generated for the other ecdysozoan phyla. Consequently, on the basis of molecular evidence alone ecdysozoan phylogeny is not yet well resolved. However, on the basis of combined molecular and morphological evidence three likely clades can be hypothesized: Panarthropoda (arthropods, tardigrades, and onychophorans), Scalidophora (priapulids, kinorhynchs, and loriciferans), and Nematoida (nematodes and nematomorphs). The most recent molecular and combined molecular and morphological phylogenetic analyses suggest a sister group relationship between the Nematoida and Panarthropoda, with Scalidophora as a sister group to this clade (Figure 7). However, robust support for this topology remains to be discovered.

1.02.3.4.1 Panarthropoda: Arthropoda, Onychophora, and Tardigrada Onychophorans are terrestrial, 15–150 mm long, somewhat cigar-shaped animals that are readily identifiable by their 13–43 pairs of walking limbs known as lobopods, and a prominent pair of antennas that adorns the head. This undoubtedly monophyletic group has been at the center of evolutionary speculations ever since the last quarter of the nineteenth century, when onychophorans were considered an important evolutionary link between annelids and arthropods.

Tardigrades, or water bears, are small (mostly less than 1 mm) animals. Their generally roundish bodies are carried on four pairs of stubby legs that identify four body segments. They are well known for their ability to survive for extended periods in a state of extreme inactivity while being virtually completely dehydrated, a phenomenon called cryptobiosis. This ability is an obvious advantage to the many tardigrades that live in the thin and ephemeral films of water that surround terrestrial lichens and mosses. Unfortunately, their small size makes it very difficult to reconstruct their phylogenetic position with morphological evidence alone because their lack of certain important features uniquely shared between the larger-bodied onychophorans and arthropods may have been secondarily lost, rather than primitively absent. This might be true, for example, of metanephridia that are restricted to a reduced coelom called a sacculus, and a dorsal heart with openings called ostia, two characters shared by onychophorans and arthropods.

The Arthropoda is an amazingly diverse group of animals, with about 1 million described species, and total estimates suggesting up to 10-fold higher diversity. About two-thirds of described invertebrate species are arthropods. They are characterized by the possession of a more or less rigid, articulated chitinous exoskeleton that covers the entire body surface, and the possession of articulated limbs.

There are four extant arthropod groups: (1) Hexapoda or Insecta (note that there is some variation in the use of these terms in the literature, principally by considering the insects as a subgroup of the Hexapoda); (2) Myriapoda (millipedes and centipedes); (3) Crustacea (crabs, lobsters, etc.); and (4) Chelicerata (horseshoe crabs, spiders, scorpions, etc.). The literature on arthropod phylogeny is one of the most voluminous in systematic zoology, and chronicles a rich history that extends back to the very beginning of evolutionary biology. These extensive efforts to reconstruct the phylogenetic relationships of arthropods are classically rooted in morphological (including fossil) information, but the recent application of an increasingly diverse array of molecular data has yielded several important advances in our understanding.

In contrast to traditional ideas that united the myriapods and the hexapods, molecular evidence instead supports a close relationship of the crustaceans and hexapods, either as sister groups, or with hexapods derived from within the paraphyletic crustaceans. In addition, and more controversially, various nuclear and mitochondrial genes support chelicerates and myriapods as closest relatives in a clade that has been named Paradoxopoda or Myriochelata (Mallatt *et al.*, 2004; Pisani *et al.*, 2004). However, whether myriapods and chelicerates indeed form a clade, or whether chelicerates represent the earliest diverging extant taxon (Wheeler *et al.*, 2004; Giribet *et al.*, 2005), and whether hexapods and crustaceans are really closest relatives awaits further study.

The monophyly of Panarthropoda is widely accepted (Figure 7), but at present its support is mainly morphological. Comprehensively sampled molecular sequences, mainly those of SSU and LSU, provide decidedly less support for panarthropod monophyly, or relationships within Panarthropoda. Morphological phylogenies either support the onychophorans or the tardigrades as the sister group to extant arthropods, and a combination of SSU and LSU sequences has recently

suggested a clade of tardigrades and onychophorans. Before a robust phylogeny of the Panarthropoda and the Arthropoda can be achieved, more sequence data is needed, the choice of morphological characters used in phylogenetic analyses should be better justified, and the crucial role of fossils should be seriously considered. The panarthropods have a rich fossil record, and it has been shown that the incorporation of fossils into a phylogenetic analysis combining both molecular and morphological information may yield dramatically different phylogenies. For example, inclusion of just seven Paleozoic fossils into a monster phylogenetic analysis of arthropods, including almost 250 taxa, more than 800 morphological characters, and more than 2 kilobases of molecular sequence data, changes support for a clade of hexapods and crustaceans to the traditional Atelocerata hypothesis uniting hexapods and myriapods (Wheeler *et al.*, 2004). Such phylogenetic instability due to the inclusion of different sources of data needs to be more fully explored in future work.

1.02.3.4.2 Scalidophora: Priapulida, Kinorhyncha, and Loricifera The priapulids (penis worms), kinorhynchs (mud dragons), and loriciferans are thought to be a clade called Scalidophora, referring to their most conspicuous synapomorphy: the possession of an anterior end or introvert with spines or scalids, which are epidermal specializations with ciliary receptors. Molecular phylogenetic analyses based on ribosomal sequences support priapulids and kinorhynchs as sister groups, but so far no sequence data has been obtained from loriciferans.

Priapulids are carnivorous worms that possess a large introvert adorned with many spines, and they include both tiny meiobenthic (about 0.5 mm) and larger (up to 40 cm) macrobenthic species. Although only 18 extant species of priapulids have been described, their fossil record extends back to the Cambrian, showing that priapulids were once a speciose and important component of benthic communities. However, considering that within the last 30 years no less than 10 new species of priapulids have been described (with several collected new species still awaiting description), including the most recent description of a giant Alaskan species (up to 40 cm), the group may be more diverse than previously suspected.

All kinorhynchs are tiny (generally less than 1 mm) denizens of the marine meiobenthos. They have relatively narrow and slender bodies that are subdivided into 13 segment-like units called zonites, and their spiny heads covered with scalids make them easy to recognize. Despite superficial similarities to the somites or segments of the arthropod body plan, segmentation of the kinorhynch integumentary, muscular, and nervous systems is generally interpreted to support only the monophyly of the phylum.

The first species of loriciferan was described in 1983. Loriciferans are tiny (between 0.1 and 0.5 mm), and exclusively marine and meiobenthic. Loriciferans are encased in a vase-like exoskeleton called a lorica that is composed of six cuticular plates. From the lorica sprouts forth an introvert with a narrow mouth cone surrounded by spiny scalids similar to those that decorate the kinorhynch head.

Although the monophyly of the Scalidophora seems established (Figure 7), the internal phylogenetic relationships are not yet robustly supported. Most morphological cladistic analyses support kinorhynchs and loriciferans as sister taxa, but some zoologists favor a sister group relationship between priapulids and loriciferans. Sometimes the meiofaunal loriciferans are hypothesized to be the pedomorphic descendants of the larger-bodied priapulids.

1.02.3.4.3 Nematoida: Nematoda and Nematomorpha The Nematoda is a highly successful phylum. Nematodes or roundworms are small and very slender noncoelomate worms, and they inhabit every part of the world that is even marginally inhabitable. This realization has led to a staggering image: if the entire earth except nematodes were to become invisible, we would still be able to make out most of the outline of the planet surface, including mountains, and most organisms, both plants and animals, which serve as hosts for a fantastic diversity of roundworms. Interestingly, parasitic nematodes specialized for a range of plant and animal hosts have evolved multiple times convergently.

The nematomorphs or horsehair worms are thin, very long worms (up to 1 m, while being only 1–3 mm wide). The adults are free-living, but earlier life-cycle stages are all parasitic, mostly on arthropods. The Nematomorpha strongly resemble mermithid nematodes in both morphology and life-cycle characteristics, and some zoologists have regarded these features as homologous. However, recent information strongly suggests that these correspondences have evolved convergently, in the monophyletic Nematoda and Nematomorpha.

Nevertheless, a sister group relationship between the nematodes and nematomorphs in a clade Nematoida is generally accepted on the basis of morphological evidence (Figure 7). Synapomorphies

include the presence of longitudinal epidermal cords with nerve cords, a basal cuticle layer with thick, crossing collagenous fibers, and the absence of circular body wall muscles. Molecular phylogenies do not always support Nematoida, but a recent analysis of combined SSU and LSU sequences strongly supported Nematoida (Mallatt *et al.*, 2004).

1.02.3.5 Lophotrochozoa

The clade Lophotrochozoa (Figure 8) was originally proposed on the basis of SSU sequence data to designate the lophophorates (brachiopods, phoronids, and ectoprocts), annelids, and mollusks. Further investigations have increased lophotrochozoan membership also to include the echiurans, sipunculans, entoprocts, platyhelminths, nemerteans, gnathostomulids, rotifers, acanthocephalans, cycliophorans, micrognathozoans, and possibly gastrotrichs and chaetognaths. Lophotrochozoan monophyly is furthermore robustly supported by additional molecular evidence, including LSU data, Hox gene data, mitochondrial gene sequence and gene arrangement data, myosin heavy-chain type II data, intermediate filament data, and sodium-potassium ATPase α-subunit sequences.

The abundant molecular evidence for lophotrochozoan monophyly stands in sharp contrast to the resolution of its internal phylogeny and the strength of its morphological support. Using SSU sequences, for example, the monophyly of even morphologically well-defined phyla, such as Mollusca, Ectoprocta, or Nemertea, may not be supported, and, with the exception of a few possible clades, relationships within the Lophotrochozoa remain largely unresolved with molecular evidence. As a consequence, resolution of lophotrochozoan phylogeny is currently heavily dependent on morphological evidence analyzed either in isolation, or in combination with molecular sequence data.

1.02.3.5.1 Lophophorata: Phoronida, Brachiopoda, and Ectoprocta Adult phoronids are slender worm-like animals that live in secreted tubes, from which they protrude their ciliated feeding tentacles (lophophore) that surround the mouth. Like brachiopods and ectoprocts they possess a U-shaped gut, and some zoologists think that both ectoprocts and brachiopods have evolved from a phoronid-like ancestor. However, available phylogenetic evidence does not support this hypothesis.

Brachiopods, or lampshells, are sessile animals enclosed in a bivalved shell. However, their similarity to bivalves is only superficial since brachiopods are flattened dorsoventrally while bivalves are flattened laterally. Somewhat simplistically, architecturally brachiopods can be regarded as shelled phoronids. Similar to ectoprocts and phoronids, brachiopods possess a crown of ciliated feeding tentacles called a lophophore.

With the exception of two genera, one solitary and one nonsessile, ectoprocts are sessile colonial animals, with individuals (called zooids) that measure less than 0.5 mm in length, and that may be box-shaped, oval, or tubular. Ectoprocts superficially resemble entoprocts with their ciliated crown of tentacles commonly referred to as a lophophore (but see below), and the possession of a U-shaped gut. When the zooids in a colony extend their lophophores, the colony looks a little like a patch of moss, which has led to their general name moss animals.

As noted above, brachiopods, phoronids, and ectoprocts possess ciliated feeding tentacles traditionally referred to as a lophophore. However, the structural and functional uniqueness of the ectoproct tentacles has served as the basis for denying their homology with those of the brachiopods and phoronids, lessening morphological support for Lophophorata. Indeed, available morphological and molecular evidence only supports a close relationship between brachiopods and phoronids (Figure 8), either as sister taxa or with phoronids derived from within brachiopods (Cohen and Weydmann, 2005). SSU sequences and Hox gene data suggest that ectoprocts are at least lophotrochozoans, but of very uncertain phylogenetic position. So far, morphological evidence has not helped to pinpoint the phylogenetic position of the ectoprocts.

1.02.3.5.2 Eutrochozoa: Nemertea, Mollusca, Sipuncula, Annelida, Echiura, Siboglinidae, and Myzostomida Nemerteans, or ribbon or proboscis worms, are all (with the exception of one species) characterized by the possession of an eversible proboscis enclosed by a fluid-filled coelom, the rhynchocoel. The proboscis apparatus is used in prey capture, and the proboscis can be rapidly everted to coil around the prey. Secreted toxins will help subdue the prey that mainly consists of small crustaceans and annelids.

On the basis of molecular phylogenetic evidence alone it can be concluded that nemerteans are lophotrochozoans, but their precise position remains unclear. In contrast, most phylogenetic analyses based on morphology alone or in combination with molecular evidence place nemerteans together with the neotrochozoans: mollusks, sipunculids, echiurans, and annelids (plus groups derived from

within the annelids) (Figure 8). This hypothesis is supported, among others, by the shared possession of mesodermal bandlets derived from a 4d cell, and the derivation of a schizocoelic coelom from these bandlets (Jenner, 2004b). Although nemerteans are generally thought to lack trochophore larvae, in contrast to the neotrochozoans, the recent discovery of a hidden trochophore larva in the life cycle of a basal nemertean (Maslakova *et al.*, 2004) implies that the trochophore larva may be an additional synapomorphy of nemerteans and neotrochozoans.

Mollusca is a highly diverse but clearly defined group of animals. Familiar mollusks include snails, slugs, bivalves, chitons, and cephalopods. Molluscan synapomorphies include a coelomic pericardium, a mantle that secretes the shells, and a radula used in feeding. Mollusks have adapted to a wide range of marine, freshwater and terrestrial habitats, and can be considered one of the most successful groups of animals on earth.

The phylogenetic position of the mollusks remains unclear. On the basis of morphological evidence various sister groups have been suggested, including entoprocts, sipunculans, or a clade of varying membership, including neotrochozoans and panarthropods. Molecular evidence has so far not allowed the resolution of this problem, and broadly sampled rDNA sequences have frequently failed to support even a monophyletic Mollusca.

Sipunculans, or peanut or star worms, form a well-demarcated phylum. They are nonsegmented, coelomate worms that are denizens of marine benthic communities. Their bipartite body has a posterior widened trunk, an anterior slender part called the introvert, with a terminal ciliated tentacle crown that is arranged as a star around the mouth.

The precise phylogenetic position of sipunculans remains unclear. Morphology suggests an affinity to the mollusks, or to a clade of variable membership that includes various neotrochozoans and panarthropods. Molecular evidence suggests sipunculans are closely related to annelids.

The annelids, or segmented worms, are among the most familiar invertebrates, and they principally comprise the polychaetes and the clitellates. The polychaetes encompass a great diversity of forms, and molecular phylogenetic evidence suggests that they probably also include the vestimentiferans and pogonophores (now united as Siboglinidae), and the echiurans. Clitellates include the oligochaetes, including earthworms, and the parasitic hirudineans, or leeches.

The phylogenetic position of annelids on the basis of morphology remains contentious, because of the difficulty of interpreting the characters related to segmentation in the annelids and the arthropods. Traditionally their shared segmentation has been interpreted to support a close relationship. In contrast, molecular evidence firmly places the annelids within the Lophotrochozoa and the arthropods in the Ecdysozoa, suggesting the possibility that their segmentation is not homologous. The sister group to the annelids remains unknown. However, molecular evidence has suggested a larger membership of the Annelida than was sometimes suspected on the basis of morphology alone. Molecular evidence now supports the inclusion of the echiurans, vestimentiferans, and pogonophores (together siboglinids) within the polychaete annelids as well.

Adult echiurans, or spoon worms, are unsegmented, coelomate worms. They share the chaetae characteristic of annelids, and they possess a characteristic flat or grooved proboscis that can be stretched to extreme lengths in the search for food while the rest of the animal remains hidden in a protective burrow or rock crevice.

The lack of body segmentation has caused morphological phylogenetic analyses to place the echiurans outside the annelids, frequently as its sister group. In contrast, accumulating molecular evidence from various sources now support the inclusion of echiurans in the polychaete annelids. This implies that echiurans have secondarily lost such characters as parapodia and pronounced metamery of the body.

Pogonophores and vestimentiferans are now united on the basis of both molecular and morphological evidence as the family Siboglinidae that is placed within the polychaetes. They are long worms that live in secreted tubes. They have an occluded gut, and highly modified and reduced segmentation. Perhaps the most familiar examples are the large vestimentiferans (up to 1.5 m), which live associated with deep-sea hydrothermal vents. They harbor chemoautotrophic symbiotic bacteria from which they derive a significant amount of nourishment.

Myzostomids are peculiar worms that look like little pancakes with stubby legs with which they cling on to their echinoderm hosts on which they parasitize. They seem to lack a coelom, but they do exhibit signs of segmentation, and they possess several characters unique to polychaetes or subgroups of polychaetes, including parapodia adorned with modified chaetae reminiscent of annelid chaetae, internal chaetae (called aciculae and functioning as support rods inside the parapodia), a nectochaete larva, and nearly identical innervation patterns of the parapodia and cirri (marginal sensory organs) in polychaetes and myzostomids.

The phylogenetic position of the myzostomids remains contentious (Jenner, 2003), and affinities with polychaete annelids, platyhelminths, and cycliophorans have been suggested on the basis of morphological, molecular, or combined evidence. However, sampling of molecular sequences is sparse and should be extended.

1.02.3.5.3 Platyzoa: Platyhelminthes, Gnathostomulida, Rotifera, Acanthocephala, Entoprocta, Cycliophora, and Micrognathozoa Platyzoa is a clade recently proposed on the basis of molecular sequence data and some combined analyses of molecular and morphological evidence (Figure 8). Platyzoa encompasses noncoelomate lophotrochozoans. Although minimally proposed to include platyhelminths, gnathostomulids, rotifers, and acanthocephalans, the broadest definition of this clade additionally includes entoprocts, cycliophorans, and micrognathozoans, and potentially gastrotrichs and myzostomids. However, phylogenetic support for this clade is currently far from robust, and the exact membership and interrelationships of Platyzoa remain to be determined.

Platyhelminths, or flatworms, are typically dorsoventrally flattened bilaterians that come in a diverse array of forms with an even more exuberant range of life cycles that may contain multiple hosts for parasitic species. About a quarter of described flatworm species are grouped as Turbellaria, which forms a paraphyletic group of mainly free-living species from which the highly specialized parasitic groups such as cestodes and trematodes have been derived. Recent evidence suggests that the acoelomorphs (acoels and nemertodermatids) are not platyhelminths, but basal crown group bilaterians. Instead Platyhelminthes now comprises Catenulida and Rhabditophora, the latter taxon containing the bulk of extant species, including all parasitic groups.

Gnathostomulids are minute noncoelomate worms that live in the interstitial spaces of marine sands (meiofauna). Their common name jaw worms refers to the set of complex cuticularized jaw elements that are found in all gnathostomulids. Gnathostomulids are invariably described as enigmatic in evolutionary studies.

Rotifers are small (most are not more than 1 mm) and common animals in marine zooplankton, freshwater, and in association with terrestrial moss plants. Their common name, wheel animals, refers to the presence of a ring of cilia at the anterior end present in many species that is used for feeding and locomotion. When the cilia beat, the ciliated band superficially resembles a rotating wheel. Rotifers possess a cuticularized pharyngeal jaw apparatus (trophi) that is very similar ultrastructurally to gnathostomulid jaw elements.

The acanthocephalans or spiny-headed worms are generally small endoparasites (not more than a few millimeters, although one species of up to 80 cm is known) that derive their name from the possession of a spiny proboscis with which they attach inside their host. All recent phylogenetic studies (based on both morphology and molecules) support a close relationship between the generally free-living rotifers and parasitic acanthocephalans, either as sister groups, or with acanthocephalans nested within a paraphyletic Rotifera. The key synapomorphy is a syncytial epidermis with an intracellular skeletal layer, which unites these taxa as Syndermata. The possession of a syncytial epidermis may be an adaptation to living in osmotically challenging environments. Many rotifers live in freshwater and acanthocephalans live as parasites inside other animals. A syncytial skin would then provide an effective tight seal to prevent osmotic stress.

Entoprocta comprises a well-demarcated monophylum. Entoprocts are tiny animals, frequently not longer than 1 mm. Entoprocts are sessile, solitary, or colonial, and resemble little stalked cups with a crown of ciliated tentacles that protrude into the water column where they filter out small food particles. Entoprocts exhibit a superficial similarity to the ectoprocts, and together they have traditionally been grouped as Bryozoa.

Another phylum of very tiny animals (less than 1 mm in length) is Cycliophora (described as a single species, *Symbion pandora*, but at least one other species awaits description). *Symbion* was described in 1995 from specimens attached to the mouthparts of the Norwegian lobster, *Nephrops* (Funch and Kristensen, 1995). One of their unique features is a very complex life cycle, with sessile and motile stages, feeding and nonfeeding stages, dwarf males and giant females, and enigmatic chordoid and Pandora larvae. The external shape of the sessile feeding stages hints at an entoproct affinity, being shaped like a minute urn attached to a stalk that ends in an adhesive disk. Ciliated tentacles, however, are lacking. Instead the animal has a bell-shaped buccal funnel with a mouth surrounded by cilia that produce a feeding current.

The first complete description of Micrognathozoa was published in October 2000, and is based on one species, *Limnognathia maerski*, which is one of the smallest metazoans ever described, measuring some 100–150 μm in length. Strikingly, its discoverers were the same zoologists who had first described Cycliophora 5 years previously (Kristensen and Funch, 2000). Its complex cuticularized jaw

apparatus is very similar to both rotifer trophi and gnathostomulid jaws.

Although the precise relationships between the platyzoans remain uncertain at the moment, several tentative conclusions can be drawn (Halanych, 2004; Jenner, 2004b; Funch *et al.*, 2005). Accumulating molecular evidence suggests that platyhelminths (catenulids and rhabditophorans) are undeniably lophotrochozoans, but neither molecular nor morphological evidence, or a combination thereof, has reliably identified a sister group of the platyhelminths.

The striking similarities of the jaw elements in syndermates and gnathostomulids support a clade Gnathifera (Figure 8). Based on the possession of similar complex cuticularized jaws and shared ultrastructural similarities of the epidermis with the syndermates, Micrognathozoa may also be a member of Gnathifera. Available nuclear and mitochondrial sequence data paint a more ambiguous picture. They provide no unambiguous support for the monophyly of Gnathifera. Depending on data source and analysis parameters, the syndermates are sometimes the sister group of Cycliophora, a clade of Cycliophora, Micrognathozoa, and Gnathostomulida, or a clade of gastrotrichs and platyhelminths. Placement of the other platyzoan taxa is equally sensitive to changes in data source and analysis parameters.

1.02.3.5.4 Gastrotricha and Chaetognatha

Gastrotrichs are microscopic, meiobenthic animals (generally <1 mm), including both freshwater and marine species. Their general biology and evolution remain poorly known. Gastrotrich monophyly is well supported, with one of the most conspicuous autapomorphies being an extracellular cuticle that covers the entire body surface, including the locomotory and sensory cilia. Their name refers to the presence of a ventral creeping surface adorned with cilia.

The phylogenetic position of the gastrotrichs in the Metazoa remains highly contentious. Morphological evidence has been used to argue for a relationship with ecdysozoans, frequently as the sister group to the remaining ecdysozoans, or the scalidophorans and nematoidans if the Ecdysozoa was not supported as a clade. The use of molecular evidence, or a combination of morphology and molecules, has not greatly clarified their phylogenetic position either, and they have been variously allied with platyhelminths, gnathostomulids, acanthocephalans, nematomorphs, or placed basal in the Bilateria. Clearly, significant research is required to resolve the phylogenetic affinities of these poorly understood creatures.

The unique morphology of chaetognaths makes it a well-demarcated group. Chaetognaths are slender marine predators between 2 and 120 mm long, with fins lining their sides and tail. Their heads are equipped with a formidable array of grasping spines used in prey capture. This general morphology and their jerky or darting swimming behavior explain their common name of arrow worms.

The possession by chaetognaths of a mixture of characters traditionally conceived as broadly protostomian, such as the organization of the nervous system and the composition of the cuticle, and broadly deuterostomian, including radial cleavage and the mode of coelom development, have ensured enduring debate about their phylogenetic relationships. Recent morphological cladistic analyses have variously placed chaetognaths at the base of the Bilateria, Ecdysozoa, or Deuterostomia, while molecular (SSU, LSU, Hox genes, and mitochondrial genome) and combined morphological and molecular analyses have recently placed them among ecdysozoans, within Lophotrochozoa, as a sister group to onychophorans or nematodes, as a basal protostome, or a basal bilaterian. Thus the phylogenetic position of the chaetognaths remains profoundly puzzling.

1.02.4 Conclusion and Future Progress

High-level metazoan phylogeny is in a state of flux. This is a time of unparalleled research activity and funding possibilities. Reconstructing the tree of life has been afforded similar priority status as the various genome-sequencing projects. As a result, the next decade will witness a great expansion and refinement of our developing views about the phylogenetic history of life. The overview presented in this article should thus be considered as merely a tentative sketch, parts of which will be consolidated as new data accrue, while other parts will inevitably be significantly altered. The monophyly of Protostomia, the phylogeny within Lophotrochozoa, and the sequence of divergences of nonbilaterians are some of the most pressing questions of high-level metazoan phylogenetics. However, similar unanswered questions also prevail on lower levels, ranging from the phylogeny of the basic gnathostome clades within the Vertebrata, to the phylogeny of extant birds. Irrespective of what the final topology of the animal tree of life will look like, we are certain to learn a lot in the next few years.

1.03 Phylogenetic Character Reconstruction

J S Albert, University of Louisiana, Lafayette, LA, USA

Glossary

adaptation A feature or phenotype or trait that evolved to serve a particular function or purpose.

anagenesis The origin of evolutionary novelties within a species lineage by changes in gene allele frequencies by the processes of natural selection and/or neutral genetic drift.

character polarity The temporal direction of change between alternative (primitive and derived) states of a character.

character state reconstruction The process of estimating the ancestral or primitive condition of a character at a given node (branching point) in a phylogenetic tree.

clade A complete branch of the tree of life. A monophyletic group.

cladogenesis The origin of daughter species by the splitting of ancestral species; may or may not occur under the influence of natural selection.

cladogram A branching tree-shaped diagram used to summarize comparative (interspecific) data on phenotypes or gene sequences. In contrast to a phylogeny, a cladogram has no time dimension.

comparative method The study of differences between species.

continuous trait A quantitatively defined feature with no easily distinguished boundaries between phenotypes (e.g., size, cell counts, and gene expression levels).

convergence Similarity of structure or function due to independent evolution from different ancestral conditions.

discrete trait A qualitatively defined feature with only a few distinct phenotypes (e.g., polymorphism; presence vs. absence).

homology Similarity of structure or function due to phylogeny (common ancestry).

homoplasy Similarity of structure or function due to convergence, parallelism or reversal.

monophyletic A systematic category that includes an ancestor and all of its descendants; a complete branch of the tree of life; a 'natural' taxon; a clade.

node An internal branching point in a phylogenetic tree.

optimization Methods for estimating ancestral trait values on a tree. Commonly used optimization criteria are: maximum parsimony (MP) which minimizes the amount of trait change, and maximum likelihood (ML) which maximizes the likelihood of a trait at a node given likelihood values for trait evolution.

parallelism Similarity of structure or function due to independent evolution from a common ancestral condition.

paraphyletic A systematic category that includes an ancestor and some but not all of its descendents (e.g., 'invertebrates', 'agnathans', 'fish', and 'reptiles' (*sans* birds)).

parsimony	A principle of scientific inquiry that one should not increase, beyond what is necessary, the number of entities required to explain anything.
phenotypic evolution	Change in the developmental program descendents inherit from their ancestors.
phylogenetic character	A homologous feature or phenotype or trait of an organism or group of organisms.
phylogenetic systematics	A method for reconstructing evolutionary trees in which taxa are grouped exclusively on the presence of shared derived features.
phylogenetic tree	Genealogical map of interrelationships among species, with a measure of relative or absolute time on one axis. Also called a tree of life or a phylogeny.
phylogeny	The evolutionary history of a species or group of species that results from anagenesis and cladogenesis.
polyphyletic	A systematic category that includes taxa from multiple phylogenetic origins (e.g., 'homeothermia' consisting of birds and mammals).
reversal	Change from a derived character state back to a more primitive state; an atavism. Includes evolutionary losses (e.g., snakes which have 'lost' their paired limbs).
synapomorphy	A shared, derived character used as a hypothesis of homology.
taxon	A species or monophyletic group of species (plural taxa).
trait evolution	The sequence of changes of a feature or phenotype on a phylogeny.

1.03.1 Introduction to Character State Reconstruction and Evolution

Comparisons among the features of living organisms have played a prominent role in the biological sciences at least since the time of Aristotle. The comparative approach takes advantage of the enormous diversity of organismal form and function to study basic biological processes of physiology, embryology, neurology, and behavior. This approach has given rise to the widespread use of certain species as model systems, based on what has become known as the August Krogh Principle: "For many problems there is an animal on which it can be most conveniently studied" (Krebs, 1975).

From an evolutionary perspective, interspecific (between species) comparisons allow for the systematic study of organismal design. Rensch (1959) conceived of phylogeny as being composed of two distinct sets of processes: anagenesis, the origin of phenotypic novelties within an evolving species lineage (from the Greek *ana* = up + *genesis* = origin), and cladogenesis, the origin of new species from lineage splitting (speciation) (from the Greek *clado* = branch). Anagenetic changes arise within a population by the forces of natural selection and genetic drift. Cladogenesis may or may not arise from these population-level processes, and in fact many (or perhaps most?) species on Earth are thought to have their origins from geographical (allopatric) speciation under the influence of landscape and geological processes (Mayr, 1963; Coyne and Orr, 1989).

Because species descend from common ancestors in a hierarchical fashion (i.e., from a branching, tree-like process of speciation) closely related species tend to resemble each other more than they do more distantly related species. Patterns in the diversification of phenotypes have therefore been described as mosaic evolution, in which different species inherit distinct combinations of traits depending on the position of that species in the tree of life (McKinney and McNamara, 1990). Under this view, character evolution is regarded as a process of historical transformation from a primitive to a derived state, and study of this process necessarily presumes knowledge of primitive or ancestral conditions. In other words, because character evolution is perceived as trait change on a tree, it is necessary to estimate 'ancestral trait values'.

Direct observations of ancient phenotypes may be taken from fossils, which provide unique information on entirely extinct groups of organisms, and are usually associated with stratigraphic information pertaining to relative and absolute geological ages (Benton, 1993). Nonetheless, the fossil record has many well-known shortcomings, including the famously incomplete levels of preservation, and usually very limited information about the nature of soft tissues such as nerves and brains (but see Edinger, 1941; Stensiö, 1963). Paleontological information on ancient physiological and behavioral traits is even more scanty (but see Jerison, 1976; MacLeod and Rose, 1993; Rogers, 2005).

Recent years have seen great advances in the formulation of comparative methods to estimate or infer ancestral phenotypes from extant (living) species (Garland *et al*., 1992, 1999; Martins, 2000). These methods use patterns in the mosaic of traits present among species in the context of an explicit hypothesis of interrelationships. These methods also address new topics, such as whether rates of

phenotypic evolution have differed among lineages (clades), the circumstances in which a phenotype first evolved, the selective and developmental mechanisms underlying the origin of new phenotypes, and the evolutionary lability of phenotypes (Albert *et al.*, 1998; Blomberg *et al.*, 2003; Blackledge and Gillespie, 2004).

In this article, I summarize the major recent developments in phylogenetically based methods of studying character evolution, with the goals of explaining both the strengths and weaknesses of alternative methods. Most of the empirical examples cited are among animals with the most complex central nervous systems (e.g., vertebrates) in which neurological and behavioral evolution has been (arguably) most extensively studied. A major goal of this article is to highlight some of the most exciting new developments in the study of character evolution now being explored in this fascinating area of comparative neurobiology.

1.03.2 Basic Concepts

1.03.2.1 Homology: Similarity Due to Common Ancestry

All methods of ancestral character state reconstruction make explicit assumptions about the homology of the traits under study. In comparative biology the term 'homology' refers to similarity in form or function arising from common ancestry. In other words, homologous features among organisms can be traced to a single evolutionary origin. In the language of Garstang (1922), a homologous trait is a unique historical change in the developmental program of an evolving lineage. Homologous similarities may be observed in any aspect of the heritable phenotype, from properties of genetic sequences (e.g., base composition and gene order), through aspects of development, including cellular, tissue, and organismal phenotypes, to aspects of behavior that emerge from the organization of the nervous system. Homology in behavioral traits has been examined in a number of taxa, and in a variety of contexts (de Queiroz and Wimberger, 1993; Wimberger and de Queiroz, 1996; Blomberg *et al.*, 2003). Taxa are individual branches of the tree of life, and may include species or groups of species that share a common ancestor (the latter are also referred to as clades or monophyletic groups).

It is important to note that developmental, structural, positional, compositional, and functional features of phenotypes are all useful in proposing hypotheses of homology. Yet by the evolutionary definition employed above, only features that can be traced to a common ancestor in an explicitly phylogenetic context are regarded as homologues. Because phylogenies are the product of comparative analyses using many traits, it is in fact congruence in the phylogenetic distribution of characters that serves as the ultimate criterion for homology. By this criterion homologous characters are said to have passed the test of congruence. In other words, congruence in the phylogenetic distribution of numerous character states is regarded to be the ultimate evidence for homology (Patterson, 1982; see Primate Brain Evolution in Phylogenetic Context, Electric Fish, Electric Organ Discharges, and Electroreception).

1.03.2.2 Homoplasy: Convergence, Parallelism, and Reversal

All other forms of phenotypic similarity that arise during the course of evolution are referred to collectively as homoplasy (similarity due to causes other than homology). Homoplastic characters may arise from several sources: convergence due to similar functional pressures and natural selection, parallel (independent) evolution to a common structure or function from organisms with similar genetic and developmental backgrounds, or convergent reversal to a common ancestral (plesiomorphic) condition. Some well-known examples of convergent evolution in the nervous system include: image-forming eyes of cephalopod mollusks (e.g., squids and octopods) and vertebrates (Packard, 1972), and the evolution of G-protein-coupled receptors as odorant receptors in many animal phyla (Eisthen, 2002). Examples of parallel evolution in the nervous system of vertebrates have been summarized in several recent reviews (Nishikawa, 2002; Zakon, 2002). These include: electric communication in mormyriform (African) and gymnotiform (South American) electric fishes (Albert and Crampton, 2005), prey capture among frogs (Nishikawa, 1999), sound localization among owls (Grothe *et al.*, 2005), and thermoreception in snakes (Hartline, 1988; Molenaar, 1992).

Reversals are among the most common forms of homoplasy, and are often the most difficult to detect even in the context of a resolved phylogenetic hypothesis of relationships (Cunningham, 1999). The reason for this is the phenotypes of some reversals may be quite literally identical, as in the case of convergent loss of structures (e.g., the derived loss of paired limbs in snakes and limbless lizards).

1.03.2.3 Character State Polarity

A central task of ancestral character state reconstruction is determining the direction or polarity of evolutionary change between alternative states of a character. The ancestral state is referred to as

plesiomorphic or primitive, and the descendent state is referred to as apomorphic or derived. Establishing the polarity of a character state transformation is critical to understanding the functional significance of that event. Phenotypes determined to be primitive simply mean they precede the derived state in time and are not necessarily functionally inferior. It is often, although by no means always, the case that characters evolve from more simple to more complex states, or from the absence of a particular state to the presence of that state.

There are several methods in use to determine character state polarity. The most widely used method is the so-called outgroup criterion, which employs conditions observed in members of clades other than the clade in which the derived state is present. The basic idea of the outgroup criterion is that for a given character with two or more states within a group, the state occurring in related groups is assumed to represent the plesiomorphic state. In other words, the outgroup criterion states that if one character is found in both ingroup and outgroup, this character is then postulated to be the ancestral state (plesiomorphic). Of course, it is always possible that a given outgroup exhibits an independently derived state of a given character, which is why the condition in several outgroup taxa is regarded as a more reliable test of the plesiomorphic condition.

1.03.2.4 Character or Trait Data

Methods for estimating ancestral character states and analyzing phenotypic evolution may treat trait data either as continuous (quantitative) or discrete (qualitative) (Zelditch *et al*., 1995; Rohlf, 1998; Wiens, 2001). Continuously distributed trait values have no easily distinguished boundaries between phenotypes. Examples of continuous traits include the sizes of brains and brain regions (e.g., nuclei), the number of cells in a brain region, pigment intensity, amplitude or timing of communication signals, and the amount of gene expression in a tissue. Continuous phenotypic variation typically reflects the additive effects of alleles at multiple loci and is frequently also influenced by environmental factors. Patterns of intraspecific (within species) continuous variation are often analyzed using parametric statistics, including such devices as the population mean and standard deviation. Methods for the analysis of interspecific (between species) continuous traits are useful for assessing the quantitative relationships among variables to address questions regarding, for example, the trade-offs and constraints among correlated traits.

Discontinuous traits have only a few distinct phenotypes. In many cases alternative alleles generate phenotypes that differ from each other in discrete steps, such that each phenotype can be clearly distinguished from the others. Many classes of phenotypic data are inherently discrete, such as meristic counts (e.g., number of body segments, rhombomeres, and cortical visual maps), and genetic polymorphisms (e.g., left- vs. right-handedness). Nucleotide bases at a locus are discrete states of a character. The presence (or absence) of derived traits on a phylogenetic tree also constitutes a class of discrete phenotypes. Such derived traits that underlie or explain subsequent evolutionary events are referred to as key innovations. Some widely cited examples of putative key innovations in the comparative neurosciences include arthropod cephalic tagmosis (Strausfeld, 1998), cephalopod eyes (Hanlon and Messenger, 1996), craniate neural crest (Northcutt and Gans, 1983), and ray-finned fish genome duplication (Taylor *et al*., 2003; Postlethwait *et al*., 2004). Each of these novelties is thought to have been critical in the diversification of the taxon in which it originated.

1.03.2.5 Adaptation

One of the most widely applied uses of ancestral character state reconstruction is in the study of adaptation. The word adaptation is derived from the Latin *ad* (to, toward) and *aptus* (a fit), and is used to imply a feature or phenotype that evolved to serve a particular function or purpose. For example, the function or purpose of an animal central nervous system is to coordinate sensory information and motor output patterns; that is to say, a centralized brain is an adaptation for sensory-motor coordination. Adaptation is therefore used both as a noun to describe the features that arose because of natural selection, and as a verb, the process of natural selection through which the features originated. In an evolutionary context, an adaptation is not only a static description of the match between form and function, but is also an explanation for the origin of that relationship (Russell, 1916).

It is important to distinguish among several distinct uses of the word 'adaptation' in the biological sciences. A physiological adaptation is an organismal response to a particular stress: if you heat up from the sun you may respond by moving into the shade (a behavioral adaptation), or you may respond by sweating (a physiological adaptation). In an evolutionary context, adaptation is also a change in response to a certain problem, but the change is genetic. Evolutionary adaptations that

result from the process of natural selection usually take place over periods of time considerably longer than physiological timescales. Traits are referred to as adaptations only when they evolved as the solutions for a specific problem; that is, for a particular function or purpose. A physiological response can itself be an adaptation in the evolutionary sense.

In reconstructing ancestral phenotypes it is important to bear in mind the primitive condition may be more or less variable than the conditions observed in living species. In some cases physiological or developmental plasticity is itself an evolutionary (genetic) specialization that permits organisms to adapt physiologically or behaviorally. For example, many species are characterized as eurytopic, or tolerant of a wide variety of habitats. Other species are stenotopic, or adapted to a narrow range of habitats. Similarly, individual characters may be more or less variable within a species, and this variability may itself be subject to evolutionary change. Flexible phenotypes may be more adaptive in a variable environment and stereotyped phenotypes more adaptive in a stable environment (van Buskirk, 2002).

1.03.2.6 Phylogenetic Trees

Implicit in all phylogenetic methods for studying character evolution is a tree-shaped branching diagram, alternatively called a dendrogram, cladogram, phenogram, or tree, depending on the methods used to construct the diagram, and the information content it is intended to convey. It is important to note that each of the many alterative methods for building trees that are currently available was designed to communicate different kinds of information. The methods grouped formally as 'phylogenetic systematics' (cladistics) exclusively use derived similarities (synapomorphies) to hypothesize genealogical relationships. This is to be contrasted with phenetic methods which use measures of overall similarity to group taxa, including both primitive and derived aspects of similarity. Cladistic methods generate branched diagrams referred to as cladograms, which should be viewed as summary diagrams depicting the branching pattern most consistent with a given data set (morphological or molecular). It is important to distinguish raw cladograms from phylogenetic trees; there is no time dimension to a cladogram *per se*, and the branch lengths are simply proportional to the minimum number of steps required to map all the character states onto that tree. A robust phylogenetic tree is usually the result of several or many phylogenetic analyses. The geological time frames associated with branching events are usually estimated from external paleontological, molecular, and biogeographic sources of information.

Figure 1 provides a conceptual overview for how phylogenetic trees may be used to study phenotypic evolution. All comparative approaches begin by assuming (or building) a hypothesis of genealogical interrelationships among the taxa of interest. There are many methods, even whole philosophies, of tree building, and the reader is referred to Page and Holmes (1998) for an introduction to this literature. Phylogenetic methods are then used to optimize character states at internal nodes of the tree; these nodes or branching points are hypothesized speciation events. Comparisons of trait values at ancestral and descendant nodes of the tree allow the history of phenotypic changes to be traced. The distribution of these phenotypic changes (also known as steps or transformations) can then be assessed, qualitatively or quantitatively, depending on the types of data examined and the analytical methods employed.

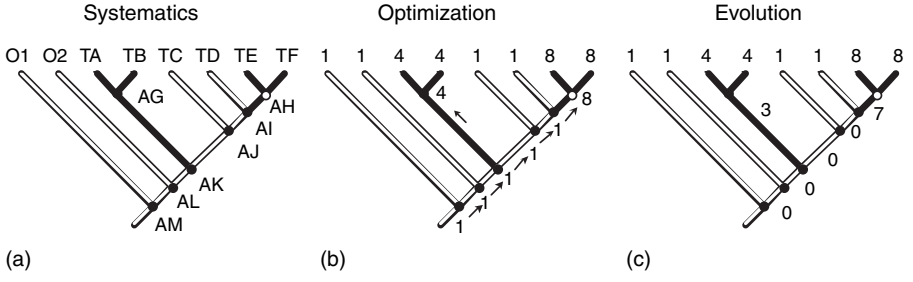

Figure 1 Summary of the comparative approach for inferring phenotypic evolution. a, Phylogenetic systematics (i.e., tree building): reconstruction of genealogical interrelationships among taxa (extant and/or fossil) using morphological and/or molecular sequence data. Taxa are species or clades (monophyletic groups of species): phylogeny includes six ingroup terminal taxa (TA–TF) and two outgroup taxa (O1 and O2). b, Character state optimization at internal nodes (branching points or hypothesized speciation events). Observed trait values at tips of the tree. Seven internal tree nodes represented by ancestral taxa (AG–AM) with trait values estimated by linear parsimony. c, Evolution: tracing the history of phenotypic changes along branches of the tree. Numbers indicate absolute amount of trait change on the branch.

A tree-shaped branching diagram conveys two kinds of information (whether they are intended or not): the tree topology, or the sequential order in which the taxa branch from one another, and the lengths of the individual branches (Figure 2). These two aspects of a tree correspond to the cladogenesis and the anagenesis of Rensch (1959). The tree topology (branching order) is reconstructed from the distribution of shared–derived traits among taxa. The traits examined may be morphological novelties or nucleotide substitutions. Branch lengths may be reconstructed from one or more sources of information, including alternative models (or modes) of character evolution, or from empirical data. Under models of constant (or near constant) evolution (e.g., molecular clocks), all terminal taxa are treated as equidistant from the root (or base) of the tree. Terminal taxa are those at the tips of the tree, as opposed to ancestral taxa at internal nodes (branching points) within the tree. Under models of punctuated equilibrium, all (or most) character evolution occurs at branching points (nodes), and all branches are therefore of equal (or almost equal) length. Branch lengths derived from empirical data sets may be treated as proportional to the amount of character state change on that particular tree topology, or from stochastic models of evolution assuming that DNA nucleotide substitutions occur at an equal rate (Sanderson, 2002). The constant evolution and punctuated equilibrium models represent extremes of branch-length heterogeneity, between which branch lengths derived from empirical data sets usually fall. Branch lengths for clades with known fossilized members can also be estimated from the geological age of these fossils (Benton *et al.*, 2000; Near and Sanderson, 2004). Calibrations based on molecular sequence divergence or fossil data can take one of two forms: assignment of a fixed age to a node, or enforcement of a minimum or maximum age constraint on a node. The latter option is generally a better reflection of the information content of fossil evidence.

It is important to recognize an analytical difference in the two kinds of information represented in a phylogeny: whereas the tree topology is transitive, the branch lengths are not. In the language of formal logic, 'transitive' means that a relationship necessarily holds across (i.e., it transcends) the particularity of data sets. In the case of phylogenetic trees, the branching order derived from analysis of one data set is expected to predict the branching order of independent data sets (e.g., those derived from different genes, genes and morphology, osteology and neurology). Branch lengths, however, are intransitive, meaning the branch length values derived from one data set are not expected to predict those of other data sets. The reason for this is that we believe there has been a single phylogenetic history of life; a unique sequence of speciation events that gave rise to the species richness of the modern world. This single history underlies the evolution of all aspects of organismal phenotypes. There are, however, no such expectations of homogeneity in the rates of phenotypic (or gene sequence) evolution; in fact,

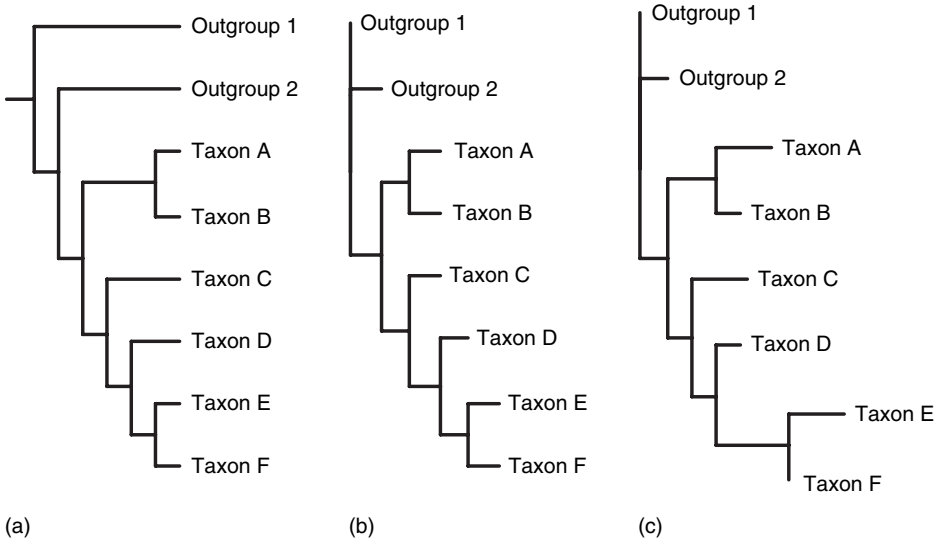

Figure 2 Alternative branch length models. a, Molecular clock: all terminal taxa equidistant from root to from an ultrametric tree. b, Equal branch lengths: all character evolution (anagenesis) occurs at branching events, as in punctuated equilibrium. c, Empirical: branch lengths proportional to amount of character evolution and/or geological ages determined from fossils. Note: tree topology is transitive; branch lengths are not.

the differential effects of directional and stabilizing selection on different phenotypes may be expected to result in longer or shorter branches for some traits than others.

1.03.3 Methods

1.03.3.1 Parsimony Optimization of Discrete Traits

The principle of parsimony (i.e., Occam's razor) is widely used in the natural sciences as a method for selecting from among numerous alternative hypotheses. The principle of parsimony underlies all scientific modeling and theory building. The basic idea is that one should not increase, beyond what is necessary, the number of entities required to explain anything. In this context, parsimony means that simpler hypotheses are preferable to more complicated ones. It is not generally meant to imply that Nature itself is simple, but rather that we as observers should prefer the most simple explanations.

Maximum parsimony (MP) is a character-based method used in phylogenetic systematics to reconstruct phylogenetic trees by minimizing the total number of evolutionary transformations (steps) required to explain a given set of data. In other words, MP minimizes the total tree length. The steps may be nucleotide base or amino acid substitutions for sequence data, or gain and loss events for restriction site and morphological data. MP may also be used to infer ancestral states of a character within a phylogenetic tree (this is discussed in the following).

1.03.3.2 Binary and Multistate Characters

Discrete characters may be characterized as either binary (coded into two mutually exclusive alternative states) or as multistate (a transformation series of three or more discrete states). The alternative states of a binary character are generally (although not necessarily) explicit hypotheses of the primitive and derived (advanced) states of a single evolutionary transformation event, such as the origin (or loss) of a novel feature. A multistate character is a more complex intellectual device with many more interpretations of meaning. Multistate characters may be presented as many stages of a long-term phylogenetic trend (e.g., larger relative brain size, larger body size) or as independent alternative trends from a common ancestral plan (e.g., large brains evolving from enlargement of the cerebellum in chondrichthyans vs. the telencephalon in mammals). An ordered transformation series models a preconceived phylogenetic sequence of changes, such that in the series 1–2–3, state 3 is only permitted to be derived from state 2. In an unordered transformation series, state 3 may be derived from either of states 1 or 2. Following a similar logic, reversals (e.g., from 2 to 1) may be allowed, penalized, or prohibited, depending on the preconceptions of the investigator. Of course, building *a priori* conceptions of order or reversibility into an analysis of character state change precludes the use of that analysis as an independent test of those assumptions. To summarize this section, treating all characters as unpolarized and unordered means that all transitions among states are regarded as equally probable.

1.03.3.3 Squared-Change and Linear Parsimony

There are two general types of MP widely used in tracing the evolution of continuous traits: squared-change parsimony and linear parsimony. Squared-change algorithms (Rogers, 1984) seek to minimize the amount of squared change along each branch across the entire tree simultaneously, using a formula in which the cost of a change from state x to y is $(x-y)^2$. Squared-change parsimony assigns a single ancestral value to each internal node to minimize the sum of squares change over the tree (Maddison, 1991). When using squared-change parsimony, the absolute amount of evolution over the whole tree is not necessarily minimized, and some degree of change is forced along most branches. Linear parsimony reconstructs ancestral node values by minimizing total changes (Figure 3). Linear-parsimony algorithms (Kluge and Farris, 1969) seek to minimize the total amount of evolution and consider only the three nearest nodes when calculating the ancestral character states. In linear parsimony the cost of a change from x to y is $|x-y|$. The result of this local optimization is that changes are inferred on very few or single branches. Linear parsimony therefore permits the accurate reconstruction of discontinuous events, or of large changes in trait values on a tree. Although evolutionary change is often thought of as gradual, large changes on a tree may result from a variety of real biological processes, not the least of which is the extinction of taxa with intermediate trait values (Butler and Losos, 1997).

1.03.3.4 Maximum Likelihood and Bayesian Optimization

Maximum likelihood (ML) methods for tracing character evolution select ancestral trait values with highest likelihood on a given phylogenetic

Taxon	*Character*
Outgroup 1	1
Outgroup 2	1
Taxon A	4
Taxon B	4
Taxon C	1
Taxon D	1
Taxon E	8
Taxon F	8

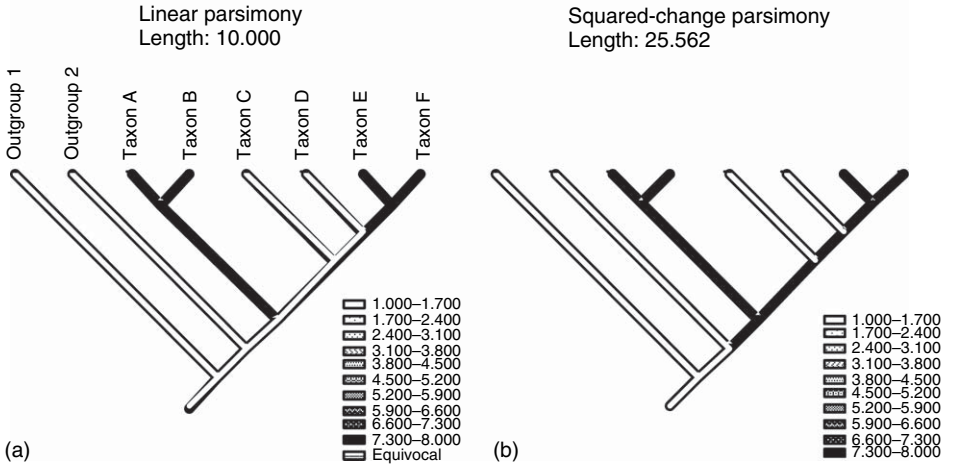

Figure 3 Alternative methods for estimating ancestral character states. a, Linear parsimony. b, Squared-change parsimony. Character state data by taxon reported in the table.

hypothesis given a model of trait evolution (defined by user). Bayesian analysis (BA) selects the ancestral trait value with the highest posterior probability, given the probabilities of priors (external evidence) and assumptions of trait evolution (defined by user). Because they are model-based approaches, ML and BA optimization methods are more commonly used in the analysis of gene sequence data, using explicit models of changes between nucleotide bases (Liò and Goldman, 1998; Sullivan *et al*., 1999). ML has been used in the analysis of continuous character evolution where the models may vary from very simple (e.g., Brownian motion) to quite complex; there is a large literature regarding methods to test the validity of using particular models (Diaz-Uriarte and Garland, 1996; Oakley, 2003).

1.03.3.5 Which Optimization Approach to Use?

Empirical studies using simulated data sets and those derived from evolution in a test tube have concluded that model-driven approaches like ML and BA give more accurate results than MP when the modeled parameters (i.e., likelihood or probability of nucleotide substitutions) are known, but can be positively misleading when the parameters are unknown (Hillis *et al*., 1992; Oakley and Cunningham, 2000). MP often provides less resolution (more interior tree nodes reconstructed with ambiguous states), than ML or BA methods, which usually give very precise estimates with high confidence levels even under circumstances in which available data are insufficient to the task. In this regard, MP methods are regarded as more conservative, with lower risk of recovering false positives (Webster and Purvis, 2002).

Most studies on the evolution of neural characters use MP approaches because, unlike molecular sequence data, it is not straightforward how to pose or parametrize models on the evolution of complex phenotypes. Continuously varying aspects of neural features, like the size or shape of structures, have been modeled as simple Brownian motion or random walk processes, under the assumptions that the trait has not experienced selection and that there are no constraints on variance through time (Butler and King, 2004). Whether or not the assumptions of Brownian motion or any other specific model are satisfied by real neural or behavioral data is almost completely unknown.

A general conclusion reached by a number of review studies is that, under most circumstances faced by comparative morphologists, linear parsimony is the most conservative method for reconstructing ancestral trait values (Losos, 1999). Unlike squared-change parsimony, linear parsimony does not average out change over the interior nodes of a tree, but rather permits

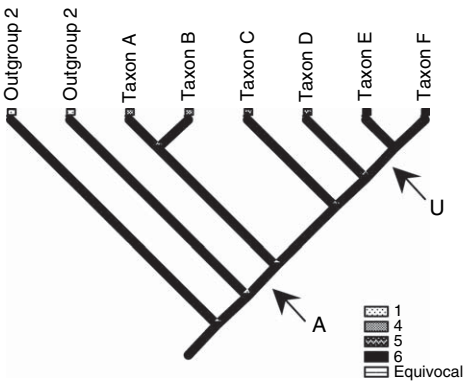

Figure 4 Ambiguous (A) vs. unambiguous (U) optimizations.

discontinuous changes along a branch. This has the advantageous effect of not forcing gradual trait evolution on the tree, and also of not forcing unnecessary trait reversals (Figure 3). A methodological advantage of linear over squared-change parsimony is that it permits the reconstruction of ambiguous ancestral character state reconstructions (Figure 4). This is a desirable property in cases where the available data are in fact insufficient to resolve the trait value at a specified internal nodes (Cunningham, 1999). A methodological disadvantage of linear parsimony is that, computationally, it requires a completely resolved tree topology in which all branching events are divided into only two daughter clades. Unfortunately, fully resolved trees are unusual in most studies with many (>30) species. By contrast, squared-change parsimony can be calculated on a tree with unresolved multichotomies (also called polytomies), and therefore often becomes the method of choice by default. One alternative to using squared-change parsimony when faced with an incompletely resolved tree is to use linear parsimony on numerous (100, 1000) arbitrarily resolved trees, and then report statistics (e.g., minimum and maximum) of the trait values obtained. Software for this procedure is available in the freely available Mesquite software package (see 'Relevant Website').

1.03.3.6 Correlative Comparative Methods

Ordinary least-squares regression allows one to investigate relationships between two variables in order to ask if change in one of these variables is associated with change in the other. One may ask, for example, how is variation in brain size related to body size, ecological role (predator vs. prey), climate, life history mode, or locomotion (Albert *et al.*, 2000; Safi and Dechmann, 2005). The least-squares fitting procedure is commonly used in data analysis in comparative studies, and conventional regression analysis has been one of the main tools available to comparative neurobiology and ecological physiology to study form–function relationships and adaptation (Garland and Carter, 1994). However, it is now widely recognized that interspecific observations generally do not comprise independent and identically distributed data points, thus violating fundamental assumptions of conventional parametric statistics (Felsenstein, 1985, 1988; Pagel and Harvey, 1989; Harvey and Pagel, 1991).

Phylogenetically based statistical methods allow traditional topics in comparative neuroanatomy and physiology to be addressed with greater rigor, including the form of allometric relationships among traits and whether phenotypes vary predictably in relation to behavior, ecology, or environmental characteristics (Brooks and McLennan, 1991; Frumhoff and Reeve, 1994; Losos, 1996). In a conventional regression analysis the data points represent terminal taxa. In a phylogenetic regression the data points represent sister-taxon comparisons (Grafen, 1989). These two methods are compared in Figure 5, in which identical data are analyzed using conventional and phylogenetic regression methods. The phylogeny of Figure 5 includes six terminal taxa (TA–TF) and two outgroup taxa (O1 and O2), which are represented by two continuously distributed characters (C1 and C2). The tree topology has been determined from data other than characters 1 and 2, and the branch lengths are treated as equal (under a model of punctuated equilibrium). There are seven internal tree nodes represented by ancestral taxa (AG–AM) with trait values estimated by least-square parsimony. By removing psuedorepilcates, the phylogenetic regression compares fewer taxa, has fewer degrees of freedom, and has a lower correlation coefficient (R^2 value) than does the conventional regression. The phylogenetic regression, therefore, provides a better quantitative measure of correlated evolution between the two traits, and is a more conservative measure of the strength of adaptive pressures.

Relationships between brain size and the volume of frontal and visual cortices in mammals have recently been studied using the methods of phylogenetic regression analysis (Bush and Allman, 2004a, 2004b). These studies found that size has a profound effect on the structure of the brain, and that many brain structures scale allometrically; that is, their relative size changes systematically as a function of brain size. They also conclude that the three-dimensional shape of visual maps in anthropoid

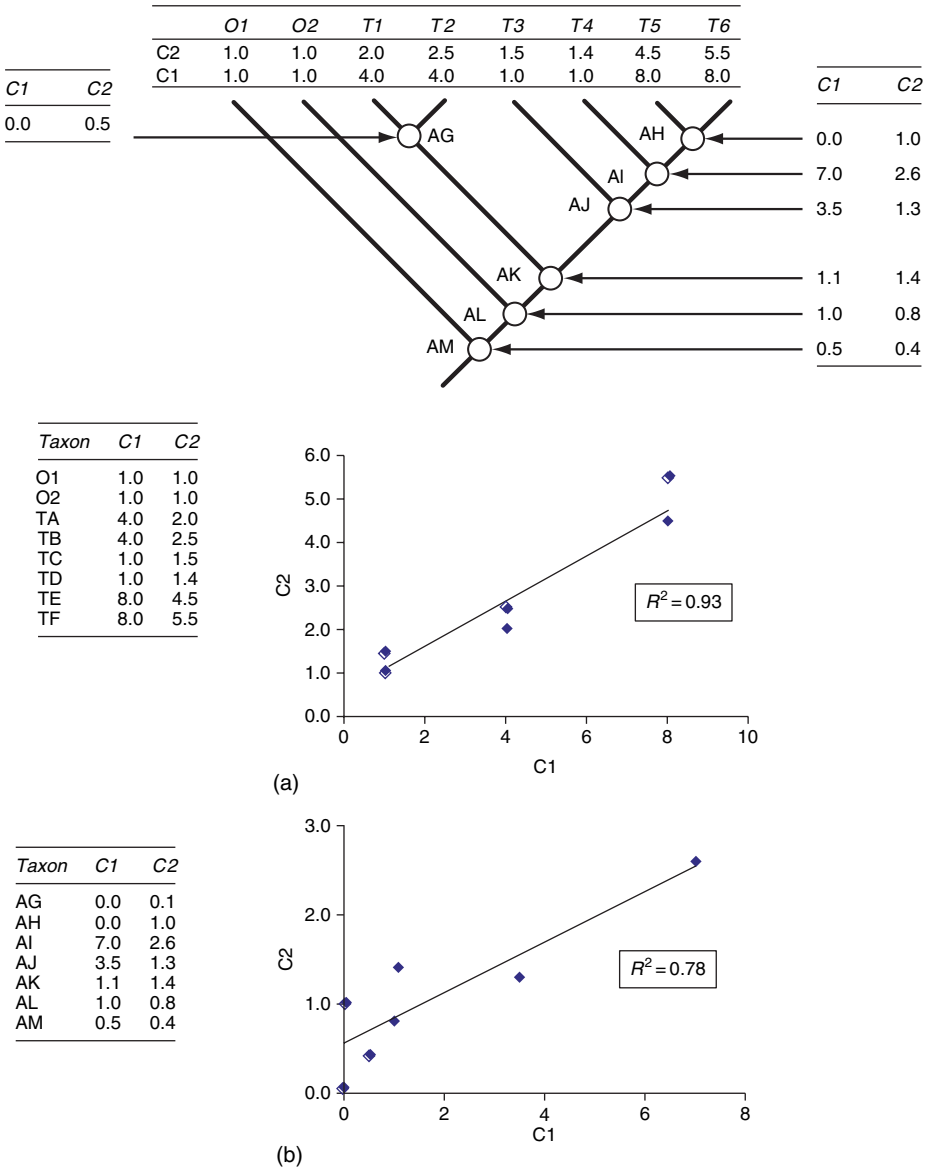

Figure 5 Comparison of conventional and phylogenetic regression analyses. Phylogeny of six terminal taxa (TA–TF) and two outgroup taxa (O1 and O2), represented by two continuously distributed characters (C1 and C2). Tree topology determined from data other than characters 1 and 2, and branch lengths treated as equal. Seven internal tree nodes represented by ancestral taxa (AG–AM) with ancestral trait values estimated by least-squares parsimony. a, Conventional regression of trait values from terminal taxa. b, Phylogenetic regression of trait values at internal tree nodes using the method of independent contrasts. Note that by removing psuedoreplicates, the phylogenetic regression compares fewer taxa, has fewer degrees of freedom, and has a lower correlation coefficient (R^2 value) than does the conventional regression. The phylogenetic regression, therefore, provides a more conservative quantitative measure of correlated evolution between the two traits.

primates is significantly longer and narrower than in strepsirrhine primates. Using conventional regression analyses, von Bonin (1947) showed that frontal cortex hyperscales with brain size, and humans have "precisely the frontal lobe which [we deserve] by virtue of the overall size of [our] brain." These are, of course, precisely the qualitative conclusions arrived at by Bush and Allman using analysis of phylogenetic regressions. In fact, many studies reviewing the uses of phylogenetic methods for reconstructing ancestral states conclude that all methods will recover a very strong historical signal (Losos, 1999).

1.03.4 Limitations of Methods

The accuracy of ancestral reconstructions has been investigated by comparisons with known phylogenies (e.g., viruses, computer simulations; Oakley and Cunningham, 2000). It is well known

that all phylogenetically based methods perform poorly when taxon sampling is low and when rates of evolution in the character of interest are unequal among branches of the tree (Garland *et al*., 1993; Sullivan *et al*., 1999; Hillis *et al*., 2003). Further, all methods for studying character evolution on a tree make certain assumptions about the capacity of trees to faithfully record the actual history of character change. These include the assumptions that: phenotypic diversification results largely from speciation and that the effects of extinction have not erased the signal, that taxon sampling faithfully represent the history of diversification, and that genealogical history is largely or entirely bifurcating (vs. multifurcating or converging). Of course, all methods assume we know the 'true' (or 'nearly true') tree topology. In addition, each of the optimization methods makes assumptions about critical parameters, including branch lengths, models of character evolution, absolute rates of evolution, homogeneity (vs. heterogeneity) of evolutionary rates, reversibility (or the lack thereof), and the orderedness (or unorderedness) of multistate characters.

The accuracy of ancestral trait reconstruction also depends strongly on parameter estimation (e.g., tree topology, branch lengths, and models of trait evolution). ML and BA perform well when model assumptions match real parameters. ML and BA are positively misleading when model assumptions are violated. MP is more conservative, recovering fewer false positives than ML and BA when biological parameters are not known. Squared-change parsimony, ML, and BA minimize large changes, spreading evolution over the internal tree branches. Linear parsimony permits reconstructions at ancestral nodes with no change, and permits ambiguous reconstructions. 'Independent contrasts' assumes that selection operates in the origin but not maintenance of derived traits.

Both conventional and phylogenetic correlations of interspecific character data make assumptions about critical parameters. These assumptions are often of unknown validity, and in some cases are known to be incorrect. Conventional statistics assume that each terminal taxon (tips of the tree) may be treated as independent sample of the relationship under investigation. This means that the character value (phenotype) observed in that taxon evolved independently (without inheritance) from the values in other taxa in the analysis. In an evolutionary context, this is equivalent to assuming that trait values result primarily from stabilizing selection in each species that acts to maintain trait values, rather than from directional selection at the origin of the trait in an ancestral species (Hansen, 1997). In other words, conventional statistics assume traits to be highly labile and without significant phylogenetic inertia. Phylogenetic correlations make converse assumptions, that trait values are due largely or entirely to directional selection at the origin of a feature and that the influence of stabilizing selection is negligible. Phylogenetic correlations also must make particular assumptions about branch lengths and models of trait evolution.

1.03.5 Conclusions

As in all aspects of historical inquiry, the study of character evolution is exceptionally sensitive to the amount of information that has actually survived up to the present. The reality of neural evolution was in most cases almost certainly very complex, and may be reliably regarded to have included vastly more numbers of independent transformations than has been recorded in the distribution of phenotypes preserved among living species. The signature of many historical events has been overwritten by reversals and convergences, or eliminated altogether by extinctions. Paleontologists estimate that more than 99% of all species that have ever lived are now extinct (Rosenzweig, 1995). This figure, of course, includes higher taxa (e.g., trilobites, placoderms, plesiosaurs) that are now entirely extinct, bringing up the aggregate percentage of extinction for all taxa. The proportion of living species that persists within certain targeted taxa may be much higher (e.g., Lake Victoria cichlid fishes). Nevertheless, in comparative studies of neural, physiological, or behavioral phenotypes, it is rare to have information on all extant species. Whether it is from extinction or incomplete surveys, taxon sampling remains one of the greatest sources of error in phylogenetic estimates of character evolution (Sullivan *et al*., 1999; Zwickl and Hillis, 2002).

Despite all these reservations, we must continue to estimate ancestral traits in order to study phenotypic evolution. None of the methods reviewed in this article should be regarded as a magic bullet, but rather there are advantages and disadvantages of each method as they are applied under different circumstances. All the methods reviewed here have proved to be useful tools in the phylogenetic toolbox. As in other aspects of science, it is important to make our assumptions explicit, and to use reasonable assumptions. Further, as in other aspects of evolutionary biology, critical insights into the evolution of neural characters will come from a better understanding of the biology of the phenotypes themselves, and the organisms in which they have evolved.

1.04 Basic Nervous System Types: One or Many?

F Hirth and H Reichert, University of Basel, Basel, Switzerland

Glossary

Bilateria A monophyletic group of metazoan animals that is characterized by bilateral symmetry. This group comprises all of the Metazoa except for the Radiata (Ctenophores and Cnidaria) and the Parazoa (sponges).

blastopore The site of gastrulation initiation.

coelom Fluid-filled body cavity found in animals that is lined by cells derived from mesoderm tissue in the embryo and provides for free, lubricated motion of the viscera.

Deuterostomia (From the Greek: *mouth second*) A major group of the Bilateria including echinoderms and chordates. In deuterostomes, the first opening (the blastopore) becomes the anus and the mouth derives from a secondary invagination.

Ecdysozoa Major group of protostome animals, including the arthropods (insects, arachnids, crustaceans, and relatives), roundworms, and several smaller phyla, which are characterized by a trilayered cuticle, composed of organic material, which is periodically molted as the animal grows by a process called ecdysis.

Gastroneuralia A subdivision of the Bilateria defined by the location of the nerve cord, Gastroneuralia are characterized by a ventral nerve cord and include most protostomes except the Tentaculata.

homeodomain A 60-amino-acid part of proteins that corresponds to the homeobox sequence found in homeobox genes that are involved in the regulation of the development (morphogenesis) of animals, fungi, and plants.

homology Correspondence or relation in type of structure because of shared ancestry.

Lophotrochozoa Major group of protostome animals, including mollusks, annelids, nemerteans, brachiopods, and several other phyla characterized either by the production of trochophore larvae, which have two bands of cilia around their middle, or by the presence of a lophophore, a fan of ciliated tentacles surrounding the mouth.

Notoneuralia A subdivision of the Bilateria defined by the location of the nerve cord, Notoneuralia are characterized by a dorsal nerve cord and include most deuterostomes except the Echinodermata, Chaetognatha, and Enteropneusta.

phylogeny The origin and evolution of a set of organisms, which reveals ancestral relationships, such as monophyly (common origin) or polyphyly (independent origin), among known species.

Protostomia (From the Greek: *first the mouth*) A major group of the Bilateria including the Lophotrochozoa and the Ecdysozoa. In protostomes, the mouth forms at the site of the blastopore and the anus forms as a second opening.

Urbilateria The animal that preceded all recent bilateral symmetric animals.

1.04.1 Introduction

The diversity of nervous systems is enormous. In terms of structural and functional organization as well as in terms of levels of complexity, nervous systems range from the simple peripheral nerve nets found in some of the basal invertebrate taxa to the centralized nervous systems and highly complex brains that characterize vertebrates and cephalopods. Starting in the eighteenth century, numerous attempts were undertaken to reconstruct the evolutionary origin of the diverse nervous system types found in the animal kingdom (see Origin and Evolution of the First Nervous System). However, initially none of these attempts resulted in consensus, in part because of the uncertain and ambiguous nature of the postulated phylogenetic relationships among the various animal groups considered (see Metazoan Phylogeny). At the beginning of the twentieth century, it became evident that the bilaterally symmetrical animals, the Bilateria, could be phylogenetically subdivided into two major branches (Fioroni, 1980). This subdivision of the Bilateria into the protostome and the deuterostome animals remains valid (Brusca and Brusca, 1990) and has been confirmed by molecular analyses (e.g., Adoutte *et al.*, 2000).

Do the general nervous system types that characterize the protostome and deuterostome animals also follow this binary subdivision? Classical neuroanatomical and embryological studies suggest that this is the case, at least in part. Accordingly, most bilaterian animals can be subdivided into two major groups with different central nervous system (CNS) morphologies. These are the Gastroneuralia, which are characterized by a ventral nerve cord and include major protostome groups such as arthropods, annelids, and mollusks, and the Notoneuralia, which are characterized by a dorsal nerve cord and include all (deuterostome) chordates (e.g., Nielsen, 1995). The two groups often manifest different modes of CNS development. In gastroneuralians such as arthropods, the ganglionic masses detach from the ventral neuroectoderm to form a rope-ladder nervous system of connectives and commissures, whereas in notoneuralian chordates the neuroectoderm folds inwardly as a whole to form a neural tube (Figure 1; see A Tale of Two CPGs: Phylogenetically Polymorphic Networks). As a result of the Gastroneuralia/Notoneuralia subdivision, the notion of an independent evolutionary origin of the CNS of protostomes versus deuterostomes gained general acceptance and accordingly a polyphyletic origin of bilaterian nervous systems was proposed.

The alternative notion, namely, that bilaterian nervous systems might have a common evolutionary origin, was rejected precisely because of the evident dissimilarities in the mode of development, topology, and adult morphology of the nervous systems in major protostome versus deuterostome groups.

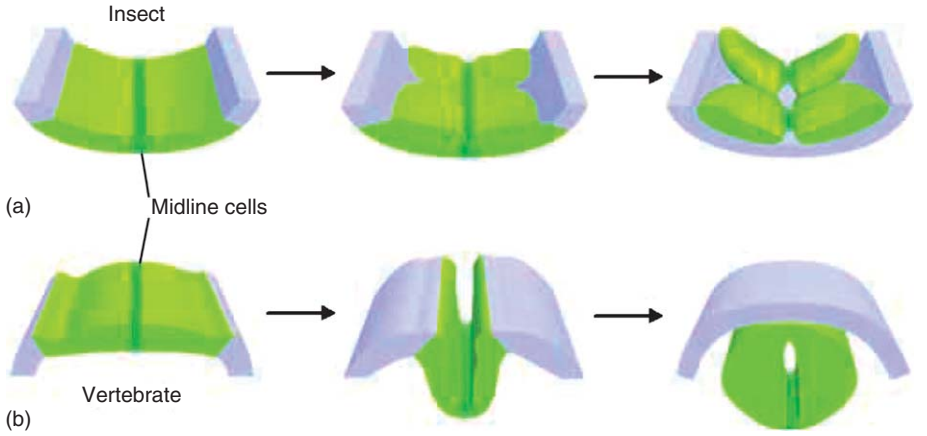

Figure 1 Morphogenesis of the ventral nerve cord in a prototype insect (a) and of the dorsal neural tube in a prototype vertebrate (b). Arrows indicate ontogenetic sequences; yellow-green, neurogenic ectoderm; blue, epidermal ectoderm. Reproduced from Arendt, D. and Nübler-Jung, K. 1999. Comparison of early nerve cord development in insects and vertebrates. *Development* 126, 2309–2325, with permission from The Company of Biologists Ltd.

However, starting in the 1980s, a number of key findings resulting from developmental biological analyses of animal body axis formation began to call into question the validity of the Gastroneuralia/Notoneuralia subdivision and, in doing so, provided initial support for the idea of a monophyletic origin of the bilaterian nervous system. In a nutshell, these findings demonstrated that the molecular genetic mechanisms of anteroposterior axis formation are shared among all bilaterians and that the molecular genetic mechanisms of dorsoventral axis formation in vertebrates are similar to those that operate in insects, only that their dorsoventral topology is inverted, upside-down. If dorsal in vertebrates corresponds to ventral in insects, might not the dorsal nerve cord of Notoneuralia in fact correspond to the ventral nerve cord of Gastroneuralia?

This axial inversion hypothesis was remarkable not only because it was based on unequivocal molecular genetic evidence, but also because it provided support for an old and much-derided view that emerged in the early nineteenth century. Its first proponent was the French zoologist Geoffroy Saint-Hilaire, in opposition to his countryman, the comparative anatomist Cuvier. Both engaged in a debate about a fundamental issue in the biological sciences, namely, whether animal structure ought to be explained primarily by reference to function or rather by morphological laws. At the heart of this debate was the question of whether a common structural plan, or Bauplan, underlies all animal development, thus indicating homology of structures across different animal phyla. Contemporary developmental biological studies based on analyses of expression and function of homologous regulatory control genes in various animal model systems have revived this fundamental question and contributed novel insight into the issue of homology of nervous systems. In this article, we will begin with this famous debate, consider the impact of molecular developmental genetics on a bilaterian nervous system Bauplan, and then discuss the current data for and against a common evolutionary origin of the nervous system. Though our main emphasis will be on conserved mechanisms of anteroposterior and dorsoventral patterning of the nervous system in insect and vertebrate model systems, we will also consider gene expression studies in invertebrates such as hemichordates and cnidarians.

1.04.2 The Cuvier–Geoffroy Debate

1.04.2.1 A Common Bauplan for Animal Development?

In 1830, a series of eight public debates were held at the Académie Royale des Sciences in Paris. The two opponents, George Cuvier (1769–1832) and Étienne Geoffroy Saint-Hilaire (1772–1844), were prominent and internationally renowned scientists. Both had made major contributions in many areas of natural history, including comparative anatomy and paleontology. Cuvier divided the animal kingdom into four completely separate branches or *embranchements*: vertebrates, articulates (largely arthropods and annelids), mollusks (which at the time meant all other soft, bilaterally symmetrical invertebrates), and radiates (echinoderms, cnidarians, and various other groups). According to Cuvier, there was no affinity whatsoever between the four *embranchements*. Any similarities between organisms were due to common functions, not to common ancestry. Function determines form; form does not determine function. Thus, even within these divisions, he allowed structural similarity to result solely from the same functional demands.

Geoffroy, by contrast, insisted that function was always dependent on structure and by no means sufficed to determine structure. What counted were the interconnections between parts; structures in different organisms were the same if their parts were connected to one another in the same pattern. Eventually Geoffroy developed the doctrine of unity of composition, applicable at least within each class of animals. Each animal is formed from a structural blueprint based on a common plan, and although animal structure is modified extensively because of functional requirements, the modification is constrained by the unity of composition (which later came to be known as the basic Bauplan). This doctrine of Geoffroy's came to be known as philosophical anatomy and was founded on analogy between structures (homology in modern terminology). Geoffroy's main criterion for determining true analogies was the connectivity between structures and this could often be better determined from the embryo rather than from the adult. The value of the theory of analogues was that it offered a scientific explanation for differences in structure.

Initially, these ideas related primarily within each class of animals or *embranchements*, but Geoffroy imagined that the principle could be extended to the animal kingdom as a whole. After having established a common scheme for vertebrates, he extended this principle across the boundaries of Cuvier's four *embranchements* to articulates. In 1822, Geoffroy published a paper entitled *Considérations générales sur la vertèbre*, in which he proposed that the ventral side of arthropods was analogous to the dorsal side of the vertebrates. This dorsoventral axis inversion hypothesis was based on a dissected crayfish that he had placed upside down

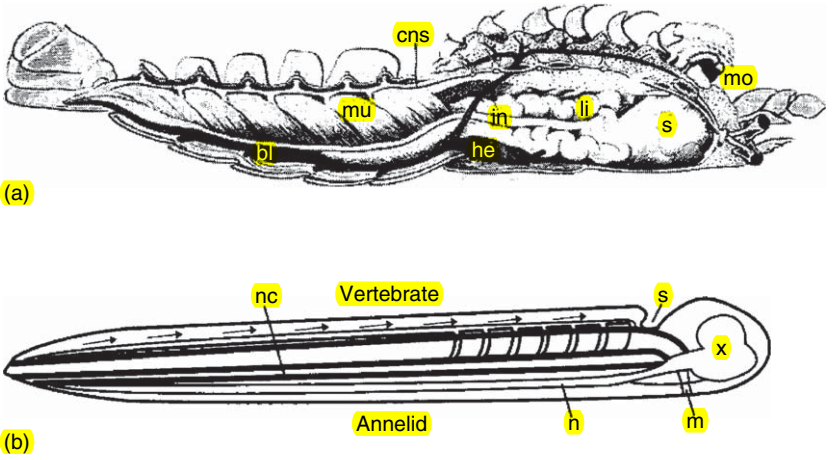

Figure 2 The dorsoventral inversion hypothesis. a, Geoffroy Saint-Hilaire's dissected lobster. In this dissection, the animal is presented in the orientation opposite to the orientation that it would normally have with respect to the ground. The central nervous system (cns) is at the top and is traversed by the mouth (mo). Below this is the digestive tract with the stomach (s), liver (li), and intestine (in). Below the gut are the heart (he) and main blood vessels (bl). Muscles (mu) flank the CNS. In this orientation, the body plan of the arthropods resembles that of the vertebrate. b, Inverted relationship of the annelid and vertebrate body plans; only the mouth changes position with inversion, making a new opening in the chordate lineage. m, mouth; n, nerve cord; nc, notochord (only in chordates); s, stomodeum (secondary mouth); x, brain. Arrows show direction of blood flow. a, Reprinted by permission from Macmillan Publishers Ltd: *Nature* (De Robertis, E. M. and Sasai, Y. 1996. A common plan for dorsoventral patterning in Bilateria. *Nature* 380, 37–40), copyright (1996). b, Modified textbook diagram; see, for example, Romer and Parsons (1977).

and, as he noted, in this orientation the organization of the main body system of the lobster resembled that of a mammal (see Figure 2). One objection readily raised against such an attempt to link arthropods and vertebrates was that the nervous system in arthropods was nevertheless found on the ventral side, whereas in vertebrates it was located on the dorsal side. Geoffroy's solution to this problem was that the definitions of dorsal and ventral were purely arbitrary, because they were based solely on the orientation of the animal to the sun. If it was assumed that the arthropod walked with its ventral side rather than its dorsal side toward the sun, then all of the organs of the arthropod would have the same topological arrangement as the organs of vertebrates.

As expected, Cuvier rejected such interpretations. For him, animals shared similar basic plans only because they carried out a similar combination of interrelated functions. Because the fundamental plan was completely different in each *embranchement,* there were no and could be no transitional forms leading from one *embranchement* to the next. Moreover, no one had ever observed the transformation of one species into another. The differences between the scientific approaches of Geoffroy and Cuvier came to a head when two young naturalists, Meyranx and Laurencet, submitted to the academy a comparison of the anatomy of vertebrates and cephalopods (squids, cuttlefish, and octopi), claiming that they were based on the same basic structural plan. Geoffroy, who was chosen by the academy to review the paper, enthusiastically adopted this claim as proof of his unity of composition shared by all animals. Cuvier could not reconcile this with the results of his careful anatomical research, and in the ensuing debates, he showed convincingly that many of Geoffroy's supposed examples of unity of structure were not accurate; the similarities between vertebrates and cephalopods were contrived and superficial. As an immediate consequence, the results of Meyranx and Laurencet never went to press (for details, see Appel, 1987).

1.04.2.2 From Unity of Composition to Unity of Nervous Systems?

Although Cuvier was considered to have won the 1830 debates, Geoffroy's philosophical anatomy remained remarkably influential during the subsequent decades. A resolution of the conflicting ideas was achieved, in part, by Darwin's evolutionary theory in which structural homology became an important criterion for establishing phylogenetic relationships. Moreover, with the advent of molecular developmental genetics, it has become clear that homology is a concept that applies not only to morphology, but also to genes and developmental processes. Indeed, and rather unexpectedly, more than 150 years after the famous debate, developmental genetics has provided experimental evidence for Geoffroy's unity of composition and

specifically for his dorsoventral axis inversion hypothesis that appeared to be so convincingly refuted by Cuvier.

The discovery that a common developmental genetic program underlies dorsoventral axis formation in both insects and vertebrates was based on the analysis of two sets of homologous genes that encode morphogens in the model systems *Drosophila* and *Xenopus* (Holley *et al*., 1995; Schmidt *et al*., 1995; De Robertis and Sasai, 1996; Holley and Ferguson, 1997). The transforming growth factor β (TGFβ) family member encoded by the *decapentaplegic* (*dpp*) gene is expressed dorsally and promotes dorsal fate in *Drosophila*, whereas its vertebrate orthologue *Bone morphogenetic protein* (*Bmp4*) is expressed ventrally and promotes ventral fate in *Xenopus*. These morphogens are antagonized by the secreted products of the orthologous genes *short gastrulation* (*sog*) in *Drosophila* and *Chordin* in *Xenopus*. Importantly, the site of action where *sog/Chordin* expression inhibits *dpp/Bmp4* signaling corresponds in both insects and vertebrates to the region of the dorsoventral body axis that gives rise to the embryonic neuroectoderm from which the nervous system derives (see below).

These results provide strong evidence that the molecular interactions that occur on the ventral side of insects are homologous (in Geoffroy's sense, analogous) to those that occur on the dorsal side of vertebrates – an observation that revitalizes Geoffroy's initial proposition of the unity of composition between arthropods and mammals and supports the hypothesis of a dorsoventral inversion of their body axes during the course of evolution (Arendt and Nübler-Jung, 1994). Moreover, these results also provide strong evidence that the molecular interactions that lead to the formation of the ventral CNS in insects are homologous to those that lead to the formation of the dorsal CNS in vertebrates, indicating a dorsoventral body axis inversion as the most parsimonious explanation for the dorsoventrally inverted topology of the CNS that characterizes Gastroneuralia versus Notoneuralia.

Comparable molecular genetic studies on other sets of homologous genes in various model systems ranging from annelids and arthropods to mammals are providing further evidence that Geoffroy's unity of composition might be the result of a developmental construction plan that is shared by all bilaterian animals. Thus, evolutionarily conserved developmental control genes act not only in dorsoventral axis specification but also in anteroposterior axis formation, segmentation, neurogenesis, axogenesis, and eye/photoreceptor cell development through comparable molecular mechanisms that appear to be conserved throughout most of the animal kingdom. The implications of these findings are far-reaching. They suggest that, although diverse in their mode of development and adult morphology, bilateral animals derived by descent from a common ancestor, the Urbilateria, which may already have evolved a rather complex body plan (De Robertis and Sasai, 1996). Accordingly, the urbilaterian nervous system may already have evolved structural features that prefigured elements of the nervous systems of the descendent bilaterian animals. If this were indeed the case, then the ventrally located arthropod nervous system may be homologous to the dorsally located chordate nervous system; the insect brain may be composed of structural units homologous to those of the vertebrate brain; the visual system of a fly may be homologous to the visual system of a mammal. The plausibility of this scenario is particularly evident with regard to the conserved mechanisms of anteroposterior and dorsoventral patterning of the nervous system that operate in insects and vertebrates.

1.04.3 Conserved Mechanisms for Anteroposterior Patterning of the CNS

1.04.3.1 *Hox* Genes Are Involved in the Regional Specification of Neuronal Identity

Along the anteroposterior axis, the insect and vertebrate neuroectoderm is subdivided into compartment-like regions, each of which expresses a specific combination of conserved developmental control genes. In both animal groups, regions of the posterior brain and the nerve cord are specified by the expression and action of homeodomain transcription factors encoded by the *Hox* genes (see Figure 3). *Hox* genes were first identified in *Drosophila* and *Hox* gene orthologues have subsequently been found in all other bilaterian animals, including mammals. During embryonic development, these developmental control genes are involved in anteroposterior patterning of features such as the morphology of segments in *Drosophila* or the morphology of axial mesoderm derivatives in mammals. *Hox* genes generally respect the co-linearity rule: they are expressed along the body axis in the same order as they are found clustered on the chromosome. Their role in anteroposterior regionalization may have evolved early in metazoan history (Carroll, 1995).

In both invertebrates and vertebrates, *Hox* gene expression is especially prominent in the developing CNS, and the nervous system may be the most

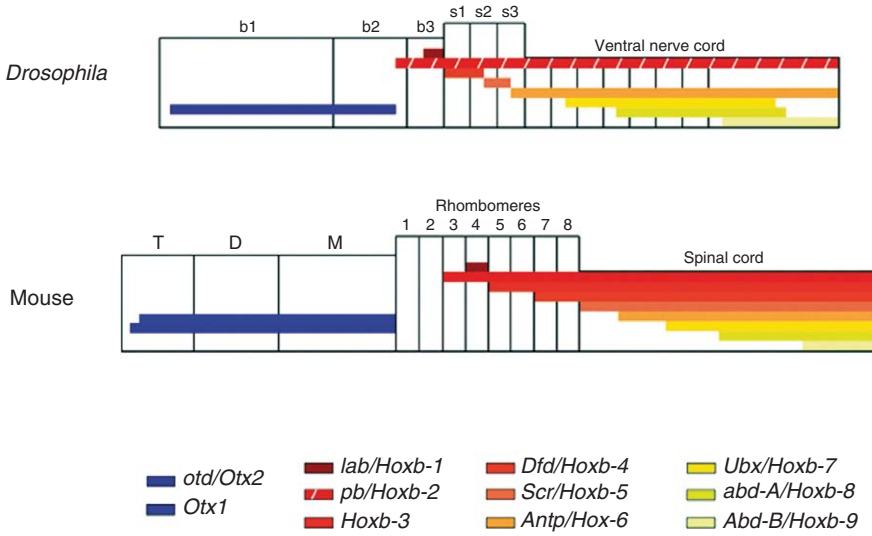

Figure 3 Conserved anteroposterior order of gene expression in embryonic brain development. Schematic diagram of *Hox* and *otd/Otx* gene expression patterns in the developing CNS of *Drosophila* and mouse. Expression domains are color-coded. (Top) Gene expression in embryonic stage 14 *Drosophila* CNS. Borders of the protocerebral (b1), deutocerebral (b2), tritocerebral (b3), mandibular (s1), maxillary (s2), labial (s3), and ventral nerve cord neuromeres are indicated by vertical lines. In contrast to the other Hox genes, *pb* is expressed only in small segmentally repeated groups of neuronal cells; this difference is indicated by a diagonally striped bar to denote the *pb* expression domain. (Bottom) Gene expression in embryonic day 9.5–12.5 mouse CNS. Borders of the telencephalon (T), diencephalon (D), mesencephalon (M), and rhombomeres are indicated by vertical lines. Reproduced from Hirth, F. and Reichert, H. 1999. Conserved genetic programs in insect and mammalian brain development. *Bioessays* 21, 677–684, with permission from John Wiley & Sons, Inc.

ancestral site of *Hox* gene action. In animal taxa investigated thus far, such as planarians (Orii *et al.*, 1999), nematodes (Kenyon *et al.*, 1997), annelids (Kourakis *et al.*, 1997; Irvine and Martindale, 2000), mollusks (Lee *et al.*, 2003), arthropods (Hirth and Reichert, 1999; Hughes and Kaufman, 2002), urochordates (Ikuta *et al.*, 2004), cephalochordates (Wada *et al.*, 1999), hemichordates (Lowe *et al.*, 2003), and vertebrates including zebra fish, chicken, mouse, and human (Lumsden and Krumlauf, 1996; Vieille-Grosjean *et al.*, 1997; Carpenter, 2002; Moens and Prince, 2002), the *Hox* gene expression patterns in the developing CNS consist of an ordered set of domains that have a remarkably similar anteroposterior arrangement along the neuraxis.

The function of *Hox* genes in CNS development has been studied through loss- and gain-of-function experiments primarily in *Drosophila*, zebra fish, chicken, and mouse. In *Drosophila*, loss-of-function studies have shown that *Hox* genes are required for the specification of regionalized neuronal identity in the posterior brain (Hirth *et al.*, 1998). Comparable results have been obtained through loss-of-function studies in vertebrates, where *Hox* genes are involved in specifying the rhombomeres of the developing hindbrain. For example, in the murine *Hoxb1* mutant, rhombomere 4 (r4) is partially transformed to r2 identity (Studer *et al.*, 1996), whereas in *Hoxa1*$^{-/-}$; *Hoxb1*$^{-/-}$ double mutants, a region corresponding to r4 is formed, but r4-specific neuronal markers fail to be activated, indicating the lack of neuronal identity of the remaining territory between r3 and r5 (Studer *et al.*, 1998; Gavalas *et al.*, 1998). This suggests that *Hoxa1* and *Hoxb1* act synergistically in the specification of r4 neuronal identity – a mode of action remarkably similar to that of their fly orthologue, *labial*, in specifying segmental neuronal identity during *Drosophila* brain development (Figure 4).

This evolutionarily conserved *Hox* gene action is underscored by experiments that show that even *cis*-regulatory regions driving the specific spatiotemporal expression of *Hox* genes appear to operate in a conserved manner in insects and vertebrates. Thus, the enhancer region of the human *Hoxb4* gene, an orthologue of *Drosophila Deformed*, can function within *Drosophila* to activate gene expression in a *Deformed*-specific pattern, whereas the enhancer region of *Drosophila Deformed* activates *Hoxb4*-specific expression in the mouse hindbrain (Malicki *et al.*, 1992). Similar results have been obtained for *Hox1* orthologues (Pöpperl *et al.*, 1995), suggesting that the expression, function, and regulation of *Hox* genes in the specification of segmental neuronal identity during CNS development may be an ancestral feature of this gene family.

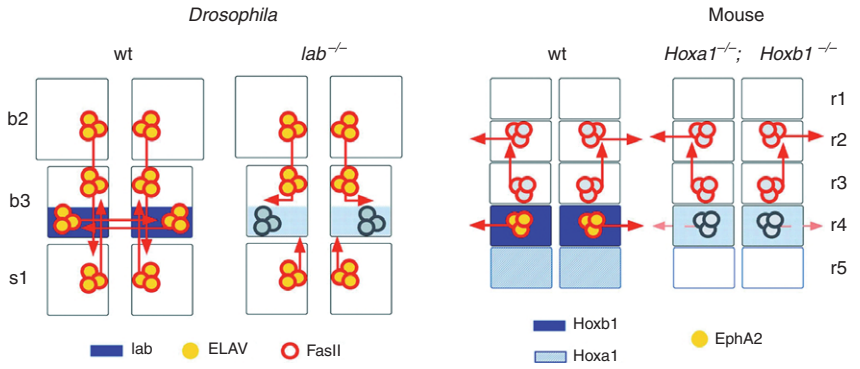

Figure 4 Comparable brain phenotypes in *lab/Hox1* loss-of-function mutants in *Drosophila* and mouse. (Left) Simplified scheme of the deutocerebral (b2), tritocerebral (b3), and mandibular (s1) neuromeres of the *Drosophila* brain. In the wild type (wt) cells in the posterior tritocerebrum express lab (blue) and also express the neuron-specific marker ELAV and the cell adhesion molecule FasII. In the *lab* null mutant (*lab*$^{-/-}$), cells in the mutant domain are present but do not extend axons and fail to express the neuron-specific marker ELAV and the cell adhesion molecule FasII, indicating a total loss of neuronal identity. Axons from other parts of the brain avoid the mutant domain. (Right) Simplified scheme of rhombomeres r1–r5 of the mouse hindbrain. In the wild type (wt) cells in r4 co-express *Hoxa1* and *Hoxb1* and also express the r4-specific marker EphA2. In the *Hoxa1*$^{-/-}$; *Hoxb1*$^{-/-}$ double homozygous mutant, cells in r4 are present but the r4-specific marker EphA2 fails to be activated in r4, indicating the presence of a territory between r3 and r5 with an unknown identity. The double mutant also exhibits multiple defects in the motor neuron axonal projections; facial motor neurons are scarce and exit randomly from the neural tube. Reproduced from Hirth, F. and Reichert, H. 1999. Conserved genetic programs in insect and mammalian brain development. *Bioessays* 21, 677–684, with permission from John Wiley & Sons, Inc.

1.04.3.2 Cephalic Gap Genes in Regionalization of the Anterior Brain: The *otd/Otx* Genes

In none of the animal species investigated to date are *Hox* genes expressed in the most anterior regions of the developing CNS. This suggests that the developing CNS is subdivided into a posterior Hox region and a more anterior non-Hox region. In both invertebrates and vertebrates, the non-Hox region of the anterior brain is characterized by the expression and action of the cephalic gap genes *tailless* (*tll*)/*Tlx*, *orthodenticle* (*otd*)/*Otx*, and *empty spiracles* (*ems*)/*Emx* (Arendt and Nübler-Jung, 1996). The most prominent example of cephalic gap genes acting in brain development is that of the *otd/Otx* genes. As is the case of the *Hox* genes, the CNS-specific expression of the *otd/Otx* genes is conserved throughout most of the animal kingdom.

otd/Otx genes are expressed in the anterior part of the developing nervous system in planarians (Umesono *et al.*, 1999), nematodes (Lanjuin *et al.*, 2003), annelids (Bruce and Shankland, 1998; Arendt *et al.*, 2001), mollusks (Nederbragt *et al.*, 2002), arthropods (Hirth and Reichert, 1999; Schröder, 2003), urochordates (Wada *et al.*, 1998), cephalochordates (Tomsa and Langeland, 1999), hemichordates (Lowe *et al.*, 2003), and vertebrates (Acampora *et al.*, 2001b; Schilling and Knight, 2001).

Functional studies, carried out primarily in *Drosophila* and mouse, have shown that *otd/Otx* gene activity is essential for the formation of the anterior neuroectoderm. In *Drosophila*, *otd* is expressed in the developing brain throughout most of the protocerebrum and adjacent deutocerebrum. In *otd* mutants, the protocerebrum is deleted due to defective neuroectoderm specification and the subsequent failure of neuroblast formation (Hirth *et al.*, 1995; Younossi-Hartenstein *et al.*, 1997). Loss-of-function analyses for *Otx* genes carried out in the mouse show that these genes are also critically required at different stages in the development of the anterior brain. *Otx2* null mice are early embryonic lethal and lack the rostral neuroectoderm that is normally fated to become the forebrain, midbrain, and rostral hindbrain due to an impairment in early specification of the anterior neuroectoderm by the visceral endoderm. *Otx1* null mice show spontaneous epileptic seizures and abnormalities affecting the telencephalic dorsal cortex and the mesencephalon, as well as parts of the cerebellum and certain components of the acoustic and visual sense organs (Acampora *et al.*, 2001b).

These essential roles of the *otd/Otx* genes in anterior brain development of insects and vertebrates suggest an evolutionary conservation of *otd/Otx* genes in embryonic brain development that extends beyond gene structure to patterned expression and function (Figure 5). A direct experimental demonstration of this functional conservation has been carried out in genetic cross-phylum rescue experiments. Thus, human *Otx* transgenes have been expressed in *Drosophila otd* mutants (Leuzinger *et al.*, 1998) and, conversely, the murine *Otx1* and

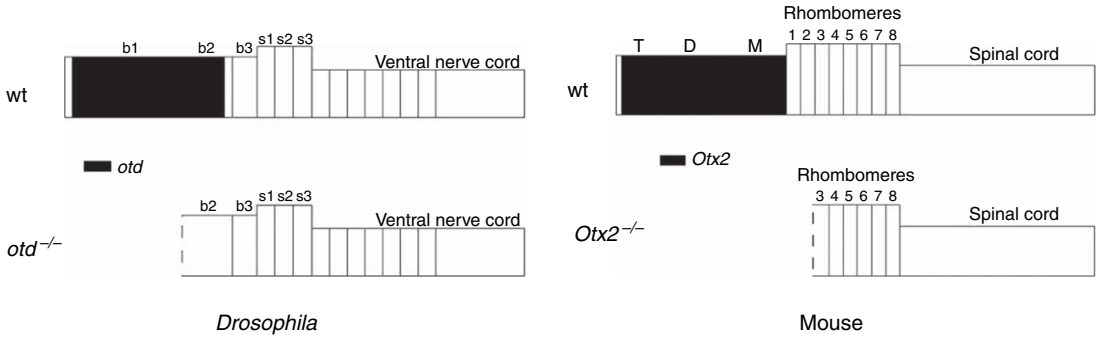

Figure 5 Conserved expression and function of the *otd/Otx2* genes in embryonic brain development. Schematic diagram of *otd* and *Otx2* gene expression patterns and *otd* and *Otx2* mutant phenotypes in the developing CNS of *Drosophila* and mouse. (Top) *otd* gene expression in the wild type (wt) and brain phenotype of *otd* null mutant in embryonic stage 14 *Drosophila* CNS. Borders of the protocerebral (b1), deutocerebral (b2), tritocerebral (b3), mandibular (s1), maxillary (s2), labial (s3), and some of the ventral nerve cord neuromeres are indicated by vertical lines. (Bottom) *Otx2* gene expression in the wild type (wt) and brain phenotype of *Otx2* homozygous null mutant in embryonic day 12.5 mouse CNS. Borders of the telencephalon (T), diencephalon (D), mesencephalon (M), and rhombomeres are indicated by vertical lines. Reproduced from Hirth, F. and Reichert, H. 1999. Conserved genetic programs in insect and mammalian brain development. *Bioessays* 21, 677–684, with permission from John Wiley & Sons, Inc.

Otx2 genes have been replaced with the *Drosophila otd* gene in the mouse (Acampora *et al*., 1998a, 2001b). Intriguingly, despite the obvious anatomical differences between mammalian and *Drosophila* brains, the human *Otx1* and *Otx2* genes complemented the brain defects in *otd* mutant *Drosophila* and, similarly, the *//*$^{-}$ *Drosophila otd* gene was able to rescue most of the CNS defects of *Otx1*$^{--}$ and *Otx2*$^{-}$ mutant mice (Acampora *et al*., 1998a, 1998b, 2001a; Leuzinger *et al*., 1998).

1.04.3.3 A Tripartite Organization of the Insect and Chordate Brain?

The conserved expression and function of *otd/Otx* and *Hox* genes suggest that invertebrate and vertebrate brains are all characterized by a rostral region specified by genes of the *otd/Otx* family and a caudal region specified by genes of the *Hox* family. However, in ascidians and vertebrates, a *Pax2/5/8* expression domain is located between the anterior *Otx* and the posterior *Hox* expression regions of the embryonic brain (Holland and Holland, 1999; Wada and Satoh, 2001). In vertebrate brain development, this *Pax2/5/8* expression domain is an early marker for the isthmic organizer positioned at the midbrain–hindbrain boundary (MHB), which controls the development of the midbrain and the anterior hindbrain (Liu and Joyner, 2001; Rhinn and Brand, 2001; Wurst and Bally-Cuif, 2001). The central role of this MHB region in brain development together with the conserved expression patterns of *Pax2/5/8* genes in this region have led to the proposal that a fundamental characteristic of the ancestral chordate brain was its tripartite organization characterized by *Otx*, *Pax2/5/8*, and *Hox* gene expressing regions (Wada *et al*., 1998).

An analysis of brain development in *Drosophila* has uncovered similarities in the expression and function of the orthologous genes that pattern the vertebrate MHB region (Hirth *et al*., 2003). Thus, a *Pax2/5/8* expressing domain was found to be located between the anterior *otd/Otx* expressing region and the posterior *Hox* expressing region in the embryonic brain. In *Drosophila*, as in vertebrates, this *Pax2/5/8* expressing domain is positioned at the interface between the *otd/Otx2* expression domain and a posteriorly abutting *unplugged/Gbx2* expression domain. Moreover, inactivation of *otd/Otx* or of *unplugged/Gbx2* results in comparable effects on mispositioning or loss of brain-specific expression domains of orthologous genes in both embryonic brain types. These developmental genetic similarities indicate that the tripartite ground plan, which characterizes the developing vertebrate brain, is also at the basis of the developing insect brain (Figure 6). This, in turn, has led to the suggestion that a corresponding, evolutionarily conserved, tripartite organization also characterized the brain of the last common ancestor of insects and chordates (Hirth *et al*., 2003).

1.04.4 Conserved Mechanisms for Dorsoventral Patterning of the CNS

1.04.4.1 Antagonistic Activity of Dpp/BMP-4 and sog/Chordin

As briefly mentioned above, among the significant molecular control elements involved in the embryonic establishment of the dorsoventral body axis are

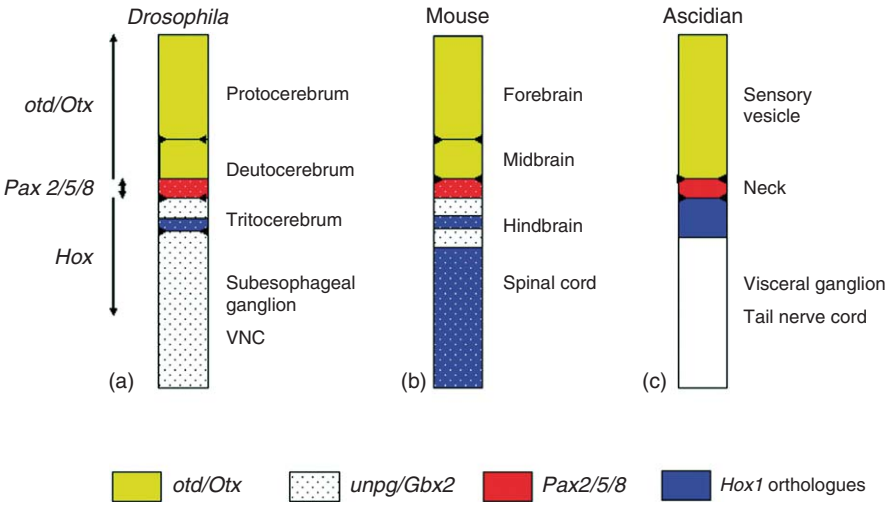

Figure 6 Tripartite organization of the (a) *Drosophila*, (b) mouse, and (c) ascidian brain, based on expression patterns of orthologous genes. The expression of *otd/Otx2*, *unpg/Gbx2*, *Pax2/5/8*, and *Hox1* gene orthologues in the developing CNS of (a) stage 13/14 *Drosophila* embryo, (b) stage E10 mouse embryo, and (c) neurula ascidian embryo. In all cases, a *Pax2/5/8*-expressing domain is located between an anterior *otd/Otx2* expressing region and a posterior *Hox* expressing region in the embryonic brain. Moreover, in *Drosophila*, as in mouse, a *Pax2/5/8*-expressing domain is positioned at the interface between the *otd/Otx2* expression domain and a posteriorly abutting *unplugged/Gbx2* expression domain. This *otd/Otx2–unpg/Gbx2* interface displays similar developmental genetic features in both *Drosophila* and mouse. Reproduced from Hirth, F., Kammermeier, L., Frei, E., Walldorf, U., Noll, M., and Reichert, H. 2003. An urbilaterian origin of the tripartite brain: Developmental genetic insights from *Drosophila. Development* 130, 2365–2373, with permission from The Company of Biologists Ltd.

signaling molecules of the TGFβ family such as Dpp, studied most extensively in *Drosophila*, and BMP-4, one of the vertebrate homologues of Dpp (De Robertis and Sasai, 1996). These proteins establish dorsoventral polarity in the insect embryo and in the vertebrate embryo. In both cases, they are restricted in their spatial activity by antagonistically acting extracellular signaling proteins. These antagonists are Sog in *Drosophila* and its homologue Chordin in vertebrates. The two groups of interacting signaling molecules, Dpp/BMP-4 and Sog/Chordin, act from opposing dorsoventral poles in both insects and vertebrate embryos (Holley *et al.*, 1995). Remarkably, in *Drosophila*, Dpp exerts its activity on dorsal cells and Sog on ventral cells, whereas in vertebrates BMP-4 acts on ventral cells and Chordin activity is found in dorsal cells. In both cases, it is the region of the embryo that attains neurogenic potential and forms neuroectoderm in which Sog/Chordin is expressed and inhibits the action of invading Dpp/BMP-4 signals.

Thus, despite the morphological differences between embryos of the two species, the *Sog/Chordin* gene is expressed on the side from which the CNS arises, whereas the *dpp/Bmp-4* gene is expressed on the opposite side of the embryo where it promotes ectoderm formation. This functional conservation of the Sog/Chordin and the Dpp/BMP-4 morphogens suggests an evolutionarily conserved, homologous mechanism of dorsoventral patterning. This suggestion is further substantiated by experimental studies showing that injection of *Chordin* RNA (from *Xenopus*) promotes ventralization of cell fates in *Drosophila* embryos, including the formation of ectopic patches of CNS. Correspondingly, injection of *sog* RNA (from *Drosophila*) causes dorsal development in *Xenopus*, including the formation of notochord and CNS (Holley *et al.*, 1995; Schmidt *et al.*, 1995). Thus, the function of *sog/Chordin* is reversed in insects and vertebrates; in both cases, injection of the gene product promotes the development of the side of the embryo that contains the CNS: dorsal in vertebrates, ventral in insects. This pervasive equivalence of gene structure and function points to an essential role of *Sog/Chordin* and *Dpp/BMP-4* in CNS induction/specification in insects and vertebrates, irrespective of the location along the dorsoventral axis at which the CNS forms (Figure 7).

1.04.4.2 vnd/Nkx, ind/Gsh, and msh/Msx: Specification of Longitudinal Columns

Beyond the mechanisms of early neuroectoderm formation, a further set of genetic elements involved in early dorsoventral patterning of the CNS appears to be evolutionarily conserved (Cornell and Ohlen, 2000). These genetic regulatory elements are three

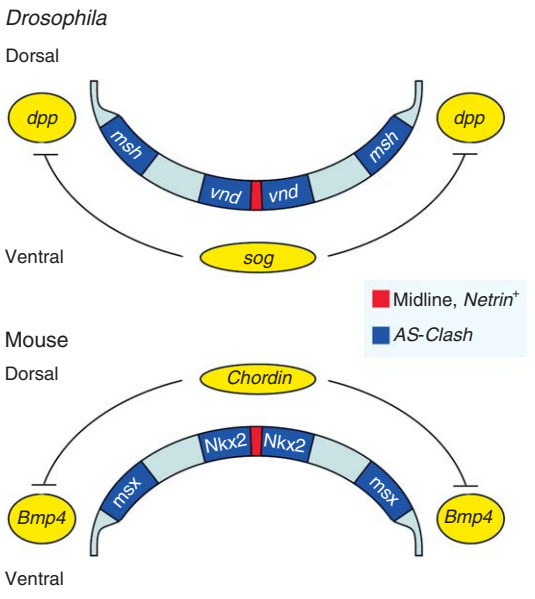

Figure 7 Transverse sections through the *Drosophila* and mouse CNS primordia showing similar dorsoventral regulation of pattern by the *sog* (*short gastrulation)/Chordin*, *dpp* (*decapentaplegic)/BMP4*, *Msx/msh*, *Nkx2/vnd, AS-C* (*achaete–scute complex)/ash* (*AS-C homologues*), and *Netrin* gene families. Reproduced from Sharman, A. C. and Brand, M. 1998. Evolution and homology of the nervous system: Cross-phylum rescues of *otd/otx* genes. *Trends Genet.* 14(6), 211–214, with permission from Elsevier.

sets of homeobox genes that control the formation of columnar dorsoventral domains in the ventral neuroectoderm of *Drosophila*; their homologues may act in a similar fashion in dorsoventral patterning in the neural plate of vertebrates (Figure 7). In *Drosophila*, the homeobox genes are *ventral nerve cord defective* (*vnd*), *intermediate nerve cord defective* (*ind*), and *muscle-specific homeobox* (*msh*) and they are expressed in longitudinal stripes along the ventral (*vnd*), intermediate (*ind*), and dorsal (*msh*) columns in the neuroectoderm (Isshiki *et al.*, 1997; McDonald *et al.*, 1998; Chu *et al.*, 1998; Weiss *et al.*, 1998). In each column, expression of the appropriate homeobox gene is required for neuroblast formation and for specification of columnar identity. Comparable expression patterns have been reported for the beetle *Tribolium* (Wheeler *et al.*, 2005).

In vertebrates, homologues of the *Drosophila* columnar genes that belong to the *Nkx* (*vnd*), *Gsh* (*ind*), and *Msx* (*msh*) gene families have been identified. These genes are expressed in columnar domains in the neural plate and neural tube of the embryonic CNS. (Invagination of the vertebrate neural plate to form the neural tube results in translocation of the lateromedial position into the dorsoventral position.) In vertebrates, several *Nkx* family members are expressed in ventral regions of the neural tube and at least one of these is expressed earlier in the corresponding medial region of the neural plate (Qiu *et al.*, 1998; Pera and Kessel, 1998; Pabst *et al.*, 1998; Shimamura *et al.*, 1995). Similarly, expression of vertebrate *Msx* family members is seen in the lateral neural plate, which later forms the dorsal neural tube (Wang *et al.*, 1996). Finally, vertebrate *Gsh* family genes are expressed at dorsoventrally intermediate levels in the neural tube (Valerius *et al.*, 1995; Hsieh-Li *et al.*, 1995). Functional studies suggest that some of these genes are involved in controlling regional identity along the dorsoventral axis of the neural tube (Briscoe *et al.*, 1999; Sussel *et al.*, 1999). These findings indicate that in the developing CNS of insects and vertebrates, the expression domains of columnar genes in the neuroectoderm/neural plate are comparable (Figure 7). This, in turn, has led to the proposal that the medial, intermediate, and lateral neurogenic columns of the *Drosophila* embryonic neuroectoderm correspond to the medial, intermediate, and lateral columns of the vertebrate neural plate, albeit in dorsoventral inverted orientation (D'Alessio and Frasch, 1996; Weiss *et al.*, 1998).

1.04.4.3 The CNS Midline: Pattern Formation and Axonal Guidance

In the nervous systems of bilaterians, specialized cells located at the midline of the neuroectoderm play an essential role in organizing the development of the CNS (Tessier-Lavigne and Goodman, 1996; Dickson, 2002). In insects and vertebrates, cells of the CNS midline are known to represent inductive centers for the regional patterning of the neuroectoderm. Moreover, the CNS midline represents an important intermediate target where growing axons either cross and project contralaterally or remain on the same side of the body. The midline cells express at their surface membrane-bound guidance molecules and secrete diffusible factors that act as attractive or repulsive guidance cues and guide growing axons from a distance; under the influence of these molecules, some axons avoid the midline, whereas others grow toward it and cross it once.

The developmental control genes that specify these midline cell populations appear to differ between insects and vertebrates. In *Drosophila*, formation of midline cells requires the specific expression of the *single-minded* gene (Nambu *et al.*, 1990), whereas in vertebrates, the formation of midline cells requires the specific expression of *HNF3beta* (Ang and Rossant, 1994; Weinstein *et al.*, 1994). Also, the morphogens that mediate

the inductive interactions of the midline cells differ in vertebrates versus insects. In vertebrates, *Sonic hedgehog* signaling from the floor plate exerts its patterning function on the adjacent dorsal neuroectoderm (Ho and Scott, 2002), whereas in *Drosophila*, *EGF* signaling exerts patterning on the adjacent ventral neuroectoderm (Skeath, 1999).

In contrast, many aspects of midline cell-mediated axon guidance are controlled by functionally and evolutionarily conserved ligand–receptor systems that include the *Netrin*, *DCC*, *Slit*, and *Robo* gene families (Araujo and Tear, 2002; Kaprielian *et al*., 2001). Homologous *Netrin* genes encode soluble attractor molecules that are detected in the floor plate and ventral neural tube of vertebrates as well as in the midline glial cells of *Drosophila* and that serve to guide commissural axons toward the midline. In both cases, the *Netrins* are expressed at a time when first commissural growth cones, which express the homologous *frazzled/DCC* genes that encode transmembrane receptors, are extending toward the midline. *Netrin* mutant embryos exhibit defects in commissural axon projections in mice and flies, indicating similar functional roles of these attractants. Moreover, in *Drosophila* as well as in vertebrates, axonal projections away from the midline depend on the presence at the midline of a repellent molecule, which binds and interacts with axonal receptors. In *Drosophila*, the midline repellent that expels commissural axons and prevents them from recrossing is the ligand Slit, which mediates its repulsive effects via receptors of the Roundabout (Robo) family that are dynamically expressed on commissural axons. In vertebrates, three *Slit* homologues (*Slit1*, *Slit2*, and *Slit3*) and three *Robo* homologues (*Robo1*, *Robo2*, and *Rig-1*) have been identified, with expression patterns reminiscent of their *Drosophila* counterparts. The vertebrate *Slit* genes are expressed in the floor plate at the ventral midline of the spinal cord, and their corresponding *Robo1* and *2* receptors are expressed by commissural axons. Studies indicate that vertebrate commissural axons become insensitive to floor plate attraction and sensitive to *Slit*-mediated repulsion after crossing the midline; this modulation of repulsion at the midline is reminiscent of the situation in the *Drosophila* CNS.

1.04.5 Evolutionary Origin of the CNS

1.04.5.1 Molecular Phylogeny: Several Possibilities

The similarities in anteroposterior and dorsoventral patterning genes as well as their conserved relative topological expression patterns and functional roles implicate a common genetic program underlying insect and mammalian nervous system development (Hirth and Reichert, 1999; Arendt and Nübler-Jung, 1999; Reichert and Simeone, 2001). This suggests that orthologous genes were already involved in neural specification in the insect and vertebrate stem species, if not already in a common bilaterian ancestor. Does this mean that the insect and chordate CNS are homologous structures and therefore of monophyletic origin? Two alternative hypotheses, which are not mutually exclusive, can be envisaged. The first of these postulates that the ancestral bilaterian nervous system was already centralized and had its development governed by conserved genetic mechanisms that are still apparent in extant insects and mammals (monophyletic origin of the brain). The second hypothesis is that the ancestral bilaterian nervous system was controlled by conserved genetic mechanisms that still operate in arthropods and vertebrates, but that centralization of the nervous system occurred independently in protostome and deuterostome lineages (polyphyletic origin of the brain).

Based on classical phylogeny, which places acoelomates, such as platyhelminthes, and pseudocoelomates, such as nematodes, nearer to the base of the Bilateria than the coelomate protostomes and deuterostomes, the first hypothesis seems more likely (Figure 8a). Since flatworms and nematodes have a CNS with a brain and a ventral nerve cord, a comparable centralized nervous system would be likely to reflect the ancestral state for both Protostomia and Deuterostomia, and indeed for all Bilateria.

In this view, the evolutionary advance of centralizing the nervous system occurred only once. In contrast, molecular phylogenetic analyses no longer provide evidence that preferentially supports one of the two hypotheses. According to studies based on 18S rRNA sequence comparisons, there are no longer any living bilaterians that can be considered to be evolutionary intermediates between the radially (or biradially) symmetric animals and the bilaterally symmetric protostomes and deuterostomes (Figure 8b). Invertebrate lineages such as platyhelminthes and nematodes, which were considered to be near the base of the bilaterian tree in classical phylogeny, are now placed next to protostome groups with highly complex body and brain morphology such as mollusks and arthropods in the two new protostome subgroupings, the lophotrochozoans and ecdysozoans (Adoutte *et al*., 2000). Thus, although neurons and nervous systems, which are present in radiate cnidarians and ctenophores, apparently existed before the origin of bilaterian animals,

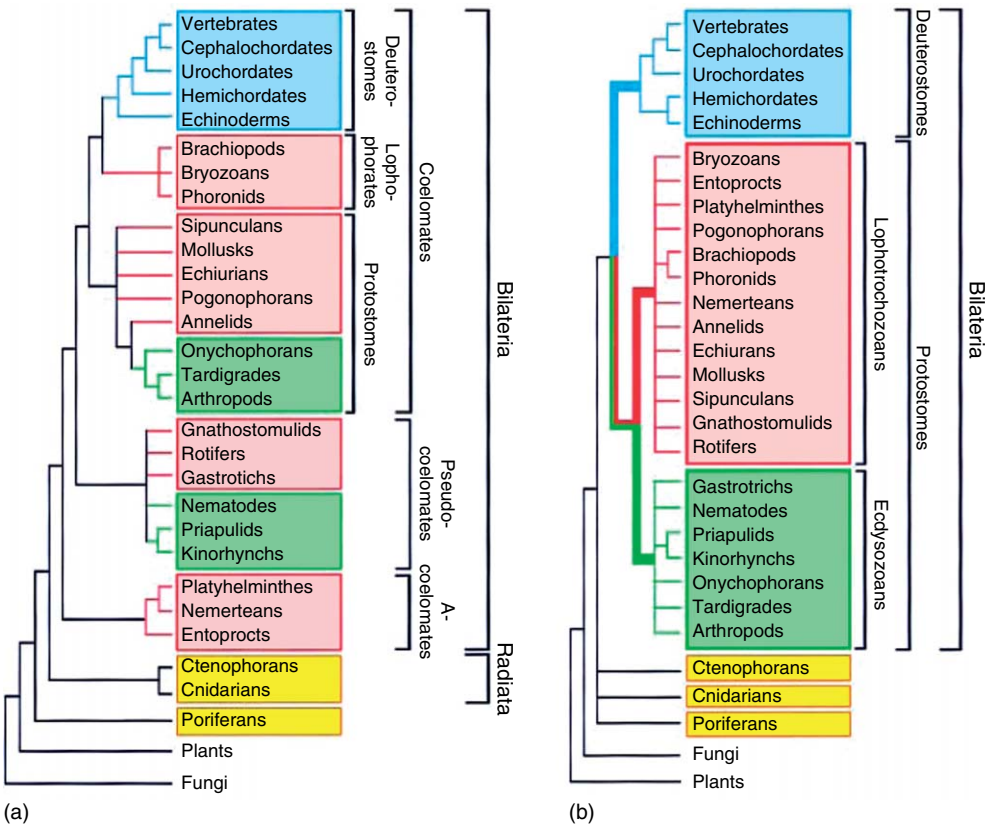

Figure 8 Metazoan phylogenies. a, The traditional phylogeny based on morphology and embryology. b, The new molecule-based phylogeny. Reproduced from Adoutte, A., Balavoine, G., Lartillot, N., Lespinet, O., Prud'homme, B., and de Rosa, R. 2000. The new animal phylogeny: Reliability and implications. *Proc. Natl. Acad. Sci. USA* 97, 4453–4456. Copyright 2000 National Academy of Sciences, USA, with permission.

the evolutionary origin of nervous system centralization and brain formation cannot be deduced from molecular phylogenetic data alone (see Origin and Evolution of the First Nervous System). This means that in terms of nervous system organization of the last common ancestor of modern bilateral animals, current molecular phylogeny is compatible with a number of possibilities (see, for example, Arendt and Nübler-Jung, 1997; Adoutte *et al.*, 2000; Gerhart, 2000; Shankland and Seaver, 2000; Meinhardt, 2002; Erwin and Davidson, 2002; Holland, 2003; and references therein).

1.04.5.2 Do Specialized Gene Expression Patterns Predict Specialized Brain Structures?

Since molecular phylogeny does not support preferentially either of the two hypotheses for the evolutionary origin of the CNS, we are left with the molecular data provided by comparative developmental genetic studies. Given the conserved molecular patterning mechanisms, or at least the conserved gene expression patterns, that characterize brain development in all bilaterians examined, what inferences can be made about the evolution of the CNS? The hypothesis of a monophyletic origin of the CNS is underscored by the notion that specialized developmental patterning mechanisms and patterned anatomical complexity evolved together (Tautz, 2003). Since comparative developmental genetics indicates that a complex set of conserved and specialized anteroposterior and dorsoventral patterning genes were operative in the nervous system of the urbilaterian ancestor of protostomes and deuterostomes, it is reasonable to assume that these genes generated an urbilaterian nervous system that also manifested complex anatomical specializations along the anteroposterior and dorsoventral axes (Hirth and Reichert, 1999; Arendt and Nübler-Jung, 1999; Reichert and Simeone, 2001). Thus, the conservation of expression and function of the dorsoventral columnar genes, including their dorsoventral inversion, provides strong evidence for the existence of an urbilaterian nervous system that was already dorsoventrally regionalized. Moreover, the observed

dorsoventral inverted expression of these genes in the CNS of insects versus vertebrates is precisely what would be predicted by the body axis inversion hypothesis, which in turn is substantiated by independent molecular evidence from gene expression data on heart development and gastrulation (e.g., Cripps and Olson, 2002; Arendt and Nübler-Jung, 1997).

Alternative scenarios for the evolution of centralized nervous systems in protostomes and deuterostomes have been proposed in which the CNSs occurred independently, after the split of the two groups, and without a dorsoventral inversion (reviewed in Gerhart, 2000; Holland, 2003; Lacalli, 2003). An implicit assumption of these proposals is that the bilaterian ancestor did not exert a dorsoventrally centralized nervous system but instead already had a structured map of patterning gene expression, which was then independently used for generating the CNS in different phyla. In the *Auricularia* hypothesis originally put forward by Garstang (1894; see also Nielsen, 1999), the evolutionary origins of the chordate nervous system are thought to be found in the ciliary bands of a deuterostome dipleurula-type larval ancestor resembling an echinoderm *Auricularia* larva. During the evolution of the chordate CNS, bilateral rows of cilia and the associated nerves were said to have converged through complex morphogenetic movements to the dorsal midline and fused to form the neural tube. Evidence for this view was found in comparative anatomical studies between echinoderms (particularly *Auricularia* larvae), hemichordates, and urochordates, and data show that a number of genes involved in chordate CNS development, including *SoxB3, Nkx2.1*, and *Otx*, are expressed in ciliary bands of larval hemichordates and/or echinoderms (Taguchi *et al.*, 2002; Takacs *et al.*, 2002; Tagawa *et al.*, 2001). Thus far, however, the ciliary band derivatives have not been shown to give rise to cells of the adult nervous system after metamorphosis. Furthermore, the *Auricularia* hypothesis does not take into account the molecular genetic similarities between the CNS of protostomes and that of chordates.

A comparative study on an enteropneust hemichordate has shown that the anteroposterior expression pattern of a large number of genes, which are involved in axial patterning of the vertebrate and arthropod CNS, is conserved in the apparently diffuse nervous system of the enteropneust acorn worm. The body-encircling basiepithelial nerve net of the directly developing hemichordate *Saccoglossus kowalevskii* expresses a complex set of regulatory genes in circumferential networks (Lowe *et al.*, 2003). Among these are the orthologues of the *otd/Otx*, *tll/Tlx*, *ems/Emx*, *unpg/Gbx*, *dll/Dlx*, *Pax*, *En*, *Lim*, *Hox*, and other highly conserved gene families, which reveal an anteroposterior order of domains that is remarkably similar to the insect and mammalian gene expression patterns (Figure 9). Unfortunately, almost nothing is known about the expression of hemichordate *dpp/BMP-4* and *sog/Chd* homologues and whether they might possess a neural/antineural antagonism that could limit and/or condense the nerve net into a CNS to one side of the body. Only in the indirectly developing hemichordate *Ptychodera flava* has a BMP2/4 homologue been described; however, no expression was observed during embryogenesis, suggesting that it is not involved in axis formation (Harada *et al.*, 2002). Moreover, little is currently known about *vnd/Nkx, ind/Gsh*, and *msh/Msx* orthologous gene expression and whether these genes might possess any early dorsoventral patterning functions in longitudinal column formation of the hemichordate nervous system. Thus far, only the expression of a hemichordate *Nkx2.1* homologue, which is specifically expressed in a ventral sector of the anterior ectoderm, is known (Lowe *et al.*, 2003).

Based on the gene expression studies in *Saccoglossus*, Lowe and co-workers have proposed that the nervous system of the deuterostome ancestor of hemichordates and chordates was also organized in a diffuse, body-encircling, basiepithelial nerve net (Lowe *et al.*, 2003). According to molecular phylogeny, this indicates that the bilaterian ancestor preceding protostomes and deuterostomes also possessed a diffuse, body-encircling, basiepithelial nerve net. Independent centralization events in protostomes and deuterostomes without dorsoventral inversion could then have resulted in anteroposteriorly oriented CNSs with similar gene expression domains (Holland, 2003).

Alternatively, the diffuse nervous system of *Saccoglossus* may represent the secondary loss of a centralized nervous system. Like cnidarians and ctenophores, hemichordates exhibit only neuroepidermal fibers without organized ganglia, brain, or other obvious specialized neural structures. Indeed, most of the data of Lowe *et al.* (2003) are equally compatible with a secondary reduction scenario, in which the ancestor of the deuterostomes would have had a centralized nervous system, which was lost in the hemichordates due to their peculiar lifestyle as sediment-burrowing worms. Moreover, the apparently simple, nerve net-like

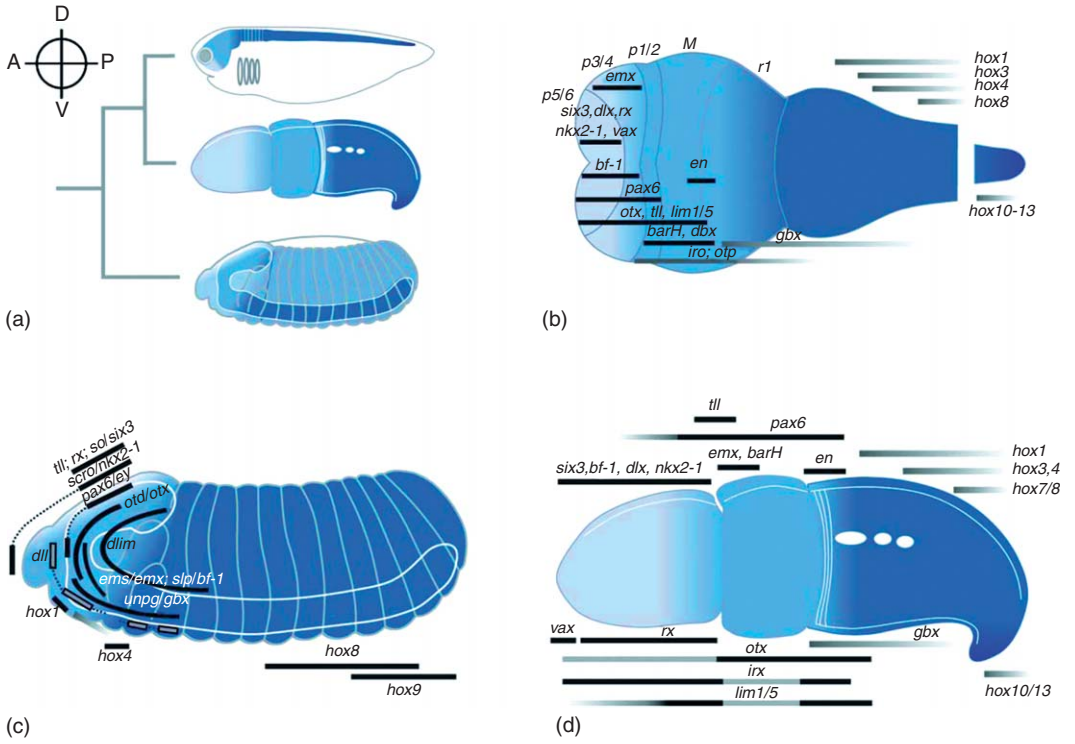

Figure 9 Comparison of the neural gene domain maps of hemichordates, chordates, and *Drosophila*. In addition to individual gene domains, the color gradient in each panel indicates general similarities of gene expression domains. a, Representation of the general organizational features of the CNSs of chordates and arthropods and the diffuse nervous system of hemichordates arranged on a phylogram. The compass indicates the axial orientation of each model. b, Representation of a dorsal view of a vertebrate neural plate (see Rubenstein *et al.*, 1998). p1/2, prosomeres 1 and 2; p3/4, prosomeres 3 and 4; p5/6, prosomeres 5 and 6; M, midbrain; r1/2, rhombomeres 1 and 2. The discontinuous domain represents the postanal territory of the nerve cord. All 22 expression domains are shown. c, *Drosophila* late stage 12 embryo model with 14 expression domains shown (lateral view, post-germ-band retraction, before head involution). All models are positioned with anterior to the left. d, The acorn worm (lateral view), with its diffuse nervous system, is shown with a blue color gradient of expression in the ectoderm; the anterior domains, the midlevel domains, the posterior domains, and the postanal territory are color matched to the anteroposterior dimension of the chordate model. Reproduced from Lowe, C. J., Wu, M., Salic, A., *et al.* 2003. Anteroposterior patterning in hemichordates and the origins of the chordate nervous system. *Cell* 113, 853–865, with permission from Elsevier.

nervous system of hemichordates may display further substructures, including CNS elements, as suggested by earlier neuroanatomical analyses: nerve fiber tracts are formed in the epithelium, including major ventral and dorsal tracts (Bullock, 1945; Knight-Jones, 1952).

1.04.5.3 A Simple Nerve Net at the Base of Nervous System Evolution?

There is some evidence that a basiepithelial, noncentralized nerve net, perhaps comparable to those found in extant hemichordates, may indeed represent the basal evolutionary state from which bilaterian nervous systems evolved. Basiepithelial nervous systems exist in some gastroneuralians, and the subepithelial nervous systems, as in insects, often go through a basiepithelial state during their development (Nielsen, 1995; Arendt and Nübler-Jung, 1999). However, the question remains of how such a simple nerve net condensed into a centralized nervous system and when this occurred in evolution. Paleontological evidence can provide a reasonable estimate of when CNSs were already formed in protostome and deuterostome animals. A conservative estimate is a date of 530–540 Mya in the early Cambrium, when a complex variety of bilaterian forms representing most of the modern major animal groups was present (Grotzinger *et al.*, 1995; Conway-Morris, 2000). These forms included arthropods such as trilobites and early agnathan-like stem vertebrates and the fossil record for both of these animal forms indicates that they already had brains and CNS with features typical for arthropods and vertebrates (Fortey, 2000; Holland and Chen, 2001). Thus, centralization of nervous systems must have occurred earlier, probably after the split between the cnidarians and the bilaterians, which is thought to have occurred between 600 and

630 Mya (Peterson *et al.*, 2004). If this is the case, then the cnidarian nervous system might be more informative of early CNS evolution in stem Bilateria than that of hemichordates.

The basic organization of the nervous system in cnidarians (and ctenophores) is that of a diffuse nerve net that can also manifest centralized elements such as nerve rings and ganglionic centers. Moreover, many of the conserved developmental control genes that operate in the insect and vertebrate nervous system are also present in Cnidaria and thus at least some of these differentiation gene batteries date to the last common ancestor of cnidarians and bilaterians (Finnerty *et al.*, 2004; Ball *et al.*, 2004; Finnerty, 2003; Galliot, 2000). Among these are anterior and posterior *Hox* genes, an asymmetrically expressed *dpp* gene, and an *Otx* gene. However, the expression patterns of these genes differ among cnidarian species and are inconclusive as far as anteroposterior or dorsoventral axis determination is concerned (Yanze *et al.*, 2001; Finnerty *et al.*, 2004). For example, the typical bilaterian head gene *Otx* is expressed along the entire primary body axis in cnidarians. In *Hydra*, the *CnOtx* gene is expressed at a low level in the ectodermal epithelial cells of the body, during early budding in the region of the parental body column from which cells will migrate into the developing bud, and *CnOtx* is strongly upregulated during reaggregation, in contrast to head or foot regeneration where it is downregulated (Smith *et al.*, 1999). In *Podocoryne*, the *Otx* gene displays two types of expression: in the gonozooid polyp at every developmental stage of the budding medusa and in the mature medusa, restricted to the striated muscle cells (Müller *et al.*, 1999). These data suggest that *Otx* is not involved in axis determination or head specification in *Hydra* and *Podocoryne*. Thus, ambiguous species-specific gene expression data in cnidarians make comparisons between cnidarian and bilateral nervous systems difficult and thus far are inconclusive concerning CNS evolution.

1.04.6 Conclusions

Contemporary experimental studies analyzing the expression and function of homologous genes in various animal model systems are reviving a fundamental question raised more than 150 years ago in the famous academic debate between Cuvier and Geoffroy Saint-Hilaire: does a common Bauplan underlie animal development, indicating homology of structures such as the ventrally located insect and the dorsally located chordate nervous system? Comparisons of the expression, function, and regulation of genes and genetic networks involved in anteroposterior and dorsoventral patterning of the insect and vertebrate nervous systems suggest that orthologous genes were already involved in neural specification in the insect and vertebrate stem species. Thus, the pervasive equivalence of the *Dpp/BMP-4* and *sog/Chd* antagonism in executing the distinction between neural and non-neural, the *vnd/Nkx*, *ind/Gsh*, and *msh/Msx* gene network involved in early dorsoventral columnar patterning, the role of the *otd/Otx* genes in anterior CNS regionalization, and the action of *Hox* genes in the specification of segmental neuronal identity are all conserved in both insect and mammalian CNS development. This strongly suggests that these molecular genetic mechanisms were already apparent in an urbilaterian ancestor and that the insect and vertebrate nervous systems evolved from a common ancestral urbilaterian brain.

However, it is also conceivable that complex gene expression characteristics pre-dated the generation of morphological complexity in the course of nervous system evolution. The analysis of developmental control gene expression in a hemichordate demonstrates that complex gene expression patterns, comparable to those observed in the CNS of insects and vertebrates, are compatible with the existence of a diffuse basiepithelial nerve net. Nevertheless, the hemichordate body plan is clearly derived and its basiepithelial nerve net may be the result of a secondary reduction or loss of an ancestral CNS. Some of the developmental control genes that operate in CNS development in arthropods and chordates are also expressed during cnidarian development. Although a diffuse, net-like nervous system is apparent in Cnidaria, the ambiguous data on orthologous gene expression in these animals impede any conclusive comparisons between cnidarian and bilateral nervous systems. The available data therefore suggest that only one ancestral, albeit rather complex, nervous system type was at the origin of bilaterian CNS evolution.

1.05 Field Homologies

L Medina, University of Murcia, Murcia, Spain

Glossary

developmental regulatory gene A gene encoding a transcription factor or a signaling protein, which is expressed during development in specific patterns, and is able to regulate expression of other genes and control patterning and morphogenesis of specific body parts.

homologous Exhibiting biological homology; having the same relative position (topologically), embryological origin and common ancestor. For animal or body parts having the same basic organization plan, topological position of homologous morphogenetic fields and radial histogenetic divisions is generally identical; however, for identifying homologous cell groups, embryological origin is a prevalent criterion, since their topological position may differ between animals due to distinct migration.

homologue The same organ in different animals under every variety of form and function, inherited from a common ancestor. See also 'homologous'.

homology A similarity attributed to common evolutionary origin. See also 'homologous'.

homoplasy A similarity not due to common evolutionary origin, but to convergent or parallel evolution.

modularity Principle by which biological systems are made up of discrete units or modules, which are self-regulated and dynamic entities able to change independently of the rest of the body during development and evolution.

module Each unit of a modular organism or organ, from genetic cascades to cells and cell fields. A module is a self-regulated and dynamic entity that can change independently of the rest of the body without lethal consequences, producing phenotypic variations.

morphogenetic field Higher-order module, specified by a particular combination of developmental regulatory genes, that gives rise to a particular body division or subdivision. It constitutes a major unit of development and evolution, and the natural comparison character for homology considerations.

radial histogenetic division A radially arranged region or territory of the brain, whose neurons primarily derive from a specific morphogenetic field (i.e., from a restricted ventricular sector of the neural tube). The radial feature of brain histogenetic divisions is based on the predominant glial fiber-guided migration of immature neurons in their way from the ventricular zone to the mantle during development. Nevertheless, radial histogenetic divisions can contain immigrant cells coming from other fields by tangential migration. The fact that the majority of the cells in each radial

histogenetic brain division originate in a specific morphogenetic field, makes these divisions natural comparison units for field homology considerations in adult animals. This does not mean that all cells in a particular division in one animal are necessarily homologous to the cells of the same division of other animals.

telencephalon Bilateral evaginations of the rostral forebrain. It shows two major divisions in all vertebrates: pallium and subpallium.

topology Geometric configuration of any given structure (such as the brain) according to internal coordinates, which remain unaltered, independent of deformations or differential growth of subdivisions that occur during development. According to this, the topological position of any division/subdivision within the structure, and its relation to neighbors, remain the same throughout ontogeny. Further, in organisms sharing the same configuration and basic organization plan (e.g., vertebrates), the topological position of homologous divisions/subdivisions should be the same across species. In contrast, some homologous cell groups may vary their topological position by differential migration in different animals.

1.05.1 Introduction

We humans have always been intrigued by the astonishing cases of structural or functional similarities between body parts found in the animal kingdom (e.g., wings of insects and birds, eyes of squids and vertebrates, and so on). This issue was deeply investigated by the nineteenth-century naturalists and anatomists, who gained access to a large variety of new species, thanks to the European exploratory voyages to new worlds, favoring their 'intellectual voyage' in search of the archetype. Owen was one such anatomist who realized that not all similarities are equal, coining the term 'homologue' to define "the same organ in different animals under every variety of form and function" (Owen, 1843; A History of Ideas in Evolutionary Neuroscience; see also Mayr, 1982; Raff, 1996; Panchen 1999; Butler and Saidel, 2000; Puelles and Medina, 2002; Wake, 2003). He also coined the term 'analogue' to define a part or organ in one animal that has the same function as another part or organ in a different animal (Owen, 1843; Wake, 2003). Soon after the introduction of these terms, evolution came into the scene to explain why similarities exist (Darwin, 1859), and evolutionary biologists used the term 'homology', under a new perspective. For evolutionary biologists, two structures are homologous if they can be traced back to a common ancestor (i.e., homology is similarity due to inheritance from common ancestor) (Striedter and Northcutt, 1991; Raff, 1996; Gilbert and Burian, 2003; Wake, 2003). In this view, the existence of homologues is the consequence of evolution, and the study of homologies is, in essence, the study of evolution. In addition to homology, another key concept for evolutionary biologists is 'homoplasy', a term coined by Lankester to define similarity not linked to common ancestor, but due to convergent or parallel evolution (Lankester, 1870; Hall, 1999; Panchen, 1999; Wake, 2003). To discern between homology and homoplasy is not an easy task since it is difficult to know what the prevalent characters are that should be chosen for comparison. Moreover, many problems arise when trying to consider intriguing cases such as similarities not linked to common ancestor but being produced by a similar developmental pathway (i.e., sharing a common generative pathway), or similarities linked to common ancestor but produced by different developmental mechanisms (Striedter, 1998; Butler and Saidel, 2000; Puelles and Medina, 2002; see A History of Ideas in Evolutionary Neuroscience). One very useful way to approach the study of homologies is by combining developmental and evolutionary views (Gould, 1992; Raff, 1996; Gilbert *et al*., 1996; Striedter, 1998; Gilbert and Burian, 2003), which makes sense since evolution occurs as a consequence of changes in developmental mechanisms that produce phenotypic variations, which are then exposed to natural selection (de Beer, 1951; Waddington, 1966; Gilbert *et al*., 1996; Raff, 1996). This combined 'evo–devo' approach has provided unequivocal evidence for the modular nature of embryos, and for the existence of discrete fields, the morphogenetic fields, which represent major ontogenetic units (modules) able to change independently, producing variation and diversity in evolution (Raff, 1996; Gilbert *et al*., 1996; Gilbert and Burian, 2003; Gass and Bolker, 2003). This evidence has been extremely important for rescuing the concept of 'field homology', first introduced by Smith (1967) to define correspondence due to derivation from a common embryonic anlage, and used later by comparative neurobiologists to

homologize brain regions assumed to develop from homologous precursors (Northcutt, 1981; Butler, 1994a, 1994b; Striedter, 1997). Based on the importance of morphogenetic fields as major ontogenetic and phylogenetic units, the concept of field homology has recently been reformulated under the modern perspective of evolutionary developmental biology, to be used in a dynamic rather than static sense, as one of the natural comparison characters for evolutionary studies in general and, in particular, for studies of brain evolution (Puelles and Medina, 2002). Below I briefly summarize some ideas related to this concept.

1.05.2 Conceptual Considerations

Evolutionary developmental biologists try to understand the mechanisms that produce homologous and homoplastic structures, and how variation and novelties originate during development and in evolution. Understanding these principles is essential for studying evolution of a complex biological structure, such as the brain. In this section, I provide a very brief analysis of the causes and principles of evolution, for then applying these ideas to the study of brain evolution in the following section.

1.05.2.1 Causes of Homology, Convergence, and Divergence: Development, Evolution, Epigenesis

Homologous structures can show a high degree of similarity (involving static or conservative evolution) or can differ in form and/or function (involving important evolutionary changes). Nonhomologous structures can reach a high degree of similarity by way of either convergent or parallel evolution (Striedter and Northcutt, 1991). Further, many biological systems exhibit new characters or features with no counterpart in the ancestor (i.e., they have been produced as novelties during evolution) (Striedter, 2005). The reason for all of these examples of static, divergent, convergent, or parallel evolution can be found in development and in the genetic regulatory programs underlying it. Developmental mechanisms and the genetic regulatory networks involved in the formation of complex structures are often highly integrated systems subjected to constraints impeding significant changes, and random variation. Developmental and evolutionary changes are possible due to the modular nature of biological systems, from the level of genetic cascades to the levels of cells and morphogenetic fields (Raff, 1996; Gilbert *et al*., 1996). Modules, such as morphogenetic fields, are dynamic, highly stable, and self-regulated systems, able to absorb perturbations produced in the field or outside it (i.e., they are internally constrained). However, some changes in their genetic regulatory programs can alter their development and, if not lethal, can lead to phenotypic variations in the adult. The resultant phenotypes are then selected by external pressures. Genetic regulatory programs can be affected by epigenetic interactions with other modules, such extracellular signaling molecules involved in inductive interactions, and changes in these interactions can lead to phenotypic variations (Raff, 1996). In addition, genetic regulatory programs can be affected by epigenetic environmental features such as temperature, nutrition, or population density, and the phenotypic result can be different under different conditions (Raff, 1996; Hall *et al*., 2004; see Epigenetic Responses to a Changing Periphery – Wagging the Dog). This takes us to the concept of phenotypic plasticity, according to which each genome is able to produce a range of phenotypes, as a critical adaptive response to different environments (Waddington, 1956; Raff, 1996; Gilbert and Burian, 2003). The issue of developmental and evolutionary constraints, the principle of modularity, and the concept of morphogenetic field are explained in more detail in separate sections.

1.05.2.2 Internal Constraints in Development and Evolution. Epigenetic Constraints

In spite of the rich structural and functional variety of animal body forms found in nature, no more than about 35 different body plans exist, all of which appeared during the Cambrian radiation over a half billion years ago, indicating an astonishing stability of structure once integrated as a complex form (Raff, 1996). Although extensive evolutionary changes have occurred since the Cambrian, the underlying body patterns have been conserved. This means that there are constraints in evolution, which include at least physical/morphological, genetic, developmental, historical, and epigenetic constraints (Raff, 1996; Striedter, 1998, 2005). Once a body plan is assembled, the genetic regulatory programs and developmental mechanisms underlying it become tightly integrated, and significant change is severely constrained (Raff, 1996). The integration of genetic and developmental controls of a body plan during evolution is irreversible, which means that a body plan cannot be transformed into another one without fatally disrupting its ontogeny (Raff, 1996). Once an integrated body plan is established, selection favors improvements/changes within that body plan, and disfavors new body plans that are unable to compete as well as

established ones (Raff, 1996). In addition to genetic constraints due to tight integration of genetic networks making small changes lethal (this does not occur when duplications or alternative links exist), the genomic size is also a source of constraint since it affects properties such as cell size and division rate (Raff, 1996), which affect the morphology. Some simple vertebrates such as lungfish or salamanders have disproportionately huge genomes, much larger than that of humans (Raff, 1996). Larger genomes result in larger cells, and cells containing large genomes have a slower DNA replication, constraining the growth rate of the organism. In frogs and salamanders having a large genome and, as a result, larger cells, this is related to a simplification of brain morphology (Roth *et al*., 1994).

It appears that the developmental and genetic internal constraints are not equally tight during the whole development, thus allowing for some degree of variation within body plans observed during evolution. Such changes are possible due to the modular nature of development (genetic cascades and networks, transduction/signaling pathways, cells, morphogenetic fields), which allow changes in one module without affecting the rest (Gilbert *et al*., 1996; Raff, 1996; Gass and Bolker, 2003; Gilbert and Burian, 2003). In vertebrates, echinoderms, and possibly other animal groups, internal developmental constraints are maximal during the phylotypic stage, but are relatively loose during early and late development. The phylotypic stage (called pharyngula in vertebrates) represents the most evolutionarily conserved stage of development, in which embryos of different species share a comparable regional/modular organization and comparable expression patterns of developmental regulatory genes. The stability of this stage is due to the existence of tight and complex integration (interactions) between modules, which impeds variation without fatal consequences (Raff, 1996). Curiously, and paradoxically, this highly constrained stage, which later gives rise to a highly conserved body plan, can be achieved by way of very different developmental mechanisms, meaning that early development is loosely constrained. Striedter (1998) explains this paradox of many different developmental mechanisms leading to a conserved phylotypic stage by proposing the existence of attractors, represented by valleys in epigenetic landscapes. These attractors represent the different dynamic states of modules (Raff (1996); these are discussed in the following section). Integration between modules is less strict before and after the phylotypic stage, allowing evolutionary changes. When these changes occur after the phylotypic stage, they produce phenotypic variation in the adult that affect specific modules and their derivatives (mosaic evolution).

1.05.2.3 The Principle of Modularity: Genetic Cascades, Cells, Cell Fields, and Organs

As noted above, evolutionary changes during development are possible due to the modular organization of developing embryos. Developing organisms are made up of partially independent, interacting units or modules at several hierarchical levels (from genetic cascades to cell lineages and cell fields), which are able to change independently of the rest of the body, allowing mosaic evolution in both genes and morphology (Raff, 1996; Gass and Bolker, 2003; Gilbert and Burian, 2003). Modules are thus important units, in both development and evolution, that link genotype to phenotype. Within some limits (due to constraints), modules can become semi-independent entities (dissociation), allowing nonrandom evolutionary variation without fatal consequences for the embryo. Evolutionary variation can occur by changes in timing or location of regulatory gene expression or other processes (including signal transduction interaction between modules), by changes of growth rate or duration within a module, by module duplication followed by divergence (this occurs in the production of serial homologues), or by co-option (Gould, 1977; Gilbert *et al*., 1996; Raff, 1996; Gass and Bolker, 2003; Gilbert and Burian, 2003).

The correct expression of developmental regulatory genes is essential for body and body part formation. Changes in their expression (timing or location) can produce important morphological alterations, and the occurrence of such changes is considered a major cause for the production of morphological diversity in evolution (Carroll *et al*., 2001). Developmental regulatory genes, also called master control genes, constitute a small fraction of the genome, and encode transcription factors or signaling proteins, that directly (through direct DNA biding) or indirectly (through signal transduction cascades) regulate the expression of other genes and control key aspects of development and formation of specific body parts (Carroll *et al*., 2001). The coding region of these genes is extremely well conserved in evolution, but the regulatory region, containing key elements (enhancers) for gene transcription regulation, can change in evolution, producing gene expression changes in timing or location. Such evolutionary variation in gene regulatory regions is possible due to its modular organization, which allows variations such as addition of new enhancers or binding sites for new

activators or repressors, that can affect positively or negatively the gene transcription (Gilbert, 2000; Carroll *et al*., 2001). Evolutionary changes have often occurred at the level of the gene regulatory regions, as well as with the evolution of new activators, repressors, or cofactors acting directly or indirectly on the regulatory region of master control genes (Carroll *et al*., 2001). Changes can also occur at the level of the downstream targets of master control genes, also in the regulatory region of those target genes, which may produce, for example, a particular transcription factor that can act through a different downstream cascade of genes, producing a different effect and a different phenotype. The modular nature of the regulatory region of genes, of the genetic cascades, and of the embryo (in different fields) makes possible that particular master control genes can have different effects when acting, in different contexts, in different parts of the body (Carroll *et al*., 2001). Modular interaction between genetic regulatory cascades is also essential to understand how so much morphological diversity and so many different cell types can be produced from relatively few master control genes. Through such interactions, different master gene combinations defining distinct morphogenetic fields can lead to different body parts and subdivisions (Carroll *et al*., 2001).

Developmental modules are dynamic and self-regulated entities, that have specific locations in the embryo, and show specific properties (such as specific gene expression patterns) and capacities of interaction with other modules, than can change dynamically during the course of development (Raff, 1996; Gass and Bolker, 2003). Thus, developmental modules are usually transient entities (e.g., cascades of developmental regulatory genes, such as those expressing transcription factors; or morphogenetic fields) that, in general, are not found as such in the adult but produce specific adult phenotypes (e.g., expression of specific structural genes, specific sets of differentiated cells, specific regions or organs). Each state of the module (e.g., each state to pass from being a stem cell, to a neural stem cell, and from here to a forebrain neural stem cell, and so on, to finally become a differentiated cholinergic neuron in the basal telencephalon; or the transient states between a morphogenetic field and a particular adult brain division) can be considered as a 'basin of attraction' or 'attractor', and developmental genes act as regulators to make the transition between different 'basins of attraction' (between transient cell types) (Kauffman, 1987, 1993; Raff, 1996; Striedter, 1998). Of interest, these attractors are the characters or natural units of comparison between different organisms for homology considerations. If the phylogenetic continuity criterion is met (analyzed using a cladistic method), particular attractors in two animals can be considered homologous (see Phylogenetic Character Reconstruction). However, it is important to note that homology at a particular attractor state (e.g., a transient state during development) does not neccessarily mean complete homology at the final state. For example, a particular morphogenetic field can be homologous in two different animals, but its final product in one of the animals may contain cell populations homologous to similar cells in other animals, plus other nonhomologous cell populations (with no counterpart in other species or the common ancestor, as inferred using a cladistic analysis).

Although developmental modules generally lose some of their attributes after the major developmental events have occurred (e.g., when cells reach a differentiated state), there are cases of modules that either keep their properties (e.g., as stem cells) or are able to recover them in adult animals, and are responsible for cases of regeneration or continuous cell production. This would explain the continuous production of blood cells or epithelial cells in the adult (Gilbert, 2000). This also happens in the brain of different animals, including mammals, where localized foci of adult neurogenesis are found in the subventricular zone leading to the rostral migratory stream (giving rise to cells that migrate tangentially to the olfactory bulb) or in the hippocampal formation (García-Verdugo *et al*., 2002; Alvarez-Buylla and García-Verdugo, 2002; Merkle *et al*., 2004). These examples of developmental modules keeping or recovering their 'generative' properties in the adult are more common in amphibians and fish, but often are also found in reptiles (Gilbert, 2000). For example, amphibians and reptiles are able to regenerate some distal body parts, such as the tail, following amputation. The enigmatic case of 'Wolffian' regeneration in urodele amphibians (regeneration of the eye lens but from a different origin, the iris edge; Gilbert, 2000) may also be a consequence of the persistence of developmental modules with intact generative and self-regulatory properties after the major developmental events have occurred (see also Puelles and Medina, 2002).

1.05.2.4 Morphogenetic Fields as Evolutionary and Developmental Higher-Order Modules Linking Genotype and Phenotype

Among modules, morphogenetic fields constitute higher-order units of embryonic development, that are specified by particular combinations of

developmental regulatory genes (master control genes) and that give rise to specific cellular groups and structures found in the adult. They represent the major units establishing the link between genotype to phenotype, and the major units of ontogenetic and phylogenetic change (Gilbert *et al*., 1996). Further, they constitute major natural units or characters for comparison between species and for homology studies.

In the brain, morphogenetic fields are represented by segments (rhombomeres, prosomeres) and smaller divisions and subdivisions within them (Raff, 1996; Gilbert *et al*., 1996; Puelles and Rubenstein, 1993, 2003). The evidence for their existence is ample, and includes:

1. data on expression of developmental regulatory genes in different species, allowing visualization of fields as discrete expression domains characterized by specific combinations of genes (Simeone *et al*., 1992; Bulfone *et al*., 1993, 1995, 1999; Puelles and Rubenstein, 1993; Puelles *et al*., 2000; Bachy *et al*., 2002; Brox *et al*., 2003, 2004; Lumsden, 2004; see Origins of the Chordate Central Nervous System: Insights from Hemichordates);
2. knockout mutations showing specific alterations of the field and its derivatives, either by lack of formation, malformation, or transformation into an adjacent field (Schneider-Maunoury *et al*., 1993; McKay *et al*., 1994; Stoykova *et al*., 1996; Sussel *et al*., 1999; Yun *et al*., 2001, 2003; Bishop *et al*., 2002, 2003; Muzio *et al*., 2002);
3. fate map studies showing clonal restriction at least at the level of the ventricular zone (Fraser *et al*., 1990; Marin and Puelles, 1995; Cambronero and Puelles, 2000; Cobos *et al*., 2001b; García-López *et al*., 2004); and
4. in the case of brain segments, transplantation studies showing replication of the field and its derivatives when a specific rhombomere is grafted into a different position of the embryo (Kuratani and Eichele, 1993; Martínez *et al*., 1995).

During development, fields can be patterned and/or can reach a new order (including new gene expression) by interaction with other fields. This can occur by way of signaling proteins produced by cells in particular fields or organizer centers (such as Sonic hedgehog, Wnt, BMP, and FGF proteins), that are secreted to the extracellular medium and diffuse to act at a distance in a concentration-dependent manner (Carroll *et al*., 2001). The response of cells to such inductive proteins depends on both the distance from the source and their expression of appropiate receptors. Examples of such interactions are common in the central nervous system and constitute an important mechanism for patterning (Ericson *et al*., 1997; Shimamura and Rubenstein, 1997; Ragsdale and Grove, 2001). The internal order of fields can also be affected by signaling from boundaries separating the field from neighbors (Echevarría *et al*., 2003; Riley *et al*., 2004).

One important aspect of morphogenetic fields is that, as modular units, they exist in specific locations within the embryo and, for adequate comparison of these fields in different animals, it is important to understand the overall organization plan and major axis (rostrocaudal, dorsoventral) of the embryo or organ/region containing the field. This allows one to know the correct location of the field according to the internal coordinates of the embryo/organ, including its relation to neighbors (topological position; Kuhlenbeck, 1978; Nieuwenhuys, 1974, 1998a, 1998b; Puelles and Medina, 2002). Analyzing the correct topological location of the field avoids wrong comparisons of fields sharing some of the same genetic programs and producing similar cell types, such as the subpallium (in the telencephalon) and the ventral thalamus (also called prethalamus; in the diencephalon) (Figure 1), both of which express homeobox genes of the *Dlx/Distal-less* family, and give rise to GABAergic neurons, but are located in completely different positions (Puelles and Rubenstein, 1993; Bulfone *et al*., 1993; Puelles *et al*., 2000; Brox *et al*., 2003). Comparisons of field topological location between animals are useful and make sense when the compared animals, or the organs/regions where the fields are located, share a common organization plan (Kuhlenbeck, 1978; Nieuwenhuys, 1998b; Puelles and Medina, 2002). This is the case with vertebrates, and with the central nervous system of vertebrates (see Basic Nervous System Types: One or Many?, Evolution of the Deuterostome Central Nervous System: An Intercalation of Developmental Patterning Processes with Cellular Specification Processes, Origins of the Chordate Central Nervous System: Insights from Hemichordates).

Another important aspect of morphogenetic fields is that, although highly stable, they are dynamic entities. They exist at a particular place within the embryo, and at a particular time, and their internal features (given by the lower-order modules within them, such as genetic cascades and networks and cells) and interactions with other fields change dynamically during development. At the end, each morphogenetic field gives rise to a particular set of derivatives, but homology of morphogenetic fields in two animals at a particular stage of development does not necessarily mean homology of all their

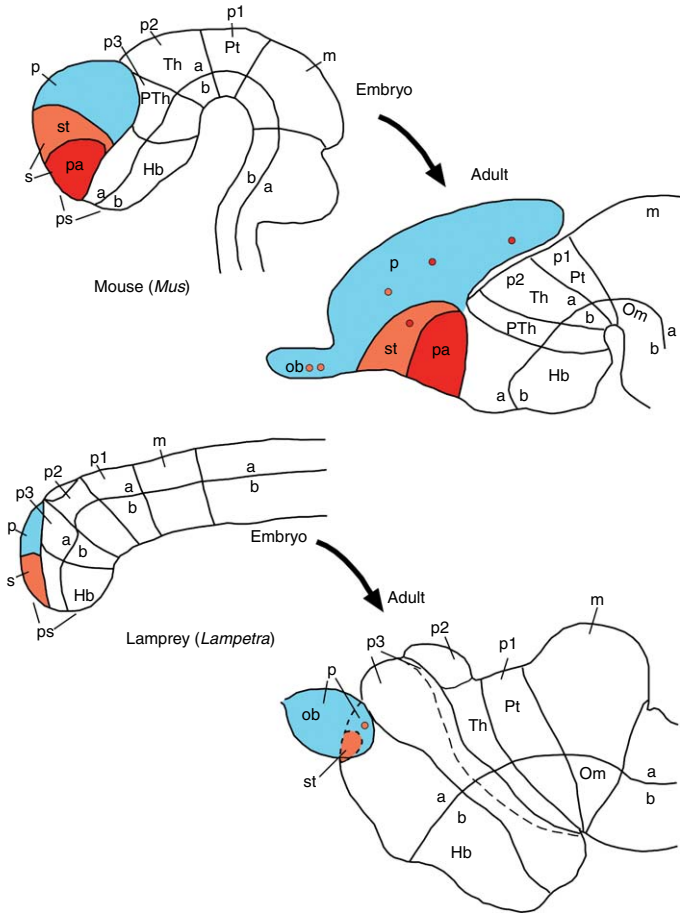

Figure 1 Schematic lateral views of the embryonic and adult brains of a mouse and a lamprey (a jawless fish close to the origin of vertebrates), showing some of the major divisions and subdivisions as understood nowadays based on available data, including data on expression of developmental regulatory genes (master control genes) during development (Pombal and Puelles, 1999; Murakami *et al.*, 2001; Puelles and Rubenstein, 2003). During development, each division and subdivision is characterized by expression of a specific combination of master control genes, and constitutes a distinct self-regulated morphogenetic field, which gives rise to a particular set of derivatives in the adult. Each morphogenetic field occupies a specific topological position within the brain basic organization plan (or brain archetype). Morphogenetic fields of two animals showing comparable molecular features (similar expression of master control genes) and comparable topological position within the general brain archetype can be considered homologous (if the phylogenetic continuity applies, which can be analyzed using a cladistic method; see A History of Ideas in Evolutionary Neuroscience). For instance, using this analysis, the alar regions of prosomere 2 (p2) of mouse and lamprey, giving rise to the thalamus (Th, or dorsal thalamus), are field-homologous. Also, the basal regions of the mesencephalon (m) of mouse and lamprey are homologous as a field, and the oculomotor neurons (Om, motor neurons of the third cranial nerve) derived from this field are homologous as well. Other cell groups found in adult basal mesencephalon may not be homologous between mouse and lamprey (or between mouse and another vertebrates), since divergent evolution may have led to the appearance of novel cell groups. In the telencephalon (colored in the schematics), two major homologous morphogenetic fields exist in the embryonic brain of both mouse and lamprey, called pallium (blue) and subpallium (orange-red), showing distinct gene expression (*Pax6* and *Emx1* in the pallium versus *Dlx* in the subpallium). In addition, mouse (as well as chicks, frogs, and zebra fish) show a smaller expression domain of the homeobox gene *Nkx2.1* within the subpallium, allowing subdivisions of this field into two smaller morphogenetic fields, called striatal field (orange) and pallidal field (red), giving rise to the striatum and pallidum, respectively, in the adult. However, lampreys do not show expression of *Nkx2.1* in the telencephalon (Murakami *et al.*, 2001; this gene is also previously called *TTF-1*), suggesting that a pallidal morphogenetic field is absent in lampreys and possibly was absent in the origin of vertebrates. This agrees with the apparent lack of a pallidum in adult lampreys (Pombal *et al.*, 1997a, 1997b). This also suggests that the pallidal morphogenetic field was a novel acquisition during the transtition from jawless to jawed vertebrates. The appearance of a new field does not only imply evolution of a novel histogenetic division, but possibly triggers changes in adjacent or distant fields due to interfield (intermodular) interactions. In the case of the telencephalon, the appearance of a new pallidal field possibly triggered changes in the striatum and even the pallium, part of which was related to the existence of tangential cell migrations from the pallidum to those divisons, involving the acquisition of new cell types (integrated as interneurons of the striatum or pallium, colored in red in schematic) and new modulatory functions on the activity of native striatal and pallial cells. The striatal field also produces part of the interneurons found in the pallium in different vertebrates (colored in orange in the schematic), and this may also be true in lampreys (Pombal and Puelles, unpublished observations). a, alar region (dorsal); b, basal region (ventral); Hb, basal hypothalamus; m, mesencephalon; ob, olfactory bulb; Om, oculomotor neurons; p, pallium; pa, pallidum; Pt, pretectum; PTh, prethalamus or ventral thalamus; ps, secondary prosencephalon; p1, p2, p3, prosomeres 1, 2, or 3; s, subpallium; st, striatum; Th, thalamus or dorsal thalamus.

derivatives at the final stage, because some evolutionary divergence may have occurred during later development, producing novel cell groups and features. Abnormal changes in the internal order of the field or in the interaction with other fields (e.g., due to mutation of master control genes, or alteration in their regulatory region) can lead to field reorganization (to reach a new order) and changes in size, sometimes involving repatterning events. This occurs in the telencephalon after knockout mutation of homeobox patterning genes such as *Pax6*, *Emx2*, *Gsh2*, or *Nkx2.1* (Sussel *et al*., 1999; Yun *et al*., 2001; Stoykova *et al*., 2000; Toresson *et al*., 2000; Bishop *et al*., 2002, 2003; Muzio *et al*., 2002). For example, knockout mutation of *Nkx2.1* in mouse produces severe malformation and size reduction of the pallidal subdivision (medial ganglionic eminence or MGE), and repatterning of most of its former primordium to give rise to a larger striatal subdivision (lateral ganglionic eminence or LGE) (Sussel *et al*., 1999). In *Emx2*/*Pax6* double mutant, the pallium is severely malformed and reduced, and its primordium is repatterned to become subpallium (Muzio *et al*., 2002). These examples indicate the importance of master control genes in the patterning and specification of morphogenetic fields, and show the self-regulatory and dynamic properties of the fields. These dynamic properties of morphogenetic fields are important for homology considerations. Thus, instead of saying that the resultant extra-large striatal subdivision found in *Nkx2.1* knockout mice (or at least the part derived from the repatterning of MGE into LGE) is not homologous to the striatal subdivision of wild-type animals because of their different origin, we should consider the LGE of both mutant and wild-type mice as an attractor homologous state (in the sense explained above; see also Raff, 1996; Striedter, 1998), no matter how this was reached.

1.05.3 Field Homology: A Useful Concept in Studies of Brain Evolution

The importance of morphogenetic fields as major units of development and evolution, and as major natural comparison characters for homology considerations makes the field homology concept very useful in evolution studies, including the brain evolution studies (Puelles and Medina, 2002). Each morphogenetic field gives rise to a specific set of derivatives found in the adult, and each organ, region, or subdivision found in the adult is the result of a specific field and its interactions with other fields, and can be formed with derivatives of several morphogenetic fields. In the brain, most cellular derivatives of each morphogenetic field remain in close association within specific radial histogenetic divisions, or in specific nuclei, areas, or cell condensations (such as patches or islands) within radial divisions. This is so because of the predominant radial glial-guided migration followed by immature neurons during development, in their way from the ventricular zone to the mantle (Rakic, 1972, 1995; Nieuwenhuys, 1998c; see 00116), although some subpopulations of cells undergo long-distance tangential migration (Anderson *et al*., 1997, 2001; Marín and Rubenstein, 2001). Another reason for the close association of cells derived from a particular morphogenetic field is that they tend to express similar combinations of cell adhesion molecules (such as cadherins) allowing their aggregation by homotypic binding, but distinct from those of adjacent fields (Redies *et al*., 2000). The prevalence of radial migration and the existence of radial histogenetic domains in the brain has been observed using fate map studies of different brain fields (Marín and Puelles, 1995; Cobos *et al*., 2001a, 2001b; García-López *et al*., 2004). This is also observed after labeling of discrete cellular clones in the ventricular zone of the embryonic telencephalon, which produces mature cells that are aligned along a narrow band extending from the ventricle to the pial surface (Striedter *et al*., 1998; Noctor *et al*., 2001). The existence of radial histogenetic domains in the adult brain, whose cellular components are mostly derived from specific morphogenetic fields, allows the use of such radial divisions as the natural comparison units for homology considerations in the adult brain. Thus, specific radial histogenetic divisions found in the adult in different animals, and having the same morphogenetic origin and topological location, such as the dorsal thalamus, the striatal domain, or the derivatives of a particular rhombomere, can be considered homologous as a field (Puelles and Medina, 2002).

However, for further homology considerations, careful analysis of the different cell groups found in the radial histogenetic division must be done, since a division may contain both homologous and nonhomologous cell groups when compared to the cell groups in the same radial division of another vertebrate (Puelles and Medina, 2002). This can be due to the fact that, as noted above, homologous morphogenetic fields may undergo partially divergent evolution during late development, producing novel cell groups and features with no counterpart in other animals or in the ancestor. This is the case of the dorsal thalamus, which becomes very large in birds and mammals and contains many cell groups with no apparent counterpart in the dorsal thalamus

of extant reptiles, or possibly in the common ancestor of extant birds, mammals, and reptiles (Butler, 1994a, 1994b). In addition, adult radial histogenetic divisions may contain immigrant cells that originate in different morphogenetic fields. These immigrant cells in a specific histogenetic region are not homologous to 'native' cells of the region, in the same animal or in other animals. However, they can be homologized to similar immigrant cells of the same region in other animals if they have an identical origin (and other similar features, such as neurotransmitter content) and can be traced back to the common ancestor (using cladistic analysis). An example of this is found in the striatum (Figure 1), a part of the basal ganglia found in the basal telencephalon of adult reptiles, birds and mammals, and derived from a homologous subpallial morphogenetic field (LGE in mammals), expressing *Dlx* family genes (Reiner *et al*., 1998; Marín *et al*., 1998; Smith-Fernandez *et al*., 1998; Puelles *et al*., 2000). The striatum in these animals contains homologous GABAergic projection neurons that originate in the LGE or LGE-like field, having specific neuropeptide contents and connections (Reiner *et al*., 1998). In addition, the striatum in these animals contains similar sets of interneurons, such as the cholinergic interneurons (Reiner *et al*., 1998). In mouse, the striatal cholinergic interneurons immigrate from a different morphogenetic field of the subpallium, characterized by expression of the homeobox gene *Nkx2.1* (Marín *et al*., 2000), and with the involvement of a *Lhx7/8*, a LIM-homeobox gene dowstream of *Nkx2.1* (Zhao *et al*., 2003). This is possibly true for the striatal cholinergic interneurons of birds and reptiles as well. The cholinergic interneurons of the striatum are neither homologous to the striatal projection neurons nor to other groups of striatal noncholinergic interneurons, but – if their identical origin is confirmed – they could be homologous to the striatal cholinergic neurons of different reptilian, avian, and mammalian species.

In a few cases, homologous cell groups occupy very different locations in the adult, in different histogenetic radial divisions, although they originate in the same morphogenetic field. This is the case of the facial branchial motoneurons, which in reptiles, birds, and mammals originate in rhombomeres 4 and 5, and their axons exit the brain in the 7th cranial nerve (facial nerve), through rhombomere 4 (Lumsden and Keynes, 1989; Medina *et al*., 1993; Medina and Reiner, 1994; McKay *et al*., 1997). However, after being born and starting to grow their axon, these motoneurons migrate caudally in reptiles and mammals (forming the facial nerve genu), to finally occupy a position at the level of rhombomeres 6–7 (Medina *et al*., 1993; Auclair *et al*., 1996; McKay *et al*., 1997). In birds, however, facial motoneurons stay within rhombomeres 4–5 and are seen at this same location in the adult (Medina and Reiner, 1994). In this case, the general segmental division derived from each rhombomere can still be homologized as a field between species, and also occupy comparable topological positions and relation to neighbors. When analyzing the specific cell groups, it is clear that, independent of their distinct position in the adult, the facial motoneurons of birds, reptiles, and mammals are homologous. Thus, for homology considerations of specific cell groups in the adult, it is extremely important to know the exact morphogenetic origin of the group (i.e., origin with respect to the morphogenetic fields found during development), and the origin is a prevalent criterion independent of the final location of the cells in the adult. Once an identical origin from homologous morphogenetic fields has been confirmed, other attributes can be considered for investigating the putative homology of specific cells found in the adult, such as neurotransmitter and/or neuropeptide content, connections, neurotransmitter receptor expression, etc. Connectivity and receptor features need to be considered with caution since these may have changed during the evolution of homologous cells (Striedter, 1998; see A Tale of Two CPGs: Phylogenetically Polymorphic Networks).

1.05.3.1 In Search of the Brain Archetype in Vertebrates: Developmental Regulatory Genes as Useful Tools for Deciphering the Archetype and Identifying Homologous Fields

As noted above, morphogenetic fields exist in specific locations within the animal or organ/region, and this also applies to the brain. The brain of vertebrates shares a common basic organization plan (or archetype; also called 'Bauplan'; see Basic Nervous System Types: One or Many?, Evolution of the Deuterostome Central Nervous System: An Intercalation of Developmental Patterning Processes with Cellular Specification Processes) where the morphogenetic fields and their derivatives are located. This basic organization plan is better appreciated during development, and developmental regulatory genes, combined with other data such as fate mapping results, are very useful tools for trying to unravel it (Puelles and Rubenstein, 1993, 2003; Puelles and Medina, 2002; see Evolution of the Deuterostome Central Nervous System: An Intercalation of Developmental Patterning Processes with Cellular Specification Processes, Origins of the Chordate Central Nervous System: Insights from Hemichordates). As noted above, these master control genes show highly evolutionarily

conserved sequences, and encode transcription factors or signaling proteins that regulate expression of other genes, thus controlling patterning and morphogenesis of specific body parts (Carroll *et al*., 2001). They also show generally conserved expression patterns in the embryonic brain, and restricted expression domains comparable across species (Smith-Fernandez *et al*., 1998; Puelles *et al*., 2000; Murakami *et al*., 2001; Bachy *et al*., 2002; Brox *et al*., 2003, 2004). These genes help in understanding important organization features of the developing brain, such as its curved longitudinal axis, the existence of longitudinal and transverse (segmental) divisions, and the existence of smaller subdivisions, each one in a specific location within the general plan. Expression of these genes indicates that, during development, the brains of different vertebrates pass through a highly similar stage (a kind of phylotypic stage), in which the embryonic brain shows clearly comparable molecularly distinct divisions and subdivisions, and a common archetype. These divisions and subdivisions represent distinct morphogenetic fields, and each one is characterized by the expression of a specific combination of master control genes. Thus, these genes are very valuable tools for locating these morphogenetic fields within the general brain archetype, and for finding homologous morphogenetic fields in the brain of different vertebrates (Puelles and Medina, 2002). Understanding this is very important for later studying the derivatives of each field in the adult, for searching cases of field homology and cell group homology in the adult, and for understanding how morphological divergence occurs in evolution.

1.05.3.2 Evolution of Homologous Fields in the Brain: The Case of the Pallium

In the brain, homologous morphogenetic fields can give rise to adult homologous structures showing a high degree of evolutionary conservation, such as the striatum (Figure 1; Reiner *et al*., 1998; Marín *et al*., 1998; see The Evolution of the Basal Ganglia in Mammals and Other Vertebrates) or, often, give rise to structures that are homologous as a field in different vertebrates, but that show a high degree of variation between species though keeping a few basic common features (e.g., the neocortex of mammals, the hyperpallium of birds, and the dorsal cortex of reptiles, all of which derive from the dorsal pallium; Medina and Reiner, 2000; see Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?, The Origin of Neocortex: Lessons from Comparative Embryology). Within the pallium, there are striking differences between animal groups. For example, the dorsomedial pallium shows an extraordinary development in mammals (in particular, its dorsal pallial derivative, the neocortex) but, in contrast, the ventrolateral pallium shows the greatest development in reptiles and especially in birds, giving rise to a large structure called dorsal ventricular ridge (Butler, 1994b; Striedter, 1997; see Evolution of the Nervous System in Reptiles, Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?, The Evolution of Vocal Learning Systems in Birds, Evolution of the Amygdala in Vertebrates, The Origin of Neocortex: Lessons from Comparative Embryology). One of the main factors that may be involved in such variations is the possible existence of changes in the networks of developmental regulatory genes that operate in forebrain development (Carroll *et al*., 2001; Gilbert and Burian, 2003). Indeed, numerous developmental regulatory genes play key roles in patterning, specification, cell proliferation, and/or cell differentiation of specific parts in the central nervous system (from the spinal cord to the telencephalon), and changes in their expression (e.g., by knockout mutation producing a lack of function) lead to morphological alterations that include changes in the relative size of regions and lack of formation of particular sets of neurons, among other changes (Ericson *et al*., 1997; Briscoe *et al*., 1999; Sussel *et al*., 1999; Yun *et al*., 2001, 2003 Bishop *et al*., 2002, 2003; Muzio *et al*., 2002). An interesting observation is that the relative size of one particular region (radial histogenetic division) can be affected by both genes expressed in its own primordium during development, or genes expressed in adjacent morphogenetic fields, and it appears that several patterning genes play key opposing roles in establishing the relative size of regions. This occurs in the telencephalon, where the relative size of the pallium is enlarged by knockout mutations affecting homeobox genes expressed in the subpallium (such as *Gsh2*), and is reduced by knockout mutations affecting homeobox genes expressed in the pallium (such as *Pax6*) (Stoykova *et al*., 1996, 2000; Toresson *et al*., 2000; Yun *et al*., 2001). Any alteration in the equilibrium between genes having opposing roles in specifying subpallial versus pallial territories (either by overexpression or by lower expression of one of the two groups) may have led to the very large pallium observed in mammals and birds.

Within the pallium, the opposing roles of *Emx1/2* versus *Pax6* (expressed in opposing gradients in the pallium) can affect the relative size of caudomedial versus rostrolateral pallium and the specific areas in them (Bishop *et al*., 2002, 2003). This, in fact, is affecting the relative size of the medial pallium

(displaced caudally in mammals) and adjacent parts of dorsal pallium versus the rest of the pallium, including the ventrolateral pallium or part of it (i.e., piriform cortex and claustrum; Stoykova *et al*., 1996). In addition, some of the genes involved in internal pallial patterning and specification, such as *Emx1* and *Emx2*, also have a role in cell proliferation, thus affecting growth and size of the pallial areas where they show higher expression (Bishop *et al*., 2003), and the level of expression of these genes can be affected by signaling proteins that diffuse from organizer centers, such the cortical hem located at the edge of the medial pallium (Ragsdale and Grove, 2001; Garda *et al*., 2002). Other developmental regulatory genes (such as the LIM-homeobox genes and several LIM cofactor genes) are expressed in combinatorial patterns in the pallium and other parts of the forebrain, and – as in the spinal cord – may play key roles in the differentiation of specific sets of neurons and in the establishment of specific connections (Rétaux *et al*., 1999; Bulchand *et al*., 2001, 2003; Moreno *et al*., 2004). In addition, one of these genes (*Lhx2*) plays a role in the formation of the dorsomedial pallium and its boundary with the cortical hem, and lack of its function produces severe malformation of the dorsomedial pallium (affecting specially the medial pallium), without affecting any part of the ventrolateral pallium, which expresses the antagonist LIM protein Lmo3 (Bulchand *et al*., 2001; Vyas *et al*., 2003).

This provides an idea of only some of the complex and important networks of regulatory genes operating in pallial development (as in the development of other brain regions). Any alteration in the expression of these regulatory genes within or near the pallium may have led to the differences observed within the pallium between mammals and birds. Further, the pallium has important reciprocal connections with the thalamus, and a recent study indicates that developing thalamocortical axons releases a mitogenic factor that increases cell proliferation of pallial cells, indicating that epigenetic influences from distant regions can also modulate pallial development (Dehay *et al*., 2001). Thus, alterations affecting the number or the pathfinding of thalamocortical axons may influence the final size of cortical areas as well. Nevertheless, this does not affect the initial specification and area formation of the pallium, which is due to intrinsic factors, mediated by locally expressed developmental regulatory genes (Miyashita-Lin *et al*., 1999). Until now, developmental evolutionary neurobiologists have focused on analyzing similarities in expression pattern of a number of these regulatory genes, and this has been extremely valuable for understanding the brain archetype and finding homologous fields. In the future, we will have to center on investigating what differs in brain development of different animals, by searching for differences in expression patterns of some master control genes and by searching changes at the level of promoter/enhancer, activators, repressors, and cofactors regulating the expression of master control genes (Medina *et al*., 2005). This will help us understand what exact developmental mechanisms led to the morphological variations found in the brain of different vertebrates.

1.05.3.3 Evolution of New Fields in the Vertebrate Brain: Analysis of the Lamprey

Although most vertebrates share a basic brain archetype, it appears that early vertebrates (see Evolution of the Deuterostome Central Nervous System: An Intercalation of Developmental Patterning Processes with Cellular Specification Processes) lacked at least some of the whole set of morphogenetic fields found in the forebrain of tetrapods, suggesting that some new fields evolved after vertebrates first appeared (Medina *et al*., 2005). This is based on analysis of the lamprey, a jawless fish close to the origin of vertebrates. During development, the forebrain of these animals show some of the same molecularly distinct divisions found in tetrapods, including comparable diencephalic divisions/subdivisions, and comparable pallial and subpallial divisions in the telencephalon (Murakami *et al*., 2001). In the telencephalon of developing lamprey, the subpallium is characterized by *Dlx* expression, whereas the pallium expresses *Pax6* and *Emx1* genes, showing patterns comparable to those observed in other vertebrates. However, the subpallium does not show any expression of the pallidal marker gene *Nkx2.1*, suggesting that these animals lack the morphogenetic field giving rise to the pallidum (Murakami *et al*., 2001; this gene is also called *TTF-1*), which agrees with the apparent absence of this structure in adult lampreys (Pombal *et al*., 1997a, 1997b). In zebra fish, a teleost jawed fish, the subpallium includes both striatal and pallidal subdivisions, expressing either only *Dlx* or both *Dlx* and *Nkx2.1* orthologue genes (Rohr *et al*., 2001), suggesting that the pallidal subdivision appeared in the telencephalon as a novel morphogenetic field during the transition from jawless to jawed vertebrates (Medina *et al*., 2005). This example indicates that novel morphogenetic fields can evolve by appearance of novel expression domains of developmental regulatory genes (also involving a cascade a

downstream genes), and these novel fields can lead to the production of novel histogenetic divisions and cell groups in the adult. Understanding what exact mechanisms lead to the appearance of novel expression domains of master control genes during development will be essential for understanding evolution of novel structures in the brain.

For homology and evolutionary considerations, another way of looking at this is by analyzing the hierarchy of the fields, and how addition of a new field can affect the rest. The whole embryo is considered to be the primary field, being later subdivided into secondary and then tertiary fields, and so on (Gilbert *et al*., 1996; Carroll *et al*., 2001). If we arbitrarily consider the telencephalic vesicle as a 'primary' field (to simplify counts), then pallium and subpallium are 'secondary' fields (Figure 1). Within the subpallium, the appearance of a *Nkx2.1* expression domain divides it into two 'tertiary' fields (striatal and pallidal). (This is an oversimplification, since – atleast in tetrapods – the *Nkx2.1* expressing domain of the subpallium is further subdivided into at least two fields: a 'true' pallidal field expressing *Nkx2.1* and *Dlx* genes, and an anterior entopeduncular field expressing *Nkx2.1, Dlx* plus sonic hedgehog (Puelles *et al*., 2000; Marin and Rubenstein, 2002).) At a certain point of development, the lamprey subpallium can be considered homologous to that of jawed vertebrates as 'secondary' morphogenetic fields. They give rise to subpallial divisions in the adult that can be considered homologous as a field, but have the following major differences. After subpallial subdivision into 'tertiary' fields, the *Nkx2.1* expressing pallidal field of jawed vertebrates is not homologous to any field in the lamprey. The striatal 'tertiary' field (expressing only *Dlx* genes) of jawed vertebrates remains homologous to the single subpallial field of lamprey, and both give rise to a homologous striatum (Figure 1). Nevertheless, the striatum produced in jawed vertebrates is the result of both similar plus newly evolved interactions of its primordium with other modules, such as the novel *Nkx2.1* expressing field. For this reason, the resultant striatum of jawed vertebrates has some new features with no counterpart in the lamprey striatum. The new features of the striatum can even go further if immigrant cells coming from the newly evolved field arrive in the striatum and integrate establishing connections with native cells, as it occurs with striatal interneurons in amniotes (see above) and in some amphibians (Figure 1). This involves an evolutionary increase in both morphological and functional complexity of the striatum. Thus, novel fields can have consequences that go further than just producing a new histogenetic territory, since they can influence, and trigger, important morphological and functional changes in adjacent and/or distant fields.

1.05.4 Conclusions

The concept of field homology has recently been reformulated under the modern perspective of evolutionary developmental biology (Puelles and Medina, 2002), based on the existence of morphogenetic fields as major units of development and evolution, linking the genotype to the phenotype, which are considered as the natural comparison characters for homology considerations. Morphogenetic fields are self-regulated entities, having specific properties (such as expression of specific combinations of developmental regulatory genes), and specific interactions with other fields, which change dynamically during development. They exist in specific topological locations within the organism and give rise to specific sets or lineages of cells. In the brain, morphogenetic fields are represented by segments, and by divisions and subdivisions within them (different hierarchies). Based on the predominant radial glial-guided migration of neurons during development, the majority of their cellular derivatives stay within single radial histogenetic divisions, which therefore constitute natural comparison units for field homology considerations in the adult brain. However, homology of a specific morphogenetic field in two animals does not necessarily mean complete homology of the cell groups in the derived histogenetic divisions, since some evolutionary divergence may have occurred, involving the appearance of novel, nonhomologous cell groups in one of the animals, or in both (which may be native cells of the same field or immigrant cells from other fields).

1.06 Reelin, Cajal–Retzius Cells, and Cortical Evolution

F Tissir and A M Goffinet, University of Louvain Medical School, Brussels, Belgium

Glossary

CP	Cortical plate.
Dab1	Disabled-1 gene or protein.
DC	Dorsal cortex.
DVR	Dorsal ventricular ridge.
LC	Lateral cortex.
MC	Medial cortex.
Myr	Mega-year.
MZ	Marginal zone.
VZ	Ventricular zone.

1.06.1 Introduction

One of the most fascinating questions in neurobiology concerns the evolution of the cerebral cortex, a sequence of events that leads to the development of the human cortex and its cognitive abilities (see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates). Genes that control development and growth are privileged targets of evolutionary selection (Raff, 1996), and comparative studies of cortical development may shed light on this process (see Cortical Evolution as the Expression of a Program for Disproportionate Growth and the Proliferation of Areas; Captured in the Net of Space and Time: Understanding Cortical Field Evolution). In the absence of fossil material, however, the evolution of cortical development can only be inferred from comparative studies of modern organisms (Butler and Hodos, 1996).

Studies carried out during the last decades demonstrated that basic, conserved developmental mechanisms pattern the brain in general and the telencephalon in particular (Monuki and Walsh, 2001; Grove and Fukuchi-Shimogori, 2003). Secreted factors (such as Shh, Wnts, Bmps, and Fgfs) establish morphogenetic gradients to which precursors in the neuroepithelial sheet respond by modulating expression of arrays of transcription factors (such as Pax6, Emx1/2, and Tbr1), thereby adapting neuronal cell numbers and types. Different neuronal classes migrate following different routes to colonize various structures.

The cortex is reduced to a periventricular layer in anamniotic vertebrates and increases in size and organization in amniotes. It gains prominence in synapsids, the lineage leading to mammals, and evolves explosively in primates. Despite their obvious importance, however, the molecular events that underlie cortical evolution remain mostly unknown. Work in mice identified several genes with a role in cortical development and presumably evolution (Lambert de Rouvroit and Goffinet, 2001; Monuki and Walsh, 2001). Among them, reelin and its signaling partners may be critical players in the evolution of the mammalian laminar cortical plate (CP) (Bar *et al.*, 2000). In addition, in humans, reelin signaling is essential for cortical foliation (Hong *et al.*, 2000). Comparisons of reelin expression in mammals, reptiles, and birds show that reelin-expressing cells are present in the cortical marginal zone (MZ), from the preplate (PP) stage, in all amniotes, but both the number of positive cells and their level of expression are much higher in mammals than in other lineages. In this article, we will briefly review data on comparative reelin expression during cortical development and discuss some questions that we consider of special neurobiological interest because they would be amenable to study, provided more efforts are invested to provide access to genomic sequences and high-quality embryonic material from multiple species.

1.06.2 Reelin Signaling During Cortical Development and Evolution

A schematic cladogram of evolutionary filiations from stem amniotes to modern reptiles, birds, and mammals is provided in Figure 1 (Colbert *et al.*, 2001). In all

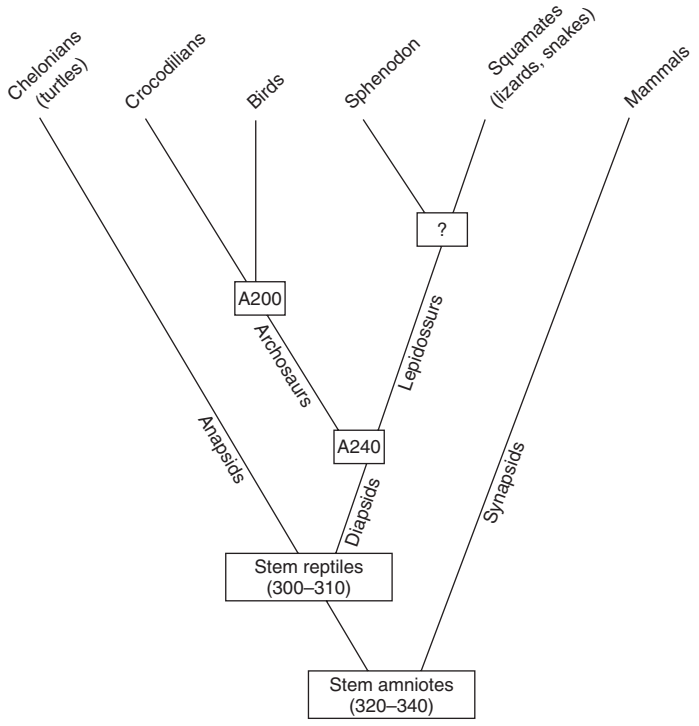

Figure 1 Summary of geological epochs, and simplified evolutionary filiations of amniotes. Numbers refer to estimated time of phyletic divergence (in mega-years (Myrs)). Adapted from Bar, I., Lambert de Rouvroit, C., and Goffinet, A. M. 2000. The evolution of cortical development. An hypothesis based on the role of the reelin signaling pathway. *Trends Neurosci.* 23, 633–638, with permission from Elsevier.

amniotes, telencephalic development follows a basic, evolutionary homologous Bauplan. This basic organization includes a medial, dorsal, and lateral cortex located at the external aspect of the ventricle, and the dorsal ventricular ridge (DVR) located ventral to the ventricle (Figure 2). There is a consensus that the medial cortex is homologous to the mammalian hippocampal formation, whereas the dorsal and lateral cortices are the precursors of the neocortex and the pyriform cortex or rhinencephalon, respectively. Views about the DVR, which is diminutive in mammals, are more controversial (Northcutt, 1981; Butler and Hodos, 1996; Fernandez *et al.*, 1998).

In mammals, cortical development begins with the appearance of the PP (Caviness, 1982; Allendoerfer and Shatz, 1994; Sheppard and Pearlman, 1997; Super *et al.*, 2000), a heterogeneous structure that contains future subplate cells, reelin-negative pioneer neurons and reelin-positive subpial cells destined for the MZ (Meyer *et al.*, 1998, 2000), and probably other cell types. The next stage is the condensation of the CP, densely populated with radial bipolar neurons. The appearance of the CP results in the splitting of the PP, elements of which are displaced in the subplate (Allendoerfer and Shatz, 1994) and in the MZ (Caviness, 1982; Sheppard and Pearlman, 1997). The CP develops from inside to outside, by migration of new neurons that cross previously established layers and settle at progressively more superficial levels. The organization of the CP is controlled by the reelin-signaling pathway (Rice and Curran, 2001; Tissir and Goffinet, 2003). Defective reelin signaling results in a loosely organized CP, with absence of PP splitting, and inverted maturation, from outside to inside (Caviness and Rakic, 1978; Rakic and Caviness, 1995). Normal reelin signaling is necessary but not sufficient for the development of the CP. For example, in mice deficient in cyclin-dependent kinase 5 (Cdk5) or its cofactors p35 and p39 (Ohshima *et al.*, 1996; Chae *et al.*, 1997; Gilmore *et al.*, 1998; Ko *et al.*, 2001), the radial organization of the early CP is preserved, yet its maturation proceeds from outside to inside as in

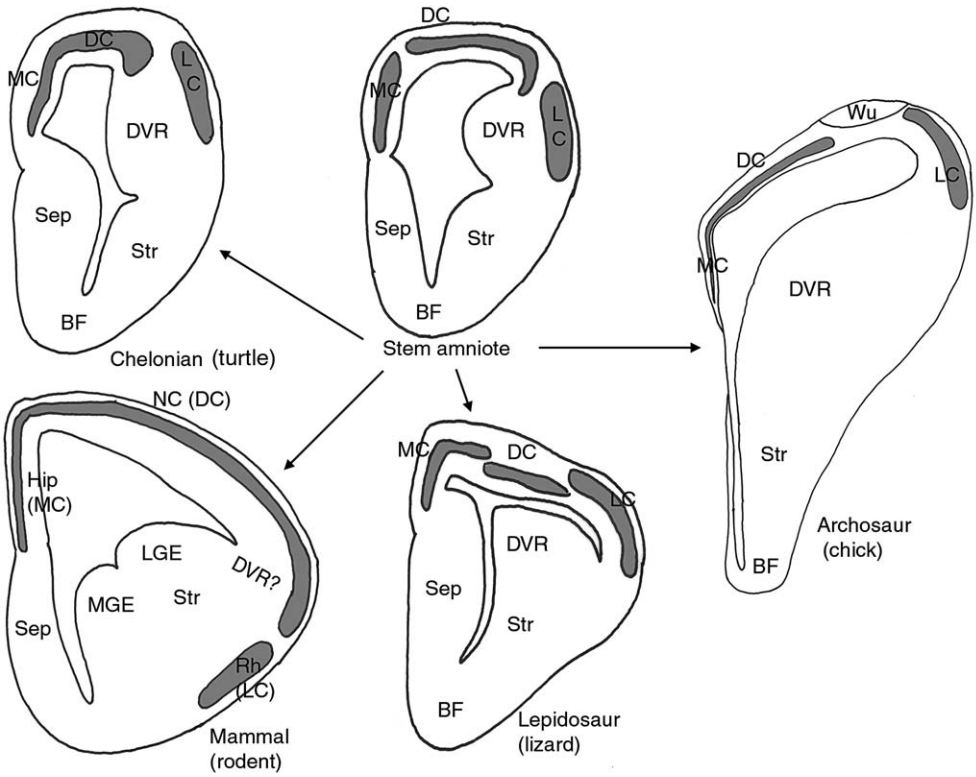

Figure 2 Schematic organization (frontal sections) of the dorsal embryonic telencephalon in putative stem amniotes, chelonians (turtles), squamates (lizards and snakes), archosaurs (birds and crocodiles), and mammals. BF, basal forebrain; DC, dorsal cortex (mammalian NC, neocortex); DVR, dorsal ventricular ridge; LC, lateral cortex (mammalian Rh, rhinencephalon); MC, medial cortex (mammalian Hip, hippocampus); MGE and LGE, medial and lateral ganglionic eminences; Sep, septal nuclei; Str, striatum; Wu, avian Wulst. Reproduced from Bar, I., Lambert de Rouvroit, C., and Goffinet, A. M. 2000. The evolution of cortical development. An hypothesis based on the role of the reelin signaling pathway. *Trends Neurosci.* 23, 633–638, with permission from Elsevier.

reelin-deficient mice. Two reelin-dependent developmental events, CP organization and inside-out maturation, were presumably also important acquisitions during cortical evolution (Bar *et al.*, 2000). Additional factors of cortical evolution include increased neuron generation in the ventricular zone (VZ) and the necessity to migrate over longer distances, requiring a sophisticated migration machinery in which Cdk5, p35/p39, and other genes such as filamin-1, *Lis1*, or doublecortin participate (Lambert de Rouvroit and Goffinet, 2001; Grove and Fukuchi-Shimogoril, 2003).

Reelin is a large extracellular glycoprotein that is secreted by Cajal–Retzius neurons in the MZ (Bar *et al.*, 1995; D'Arcangelo *et al.*, 1995). It binds to two receptors of the lipoprotein receptor family, very low density lipoprotein receptor (VLDR) and apolipoprotein E receptor type 2 (ApoER2) that are expressed at the surface of CP cells (Hiesberger *et al.*, 1999; Trommsdorff *et al.*, 1999). This triggers the activation of an intracellular signal that ultimately directs the architectonic organization of the CP. Upon reelin-receptor binding, the adapter disabled-1 gene or protein (Dab1) is tyrosine phosphorylated by Scr family kinases (Howell *et al.*, 2000), but the rest of the mechanism is still poorly understood (Bock *et al.*, 2003; Pramatarova *et al.*, 2003; Ballif *et al.*, 2004; Jossin *et al.*, 2004).

Reelin and Dab1 expression have been studied in mouse (Rice and Curran, 2001; Tissir and Goffinet, 2003), human (Meyer and Goffinet, 1998; Meyer *et al.*, 2002, 2003), turtle (Bernier *et al.*, 1999), lizard (Goffinet *et al.*, 1999), chick (Bernier *et al.*, 2000), and crocodile (Tissir *et al.*, 2003), allowing comparisons and correlations with architectonic patterns in representatives of the main amniote lineages (Figure 3; Goffinet, 1983). The expression of VLDLR and ApoER2 is supposed to overlap largely that of Dab1, but this remains to be studied. In turtles, which are considered the most closely related to stem amniotes, cortical architectonics is the most rudimentary. Reelin-positive neurons are present in the MZ of the medial and dorsal cortical fields. In addition, some less strongly labeled neurons are dispersed in the CP. The situation in the lateral cortex is different, with reelin-positive neurons scattered diffusely in the cortex (Bernier *et al.*, 1999). Dab1 is expressed in CP cells in all sectors

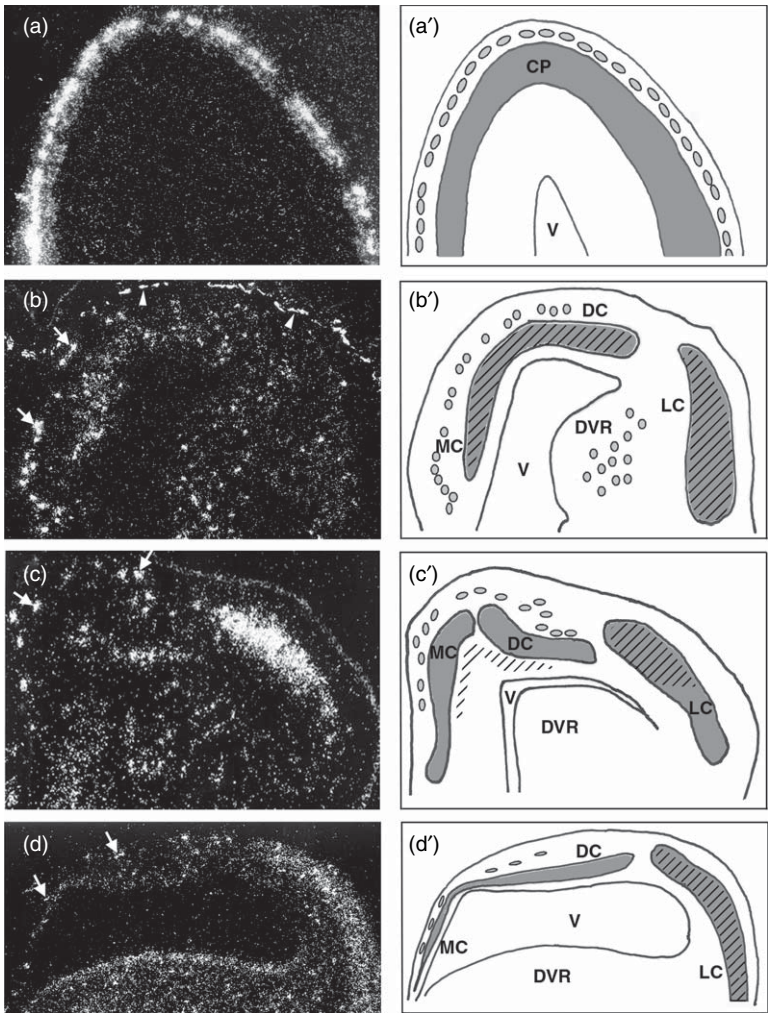

Figure 3 Comparison of reelin mRNA expression. Frontal sections in the embryonic cortex of the mouse (a, a′), turtle (b, b′), lizard (c, c′) and chick (d, d′). Expression patterns of reelin mRNA are shown in darkfield views (a–d). Schematic drawings (a′–d′) show reelin-positive zones (circles for cells in marginal zone, and hatched areas for more diffuse expression in cortical plate or subcortex). CP, cortical plate; DC, dorsal cortex; DVR, dorsal ventricular ridge; LC, lateral cortex; MC, medial cortex; V, ventricle.

a, a′, The mouse cortex is characterized by an almost continuous subpial layer of neurons that express extremely high levels of reelin. The underlying CP is reelin-negative but expresses Dab1. Detailed descriptions are provided in Alcantara *et al.* (1998) and Schiffmann *et al.* (1997).

b, b′, In the turtle cortex, reelin-positive cells (arrows) are dispersed in the marginal zones of the MC and DC, and to a lesser extent in the lateral cortex and DVR. The cortical plate in MC and DC is weakly reelin-positive and Dab1-positive. Arrowheads point to spontaneously darkfield-positive melanophores. Detailed description in Bernier *et al.* (1999).

c, c′, In the lizard MC and DC, reelin-positive neurons (arrows) are abundant in the marginal zone, and there is a second layer of reelin expression in the subplate (hatched area in c′), whereas the cortical plate is reelin-negative but Dab1-positive. The LC is diffusely Dab1-positive, and its dorsal component expresses reelin (hatched in c′). Detailed description in Goffinet *et al.* (1999).

d, d′, In the chick, subpial reelin-positive cells (arrows) are found only in the diminutive MC (hippocampus) and DC (parahippocampus), and the cortical plate is negative. There is diffuse reelin expression in the LC. Detailed description in Bernier *et al.* (2000).

(Goffinet, unpublished). In chicks (Bernier *et al.*, 2000), a CP is evident only in the medial cortex and in the adjacent, dorsal parahippocampal cortex. At this level, a few strongly reelin-positive neurons are found in the MZ, but not in the CP itself. A similar canvas of reelin-positive cells in the MZ and reelin-negative CP is found in crocodiles (Tissir *et al.*, 2003). Dab1 expression has not been studied in the chick and crocodilian telencephalon.

In lizards (squamates), an elaborate architectonic organization of the medial and dorsal cortices develops in parallel with a specific, bilaminar expression of reelin, bracketing a reelin-negative and Dab1-positive CP (Goffinet *et al.*, 1999). Large reelin-positive neurons are present in the MZ, as in other species. Unlike in other amniotes, a second layer of reelin-positive cells is found in the subcortex. As in turtles, the lateral cortex expresses both reelin and

Dab1. In turtles, lizards, and chicks, maturation of the CP proceeds from outside to inside (as in reelin-deficient mammals; Tsai *et al.*, 1981; Goffinet *et al.*, 1986). Mammals (synapsids) are characterized by a spectacular development of the CP both in terms of cell numbers and architectonic organization, and by its maturation from inside to outside (Caviness and Rakic, 1978; Rakic and Caviness, 1995). This is accompanied by an amplification of reelin production in Cajal–Retzius cells (CRc) – as estimated using *in situ* hybridization with species-specific probes and monoclonal antibodies with conserved epitopes – and anomalies in reelin-deficient mice indicate that this modification of reelin expression was necessary for the evolution of the mammalian cortex.

Although several pieces of the puzzle are lacking, such as the expression of lipoprotein receptors and the analysis of more species, these data clearly suggest that the production of reelin by early neurons in the MZ and the expression of Dab1 (and reelin receptors) by CP neurons is a feature of all amniotes. This pattern, presumably present in stem amniotes, is evolutionarily homologous. From this ancestral pattern, the expression profiles have evolved differently in divergent lineages; similar elaborate CP organizations in mammals and in some cortical areas in lizards were probably acquired by convergent evolution. In addition to the control of neuronal numbers and differentiation, and of hodological relationships, the modulation of architectonic organization is an important, hitherto neglected, parameter of cortical evolution, in which the reelin-signaling pathway plays an important role.

1.06.3 The Puzzle of Cajal–Retzius Cells

CRc are complex neuronal cells that develop early in the mammalian cortical MZ and undergo apoptotic degeneration near the end of cortical neuronal migration (Del Rio *et al.*, 1996; Mienville, 1999; Frotscher *et al.*, 2001; Grove and Fukuchi-Shimogori, 2003). They have multiple origins in telencephalic VZs and migrate in the PP by following several routes, particularly by tangential migration (Meyer and Wahle, 1999; Meyer *et al.*, 2002; Takiguchi-Hayashi *et al.*, 2004). In spite of heterogeneity of origin and migration pathways, mammalian CRc are uniquely characterized by a co-expression of reelin and the transcription factor p73, a member of the p53 family (Kaghad *et al.*, 1997; Yang *et al.*, 2000; Meyer *et al.*, 2002) that may regulate their apoptosis.

As mentioned above, reelin-positive neurons are present in the early MZ in all amniotes, indicating, as a parsimonious hypothesis, that these cells may all be evolutionary-related and could have evolved from an ancestral CRc present in stem amniotes. On the other hand, the neuronal population of the embryonic MZ is more complex than previously thought (Meyer *et al.*, 1998; Fairen *et al.*, 2002), suggesting that the evolutionary history of CRc may be more intricate than such a simple evolutionary homology. Recently, co-expression of reelin and p73 was shown to be a defining feature of embryonic CRc in humans and rodents (Yang *et al.*, 2000; Meyer *et al.*, 2002). In order to assess whether CRc are indeed evolutionarily homologous, we studied reelin and p73 mRNA expression using double *in situ* hybridization with species-specific probes in the embryonic cortex of mice, turtles, lizards, crocodilians, and chicks.

As illustrated in Figure 4, early-born neurons in the embryonic cortical MZ in turtles and crocodiles co-express reelin and p73, as they do in mammals. The two probes label the same cells and single positive cells are rare. In turtles, the reelin-positive cells scattered in the CP are p73-negative. In crocodiles, the stream of reelin mRNA-expressing cells in the intermediate zone (Tissir *et al.*, 2003) does not express p73 and thereby differs from MZ cells. Rather surprisingly, in chicks, despite the close similarity in terms of brain organization and evolutionary relationships with crocodiles, reelin and p73 are rarely co-expressed in MZ neurons. Similarly, in lizards, very few among the abundant reelin-positive MZ neurons are labeled with the p73 probes. There are several possible explanations to these findings, such as trivial problems in cloning and using p73 mRNA probes. p73 mRNA sequences are closely related to p53 and even more so to p63, and proved particularly difficult to clone in lizards. But, even with that restriction, the results at least show that expression of p73 is very low in chick and lizard and/or that reelin and p73 co-expression is rare in those species. The *p73* gene is thought to regulate apoptosis and this regulation may be less important in reelin-positive subpial cells in chicks and lizards than in other species. If this is true, the co-expression of p73 and reelin may not be the best criterion to assess putative evolutionary homologies. Reelin-positive neurons are present in the developing brain of the lamprey (Perez-Costas *et al.*, 2002), zebra fish, and *Xenopus* (Costagli *et al.*, 2002), and the *p73* gene was identified in zebra fish (Pan *et al.*, 2003; Rentzsch *et al.*, 2003). With the discovery of new molecular markers and the definition of more genomic sequences, tools should become available in the coming years to unravel the complex evolutionary history of MZ neurons.

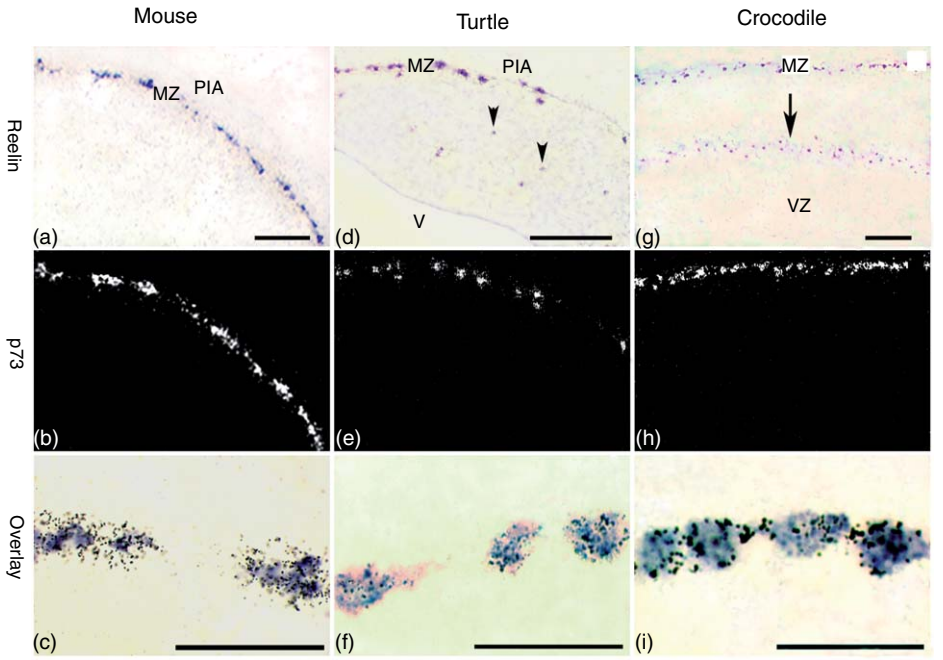

Figure 4 Co-localization of reelin and p73 mRNA in CRc. Double *in situ* hybridization studies of reelin mRNA (digoxigenin-labeled probes, first row), p73 mRNA ([^{33}P]-labeled probes, second row), and their co-localization (overlay, third row) in the embryonic cerebral cortex of the mouse (a–c), turtle (d–f), and crocodile (g–i). Almost all subpial reelin-positive neurons express p73 in all three species. In contrast, the reelin-positive cells in the turtle cortical plate (d, arrowheads) and in the crocodilian subcortex (g, arrow) are p73-negative. Note that the reelin signal illustrated in the mouse was underexposed for histological analysis and is relatively much higher than in other species. PIA, pial surface; MZ, marginal zone; V, lateral ventricle; VZ, ventricular zone. Scale bar: 100 μm (a, d, g); 50 μm (c, d, f).

1.06.4 Redundant Expression of Reelin in Mice: What Could It Teach Us about Evolution?

The reelin expression studies summarized above clearly demonstrate a drastic amplification of the mRNA and protein levels in mammalian CRc as compared to other reelin-positive neurons in the reptilian and avian MZ. It is tempting to assume that high levels of reelin are required during cortical spreading, and indeed a sustained supply of reelin-positive cells is observed in the human MZ throughout fetal development (Meyer and Goffinet, 1998). On the other hand, there is ample evidence that the concentration of reelin in the mouse cortical MZ is in large excess. The reeler (reelin-deficient) mutant phenotype only appears in brains of chimeric mice when reeler cells greatly outnumber normal cells (Mikoshiba *et al.*, 1986; Terashima *et al.*, 1986; Mullen *et al.*, 1997; Yoshiki and Kusakabe, 1998). In spite of a loss of CRc and a drastic decrease of reelin concentration, homozygous p73 mutant mice do not have a reeler-like cortex (Yang *et al.*, 2000). A normal CP develops *in vitro* in serum-free culture medium without the addition of exogenous reelin, and addition of reelin to reeler slice *in vitro* (Jossin *et al.*, 2004), or ectopic expression of low levels of reelin in the VZ in transgenic reeler mice malformation (Magdaleno *et al.*, 2002), are able to partially correct the reeler trait. These observations suggest that reelin may diffuse from sources other than CRc and that the expression of receptors and Dab1 may be more important than the site of ligand production.

Why did mammalian CRc amplify a production that appears so redundant in mice? As a way of explaining this apparent contradiction, we would like to suggest the following scenario. Amplification of reelin synthesis in CRc was necessary for the development of a foliated cortex, and stem mammals initially developed a moderately folded, not a lissencephalic, cortex. During evolution, some cortices, such as that of rodents, evolved secondarily into a lissencephalic type. Not being detrimental, elevated reelin production in CRc was not necessarily adjusted in parallel with the reduction of cortical surface. Other lineages, most notably primates, acquired increasingly more foliated cortex and, in humans, additional numbers of reelin-expressing cells became necessary. This idea is compatible with observations that cortical foliation can vary widely within closely related

lineages. For example, in monotremes, Echidna has an elaborate, highly foliated cortex, whereas Platypus is almost lissencephalic (Rowe, 1990). Similar examples can be found in other phyla, including primates. Production of a gyrated mouse cortex is artificially accomplished by elegant, yet relatively simple, manipulations (Rakic, 2004), such as germline inactivation of caspases 3 and 9 (Kuida *et al.*, 1996, 1998), increased expression of beta-catenin in transgenic mice (Chenn and Walsh, 2002, 2003), or incubation of embryonic cortex *in vitro* in the presence of lysophosphatidic acid (Kingsbury *et al.*, 2003; Price, 2004). When such an increase in foliated cortex is observed, the cortical ribbon is nearly normal and, unlike the reeler cortex, shows that the production of reelin is largely sufficient. These observations indicate that the production of a gyrated cortex does not require extensive genetic modifications and could have evolved in any phylum, for example, by acquisition of more precursors of radial units in VZs.

As no living species are closely related to stem mammals, the hypothesis proposed above will always remain somewhat speculative. However, it predicts that, in a given lineage, the density of reelin-positive cells (per cortical surface area) should be higher in the embryonic brain of representatives with a smooth cortex than in those with a gyrated cortex. The mean density of reelin-positive cells, averaged over large areas, including gyral crowns and sulci, could be compared in embryonic cortices of rodents versus animals that are thought to have evolved little, but have some cortical gyration, such as hedgehogs or spiny anteaters. Potentially the best possible test would be to compare the density of CRc in the embryonic MZ of Echidna and Platypus.

All components of the reelin and other signaling cascades were probably present in stem amniotes, available as basic building blocks for cortical evolution. Why then did significant cortical foliation occur only in mammals? Foliation correlates nicely with cortical volume and may be required to increase it beyond some threshold, but how is it achieved? Surely the amplification of reelin production in MZ cells was not the sole limiting factor, as the examples above indicate, nor was the necessary increase in the number of radial cortical units. We would propose that increased reelin synthesis and the development of an enlarged number of precursors and radial cortical units were not hard to achieve, but that the resulting increase in cortical surface did not occur widely because it was difficult to master for some unknown reason. One difficulty could be the coordinate growth of mesodermal components, such as blood vessels and the cranial envelope that must accompany brain growth. Another problem that had to be solved in order to evolve a laminarly organized and tangentially widespread cortex is that of increased neuronal excitability and susceptibility to seizures. A consequence of the highly geometrical arrangement of radial cortical columns is that it facilitates modification of the membrane potential by field effects (ephaptic interactions), largely believed to be involved in the oscillations of electrocortical rhythms such as the alpha or theta rhythms. This quasicrystalline arrangement presumably has advantages in terms of computational power, but also comes at a price, as ephaptic excitation facilitates the tangential spreading of activity and decreases the threshold for aberrant epileptic discharges (McCormick and Contreras, 2001).

1.06.5 Conclusions

Despite the huge complexity of the question, our understanding of cortical evolution has progressed recently in parallel with our understanding of developmental mechanisms. Further advances can be made by careful comparative analyses of cortical development in different species, using simple techniques such as comparative genomics, immunohistochemistry, and *in situ* hybridization. Two conditions are requisite to make this possible, however. First, genomic sequences should be available for monotremes and at least one member of other amniote lineages (chelonians, crocodilians, sphenodon, squamates). Second, a significant multi-national effort should aim at providing access to high-quality embryonic material from representatives of these lineages.

1.07 Evolutionary Neuroethology – A Case Study: Origins and Evolution of Novel Forms of Locomotion in Hippid Sand Crabs (Malacostraca, Decapoda, Anomala)

D H Paul, University of Victoria, Victoria, BC, Canada

Glossary

A6	Abdominal ganglion 6 (fusion of at least four embryonic neuromeres); innervates the sixth abdominal segment and tailfan.
arthrodial membrane	Tough flexible cuticle occurring between skeletal elements that allows relative movement.
AT	Anterior telson muscle; an ancestral, malacostracan muscle absent in Anomala.
ATU muscle backfilling	Anterior telson–uropod muscle. Technique of staining individual neurons from their cut axons, revealing their entire structure.
electromyograms (EMGs)	Recording of the electrical activity of a muscle by placing extracellular electrodes on or in the muscle.
extensor muscles	Muscles used to straighten the abdomen after bending; straighten out limb.
flexor muscles	Muscles that decrease the angle between two segments of the body or a limb, e.g., to bend the abdomen as during a tailflip; draw a limb toward the body.
interneuron	Neuron that is neither purely sensory nor motor.
LG	Lateral giant interneurons; bilaterally paired chain of command neurons (one pair/segmental ganglion) for one form of tailflip.
LTU muscle	Lateral telson–uropod muscle.
MG	Medial giant interneurons; bilateral pair of command neurons for one form of tailflip.
MoG	Motor giant, a particularly large and specialized fast flexor motoneuron.
muscle pioneer	Mesodermal muscle founder cell hat establishes attachment points, therefore, axis of mature muscle.

neuroethology	The study of the neurobiological basis of unrestrained behavior, as performed in natural habitat.
neuromere	Subdivision in developing CNS; in arthropods, generally one neuromere/segment.
nongiant tailflipping	Repetitive tailflips produced by nongiant circuitry (not involving LG or MG).
NSR	Nonspiking stretch receptor neuron(s); transmit(s) afferent signal as graded depolarization.
propodite	Proximal segment of uropod that is attached to the sixth segment.
PS	Uropod power-stroke muscle, in Hippidae; homologue of PTU muscle in other species.
PTF muscle	Posterior telson flexor muscle; converted to uropod power stroke synergist (insertion moved to uropod) in hippid crabs.
PTU	Posterior telson–uropod muscle.
RS	Uropod return-stroke muscle; new muscle in telson of sand crabs (Albuneidae, Hippidae).
tailfan	Three-component structure (telson flanked by uropods) at posterior end of malacostracan body.
tailflip	Rapid, ventral flexion of abdomen; generates propulsive force for escape or backward swimming.
telson	Terminal appendix posterior to the sixth (terminal) abdominal segment, caudomedian element of tailfan; not a true segment.
telson–uropod muscle	The only ancestral musculature directly linking the telson and uropod propodite.
TUSR	Telson–uropod stretch receptor.
uropod	Paired appendages of sixth abdominal segment; form tailfan together with the median telson.
VTF	Ventral telson flexor muscle.

1.07.1 Background and Introduction

1.07.1.1 Why Evolutionary Neuroethology?

The question of how nervous systems and behavior evolve is a core issue in both neurobiology and evolutionary biology. How can something as extraordinarily complex as the neuronal networks underlying behavior (neurobehavioral networks) tolerate change without compromising function? The nervous systems, including the brains, of species within large taxonomic groups look remarkably similar while often producing strikingly different behaviors. Biologists, at least since Darwin, have puzzled over this conundrum of conserving neural architecture yet diversifying behavior during evolution. Current research using molecular techniques to analyze the development of nervous systems has made remarkable progress in exposing how the conserved genetic tool kit allows the generation of novel features. But are the principles derived from comparative genetic-developmental analyses sufficient to explain how behavior evolves under natural selection? "It is one thing to know the laws of Nature, and quite another to know the outcomes of those laws" (Barrow, 1998, p. 66). Evolutionary neuroethologists ask the question: How do nervous systems really evolve? In this article, I reconstruct the pedigrees of the two unusual and surprising modes of locomotion displayed by all species in one decapod crustacean family. Some aspects of the gross anatomy of these animals have diverged so much from the corresponding parts in their close relatives that at first glance they appear unrelated. Why is it important to find out how individual nervous systems have evolved? An ultimate goal of basic neuroscience research is to understand the rationale for the functional organization of neural circuits, including those in the brain. These extraordinarily complex and species-specific networks are not what an engineer would design to execute the appropriately adaptive movements or to register only relevant physical characteristics of each species' environment because they are compromises between inheritance and natural selection. Thus, neither the nervous system nor the behavior of any species is fully understandable without knowing both the neural mechanisms producing its behaviors in its natural environment (neuroethology) and the ancestry of the neurobehavioral circuitry. Motor mechanisms are fundamental to all aspects of behavior, because movements present sensory structures to changing conditions, which leads to active as well as passive sensation. Furthermore, mutations are likely to be more serious (detrimental to survival) in motor control networks, particularly for locomotion, than in sensory systems, because sensory modalities are generally used in parallel to acquire information about the outside world. From this, it is expected that neural evolution would be more conservative in motor control than in sensory systems and, therefore, result in greater conservation of ancestral organization in motor than in sensory centers in the central nervous system of any group of animals (see Relevance of Understanding Brain Evolution, A Tale of Two CPGs: Phylogenetically Polymorphic Networks).

1.07.1.1.1 Prerequisites for tracing the evolutionary history of neurobehavioral circuitry To reconstruct the evolution of a species' functional neural networks requires that four criteria be met:

1. adequately known phylogeny to allow neural differences among species to be mapped in the sequence of their appearance during speciation;
2. experimentally accessible nervous systems (presence of individually identifiable neurons in species exhibiting distinctively different behaviors that are amenable to detailed analysis by kinematic and physiological methods);
3. surrogates for ancestral systems of interest in modern species; and
4. insight into the selective forces that shaped the evolutionary changes in the nervous system under study.

1.07.1.1.2 Hippid sand crabs satisfy the prerequisites for evolutionary neurobehavioral analysis Hippid sand crabs meet the criteria outlined above. Although there are controversies about some relationships within the Decapoda, they are peripheral to the discussion of the lineage of sand crabs. Sand crabs and their close relatives are amenable to investigation by the full spectrum of experimental, anatomical, and physiological techniques (Paul, 1991, 2003). Their one drawback as subjects for evolutionary neurobiological research is the extended time of their embryonic and larval development (Johnson and Lewis, 1942; Harvey, 1993), which severely limits their potential as subjects in genetic and developmental analyses. On the other hand, a fortuitous fact in the history of neuroscience is that crayfish have long been favorite experimental subjects (Huxley, 1880; Edwards *et al.*, 1999) and have retained key traits not only of ancestral decapod skeletomusculature, but also neuroanatomical and behavioral traits that can be traced back to the earliest Malacostraca (Figures 1c and 2; Sections 1.07.4 and 1.07.5). The motor systems in crayfish are thus suitable surrogates for the ancestral motor systems from which sand crab neurobehavioral networks would have evolved.

1.07.1.2 Neurobehavioral Evolution

Novelties in evolution – such as invasion of new niches or evolution of new locomotor behaviors (which may or may not appear conjointly with the former) – are often associated with loss, reduction, or alteration of ancestral structures rather than evolution of new structures. Structural changes in a neural network, i.e., additions or deletions of neurons and changes in synaptic wiring, correlated with behavioral evolution are difficult to identify. Evolutionary losses of identified neurons have been documented in taxa whose behaviors clearly differ from those of their ancestors (Wilson and Paul, 1987; Antonsen and Paul, 2001; Paul, 2003; Faulkes, 2004), but whether they caused, resulted from, or were incidental to the behavioral change in the lineages in question is not easily recognized. The appearance of new types of neurons in a neurobehavioral network is, on the other hand, likely to be directly linked to behavioral evolution and, when identified, offers unique opportunities to question how nervous systems evolve. The rarity of examples of new neurons may reflect the fact that they are recognizable only by their absence from the homologous (similar to presumed antecedent) neurobehavioral circuit, i.e., appropriate comparative data must be available. The larger the nervous system, the more difficult it is to identify unique, functional contributions of particular neurons in individual species, let alone in related species with divergent behavior, and success in this regard has been greatest in the analysis of neurobehavioral networks in arthropods and mollusks (Katz and Harris-Warrick, 1999; Katz *et al.*, 2001).

1.07.1.3 The Basic Plan of the Decapod Central Nervous System

The basic plan of the decapod body and central nervous system was established with the appearance of Malacostraca in the Paleozoic. Of particular interest here is the architecture of the last, sixth, abdominal ganglion (A6), because it innervates the tailfan, a defining character of the class Malacostraca (Hessler, 1983). This ganglion is more complex than the anterior segmental ganglia, because it is evolutionarily and ontogenetically the fusion of as many as four neuromeres (Dumont and Wine, 1987; Scholtz, 1995; Harzsch, 2003). Nevertheless, homologous elements in A6 of different species, as well as in A6 and ganglia of anterior segments, can be inferred by their positions relative to recognizable landmarks (Dumont and Wine, 1987; Strausfeld, 1998; Harzsch and Waloszek, 2000; Mulloney *et al.*, 2003). Condensation of neural centers has been a recurrent theme in the evolution of both invertebrates and vertebrates (see Aggression in Invertebrates: The Emergence and Nature of Agonistic Behavioral Patterns). Because the complexity of the malacostracan A6 is intermediate between that of single neuromeres and that of the larger subesophageal ganglion or the brain, it is potentially informative for comparative research into the ways neural architecture is affected by condensation of neural centers as their functions adapt during morphological and

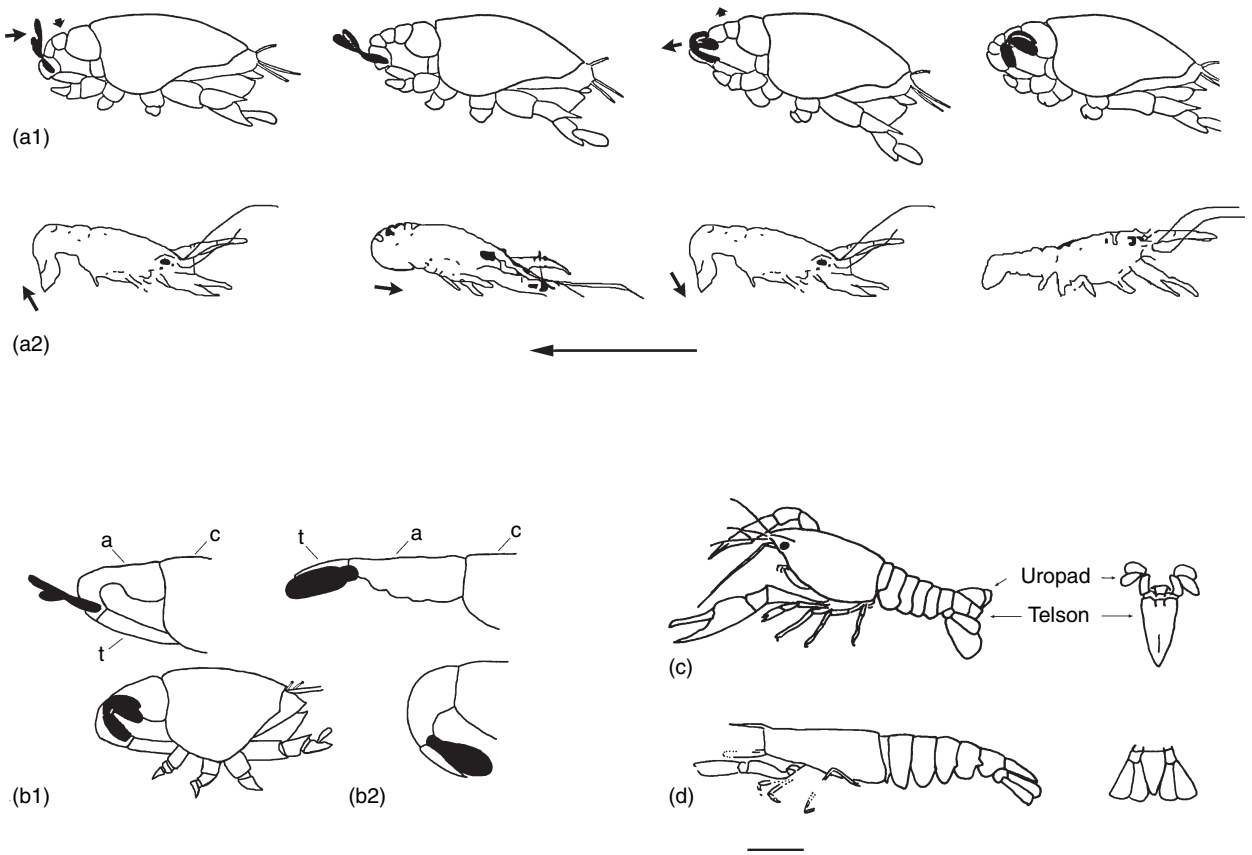

Figure 1 Comparison of swimming with the uropods and tailflipping. Direction of movement shown by long arrow. Tracings of single movie frames of (a1) a hippid crab, *Emerita analoga*, swimming by beating the uropods while keeping the telson flexed under the body and (a2) a tailflipping crayfish. Frames are selected to show form of movements and are not consecutive. Starting from rest position (right frame), hippids extend the uropods rearward (middle two frames) during the return stroke, then rapidly sweep them forward during the power stroke (left frame). When swimming hard (high frequency, large-amplitude uropod strokes), a slight extension of the anterior abdominal segments accompanies the return stroke and is reversed during the power stroke (short arrows over abdomen). Tailflip swimming (a2) begins with an extension of the abdomen (right frame; always evident in electromyograms, although its amplitude depends on the starting posture of the abdomen) prior to the powerful ventral flexion (the power stroke) of the abdomen, which carries the tailfan with it; followed by re-extension (left frame). b, The near immobility of the abdomen and telson during the large ark of the uropod stroke in hippids (b1) contrasts with the large excursion of the abdominal segments (extension–flexion) in crayfish (b2). In both behaviors, the blades of the uropod flare open just prior to the onset of the power stroke and increase surface area and hence thrust is generated. c, The uropods of sand crabs flank the abdomen (right, dorsal view of telson and uropods of *E. analoga*) rather than the telson as in crayfish, left. d, The external form, particularly of the abdomen and tailfan, of this decapod fossil from the Devonian resembles that of crayfish and other long-bodied, extant decapods. Scale bar (in d): a1, ~1 cm; a2, 3–4 cm; d, 1 cm. a1, Adapted from Paul, D. H. 1971. Swimming behaviour of the sand crab, *Emerita analoga* (Crustacea, Anomura). I: Analysis of the uropod stroke. *Z. Vergl. Physiol.* 75, 233–258. a2, Adapted from Krasne, F. B. and Wine, J. J. 1987. Evasion responses of the crayfish. In: Aims and Methods in Neuroethology (*ed.* D. M. Guthrie), pp. 10–45. behavioral evolution (Paul and Macmillan, 1997; Strausfeld, 1998; Loesel *et al.*, 2002; Mulloney *et al.*, 2003).

1.07.2 Locomotion in Hippid Sand Crabs

Comparing motor patterns, muscles, and neurons in members of selected decapods has revealed that the evolution of sand crabs' novel behaviors occurred in stages and involved deleting from, adding to, and messing around with ancient neurobehavioral circuitry. Loss of certain highly specialized neurons appears to have removed constraints against modifying neuromusculature and behavior and precipitated the evolution of the Anomala by allowing body form and locomotion to change (see Section 1.07.3).

1.07.2.1 The New and Ancestral Modes of Swimming

The swimming and digging behaviors of sand crabs differ between the two families (Hippidae and Albuneidae), and both forms of locomotion are

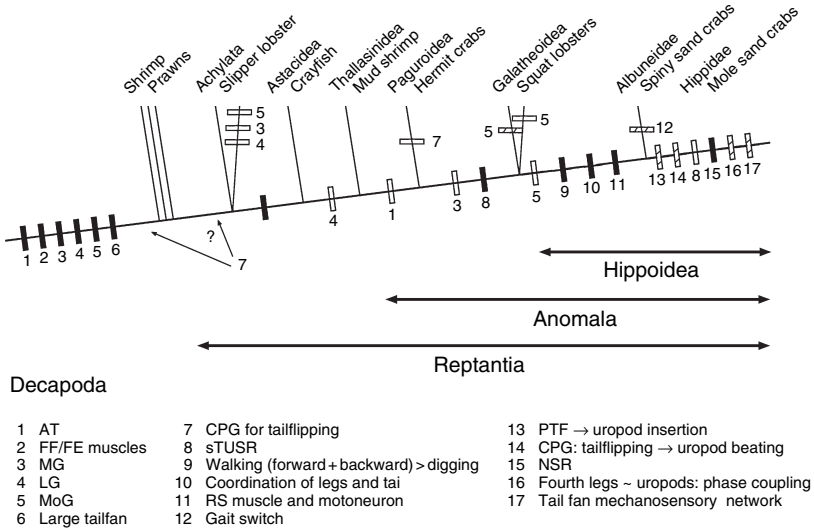

Figure 2 Neurobehavioral traits discussed in this article mapped on a partial phylogeny of decapod crustaceans; most prominent exclusion are the Brachyura, true crabs (based primarily on Scholtz and Richter, 1995; see also Martin and Davis, 2001). The organization of the tailfan musculature is the same in shrimp and prawns and members of the first three divisions of the Reptantia (except unknown for slipper lobster), but has been modified in different ways within the Anomala (also referred to as Anomura, which originally included the Thallasinidea). Character 7 (the existence of a central pattern generator (CPG) for tailflipping = nongiant tailflipping) has been demonstrated only in crayfish (Reichert *et al.*, 1981), but is generally assumed to be present in other Astacidea, all Achylata, and shrimp and prawns, and perhaps Thallasinidea. Since slipper lobsters tailflip without the giant interneurons (3, 4), either 7 appeared prior to the Achylata (and perhaps is a decapod synapomorphy) or nongiant tailflipping evolved independently in slipper lobsters. Data from Paul *et al.* (1985), Wilson and Paul (1987); Faulkes and Paul (1997a, 1997b, 1998); Paul (1981a, 1981b, 2004), Paul and Wilson (1994), and Faulkes (2004).

unlike those of any other crustaceans. Most remarkable is hippid crabs' use of the uropods to rapidly propel themselves backward (Figures 1 and 3). These animals keep their abdomen and elongate telson flexed beneath the body at all times and rapidly beat their relatively long uropods through a large arc to swim and, in conjunction with the legs, to dig into sand (Paul *et al.*, 2002). The large-amplitude movements of the uropods, independent of the abdomen and telson, contrast with the tight coupling of the uropods with axial (abdomen–telson) movements in crayfish and other species with tailfans, including albuneid sand crabs (Figure 1b).

1.07.2.2 The Hypothesis

Swimming by uropod beating almost certainly evolved from swimming by repetitive tailflipping (Paul, 1991). Three partially separate neural mechanisms are known to mediate the tailflip behaviors of crayfish. Two involve paired giant interneurons (the medial giants, MGs, and lateral giants, LGs), which mediate different forms of powerful ventral flexions of the abdomen and tailfan. The third, known as nongiant tailflipping because neither MG nor LG are involved, mediates repetitive extensions and flexions of the abdomen for rapid backward swimming (Reichert *et al.*, 1981). The giant interneurons were lost sequentially in the lineage leading to sand crabs (Figure 2), and it was the nongiant circuitry for tailflipping from which hippids' mode of swimming with the uropods is thought to have evolved. The digging behaviors of sand crabs are also unique and not identical in the two families (Hippidae and Albuneidae). They are summarized in the next section.

1.07.2.3 Digging Preceded Uropod Beating: The Mosaic Ancestry of Sand Crab Digging Behaviors

Three pairs of legs (legs 2–4, innervated by thoracic neuromeres 5–7) that other decapods use for walking have been so modified in sand crabs that they are unable to walk across the surface (Faulkes and Paul, 1997a, 1997b, 1998; Paul *et al.*, 2002). Analyses of electromyograms (muscle activity) in individual muscles for each leg joint while sand crabs were digging provided descriptions of the temporal patterns of the motor output to each leg, as well as the coordination between limbs of different body segments. From this, it became apparent that digging is a mosaic of disparate behaviors that are mutually incompatible in sand crabs' walking relatives: walking forward, walking backward, and tailflipping (Figure 4; Paul *et al.*, 2002). The fundamental similarities between the ways all sand crabs dig indicate that digging evolved in their common ancestor and later diverged in certain details following separation

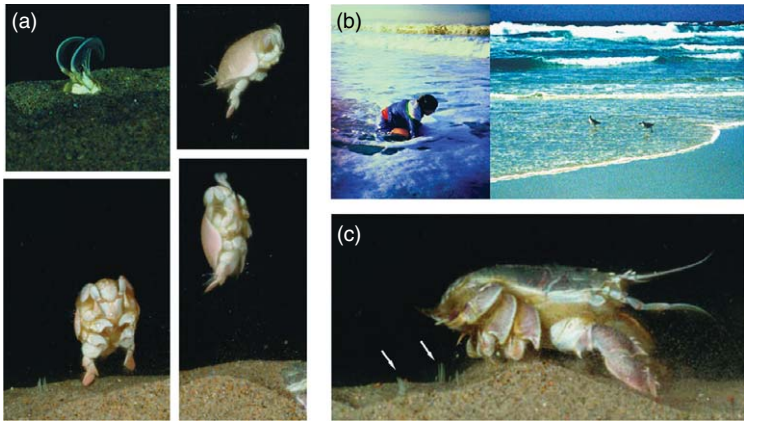

Figure 3 Sand crabs at home in aquariums and their natural habitat. a, Mole sand crabs (Hippidae; shown here *Emerita analoga*) filter-feed by extending their long, plumose second antennas above the sand (top left). The other three panels show an individual emerging from sand (bottom left), swimming (top right), and treading water, i.e., beating the uropods to keep itself suspended, but not moving relative to the substrate. To stay positioned at the appropriate level for feeding during the downwash from breaking waves, which shifts with the tide, hippid crabs emerge from the sand periodically to swim with the current (up or down the beach, depending on the direction of the tide), and rapidly dig in again before being carried too far up or down the beach. b, Hippid behaviors are superbly adapted for an active life in the turbulent physical environment of intertidal sandy beaches (Dugan *et al.*, 2000), which makes them easy to collect by hand when they are close to the sand's surface (left; see (a)); shore birds are major predators of hippid crabs (right). c, A spiny sand crab, *Blepharipoda occidentalis* (Albuneidae) moving across two *E. analoga* buried just beneath the surface with their first antennas protruding (white arrows). Carapace length of *E. analoga* = 2.0–2.5 cm and of *B. occidentalis* ~7 cm.

of Albuneidae and Hippidae (Faulkes and Paul, 1997b). The members of these families live in dissimilar niches and require different locomotor capabilities. Albuneids are subtidal and intertidal scavengers that remain buried beneath the surface and are weak swimmers. Hippids, in contrast, are intertidal filter feeders that must maintain themselves in the swash zone as the tide shifts, and to do so emerge periodically from the sand to swim up or down the beach before digging in again to feed (see Figure 3a). Their prowess in both digging through sand and swimming or treading water (Section 1.07.5.2.2) is the *sine qua non* of their existence. The abilities of hippids to disengage leg (digging) movements during swimming and to couple rhythmic movements of the digging legs with the uropods during digging presumably evolved conjointly with their peculiar mode of swimming with the uropods. Furthermore, the phase separation between their fourth legs and uropods, which cycle together, is complex and apparently critical for their ability to maintain their position on surf-swept sandy beaches (Figure 3b; Paul *et al.*, 2002). The power strokes of the left and right fourth legs and uropods remain evenly spaced as frequency changes because the phase relationship between the fourth legs shifts from bilateral synchrony to one-third out of phase as overall frequency drops during the course of a dig (Figure 4b; Faulkes and Paul, 1997a). This pattern ensures continuity in the collective force generated by the fourth legs and uropods. As their force vectors are slanted with respect to the long axis of the body (see tilt of fourth leg and uropod tip trajectories in Figure 4), this coordination maintains the rear-down slant of the body while the powerful digging legs 2 and 3 provide the propulsive force for submerging the animal beneath the sand's surface. The coupling (and uncoupling) of the hind digging legs with the uropods accounts for hippid sand crabs' seamless transitions between two such different media as water and sand. The different coupling patterns between limb segments displayed in sand crabs (Figure 4) exemplifies well the inherent functional and evolutionary flexibility of modularity in the organization of neuromotor networks (Paul *et al.*, 2002) and the developmental mechanisms that give rise to them (Section 1.07.5).

1.07.3 Neurobehavioral Mechanisms and Biomechanics are Inseparable

Tailfan skeleton musculature, tailflip behaviors, and MG and LG neurons are interrelated. Before plunging into the analysis of any central nervous system, the machinery that the particular nervous system operates must be considered. For example, cephalopod mollusks have excellent visual capabilities and manipulative skills, as do humans, but our brain in an octopus would be as helpless in controlling

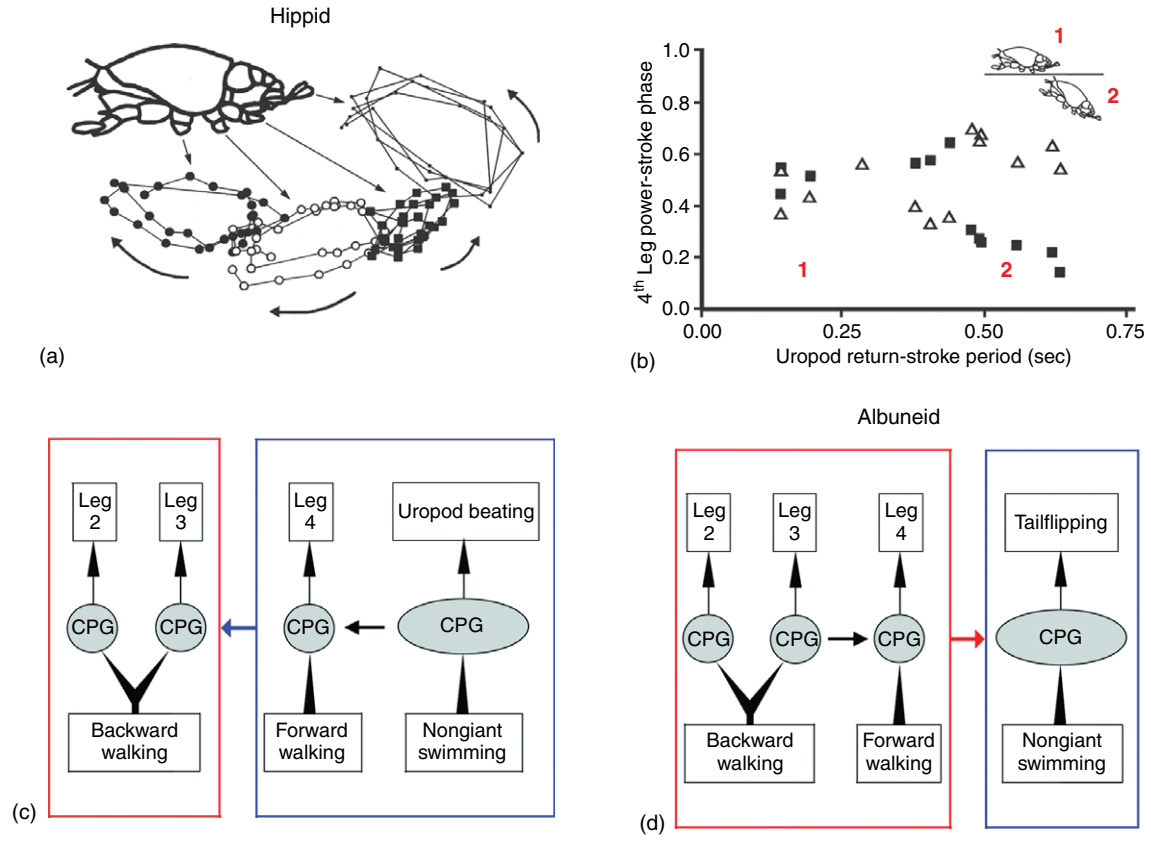

Figure 4 The mosaic ancestry of sand crab digging behaviors. Limb movements of hippids (a, c) and albuneids (d). The movements and motor patterns of the second and third digging legs resemble those used by other decapods to walk backward, while those of the fourth legs resemble patterns for forward walking in other species. a, Hippid uropods cycle in the same, bilaterally synchronous pattern during swimming and digging, but during digging the three pairs of digging legs also move rhythmically. The fourth legs cycle in the same direction as the uropods, whereas the second and third pairs cycle in the opposite direction (curved arrows). b, The coordination between the cycling of left (solid box) and right (open triangle) fourth legs with respect to the uropod period changes during the course of a dig according to the frequency of uropod beating (data are onset of electromyograms bursts recorded from unrestrained animals). The fourth legs move in unison and in antiphase to the uropods at the beginning of a dig (time 1), and drift apart when overall frequency drops until they are cycling about one-third of a cycle out of phase with each other and the uropods (time 2). Inset: position at start of dig, above (1) and when submerged below (2) surface of sand (horizontal line). c and d, Summary diagram of the neural organization of digging in hippid (c) and albuneid (d) sand crabs. The evolutionary change in coordination between limb CPGs (central pattern generators) was greater than in the CPGs themselves (see character 12 in Figure 2). Adapted from Faulkes and Paul (1997a, 1997b, 1998); see also Paul *et al.* (2002).

tentacle movements as octopus motor circuitry would be in controlling our hands and feet. What skeletal–muscular requirements must be met for a decapod crustacean to be able to swim with the uropods?

1.07.3.1 Hinged versus Single-Pivot Joints

Two basic requirements for generating propulsive force with any limb that functions as a lever are a basal joint that allows limb movement through a sufficiently large arc and musculature capable of generating powerful movement of the limb through its full trajectory while providing stabilization against counter forces. Arthropod joints are typically double hinged, with movement restricted to one plane. The uropod has just one articular point with abdominal segment 6, but in most decapods this joint is so deeply recessed between the telson and the sixth segment that elevation of the propodite (the basal segment of the uropod) above the horizontal plane is impossible and protraction and retraction in the horizontal plane are severely restricted. The joint does, however, allow uropod depression, which results in cupping of the tailfan (Figure 1b2). Hippids, by contrast, have evolved a 'socket-and-ball' uropod joint with the sixth segment that is biomechanically analogous to a vertebrate ball-and-socket joint (Figure 5d; Paul *et al.*, 1985). This allows the uropod propodite to be swung through large arcs nearly comparable to the range of motion of the human shoulder joint. Hippids swim exclusively with the equivalent of a human swimmer's backstroke.

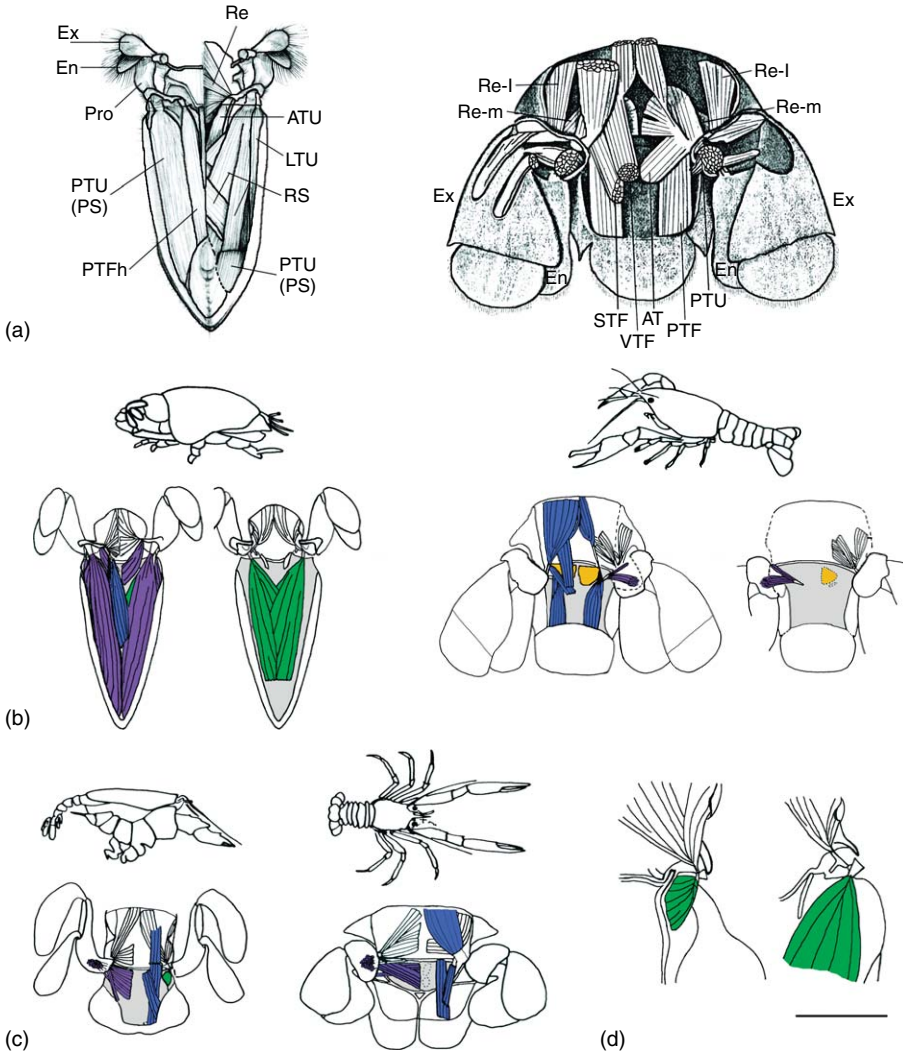

Figure 5 The divergence of telson musculature in Hippidae from that typical of the decapod telson is so extreme that no specific homologies can be suggested by visual inspection alone; analysis of the innervation is required. a, Ventral views of the tailfans of *E. analoga* (left) and crayfish (right) show the most ventral muscles in place on the left and removed on the right. Note that all of the telson muscles in *E. analoga* arise from broad areas of the inner dorsal telson and insert directly on the uropod propodite via discrete tendons. This is in marked contrast to crayfish, where nearly all of the muscles in the telson are the terminal elements of the series of abdominal fast flexor muscles, and all insert on or are linked to the flexor tendon in the posterior–lateral abdominal segment 6, which, in turn, is linked to the ventral side of the uropod. The fibers of the trio of relatively small telson–uropod muscles in crayfish (only PTU labeled) insert directly, without tendons, over the proximal ventral surface of the propodite, but are attached to the dorsal–anterior telson via a slender tendon, which is bound to the flexor tendon by connective tissue. b and c, The modifications of conserved telson muscles (blue), loss of an ancestral muscle (orange), and appearance of a new muscle (green) in the anomalen species were discovered by inspection of the tailfans of two anomalen species that continue to tailflip, *B. occidentalis* and *M. quadrispina* (Paul *et al.,* 1985; Paul, 1991; Wilson and Paul, 1987). The ventral (blue) muscles are removed from one side to expose the deeper/more dorsal muscles. b, *E. analoga* (Hippidae, left) compared with crayfish (right; the inset shows a more dissected view to reveal the three telson–uropod muscles attached to the dorsal telson by a single tendon, left side; the area of attachment of AT muscle fibers (orange oval), right side. c, *B. occidentalis* (Albuneidae, left), *M. quadrispina* (Galatheidae, middle). Muscle homologies were surmised by examination of their positions relative to each other and skeletal landmarks and confirmed by the similarities in central positions and morphologies of the motoneurons innervating them (see Figure 7). d, Detail of the dorsal insertion on the uropod of the uropod RS muscle in the albuneid *B. occidentalis* (left) and hippid *E. analoga* (right); note that it is adjacent to the tendon of the uropod remoter muscle, which arises in the sixth segment, and is similarly positioned in crayfish (shown in a). AT, anterior telson muscle; En, uropod endopodite; Ex, uropod exopodite; Pro, uropod propodite; PTF, posterior telson flexor muscle; PTU, posterior telson–uropod muscle; Re-l, lateral uropod remoter muscle; Re-m, medial uropod remoter muscle; STF, slow telson flexor muscle (present in all species, function unclear); VTF, ventral telson flexor muscle. a (right), Adapted from Schmidt, W. 1915. 1.07.3.2 Neuromuscular Repercussions of Increasing a Joint's Freedom of Movement

The evolution of musculature capable of generating controlled, forceful movements around such a flexible joint, while simultaneously stabilizing it against counter forces as the uropod is swept through its full trajectory, is no mean feat. The divergence of proximal tailfan musculature in hippids from that of typical decapod tailfans is so extreme that visual inspection alone gives no clues about muscle homologies. In fact, the one apparent exception turned out to be a false lead: the strikingly similar muscles in the anterior telson of crayfish and hippids, which also have approximately equivalent actions on the uropod, are not homologues, as was made evident by analysis of their innervations (Figures 5–7; Paul *et al.*, 1985). Comparison of the motoneurons showed that the muscle in crayfish (the anterior telson (AT) muscle) had been lost in the sand crab lineage long before the advent of Hippidae, and was accompanied (or followed) by expansion of a smaller muscle (the anterior telson–uropod (ATU) muscle) into the vacated space in the anterior telson. The modifications of conserved telson muscles (e.g., the ATU muscle), the loss of an ancestral muscle (the AT muscle), and the appearance of a new muscle (below) in the hippid lineage are illustrated in Figure 5 and summarized in Figure 6. Two obvious differences distinguish the tailfan muscles of hippid sand crabs and prototypical tailflipping species, such as crayfish. One is the massive uropod return-stroke muscle (RS muscle, Figures 5 and 6), which is absent from crayfish and allies. This muscle is responsible for swinging the uropod rearward preceding each power stroke, which corresponds to the extension phase in swimming by repetitive tailflipping and is equivalent to the upstroke of a wing beat in flying species. Without this muscle, swimming by uropod beating could not have evolved, for no conceivable morphological changes could have produced its biomechanical equivalent from ancestral telson muscles. The second obvious difference is the pair of ventral muscles that insert on the ventral side of the uropod propodite and are responsible for the uropod power stroke. The large uropod power-stroke muscle (PS ≡ homologue of crayfish's ATU

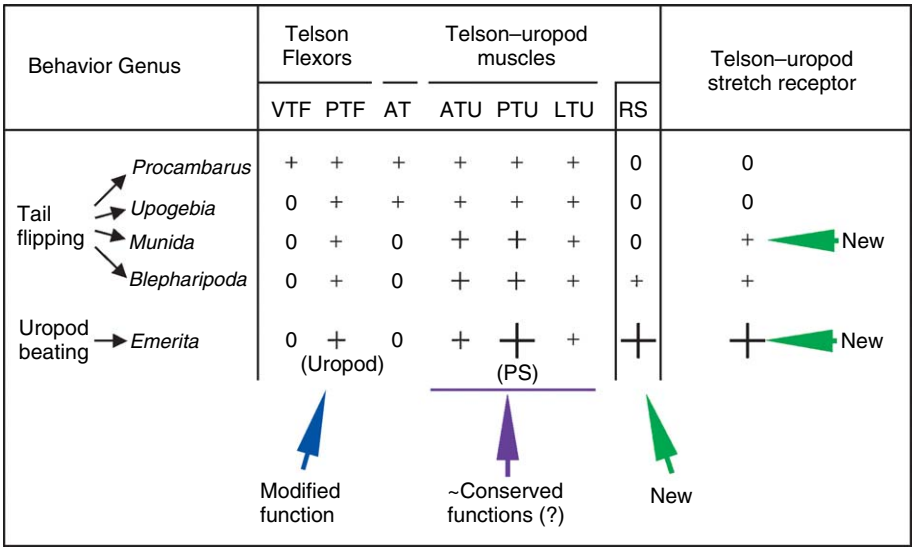

Figure 6 Summary of the muscles and stretch receptors in the telson of crayfish (*Procambarus*, Astacidea), mud shrimp (*Upogebia*, Thallasinidea), squat lobster (*Munida*, Galatheidae), albuneid sand crab (*Blepharipoda)*, and hippid sand crab (*Emerita*). In crayfish and mud shrimp, uropod movements independent of the telson are severely limited by the recessed joint, the linkages between the proximal uropod musculature and the musculature of the sixth abdominal segment and telson (see Figure 5b; Paul *et al.*, 1985; Paul, 1991), and the overlapping neural control of uropod and abdominal–telson movements (Larimer and Kennedy, 1969; Dumont and Wine, 1987). The sequential changes in the muscles that preceded the advent of hippid sand crabs' new mode of swimming with the uropods began with the shift of their combined action from axial flexion to uropod control when the AT muscle was lost and a new proprioceptor, which senses elevation of the uropod, appeared; these changes continued with the evolution of a muscle that inserts dorsally on the uropod (RS) in albuneid sand crabs, in which RS is too small to have any biomechanical action on the uropod. Finally, the shift in the insertion of the remaining axial flexor muscle (PTF) to the uropod and hypertrophy of the pair of antagonists, PTU and RS (see Figure 5), completely freed the hippid uropods from the axial neuromusculature. At the same time, a different telson–uropod stretch receptor replaced the original telson–uropod stretch receptor present in tailflipping anomalans. Muscles: AT, anterior telson; ATU, anterior telson–uropod; LTU, lateral telson–uropod; PTF, posterior telson flexor; PTU, posterior telson–uropod (PS, uropod power-stroke muscle in Hippidae); RS, uropod return stroke; VTF, ventral telson flexor. Data from Dumont and Wine (1987), Paul (1972, 1981b), Maitland *et al.* (1982), Paul *et al.* (1985), and Paul and Wilson (1994).

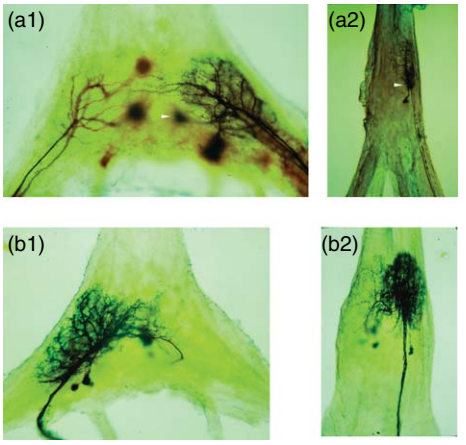

Figure 7 Similar central position and morphology of motoneurons provide evidence for muscle homologies. Photomicrographs of motoneurons in the sixth abdominal ganglion revealed in silver-intensified backfills from their axons. a1 (right side) The three uropod RS motoneurons in *E. analoga* (left side, the two uropod PS (PTU) motoneurons); a2, the RS motoneurons in *B. occidentalis* (white arrow to small medial soma in comparable relative position to its larger homologue in *E. analoga*). The intermingling of RS and uropod rotator motoneurons in sand crabs' sixth abdominal ganglion (not shown) and the similar positions and morphologies of the rotator motoneurons in sand crabs and crayfish may be evidence of the derivation of the RS neuromusculature from the sixth segment's uropod rotator neuromusculature (Paul, 1981b; Vidal Gadea *et al.*, 2003). b, The PTF motoneurons in A6 backfilled from the left side in *E. analoga* (b1) and the right side in *B. occidentalis* (b2); see Dumont and Wine, 1987 for their homologues in crayfish. Maximum width of ganglia: *E. analoga*, 1 mm; *B. occidentalis*, 0.35 mm.

muscle; Paul *et al.*, 1985) inserts directly opposite (ventral to the pivot point) the insertion of the RS muscle, whereas its smaller synergist (posterior telson flexor (PTF) homologue) inserts more medially. These muscles have homologues with different mechanical actions in crayfish (Figures 5 and 6, and Section 1.07.3.2.2 below).

Did the unique joint and constellation of muscular elements needed to swim with the uropods evolve together as a massive developmental transformation in the tailfan? Tracing backward the evolutionary history of hippids (Figure 2), starting with relatives most closely resembling hippids and moving to those more similar to crayfish in morphology and behavior, uncovers in reverse order the major evolutionary transitions on the way to the appearance of uropod beating. Comparative analysis of anomalan species that display less modified locomotion and tailfans than those of hippid crabs revealed that the uropod RS muscle is a new muscle that appeared prior to the split of the two sand crab families. Transformation of ancestral decapod neuromusculature began even earlier. I will briefly describe these events in reverse order of their occurrence.

1.07.3.2.1 New muscle, new motoneurons The RS muscle homologue in spiny sand crabs, which tailflip and retain telson flexor and telson–uropod muscles in their ancestral positions (see below), is so small and inconspicuous that it was overlooked until an anomalous tiny branch from the nerve innervating the uropod remoter muscles in the sixth abdominal segment was traced (Paul, 1981b). This tiny branch turns posterior into the telson to end on what appeared to be folds of arthrodial membrane in the anterolateral corner of the telson. These folds turned out to be a few short muscle fibers converging to an attachment on the dorsal arthrodial membrane of the uropod joint, a position corresponding precisely to that of the massive RS muscle of hippid crabs; this muscle has no counterpart in crayfish or other decapods (Figure 5). The hypothesis of homology of these vastly different-sized muscles is predicated on the assumption that a spiny sand crab's homologue of the RS muscle is innervated by three motoneurons having central positions and morphologies similar to those of the three RS motoneurons of mole crabs, and this proves to be the case. Although the RS motoneurons are vastly different in size, reflecting the size difference of the muscles innervated, their positions in the ganglion and the branching patterns of their neurites are very similar, despite the different overall shapes of this ganglion in the two sand crabs (Figure 7). The few, short muscle fibers of the albuneid RS muscle could have no mechanical action on the uropod, nor do they appear capable of even stiffening the joint. Their appearance in sand crabs that tailflip was presumably the result of an ontogenetic error in the common ancestor of hippids and albuneids that, while serving no function, had no detrimental effect and became fixed in the lineage and a preadaptation for uropod swimming.

1.07.3.2.2 Altered (and conserved) functions of conserved neuromusculature While the relative sizes of homologous muscles in mole crabs and spiny sand crabs differ, there is only one qualitative (functional) difference that distinguishes their tailfan neuromusculature. The insertion of the PTF muscle in hippids has been switched to the ventral–medial propodite, making it a limb muscle rather than the terminal member of the axial flexor musculature (Paul, 1981b; Paul *et al.*, 1985; Dumont and Wine, 1987). Thus, in contrast to the recent origin of the uropod RS muscle, the PS musculature turns out to have heterogeneous derivations from

separate components of ancestral tailfan muscles. Interestingly, the latter muscles assist in the PS phase (flexion) of tailflipping (Paul, 1981a, 1981b). That is, retained muscles that are PS synergists in tailflipping species became the PS muscles for uropod beating in Hippidae. This discovery was important, because it implies that qualitative changes in the central neural circuitry for swimming need not have been substantial in the transition from tailflipping to swimming with the uropods. In hippids, changes in the development of the tailfan brought together ancestrally disparate components that serve different mechanical actions in other species, but retained the ancestral association of PS (and recovery stroke, i.e., extension) neuromusculature. The conversion of decapod PTF muscle to a uropod PS synergist (Figures 5 and 6) would have removed the last constraint against uropod movement independent of the body axis, an essential step for evolution of hippids' mode of swimming with the uropods. Although recent molecular data have been interpreted to suggest a basal position of hippids within the Anomala (Haye *et al.*, 2002), the combined morphological, physiological, behavioral, and ecological data support the contrary view that hippids are more derived than albuneids, as shown in Figure 2. The small size of the RS muscle in albuneids, therefore, is not the result of reduction of a larger muscle, as would be implied by placement of Hippidae at the base of the Anomala. A basal position of the Hippidae in the Anomala would mean that several reversals in transformation of neuromuscular elements would have had to occur. However, spiking telson–uropod stretch receptors (TUSR) (see Section 1.07.4) could have arisen once, even if sister group status of Galatheidae and Albuneidae were supported.

1.07.3.3 Ontogeny and Evolution of Neuromusculature

The development of neuromusculature in arthropods starts with the muscle fiber pioneers, which are mesodermal cells that extend between attachment points of future muscles and, hence, determine the orientations and biomechanical actions of muscles (Ho *et al.*, 1983; Steffens *et al.*, 1995; Halpern, 1997). Later, the growth cones of motor axons exiting the central nervous system seek out the correct target muscle head or heads to innervate. The conversion of the axial PTF muscle to a limb muscle (PTFh in Figure 5a) described above probably arose by the wayward positioning of one or more muscle pioneers.

Muscles with multiple heads and new muscles are thought to originate by division of ancestrally unitary muscles, presumably by duplication of muscle pioneers (Ho *et al.* 1983; Halpern, 1997). One head can continue to serve the basic function, while the other(s) are less constrained functionally and may acquire new biomechanical and/or behavioral roles in response to selective pressure (Friel and Wainwright, 1997; Antonsen and Paul, 2000; Paul *et al.*, 2002). This process may have given rise to the uropod RS muscle in sand crabs: its dorsal position in the telson and insertion adjacent to the complex tendon of the uropod rotator musculature in abdominal segment 6 (Figure 5) suggest that the RS muscle might have evolved by the wayward positioning of a rotator muscle fiber pioneer to place its axial attachment within the telson. Originally a triply innervated single head, as in albuneid sand crabs, this new muscle would have subsequently divided (or duplicated) to produce the four heads of the large uropod RS muscle in hippid sand crabs (Figures 5 and 7).

1.07.3.4 Intermediates between Sand Crab and Crayfish Tailfans

Stepping further down the hippid phylogenetic tree brings us to the Galatheidae (squat lobsters) (Figure 2). Apart from the absence of the uropod RS muscle from galatheids, the tailfan neuromusculature of squat lobsters and albuneid sand crabs is very similar (Figures 5 and 6). Squat lobsters, however, walk on the surface rather than locomote through substrate. (The major neurobehavioral adaptations in control of thoracic appendages and intersegmental coordination that enable sand crabs to dig through sand are described in Section 1.07.2.3.) Did loss of an ancient tailfan muscle precipitate alterations in the decapod tailfan and evolution of Anomala?

Preceding the transformations described above (and others) was the demise of the only telson muscle that has no anterior segmental homologue in decapods or any malacostracan, the AT muscle described above (Dumont and Wine, 1987; Paul and Macmillan, 1997). The large area of the inner telson surface vacated was then filled by the spread of the ATU muscle fibers, which in species with the AT muscle attach to the dorsal telson via a slender tendon (Figure 5). The discovery that the similarly positioned and oriented anomalan ATU muscle and crayfish's AT muscle are not homologues (Figure 5) opened the way to solving the puzzle of how the telson musculatures in these two groups were related (Paul *et al.*, 1985). None of the anatomical

literature on hermit crabs (Paguroidea) illustrates a muscle in the appropriate position (although a modified AT muscle could perhaps have been useful in gripping the inner whorl of gastropod shells with the uropod). If the AT muscle is indeed absent from hermit crabs, then its loss might have triggered the evolutionary modifications of the tail for which the Anomala are famous.

1.07.4 Did Loss of an Ancient Tailfan Muscle Precipitate Alterations in the Decapod Tailfan and Origin of the Anomala?

1.07.4.1 Identifying Neural Homologies in Divergent Species

Neuroblasts generally do not migrate from their birthplace during the embryonic development of the central nervous system in arthropods (Harzsch, 2003). Neurons with somata in similar positions relative to other landmarks in different species are, therefore, likely to be homologous (Figure 5). Motoneurons are more easily identified functionally and described morphologically than interneurons, because of the ease of applying the backfilling technique. Homologous motoneurons in turn serve as landmarks for comparing other neurons, as well as architectural features such as axonal tracts, commissures, and neuropil areas (Figure 8; Paul, 1989, 1991; Strausfeld, 1998; Loesel *et al.*, 2002; Mulloney *et al.*, 2003). Conserved central neural architecture of the tailfan ganglion provides the backdrop against which the new RS motoneurons were discovered in hippids, and from which corresponding (homologous) motoneurons were postulated and found in albuneids (above). Their possible derivation is addressed in Section 1.07.3.3. The RS motoneurons were not the only new neurons essential for swimming with the uropods.

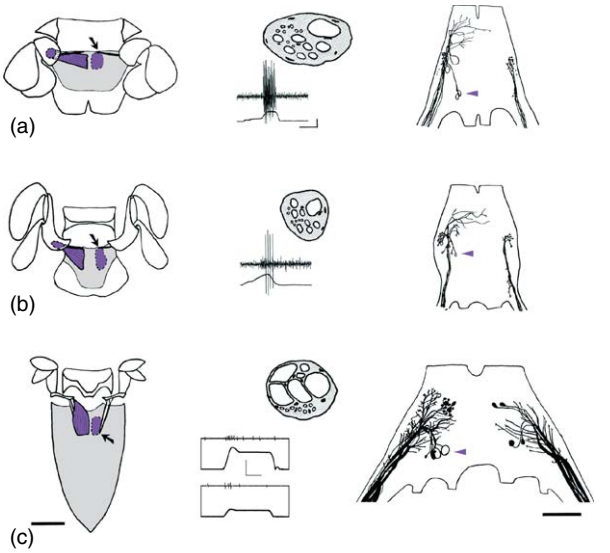

Figure 8 The spiking (a, b) and nonspiking (c) telson–uropod stretch receptors compared. Left column, ventral views of dissected tailfans to show position of the ATU muscle and the receptors in: a, *M. quadrispina* (Galatheidae); b, *B. occidentalis* (Albuneidae); and c, *E. analoga* (Hippidae). On the right side, the area of dorsal telson from which the ATU muscle fibers arise is shown; compare to position of AT muscle in crayfish (Figure 5b). Arrows point to dorsal attachment of receptor strand on inner surface of telson. Middle column, transverse sections of the receptor nerve midway between the receptor strand and the mixed nerve from the lateral telson which it joins (for nerve homologies, see Paul *et al.*, 1985). Sample recordings of the response to stretch of the receptor strand: extracellular receptor nerve recordings from *M. quadrispina* and *B. occidentalis*; intracellular recording from one of the four nonspiking sensory neurons (NSRs) of *E. analoga* (lower trace: stretch stimulus). Right column, camera lucida drawings of abdominal ganglion 6 with silver-intensified, CoCl-backfilled neurons from sensory nerves in the three species. On the right side, fills from close to the receptor strand show only the sensory neurons filled; on the left side, backfilled farther from the receptor, show a few other neurons, including the pair of ATU motoneurons with caudal somata easily identified in all species (purple arrow) also filled. Adapted from Paul, D. H. and Wilson, L. J. 1994. Replacement of an inherited stretch receptor by a newly evolved stretch receptor in hippid sand crabs. *J. Comp. Neurol.* 350, 150–160.

1.07.4.2 Joints with Wide Freedom of Movement Require Proprioceptors to Keep Them in Line

Sensory feedback from stretch receptors and other internal proprioceptors, which detect changed position or tension between body parts, is used to sustain strong adaptive movements during locomotion (Pearson and Ramirez, 1997; Hooper and DiCaprio, 2004). On basic principles, one would predict that any joint as flexible as that of hippids' uropod articulation with abdominal segment 6 would display one or more stretch receptors, and this is the case. Hippids posses a TUSR that is exquisitely sensitive to remotion and rotation movements of the uropod with respect to the body axis, i.e., the movement produced by the new RS muscle. Its sensory neurons are unusual both morphologically in having centrally located cell bodies and physiologically in that they are nonspiking (NSR, nonspiking stretch receptor). Nonspiking neurons transmit only graded potentials and are incapable of generating action potentials (Figure 8c; Paul and Bruner, 1999).

1.07.4.2.1 TUSRs evolved twice The discovery of TUSRs in albuneid sand crabs and squat lobsters in a roughly similar position as the nonspiking TUSR in hippids should not have been a surprise, because,

although these animals retain the ancestral behavior of tailflipping, their uropod articulation allows greater freedom of movement than that in crayfish (Paul *et al.*, 1985). Like the hippid TUSR, the albuneid and galatheid TUSRs arise from the dorsal telson and insert on the ventral–medial rim of the uropod propodite. In each of the three groups, the receptor flanks the major uropod depressor muscles, the anterior telson–uropodalis muscle (ATU), which is considerably larger in these Anomala than its homologue in crayfish (Figures 5 and 8). The hippid receptor strand, however, arises on the lateral side of the ATU, whereas the receptor strand in the two tailflipping anomalans arises adjacent to the medial–anterior face of this muscle. Also, the sensory neurons of the latter are spiking (generate action potentials).

No comparable proprioceptor monitoring movements of the basal joint of the uropod has been found in any macruran or paguroid. This suggests that the greater freedom of movement of the uropods relative to the rest of the tail in sand crabs and galatheids was not only accompanied by alterations in neuromusculature, as discussed above, but made desirable the evolution of a proprioceptor that could monitor whole limb movement and, therefore, mediate stabilizing reflexes in uropod motoneurons. In fact, all three TUSRs are ideally positioned to sense elevation of the propodite, and *in vitro* experiments show that they mediate similar stabilizing (negative feedback) reflexes (Paul and Wilson, 1994); *in vivo*, however, the roles of the TUSRs are more complex (see Section 1.07.5.2).

The most unusual features of all three TUSRs are the morphology of their sensory neurons (they are monopolar) and the central location of the sensory somata (within the sixth abdominal ganglion) (Figure 8; Maitland *et al.*, 1982; Paul and Wilson, 1994). This contrasts with typical arthropod mechanosensory neurons, including most proprioceptors, which are bipolar or multipolar and have peripherally located cell bodies. The TUSR sensory neurons are similar to those of stretch receptors associated with crayfish swimmerets and crayfish and brachyuran crab walking legs and all resemble motoneurons in general structure (Bush, 1976).

Given the phyletic relationships of these animals (Figure 2) and the comparative data on their neuromusculature (Figure 5; Paul *et al.*, 1985), it was reasonable to have assumed that spiking TUSRs were the precursor of the NSR in hippids. Why, then, are the hippid and the albuneid/galatheid receptors not homologues?

The clues are the different positions in the sixth abdominal ganglion of the sensory neuron somata and the orientations of the primary neurites relative to common landmarks, such as conserved (homologous) motoneurons and axon tracts in A6. The central features of the galatheid and albuneid spiking sensory neurons are almost identical, more similar even than their peripheral morphologies, but they are strikingly different from the central positions and morphology of the nonspiking sensory neurons, NSRs, in hippids (Figure 8, right column). These central differences stand out against the background of conserved ganglionic structure and lead to the conclusion that TUSRs evolved (at least) twice, once in the common ancestor of squat lobsters and sand crabs and once in hippids (Figures 2 and 6).

1.07.4.2.2 The extraordinary nonspiking TUSR of hippid sand crabs Why replace the spiking telson–uropod receptor that appeared in the common ancestor of sand crabs and squat lobsters with a nonspiking receptor across the same joint that mediates similar resistance reflexes (Figures 2 and 8)? The answer may be that the demise of the spiking receptor was a byproduct of the elongation of the telson in the hippid lineage (Figure 5). This shifted to longitudinal the orientation of the muscles, thereby giving them the mechanical leverage to execute large excursions of the uropods during swimming and digging, when both the load on the uropods and the variability of that load are likely to be greater. A more interesting question is why are the neurons of the hippid receptor nonspiking? What is the adaptive value of graded rather than action potential signaling in proprioceptors? Nonspiking cells are common in places where conduction distances are short; also, the speed of information transfer is higher than for action potential transmission (as in visual and auditory centers), but the former is untrue for the NSRs and the latter is an unlikely requirement for stretch receptors responding to whole limb movement. Combining neurobehavioral data on the motor system and what is known about how the NSRs mediate their diverse functions (next section) with data from the much better understood sensory and motor systems of crayfish suggests that these new neurons were wired into ancestral circuitry serving the tailfan. Nonspiking neurons are prominent in this and other neural networks (references in Paul, 2004). The evolution of the NSRs' physiological properties might have been determined by their being interconnected with nonspiking neurons in the central pattern generator (CPG) circuitry for the uropods; that is, proprioceptive feedback transmitted by graded-potential neurons could have been favored

for smoother integration by a network using graded potentials to perform its neurobehavioral functions (Paul and Bruner, 1999; Paul, 2004; see Section 1.07.5.2). Whatever its evolutionary cause, having nonspiking membranes may have been influential in the evolution of these sensory neurons' extraordinary peripheral morphology (Figure 9), which is thought to explain the unusual combination in single neurons of high sensitivity and ability to respond over the entire range of tension experienced by the receptor strand (Figure 9; Wilson and Paul, 1990; Paul and Wilson, 1994).

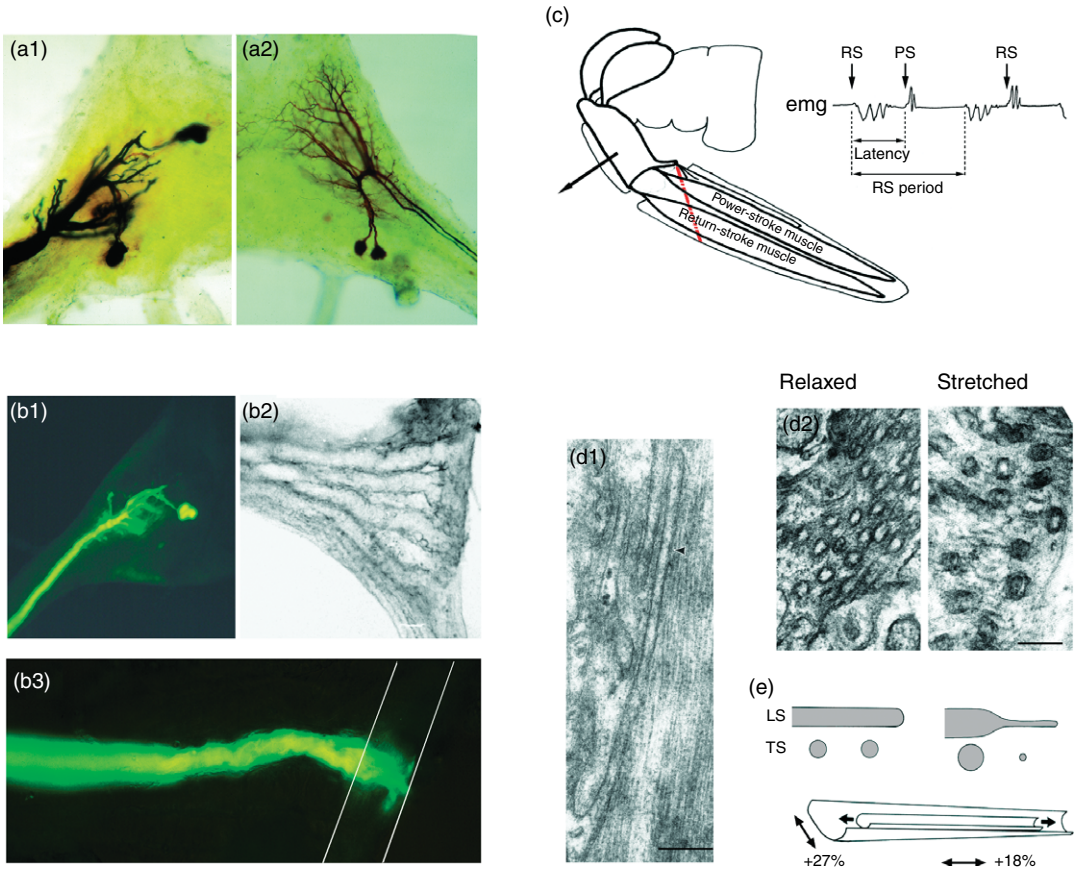

Figure 9 The NSRs of *E. analoga* (Hippidae) have distinctive central (a1, b1) and peripheral (b2, b3, d) morphology. a1 and a2, Silver-intensified backfills showing two of the four sensory neurons (a1) and the two relatively large ATU motoneurons (a2; see Figure 8c), each in one hemiganglion; note the general similarity between the sensory and motor neuron structures. b1, An NSR filled with Lucifer yellow by microelectrode injection. b2, The peripheral dendrites of the NSRs terminate linearly along the elastic receptor strand (uropod end toward top of page) in which their dendritic tips extend longitudinally for a short distance. b3, A peripheral end of a Lucifer yellow-filled NSR dendrite penetrating the elastic receptor strand (edges of strand marked by white lines). c, Cartoon cut-away view from the right side of the tailfan with uropod in rest position (see Figure 1), showing the receptor strand (red line) to which the NSRs attach, which is stretched during the uropod return stroke (arrow). The inset shows a sample electromyogram pattern recorded in freely swimming *E. analoga*. The motor patterns during swimming and treading water differ; the treading water motor pattern is dependent on the presence of intact NSRs, whereas the swimming pattern is unchanged after bilateral receptor ablation (Paul, 1976). d, The ultrastructure of the NSR dendrites within the elastic strand may explain these sensory neurons' unusual combination of features: (1) high sensitivity to stretch of the receptor strand and (2) ability to respond over the full range of tensions experienced by the whole stretch receptor. d1, The dendrite of each NSR gives rise to approximately 21 000, 0.1 μm-diameter tips oriented longitudinally within the receptor strand. d2, Cross-sectional profiles of these tips are larger and less numerous in stretched than relaxed receptors. e, Model to illustrate how differential compressibility of the extracellular matrix surrounding the dendritic tips could account for the change in tip profiles shown in (d2) by producing hydrostatic forces that would cause concomitant constriction of the distal portions and expansion of the proximal portions of the tips (and open stretch-activated ion channels); LS, longitudinal section; TS, transverse section profiles of tips. The number of tips contributing to the receptor potential recorded outside of the strand would increase with increasing stretch amplitude (full range fractionation by each sensory neuron). Below, diagram showing the difference in shape and dimensions of the elastic receptor strand between the relaxed and fully stretched states. d, Adapted from Wilson, L. J. and Paul, D. H. 1990. Functional morphology of the telson-uropod stretch receptor in the sand crab *Emerita analoga*. *J. Comp. Neurol.* 296, 343–358.

1.07.5 Life in the Swash Zone of Sandy Beaches: New Behaviors ↔ New Niche → New Sensory World

1.07.5.1 New Niche Means Altered Sensory Environment

Hippid sand crabs spend their lives alternating between two environments, above and in the sand, on beaches exposed to wave action (Figure 3; Dugan *et al.*, 2000), in which tailfan mechanosensory setae would not be expected to provide much meaningful information. The unpredictable turbulence in the swash zone alone would limit the kinds of information hydrodynamic sensors on the tailfan could provide, in contrast to the importance of this modality in crayfish (Paul, 2004). In addition, hippid uropods beat continuously both for swimming and treading water when the animals are up in the swash zone and while digging into sand, when they are coordinated with the second through fourth thoracic legs (Section 1.07.2.3). Not surprisingly, differences between the mechanosensory integrating network of neurons in the sixth abdominal ganglion of hippids and crayfish are evident. They suggest that alterations in integration of sensory input from the tailfan were important components in the neural evolution that made hippids' new modes of locomotion fully adaptive for their active life on wave-swept beaches. As I treated this subject at length elsewhere (Paul, 2004), I will not discuss it further here.

1.07.5.2 Roles of Hippid Sand Crabs Nonspiking Proprioceptor

Two functions have been ascribed to the NSRs and a third appears likely. They provide clues about these new neurons' connections with ancestral decapod sensorimotor networks serving the tailfan. These clues suggest several potential explanations for the selective advantage of the use of graded potentials in neurons that send signals from the periphery to the central nervous system.

1.07.5.2.1 Suppress reafference during uropod beating The integration of the phylogenetically new NSR input with the sensorimotor network for the tailfan is such that exteroceptive input from the tailfan is depressed whenever the uropods are beating, i.e., continues through the RS and PS phase. The long-lasting nature of the inhibition mediated by the NSR may stem from the combination of the sustained (graded) input and long-lasting inhibitory synapses downstream (Paul, 2004). The ability of hippids to move seamlessly across the water–sand interface, for which continuous uropod beating is required (see above), may have been contingent upon the evolution of proprioceptors that could suppress tailfan mechanosensory input whenever the uropods are beating.

1.07.5.2.2 Switch between motor patterns for swimming and treading water Whenever hippids are above the sand, they are either swimming, i.e., moving with respect to the substrate, or treading water, i.e., keeping themselves suspended vertically (Figure 3) – except when being swept by surging currents! In the electromyogram pattern for swimming (Figure 9c), the phase of the power stroke with respect to RS period is relatively constant (around 0.55), whereas in the electromyogram pattern for treading water, PS muscle bursts occur at relatively constant latency with respect to return strokes. Switching between motor patterns often occurs in the course of one swim sequence. The treading water motor pattern is dependent on intact NSRs, since bilateral ablation of the receptor strands deletes this motor pattern from these animals' behavioral repertoire without diminishing their ability to swim (Paul, 1976).

1.07.5.2.3 Coordinate fourth legs and tail? The NSR input reinforces power strokes during high-frequency uropod beating (Paul, 1976), which occurs during digging as well as in spurts during swimming. When digging, the fourth legs cycle at the same frequency as the uropods (Figure 4), but never in unison with them. The power strokes of the left and right fourth legs are evenly spaced between the uropod return strokes, which means that the phase relationship between the fourth legs shifts from bilateral synchrony to one-third of a cycle out of phase as uropod frequency declines during a dig (Figure 4). The behavioral significance of this complex motor pattern was explained above (Section 1.07.2.1.2). In other species, including crayfish, leech, and lamprey, sensory feedback is incorporated into the intersegmental coupling signals between CPGs located in different parts of the body (Friesen and Chang, 2001), and the NSRs may do the same (they influence the activity of several candidate neurons for this coordination; Paul, 2004). Evolutionarily speaking, the interest of this is that it would mean the superposition of the new afferent signals onto an inherited set of coordinating neurons between dissimilar CPGs, paired for the fourth legs and unpaired (most likely) for the uropods – assuming the uropod and nongiant tailflipping circuitries are homologues (see Section 1.07.2.2).

Paul and Bruner (1999) discuss the possibility that the NSRs are ontogenetically related to motoneurons (see also Bush, 1976; Wilson and Paul, 1990).

1.07.6 Discussion: Lessons from Reconstructing Neurobehavioral Pedigrees

Tracing the evolutionary history of an individual neurobehavioral circuit backward through time uncovers sequential convergences with other behavioral lineages (these are more commonly described in the reverse order, i.e., as major branch points) in its lineage, and should ultimately lead to its origin. This approach is akin to the one used by Dawkins to arrive at his series of concestors in his pilgrimage to the dawn of life (Dawkins, 2004). Some discoveries made along the way, at confluences with variants of the circuit whose lineage is being traced, may seem counterintuitive and offer wonderfully assorted jumping off points for new lines of neurobehavioral investigation. Because nervous systems are heterarchically rather than hierarchically organized (Cohen, 1992), each change, whether peripheral or central, in the ancestry of sand crabs, or any other species, would have presented a new challenge to inherited central circuitry.

Ontogenetic variation within populations arises by chance and then evolves to make species anatomically and behaviorally distinct (True and Haag, 2001; Shubin and Dahn, 2004). The initial mutations may affect peripheral or central structure or function. The neurobehavioral lineage of sand crabs presents examples of both (Figures 2 and 10). The pedigrees of individual species' neurobehavioral mechanisms offer more than descriptions of nervous system evolution. The comparative data generate functional hypotheses for individual species that are testable when the species have identifiable neurons that can be studied physiologically.

1.07.6.1 Peripheral Is Important

Patterns of efferent activity produced by the central nervous system are transformed into sequences of movements by the neuromusculature that operates the skeleton (whether internal, external, or hydrostatic). The association of peripheral morphological changes with major evolutionary events, such as vertebrates' movement onto land and the repeated evolution of flight (in insects, reptiles, and mammals), is well known. However, ignoring the contributions that peripheral differences in musculature make to species-specific behaviors risks misinterpreting the roles of central mechanisms in producing those behaviors and may obscure the very features sought in comparative neuroethological studies (Friel and Wainwright, 1997, 1999; Antonsen and Paul, 2000; Hooper and Weaver, 2000). In addition to illustrating well the interplay of peripheral and central factors during the evolution of adaptive behavior in new species, reconstructing the neural pedigrees of sand crab swimming and digging behaviors has opened new avenues for investigating function and evolution of nervous systems in other species that otherwise would have gone unnoticed.

1.07.6.2 Spin-Offs from Reconstructing the Neurobehavioral Pedigrees of Hippid Sand Crabs

The species encountered at convergence points along the backward evolutionary chronology of neurobehavioral circuitry raise new questions, provide new experimental animals, and suggest mechanisms for neurobehavioral evolution that could not be evident from research on a few model systems or *in vitro* experimentation, useful as the latter are for elucidating potential morphogenetic mechanisms that could lead to similarity by either common descent or convergence (Gerhart and Kirschner, 1997; Hall, 1999; True and Haag, 2001; Antonsen and Paul, 2001, 2002; Eisthen and Nishikawa, 2002; Wainwright, 2002; Wray, 2002).

1.07.6.2.1 Testable hypotheses from comparative studies Because neuronal positions and basic morphologies are conserved between species, comparison of the central positions and morphologies of motoneurons innervating individual heads of complex musculature both within and between species assists in identifying homologous muscles. The power of comparative morphological analysis is beautifully exemplified by the results of its application to the innervation of electric organs in fish (electrocytes are modified muscle fibers), which illustrate well the greater evolutionary plasticity of the physiology than of the morphology of neurons (Labas *et al.*, 2000).

Similar central morphologies of motoneurons in derived and ancestral species suggest that similarly organized central motor networks control them, the root of my argument for homology of swimming by uropod beating and tailflipping. Conserved network structure does not, of course, imply identical function or behavior, as neurons and synapses may evolve individually and be correlated with behavioral differences among species (Shaw and

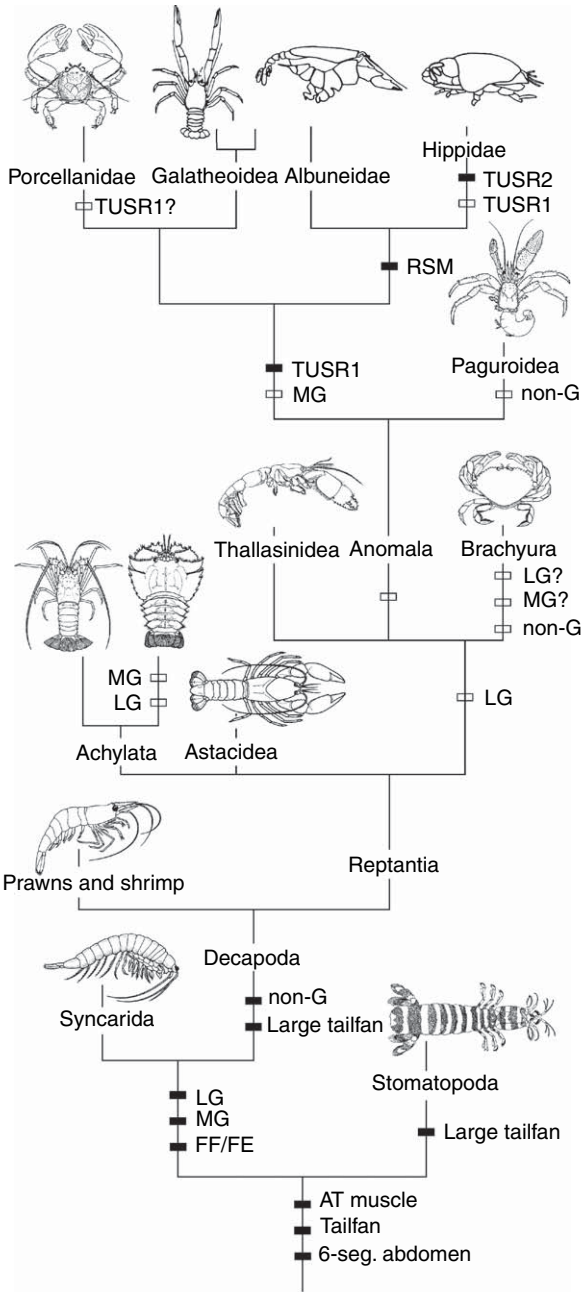

Figure 10 Partial phylogeny of the class Malacostraca with traits associated with the tailfan and tailflipping behaviors mapped. The tree includes the orders (except Euphasiacea, kril, for which neurobiological date are lacking) that retain the elongate abdomen and tailfan that distinguishes the class. Most Decapoda (e.g., shrimp, lobsters, crayfish; see Figure 2) share with the ancient orders Stomatopoda (mantis shrimp) and Syncarida (represented by *Anaspides tasmaniae*) all muscular components of the tailfan. *A. tasmaniae* share with Decapoda the characters of fast abdominal flexor and extensor muscles (FF/FE), the MG and LG interneurons, and the ability to perform rapid tailfips. Non-G (the CPG for tailflipping, character 7 in Figure 2) is shown as appearing with the Decapoda, although it may have evolved later (see Figure 2). The association of abdominal musculature for performing tailflips (not present in stomatopods) and the two sets of giant command interneurons for rapid ventral flexion of the body appeared together in syncarids, which retain many primitive features (Silvey and Wilson, 1979). Note the evolution of the machinery for tailflipping (FF/FE in the abdomen, giant interneurons (MG, LG)) after the divergence of Stomatopoda and the greater antiquity of the tailfan muscles (their number is the same and their organizations are very similar in these three orders, Paul and Macmillan, 1997). Clearly, the enlargement of the tailfan in Decapoda and Stomatopoda, which do not tailfip, evolved independently. N.B. the loss of the AT muscle at the base of the Anomala (absent also in Brachyura, whose relationship with the Anomala are poorly understood). The subsequent derivation of the uropod PS musculature in Hippidae from heterogeneous components of ancient malacostracan tailfan muscles that flex the telson or help cup the tailfan is summarized in Figure 2 and illustrated in Figures 5 and 6.

Moore, 1989; Fetcho, 1992; Katz and Harris-Warrick, 1999; Katz *et al.*, 2001; Remmers *et al.*, 2001). Differences between homologous motoneurons in squat lobsters and crayfish, for example whether neurites cross or do not cross the midline, may indicate differences in central circuitry correlated with the degree of bilateral interactions between motor centers or reflex pathways (Antonsen and Paul, 2000). Neural differences without apparent behavioral differences occur between two species of squat lobsters (Wilson and Paul, 1987). Future comparative neuroethologists may identify, with hindsight, this difference as incipient behavioral evolution! Behavioral evolution without altering central circuitry may occur by altering neuromodulatory control, as when key neurons loose, gain, or change their ability to synthesize or release a neurotransmitter or modulator (Harris-Warrick *et al.*, 1992; Katz *et al.*, 2001). An example of altered neuromodulatory control of a complex behavior is the ability of artificially elevated blood serotonin levels to transform normally gregarious squat lobsters (*Munida quadrispina*) into aggressive and vicious combatants (Antonsen and Paul, 1997, 2002). The details of this uncharacteristic behavior, which is displayed only under the influence of serotonin, strongly resemble the aggressive behavioral repertoire displayed by dominant crayfish, and some other crustaceans, to maintain their position in the social hierarchy (Edwards *et al.*, 1999). We think that fighting is the ancestral condition and its expression was lost in *M. quadrispina*'s lineage while the fight circuitry was retained, at least in part (Antonsen and Paul, 1997). Detailed comparisons of immunocytochemical maps of the nerve cords of crayfish and *M. quadrispina* could not provide suggestions for which neurons might be involved with fight initiation, but did provide suggestions about possible loci of some other functional differences between these species, along with insights into the evolution of aminergic systems (Antonsen and Paul, 2001).

1.07.6.2.2 Mosaic neurobehavioral evolution from modularity of neural mechanisms and ontogeny Some themes recur frequently, and similarities by homoplasy are possible. Grillner and Dickinson (2002) caution against associating common themes in motor mechanisms and homology between motor elements, especially when the phylogenetic relatedness of the species is not close. Recognition of convergence requires well-understood functional demands. These are more easily specified for sensory than motor systems, which explains in part the larger number of examples from sensory systems (Eisthen and Nishiikawa, 2002). The requirement for controlled movements for survival appears to constrain rapid evolutionary change in core elements of motor systems (e.g., CPGs) but allows changes in their coupling and control by other neural centers (Figure 4; Cohen, 1992; Fetcho, 1992; Nishikawa *et al.*, 1992; Remmers *et al.*, 2001; Paul *et al.*, 2002; Vasilakos *et al.*, 2003). Recent advances in our understanding of the ontogenetic processes that can give rise to convergent similarities provide insight into how morphological novelty and selection bring about evolution (Gerhart and Kirschner, 1997; Hall, 1999; True and Haag, 2001; Wray, 2002).

1.07.6.3 The Emerging Picture

1.07.6.3.1 Understanding the present by reconstructing the past A brief look further back into the ancestry of hippid sand crabs' mode of swimming with the uropods, stepping back into the phylogeny of Malacostraca (Figure 10), provides greater depth to the timescale and gives a sense of relatively rapid and recent upheavals in an ancient neurobehavioral network in anomalen decapods. The decapods share with some other, including the most basal, malacostracan orders: (1) organization (but not size) of tailfan musculature, (2) the MG and LG interneurons, and (3) the ability to tailflip. Most interesting is the appearance of these features in the syncarid *Anaspides tasmaniae* (Silvey and Wilson, 1979; Paul and Macmillan, 1997), which is one of the two most ancient orders of Malacostraca (Figure 10). From the distribution of neurobehavioral traits in Figure 10, a picture of sets of nested changes seems to emerge. The number and organization of tailfan muscles are essentially the same in stomatopods, syncarids, and decapods, although the tailfans differ substantially in size, shape, and behavioral use (Paul and Macmillan, 1997). Not until the loss of the only axial muscle without serial homologues in anterior abdominal segments (the AT muscle) in reptantian decapods was there any change in this ancestral plan.

The well-developed abdominal flexor and extensor muscles and the MG and LG interneurons preceded evolution of the stiff decapod tailfan, with its recessed uropod joint, which increased the power of tailflips. The tailfan (telson and uropods) of crayfish is often referred to as an appendage so tightly integrated are its parts. It is hard to escape the impression that this complex structure of tightly integrated parts with the MG and LG neurons as centerpiece restrained evolution of new morphologies and uses of the malacostracan tail until one

or both of these interneurons were lost, as happened apparently several times (Figures 3 and 10). The more ancient AT muscle was apparently an even greater restraint on tinkering with the premiere malacostracan invention, the tailfan, because only following its demise did evolution produce a delightful assortment of anomalan tails, some of which are described in this article. Evolutionary neuroethology, by its comparative analytical approach to understanding motor systems, and other neural networks in general, is becoming increasingly fruitful. This is because the rapid progress in understanding the mechanisms that work at different levels of organization to foster and limit morphological and functional evolution provides plausible explanations for how the neural evolutionary events, charted by comparative anatomy and physiology of extant species, may have come about (Gerhart and Kirschner, 1997; Hall, 1999; True and Haag, 2001; Shubin and Dahn, 2004). These hypotheses are testable if the species in question are amenable to genetic and developmental analysis. Stated in reverse: evolutionary neuroethology tests the plausibility and sufficiency of mechanisms described in research on *in vitro* systems and model organisms (which model only themselves) to explain how nervous systems really evolve.

1.07.6.3.2 Predicting the future The ability to predict the course of future neurobehavioral evolution in any lineage would be proof that neurobiologists have achieved their goal of understanding the rationale behind the organizations of neurobehavioral networks (Section 1.07.1.1). The degree of understanding that will be required may not be achievable, given the dynamic interactions among the numerous systems at play, many of which are themselves already quite complex (Barrow, 1998). What can be predicted, however, is the course evolutionary neurobiological research will take in the near future to bring us closer to this goal. The combined use of diverse new research tools and methods of computational analysis now available for research at single levels of organization, from synapses and single neurons to large networks and whole nervous systems, will be applied comparatively to carefully chosen species, and the results should greatly deepen our understanding of how nervous systems evolve as conditions change.

Glossary

allometry The scaling relationship between two characters A and B (e.g., brain mass and body mass), where changes in A and B are not proportional. (Proportional change in A and B is termed isometry.) Allometry is thought to reflect design constraints, so predictions on the effects of directional selection are usually conducted on residual trait variance after removal of allometric scaling.

altricial A relatively slow mode of juvenile development, where offspring are usually not mobile and are strongly dependent on parental care. The term can be opposed to 'precocial.'

behavioral drive hypothesis The idea that generalism, exploration, opportunism, social learning, and behavioral flexibility can have accelerating effects on evolutionary rate, by increasing the range and frequency of selective contexts in which randomly occurring mutations can confer higher fitness.

behavioral flexibility A general term describing the capacity to modify behavior. Often used as blanket term that encompasses learning (a change in behavior contingent on an association with a stimulus and/or a reward), opportunism (exploitation of a temporarily abundant resource not part of the usual diet of a species), or innovation (see definition below).

ecological intelligence Cognitive complexity selected in the context of interactions with the physical environment. Usually contrasted with Machiavellian (or social) intelligence, which is selected in the context of social interactions.

encephalization In comparative biology, the term describes the difference between animals in the amount of neurons available beyond the average determined by allometric body design. In paleoanthropology, it designates the observed increase over evolutionary time in the absolute and relative size of the brain in hominids. In neuroanatomy, it describes the increased importance that higher brain structures play over lower ones in birds and mammals compared to other vertebrates and to invertebrates.

generalism	One extreme of a continuum where the other extreme is specialization, generalism refers to the use of a relatively broad range of foods or habitats by a taxonomic group or an individual.
independent contrasts	The most widely used procedure for removing the effects of common ancestry on taxonomic similarities or differences between traits. The technique measures 'differences' between related taxonomic groups in the values of biological traits, rather than actual trait values on extant taxa. Relatedness between groups is usually measured through mitochondrial or nuclear DNA data.
innovation	A behavior pattern performed for the first time by an animal and that is not the result of a genetic change or a pathology. The novel behavior is an attempt to solve a problem (feeding, social) that the standard repertoire cannot resolve. Also defined as a new or modified learned behavior not previously found in the population (Reader and Laland, 2003, p. 14).
specialized cognitive skills	Cognitive abilities that are specific to a restricted selective context (e.g., spatial memory, learned song) and whose neural substrate is often a restricted brain area (e.g., hippocampus, nucleus HVC). The terms 'adaptive specialization' (implying adaptation to a particular selective context, e.g., food caching, brood parasitism) or 'module' (implying that information relevant to one specialized context or domain is not available in other contexts) embody related ideas. The term can be opposed to general process skills, where cognitive differences between taxonomic groups are thought to reflect broad, unspecialized abilities based on large and/or diffuse neural substrates.

1.08.1 Introduction

The term 'encephalization' expresses different ideas in different scientific disciplines. In comparative biology, it describes the difference between animals in the amount of neurons available beyond the average determined by allometric body design (e.g., Jerison, 1991; Schoenemann, 2004). Porpoises, for example, are said to be more encephalized than tenrecs because they are far above the regression line of log brain size plotted against log body size for all mammals, while tenrecs are far below. In paleoanthropology, encephalization designates the observed increase over evolutionary time in the absolute and relative size of the brain in hominids (e.g., McHenry, 1994; Bruner *et al.*, 2003; Rightmire, 2004; Stedman *et al.*, 2004). The brain of *Homo erectus*, at *c.* 1000 g, is thus considered to be more encephalized than the brain of *Australopithecus*, at *c.* 500 g. In neuroanatomy, encephalization describes the increased importance that higher brain structures play over lower ones in birds and mammals compared to other vertebrates and to invertebrates (Reiner *et al.*, 2004). In this view, the average mammal brain is more encephalized than the average fish brain.

Despite their differences, all three usages share one common assumption: the information-processing advantage provided by extra neurons, increased size, and increased forebrain involvement should normally be the major evolutionary driving force behind encephalization. Extra neurons in the forebrain, whether they evolve in a hominid, a cuttlefish, a capuchin monkey, or a crow, should provide faster and/or more complex and/or a greater amount of information processing and information storage about changing environmental conditions. Natural selection can lead to efficient genetically biased responses to conditions that are stable over long periods of time. But when relationships between events change rapidly, neuronal storage allows animals to respond faster than information stored only in the genome. The main functional and evolutionary hypothesis on encephalization is thus that something about extra neurons, increased size, and increased forebrain involvement is associated with the speed, complexity, and amount of information processing in these structures.

It is useful to envision variation between animals in information-processing capacity as a cognitive continuum. A corvid, for example, seems to learn more items faster (Wilson *et al.*, 1985) and with more complex processes (e.g., episodic memory, prospection; Emery and Clayton, 2004) than a columbiforme does. Its higher brain centers (the meso- and nidopallium) are eight times larger than that of a columbiforme of the equivalent body size (Rehkämper *et al.*, 1991a; Boire, 1989). The whole brain of a corvid is more than 1.5 standard deviations above that of the average bird, while a columbiform brain is 1.5 standard deviations below. This kind of organ–function correlation is not very controversial when it involves wings and flight or beaks and feeding. When the correlation involves brains and cognition, however, this is often a different story. Critics plead that cognitive complexity is difficult to assess in a way that is

fair to all species (Macphail, 1982). They say that brains have many contradictory functions unlikely to lead to directional selection for an overall size increase (Shettleworth, 1998). Others claim that a correlation between morphology and function does not necessarily imply adaptation (Gould and Lewontin, 1979) and point out that adaptationist accounts of brain–cognition co-evolution in humans have often been politically tainted (Gould, 1981; see Human Cognitive Specializations).

Such qualms are legitimate and must be addressed, but they do not invalidate a critical empirical examination of brain–cognition questions. How is brain size variation distributed among taxa? Is the distribution continuous or patchy? Is it whole brain variation that we should be concerned with or variation in some specific structures? Is it relative rather than absolute size of neural structures that matters and if the former, relative to what? Can we reliably show that brain size variation is associated with variation in cognition? How did the variation evolve? What are the costs and benefits of larger versus smaller brains, and in what ecological contexts do these costs and benefits apply? These are the who, what, and why questions we will examine in this article.

1.08.2 How Is Encephalization Distributed Among Taxa?

1.08.2.1 Variation Between Classes

Size and structure of the central part of the nervous system differ clearly between the major animal taxa. From the nerve ring of nematodes to the cerebral ganglion of insects to the brains of cephalopods, birds and mammals, there are major discontinuities in the size and organization of the central organs. If we were to statistically partition the variance in nervous system characteristics over all animals, we would likely find that most of it lies at very high taxonomic levels. Neurons themselves are highly conserved in all animals, as are synaptic processes. For example, memory appears to be based on similar rules of long-term potentiation via glutaminergic synapses from Aplysia (Bailey *et al.*, 2000; Pittinger and Kandel, 2003) and cephalopods (Hochner *et al.*, 2003) to humans. The basic building blocks of learning and cognition might thus show a strong constancy throughout evolution.

The way these neurons are organized in the brain and how many of them are available for more complex information processing also appear to be conserved within major taxa. A mammalian brain is, on average, larger than an avian brain and features a laminar cortex, while avian brains are organized in discrete nuclei (Karten, 1997). In turn, bird brains are larger than cephalopod brains, which are organized in supra- and subesophagal lobes. These average differences have sometimes led to a *scala naturae* vision of brain evolution, where more recent lineages are seen as more encephalized on average than older ones. At least two hypothetical mechanisms could produce such a trend. The first is the possibility of an evolutionary arms race. The oldest animals on earth had no nervous system at all. These were followed by animals with neurons that are linked by a central chain, then by animals with neurons linked to a central organ. Odontocetes and apes have the largest brains and are relatively recent (23 and 34 My respectively; Marino, 2002; Marino *et al.*, 2004). The assumption here is that the bigger the brain, the more information it can store, the faster it can change behavior in response to environmental contingencies (Sol, 2003), and the more complex a behavioral repertoire it can program (Changizi, 2003). Animals that can do more of all this are assumed to have an advantage over those that can do less, once the costs of an enlarged brain are taken into account. A further positive feedback effect of the behavioral flexibility associated with larger brains may add extra pressures for encephalization via social channels. The more flexible the behavior, the trickier it is for other animals to predict and the more useful is a large brain to make such predictions and change behavior quickly in response to the rapid change of others (Byrne and Whiten, 1988). The consequence of these mechanisms is that a competitive arms race might then follow, as it does for sexual selection, limited by the costs of increasing the size of the organ.

The second evolutionary phenomenon that would lead to encephalization over time is behavioral drive (Wyles *et al.*, 1983; Wilson, 1985). All other things being equal, animals that come into more frequent contact with environmental conditions likely to provide a selective context for randomly occurring mutations should be characterized by faster evolutionary rates. Opportunism, generalism, and invasiveness are three traits that will increase the rate of contact with new selective pressures. If these traits are associated with larger brains (see below), then encephalization should also correlate positively with rate of evolution. Because generalism and invasiveness also make animals more likely to range farther, they should also increase the probability of allopatric speciation. If larger-brained taxa beget more descendant species than smaller brained ones, then the average size of the brain

should increase over time. The fact that individuals from larger-brained species tend to have fewer descendants per unit time than those from smaller-brained taxa will, to a certain degree, counteract the positive effects of an arms race and behavioral drive.

Discontinuities in encephalization over major clades prompted comparative psychologists in the 1960s to ask whether certain learning differences paralleled neuroanatomical trends. Overall, the results of these programs tended to show that there are quantitative differences in learning performance in the direction predicted by encephalization differences. Some researchers however, have questioned the heuristic value of these findings. One comparative learning researcher, Riddell (1979, p. 95), ironically summarized his experience:

> The comparative psychologist often appears to know little more than a grade school child who would rather have a pet dog than bird, or bird than fish, or fish than worm, simply because they make better friends, as they can be taught more.

Beyond these problems, there are two other limits to comparisons between classes: small sample sizes and the overlap between the encephalization distributions of the taxa. Because each class is $n = 1$, comparative statistics cannot be used to test predictions about the costs, benefits, evolutionary history, ecological associations, and behavioral correlates of encephalization. Comparing the average fish to the average bird to the average mammal has a sample size of 3. Some birds are as or more encephalized than some mammals. If a crow has a larger brain and more complex cognition than does a tenrec, is it useful to think of an average mammal versus an average bird? Intraclass variance might be biologically as important as interclass variance and the question of whether similar patterns govern intraclass or order variation in different taxa might be the more useful one to ask.

1.08.2.2 Variation Within Classes

The study of intraclass variation solves the statistical problem mentioned above (classes Aves vs. Mammalia: $n = 2$; variation between avian species: $n = 10000$). It also increases the validity of cognitive comparisons by measuring animals with more similar sensorimotor worlds. Comparing the results of several within-class or within-order analyses might thus be a good way of finding general patterns in encephalization.

The taxonomic distribution of a trait as well as its co-occurrence with other traits can be due to two types of processes: ancestral descent and repeated independent evolution. Ancestral descent may represent simple inertia or it may be the source of an important adaptive radiation. To separate ancestral descent and repeated independent evolution, we must know something about the phylogeny of the taxon and control for its effects on the distribution of apparently co-evolved traits. Most phylogenies today are based on differences in molecular sequences of either nucleic or mitochondrial DNA. When a well-resolved (a complete, well-differentiated tree at all levels) and robust (different parts of the genome lead to similar phyletic conclusions) molecular phylogeny is not available for a given taxon, a classical taxonomy, based either on Linnean characters or cladistics is still useful, but some degree of resolution will be sacrificed, usually yielding nonbranching elements and/or equal branch lengths (i.e., with no known genetic distance or estimated time of divergence).

Evolutionary biologists have long been concerned that interpreting correlations between traits in extant species as adaptive consequences of co-evolution might be biased by two sources of type 1 error (Felsenstein, 1985; Harvey and Pagel, 1991). First, two species might show similar values on two traits because they are closely related, not because of independent evolutionary events. This violates the assumption of data point independence for correlations and inflates the sample size via pseudoreplication. The similar values might thus be the result of inertia from an ancestral state, and cannot be considered the result of adaptive co-evolution. Techniques such as independent contrasts have since been routinely applied to trait correlations to deal with such problems. Contrasts are nodal differences between estimated ancestral values of the traits we are interested in. The nodes represent hypothetical ancestors, whose values are assumed to be averages of the trait values for the two branches descending from the node, often weighted for genetic distance. While the trait values of a given pair of taxa may not be independent, the difference between them can be assumed to represent independent evolution. Imagine that we have data for relative brain size and for diet breadth on 100 species and that the independent contrasts yield a nonsignificant correlation between the two traits. Comparative biologists will usually conclude that the null hypothesis for adaptive co-evolution has not been rejected. Imagine now that you examine the taxonomic distribution of your two traits and find that of the two subgroups in your taxon, one contains 85 large-brained species whose diet varies from three to ten food types, and a second one contains 15 small-brained species whose diet varies from one to four food types. What can we conclude?

That there has been no repeated co-evolution of generalist diets and large brains in this order? In all likelihood, yes. That diet and brain size cannot be proven to have had a selective effect on each other in this group? Yes. However, if we run a normal regression (nonphyletically corrected) on the 100 extant species and find a highly significant brain–diet correlation, we would run the risk of type 2 error if the nonsignificant contrast analysis leads us to conclude that the observed pattern contains nothing of evolutionary interest. Clearly, species that combine large brains and a generalist diet are or have been in the recent past quite successful. How they got the combination of the two traits is what a nonsignificant regression on the independent contrasts tells you: they inherited it from their ancestors and the combination did not appear through repeated independent evolution.

Despite its difficulties, the phylogenetic approach has two advantages: the occurrence of repeated independent events is a much more stringent test for adaptative co-evolution than is a single ancestral event. Phyletic trees, combined with molecular clocks, can also generate hypotheses on evolutionary sequences and timescales. If the large-brained generalist combination occurs in six widely separated clades and there is more brain size variance at older phyletic levels, (corresponding, say, to 100 My BP) and more diet breadth variance at more recent levels (say, 20 My BP), then we can hypothesize that large brains in general allow the evolution of broader diets, because variation in brain size precedes variation in diet. For example, most of the variance in avian brain size is at high phyletic levels like the parvorder. The molecular data of Hedges *et al.* (1996) suggests that divergence of extant birds at this level is 100–125 My old and may coincide with episodes of continental splitting. In contrast, the variance in avian innovative feeding (see below) is highest at much more recent levels of divergence, e.g., the species. The hypothesis that brain size divergence preceded feeding divergence thus follows and can be tested with statistical techniques such as path analysis.

1.08.3 What Is Encephalized?

1.08.3.1 Relative Brain Size

As recently as the 1960s, some researchers had a logic based on uncorrected absolute size for their evolutionary and/or ecological hypotheses on encephalization. Most researchers today (although see Byrne and Corp, 2004, for discussion) assume that encephalization should be studied after some kind of complete or partial control for allometry, often assessed by body size (see Scaling the Brain and Its Connections, Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals, Principles of Brain Scaling).

Usually, body size allometry is considered a confounding variable and is removed from most analyses of relative brain size. The assumption here is that as a body gets bigger, it takes more brain cells to analyze the information coming from more skin, a bigger retina, larger ears, a bigger nose, as well as to program more motoneurons for bigger and more numerous muscles. It also takes more interneurons to mediate all this added sensory and motor machinery. The brain–body relationship is not 1 to 1. As bodies get bigger, the increase in brain size follows at a slower pace. Not all organs follow this trend; the heart/body relationship, for example, is linear even when the data are not log transformed. The brain is thus a peculiar organ and its relationship with body size may differ from that of other organs. The decreasing slope of the brain–body relationship might mean that ever-larger bodies require proportionally fewer and fewer extra neurons in the brain or that the cost of enlarging the brain increases faster than the cost of enlarging the body. However, metabolic costs, one of the best known costs of encephalization (and the interpretation often cited for the slope of the log-log brain–body line; Martin, 1981; see however, Symonds and Elgar, 2002), decrease with body size. As animals get bigger, there is less surface-to-volume heat loss, body temperatures decrease, and it takes proportionally less energy to fuel a large body compared to a small one.

Another problem with using body size as an allometric control is that selection, both natural and sexual, operates on it and that a seemingly small brain relative to a large body may simply mean that there has been stronger selection on an enlarged body than on an enlarged brain. When sexual selection for enlarged bodies leads to gender dimorphism, this presents a further problem, though one possible solution is to take only the brain and body measurements of the gender under the lowest sexual selection pressure. Selection for specific organs that make up a large proportion of the body could also affect total size estimates. Herbivores and folivores have a large digestive system because the low digestibility and nutrient quality of their food requires larger amounts of food and longer digestion. Gorillas and ruminants may thus have a spuriously small relative brain size if allometry controlled via body size is biased by selection on a large digestive system. Some estimates

of size (e.g., body length) may be less sensitive to this problem than others (e.g., mass), but the general problem remains. An alternative explanation for small brains in herbivores and folivores would argue that the demands of eating leaves and grass do not select for a large brain relative to body size because these foods are abundant and predictable, but the point is that both explanations are logical.

A third problem with body size is that large bodies are associated with longer generation times. When environments change, there are two ways an animal can modify its response. First, natural selection can increase the frequency over successive generations of alleles (mutated or already appearing in low frequencies) coding for traits that lead to higher fitness in the changed conditions. Alternatively, phenotypic plasticity such as innovation, individual learning, or social learning may allow animals to track the changed conditions. If large brains favor behavioral flexibility and large bodies (and brains; see below) decrease the rate of natural selection via long generation times, then bodies again will not have a neutral effect on brain size. Encephalization might thus follow evolution of enlarged body size, as Nealen and Ricklefs's (2001) analysis of birds suggests (but see Deaner and Nunn, 1999 on primates).

One proposed solution to the problems posed by body size allometry is to use a part of the nervous system itself as a control. This solution also reduces the measurement error inherent to estimates such as body mass, which can change rapidly as a result of food conditions. Harvey and Krebs (1990), Barton (1999), and Deaner *et al.* (2003) have pointed out that such measurement errors can create spurious positive correlations between relative brain size and other allometrically corrected variables such as life history traits. For example, correcting absolute brain size and longevity by the same erroneous body mass estimate will create a similarly high residual of the two traits in a species whose correct mass is underestimated by the erroneous estimate, and a similarly low residual for the species whose mass is overestimated. These correlated errors may create artificially correlated traits.

When a part of the nervous system is used to remove allometry, we need to specify the higher level centers that are assumed to be more closely involved with cognitively driven encephalization and the lower brain areas that can be used as the control. For this, we depend on neuroanatomy and neuropsychology. The encephalized areas can be very broad, such as the telencephalon in birds and mammals or the supraesophagal lobes in cephalopods. The areas chosen for the allometric control could, for example, be the brainstem in birds and mammals and the subesophagal lobes in cephalopods. The lower brain structure could be either that of the species itself or of a primitive evolutionary baseline. Portmann (1946, 1947a, 1947b) pioneered the use of these methods, which were later applied to mammals and cephalopods by Wirz (1950, 1959) and primates, bats, and insectivores by Stephan and collaborators (Stephan *et al.*, 1988, 1991; Baron *et al.*, 1996). In birds, the primitive reference group is usually galliformes, while in mammals, it is insectivores. For this method of removing allometry, there are thus three assumptions: the upper brain structure is the one most closely involved in encephalization, the lower brain structure has been subject only to the allometrically driven selection, and encephalization can best be understood by comparing primitive taxa to more recently encephalized ones. All these assumptions can be questioned.

Whether one uses whole bodies or lower brain structures as controls, there are in essence two statistical approaches to the removal of allometry: residuals and ratios. Residuals use the deviation from the best fit log-log regression as the measure of relative size, often transformed to a standardized scale so that all distributions are comparable from one analysis to another and normalized for parametric statistics. A problem with residuals is that they all change when you add only one new species. If this species has unusual weighting in the data point cloud, this will have a strong effect on all residuals. For example, if you add Rehkämper *et al.*'s (1991b) 23 hummingbird species to Portmann's (1947a) 140-species database, you tip the best-fit line counterclockwise due to the small body and brain size of hummingbirds. This might introduce an artifact due to the particular flight mode of hummingbirds, which might constrain both brain and body size evolution. You would thus be allowing a taxon that is a special case to influence every single residual.

In analyses that use ratios, the numerator is the brain part predicted to be most closely involved in cognitively driven encephalization (e.g., the neocortex of mammals, the mesopallium–nidopallium complex of birds, the vertical lobe system of cephalopods, and the mushroom bodies of insects; see below). The denominator is either a structure that encompasses the one in the numerator (e.g., whole brain or telencephalon or supraesophagal lobes or cerebral ganglia) or the lower brain structure not thought to control cognition (e.g., the brainstem, the subesophagal lobes, and the spinal ganglia). Allometric effects are assumed to be (wholly or partly; see below) controlled in ratios, because they apply to both the numerator and denominator.

One problem with ratios is that they are not normally distributed and thus present a statistical problem for parametric statistics. Large ratios tend to get larger faster than do small ratios. For example, parrots and corvids may easily reach values of 20 in a Portmann ratio, while ducks vary only around 1.6. Log transformations of the ratios can solve the problem by compressing the skewed high values (Lefebvre *et al.*, 1997). A second, more important, problem is that ratios may not entirely remove the confounding effect of body mass (Deacon, 1993). If we conclude, for example, that carnivory is associated with large brains and our estimate of relative brain size is confounded with body mass, there is a risk of type 1 error if carnivores also have larger bodies. In this case, the apparent brain–diet relationship could be a spurious effect of the brain–body and diet–body associations.

A third problem is that ratios of variables whose relationship is not 1 to 1 will overestimate one end of the continuum and underestimate the other. The lower the slope is below 1, the more neural structure size (normally plotted on the y axis) of animals that are at low values of the x axis will be overestimated. When the slope is above 1, the reverse will hold, with larger x values being overestimated. It is well known, for example, that expressing relative brain size as the proportion of total body mass represented by the brain will result in higher ratios in chickadees than parrots simply because chickadees are much smaller (Packard and Boardman, 1999). The brain-to-body-size ratio is often used in human paleoanthropology. The same problem may occur if the telencephalon is expressed as a proportion of the whole brain or the neocortex as a proportion of either the brain or the telencephalon (Clark *et al.*, 2001; Burish *et al.*, 2004). If the structures are thought to be progressive, the slopes of the y–x relationship are likely to be higher than 1. This will overestimate the larger-brained species (Barton, 2002), potentially favoring type 1 error of any prediction associating relative brain structure size and cognition.

It may be noted that one quantitative expression of encephalization, Jerison's (1973) encephalization quotient (EQ), combines the advantages and disadvantages of residuals and ratios. EQ expresses relative brain size as the ratio of the observed (unlogged) y value of a given species on a log-log body–brain graph, divided by the unlogged y value of the best fit regression for the x value of the species. If a species has a brain size of 20 g and the y value of the brain–body regression for an equivalently sized animal is 5, then EQ = 4. If the brain mass of a small-brained species of equivalent body size is 2.5, then EQ = 0.5. Given that EQ is based on a log-log regression, it is statistically better to calculate standardized residuals from this regression, which by definition will be normally distributed, instead of using ratios, which are not. If EQ was intended as a reference to IQ, it is puzzling that Jerison did not express his results as standardized residuals fitted to a mean of 100 and a standard deviation of 16. On this scale, parrots would score around 130, while quail would score around 75. Another problem with EQ is that values calculated from a regression line at one taxonomic level may be biased when they are used to test a hypothesis at another taxonomic level. For example, the EQ values of cetaceans (see Cetacean Brain Evolution) are routinely calculated with respect to the log-log regression line for all mammals. If one then tests a hypothesis on variation within cetaceans only, EQ may hide a confounding negative correlation with body size; small-bodied cetaceans tend to have larger EQs than large-bodied ones (Marino *et al.*, 2006). Allometry can thus still be present in EQ, even if the calculation was initially designed to remove it.

1.08.3.2 Whole Brains or Parts Thereof?

Are larger whole brains the consequence of selection for increased size of some of its components only or is enlargement of the whole brain the means by which larger specific structures evolve? Do these components vary independently of others or are there functional links between anatomically distant areas that cause change in them to occur together? The answer to these questions will depend in part on how much room the components occupy in the brain. The higher the proportion of the whole brain a component structure occupies, the more its enlargement will have a consequence for the size of the whole brain. For example, the mesopallium–nidopallium complex of a crow represents 72% of its telencephalon, which represents 78% of its whole brain. When we say a crow has a large brain, we might really only be saying that it has a large mesopallium. Selection for an enlarged high vocal center (HVC) or hippocampus in a chickadee will not have that effect, because these are small structures compared to the whole brain.

1.08.4 Why Be Encephalized?

1.08.4.1 Costs

Encephalization should normally only occur if the benefits of enlarged brains exceed its costs. These benefits and costs will operate in specific lifestyles,

which need to be specified in any evolutionary account (Johnston, 1982). The two major costs to encephalization appear to be developmental and metabolic (Bennett and Harvey, 1985b). All other factors being equal, bigger brains require a longer time to develop and are energetically more expensive to maintain. The metabolic cost of brains is particularly high in humans and other primates (Aiello and Wheeler, 1995; Aiello and Wells, 2002; Fish and Lockwood, 2003), but less clear in other taxa (e.g., bats; Jones and MacLarnon, 2004). It is important to note that both metabolism and development are related to body size and diet and that their relationship to brain size is thus likely to be complicated by these interactions. If slower development means fewer offspring per unit time and is an allometric correlate of large body size, then the relative importance of natural selection and behavioral flexibility as alternative mechanisms to track environmental change will be affected. If high metabolic rate is associated with the higher surface-to-volume mechanism of heat loss in small-bodied animals, then this might affect the amount of energy available for encephalization. If herbivores are on average characterized by precocial development, low metabolic rates due to low nutrient quality, large ranges required to collect large amounts of low-quality food and large body size due to selection for an enlarged digestive system as well as defense against predators, then all these factors are also likely to affect brain size.

The brain develops slowly and some researchers have proposed that it is the major developmental constraint on time to reproduction (Sacher, 1978). Apart from parental behavior, four life history traits will affect the number of descendants per unit time, which affects the selection probability of a mutation favoring adaptation to environmental change: length of the reproductive period (reproductive longevity, time to sexual maturity), number of offspring per reproductive event, time to sexual maturity of the offspring, and time intervals between successive reproductive events. An animal that lives for 25 years, takes 5 years to mature sexually, and has one offspring every 2 years will have far fewer descendants at the end of 100 years than an animal that has three offspring per yearly reproductive event, lives for 5 years and takes 1 year to mature. Changes due to selection will occur much more slowly in the first species because fewer generations per century mean both fewer mutations and less differential reproduction, thereby increasing the value of behavioral flexibility as a mechanism for change.

1.08.4.2 Benefits

The major hypothesis for the explanation of encephalization is that bigger brains allow enhanced cognitive abilities, abilities useful in certain lifestyles. The problem then becomes the definition of enhanced cognitive abilities and the lifestyles they could be useful in. This hypothesis can be tested by specifying the lifestyles that could benefit from more complex cognition, operationalizing the complexity of cognition, then looking for a statistical association between lifestyle, brain size, and cognitive complexity. General cognitive complexity can be opposed to specialized cognitive skills associated with specific lifestyles in a restricted set of taxa. The spatial memory associated with food caching in corvids and parids or brood parasitism in cowbirds is thought to be one example of the latter, as is the acoustic memory associated with song repertoire size in oscines (DeVoogd *et al.*, 1993). In these cases, specialized neural structures are studied and the cognitive variation is relatively easy to operationalize: memory for more cache locations or acoustic memory for more songs. The small size of the structures (HVC, RA, hippocampus) implies that they are unlikely to form the basis of encephalization. What we are looking for instead is variation in unspecialized cognition over potentially all species, based on the involvement of a large enough part of the brain that can address the issue of whole brain encephalization.

The difficulty is operationalizing unspecialized cognition in all species. Researchers usually look to abilities associated with complex cognition in humans. If we want to include as many taxa as possible in our tests, we have to look outside of tests that only a few nonhuman species can solve, such as learned sign language, episodic memory, fast-mapping, or understanding of the mental states of others (theory of mind). Associative learning is one obvious possibility. If we define the continuum of cognitive complexity as the latency of or the number of errors in learning, however, we face the problem of confounding variables and ecological validity. If a crow solves a learning test in the lab faster than does a kiwi, this might be because that the crow is tamer and less neophobic in the lab, the task favors visual rather than olfactory cues, or the task resembles situations crows encounter often in the field but kiwis do not. What we need is cognition that occurs spontaneously in the field, without the confounding variables of tests in captivity and in a situation that is natural to each animal. Tool use, play, and presumed deception and social learning are possible choices. We can also look to innovative behavior.

We then plot the taxonomic distribution of our cognitive measure from the field and see if, as predicted by encephalization theory, the distributions correlate positively with relative brain size, taking out as many confounding variables as possible. If the results of field and laboratory tests are positively correlated, this would support the assumption that they are both valid estimates of cognition. Research on birds and primates, based on re-analyses of published data as well as new tests (Webster and Lefebvre, 2001; Reader and MacDonald, 2003; Lefebvre *et al.*, 2004), suggests that tests in captivity are indeed positively correlated with field measures. We can further test our assumption that unspecialized cognition exists by predicting positive correlations between the distribution of the different cognitive measures. All of these relationships have been tested in birds and primates (see below). Overall, the analyses conducted up to now on the two taxa suggest convergent evolution of interspecific variation in cognitive abilities (see also Emery and Clayton, 2004). Similar positive correlations between innovation rate, tool use rate, and reversal learning performance have been found in birds and primates, perhaps suggesting that these cognitive abilities are nonmodular (Lefebvre *et al.*, 2004). The only exception for the moment seems to be the relationship between food storing and innovation in 22 species of birds; a negative relationship is found in New World corvids and Old World parids, suggesting a (possibly modular; Lefebvre and Bolhuis, 2003) trade-off between storing and innovativeness.

It is important to note that correlations between brain size and cognitive variables do not demonstrate the survival value of having a large brain, nor are they evidence for natural selection on enlarged brains. The correlations suggest that large brains are on average present in tool using, innovative, playful, social taxa that develop slowly, but they also suggest that small-brained taxa can do well, provided their lifestyles do not include these attributes. A survey of long-term population trends (1968–95) in 40 British bird species provides evidence for selection on large over small brains, with larger declines observed in small-brained species than in large-brained ones (Schultz *et al.*, 2005). Sol *et al.* (2002, 2005) examined colonization success of introduced birds in different parts of the world; some species succeed almost everywhere (e.g., sparrows and blackbirds), while others are extinct after only a few years. Relative brain size (and innovation rate in the zone of origin) significantly predicts variance in colonization success. Contrary to natural invasions, where unsuccessful cases are seldom documented, introductions allow good coverage of the entire spectrum of responses. If introductions are an unbiased estimate of all invasions, then establishment in new areas might be one of the key selective forces that affect encephalization trends (Sol *et al.*, 2005) and the allopatric divergence that often follows invasion, a key mechanism in the association between speciosity and relative brain size in birds (Nicolakakis *et al.*, 2003).

1.08.4.3 Ecology and Lifestyles

To express ecological theory in a very simplified way, the distribution of abiotic factors drives the distribution of vegetation, which in turn drives the distribution of animals. Lifestyles (diet, sociality, and sexual selection) are then driven by the distribution of animals and plants. If biotic and abiotic resources are spatially and temporally predictable and in relatively low-density clumps, a specialized, conservative, territorial polygynist with monoparental care may do better than a generalist, opportunistic, invasive, gregarious monogamist with biparental care. The reverse would apply to spatially and temporally unpredictable resources found in abundant patches. We would then expect selection to act on cognition to provide the information-processing capacity that best suits each lifestyle, with accompanying selection on encephalization (Bennett and Harvey, 1985a). Testing the idea that omnivory should be associated with brain size is thus not an ecological prediction on cognition, but a dietary prediction on encephalization with two missing links: how does resource distribution favor omnivory and how does omnivory require more complex cognition or lift dietary constraints on brain size? The use of an ecological framework is all the more important because the same resource distribution may lead to similar predictions on lifestyle differences that are sometimes viewed as independent pressures for complex cognition and encephalization. For example, social and diet breadth pressures on the evolution of cognition and brains are often seen as alternatives (see Forebrain Size and Social Intelligence in Birds). If, however, one type of resource distribution favors gregarious generalists and another favors territorial specialists, then the two pressures go in the same direction. Whether or not the lifestyle differences are independent is a matter of empirical test (with multivariate techniques, for instance), not a logical *a priori*.

Diet (Eisenberg and Wilson, 1978), sociality (Dunbar, 1992; Dunbar and Bever, 1998), sexual selection (Madden, 2001), and parental care (Gittleman, 1994) have all been shown to be associated with encephalization. In some of these tests, we do not know to what extent the apparent

co-evolution of the traits is due to common ancestry or repeated independent events, given that independent contrasts have not been conducted. Larger brains have been found in omnivorous and frugivorous groups (Allman *et al.*, 1993) compared to folivorous or herbivorous animals. For sexual selection, there is interspecific evidence for an association between brain size and bower building (Madden, 2001) and intraspecific evidence for an association between telencephalon size and song repertoire size in zebra finches (Airey and DeVoogd, 2000). Monoparental versus biparental care, which is a consequence of sexually selected mating systems, has also been implicated in brain size differences (Gittleman, 1994).

1.08.5 Mammals

Mammalian encephalization has received considerable scientific attention, probably because the class contains two of the most encephalized orders, primates and cetaceans, and because we humans number among the 5000 or so mammal species (see Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals). Mammals thus provide a valuable case study for understanding the selection pressures favoring evolutionary changes in brain size, with many hypotheses regarding brain evolution originally applied to mammals and relatively large databases of whole brain and brain component volumes available (for extensive discussion, see the articles on brain evolution in mammals, various mammalian orders, and humans, this volume, e.g., Primate Brain Evolution in Phylogenetic Context, The Evolution of Hemispheric Specializations of the Human Brain, The Evolution of Human Brain and Body Growth Patterns, Mosaic Evolution of Brain Structure in Mammals, Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals, Evolution of the Cerebellum, Evolution of the Hippocampus). This has made possible large-scale comparative studies. Moreover, experimental data have been combined with comparative studies of brain evolution, and breeding experiments have also addressed the evolution of larger brains.

Mammalian encephalization, like encephalization in all animals, is generally assumed to result from the selective benefits of enhanced cognitive, perceptual, or motor abilities, with most research focusing on cognition (Macphail, 1982; Barton, 1999). Evidence regarding the assumed link between brain volume and cognitive capacity has come from two sources: correlations of behavioral demonstrations of cognitive ability and brain size, and from associations between enlarged brains and lifestyles thought to require increased cognitive demands. The behavioral data provide a more direct test of the assumption that cognitive capacity and brain size are linked, and so are key in this respect (Macphail, 1982; Deaner *et al.*, 2000). Several lines of evidence in mammals have pointed to a correlation between a species' relative brain volume and its cognitive capacity. First, laboratory learning data collated from a variety of sources has been shown to correlate with relative whole brain size, although the number of species tested is small (Riddell and Corl, 1977). Second, various measures assumed to indicate general cognitive capacities correlate with relative neocortex size: the frequency of reports of tactical deception, innovation, social learning, and tool use all correlate with relative neocortex volume in primates (Reader and Laland, 2002; Byrne and Corp, 2004). These latter measures have the advantage of covering a larger number of species. Third, it has been proposed that the ability to perform apparently complex cognitive acts such as imitation and understanding the intentions of others are associated with brain enlargement (Byrne, 1992). For example, among mammals, the consensus view is that true imitation has only been experimentally demonstrated in large-brained apes and dolphins, while the smaller-brained mammals tested present equivocal evidence of imitation (Mitchell *et al.*, 1999; Caldwell and Whiten, 2002). However, tests of complex cognition have been the subject of much controversy (e.g., Tomasello and Call, 1997). Moreover, because research has tended to focus on only a few, typically large-brained mammal species, it is difficult to know the true phylogenetic distribution of such traits and to conduct proper comparative analyses.

Problems with comparative studies can be solved by experimental studies of evolution. Studies on rhesus macaques and mice have demonstrated that brain size is heritable (Jensen, 1979; Atchley *et al.*, 1984; Cheverud *et al.*, 1990; Markina *et al.*, 2001), which indicates that it is open to modification by selection. Moreover, selection experiments in mice have bred large- and small-brained lines and have found differences between the lines in performance on learning tasks (Markina *et al.*, 2001). Interpretation of these findings is controversial, not least because learning ability is inferred from performance and a number of other behavioral changes are observed in the selection lines, such as changes in anxiety or exploratory behavior (Jensen, 1979; Johnston, 1982; Markina *et al.*, 2001). A further problem is that selection on learning performance has tended to result in selection for task-specific abilities (Jensen, 1979). Moreover, the critical test of whether selection on learning capacities can lead to evolutionary changes in brain size would be to

select for cognitive ability and to examine the effect on brain size (Johnston, 1982). As far as we are aware, such experiments have not been done, although one study reports a decrease in size of a hippocampus area in mice lines exposed to environmental stressors (such as natural predators; Poletaeva *et al.*, 2001).

The vast majority of work on encephalization has focused on identifying the selection pressures associated with brain enlargement. Hypotheses have tended to fall into two camps, social and ecological explanations for brain enlargement. Social (or Machiavellian) intelligence hypotheses argue that enlarged brains evolved as an adaptation to living in large, complex social groups (Jolly, 1966; Humphrey, 1976; Byrne and Whiten, 1988; Flinn, 1997; Whiten and Byrne, 1997). Byrne and Whiten (1997) distinguish the term "narrow Machiavellianism," the idea that it is selection for strategies of social manipulation or deception that has driven brain evolution, from their own broader use of the term "Machiavellian intelligence," which includes all forms of social intelligence such as social learning. Ecological explanations for the evolution of large brains are also common and include the extractive foraging (Parker and Gibson, 1977) and cognitive/spatiotemporal mapping hypotheses (Milton, 1988; Deaner *et al.*, 2000). Unpredictability and patchiness of resources are often cited as key ecological factors favoring brain enlargement (Eisenberg and Wilson, 1978). For example, fruit is likely to be distributed more patchily in space and time than are leaves, and so a fruiteating diet may be expected to have more cognitive demands than a leaf-eating one. Technical intelligence hypotheses that argue that technology or technical skills drove brain evolution can be considered with the ecological intelligence hypotheses, because they tend to focus on foraging or antipredator tool use (Passingham, 1982; Byrne, 1997a, 1997b).

What evidence is there in support of these hypotheses? Relative neocortex or brain size is positively correlated with social group size in nonhuman primates, carnivores, cetaceans, bats, and some insectivores, consistent with social intelligence hypotheses (Worthy and Hickie, 1986; Sawaguchi and Kudo, 1990; Dunbar, 1992; Marino, 1996; Barton, 1999; but see Connor *et al.*, 1998; van Schaik and Deaner, 2003 on cetaceans). In ungulates, social species tend to have larger relative brain and neocortex sizes than do nonsocial species, (Schultz and Dunbar, 2006). Barton (1993) finds a correlation between group size and neocortex size in haplorhine primates, but not strepsirhines, which may indicate that group living favored brain size evolution among haplorhines only. Adding support to Machiavellian intelligence hypotheses, the frequency of reports of deceptive behavior has been found to correlate with relative neocortex size (Byrne and Corp, 2004). The findings that human and other primates tend to have superior abilities in problems involving social knowledge versus those involving nonsocial knowledge has also been taken as evidence that cognitive abilities developed as a response to social pressures (Cheney and Seyfarth, 1988; see also Baron-Cohen *et al.*, 1999).

In support of ecological intelligence ideas, diets presumed to require increased cognitive demands have been shown to correlate with relative brain volume in several mammalian groups. For example, primate relative whole brain size and neocortex size correlate with frugivory (Barton, 1999) and diet breadth and relative neocortex volume are correlated in African anthropoid primates (Reader and MacDonald, 2003). Similar associations with diet, albeit not based on independent contrasts, have been found in bats (aerial insectivores have smaller brains for their body size than frugivores and nectarivores, with piscivores, foliage gleaners, carnivores, and sanguivores falling between the two extremes; Eisenberg and Wilson, 1978), small mammals (in rodents and lagomorphs, folivores and insectivores have small brains relative to their body mass and body length compared with those of other dietary categories; Harvey *et al.*, 1980), and the Carnivora (carnivorous and omnivorous species have larger relative brains, though not significantly so, than insectivorous carnivora; Gittleman, 1986). In a phylogenetically controlled study of 59 bat species, Ratcliffe *et al.* (2006) have recently reported a larger relative brain size in species that use a flexible combination of gleaning and hawking techniques, compared to those that are specialized on either of the hunting modes. Home range correlates with relative brain size in primates, in support of spatiotemporal mapping ideas (Clutton-Brock and Harvey, 1980; Deaner *et al.*, 2000). Consistent with technical intelligence hypotheses, tool use frequencies correlate with relative neocortex volume in primates (Reader and Laland, 2002; Lefebvre *et al.*, 2004). However, the fact that few primates appear to make regular use of tools in the wild questions the idea that technical intelligence was a driving force for primate brain enlargement (van Schaik *et al.*, 1999).

A number of other lifestyle correlates of relative brain size have been described. For example, in didelphid marsupials, preference for arboreal activity is associated with relative brain volume (Eisenberg and Wilson, 1981). Cerebellum volume

has also been linked to locomotion mode in primates, bats, and cetaceans (Stephan and Pirlot, 1970; Rilling and Insel, 1998; Marino *et al.*, 2000). Females of carnivore species where the females provide the sole parental care have larger brains than those of biparental or communal species (Gittleman, 1994). Neocortex volume has also been linked to sexual selection, being correlated with mating competition in frugivorous primates (Sawaguchi, 1997).

Potential costs and constraints of mammalian encephalization have received less attention, though there is support for the idea that brain enlargement carries metabolic and developmental costs, with brain size negatively correlated with litter size in marsupials (Eisenberg and Wilson, 1981), and positively correlated with the age of sexual maturity and life span, but not gestation length, in primates (Barton, 1999; Allman *et al.*, 1993; Kaplan and Robson, 2002; van Schaik and Deaner, 2003). In odontocetes, relative brain size is also associated with relative time to sexual maturity and life span. Within life span, however, length of the adult period is more closely correlated with relative brain size than is length of the juvenile period, suggesting that the temporal costs of delayed maturity might be compensated by a longer time as a reproducing adult (Lefebvre *et al.*, 2006). Primate brain size is not correlated with basal metabolic rate, and comparative analysis indicates that improved diet quality, by allowing reduction in gut mass relative to body size, is one possible mechanism allowing the energetic constraints on the evolution of the metabolically expensive large brain to be lifted (Aiello and Wheeler, 1995; Barton, 1999; Fish and Lockwood, 2003).

Given that there is support for a number of hypotheses regarding mammalian encephalization, can any consensus be formed? The findings described above are consistent with the idea that several selective pressures are responsible for the evolution of encephalization. An alternative view is that one factor is driving brain evolution, but that the cognitive abilities afforded by a large brain are applied to other domains. Determining causation is difficult since most comparative studies are based on correlational evidence. Moreover, the divisions between social and ecological intelligence may be fuzzy and social and ecological demands on cognition may evolve together, making it difficult to consider social and ecological intelligence hypotheses as alternatives (Barton, 1999; Deaner *et al.*, 2000; Reader and Laland, 2002; Seyfarth and Cheney, 2002). It is also difficult to separate perception from cognitive demands. For example, primate brain size variation is associated with visual specialization. Visual processing may be critically involved in the treatment of both social and ecological information; relative expansion of parts of the visual system is correlated with both frugivory and group size (Barton, 1999). What is clear, however, is that evolution has shaped mammalian brains in response to the demands of their lifestyles, with convergent evolution of brain structures in several groups (De Winter and Oxnard, 2001; Kaas, 2002).

1.08.6 Birds

It was long believed that the avian forebrain was composed of hypertrophied basal ganglia with only meager pallial derivatives, whereas in mammals, the pallium had grown into a highly parcellated laminar neocortex (Ariens-Kappers *et al.*, 1936). The recent revised nomenclature of the avian telencephalon (Reiner *et al.*, 2004) recognizes many anatomical and functional similarities between the avian and mammalian forebrains. In particular, the newly named avian nidopallium, mesopallium, and arcopallium are considered homologous to mammalian pallial derivatives, the neocortex, claustrum, and pallial amygdala (Karten, 1969, 1991; Güntürkün, 1991; Wild *et al.*, 1993; Butler, 1994; Veenman *et al.*, 1995; Striedter, 1997; Reiner *et al.*, 1998; Smith-Fernandez *et al.*, 1998; Medina and Reiner, 2000; Puelles *et al.*, 2000).

A large amount of variance in the size of both adult and hatchling avian brains can be explained by the altricial versus precocial dichotomy in development mode. Birds that develop slowly and require extensive parental care are born with relatively smaller brains than birds that are mobile only a few minutes or hours after birth. The reverse applies to adult brain size, where altricial birds have larger brains than do precocial ones (Portmann, 1946; Bennett and Harvey, 1985a, 1985b). In Bennett and Harvey's study, most of the ecological variables (e.g., diet, habitat) that showed a relationship with relative forebrain size in univariate analyses became nonsignificant when development mode was included in multivariate statistics. Only mating system (monogamous → polygynous) and mode of prey capture (moving from a perch vs. other categories) remained significant predictors of relative size of the brain and forebrain. All large-brained avian clades develop slowly, but the reverse is not true. The altricial Columbiformes (pigeons and doves) and Caprimulgi (nightjars) are, in relative terms, not much more encephalized that the precocial Galliformes and ratites. On average, growing a large brain may impose some limits on incubation

energetics, as well as the length of intrauterine growth. It might not be possible for birds to stock sufficient energy in the egg for extensive brain growth. Stark (1993) offers some interesting observations of the comparison of brain growth in altricial and precocial birds. He found that in the freshly hatched buttonquail, a precocial species, all telencephalic areas and fiber pathways have undergone differentiation and started myelinization. There are no more areas of cell proliferation in the hatchling, indicating that the number of neurons is definite and that postnatal volume increase can be exclusively attributed to growth. Similarly, the optic tectum of the hatchling muscovy duck has almost reached adult size and differentiation level. In contrast, the three altricial species that Stark (1993) studied have a significant posthatch cell proliferation in the periventricular zone. In the budgerigar and Java sparrow, cell proliferation continues until the 10th postnatal day. Stark suggests that a large postnatal increase in the volume of the brain depends on a persistence of this large periventricular proliferation zone, which can be maintained as long as there are no functional demands on the developing systems. This is possible in altricial hatchlings freed from the need for a functional forebrain by extended parental care. Stark (1993) proposed that to arrive at a larger brain volume, more cells have to divide during the proliferation phase. Theoretically, the increase in cell numbers can be achieved in three ways: increasing the rate of periventricular cell division, increasing the area of cell proliferation, or lengthening the proliferation period. There is no empirical support for the first two options in birds; the third option is possible only in altricial species where parental care compensates for the lack of functional independence by the chicks. Stark (1993) also suggests that nutritional constraints on the hatchlings affect the options: precocial species tend to eat foods that can be easily obtained, while altricial ones eat foods that are widely dispersed or difficult to find. In a recent study, Iwaniuk and Nelson (2003) corroborate the conclusions of Stark (1993) using continuous development time measures in addition to the dichotomous precocial/altricial classification. They divide development into four periods: incubation, fledging, postfledging parental care, and total period of parental care. All developmental periods except time to fledging are significantly correlated with brain size, once common allometric correlates are removed. The relationships vary with development mode, and Iwaniuk and Nelson (2003) suggest that factors such as diet and foraging techniques interact with development in determining brain size.

If the relationship between ecology and encephalization appears to be confounded by developmental constraints, this is not the case for more direct measures of cognition. Lefebvre and collaborators have quantified avian cognition in the field by measuring the frequency of novel, unusual, or rare feeding behavior in over 800 species in five areas of the world (see Lefebvre *et al.*, 1997, 1998 for examples). They have collated over 2300 cases of innovative feeding and 130 cases of tool use and shown that both measures of cognition show taxonomic distributions that are positively correlated with relative size of the brain and forebrain (Lefebvre *et al.*, 1997, 1998, 2001, 2002, 2004; Nicolakakis and Lefebvre, 2000). Nine potential confounding variables have been included in these analyses, to ensure that biases inherent to the quantification of anecdotal judgments on novelty and cognitive complexity do not affect the biological trends. One of these confounding variables was development mode, which does not account for the correlation between encephalization and either innovation rate or tool use frequency.

Using the detailed brain data on 32 species from 17 parvorders gathered by Boire (1989) and Rehkämper *et al.* (1991a), and the innovation and tool use rates from previous papers, Timmermans *et al.* (2000) and Lefebvre *et al.* (2002) were able to pinpoint the avian telencephalic areas most closely associated with cognition. Rehkämper and Zilles (1991) and Boire and Baron (1994) have suggested that it is the disproportionate increase of the size of the nidopallium and mesopallium that drove the enlargement of the avian telencephalon. Consistent with these predictions, Timmermans *et al.* (2000) showed that it is the relative size of the mesopallium that correlates most closely with innovation rate. In simple regressions, the nidopallium, hyperpallium (Wulst), and components of the striatopallidal complex were also all correlated with innovation rate, with or without phylogenetic corrections. In multiple regressions, however, these structures dropped out of the model because of their strong correlations with the size of the mesopallium, which explains a larger proportion of the common variance. Lefebvre *et al.* (2002) repeated a similar analysis with two types of tool use, true tools and proto-tools, which are described in over 100 avian species (see also Boswall, 1977, 1978, 1983a, 1983b for comprehensive reviews). Proto-tools involve the use of objects that are part of a substrate, e.g., anvils on which prey are battered or dropped, or wedges and thorns with which food is held. True tools are detached from the substrate, e.g., hammers, probes, scoops, sponges, and levers held directly in the beak or foot;

their use is presumed to require more complex cognition that that of proto-tools. Lefebvre *et al.* (2002) confirmed that true tool users have larger brains than do proto-tools users and that, within the forebrain, relative size of the nidopallium and mesopallium are the best predictors of avian tool use frequency. The mesopallium comprises higher-order, multimodal processing areas. The nidopallium features tertiary areas of this type, but also includes primary projection fields from both somatosensory and visual pathways, as well as secondary areas that receive input from these primary fields (Rehkämper *et al.*, 1985). The nidopallium thus has the necessary features for both the cognitive and sensorimotor aspects of tool use, in particular the integration of visual and somatosensory information involved in the fine manipulation of objects.

Beyond these comparative studies of the whole avian spectrum, a few authors have concentrated on encephalization patterns within particular orders such as Anseriformes, Trochiliformes, and Psittaciformes. Iwaniuk and Nelson (2001) recently examined a large number of waterfowl. This group is of particular interest because it is precocial, keeping constant the main confounding variable identified by Bennett and Harvey (1985a). Iwaniuk and Nelson worked from endocasts of museum specimens of 354 individuals representing 55 species. Their analysis did not show any significant relationship between foraging mode or diet and relative brain size in Anseriformes, which does not preclude that further analyses on finer brain structures might not reveal clearer trends. One interesting species in their sample is the musk duck, *Biziura lobata*. It has a large brain compared to its sister species and also shows a much more altricial mode of development than do other Anseriformes, raising only one or two offspring that do not feed themselves right after hatching, but rely instead on the mother and slowly become independent. Trochiliformes (hummingbirds) were studied by Rehkämper *et al.*, (1991b); they show a level of encephalization intermediate between that of Galliformes and Passeriformes. It is not clear if hummingbirds' encephalization level is a product of relative brain enlargement or selection for small bodies. Boire (1989) and Boire and Baron (1994) suggest that it is cerebellum size that might be the main component of brain enlargement in this order, in line with the complex motor control required for hovering. Terns and swifts, which have more complex flight behavior than other birds, also show an enlarged cerebellum (Boire, 1989; Boire and Baron, 1994). Psittaciformes have recently been examined by Iwaniuk *et al.* (2005), who measured whole brain size in 180 species, as well as the size of brain regions in 19 species. Their study confirms previous work (Portmann, 1946, 1947a; Boire, 1989, Boire and Baron, 1994) showing that this order, which shows complex cognitive abilities (Pepperberg, 1999, 2002; Borsari and Ottoni, 2005), has a larger telencephalon than other nonpasserine birds, while subtelencephalic brain components show a much smaller range of variation. Psittaciformes are among the birds showing transactional social behavior in the classification proposed by Burish *et al.* (2004). This complex form of sociality is associated with larger ratios of telencephalon to total brain size.

Besides the avian equivalents of the mammalian neocortex, the mesopallium and nidopallium, areas such as the olfactory bulb and the hippocampus have also been subject to comparative studies. In general, birds are considered microsmatic, but there is increasing evidence that many of them use smell in foraging, orientation, and homing, as well as site and individual recognition (see references in Healy and Guilford, 1990). There is a large database on the size of avian olfactory bulbs (Bang and Cobb, 1968) showing considerable taxonomic variation; unfortunately, these data are not actual volumes, but the ratio between the largest diameter of the olfactory bulb and that of the longest length of the cerebral hemispheres. This measure is not independent of the size and shape of the cerebral hemispheres, and the data should therefore be interpreted with care. Initial interpretations of these data led to the conclusion that large olfactory bulbs are associated with aquatic habitats (Bang and Cobb, 1968; Bang, 1971). A more careful statistical analysis suggested that nocturnal birds have larger olfactory bulbs (Healy and Guilford, 1990). The hypothesis was that olfaction might be useful for birds in low-light conditions for tasks such as site recognition and location of predators and slow-moving or stationary prey. For the moment, this proposed association between activity pattern and olfactory bulb size is interesting, but awaits a more reliable database. It should be noted that large olfactory bulbs in birds are not generally associated with the enlargement of the telencephalon. However, it has been suggested that in Anseriformes, the increased telencephalization is in part correlated with enlarged olfactory structures (see Rehkämper *et al.*, 2001). This is shown by the considerable expansion of telencephalic targets of olfactory projections (Ebinger *et al.*, 1992). For example, the olfactory structures in Anseriformes are twice the size of those in the pigeon (Ebinger *et al.*, 1992).

In absolute size, the avian hippocampus is quite small compared to that of mammals, but several

studies suggest a correlation between the size of this structure and lifestyles implying more spatial cognition. The hippocampus is larger in food-storing birds than in nonstorers (Krebs *et al.*, 1989; Sherry *et al.*, 1989; Healy and Krebs, 1992, 1996; Healy *et al.*, 1994; Hampton *et al.*, 1995; Basil *et al.*, 1996; Volman *et al.*, 1997). Spatial cognition is not only relevant to food gathering, but also to homing abilities (Rehkämper *et al.*, 1988) and spatial abilities in finding host nests in brood-parasitic cowbirds (Sherry *et al.*, 1993; Reboreda *et al.*, 1996). Some authors (e.g., Bolhuis and Macphail, 2001) have criticized this literature, but Lucas *et al.* (2004) have recently shown that despite differences between species from North America and Europe (Brodin and Lundborg, 2003), there is a clear correlation between the degree of food-caching specialization and hippocampus size in Corvidae and Paridae. In pigeons, breeds that were artificially selected for homing have a larger telencephalon than nonhoming breeds, and this seems to be the result of an enlarged hippocampus (Rehkämper *et al.*, 1988). In food-caching birds, most studies conducted at the species level report no correlation between the size of the hippocampus and that of the telencephalon (Healy and Krebs, 1992, 1996; Healy *et al.*, 1994; Hampton *et al.*, 1995; Basil *et al.*, 1996), but others have found a correlation at the level of the subfamily and family within Passerines (Sherry *et al.*, 1989). It is interesting to note that food-caching experience leads to neurogenesis both in the hippocampus of young marsh tits and in the mesopallium (Patel *et al.*, 1997). This could mean that the more specialized, hippocampal, component of spatial memory may be linked to more generalized problem-solving processes in the mesopallium. This might explain the fact that species differences in food caching in the field are often stronger than those seen in spatial memory tests in captivity. Lefebvre and Bolhuis (2003) report a negative or zero correlation between innovation rate and reliance on food caching in corvids and parids. If the captive tests solicit both specialized spatial memory and more general problem-solving ability, interspecifc differences would be magnified by a positive correlation between the two processes, but dampened by a negative or zero correlation. More research is clearly needed on this point. In the other intensively studied avian specialization, imitated song (Jarvis *et al.*, 2000), correlated evolution of small, specialized nuclei and larger telencephalic structures has been suggested by DeVoogd and coworkers. Airey *et al.* (2000) have shown that zebra finches have heritable variation in both the size of their song repertoire and the size of nucleus HVC, the control center for syllable organization (Yu and Margoliash, 1996). HVC size is positively correlated with whole telencephalon size in zebra finches, leading DeVoogd (2004) to suggest that song repertoire might be an honest signal for general cognitive ability.

1.08.7 Invertebrates

Encephalization has not been as well studied in invertebrates as in vertebrates. Some structures have, however, been thought to play equivalent roles to the ones that the forebrain plays in mammals and birds. Invertebrates often cited for their cognitive skills are the hymenoptera on the one hand and the octopus and cuttlefish on the other (see Cognition in Invertebrates). Hymenoptera have the most complex social behaviors of all insects. Octopus and cuttlefish are at the extremes of the habitat complexity distribution proposed by Hanlon and Messenger (1996, figure 3.9). The same intraclass logic we have applied earlier to birds and mammals can thus be applied to the groups that hymenoptera and octopus belong to, insects and cephalopods. In these classes, the mushroom bodies and vertical lobes, respectively, are the brain structures most often mentioned in studies of encephalization.

1.08.7.1 Insects

In insects, the mushroom bodies have long been seen as the higher centers that might be the substrate of cognition (see Strausfeld *et al.*, 1998, and Farris, 2005, for reviews). They control sensory integration, learning, and memory, and, according to Farris (2005), are convergent equivalents of the mammalian cortex. Their crucial role in memory is evidenced by *Drosophila* mutants that lack both the vertical lobes of the mushroom bodies and long-term (but not short-term) memory (Pascual and Préat, 2001). The insect taxa (ants, honeybees, and wasps) that have evolved complex societies with division of labor, as well as altruistic reproduction and nest defense, have enlarged mushroom bodies (Howse, 1974; Gronenberg *et al.*, 1996; Ehmer and Hoy, 2000). Diet might be as important as social life in determining insect mushroom body size. Mares *et al.* (2005) found that honeybees (*Apis mellifera*) do not have larger mushroom bodies than does the bumblebee *Bombus impatiens*, as one would have predicted from the much more complex social life of honeybees. *B. impatiens* is a dietary generalist, however, which raises the intriguing possibility that specialized species of *Bombus* might have smaller

mushroom bodies than either *B. impatiens* or *A. mellifera*. Farris and Roberts (2005) compared 11 generalist and specialist scarab beetle species and found sharp differences in mushroom body size and structure associated with dietary differences. Generalist (e.g., phytophagous) beetles have larger and more convoluted mushroom bodies featuring double calyces, whereas specialist species (e.g., dung beetles) have smaller mushroom bodies with single calyces. Ontogenetic changes, both natural and experimentally manipulated, that make honeybees switch from larval care to the much more complex task (e.g., learning and dance communication of flower patches, swarming; Seeley and Burhman, 1999) of foraging outside the hive are accompanied by an increase in the Kenyon cells of the mushroom bodies (Withers *et al.*, 1993). Similar results have also been reported for carpenter ants (Gronenberg *et al.*, 1996)

1.08.7.2 Cephalopods

Compared to other classes, the relative brain size of cephalopods is between that of fish and reptiles on the one hand and birds and mammals on the other (Packard, 1972). Within the 800 or so cephalopod species, there is a large degree of variation in learning performance, brain size, and vertical lobe size. The vertical lobe is the area of the cephalopod brain that Nixon and Young (2003) describe as the modulator for the systems that guide visual and tactile responses. Nixon and Young (2003) list the relative size of 14 brain areas in 63 species (see also Wirz, 1959). The data in their table 2.6 are expressed as fractions of total brain size. As Hanlon and Messenger (1996) point out, the two genera that are most often mentioned as intelligent, octopus and cuttlefish (*Sepia*), do not have the largest vertical lobes according to this fraction estimate. However, when we use the more usual technique of regressing either whole brain size or vertical lobe size against body size (in this case, mantle length, given for 49 of the species), the two species are 1.5 (octopus) and 2.5 (cuttlefish) standard deviations above the mean cephalopod regression line. The third cephalopod whose nervous system has been intensively studied, the squid *Loligo*, places around 2 standard deviations above the line.

Many studies have been conducted on associative learning in octopus by Young and his colleagues (Wells, 1966). Three features of avian and primate cognition, innovation, social learning, and improvement over successive learning reversals, have been described in the field by Norman (1999) and in the lab by Fiorito and Scotto (1992) and Mackintosh and Mackintosh (1964). Octopus in Indonesia forage for complimentary fragments of coconut shells thrown by humans in shallow water, using them as portable dens (Norman, 1999). Octopus (Fiorito *et al.*, 1998) can also solve the kind of innovative food-finding problem that passerines, but not doves, readily succeed at (Webster and Lefebvre, 2001; see however, Bouchard, 2002 for pigeons). Finally, octopus that observe a trained conspecific attack a white stimulus (instead of the normally preferred dark stimulus), will also attack the white stimulus when tested alone after the observation sessions (Fiorito and Scotto, 1992). Lesions of the vertical lobe, which are known to affect associative learning in octopus, also affect observational learning, but only over short time intervals (Fiorito and Chichery, 1995). The octopus vertical lobe seems to show evidence of convergent evolution with vertebrate learning mechanisms, with long-term potentiation of glutaminergic synaptic field potentials (Hochner *et al.*, 2003). In cuttlefish, the vertical lobe also appears to be involved in learning. In particular, Dickel *et al.* (2001) show a striking similarity between ontogenetic increases in the relative size of the vertical lobe (but not of other areas) and improvements in learning.

1.08.8 Conclusion

Studies of encephalization often focus on taxonomic differences in the size of whole brains or of forebrain areas. This does not necessarily mean that size is the key causal variable behind differences in cognitive performance. Many other features of nervous systems, e.g., synaptic networks, neuronal density, neurotransmitter facilitation, might be equally or more important. Comparative studies on brain size have often been justified by the ease with which broad data bases could be gathered on preserved brains (Portmann, 1946, 1947a, 1947b), endocasts (Mlikovski, 1989a, 1989b, 1989c, 1990; Iwaniuk and Nelson, 2002) and fossils (Burish *et al.*, 2004; see The Hominin Fossil Record and the Emergence of the Modern Human Central Nervous System). However, recent molecular work suggests that size may indeed be one of the crucial aspects of adaptive evolution of brains. Dorus *et al.* (2004) examined 214 genes in humans, macaques, mice, and rats and found that those with the highest rates of evolution in primates determine brain size. Genes not involved with the nervous system or involved in physiological rather than developmental aspects of the brain showed similar evolutionary rates in rodents and primates. This suggests that size differences may be more than easy proxies for subtler differences in anatomy and function. Disregarding for the

moment the major interclass transitions in the way the nervous system is organized, comparisons within taxa suggest that differences in cognitive performance show convergent co-evolution with differences in the size of association areas and of whole brains. Within the constraints of a highly conserved neuronal and synaptic machinery, building an intelligence might be similar to moving an animal through the air. In the same manner that locusts, bats, and albatrosses have evolved convergent, independent solutions to similar problems posed by gravity and lift, honeybees, cuttlefish, crows, and chimpanzees might also have evolved convergent solutions to the common problem of flexible processing and storage of information.

1.09 Epigenetic Responses to a Changing Periphery – Wagging the Dog

K C Catania, Vanderbilt University, Nashville, TN, USA

Glossary

cortical barrel A circular region of the neocortex visible in various histological stains of the somatosensory area in rodents where touch information from a single whisker projects. First recognized by Woolsey and Van der Loos (1970) in mice.

cortical magnification The relative size of a representation, or processing area for a sensory input, in the cortical map. This generally refers to the larger representations of behaviorally important sensory inputs as compared to less important inputs. A common example in humans is the large area of cortex devoted to processing touch information from the hand relative to other, larger body parts (such as the leg or back) that have a proportionally much smaller representation in the cortex.

cytochrome oxidase A mitochondrial enzyme. Processing brain tissue to reveal the distribution of this enzyme often reveals different subdivisions, particularly in the neocortex. Cortical barrels can be seen in the distribution pattern of this enzyme (Figure 1).

Eimer's organ A small (40–80 μm) swelling in the nasal epidermis of talpid moles that contains an orderly array of mechanoreceptors used for tactile discriminations. Similar to a push-rod in monotremes.

epigenetic Generally refers to changes to the phenotype that are not the direct result of alterations to the DNA sequence. In the more restricted case of this review, changes to the phenotype of the brain are considered that may result from alterations to the body, rather than from changes in gene expression in the central nervous system.

glabrous Hairless.

mystacial vibrissae The large, mobile whiskers on the face of a rodent.

neocortex The outer six-layered sheet of brain tissue in mammals where much of the information from sensory receptors projects. Often shortened to 'cortex' in discussions of the mammalian brain. Many investigators prefer the term 'isocortex' to avoid the implication of an invalid phylogenetic sequence suggested by the term 'neo'.

ocular dominance column Stripes of cortical tissue in layer IV of primary visual cortex that receive input from the lateral geniculate nucleus projecting information from primarily only one eye. Each stripe is generally bound by similar stripes representing the opposite, contralateral eye.

saccadic In a manner similar to a saccade. A saccade is a sudden, jerky movement. The term 'saccade' is most frequently used in reference to an eye movement. In the visual system a saccade is the characteristic sudden movement of the eye that positions different parts of a visual scene on the retinal fovea.

sensory representation Generally refers to a topographic map of primary afferent inputs to the central nervous system. In the case of the somatosensory system, the sensory representations reflect the distribution of mechanoreceptors in the skin, and as such they form a map of the body surface which can be identified in neocortex by recording the activity of nerve cells in response to stimulating the skin.

somatosensory cortex The area of neocortex that receives and processes touch information from mechanoreceptors on the body.

tactile fovea The descriptor draws an analogy between the high-resolution retinal fovea in the visual system and the high-resolution part of the star-nosed mole's nose used for detailed, tactile investigations of objects of interest. A similar analogy with the visual system has been made in the auditory system of bats, where an auditory fovea is said to represent the most important echolocation frequencies.

1.09.1 Introduction

Recent advances in the ability to investigate gene expression during brain development have revealed a number of ways in which the neocortex is patterned during development and suggested how these patterns may have been altered in the course of mammalian evolution. Accumulating evidence indicates that gradients of proteins produced from signaling centers provide a coordinate system for the position of cortical fields and incoming thalamocortical afferents during development, and manipulation of the expression patterns of these molecules results in predictable alterations in the positions of entire cortical fields (Nakagawa *et al.*, 1999; Bishop *et al.*, 2000; O'Leary and Nakagawa, 2002; Fukuchi-Shimogori and Grove, 2003; Shimogori *et al.*, 2004).

In a recent landmark study, Fukuchi-Shimogori and Grove (2001) were able to induce the development of a second, mirror-image representation of the mystacial vibrissae in mouse somatosensory cortex by generating an extra, caudally located signaling center producing the fibroblast growth factor FGF8. This result is of particular relevance for theories of brain evolution in mammals because the addition of a mirror-image cortical area, or map, adjacent to an existing sensory representation has clearly occurred repeatedly in the course of mammalian evolution as brains have become larger and more complex (Kaas, 1987, 1993; Krubitzer, 1995). Thus, Fukuchi-Shimogori and Grove have been able to alter gene expression to produce a configuration of cortex that mimics a commonly observed product of brain evolution. Such studies suggest the genetic mechanisms by which relatively large-scale changes to sensory representations may have occurred.

However, my purpose is to emphasize a more gradual process of brain evolution that may often be a precursor to larger-scale changes requiring altered gene expression in the central nervous system (CNS). Here I suggest that many important evolutionary changes in brain organization occur simply by altering the development of the body. The well-documented, plastic nature of the developing nervous system could then accommodate new configurations of the sensory periphery through cascades of inductive events, largely independent of altered expression of patterning genes in the CNS. This idea is not new, or necessarily surprising. However, much attention is currently being focused on gene expression in the CNS and it seems important to consider simultaneously the sensory periphery – the interface between an animal and its environment.

My goal is briefly to summarize evidence from studies that support the instructive relationship between the sensory periphery and the CNS and to extend the discussion in some small but important ways. In particular, I will present evidence for variations in the sensory periphery that are paralleled in the brains of star-nosed moles. The mechanosensory star in this species and corresponding modular representation in cortex are the result of relatively recent selective pressure for elaboration of the somatosensory system, and the variations reported here were found in adult animals captured in the wild. These variations therefore represent the raw materials upon which natural selection is currently acting in these populations, and as such they are particularly relevant examples for the topic of brain evolution. I will also discuss evidence for another mechanism by which evolution may alter brain organization by acting in the periphery. Evidence from star-nosed moles suggests that the timing of developmental events in sensory sheets may have an important effect on the corresponding magnification of these areas in developing cortical maps. To lay the groundwork for this discussion, I first describe the whisker-barrel system in cortex of rodents and some of the variations observed in their sensory systems (see Mosaic Evolution of Brain Structure in Mammals, The Evolution of Neuron Classes in the Neocortex of Mammals, Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications, Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals, The Evolution of Crossed and Uncrossed Retinal Pathways in Mammals, Do All Mammals Have a Prefrontal Cortex?, The Evolution of the Basal Ganglia in Mammals and Other Vertebrates, The Evolution of the Dorsal Thalamus in Mammals).

1.09.2 Supernumerary Whiskers Revisited

Van der Loos and Dorfl (1978) published a short paper posing the provocative question: does the skin tell the somatosensory cortex how to construct a map of the sensory periphery? The focus of their investigation was the relationship between the whisker pattern on the face of mice and the visible, isomorphic reflection of this pattern in the primary somatosensory face region by a series of cortical barrels (Figure 1). The authors suggested three alternative possibilities for how this relationship becomes established: (1) the brain imposes a map on the periphery, (2) the periphery imposes its spatial organization on the brain, and (3) brain maps and the periphery develop independently.

Their paper revolved around the observation that some of the mice in their colonies were born with extra whiskers, and in these cases there were invariably corresponding extra barrels in the cortical representation in the correct spatial location. The central question was how the cortex became matched to the altered sensory periphery (Figure 2). The possibility that the brain imposes a pattern on the periphery was ruled out on the basis of clear developmental evidence showing that the sensory periphery develops well before the map in the somatosensory cortex and thus the sensory representation does not have an opportunity to direct the development of whiskers (for review, see Killackey *et al.*, 1995). At the same time, the peripheral-to-central developmental sequence provides at least the opportunity for the sensory periphery to guide the formation of somatosensory cortex through cascades of inductive events that are communicated from the skin, to the brainstem nuclei, to the thalamus, and finally to the developing neocortex.

The last possibility, that the brain and periphery make their debut independently, was considered unlikely. Van der Loos and Dorfl (1978) argued that it would be an extraordinary task for the genome to code for these changes independently, and concluded that the answer to the question in their title was yes – the skin tells the somatosensory cortex how to construct a map of the periphery.

Yet despite the well-reasoned argument from supernumerary barrels, it was not possible to rule out completely a genetic code for their representation in the brain. A recent investigation by Ohsaki *et al.* (2002) provides new evidence for the role of the skin surface in guiding the developing barrel cortex by selectively altering early gene expression specifically at the whiskerpad to induce the development of extra whiskers. By transfecting the follicular skin surface of early mouse embryos (E9.5–E11.5) with an adenovirus containing the Sonic hedgehog gene from chicken, various configurations of supernumerary whiskers were induced. The supernumerary whiskers were represented in the contralateral somatosensory cortex by extra barrels in the correct topographic position. This elegant separation of gene expression in the skin surface and CNS seems to provide conclusive support for the extrinsic nature of the signal to cortex for producing an extra barrel, as originally suggested by Van der Loos and Dorfl (1978).

The whisker-barrel system in rodents has thus been a critical model system for investigating the instructive relationship between the sensory periphery and the brain. This was possible because of the clear reflection of peripheral receptor topography in the architectural organization of rodent somatosensory cortex (Woolsey and Van der Loos, 1970). But how general is this kind of relationship between sensory organs and modules in the brain, and what kinds of variations of receptors arrays are found outside laboratory rodents?

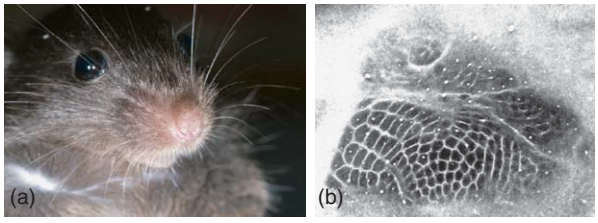

Figure 1 Cortical barrels in the mouse as revealed by cytochrome oxidase histochemistry. In many rodents, the cortical representation, or map, of various body parts in primary somatosensory cortex (S1) can be made visible with a range of cellular stains when the cortex is flattened out and sectioned from the top down to reveal layer IV. a, The face of a mouse showing the prominent facial vibrissae. b, A section of flattened right cortex processed for the metabolic enzyme cytochrome oxidase to reveal the prominent cortical barrels in layer IV. Rostral is to the right and medial is up. The large facial vibrissae correspond to the barrels visible in the lower left quadrant, whereas the smaller facial whiskers are represented by the smaller, more rostral barrels.

1.09.3 Stars and Stripes in the Cortex

Star-nosed moles have an exceptionally well-developed somatosensory system allowing them to identify and consume small prey items faster than any other mammal (Catania and Remple, 2005). This ability stems from the densely innervated mechanosensory star covered by tens of thousands of tactile Eimer's organs (Catania, 1995). As occurs for whiskers in rodents, the specialized glabrous

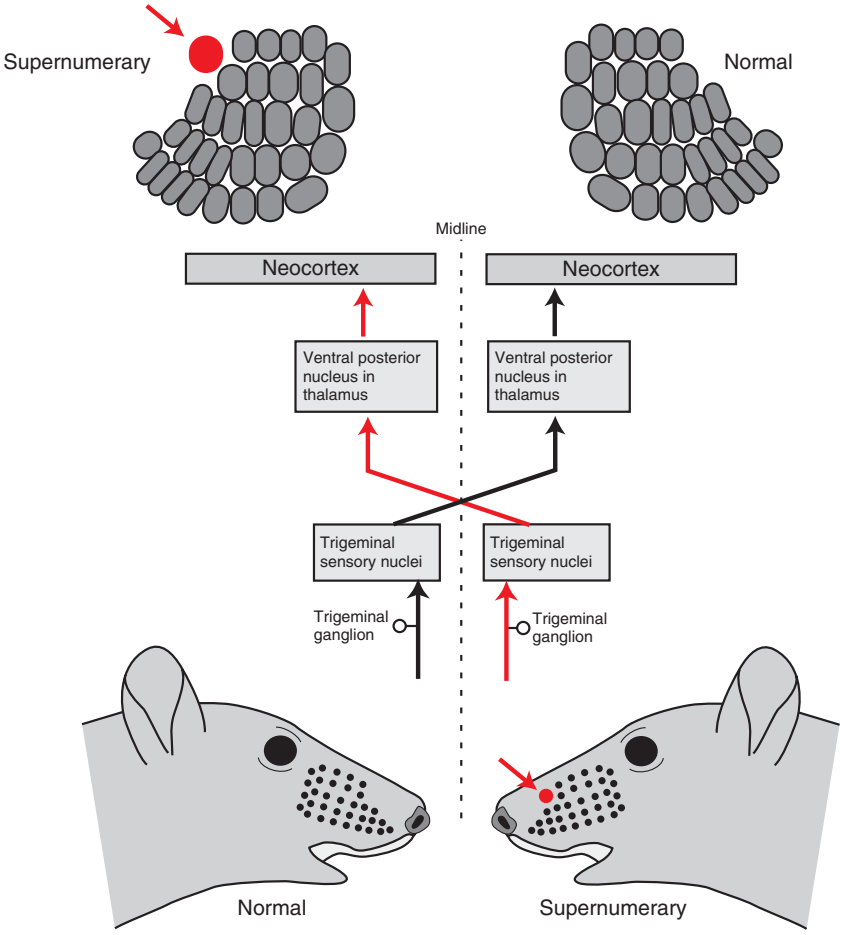

Figure 2 The relationship and pathways between the sensory vibrissae on the rodent snout and their representation in cortex by a series of barrels. Note the extra whisker illustrated on the left face of the mouse (right bottom side of figure) and the corresponding extra barrel in the contralateral somatosensory cortex. This observation inspired Van der Loos and Dorfl (1978) to suggest that the skin surface tells the somatosensory cortex how to construct a map of the sensory periphery.

skin surface of the mechanosensory star is represented in somatosensory cortex by a series of modules that reflect the topographic arrangement of mechanosensors in the periphery. The modules appear as a series of stripes visible in flattened brain sections processed for the metabolic enzyme cytochrome oxidase (Figure 3; Catania *et al.*, 1993). In star-nosed moles, histologically visible representations of the mechanosensory appendages are found in three separate cortical areas (S1, S2, and a third area we have called S3). Similar modular representations of skin surfaces (including the primate hand) have since been identified in other species as well (for review, see Catania, 2002).

The elaborate mechanosensory star and its multiple, modular representations in cortex are the result of comparatively recent selective pressure for the expansion of the somatosensory system (Catania, 2000; Catania and Remple, 2005). As a result this is a particularly useful species to examine when searching for clues to how peripheral receptor arrays and central brain organization have coevolved to produce complex sensory systems that are functionally integrated.

Star-nosed moles usually have a complement of 22 appendages ringing the snout. These occur as 11 symmetric pairs that are numbered from 1 to 11 on each side, starting with the dorsal-most appendage (Figure 3). As is the case for laboratory rodents, star-nosed moles are sometimes born with an abnormal configuration of the snout. This often includes the loss or addition of an appendage to one side of the nose and, when this occurs, the contralateral somatosensory cortex (Figure 4) invariably reflects the topography of the abnormal star (Catania and Kaas, 1997a).

There are a number of interesting implications of this result. Most obviously, this finding parallels the results of Van der Loos and Dorfl (1978) supporting the contention that skin surfaces play an instructive

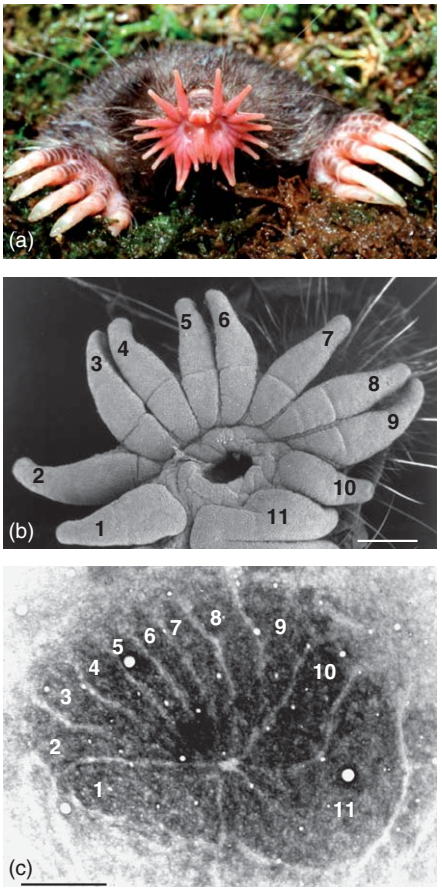

Figure 3 The sensory system of the star-nose mole. As occurs for the whiskers of rodents, the cortical representation of the mechanosensory appendages of the star-nosed mole is visible in various histological stains of the cortex. a, A front view of the star-nosed mole emerging from its underground burrow. Note the 22 appendages ringing the nostrils. b, A scanning electron micrograph of half of the star, rotated to match the representation in cortex in plate (c) below. The dark ring in the middle is the nostril. Dorsal (appendage 1) is to the left. c, A section of the flattened somatosensory cortex processed for the metabolic enzyme cytochrome oxidase to show the 11 modules where information from each of the 11 nasal appendages projects in primary somatosensory cortex (S1). Note the greatly overrepresented (enlarged) representation of the 11th appendage. The 11th appendage is the somatosensory fovea of the star (see text). Scale bars: b, 1 mm; c, 500 μm. b and c, Reproduced from Catania, K. C. 2001. Early development of a somatosensory fovea: A head start in the cortical space race? *Nat. Neurosci.* 4, 353–354, with permission.

role in guiding the formation of topographic maps in the CNS, and demonstrating the generality of this instructive relationship beyond the whisker-barrel system of rodents. It also shows that these variations are occurring in wild populations of mammals upon which natural selection is currently acting to shape the sensory periphery, and therefore the brains, of natural populations. Finally, the relatively frequent occurrence of these abnormalities is interesting. We have found as much as 5% of the population may have an abnormal number of appendages. This can be contrasted with the much lower rate of abnormalities for other appendages (Castilla *et al.*, 1996; Zguricus *et al.*, 1998). Darwin (1859) suggested an explanation for this kind of observation in *On the Origin of Species*, stating that "in those cases in which the modification has been comparatively recent and extraordinarily great ... we ought to find the *generative variability* still present to a high degree." The argument is that selection has had less time to fix characteristics of recently evolved complex structures which are the product of selection for variations. This is exactly what we find in wild populations of star-nosed moles and this is not surprising given that the star, and its modular reflection in cortex, are "comparatively recent and extraordinarily great" modifications of the mole's snout.

The conclusion that can be drawn from the observations in laboratory rodents and star-nosed moles is that the sensory periphery and corresponding neocortical areas are developmentally linked in such a manner that variations in the periphery, which may be the result of small, local changes in the expression patterns of morphogenetic genes, are communicated to the brain through inductive cascades. As a consequence minor (and perhaps major) alterations to receptor arrays result in functional representations in the CNS upon which natural selection can act to modify sensory systems efficiently. For instance, it is hard to examine variations of the nose and cortex in star-nosed moles (Figure 4) without imagining ancestral stars with fewer and perhaps shorter appendages similarly reflected in the somatosensory cortex, or even a potential future mole with 24 or more appendages ringing the snout.

So far I have emphasized evidence that sudden changes to discrete structures in the sensory periphery can be communicated to the CNS during development to produce matching cortical representations. However, we have also found intriguing evidence that the sizes of cortical sensory representations may be influenced by differential timing of development in the sensory periphery. This may be a convenient mechanism by which behaviorally important sensory surfaces capture the most cortical territory.

1.09.4 Cortical Magnification in Star-Nosed Moles

In a striking example of convergent evolution, star-nosed moles have developed a mechanosensory system that functions like an eye. The star has a

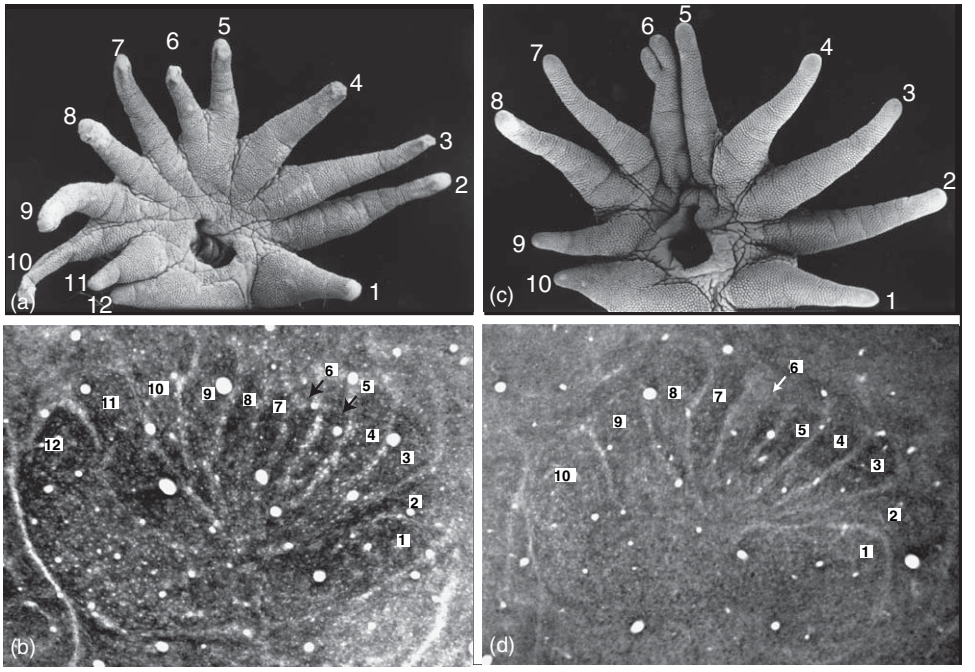

Figure 4 The nasal appendages and cortical representations of the half-nose for two abnormal star-nosed moles. a, Scanning electron micrograph of 12 appendages of an abnormal star. b, Section of flattened cortex processed for cytochrome oxidase to reveal the corresponding 12 modules in the primary somatosensory area. c, Scanning electron micrograph of 10 appendages of an abnormal star. d, Section of flattened cortex processed for cytochrome oxidase to reveal the corresponding 10 modules in the primary somatosensory area.

central tactile fovea (the 11th appendage) used for detailed exploration of objects of interest, whereas the larger peripheral appendages (1 through 10) are used to scan for potentially interesting objects or food items (Catania and Kaas, 1997b). This functional division is apparent in star-nosed mole behavior, which includes frequent saccadic movements of the star that bring the high-resolution tactile fovea into contact with objects of interest. In addition, the preferential use of the fovea is reflected in the organization of somatosensory cortex (Figure 3). The 11th foveal appendage is greatly overrepresented, occupying approximately 25% of the star representation in primary somatosensory cortex (S1). The enlargement of the 11th appendage is not simply a reflection of a higher innervation density (Catania and Kaas, 1997b), as suggested by previous investigations in rodents (Welker and Van der Loos, 1986), but rather is an overrepresentation of the primary afferent input – much like the retinal fovea is overrepresented in cortex relative to the number of ganglion cells concentrated in the fovea (Perry and Cowey, 1985; Silveira *et al.*, 1989; Azzopardi and Cowey, 1993; Quevedo *et al.*, 1996).

An obvious question is how afferents capture more than their share of somatosensory cortex relative to behaviorally less important inputs. The observation that star-nosed moles preferentially use the 11th appendage for tactile investigations, coupled with previous studies that indicate cortical representational areas may expand as a result of preferential stimulation and use (Recanzone *et al.*, 1992a, 1992b; Xerri *et al.*, 1999), suggest that behavior patterns may play an important role in establishing this relationship. However, our developmental studies suggest an alternative and perhaps surprising explanation for how the periphery may drive the expansion of the fovea representation in cortex.

In the course of investigating how the appendages of the star develop (Catania *et al.*, 1999) an unusual discrepancy in the relative sizes of embryonic and adult appendages on the star was noticed. In contrast to the small size of the 11th appendage in adult star-nosed moles, this appendage was comparatively large in embryos (Figure 5). In fact, the relative sizes of the star appendages in embryos reflect the relative sizes of the cortical representations seen later in adults (Figure 6a). Over the course of subsequent development, the proportion of the star taken up by the fovea gradually changes until, in adults, the 11th appendage takes up only a small fraction of the star (and contains only a relatively small proportion of the mechanosensory Eimer's organs), and thus the adult star proportions no longer reflect the magnification factors seen in cortex.

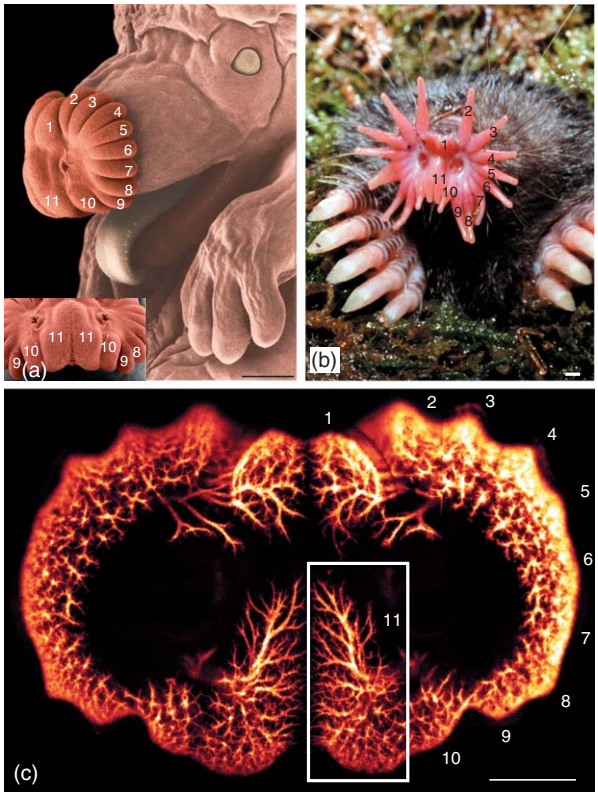

Figure 5 Embryonic star-nosed mole compared to an adult, showing the relatively large 11th appendage early in development. a, An embryonic mole showing the developing nasal appendages numbered 1–11. In early embryos the 11th appendage of the nose (the tactile fovea) is the largest and has the greatest innervated surface area. Inset shows a front view of the ventral star from the same specimen to illustrate the large 11th appendage. b, An adult star-nosed mole emerges from its tunnel. In adults the 11th appendage takes up only a relatively small proportion (7%) of the star, despite its important role as the tactile fovea. c, Scanning confocal microscopy of DiI-labeled fibers innervating the developing star. The 11th appendage (boxed area) takes up the largest area of the star and has the largest innervated surface area. The more lateral appendages have only begun to form at this stage. Scale bars: a and c, 500 μm; b, 1 mm. Reproduced from Catania, K. C. 2001. Early development of a somatosensory fovea: A head start in the cortical space race? *Nat. Neurosci.* 4, 353–354, with permission.

A more detailed examination of the developing appendages, associated sensory organs, and their innervation suggests the explanation for the changing relative proportions of the different appendages during development – the 11th, foveal appendage leads the development of the star. It is not only large earliest, but also has the largest innervated surface area in embryos and develops mature nerve terminals and associated sensory organs first in newborn moles (Catania, 2001). Finally, these patterns of development, with the 11th appendage in the lead, are reflected in the cortex by the early emergence of a cytochrome oxidase-rich zone representing the 11th appendage (Catania, 2001).

This developmental sequence provides the fovea with a strong basis for competitive advantages during development and suggests that foveal afferents may outcompete their neighbors in an activity-dependent race for cortical territory. The mechanism for this outcome is suggested by previous investigations in the visual and somatosensory systems. For example, when activity from one eye is reduced by suturing the lid shut during critical periods, ocular dominance columns devoted to the open eye develop expanded representations at the expense of the closed eye (Hubel *et al.*, 1977). Activity-dependent expansions have also been documented for the barrel system in rodents (Schlaggar *et al.*, 1993).

The suggestion is that the skin surface can provide not only instructions to the cortex regarding the arrangement and number of sensory surfaces but also information about the optimal size for these representations in later adults. Presumably the larger area for foveal representation allows for more efficient and perhaps faster sensory processing for these important inputs. The developmental sequence observed for the star suggests that evolutionary processes can change the size of representations in the brain by selectively altering the relative timing of developmental events in the periphery. It is significant in this regard that the fovea leads development in the primate retina (Rapaport and Stone, 1984) and is also overrepresented in cortex relative to the peripheral part of the retina.

1.09.5 Conclusions

In this article I have discussed some of the evidence from star-nosed moles and rodents for how changes in the details of neocortical maps may be effected through alterations of sensory surfaces in the periphery. The title of this article was inspired by the conclusion that many of these peripheral influences on the organization of the brain may not require a change in the expression of patterning genes in the CNS during the course of evolution. Rather, relatively small changes in gene expression at the level of sensory sheets may be communicated centrally by a cascade of inductive events during the course of development. The information communicated from the periphery includes not only details of how to construct a map of the topographic distribution and number of receptors in the periphery, but may also include important information about how much processing space should be devoted to the different afferent inputs. For example, the

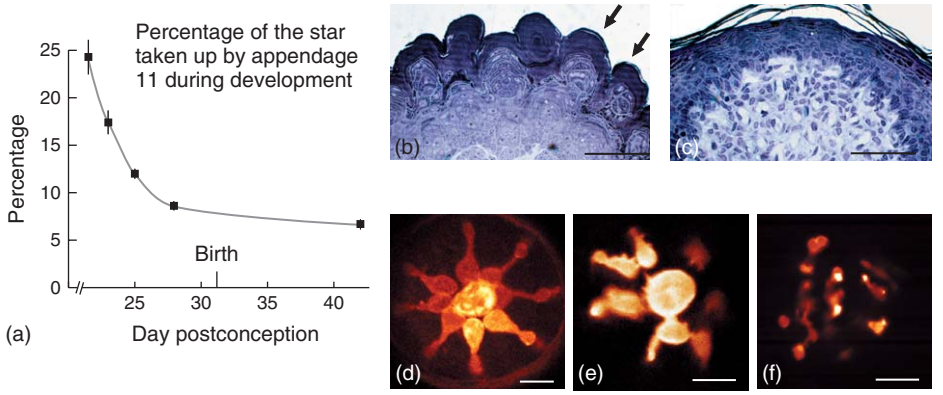

Figure 6 Differential maturation of the appendages, epidermis, and free nerve endings of the star at different postnatal stages. a, The proportion of the star taken up by the tactile fovea (appendage 11) over the course of development. b, Thin section of the epidermis of appendage 11 on postnatal day 1 showing the differentiated Eimer's organs consisting of keratinocytes in separate papillae (arrows). c, Thin section of appendage 6 at the same stage showing the undifferentiated epidermis. d, The adult configuration of free nerve endings in the epidermis at the apex of a mature Eimer's organ. The fibers form a remarkable hub-and-spoke configuration of nerve terminals just below the skin surface. e, On postnatal day 18, the fibers at the apex of each Eimer's organ on the 11th appendage have formed the hub-and-spoke configuration, though short extensions of the neurites remain. f, The fibers at the apex of each Eimer's organ on the lateral appendages remain disorganized, although they have reached the appropriate location. Thus, the 11th appendage leads the development of the star, not only in size, but also in the rate of sensory organ maturation. Scale bars: b and c, 50 μm; d–f, 5 μm. Reproduced from Catania, K. C. 2001. Early development of a somatosensory fovea: A head start in the cortical space race? *Nat. Neurosci.* 4, 353–354, with permission.

competitive nature of afferent distributions in cortical maps provides a developmental mechanism for skewing the allocation of cortical territory in favor of some inputs – namely those that lead the development of a sensory surface and are therefore most active, in the greatest numbers, at the earliest time.

It is clear that much larger-scale changes to brain organization have occurred in many mammalian lineages. Obvious examples include the Primate and Carnivore orders that have brains with more cortical subdivisions than smaller-brained rodents and insectivores. In this regard it is significant that star-nosed moles have more cortical subdivisions in their somatosensory system (S1, S2, and S3) than other moles and shrews, which have only two areas (S1 and S2). It seems likely that the additional area facilitates processing of the high volumes of complex sensory information from the star. Such changes in the number of cortical areas require corresponding changes in gene expression in the CNS, and recent studies suggest potential mechanisms by which these more global changes can occur (Fukuchi-Shimogori and Grove, 2001). However, it is possible that a modified sensory periphery often sets the stage for subsequent adaptive modifications to the CNS in the course of evolution (see Evolution of the Somatosensory System – Clues from Specialized Species). In support of this possibility, Bush *et al.* (2004) have found fossil evidence that suggests high-acuity vision preceded brain expansion in anthropoid evolution.

1.10 Compensatory Innervation in Development and Evolution

S L Pallas, Georgia State University, Atlanta, GA, USA

Glossary

altricial	The state of being born at an early stage of development. Opposite of precocial.
callosal connectivity	Connections between cerebral hemispheres made through the corpus callosum.
cortical areal specification	The developmental or evolutionary process of subdividing cerebral cortex into functional units.
cortical parcellation	The evolutionary process of subdividing cerebral cortex into functional units.
cross-modal plasticity	Plasticity induced in the brain that results in a sensory area of one modality coming to represent sensory information of a different modality.
fossorial	Animals that burrow underground.
Hebbian learning	As defined by Donald O. Hebb in 1949, synaptic changes that occur as a result of use-dependent plasticity. Inputs that succeed in activating a postsynaptic neuron become more efficacious and are stabilized.
horizontal connectivity	The lateral connections made between excitatory neurons within one cerebral cortical area.
inhibitory interneurons	Nonspiny, nonpyramidal neurons making local, suppressive connections with other neurons.
map compression	Loss of sensory target area can result in the forcing of a topographic sensory representation within the remaining target area.
orientation tuning	Neurons in visual cortex prefer elongated bars of light that have a particular orientation.
sensory substitution	After loss or deficit in a sensory organ, the cortical region that once represented the missing sensation becomes activatable by a different modality of input.
topographic map	Orderly representation of the sensory epithelium or some other type of information within a brain region.

1.10.1 Introduction

In January 2004, the State Superintendent of Schools in my adopted state of Georgia, USA, eliminated evolution from the public school science curriculum. Fortunately, a small group of dedicated activists, combined with worldwide media attention, blocked the attempt to turn back the scientific clock, for now. Nonetheless, the teaching of evolution remains under threat in many other locations around the USA and the world (Forrest and Gross, 2004; Scott, 2006). We evolutionary biologists must do something about the fact that, 150 years after Darwin's famous book, the lay public has an appallingly poor understanding of the foundational theory in biology. The production of this book series will hopefully promote not only a greater understanding of brain evolution by scientists, but also kindle a desire to provide more and better instruction in evolutionary biology for tomorrow's citizens of the world.

A major problem in obtaining public support for quality evolution education has been that the average citizen sees no need for learning evolutionary biology. The key is to illustrate for students the

connection between their everyday lives and evolutionary principles. In the following, I will discuss the largely unrecognized importance of evolutionary theory in guiding medical research toward a better understanding of brain development and pathology, and in guiding clinical interventions today and in the future (see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates, Primate Brain Evolution in Phylogenetic Context, Organization and Correspondence of the Auditory Cortex of Humans and Nonhuman Primates, The Evolution of Neuron Types and Cortical Histology in Apes and Humans, The Origin of Neocortex: Lessons from Comparative Embryology, Cortical Evolution as the Expression of a Program for Disproportionate Growth and the Proliferation of Areas, Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications, Captured in the Net of Space and Time: Understanding Cortical Field Evolution, The Evolution of the Dorsal Thalamus in Mammals, Epigenetic Responses to a Changing Periphery – Wagging the Dog).

1.10.2 Evolution Exploits Developmental Events

The relatively new discipline of evo-devo relies on the fact that, because early developmental events determine the ground plan for further development, small alterations in the genetic programs underlying early development can lead to drastic changes in phenotype. Developmental neuroscience and evolutionary biology are thus complementary approaches. By studying normal development and the plastic mechanisms used by the brain to respond to injury, we can determine the constraints under which brain evolution operates when faced with alterations in peripheral innervation.

1.10.2.1 Brain Evolution Results from Minor Variations on a Basic Vertebrate Plan

Just as constructing a building requires first laying the foundation, constructing any vertebrate requires a foundation or Bauplan, incorporating bilateral symmetry, paired appendages, a dorsal nerve cord encased in a spinal column, and so forth. This requirement ensures that, at early stages, vertebrate embryos of any type will have common features. The prediction, and the finding, is that, the more common the feature, the earlier it appeared in evolution. The morphological and resulting functional differences that distinguish one vertebrate from another arise later in development, and represent fairly small deviations from the pre-existing plan. For example, a two-chambered heart becomes a three- and then a four-chambered heart over evolutionary time, but the heart itself is universal. Similarly, the vertebrate brain consists of hindbrain, midbrain, and forebrain, but the relative size and organization of each brain division and the functional regions within them can be modified during development according to the evolutionary history of each species (Pallas, 2001b; Krubitzer and Kaas, 2005).

What sorts of beneficial evolutionary modifications have been made to developmental programs? It is difficult to imagine how changes could even be tolerated, much less produce adaptive circuits, in a highly interconnected network such as the nervous system. It would seem that a change in one brain region or a change in one morphogenetic signal would either be ignored at the next level or would create a mismatch in the network and severely disrupt function. As we know from studies of recovery from brain trauma, however, the brain has a remarkable capacity to rewire itself in an adaptive fashion.

1.10.2.2 Developmental Mechanisms can Accommodate New Neurons and Trigger Matching Changes in Connected Populations

Both neurons and synapses are massively overproduced during development, and the final circuitry is pruned by processes such as programmed cell death and collateral elimination (see Finlay and Pallas, 1989, for a review of earlier literature). This pruning is directed in large part by activity-dependent processes (Hebb, 1949; Schneider, 1973; Innocenti *et al.*, 1977; Pilar *et al.*, 1980; O'Leary and Stanfield, 1986), ensuring that the final wiring pattern is appropriate to the environment and experiences of each individual. Extra neurons and connections produced during development can be stabilized by providing additional target space (Hollyday and Hamburger, 1976). Thus the natural plasticity built into the nervous system ensures that developmental (or evolutionary) errors can be absorbed, and even exploited. Any such acquired connections gained within an animal's lifetime would of course not be heritable, but relative excesses of target neurons produced through gene duplication, modifications of the cell cycle, or cell death of input neurons would automatically integrate into a circuit. Throughout vertebrate evolution there has been a consistent trend toward increasing the number of neurons, producing local variation in size of nuclei or layers and an increasing modularization (Finlay and Slattery, 1983; Caviness *et al.*, 1995; Kornack and Rakic, 1998; Kornack,

2000; Ohki *et al.*, 2005). Because of inherent plasticity in the inputs, matching changes in the pathway are not required. Environmental change is the primary source of selection pressure over generations, and a nervous system that responds on a developmental timescale to the environment provides a huge selective advantage, if the cost in terms of unintended connections is low. More importantly to this discussion, exuberant connections and extra neurons at any level of a sensory pathway are possible sources of variation in neural circuits between individuals (Sperry, 1963), and individual variations in connectivity could be selected for if they provide a survival advantage. Thus a mutation-induced increase or decrease in a neuronal pool could influence both upstream and downstream neuronal survival and collateral elimination. In this way, a change in one component of the pathway need not require a simultaneous and matching change in all components. Hebbian mechanisms would instruct the pathway to process the new inputs sensibly. In the following, I will illustrate how this can occur in developmental time, and propose how it might have occurred over evolutionary time.

1.10.3 Target Specificity and Its Role in Development and Evolution

The task facing the nervous system during development is largely one of population matching: neuronal input populations must find the correct target populations, and form the correct number of synapses, in the correct position, within each target (Katz and Lasek, 1978). Molecular guidance cues are responsible for many aspects of target specificity, but, given the impossibility of prespecifying every connection genetically, some general rules are enforced instead. Target choice occurs in a hierarchical fashion and is not absolute. Targets apparently possess labels that are recognized by their usual input population, but if that target population is missing, other target choices are possible, with some preferred over others.

1.10.3.1 Population Matching in the Retinotectal System

Like many central sensory brain structures, the optic tectum (also known as the superior colliculus (SC), in mammals) contains a map of visual space conferred on it by the orderly projection of retinal ganglion cells. In amphibians, if an eye is surgically rotated and the optic nerve allowed to regenerate, the retinotectal projections grow to their previous termination sites, suggesting that the regenerating retinal axons follow pre-established chemoaffinity markers in the tectum (Sperry, 1963). This suggestion was supported by observations that, if half of the tectum is removed, it is initially innervated only by the corresponding half of the retina (Attardi and Sperry, 1963). With time, however, the map regulates such that the retinal axons fill the remaining target space, creating a compressed retinotectal map of visual space (Schmidt, 1982). The same regulatory process occurs during development in rodents; removal of part of the SC in neonatal hamsters results in orderly compression of the retinotopic map on to the SC fragment (Finlay *et al.*, 1979; see Goodhill and Richards, 1999, for review).

1.10.3.1.1 Role of ephrins in retinotectal map formation A large body of research points to the ephrins and the Eph tyrosine kinase receptors as the molecules responsible for chemoaffinity in the retinotectal projection (Drescher *et al.*, 1997; Flanagan and Vanderhaeghen, 1998; Frisén *et al.*, 1998; O'Leary and Wilkinson, 1999; Knoll and Drescher, 2002; McLaughlin *et al.*, 2003). EphA receptors and ephrin-A ligands are distributed in opposing gradients, with ephrin-A expression high in caudal tectum and EphAR expression high in nasal retina (Figure 1). Binding of receptor and ligand results in growth cone collapse, and thus the anteroposterior axis of the retinotectal map is built by repulsion of incorrect terminations. Knockout of ephrin-As leads to severe disruptions in map topography, in particular caudal overshoot of retinal axon targeting (Ciossek *et al.*,

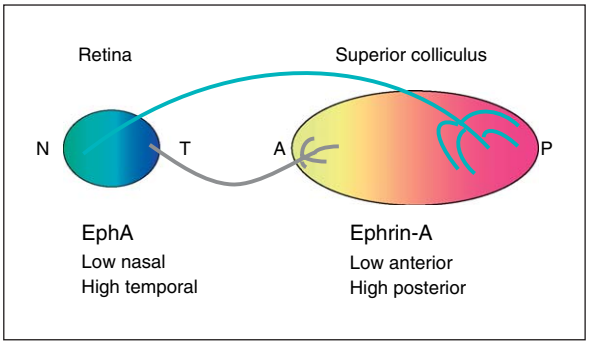

Figure 1 EphA tyrosine kinase receptors are expressed in a nasotemporally increasing gradient on retinal ganglion cells and ephrin-A receptors are expressed in a reverse gradient within the SC. Repulsive interactions between ligand and receptor-containing neurons cause temporal retinal axons to be repelled from posterior SC. The combined action across the gradient sets up the rostrocaudal topography of the retinocollicular map. Adapted from Cheng, H. J., Nakamoto, M., Bergemann, A. D., and Flanagan, J. G. 1995. Complementary gradients in expression and binding of ELF-1 and Mek 4 in developement of the topographic retinotectal projection map. *Cell* 82, 371–381.

1998; Frisén *et al.*, 1998; Yates *et al.*, 2001). This raises the question, if ephrin distributions in tectum define the termination sites of retinal axons, how can the retinocollicular map compress after caudal SC injury? It has been suggested that the ephrin gradients must be altered for compression to occur (Schmidt, 1982). Alternatively, retinal axons may be responding to relative rather than absolute expression levels of ephrins (Brown *et al.*, 2000). To investigate this question, we quantified ephrin-A expression levels in normal and compressed retino-SC maps in hamsters. We found that the reduction in target size causes a compensatory alteration in ephrin expression such that the pitch of the ephrin-A gradient is steeper in the smaller target (Tadesse *et al.*, 2004). Viewed from an evolutionary perspective, alterations in the size of a target area may produce changes in mapping cues that lead to compensatory alterations in topography, thus smoothly integrating the change in neuronal number.

1.10.3.1.2 Role of NMDA receptors in conservation of response properties It might be expected that compression of the map would result in compromised visual function. In a series of studies, we have shown that this is not the case. Instead, the circuitry within the SC compensates for the loss of target in a way that preserves the response properties of the component neurons. Rather than increasing the convergence ratio between ganglion cells and SC neurons, the retinal axon arbors are pruned in such a way that the receptive field size of individual SC neurons is conserved (Figure 2, top) (Pallas and Finlay, 1989, 1991; Xiong *et al.*, 1994). The mechanism underlying this conservation of receptive field size is the same as that operating during normal development of the map; through *N*-methyl-D-aspartate receptor (NMDAR)-dependent long term potentiation (LTP) (Constantine-Paton and Cline, 1998). Chronic blockade of NMDAR in normal SC prevents the activity-dependent refinement of retino-SC projections, resulting in stabilization of the initial, overlapped ganglion cell terminals. As a result, receptive fields of SC neurons remain larger than in normal adults (Huang and Pallas, 2001; see also Simon *et al.*, 1992). Combining NMDAR blockade with map compression results in further enlargement of receptive fields, because both the normal refinement process and the compensation process are blocked (Figure 2, bottom).

1.10.3.1.3 Role of lateral inhibition in conservation of response properties Curiously, we found that response properties such as stimulus size and velocity tuning were unaffected by either the map compression or by the NMDAR blockade and subsequent receptive field enlargement (Razak *et al.*, 2003; Figure 3), suggesting that an NMDAR-independent mechanism is responsible for conservation of stimulus tuning. In order to explore this possibility, we first had to understand the circuitry responsible for velocity and size tuning in normal animals. Previous models of velocity tuning in retinal and visual cortical neurons have direction tuning as a necessary component (Barlow and Levick, 1965; Borst and Egelhaaf, 1989; Ascher and Grzywacz, 2000), but the velocity-tuned neurons in hamster SC are not intrinsically directional. We found that temporally asymmetrical lateral inhibition within the receptive field is largely responsible for size tuning, and that surround suppression is a major component of velocity tuning (Razak and Pallas, 2005).

Given that inhibition underlies stimulus tuning, and blockade of NMDARs had no effect on tuning, we hypothesized that the reason stimulus tuning is preserved in compressed or NMDAR-blocked SC

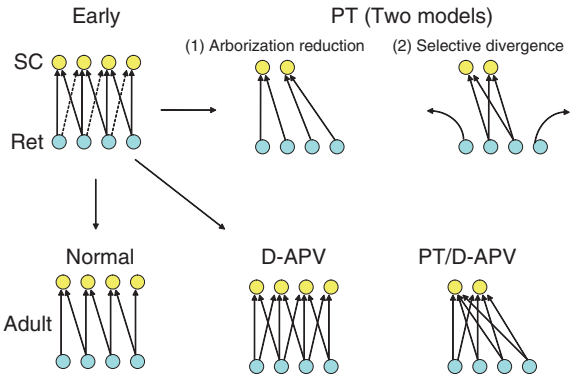

Figure 2 Left: Early in development, SC neurons (SC layer) have large and diffuse receptive fields, but the refinement of retinal ganglion cell (Ret layer) axon arbors results in smaller receptive fields by adulthood in normal animals. Top: If the caudal half of the SC is ablated at birth (PT), the retinal projection compresses on the remaining SC. The mechanisms underlying the compression include a reduction in retinal axon arbor size as well as selective collateral elimination from the SC. Note that the number of retinal inputs and the amount of visual space represented by each SC neuron is conserved, although the degree of overlap between adjacent receptive fields is reduced and multiunit receptive fields are larger. Bottom: The refinement process is dependent on NMDAR (Huang and Pallas, 2001). Chronic blockade of NMDAR with D-APV prevents the refinement process, leading to large receptive fields in adults. If the NMDAR blockade is combined with target loss (PT/D-APV), then, in addition to preventing the refinement, loss of NMDAR function prevents the compensation for target loss, leading to further receptive field enlargement. Adapted from Huang, L. and Pallas, S. L. 2001. NMDA receptor blockade in the superior colliculus prevents developmental plasticity without blocking visual transmission or map compression. *J. Neurophysiol.* 86, 1179–1194.

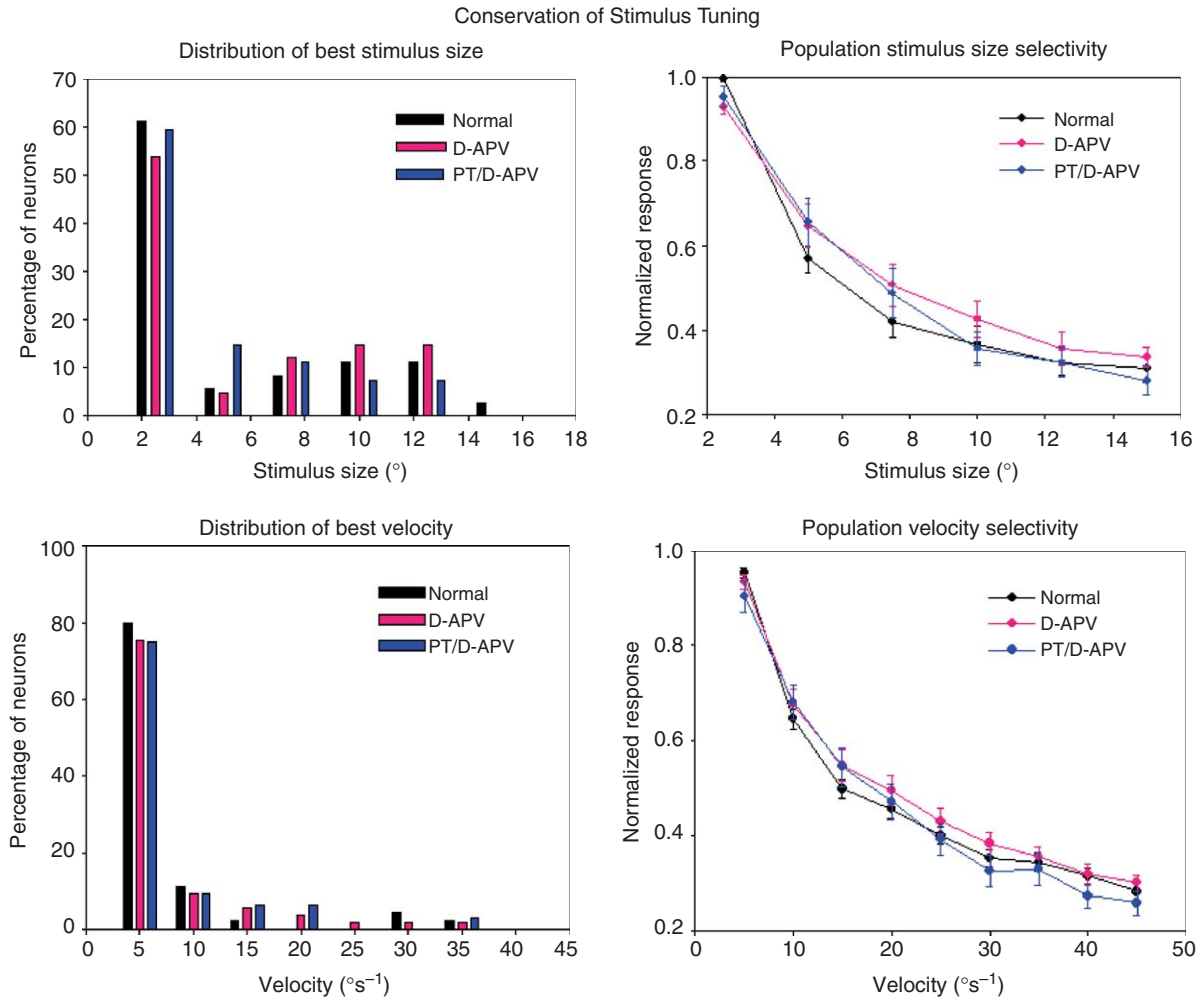

Figure 3 Although chronic NMDAR blockade in full-size or compressed retino-SC maps results in enlarged receptive fields, tuning of SC neurons to visual response properties such as stimulus size and velocity is unaffected. Measures of best stimulus size and velocity in individual SC neurons as well as normalized response levels across the population of neurons were not significantly different between the normal, chronic NMDAR blockade (D-APV), and NMDAR blockade combined with PT ablation (PT/D-APV) groups. Adapted from Razak, K. A., Huang, L., and Pallas, S. L. 2003. NMDA receptor blockade in the superior colliculus increases receptive field size without altering velocity and size tuning. *J. Neurophysiol.* 90, 110–119.

maps is that inhibitory circuits undergo compensatory modification of the enlarged receptive fields. To test this hypothesis, we used electrophysiological techniques to map out the contribution of inhibitory inputs to the receptive fields of SC neurons in partial tectum (PT) and 2-amino-5-phosphonovaleric acid (APV) cases. We found that the extent and the strength of inhibition were increased, maintaining a balance between excitatory and inhibitory subfields that compensated for the increased number of excitatory inputs in the APV group (Razak *et al.*, 2002, 2003).

These results together show that an increase in the number of afferents can be compensated for by homeostatic, matching alterations in both excitatory and inhibitory circuitry, maintaining the ability of the system to identify visual objects. This has obvious utility from an evolutionary perspective. Any individual variation producing a change in the number of inputs could not only be incorporated but could also produce an adaptive advantage.

1.10.3.2 Role of Sensory Deprivation in Specificity of Thalamocortical Pathways

Connections between sensory thalamus and sensory cortex are demonstrably quite specific from early in development (Crandall and Caviness, 1984; Miller *et al.*, 1991), and thus are a good experimental system in which to study target specificity. If sensory inputs can specify cortical identity through thalamocortical axon (TCA) pathfinding, then alteration of TCAs could change cortical identity. Multiple, large tracer injections in primary auditory cortex (A1) of

deafened ferrets revealed an anomalous thalamocortical pathway in the deaf ferret brains, connecting visual thalamus (lateral geniculate nucleus (LGN) and lateral posterior nucleus (LP)/pulvinar) with auditory cortex (Pallas *et al.*, 2002). This result is particularly surprising because previous thinking holds that thalamocortical targeting is hard-wired by molecular guidance factors and not affected by sensory experience. This LGN-A1 projection is not a normal developmental exuberance that was stabilized, rather it is novel and a response to the deafferentation occurring several synapses away. This finding is relevant clinically because it could provide a substrate for the recovery of function seen in deaf individuals (Neville, 1990). If a remodeling of the thalamocortical pathway could occur evolutionarily, it could provide a means of generating a new cortical area (Kaas, 1993). Our observation thus provides us with a model system for brain evolution. If a change in thalamocortical afferent source can direct cortical circuitry for processing to its own ends, then peripheral change could induce a matching central change without the need for genomic modification.

1.10.3.3 Cross-Modal Plasticity in the Retinogeniculocortical System

1.10.3.3.1 Parcellation of mammalian neocortex

The evolution of the mammalian neocortex has involved a spectacular amount of parcellation and diversification (Felleman and Van Essen, 1991; see Rosa and Krubitzer, 1999, for review). Several explanations for this evolutionary change seem possible. Perhaps the least likely is simultaneous, matching mutations that affect both afferent inputs and their cortical targets. Alternatively, intrinsic genetic information, either from afferent inputs or from cortex itself, could drive parcellation and circuit arrangement (Rakic, 1988). Third, unique spatiotemporal patterns of afferent activity reaching each presumptive cortical area could instruct parcellation and circuit organization (Hebb, 1949; O'Leary, 1989; Kaas, 1995; Northcutt and Kaas, 1995; Kaas and Reine, 1999). Finally, cortical circuitry could be sufficiently similar in different regions that changes would be unnecessary to accommodate adaptive changes in afferent inputs.

1.10.3.3.2 The cross-modal plasticity paradigm

Cross-modal plasticity provides a way of examining the mechanism behind cortical parcellation during development and evolution. The paradigm permits experimentally changing the modality and activity pattern within TCAs without changing their molecular identity. The hypothesis being tested with this approach is that the sensory information received by a region of cortex during development (or evolution) plays an essential role in organizing its functional identity. In contrast to specification according to intrinsic instructions, afferent instruction would allow animals to be responsive to a changing sensory environment or to alterations in peripheral sensory systems. This dependence on experience would have obvious adaptive significance. However, although some advances in understanding cortical parcellation have been made, it is not known which characteristics distinguishing different cortical areas are due to intrinsic, preprogrammed differences, and which are due to activity in the sensory inputs, and in the latter case, whether sensory activity is permissive or instructive (Levitt *et al.*, 1997; Crair, 1999).

In cross-modal plasticity experiments, afferents of one sensory modality are induced to innervate thalamus of a different modality, which then carries the cross-modal information to the sensory cortex (Figure 4). These experiments were first performed in hamsters (Schneider, 1973; Frost, 1981) and then in ferrets (Sur *et al.*, 1988), which are carnivores with sensory cortical physiology similar to that of the cat, except that they are born earlier in development. The manipulation is performed before sensory information has gained access to cortex (Luskin and Shatz, 1985; Jackson *et al.*, 1989). In ferrets, external visual and auditory cues are not available until after postnatal day 30 (Moore and Hine, 1992; Akerman *et al.*, 2002), in part because the ears and eyes open at this time. This protracted developmental period allows a more detailed examination of the process than is possible in rodents.

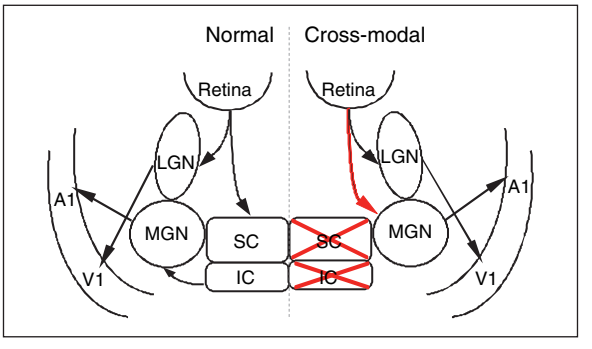

Figure 4 Procedure for inducing retinal projections into auditory thalamus (MGN). Midbrain lesions simultaneously deafferent MGN and eliminate retinal target space. As a result, retinal axons sprout into MGN. MGN in turn carries visual information into primary auditory cortex (A1).

1.10.3.3.3 Cross-modal A1 can process and map visual inputs Experiments performed in the Frost lab demonstrated that retinal axons lacking target space could invade either somatosensory or auditory thalamus, inducing visual responses and some retinotopic organization in the cortical area affected (Frost, 1981; Metin and Frost, 1989). Extending the cross-modal paradigm to ferrets (Sur *et al.*, 1988) showed that early visual activation of A1 causes auditory cortex to resemble visual cortex in both its topography and receptive field properties (Roe *et al.*, 1990, 1992; see Sur *et al.*, 1990, for review). Remarkably, cross-modal A1 in ferrets or hamsters can mediate rudimentary visual perception (Frost *et al.*, 2000; von Melchner *et al.*, 2000). Thus it appears that supplying A1 with early visual input transforms it in a functional sense into a visual cortical area. The remaining question is how this transformation occurs. Either visual and auditory cortex are so similar that they can process each other's inputs without modification, or the visual input has caused a modification in A1's circuitry that allows it to process visual information appropriately. Our goal has been to distinguish between these two possibilities.

1.10.3.3.4 Anatomical basis for visual responses and topography in cross-modal A1 Using an anatomical approach, we showed that the early anomalous visual inputs do in fact cause modifications to A1's circuitry on multiple levels, including intracortical (horizontal) and corticocortical (callosal) connectivity patterns and local inhibitory circuitry. In normal auditory cortex of cats and ferrets, callosal connections are organized into the so-called binaural bands along the tonotopic axis, uniting A1 neurons in both brain hemispheres that are excited by sound presented to either ear (EE cells: Imig and Brugge, 1978; Figure 5, normal). Another class of A1 neurons is inhibited by sound in one ear (EI cells) and does not project callosally. The EI cells form interdigitating bands with the callosally projecting EE cells (Imig and Brugge, 1978). The pattern of callosal bands arises during development from a more diffuse early pattern (Feng and Brugge, 1983), suggesting that auditory experience is involved in its refinement. Perpendicular to the tonotopic axis, intracortical, horizontal connections in A1 unite neurons that have similar frequency tuning (Matsubara and Phillips, 1988; Wallace and Bajwa, 1991; Gao and Pallas, 1999). In this case, the early projections are somewhat specific in their targeting, although there is some refinement occurring at about the time of hearing onset that is lost with early deafening (Figure 5, deaf; Gao *et al.*, 1999a; Moerschel and Pallas, 2001). Interestingly, it seems that there is more error correction occurring in visual cortex during development than in auditory cortex (Ruthazer and Stryker, 1996; White *et al.*, 2001), but in both cases neural activity is critical for normal development.

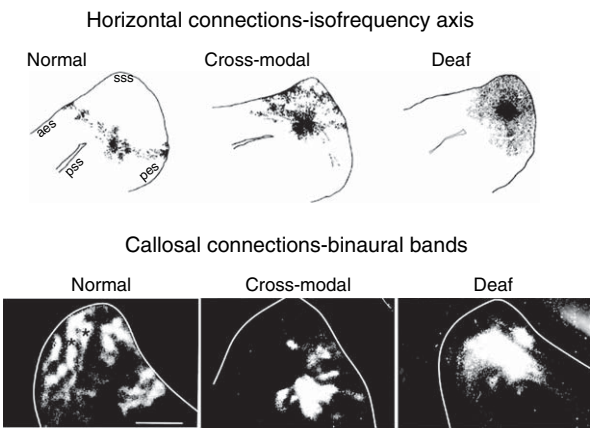

Figure 5 Injection of local or long-distance tracers reveals the connectivity of auditory cortex in normal, cross-modal, or deafened ferrets. Local horizontal projections within A1 interconnect neurons with similar sound frequency tuning. Callosal connections run along the binaural bands of neurons receiving excitatory inputs from both ears. Deafferentation of A1 results in loss of specificity in these connection systems, suggesting an activity-dependent basis. Visual input to A1 in the left hemisphere alters the connections with respect to both pattern and location. Adapted from Gao, W.-J. and Pallas, S. L. 1999. Cross-modal reorganization of horizontal connectivity in auditory cortex without altering thalamocortical projection. *J. Neurosci.* 19, 7940–7950; Pallas, S. L., Littmann, T., and Moore, D. R. 1999. Cross-modal reorganization of callosal connectivity in auditory cortex without altering thalamocortical projections. *Proc. Natl. Acad. Sci. USA* 96, 8751–8756.

We reasoned that, if the cortical connectivity pattern in A1 of adults is dependent on auditory experience, then supplying visual inputs to A1 in cross-modal ferrets should result in a pattern more closely resembling that in visual cortex. Horizontal connections in primary visual cortex (V1) are organized as a periodic, symmetrical array of clusters that interconnect neurons with similar visual orientation tuning (Callaway and Katz, 1990; Malach *et al.*, 1993). These clusters are refined under the influence of visual activity (Callaway and Katz, 1991; Ruthazer and Stryker, 1996). Callosal connections in visual cortex of adults are made between neurons at the border of visual cortical areas 17 and 18 (Lewis and Olavarria, 1995; Olavarria, 2001; Riederer *et al.*, 2004; see The Role of Transient, Exuberant Axonal Structures in the Evolution of Cerebral Cortex for review).

The rewiring manipulation is performed on one side of the brain only; thus the normal, contralateral

auditory cortex can communicate auditory information across the corpus callosum. This raises the interesting possibility that A1 may have both visual and auditory-responsive neurons. Our anatomical results were consistent with this possibility (Figure 5, cross-modal). Horizontal connections in cross-modal A1 were arranged in a radially symmetric array of clusters as in V1, and, unlike in normal A1, extended toward the medial part of cross-modal A1 (Gao and Pallas, 1999). Callosal connections, in contrast, were pushed laterally and were entirely absent from the medial part of cross-modal A1. The remaining callosally projecting neurons were organized in patches instead of the binaural bands seen in normal A1 (Pallas *et al.*, 1999).

Because we found that the callosal and horizontal connections in cross-modal A1 were arranged in a mutually exclusive pattern, we have proposed that A1 is split in two by the anomalous visual and normal auditory inputs (Pallas, 2002). Laterally, callosal connections would interconnect sound-responsive neurons in both hemispheres. Visually responsive neurons would be preferentially located in medial A1 of cross-modal ferrets, where they would be interconnected according to their orientation tuning. Evidence for iso-orientation connectivity in cross-modal A1 has been provided using optical imaging methods (Sharma *et al.*, 2000), supporting this idea. If it is the case that cross-modal A1 is subdivided by its bimodal inputs, then we can model the evolution of a new cortical area on a developmental timescale. This would provide an ideal system in which to study how evolutionary changes in sensory input could trigger development of a cortical area to process those inputs (Kaas, 1995). In either case, the results show that changing only the pattern of activity without changing the molecular identity of thalamic inputs can configure cortical circuits adaptively.

1.10.3.3.5 Role of inhibition in cross-modal plasticity We have also tested the hypothesis that rearrangements of inhibitory circuitry occur in cross-modal A1. The rationale is that the pathway from the auditory thalamus (medial geniculate nucleus (MGN)) to the auditory cortex projects as a one-dimensional sheet along the isofrequency axis (Pallas *et al.*, 1990), suggesting that in order to represent visual spatial topography in two dimensions, suppression of select subsets of these one-dimensional projections would be necessary. Using immunocytochemical methods to catalog subsets of GABAergic nonspiny, nonpyramidal interneurons, we found that there was an increase in number and a change in morphology of a calbindin-containing subset of inhibitory neurons in A1 as a result of early visual inputs (Gao *et al.*, 1999b, 2000; see Pallas, 2001a, for review). The next question that must be addressed is whether changes in inhibitory circuitry are necessary or sufficient to reconfigure auditory cortex for a visual processing role. We predict that local blockade of intracortical inhibition will eliminate response properties that depend on the two-dimensional nature of visual stimuli, as opposed to the one-dimensional arrangement of sound frequency coding.

1.10.3.3.6 Molecular specification of cortical areas through axon guidance There are several possible explanations of how the functional identity of each cortical area is established. Thalamic projections are well targeted during pathfinding (Crandall and Caviness, 1984; Miller *et al.*, 1993), forming sharp boundaries between projections to adjacent cortical areas, and thus could instruct cortical identity. How these precise projections of thalamocortical afferents are targeted remains to be determined, though previous studies have pointed to the ventral telencephalon and the cortical subplate as containing important guidance cues (Ghosh *et al.*, 1990; Catalano and Shatz, 1998; López-Bendito and Molnar, 2003), and to matching adhesion factors (cadherins) in thalamus and cortex (Gil *et al.*, 2002; Poskanzer *et al.*, 2003). Information intrinsic to cortex, such as transcription factors and markers of positional identity, may be sufficient to set up guidance of TCAs to their appropriate final cortical targets or to establish other unique features. Conversely, cortex may be a *tabula rasa* that is instructed by the TCAs to develop in a particular fashion. More likely the answer lies in between. Our recent effort has been to explore the expression and action of genes identified as candidates for a role in the specification of cortical identity.

Regionally patterned transcription factors and adhesion molecules are thought to be responsible for areal patterning, via specification of both positional information and TCA targeting (Grove and Fukuchi-Shimogori, 2003). Patterned gene expression is known to be involved in the specification of axonal projection patterns in the hindbrain (Keynes and Krumlauf, 1994) and spinal cord (Stoeckli and Landmesser, 1998). This protomap idea (Rakic, 1988) has been tested by cortical gene knockout studies (Bishop *et al.*, 2000; Mallamaci *et al.*, 2000) and by examination of mutants in which thalamocortical projections do not form or form incorrectly (Miyashita-Lin *et al.*, 1999; Nakagawa *et al.*, 1999; Tuttle *et al.*, 1999; Garel *et al.*, 2002). The finding that many patterning genes are expressed whether or not the TCAs are present

supports the idea that they instruct TCA pathfinding. None of the genes found so far are restricted to areal boundaries in their expression, however (Donoghue and Rakic, 1999). Thus, a combinatorial, threshold effect, similar to that for guidance of retinal axons by the repulsive molecules called ephrins (Hansen *et al.*, 2004; Tadesse *et al.*, 2004), has been suggested (Donoghue and Rakic, 1999).

Knockout of the transcription factor gene *Pax6*, which is expressed in a rostrolaterally increasing gradient, results in an apparent caudalization of the remaining cortical epithelium, as defined by rostral shifts in expression of the adhesion factor gene *Cad8* and other caudal marker genes (Bishop *et al.*, 2000; Mallamaci *et al.*, 2000). Conversely, knockout of *Emx2*, another transcription factor gene that is expressed in an opposite gradient to *Pax6*, anteriorizes positional identity in cortex, and is associated with caudal shifts in the normally anteriorly restricted expression of *Cad6* and other anterior marker genes. In addition, expansion or contraction of an *FGF8* expression domain induced by manipulating *Emx2* levels results in opposite shifts in the location of the somatosensory barrel field (Fukuchi-Shimogori and Grove, 2001, 2003). If there were corresponding defects in TCA pathfinding, then a role for the genes in areal specification via TCA guidance would be supported. In *Emx2* mutants, a caudal shift of TCAs to somatosensory cortex occurs, and the projection of TCAs to visual cortex is reduced concomitantly (Bishop *et al.*, 2000; Mallamaci *et al.*, 2000), prompting a suggestion that the loss of *Emx2* redirects TCAs through a change in positional identity of caudal cortex. However, this interpretation has been challenged by reports that TCAs become mistargeted in the ventral telencephalon, before they come into contact with the altered cortical regions (Caric *et al.*, 1997; Garel *et al.*, 2002; Molnar, 2000). Furthermore, another study has shown that similar Fgf8-induced shifts in patterned gene expression, and a resulting caudalization of the cortical epithelium, are not associated with any shift in TCA projection patterns in neonates (Garel *et al.*, 2003). It is possible that, rather than respecifying cortical identity, loss of Pax6 or Emx2 transcription factors interferes with the generation of neurons in cortex. Indeed, the cortex is smaller in the mutants (Bishop *et al.*, 2000), supporting this alternative interpretation. Another complication is that the knockout method eliminates gene function everywhere, throughout life, but these genes likely play multiple roles in development across space and time. In addition, the mutants die before the borders of cortical areas can be confirmed functionally, or have other profound defects that complicate interpretation of the data (Caric *et al.*, 1997; Molnar, 2000; Pratt *et al.*, 2000; Garel *et al.*, 2002). Thus the question of the role of these genes in cortical specification requires further study, with complementary approaches.

Our approach affords the unique advantage of combining physiological and molecular investigations in an animal, the ferret, with protracted postnatal development and well-characterized cortical physiology, providing a model that has major advantages over mice. We combined quantitative reverse transcriptase polymer chain reaction (RT-PCR) with neuroanatomical tracing of both TCA and corticocortical projections in ferrets, comparing A1 and V1 in normal animals in topography and levels of gene expression in relation to the timing of axon ingrowth. We found that, in normal animals, Pax6 and Emx2 expression gradients were declining by postnatal day 10 (P10) to P14, prior to TCA ingrowth. Differential expression of *Cad6* and *Cad8*, however, was maximal during the period of TCA targeting and synapse formation (P14 to P25) and overlapped with the later development of specific corticocortical connectivity (Xu *et al.*, 2003; Figure 6). The expression patterns of Pax6 and Emx2 across development and between cortical areas are consistent with a role in orchestrating gradients of neurogenesis, providing early regional patterning in cortex, and/or triggering a signal cascade that continues in their absence, but not with direct specification of axon targeting to cortex. These genes likely trigger expression of downstream genes such as the cadherins that could be more directly involved with correct pathfinding by TCA axons. The expression patterns between different cortical areas, correlated with the timing of afferent ingrowth, provided the impetus for our further investigations into the roles of cadherins in cortical plasticity.

Individual functional areas within the cerebral cortex have characteristic connectivity patterns which exhibit experience-dependent development and plasticity. Another of our efforts has been to look for a relationship between connectivity patterns and gene expression patterns. The classical cadherins may instruct, or be instructed by, thalamocortical ingrowth (Bishop *et al.*, 2000; Mallamaci *et al.*, 2000; Gil *et al.*, 2002). We tested the hypothesis that, if cadherins are instructive for TCA guidance, then in experimental models producing mistargeting of TCAs, cadherins should be misexpressed. Ferrets deafened prior to the onset of hearing exhibit mistargeting of both retinal and thalamocortical projections (see above and Pallas and Moore, 1997; Pallas *et al.*, 2002). We predicted that these deaf

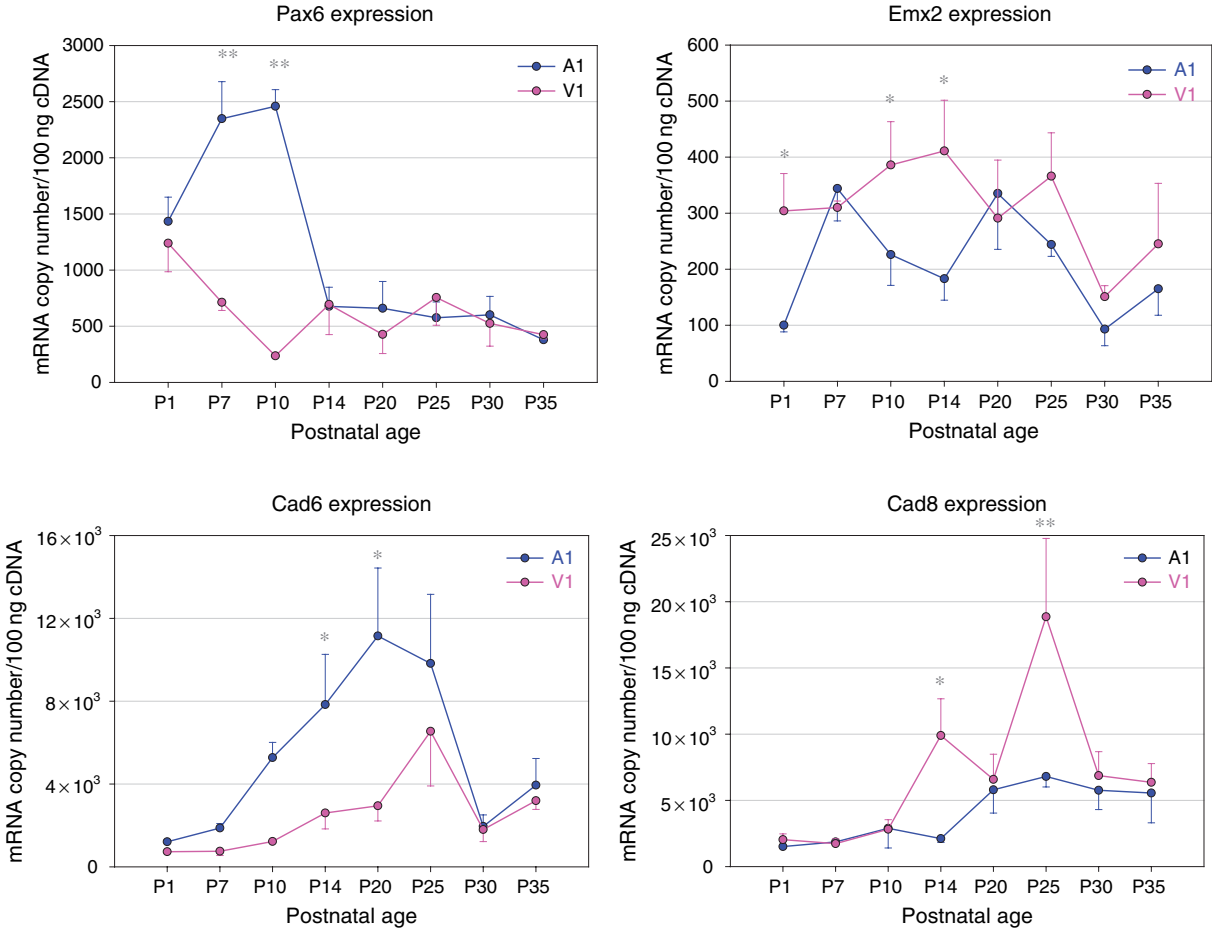

Figure 6 Expression levels of four putative cortical patterning genes were measured with quantitative RT-PCR. Top: Early in development, prior to TCA innervation, *Pax6* is high in auditory cortex and *Emx2* is higher in visual cortex, potentially providing positional information about regional cortical identity. As the TCAs are growing into the cortical plate and corticocortical connections are being formed, *Pax6* and *Emx2* levels drop, but the cadherin pair Cad6 and Cad8 form similar opposing gradients. The cadherins are thought to facilitate patterning of connections throughout the brain. Adapted from Xu, M., Baro, D. J., and Pallas, S. L. 2003. A quantitative study of gene expression topography in visual and auditory cortex during thalamocortical development in postnatal ferrets. *Soc. Neurosci. Abstr.* 29, 673–677.

ferrets with ectopic projections between visual thalamus (LGN) and auditory cortex would exhibit alterations in the spatial pattern of cadherin expression. However, this was not the case. Results from quantitative RT-PCR of cadherin mRNA and Western blots of cadherin protein were similar in normal and deafened ferrets. These data could be interpreted as evidence against a role for cadherins in TCA targeting. The LGN to A1 projections are vastly outnumbered by normal MGN to A1 projections in the deafened ferrets, however, and thus any alteration of cadherin expression may be undetectable with our method. Further study is warranted to uncover how TCA pathfinding strategies can respond to deafferentation of neighboring cortical areas, because it could provide an important basis for the recovery of function seen in humans with impaired sensory ability such as blindness or deafness (Neville, 1990; Sadato *et al.*, 1996; Cohen *et al.*, 1997; Finney *et al.*, 2001; Bavelier and Neville, 2002).

In contrast to this negative result, examination of cadherin mRNA and protein expression in cross-modal animals with altered corticocortical connectivity patterns revealed intriguing changes in cross-modal compared to normal animals. The patterning of corticocortical connectivity reflects the modular organization of the information-processing circuitry of neocortex and is essential to sensory perception. Connectivity within and between cortical areas starts out somewhat diffusely organized and refines during development, at least partly under the influence of activity (Innocenti, 1981; Feng and Brugge, 1983; Callaway and Katz, 1990; Callaway and Katz, 1991; Schlaggar and O'Leary, 1991). There is also evidence for intrinsic specification of corticocortical connectivity patterns by

restricted distribution of gene products, including cadherins (Korematsu and Redies, 1997; Suzuki *et al.*, 1997; Bekirov *et al.*, 2002; Huffman *et al.*, 2004). We reasoned that, if adhesion factors such as the cadherins are involved in targeting of cortico-cortical projections, at the direction of upstream transcription factors such as Pax6 and Emx2, then the cross-modal ferrets with experience-dependent alterations in horizontal and callosal connectivity patterns described above might have cadherin expression patterns reflective of that change. Specifically, the cadherin expression pattern in cross-modal A1 should resemble that in normal V1, given that the connectivity patterns in A1 are organized as they are in V1. Consistent with this idea, we found that expression levels of cadherin 6 and 8 mRNA and protein are similar across A1 and V1 of cross-modal ferrets, and no longer exhibit the graded differential expression seen in normal animals (Xu and Pallas, 2005). Thus cadherins could no longer provide information that could be used to differentiate auditory from visual cortex during the development and refinement of connectivity patterns.

1.10.3.4 Evolutionary Evidence of Cross-Modal Respecification of Cortical Identity

The ability to induce cross-modal projections in an experimental situation is useful only to the extent that it can model a natural event. In addition to the parallels between clinical reports of sensory substitution in the deaf and blind (Bavelier and Neville, 2002), and our findings in cross-modal ferrets, there are evolutionary experiments that also show parallels. Perhaps most well studied are the blind mole rats of the Middle Eastern desert, *Spalax ehrenbergi*. These fossorial creatures are born with a rudimentary eye that does not form images (Bronchti *et al.*, 1991). Wollberg and colleagues have shown that visual cortex in these rodents is activated by auditory stimuli (Bronchti *et al.*, 1989, 2002; Sadka and Wollberg, 2004). This evolutionary inverse of our cross-modal manipulation in ferrets provides the proof of principle that peripheral alterations that occur in evolution can be seamlessly incorporated by plasticity inherent in sensory cortex.

1.10.4 Summary and Conclusions

The three types of investigations discussed above have clearly documented the remarkable plasticity of the developing brain. In the hamster retinocollicular system, removal of more than half of the central target and/or blockade of NMDAR-based coincidence detection have no effect on visual stimulus coding. This conservation of function occurs through compensatory compression of the retinotopic map and rearrangement of inhibitory connections. Loss of sensory input, through neonatal cochlear ablation in ferrets, results in compensatory sprouting of visual thalamic axons into the silenced auditory cortex. Such sensory substitution may underlie the expanded visual capacity of humans with early hearing loss. Cross-modal rewiring of the ferret auditory cortex results in a compensatory alteration of the structure and function of auditory cortex in a way that provides it with visual processing capacity. Taken together, these studies provide insight into how developmental mechanisms such as compensatory innervation could provide an important substrate for evolutionary changes involving alterations in sensory structures or their targets. Our work and that of many others has shown that developmental studies provide a window into the past, providing insights into how the increasing complexity of mammalian sensory systems may have evolved.

1.11 Neuronal Migration

O Marín and G López-Bendito, Consejo Superior de Investigaciones Científicas y Universidad Miguel Hernández, Sant Joan d'Alacant, Spain

Glossary

cortex	Laminar neuronal structure that is formed at the surface of the central nervous system and that includes structures such as the cerebellum and cerebral cortex.
interneuron	Local circuit neuron, sometimes also referred as a Golgi type II neuron. In a general sense, any neuron that lies between an afferent neuron and an effector neuron.
leading process	Cell extension that is located in front of the nucleus and that directs the migration of neurons.
neocortex	The six-layered part of the dorsal pallium, more properly known as the isocortex.
nucleokinesis	The process of nuclear translocation in cells, including interkinetic movements during the cycle of epithelial cells or during cell migration.
pallium	Roof of the telencephalon; it contains both cortical (e.g., hippocampus and neocortex) and deep-lying nuclear structures (e.g., claustrum and parts of the amygdala). Pallium is not synonymous with cortex.
striatum	A part of the subpallium and one of the components of the striatopallidal complex. It comprises deep (caudate nucleus, putamen, and nucleus accumbens) and superficial (olfactory tubercle) parts.
subpallium	Base of the telencephalon; it consists primarily of the basal ganglia (e.g., striatum, globus pallidus, and parts of the septum and amygdala).

1.11.1 Introduction

Neurons of the central nervous system are natural migrants, as most of them originate far from the place where they will eventually perform their normal function. Indeed, the large majority of neurons are generated from precursor cells that line the walls of the ventricular system, from where they migrate until they settle at their final position. Thus, after the genesis of specific cell types through an exquisite and controlled process of patterning and regionalization, neurons of the brain are set to migrate. In some cases, new neurons migrate for relatively short distances to settle, for instance, in the ventral horn of the spinal cord, where they become somatic motor neurons. In other cases, neurons migrate for incredibly long distances, sometimes up to thousands of times their own size, to settle in remote regions of the brain, as in the case of the interneurons of the cerebral cortex or the olfactory bulb. Thus, independent of the neuronal type, location, or function, neuronal migration is always a fundamental step in brain development.

The complexity of the brain in vertebrates is proportional, to a large extent, to the elaboration of the mechanisms controlling neuronal migration. This is particularly evident in the mammalian forebrain and, more specifically, in the telencephalon, where the development of the isocortex has been accompanied by an enormous increase in the distance covered by migrating neurons from the ventricular zone to their final destination. This is in sharp

contrast with the situation found in amphibians, for example, in which neurons barely migrate away from the place they originate. Thus, as a mechanism that shapes the development of the brain, changes in neuronal migration have greatly contributed to its diversification during evolution.

In this article, we review concepts on neuronal migration through evolution, with a focus on the central nervous system (CNS). Whenever possible, we will refer to the development of the cerebral cortex as a model system for studying the cellular and molecular mechanisms controlling neuronal migration. Of note, although the general principles that control migration in the peripheral nervous system are essentially identical to those in the CNS, this subject is beyond the scope of this article. To learn more about this, the reader is referred to reviews focusing on the mechanisms controlling neural crest migration (Robinson, *et al.*, 1997; Locascio and Nieto, 2001; Kalcheim and Burstyn-Cohen, 2005).

1.11.2 Cellular Mechanisms in Neuronal Migration

Despite prominent differences in the distance covered by distinct neuronal types until their final settlement in the brain, or even fundamental discrepancies in the primary mode of migration used by different populations of neurons (discussed in detail in the next section), migrating neurons appear to use a basic set of cellular mechanisms that is roughly similar to those used by other cell types during vertebrate morphogenesis. In that sense, neuronal migration can be considered a cyclic process, in which polarization of the cell is followed by the extension of cell protrusions and differential rearrangements in the adhesion properties of the plasma membrane leading to the movement of the neuron, including its nucleus (nucleokinesis). Moreover, because cell migration is fundamental not only during vertebrate development, but also to plants and even single-celled organisms, the molecular mechanisms underlying this process are likely to be highly preserved throughout evolution.

1.11.2.1 Polarization of Migrating Neurons

The initial response of an immature neuron to a migration-promoting factor is similar to that of other cell types in different organs and organisms and includes the polarization and extension of protrusions in the direction of migration. In other words, the molecular processes occurring at the front and the back of a neuron become distinct during migration, although we still do not understand the fundamentals of these differences. In migrating neurons, the polarized protrusion in the direction of movement is known as the leading process, which appears to behave similarly to extending axons during axon growth and guidance. As growing axons, migrating neurons typically have a single leading process that constitutes the compass reading structure driving directed neuronal migration. In some cases, however, such as, for example, immature cortical interneurons, two or more leading processes seem to act coordinately to direct cell movement (Marín and Rubenstein, 2001). Moreover, although the leading process in migrating neurons is typically only a few cell diameters in length, an extremely long leading process (up to more than 1 mm long) characterizes some populations of migrating neurons. This is the case for example of basilar pontine neurons, which are born in the dorsal hindbrain and migrate to the ventral midline, where they finally reside (Yee *et al.*, 1999).

Despite the close resemblance of the leading process – in particular, of long leading processes – to growing axons, marker analysis suggests that these two structures are molecularly different to a large extent, bearing strong similarities only at their more distant tip, the growth cone (Ramóny Cajal, 1911). For example, the processes of basilar pontine neurons stain with antibodies against transiently expressed axonal surface glycoprotein-1 (TAG-1), but do not express any of the common neuronal markers associated with axons, including growth-associated protein 43 (a molecule expressed by immature axons), microtubule-associated protein-2, or neurofilament 200. Thus, leading processes and growing axons seem to represent distinct cellular specializations used by neurons at different stages of development (Figure 1).

The polarization of migrating neurons (i.e., the extension of a leading process) depends on chemotactic responses to external cues, which seem to control also the orientation of the leading process and therefore the subsequent direction of movement. The molecules that influence the behavior of migrating neurons also typically control axon pathfinding, suggesting that the mechanisms underlying the polarization of both migrating neurons and axons are very similar. For example, Netrin-1, a prototypical axon guidance molecule (Serafini *et al.*, 1994), also promotes the extension of leading processes during neuronal migration and influences the direction of migration in multiple neuronal populations through the CNS. Similarly, Slit proteins prevent axon growth into undesirable regions

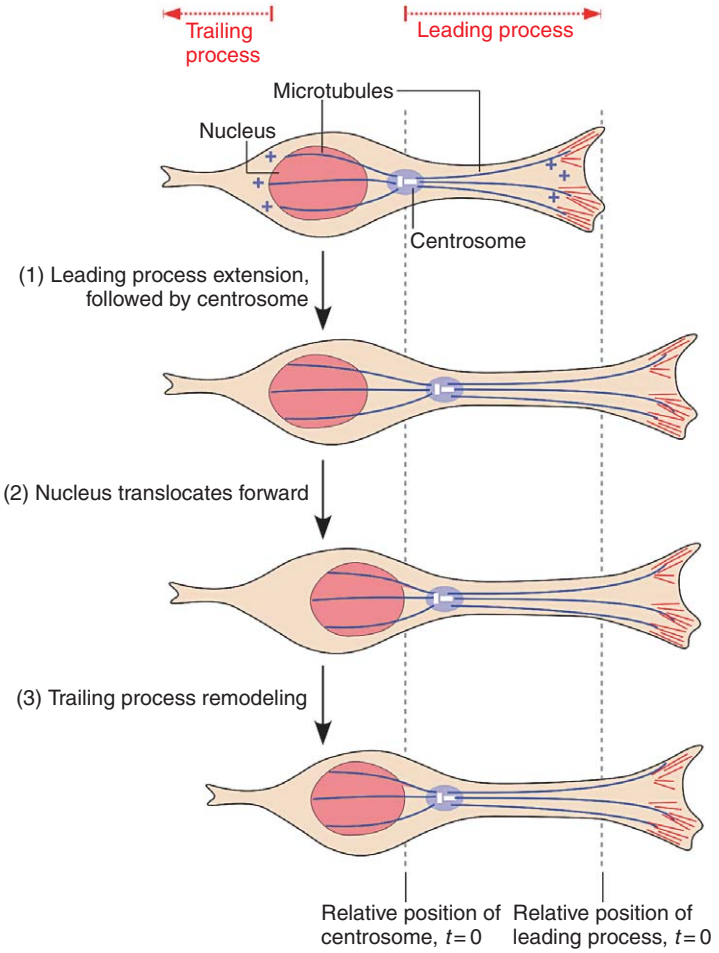

Figure 1 Steps in neuronal migration and the molecules involved. A prototypical migrating neuron contains distinct subcellular domains: the leading process, the perinuclear domain, and the trailing process. Neuronal migration involves repeated cycles of (1) polarized extension of the leading process, followed by movement of the centrosome forward, (2) a highly coordinated movement of the nucleus closer to the centrosome (nucleokinesis), and finally (3) a trailing process remodeling.

and direct neuronal migration through the CNS, acting as chemorepellent factors for both migrating axons and neurons (Brose and Tessier-Lavigne, 2000) (see also Section 1.11.5).

During chemotaxis, migrating cells – including neurons – appear to detect very small differences in chemical gradients and therefore it is likely that the process of polarization requires their amplification through steeper intracellular gradients that allow appropriate cellular responses (Figure 1). In *Dictyostelium* cells, this process involves the polarization of phosphoinositides (such as phosphatidylinositol-triphosphate (PIP3) and phosphatidylinositol (3,4)-biphosphate ($PI(3,4)P_2$)P_2) across the cell and is mediated by localized accumulation at the front of the cell of phosphoinositide 3-kinase (PI3K), which generates phosphoinositides, and restricted localization and activation at the rear of the phosphatase and Tensin homologue deleted on chromosome 10 (PTEN), which removes them (Funamoto *et al.*, 2002). In neurons, however, very little is known about how these molecules control directed polarization. Nevertheless, PI3K is required for the chemotaxis of neurons in response to neurotrophins (Polleux *et al.*, 2002) and perturbation of PTEN function causes abnormal neuronal migration (Li *et al.*, 2003).

Directed migration also requires the polarization of several organelles in slow-moving cells such as neurons. Specifically, the microtubule-organizing center (MTOC) and the Golgi apparatus are normally localized ahead of the nucleus and plays a role in defining the direction of movement. (This is not the case for fast-moving cells such as neurotrophils, in which the MTOC is behind the nucleus.) In other cell types, the small Rho GTPase Cdc42 is active toward the front of migrating cells during chemotactic responses and plays a role in localizing the MTOC ahead of the nucleus, although its contribution to the polarization of migrating neurons is still

unclear. Nevertheless, inactivation of Cdc42 appears to be required for Slit repulsion of migratory cells from the subventricular zone (SVZ) of the telencephalon (Wong *et al.*, 2001), suggesting that Cdc42 may normally help to polarize migrating neurons toward a chemoattractant source but is inactivated during chemorepulsion. Another Rho GTPase, Rac, is also polarized to the front of migrating cells and is involved in promoting directional extension of protrusions through a signaling loop that involves also Cdc42 and PI3K products. In neurons, the cyclin-dependent kinase 5 (Cdk5) and its neuron-specific regulator p35 localize with Rac during the extension of neurites and are part of the signaling machinery that may help neurons to engage in directional migration (Nikolic *et al.*, 1998). The direct interaction of Rac and possibly other small Rho GTPases with the cytoskeleton at the front of the cell appears to constitute the final effector mechanism that mediates the extension of migrating cells in a specific direction.

1.11.2.2 Nucleokinesis

One of the main differences that distinguish axon guidance from cell translocation is, obviously, the coordinated movement of the nucleus during cell migration. Thus, nucleokinesis is a fundamental step in the cycle that leads to directed cell migration and neurons are no exception to this rule. Indeed, disruption of nuclear translocation systematically leads to prominent defects in neuronal migration (Xie *et al.*, 2003; Shu *et al.*, 2004; Solecki *et al.*, 2004; Tanaka *et al.*, 2004).

Nucleokinesis in migrating neurons critically depends on the microtubule network, which plays a part in positioning the nucleus during translocation (Rivas and Hatten, 1995). As briefly mentioned in the previous section, polarization of neurons during migration includes the location of the MTOC ahead of the nucleus, an event that appears to be necessary for normal movement of the nucleus (Figure 1). This process relies on the interaction between the MTOC and the nucleus through a specialized network of perinuclear microtubules and microtubule-associated proteins, such as doublecortin (DCX) and lissencephaly-1 (LIS1). Both of these proteins bind to microtubules and appear to regulate their polymerization, bundling, and/or stabilization in migrating neurons. In humans, mutations in DCX cause an X-linked type of lissencephaly known as double cortex syndrome (also called subcortical band heterotopia), whereas mutations in the *Lis1* gene cause classic lissencephaly, the Miller–Dieker syndrome (Ross and Walsh, 2001).

As expected from their crucial function in nuclear movement, proteins involved in this process are highly conserved throughout evolution. For example, the *Lis1* homologue in the filamentous fungus *Aspergillus nidulans* is a nuclear migration gene. During development of the fungus, cells become multinucleated through several rounds of divisions and it becomes crucial that nuclei disperse uniformly within the cell for normal growth to occur. This process of nuclear migration in fungi also depends on the network of microtubules and is regulated by proteins that associate with the microtubules, such as that encoded by the *nud*F gene. (Proteins related to nuclear movement in *A. nidulans* were isolated through a screen for nuclear distribution mutants, for which they are named.) *nud*F shares 42% sequence identity with *Lis1* and both genes are considered orthologues. Analysis of other nuclear distribution mutants similar to *nud*F has helped to define the molecular mechanisms mediating the function of this protein in fungi and, by extension, in migrating neurons. For example, *nud*F closely interacts with *nud*A, a gene that encodes the heavy chain of cytoplasmic dynein and is directly involved in nuclear translocation. Another protein that appears to act as a downstream effector of *nud*F is NUDE, two homologues of which have been isolated in mammals, mNudE and NUDEL. Both of these proteins localize to the MTOC and appear to be important in controlling the movement of the nucleus through their association with other proteins, such as γ-tubulin or dynein. Indeed, Lis1, dynein, or NUDEL loss of function results in defects of centrosome–nucleus coupling during neuronal migration (Shu *et al.*, 2004; Tanaka *et al.*, 2004). In summary, these findings illustrate how the identification of homologous proteins in model systems such as *A. nidulans* is greatly contributing to the identification of the function of vertebrate proteins associated with neuronal migration and, more specifically, nucleokinesis (Feng and Walsh, 2001).

In addition to proteins that directly associate with the microtubule network encaging the nucleus during nuclear translocation, other signaling proteins appear to be crucial for normal nucleokinesis. One of these proteins is Cdk5, a serine/threonine kinase that phosphorylates proteins that maintain cytoskeletal structures and promote cell motility. Mice deficient in *Cdk5* or its activating subunits, *p35* and *p39*, exhibit prominent laminar defects in the cerebral cortex, suggesting that this signaling pathway is crucial for neuronal migration (reviewed in Dhavan and Tsai, 2001). For instance, NUDEL is a physiological substrate of Cdk5 (Niethammer *et al.*,

2000; Sasaki *et al.*, 2000). Another case is the focal adhesion kinase (FAK), which is localized in a Cdk5 phosphorylation-dependent manner to the perinuclear network of microtubules where it contributes to normal nuclear movement (Xie *et al.*, 2003). Another example is mPar6α, a protein that associates with different forms of protein kinase C and localizes to the MTOC, where it contributes to promote the polarization of the centrosome in the direction of the movement. Because movement of the centrosome precedes that of the nucleus itself, the function of proteins such as mPar6α is essential for determining the direction of nucleokinesis.

In summary, multiple components of the cellular machinery involved in nucleokinesis have been already identified and a model for understanding nucleokinesis in migrating neurons is starting to emerge (Figure 1). As in the past few years, it is expected that the discovery of other proteins involved in this process may arise through additional homology analyses, since it is clear now that the cellular mechanisms underlying nuclear migration are similar throughout evolution, from unicellular organisms to humans.

1.11.3 Modes of Migration in the Developing Brain

1.11.3.1 Two Primary Modes of Migration in the Developing CNS

As discussed in the previous section, the cellular mechanisms underlying the migration of neurons are likely to be similar to those in other cell types. Despite these molecular similarities, two different modes of migration are classically distinguished within the developing brain, radial and tangential migration. In a general sense, radial migration refers to neurons that migrate perpendicularly to the surface of the brain. In contrast, tangential migration is defined by neurons that migrate in a direction that is parallel to the surface of the brain (in either the rostrocaudal axis or the dorsoventral axis) and that is therefore perpendicular to radially migrating neurons. Although this subdivision is primarily based on the orientation of migrating neurons in relation to the neural tube coordinates, it also implicitly reflects the dependence of different classes of neurons on substantially distinct substrates for migration, as we discuss in the next section. In any case, the existence of these different modes of migration in the developing CNS does not indicate that the molecular and cellular mechanisms underlying radial and tangential migration are essentially different. In other words, independent of the mode of migration, alternating cycles of polarization and nucleokinesis are common events to any migrating neuron.

Radial migration is the principal mode of migration within the CNS. In a general sense, radial migration allows the transfer of topographic information from the ventricular zone to the underlying mantle, since neurons that are born nearby tend to occupy adjacent positions in the mantle when using radial migration to reach their final destination. This has important consequences for the organization of the brain. First, radial migration is essential to generate and maintain distinct neurogenetic compartments in the developing neural tube, which is ultimately necessary for the establishment of different cytoarchitectonic subdivisions within the brain (Figure 2). That is, different progenitor regions generate distinct structures in the CNS largely because progenitor cell dispersion is restricted in the ventricular zone (Fishell *et al.*, 1993; Lumsden and Krumlauf, 1996) and migrating neurons from different compartments do not intermingle during their migration. Second, the transfer of positional information from the ventricular zone to the mantle of the brains allows the formation of topographically organized projections, which are crucial for the proper function of the brain. For this reason, radial migration is the basic mechanism preserved throughout evolution to segregate neurons in all regions of the CNS.

Radial migration contributes to the formation of both cortical (i.e., laminar, such as the cerebral cortex, hippocampus, or cerebellum) and nuclear structures (e.g., striatum, red nucleus), although the development of laminar structures is perhaps the most remarkable example on how radial migration may contribute to the formation of complex circuits in the brain. Laminar structures are found in the brain of all vertebrates and, although the most sophisticated example is the mammalian isocortex, the optic tectum of amphibians, reptiles, or birds is a prominent antecedent of this structure. In contrast to brain nuclei, laminar structures are organized to segregate complex patterns of afferent and efferent connections. Because of this organizing principle, the formation of cortical–laminar structures requires the perfect synchronization of proliferation, cell fate, and radial migration mechanisms to determine the number of layers, as well as their cell density and arrangement.

In contrast to radial migration, which appears to play a general role in the formation of major subdivision in the brain, tangential migration is thought to increase the complexity of neuronal circuits because it allows neurons born from distinct

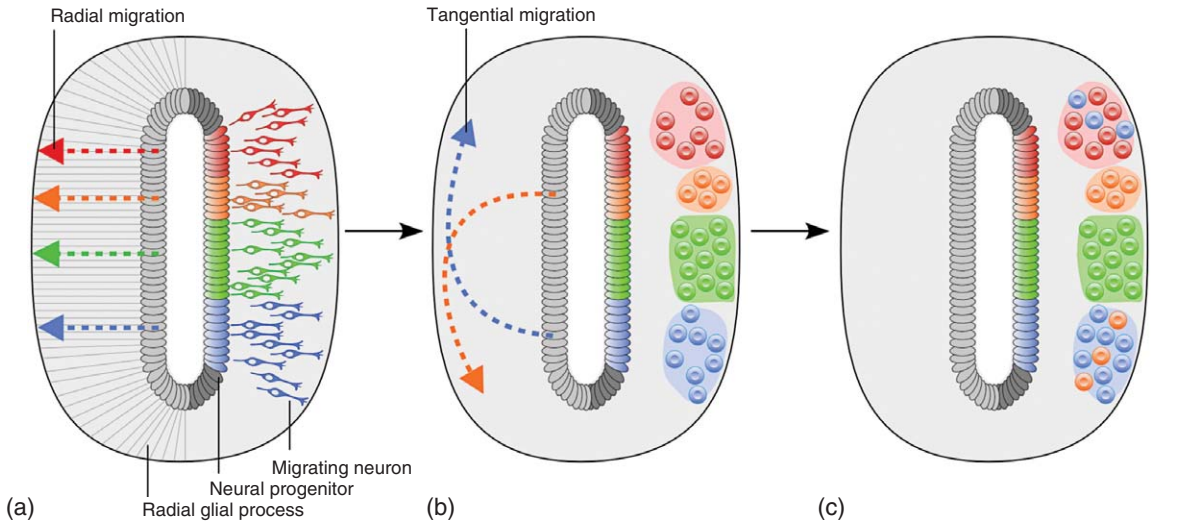

Figure 2 Radial and tangential migration in the central nervous system. a and b, Radial glial cells provide structural support for radial migration, a process that results in the generation of different nuclei that are topographically organized in relation to their place of origin. b and c, Tangential migration is independent of radial glial processes and therefore does not respect topographical references. As a result, tangential migration produces an increase in the complexity of different nuclei by providing cell types distinct from those that are locally generated.

ventricular zones to intermingle and occupy a final common destination (Marín and Rubenstein, 2001) (Figure 2). Tangential migration is likely to be a relatively modern mechanism compared to radial migration, but may have been successfully maintained during evolution because it inherently adds complexity to brain circuits through the incorporation of new cell types with those already present in each region (Figure 2).

Compared to radial migration, the existence of tangential dispersion of neurons in the developing brain has only begun to receive much attention, so it may give the impression of being a relatively contemporary discovery. During the last 30 years of the past century, the predominant view on brain development was based on the idea that radial migration was the sole mechanism allowing the movement of neurons from the progenitor regions to their final destination (Rakic, 1990). This idea was consistent with the basic notion of developmental segmentation in the brain because, as discussed earlier, radial migration contributes to the establishment of segregated cytoarchitectonic regions (Lumsden and Keynes, 1989; Puelles and Rubenstein, 1993). Nevertheless, it was clear from early studies using Golgi-stained sections or electron microscopy that some neurons within the developing brain are oriented tangentially in directions inconsistent with radial migration (Stensaas, 1967; Morest, 1970; Shoukimas and Hinds, 1978). Since then, tangential dispersion has been observed in virtually every subdivision of the developing CNS, from the spinal cord and hindbrain (Bourrat and Sotelo, 1988; Ono and Kawamura, 1989; Leber *et al.*, 1990; Marín and Puelles, 1995; Phelps *et al.*, 1996) to the telencephalon (Austin and Cepko, 1990; Halliday and Cepko, 1992; Walsh and Cepko, 1992; O'Rourke *et al.*, 1992, 1995; Tan and Breen, 1993; De Carlos *et al.*, 1996). In the case of the cerebral cortex, the most compelling experimental evidence supporting the existence of two general modes of cell dispersion, radial and tangential, came from analysis of clonally related cells using retroviral-mediated transfer or highly unbalanced chimeras (Walsh and Cepko, 1992; Tan and Breen, 1993), unequivocally demonstrated by pioneer time-lapse studies (O'Rourke *et al.*, 1992). The main conclusion from all these studies confirms a general principle in our view of brain development: the organization of distinct cytoarchitectonic regions in the CNS most frequently depends on two mechanisms of cell allocation: radial mosaicism and tangential migration.

The existence of two basic modes of migration within the CNS may lead to the erroneous conclusion that there are two major populations of neurons in the developing brain: those that migrate radially and those that use tangential migration to reach their final destination. Indeed, radial and tangential migrations are just two different mechanisms of cell dispersion that the same population of neurons may use indistinctly to reach their final position within the brain. The stereotyped behavior of the facial branchiomotor (fbm) neurons in the hindbrain perfectly illustrates this point (Figure 3). In the mouse, fbm

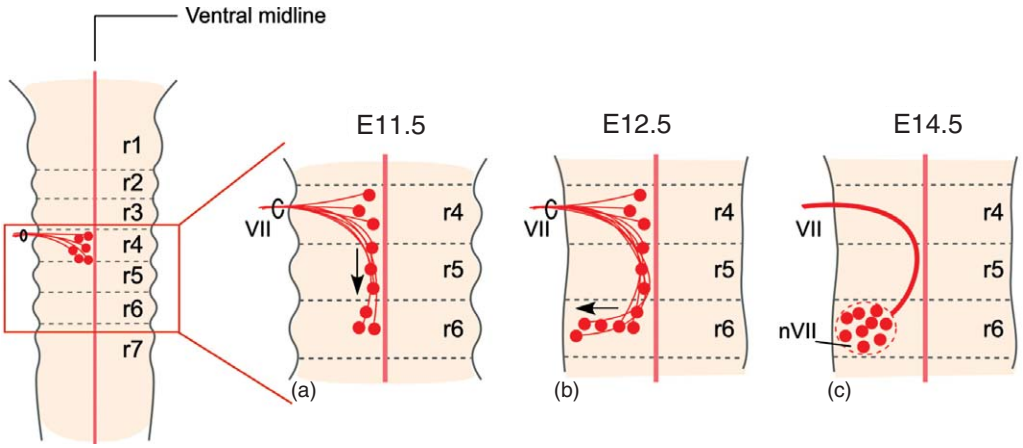

Figure 3 Facial branchiomotor (fbm) neurons adopt tangential and radial modes of migration. Schematic representation of the hindbrain showing the migration of fbm neurons (red circles) during mouse development. At embryonic (E) day 11.5 (E11.5), fbm neurons migrate tangentially (in the caudal direction) from r4, where they originated, to r6. Later, they migrate tangentially within r6, from ventral to dorsal. Finally, they adopt a radial mode of migration to finally form the facial motor nucleus laterally (nVII).

neurons are born in the basal plate of rhombomere 4 (r4), but they finally come to reside in r6. To reach their destination, fbm neurons first migrate tangentially in the caudal direction until they reach r6. Then, they turn 90° and migrate tangentially in the dorsal direction toward the alar–basal boundary. Finally, they turn 90° again and migrate radially toward the pial surface, where they settle to form the facial motor nucleus (for references, see Garel *et al.*, 2000). Similar examples of switching migratory behaviors are present throughout the CNS (cerebellar granule cells, olfactory bulb, and cerebral cortex interneurons, etc.), suggesting that this is a general trend during development. In summary, the same population of neurons may use radial and tangential migration strategies to reach their final destination, likely depending on the extracellular environment available for their dispersion.

1.11.3.2 Evolutionary Advantages of Different Modes of Migration

The development of the cerebral cortex nicely illustrates how the different modes of neuronal migration contribute to the formation of complex circuits in the CNS. The cortex contains two main classes of neurons, the glutamatergic pyramidal neurons and the γ-aminobutyric acid (GABA)-containing neurons. Both classes of neurons use largely different modes of migration to reach their final position in the cortex during development (reviewed in Corbin *et al.*, 2001; Marín and Rubenstein, 2001). Thus, pyramidal neurons migrate radially from the progenitor zones of the pallium to their final position in the cortex. In contrast, interneurons are largely born in progenitor regions of the subpallium and therefore have to migrate tangentially to reach the pallium. Once in the pallium, interneurons change their mode of migration from tangential to radial to reach their final destination in the cortex. Thus, projection neurons and interneurons use different modes of migration to arrive at the cerebral cortex largely because they derive from segregated progenitors within the telencephalon.

What advantage might there be in producing different classes of neurons at distant places in the CNS instead of producing all of them locally for each brain structure? This question might be answered if we consider that cell patterning and migration are intimately linked during the development of the CNS throughout evolution. In the telencephalon, for example, early dorsoventral patterning specifies distinct domains that produce neurons synthesizing different classes of neurotransmitters (reviewed in Wilson and Rubenstein, 2000; Campbell, 2003). Thus, the dorsal region of the telencephalon – the pallium – becomes patterned to produce glutamatergic neurons, whereas the subpallium is specified to generate GABAergic and cholinergic neurons. This organization is a primitive trend of the telencephalon in vertebrates, since it seems to be present in the different classes of living vertebrates (Puelles *et al.*, 2000; Frowein *et al.*, 2002; Gonzalez *et al.*, 2002; Brox *et al.*, 2003) and appears to represent an efficient way to pattern neural progenitors to produce different classes of neurons using a limited number of morphogenetic centers. Thus, patterning mechanisms that have been preserved throughout evolution appear to limit to some extent the generation of multiple classes of neurons in the exact same region of the brain, at least from the perspective of the neurotransmitter phenotype, and tangential

migration may have evolved, among other things, to overcome this limitation.

In mammals, the balance between excitatory (glutamatergic) and inhibitory (GABAergic) synaptic activity is critical for the normal functioning of the cerebral cortex. As a result, inherited disruption of this balance leads to important behavioral dysfunction in animal models (Liu *et al.*, 2000; Steinlein and Noebels, 2000; Powell *et al.*, 2003) and in severe neurological disorders in humans (Keverne, 1999; Lewis, 2000; Sanacora *et al.*, 2000; Holmes and Ben-Ari, 2001). In that context, the introduction of GABAergic interneurons from an external source to the population of cortical neurons may have played a pivotal role in shaping up neural circuits during the expansion of the cerebral cortex through evolution. A recent study by López-Bendito *et al.* (2006) has strongly suggested the convergence of these phenomena in the development of the thalamocortical system. This study has demonstrated the existence of a new tangential migration of GABAergic cells within the ventral telencephalon that mediates the navigation of thalamic axons toward their final destination in the neocortex. Specifically, tangential migration from an evolutionarily primitive intermediate target, the striatum, contributes to form a permissive bridge for the extension of thalamocortical axons through nonpermissive regions of the ventral telencephalon. In a more general sense, whereas radial migration has been preserved as the mechanism conferring regional identity to distinct structures in the CNS, tangential migration may represent a paradigm to increase the complexity of neuronal circuits during evolution. For instance, the casual incorporation of a migratory route that brings a new population of neurons into an established structure (e.g., through a mutation that induces the expression of a receptor for a guidance molecule in that specific population of neurons) may lead to a complete dysfunctional brain or, occasionally, to a modification of the normal function of the structure representing a competitive evolutionary advantage for the species. Such a mechanism may explain, for example, the differences observed in the number of GABAergic interneurons in the dorsal thalamus of primates – in particular humans – compared to other vertebrates (Letinic and Rakic, 2001). Moreover, the identification of a neocortical origin for a population of GABAergic neurons in the developing human cortex reinforces the existence of such evolutionary trend (Letinic *et al.*, 2002).

1.11.4 Mechanisms of Radial Migration

Radial migration has classically been known as glial-guided cell migration because during this process neurons move along the processes of specialized glial cells known as radial glia (Rakic, 1971a, 1971b, 1972; Rakic *et al.*, 1974; Edmondson and Hatten, 1987). Despite their name, however, radial glial cells do not simply function as static supportive elements. Instead, radial glial cells represent an intermediate stage in the stem cell lineage of the CNS (reviewed in Alvarez-Buylla *et al.*, 2001) and undergo mitosis to produce new neurons (Noctor *et al.*, 2001). In addition, radial glial cells have a process that spans the wall of the neural tube and reaches the pial surface (Bergman glial cells being one exception to this rule), where it is anchored to the basal membrane. This process establishes a point-to-point relation between the ventricular zone and the surface of the brain, supporting neuronal movement during radial migration. Genetic defects affecting the development of radial glia cells lead to abnormal neuronal migration in the CNS (reviewed in Ross and Walsh, 2001; Marín and Rubenstein, 2003), suggesting that radial glia integrity is fundamental for radial migration.

Although radial glia integrity is largely essential for radial migration, there seem to be exceptions to the rule described above. During early stages of corticogenesis, for example, new neurons undergo radial migration through a process known as somal translocation (described as perikaryal translocation by Morest, 1970), which appears to be largely independent of radial glial cells (reviewed in Nadarajah and Parnavelas, 2002). During somal translocation, the leading process of migrating cells terminates at the pial surface and it becomes progressively shorter as the cells approach their final position. This is also observed in cells moving through glial-guided radial migration as they approach the pial surface. Thus, for some cell types or specific developmental periods, radial migration may not directly depend on radial glial cells.

Radial migration has been preferentially studied during the development of the cerebral cortex and the cerebellum and thus most of our knowledge on the mechanisms that control radial migration derives from the analysis of these structures. *In vitro* and *in vivo* studies of radial cell migration have identified a number of molecules that mediate this mode of migration. These molecules belong to multiple categories, including motogenic factors (i.e., factors that promote migration), cell adhesion molecules, receptors, and secreted factors, some of which are described below. We have excluded from this list molecules controlling those aspects of migration that are likely to be common to any type of neuronal migration (e.g., LIS1, DCX; see Section 1.11.2), even though they have been

classically associated with radial migration defects. In that context, it is worth noting that neuronal migration abnormalities are likely to be more easily identified in laminar than in nuclear structures; this does not exclude, however, a role for these molecules in other types of migration (see, for example, McManus *et al.*, 2004b; Pancoast *et al.*, 2005).

Several classes of molecules have been described to stimulate radial migration. In the cerebral cortex, for example, members of the neurotrophin family such as brain-derived neurotrophic factor (BDNF) and neurotrophin-4 (NT-4) promote the motility of cortical cells through their high-affinity receptor tyrosine kinase B (TrkB) (Behar *et al.*, 1997; Brunstrom *et al.*, 1997). Other factors, such as (GABA) and glutamate, also appear to promote the migration of cortical neurons *in vitro*. These neurotransmitters are released independently of the conventional soluble N-ethylmaleimide sensitive fusion protein attachment protein receptor (SNARE)-dependent mode of secretion – probably through a paracrine mechanism – and mediate their effects primarily through the activation of $GABA_A$ and N-methyl-D-aspartate (NMDA) receptors (Komuro and Rakic, 1993; Behar *et al.*, 1996, 1999, 2001; Manent *et al.*, 2005).

To a large extent, most factors directly involved in controlling radial migration are molecules that regulate the interaction between migrating neurons and radial glial. This is the case of Astrotactin-1 (Astn1), which was first identified as an activity mediating the interaction of neurons and radial glial processes in cerebellar cultures (Edmondson *et al.*, 1988). Astn1 is a glycoprotein expressed by migrating neurons both in the cerebellum and in the cerebral cortex and it is required for normal migration of neuroblasts along glial processes (reviewed in Hatten, 2002). Integrins constitute another family of factors implicated in the association between migrating neurons and radial glia. Thus, function-blocking antibodies against α3, αv, and β1 integrins perturb the interaction between neurons and radial glial cells *in vitro* (Anton *et al.*, 1999; Dulabon *et al.*, 2000). Moreover, radial migration is altered in the cerebral cortex of α3, α6, or β1 integrin mutant mice (Georges-Labouesse *et al.*, 1998; Anton *et al.*, 1999; Graus-Porta *et al.*, 2001), although the precise function of integrins during *in vivo* radial migration remains unsettled. In the case of α3 integrin, however, it has been suggested that signaling through this receptor may directly control actin dynamics and consequently influence the ability of migrating neurons to search and respond to guidance cues in the developing cortex (Schmid *et al.*, 2004).

The interaction between migrating neurons and radial glial fibers may also be controlled through intracellular signaling cascades. For example, correct apposition of neurons to radial fibers may largely depend on the morphology of migrating neurons. In the cerebral cortex, migrating neurons are largely bipolar, which possibly facilitates their interaction with radial glial processes. In the absence of p35, a regulatory activator of Cdk5 that controls the function of many proteins associated with the cytoskeleton, the leading process of radially migrating neurons is branched, and this associates with an impaired neuronal–glia interaction and perturbed migration (Gupta *et al.*, 2003). Thus, the morphological organization of migrating neurons might be an important factor in determining their mode of migration.

The interaction between migrating neurons and radial glial processes is important not only for the initiation and maintenance of radial migration, but also for the control of its finalization. The precise termination of radial migration is crucial for the normal organization of brain structures. This is more evident in cortical structures, in which the pattern of radial migration termination determines the establishment of the laminar organization. In the case of the isocortex, birth-dating studies have shown that layers in the cortical plate (future cortical layers 2–6) are established according to an inside–outside pattern, where the deeper layers contain cells that become postmitotic earlier than the cells in more superficial layers (Angevine and Sidman, 1961; Rakic, 1974). During development, new neurons migrate radially toward the surface of the cortex, passing through cohorts of previously born neurons, and detach from radial glia as they approach the marginal zone. Analysis of mutations in mice and humans has revealed that the interaction between migrating neurons and Cajal–Retzius cells, a specialized cell type present in the embryonic marginal zone, is essential for controlling the detachment of migrating neurons from radial glia and, subsequently, the normal laminar organization of the cortex (reviewed in Gupta *et al.*, 2002; Marín and Rubenstein, 2003).

The interaction between Cajal–Retzius cells and radially migrating neurons is mediated, at least in part, by Reelin, a large glycoprotein secreted by Cajal–Retzius cells during early stages of the development of the cortex. Reelin is expressed in many regions of the developing brain and in many species of vertebrates, but its function has been most extensively studied in the developing cortex. (see Reelin, Cajal-Retzius Cells, and Cortical Evolution for more on Reelin and its function in neuronal migration.) Reelin is a high-affinity ligand for two members of

the LDL family of lipoprotein receptors, the very low-density lipoprotein receptor (VLDLR) and the low-density lipoprotein receptor-related protein 8 (LRP8, also known as ApoER2), which are expressed by radially migrating cortical neurons (D'Arcangelo *et al.*, 1999; Hiesberger *et al.*, 1999). Signaling through VLDLR/LRP8 mediates tyrosine phosphorylation of the mouse homologue of the *Drosophila* protein Disabled (DAB1). DAB1 is a cytoplasmic adapter protein that interacts with the cytoplasmic tails of VLDLR and LRP8 and is linked to events related to the reorganization of the cytoskeleton.

Although many aspects of the function of the Reelin–VLDLR/ApoER2–Dab1 pathway in radial migration remain unsettled, it is clear that Reelin signaling is involved in the final events that lead to the detachment of migrating neurons from radial glia. Loss of Dab1 function, for example, results in an impairment of the adhesive properties of radially migrating neurons, which fail to detach normally from the glial fiber in the later stage of migration (Sanada *et al.*, 2004). Importantly, the influence of Reelin on the adhesive properties of radially migrating neurons may be the result of its interaction with other proteins, such as $\alpha 3\beta 1$ integrin receptors, which are expressed in radially migrating neurons (Dulabon *et al.*, 2000). It should be noted, however, that Reelin function is likely not restricted to controlling the interaction between migrating neurons and glial fibers.

It is likely that the Reelin–VLDLR/ApoER2–Dab1 pathway is just one of many signaling routes controlling neuronal detachment from radial glia and movement termination in the cerebral cortex. Thus, other proteins that are specifically expressed in radial glial processes at the level of the cortical plate are also candidates for the regulation of this process. One of these proteins is secreted protein acidic and rich in cysteine-like 1 (SPARC-like 1), which appears to function in ending neuronal migration by reducing the adhesiveness of neurons to glial fibers in the cortical plate (Gongidi *et al.*, 2004).

1.11.5 Mechanisms of Tangential Migration

Tangential migration, defined as a nonradial mode of migration, includes distinct types of cell movement that differ in the type of substrate used by migrating cells. Regardless of the substrate employed, tangentially migrating cells share an important common feature: they do not respect regional forebrain boundaries. Thus, cell populations engaged in tangential migration normally move over long distances and follow complex trajectories before reaching their final destination. These migrations usually involve multiple changes in the direction of the movement, which depend on changes in the environment and/or the responses of migrating neurons. In the past few years, many studies have demonstrated the existence of environmental cues that can act as contact or diffusible attractants or repellents that provide directional information to tangentially migrating neurons through interactions with cell-surface receptors (see Table 1). Here, the cellular and molecular mechanisms controlling tangential migration are reviewed using as examples two well-characterized tangential migratory populations, cortical interneurons and facial branchiomotor neurons.

1.11.5.1 Migration of Cortical Interneurons

The tangential migration of cortical interneurons to the cortex is, most likely, one of the most intensively studied cell populations of the developing brain since the seminal discovery of their subpallial origin in mammals (Anderson *et al.*, 1997). Since then, several other studies have shown that a subpallial origin of cortical interneurons is a common feature to, at least, tetrapod vertebrates (Cobos *et al.*, 2001; Gonzalez *et al.*, 2002; Brox *et al.*, 2003), suggesting that this is a highly conserved trait in cortical evolution.

Cells migrating tangentially to the cortex have multiple origins within the subpallium (reviewed in Corbin *et al.*, 2001; Marín and Rubenstein, 2001), although most GABAergic interneurons seem to derive from the medial ganglionic eminence (MGE). Interestingly, the MGE is also the source of interneurons for other forebrain structures, such as the striatum (Marín *et al.*, 2000; Wichterle *et al.*, 2001). Consequently, most of our knowledge on the mechanisms controlling the migration of cortical interneurons refers to MGE-derived cells and it is likely that different molecules may control the migration of interneurons generated in other subpallial structures, such as the caudal ganglionic eminence (Nery *et al.*, 2002).

There are several key decision points affecting the migration MGE-derived cortical interneurons. First, interneurons initiate their migration in response to factors that stimulate their movement. Second, interneurons refrain from migrating in ventral and ventromedial regions – thus avoiding the preoptic area and the septum – directing instead their movement in a dorsal direction. Third, cortical interneurons actively avoid entering the developing striatum, a target for other classes of MGE-derived interneurons. Early during development, interneurons

Table 1 Guidance factors and neuronal migration in the CNS

Gene	*Function*	*Neuronal population*	*Refs.*
BDNF, NT4	Growth factor; motogenic; promotes neuronal migration	Cortical interneurons, cortical projection neurons	*a*
SDF1	Chemokine; chemoattractant	Cerebellar granule cells, dentate granule cells, cortical interneurons	*b*
EphrinB2, EphrinB3	Guidance molecules; chemorepellents	Rostral migratory stream	*c*
GABA	Neurotransmitter; chemoattractant	Cortical interneurons, cortical projection neurons	*d*

tend to migrate superficial to the striatal mantle. However, as development proceeds and the dorsal striatum becomes a large structure in the basal ganglia, cortical interneurons migrate preferentially deep to the striatal mantle (i.e., through the interface between the SVZ of the lateral ganglionic eminence and the striatal mantle). Fourth, interneurons cross the subpallial–pallial boundary, invading the pallium through highly stereotyped routes of migrating, which include the marginal zone, the subplate, and the cortical SVZ. And fifth, interneurons invade the cortical plate and integrate in their appropriate layer according to their birth date. Thus, the migration of cortical interneurons is a complex and well-orchestrated event in the developing forebrain. So, what are the molecular cues that regulate each of these decisions?

Cortical interneurons initiate their movement and engage in long-distance migration probably because they respond to motogenic/scatter factors along their pathway. Several such factors have been identified in the past few years, all of which have in common their ability to also influence the maturation and final differentiation of cortical interneurons. Thus, the neurotrophins BDNF and neurotrophin-4, the scattered factor/hepatocyte growth factor, and the glial-derived neurotrophic factor (GDNF) all have the ability to promote interneuron migration to the cortex (Powell *et al.*, 2001; Polleux *et al.*, 2002; Pozas and Ibanez, 2005).

Cortical interneuron migration to the cortex is strongly influenced by molecular activities that prevent interneuron invasion of unsolicited regions. This is the case in the preoptic area and the septum, where the molecular nature of the repulsive activity preventing the migration of interneurons is still unknown (Marín *et al.*, 2003). The striatum constitutes a nonpermissive territory for the migration of cortical interneurons because it expresses class 3 semaphorins (Sema3A and Sema3F) and cortical interneurons

express neuropilin receptors for these repellent cues (Marín *et al.*, 2001; Tamamaki *et al.*, 2003).

Cortical interneuron migration is also controlled by permissive and attractive factors that direct interneurons in a dorsal direction from the MGE to the cortex (Marín *et al.*, 2003; Wichterle *et al.*, 2003). However, for the first time, a chemoattractive effect on cortical interneurons by a molecule expressed at the cortex has been described. This cue is Neuregulin-1 (NRG1), a member of the neuregulin family of proteins. Of note, different isoforms of NRG1 are differentially expressed in the developing telencephalon, thus controlling distinct aspects of the migration of cortical interneurons (Flames *et al.*, 2004). Thus, membrane-bound forms of NRG1, Cystein-rich domain (CRD)-NRG1, are expressed in the route of interneuron migration from the MGE to the pallial–subpallial boundary, and it seems to create a permissive corridor for interneuron migration toward the cortex. In addition, diffusible forms of NRG1, Ig-NRG1, are specifically expressed in the cortex, from where they appear to attract interneuron migration. Other factors are likely to attract interneuron migration to the cortex. For example, GDNF also acts as an attractive cue for interneuron migration *in vitro* (Pozas and Ibañez, 2005), although its wide distribution in the telencephalon suggests that it may rather act as motogenic factor *in vivo*.

It has been suggested that cortical interneurons may use corticofugal axons as a substrate for their migration to the cortex. Axons have been proposed as substrates for other tangentially migrating cell populations, such as gonadotropin-releasing hormone neurons (Wray, 2002), and *in vitro* evidence suggests that axons may serve as substrates for the migration of cortical interneurons (McManus *et al.*, 2004a). Moreover, molecules specifically expressed in corticofugal axons appear to influence interneuron migration *in vitro* (Denaxa *et al.*, 2001). At the peak of interneuron migration, however, most cells migrate through axon-poor regions such as the cortical SVZ, suggesting that axons may influence primarily early stages of interneuron migration to the cortex.

The guidance of cortical interneurons may also be influenced by neuronal activity. In agreement with this hypothesis, several studies have described the early expression of GABA and glutamate receptors at the cerebral cortex before the formation of synapses (Métin *et al.*, 2000; López-Bendito *et al.*, 2002a, 2002b; Luján *et al.*, 2005). The function of some of these receptors has been tested *in vitro*. For example, stimulation of alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors in slice cultures induces GABA release in tangentially migrating cells (Poluch and Konig, 2002). In contrast, *in vitro* blockade of $GABA_B$ receptors leads to a derailment of GABAergic interneurons within the neocortex (López-Bendito *et al.*, 2003). Others neurotransmitter receptors, such as NMDA, AMPA/Kainate, and $GABA_A$, are also functional on tangentially migratory interneurons (Métin *et al.*, 2000; Soria and Valdeolmillos, 2002), suggesting that they also influence the migration cortical interneurons through a yet unknown mechanism.

Once interneurons reach the cortex, they invade the cortical plate and distribute through the different cortical layers. Interestingly, invasion of the cortical plate does not occur automatically as interneurons reach the cortex, but rather seems to be a highly stereotyped process designed to allow the homogeneous dispersion of cortical interneurons throughout the whole rostrocaudal and mediolateral extent of the cerebral cortex (G. López-Bendito and O. Marín, unpublished observations). In addition, invasion of the cortical plate by interneurons may depend on radial glia (Ang *et al.*, 2003; López-Bendito *et al.*, 2004; Tanaka *et al.*, 2003) and thus on the mechanisms described for cortical pyramidal cells (see Section 1.11.4). Nevertheless, some of the molecules that influence migration of projection neurons, such as Cdk5, do not seem to influence the tangential migration of cortical interneurons or their subsequent movement into the cortical plate (Gilmore and Herrup, 2001).

1.11.5.2 Migration of Facial Branchiomotor Neurons

Tangential cell movements during CNS development are not restricted to forebrain. Indeed, tangential migration is present at all rostrocaudal levels of the neural axis. In the hindbrain, for example, the facial (nVII) branchiomotor neurons of several vertebrates, including fish and mammals, follow a large stereotyped migration that includes tangential migration from their origin in r4 to caudal r6 or r7 (reviewed in Chandrasekhar, 2004). Tangentially migrating fbm neurons use a mode of migration very similar to the somal translocation described in the cortex (Book and Morest, 1990), in which the nucleus moves along a large leading extension as the migrating cell leaves behind an axonal process that reflects the migratory path.

It has been shown that environmental cues present in r5 and r6 mediate fbm neuronal tangential migration. Interestingly, chick fbm neurons undergo limited caudal migration naturally; however,

transplantation studies have demonstrated that these cells have the ability to migrate caudally when transplanted into mouse r4, demonstrating that the cues necessary for the initiation, and perhaps maintenance, of caudal migration are absent in the chick hindbrain (Studer, 2001). Additional evidence for environmental cues regulating fbm migration comes from genetic and molecular studies in zebra fish. In the zebra fish mutant *trilobite* (*tri*), fbm neurons fail to migrate tangentially into r5–7 (Bingham *et al.*, 2002). This phenotype, however, can be rescued when *tri* mutant fbm neurons are transplanted into a wild-type environment, whereas wild-type fbm neurons fail to migrate caudally in a mutant context. What molecules are responsible for this behavior? Tangentially migrating fbm neurons regulate the expression of genes encoding the cell membrane proteins, such as TAG-1, Ret, and Cadherin-8, and this regulation is dependent on their location at r4, r5, or r6 (Garel *et al.*, 2000). Interestingly, in embryos deficient for *Ebf1* or *Nkx6-1*, fbm neurons either fail to migrate or undergo an incomplete caudal migration, prematurely expressing an abnormal combination of markers (Garel *et al.*, 2000). These data suggest that fbm neurons adapt to their changing environment by switching on and off specific genes.

Finally, studies have shown that tangential migration of fbm neurons is controlled by neuropilin receptors, as is the case for cortical interneurons. Thus, loss of Neuropilin-1 (Nrp1) in the mouse compromises the tangential migration of fbm neurons, causing the formation of misshapen and malpositioned facial motor nuclei. In contrast to cortical interneurons, however, which rely on class 3 semaphorins for their guidance, soma migration of fbm neurons relies on the presence of a structurally unrelated Nrp1 ligand, an isoform of vascular endothelial growth factor (VEGF) termed VEGF164 (Schwarz *et al.*, 2004).

1.11.6 Migration in the Postnatal Brain

Neuronal precursor cells persist in the adult vertebrate forebrain and thus new neurons are continuously added to restricted regions, such as the olfactory bulb and hippocampus in mammals. Consequently, neuronal migration is not restricted to the embryonic milieu but also exists in an adult brain environment. Because the latter is thought to be largely a nonpermissive territory for cell movement – with the obvious exception of cancer cells – migration is restricted to very specific permissive pathways within the brain.

Perhaps the best-known example of adult neurogenesis and neuronal migration is among the first discovered, that of the adult songbird forebrain (Goldman and Nottebohm, 1983). Songbirds display widespread neurogenesis and migration during adulthood, most remarkably in an area of the telencephalon involved in song learning, the higher vocal center (HVC). Studies carried out by Alvarez-Buylla and colleagues (Alvarez-Buylla and Nottebohm, 1988) showed that neurons originating in the SVZ migrate to the cortex when new neurons are added to the songbird hippocampus and HVC, in a process involving the guidance of radial fibers. Moreover, both diffusible and substrate-bound molecules control this migration through a set of hormonally regulated short-distance cell–cell interactions.

In contrast to the relatively widespread neurogenesis found in songbirds, the adult mammalian forebrain utilizes progenitors to generate new neurons destined for very few regions. Specifically, the SVZ of the lateral ventricle and the dentate gyrus subgranular zone (SGZ) of the hippocampus are the regions where adult neurogenesis has been demonstrated (reviewed in Gage, 2000; Alvarez-Buylla and Lim, 2004). The adult SVZ produces new GABAergic interneurons for the olfactory bulb, whereas the SGZ gives rise to granule cells of the hippocampus. Despite the hostile territory that the adult brain represents for migration, new neurons in the hippocampus have a relatively easy path to their final destination, because they are very close to their final location. A different case is the migration of olfactory interneurons, which need to navigate through an extremely long distance from the SVZ to the olfactory bulb.

In contrast to the findings regarding neurogenesis and neuronal migration in songbirds, radial glia cells do not guide the postnatal migration of newly born cells. Instead, olfactory interneurons migrate using a cellular process called chain migration, which involves homotypic interactions between the migrating cells and tubular structures formed by specialized astrocytes (Lois *et al.*, 1996). This migration occurs through a highly restricted route termed the rostral migratory stream (RMS). Like other cell populations in the embryonic brain, tangentially migrating olfactory interneuron precursors change the direction of movement on arriving in the olfactory bulb, migrating radially into specific layers.

Defining the diffusible or membrane-bound factors that guide the tangential migration of new interneurons from the adult SVZ to the olfactory bulb is a very active field in developmental neurobiology. A polysialated glycoprotein neuronal cell

adhesion molecule (PSA–N-CAM) is highly expressed on the surface of olfactory migrating neurons and it has been shown that deletion of the gene for N-CAM or enzymatic removal of PSA results in deficits in the migration of olfactory interneurons and a reduction in the size of the olfactory bulb (Cremer *et al.*, 1994; Ono *et al.*, 1994). Evidence suggests that PSA and/or N-CAM may not be essential for chain formation but, without them, there are several alterations in the nature of the chains that may inhibit the migration of neuronal precursors (Hu *et al.*, 1996). Several additional adhesion molecules have been identified in the migratory route of olfactory interneuron precursors. For example, Tenascin-C, a ligand for αvβ3 and αvβ6 integrins, is strongly expressed in the astrocytes that form the tubes through which olfactory precursors migrate in the RMS (Jankovski and Sotelo, 1996), and αv-, β3-, and β6-integrin subunits are also present in the postnatal RMS. Nevertheless, the lack of abnormalities in the olfactory bulb of mice with individual mutations for some of these molecules prevents a more definitive evaluation of the function of these proteins *in vivo*.

The molecular mechanisms guiding the highly directed migration of olfactory interneurons in the RMS are still unclear, although both attractive and repulsive guidance cues have been proposed to mediate this process. Among the repellents, Slit proteins have been shown to repel SVZ-derived cells *in vitro* (Hu, 1999; Wu *et al.*, 1999). In addition, evidence demonstrates that the activation of the receptor tyrosine kinase ErbB4 is essential for regulating the organization of neural chains in the RMS and therefore their migration (Anton *et al.*, 2004). It seems evident that other molecules are likely to be involved in this process – future experiments will determine their molecular nature.

1.11.7 Conclusions

Studies on the cell biology of neuronal migration suggest that migrating neurons share many common mechanisms with other migrating cell types in the vertebrate body, although additional experiments are required to comprehensively decipher the cellular and molecular components of the migratory machinery in neurons. Regardless of the cell biological mechanisms, distinct modes of migration exist in the embryonic and adult brains, which seem to be adapted to fulfill different functions during evolution. Thus, whereas radial migration may have evolved as a mechanism to preserve the identity of different regions in the developing brain, tangential migration may have provided a means to increase the complexity of neural circuits during evolution.

Glossary

BMP	Bone morphogenetic protein.
CAM	Cell adhesion molecule.
C. elegans	*Caenorhabditis elegans*.
CNS	Central nervous system.
Comm	Commissureless.
CSPG	Chondroitin sulfate proteoglycan.
DCC	Deleted in colorectal cancer.
DRG	Dorsal root ganglion.
FGF	Fibroblast growth factor.
frz	Frizzled.
GDNF	Glial cell line-derived neurotrophic factor.
GFP	Green fluorescent protein.
GPI	Glycosyl-phosphatidyl.
Hh	Hedgehog.
HSPG	Heparan sulfate proteoglycan.
LPA	Lysophosphatidic acid.
MAP	Microtubule-associated protein.
NGF	Nerve growth factor.
ONH	Optic nerve head.
RGC	Retinal ganglion cell.
Robo	Roundabout.
SFRP	Secreted Frizzled-related protein.
Ti	Tibial.
Wnt	Wingless.

1.12.1 Introduction

The formidable task of accurately establishing the connections of the central nervous system (CNS) is shared by both vertebrates and invertebrates and appears to be conserved throughout phylogeny. For example, in adult humans, the nervous system consists of more than a billion neurons, each connecting to over 1000 target cells in intricate circuits (see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates, Primate Brain Evolution in Phylogenetic Context, The Evolution of Parallel Visual Pathways in the Brains of Primates, Brain Size in Primates as a Function of Behavioral Innovation, Constraints on Brain Size: The Radiator Hypothesis). The very simple nervous system of the nematode *Caenorhabditis elegans* contains only 302 neurons, yet faces similar challenges with respect to forming appropriate neuronal connections. Indeed, despite millions of years of evolutionary separation, most of the key molecules that mediate the formation of the nervous system in organisms as different as humans and *C. elegans* are highly conserved. These neuronal connections are

generated during embryogenesis in a highly specific and precise manner, which is fundamental for the proper functioning of the adult nervous system.

As development progresses, neurons connect to each other in their local environment with dendrites and to distant targets through the extension of an axon. The process of dendritogenesis is a very complex field (reviewed in Sanes *et al.*, 2000) and, in this article, we will focus solely on axon development. Observations of developing axonal projections *in vivo* have revealed that axons extend toward their targets in a highly stereotyped and direct manner (reviewed in Sanes *et al.*, 2000). Axon pathfinding is controlled by proteins present in the environment explored by each growing axon, which is tipped at its leading edge by a specialized structure called the growth cone (Ramon y Cajal, 1890). The growth cone receives and integrates local attractive and repulsive signals presented by cells in the environment, resulting in directed guidance toward its appropriate target.

How does the growth cone accomplish this? Understanding the molecular interactions between a growth cone and the environment presents a great challenge for neurobiologists. Our current knowledge comes from studies of both vertebrates and invertebrates, with each group of organisms offering specific advantages toward the elucidation of this process. For example, invertebrates are commonly used for genetic mutation screens to identify genes of interest in axon pathfinding, whereas vertebrate models have provided useful systems in unraveling the functional mechanisms of these genes.

In this article we will describe the general aspects of axon pathfinding. We will first discuss the molecular characteristics of the growth cone and some general concepts of axon guidance; second, we will describe the main families of guidance cues; third, we will focus on two model systems commonly used to study axon pathfinding, the vertebrate visual system and the CNS midline choice point; and finally, we will discuss some mechanisms known to modulate axon pathfinding.

1.12.2 The Growth Cone: A Central Player in Axon Pathfinding

The growth cone structure was first characterized more than a century ago by the Spanish neuroanatomist, Ramon y Cajal. He imagined the growth cone as a "soft battering ram" that extending axons used to force their way through the embryonic brain (Ramon y Cajal, 1890). Following this discovery, it was shown that axons of embryonic neural tube tissue are tipped with growth cones and are able to grow along a glass coverslip (Harrison, 1910). These very active structures have now been characterized using imaging techniques in both invertebrates and vertebrates and their structure shows a remarkable degree of conservation among species (reviewed in Sanes *et al.*, 2000).

1.12.2.1 The Growth Cone is a Highly Dynamic Structure and Changes Its Shape in Response to Its Environment

1.12.2.1.1 Structure and organization of the growth cone The growth cone is a highly dynamic, actin-rich structure capable of recognizing and responding to a variety of guidance cues (Figure 1). It consists of two major domains, the peripheral and central domains, which are characterized by specific cytoskeletal components. The peripheral domain is rich in actin filaments, while the central domain mainly contains microtubules, mitochondria, and various other organelles. In the peripheral domain, the actin filaments are organized into different types of membrane structure: they can extend into finger-like protrusions (filopodia), remain closely associated with the substratum (lamellipodia), or appear at the apical surface of the growth cone (membrane ruffles).

Microtubules present in the central domain are oriented with their plus ends toward or within the peripheral domain (Gordon-Weeks, 1993) and serve as the major cytoskeletal structure on which rapid vesicular transport occurs (Lockerbie *et al.*, 1991). Such vesicles deliver the molecules needed for neurite elongation, including structural proteins and lipids.

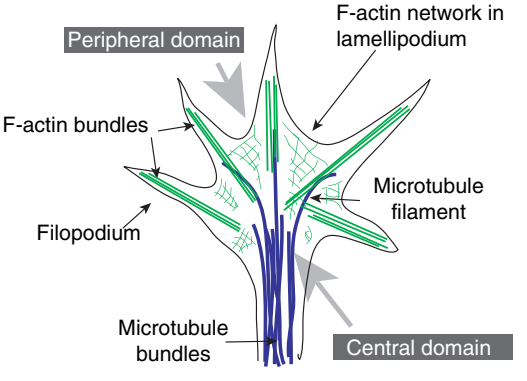

Figure 1 Structure of the growth cone. The growth cone is the highly dynamic tip of the axon that is involved in pathfinding. The growth cone consists of a central and a peripheral domain. The central domain contains stable microtubule bundles as well as membranous organelles. The peripheral domain is rich in actin filaments, which comprise either the F-actin network found in lamellipodia, or the F-actin bundles of filopodia. The growth cone cytoskeleton can be rapidly remodeled in response to environmental cues. Adapted from Dickson, B. J. 2002. Molecular mechanisms of axon guidance. *Science* 298, 1959–1964.

1.12.2.1.2 The dynamic cytoskeleton The growth cone cytoskeleton plays an important role in the process of cell movement (Reinsch *et al.*, 1991; Bentley and O'Connor, 1994; Heidemann *et al.*, 1995; Heidemann, 1996; Letourneau, 1996). The most important cytoskeleton components for axon pathfinding are actin, tubulin, and several actin- and microtubule-associated proteins (MAPs). Tubulin and actin polymerize at the distal tip to generate microtubules and microfilaments respectively. Associated proteins are involved in the assembly, disassembly, and stabilization of actin and tubulin as well as in the anchoring of actin and microtubules to the cell membrane or to other cytoskeletal components. For example, myosin, an actin-associated protein, is able to generate a vectorial force in the growth cone by pulling on the actin filaments, a mechanism similar to muscle contraction.

The filopodia dynamics largely account for the sensory capacity of the growth cone. The length of the filopodia (tens of microns, in some cases) allows them to search within the environment and to navigate across cells and obstacles. Movement at the tips of growing filopodia is generated by the rapid assembly of actin filaments, whereas microtubule assembly is involved in the advance of the body of the growth cone. Importantly, experiments performed *in vitro* have demonstrated that a single filopodium making strong contact with an adhesive substrate is able to steer the growth cone by pulling it toward the adhesive substrate (Letourneau, 1996). Furthermore, when one filopodium is detached, the growth cone changes direction due to the release of tension from that side (Wessells, 1978).

Many of our insights into the role of cytoskeleton in axon pathfinding come from experiments using depolymerizing drugs that interfere with the normal function of microtubules and filopodia. For example, cytochalasin B, an actin-depolymerizing drug, prevents filopodia formation, resulting in axons either stopping growing or slowing dramatically (Bentley and Toroian-Raymond, 1986). Moreover, retinal axons of the amphibian brain treated with cytochalasin grow past a critical turning point and fail to find their targets (Chien *et al.*, 1993). Indeed, experiments using the tibial (Ti1) pioneer neuron in the grasshopper limb have shown that cytochalasin treatment of growth cones induces a loss of filopodia, but the lamellipodia are still functional, allowing the growth cone to advance slowly (Bentley and Toroian-Raymond, 1986). The role of filopodia in directing growth cones has been demonstrated in the pioneer axons of the grasshopper limb. When a single filopodium of a Ti1 neuron makes contact with a guidepost cell indicating the direction to choose, then this filopodium stays in contact while other filopodia retract. The filopodium in contact with the guidepost cell is stabilized and eventually becomes the shaft of the growing axon (Sabry *et al.*, 1991). These results indicate that filopodia play a critical role in axon growth and navigation during pathfinding.

Interfering with microtubule dynamics with pharmacological inhibitors has also provided evidence highlighting their role in axon growth. It has been shown that axons lacking filopodia by treatment with cytochalasin are still able to grow due to the addition of tubulin at the plus end of the microtubule at the distal process. However, axon elongation can be completely inhibited by the depolymerization of microtubules at the distal tip, the most sensitive region of the growing axon to drugs (Marsh and Letourneau, 1984; Bentley and Toroian-Raymond, 1986).

In addition to microtubules, axonal growth also involves several MAPs. For example, treatment of cultured neurons with the nerve growth factor (NGF), a growth factor that promotes neurite outgrowth, results in the upregulation of the MAPs Tau and MAP1B, and inhibition of Tau function can block neurite outgrowth, indicating the critical role of this protein (Letourneau, 1996). As the coupling between the sensory and motor capabilities of the growth cone is critical for axon pathfinding, it has been hypothesized that actin and microtubules may be associated to generate cell movement (Letourneau, 1996; Williamson *et al.*, 1996). Indeed, some MAPs may also bind actin, providing a mechanical link between these two structural components. However, the mechanism of growth cone steering and how these cytoskeletal components are regulated by the environmental milieu are still incompletely understood.

1.12.2.1.3 Growth cones change their morphologies in response to the environment En route to their target, growth cones advance within their environment and display a range of morphologies, from simple cigar shapes to highly complex structures, depending on their position (Tosney and Landmesser, 1985; Bovolenta and Mason, 1987). When axons are growing in fasciculated nerve bundles along straight tracts, they often display a streamlined form with one or two filopodia pointing in the direction of growth. Studies in mice and in *Xenopus* have shown that growth speed is about $55\,\mu m\,h^{-1}$ (Harris *et al.*, 1987; reviewed in Mason and Erskine, 2000). Growth is, however, often saltatory, meaning that rapid advance is frequently interrupted by pauses. These breaks are mainly observed at critical choice points, where decisions regarding subsequent directional growth are made.

At choice points, where growth cones display highly complex morphologies, they bear a widespread lamellipodium and multiple filopodia. Indeed, it has been shown that at key choice points in the retinal pathway (see Section 1.12.3), growth cones pause for periods of approximately 30 min to determine which direction to follow (Llirbat and Godement, 1999). These morphological changes indicate that the growth cone needs to integrate signals from the environment to advance along its pathway.

1.12.2.2 Axon-Pathfinding Concepts

We have seen that the growth cone serves as both an antenna that receives directional cues from the environment and as a motor structure that drives axon growth. How do axons find their target in the highly complex environment of the developing CNS? To visualize this complex process, axon pathfinding can be compared to a maze (Figure 2). During its long journey, the axon will have to choose which direction to take by interpreting attractive or repulsive signals from the environment at each decision point. To navigate through the maze of the developing embryo to reach their final destination, growing axons are guided by various diffusible or substrate-bound molecules, which they use as navigational cues. Interestingly, the decisions at choice points are not made by trial and error; instead, the growth cone pauses, samples the environment with filopodia, and adapts its direction accordingly, resulting in an almost error-free navigation. Importantly, when growth cones are cut from their cell bodies, they still continue to navigate appropriately in the brain and detect cues, demonstrating that growth cones can function independently of their cell bodies (Harris *et al.*, 1987).

Our understanding of axon pathfinding comes from a variety of experimental data generated in both invertebrate and vertebrate model systems. The nervous system architecture of invertebrates is relatively simple, which allows researchers to trace individual neurons, so providing a useful tool to perform *in vivo* experiments. Remarkably, axon-pathfinding concepts are very well conserved and have also been found in higher organisms.

An illustrative example of the concept of axon pathfinding is the experiment performed by Sperry in 1943. In this experiment, he severed the optic nerve in a frog and rotated the eye by 180° (Sperry, 1944). After regeneration and restoration of the retinotectal projection, the animal behaved as if it saw the world upside down and back to front. Therefore, Sperry proposed his chemospecificity hypothesis, which stated that each individual neuron had its specific chemical tag to find its target. Twenty years later he refined his theory and proposed that guidance cues are expressed in gradients, which would be more economical, requiring fewer molecules than individual labels would. Gradients would also have the advantage of being able to tell the axon the direction to go, removing the necessity of searching for the target randomly. Supporting this theory, rotation experiments performed in salamander hindbrains revealed that axons still find their way to their targets, suggesting that external cues are involved in this pathfinding rather than molecules secreted by the cell bodies (Hibbard, 1965).

Complementary evidence that growth cones are guided by external cues comes from experiments performed *in vivo* using the grasshopper leg (Keshishian and Bentley, 1983; Raper *et al.*, 1983). During development of the grasshopper, a pair of afferent neurons arises in the distal tip of each limb bud. These Ti1 pioneer neurons navigate to their

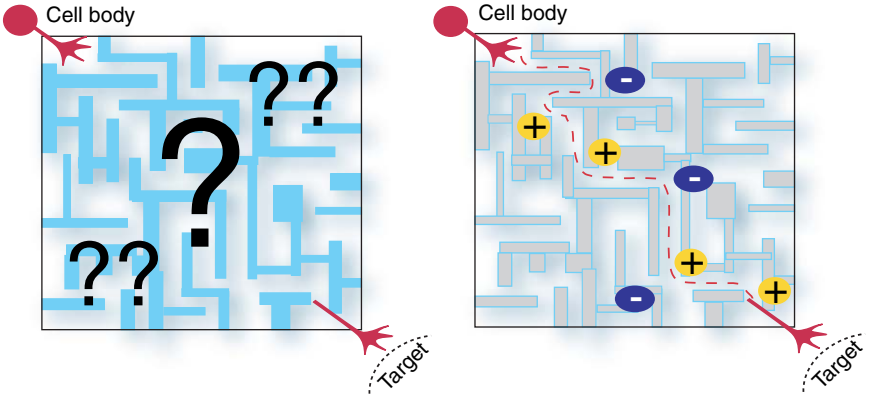

Figure 2 Axon pathfinding. The environment through which a growing axon must traverse to reach its target is analogous to a maze. The axon negotiates the maze of the developing nervous system by responding to specific positive or negative directional cues at intermediate choice points along its pathway.

final destination following a stereotypical pathway. Experiments using two sibling neurons have shown that growth cones of later-differentiating neurons elongate upon the axons of specifically labeled earlier-differentiating neurons (Raper *et al.*, 1983). When pioneer axons were ablated with a laser, the later axons could not find their way into the CNS (Keshishian and Bentley, 1983). To find their correct target, the pioneer Ti1 axons are guided by local cues or guidepost cells that are spaced at short distances (Bentley and Caudy, 1983). When these cells were obliterated using a laser, the Ti1 axons were unable to travel from one segment to another (Bentley and Caudy, 1983). In addition to these critical guidepost cells, adhesive molecules on the epithelium are also involved in directing the growth cone from one guidepost cell to the next and growth-inhibitory molecules prevent the growing axons from taking the wrong way (Singer *et al.*, 1995).

1.12.3 Growth Cone Guidance

As we previously mentioned, the process of axon guidance in both vertebrates and invertebrates has been conserved and occurs in a highly ordered and stereotyped manner (reviewed in Araujo and Tear, 2003). Studies in the past two decades have provided compelling evidence for cellular interactions between growth cones and their environment in directing axon pathfinding and have led to the identification of different families of guidance cues. Four types of basic mechanisms are thought to steer axon growth: contact attraction, chemoattraction, contact repulsion, and chemorepulsion (Figure 3; reviewed in Tessier-Lavigne and Goodman, 1996). However, these designations are dependent on the environmental context in which axon pathfinding is taking place, as some families of guidance cues have both diffusible and nondiffusible members and some individual cues themselves can act as attractants for some axons and repellents for others. Thus, axon pathfinding is directed by the coordinate action of multiple attractant and repellent cues integrated by the growth cone along the pathway. In this section, we will describe the characteristics of a guidance cue and the techniques widely used to test for guidance activity. We will then describe the main families of guidance cues identified to date.

1.12.3.1 Identification of Guidance Molecules

How are we able to identify molecules that regulate the process of axon pathfinding? A candidate protein has to fulfill several criteria to be classed as a guidance cue: (1) it has to be expressed at the right

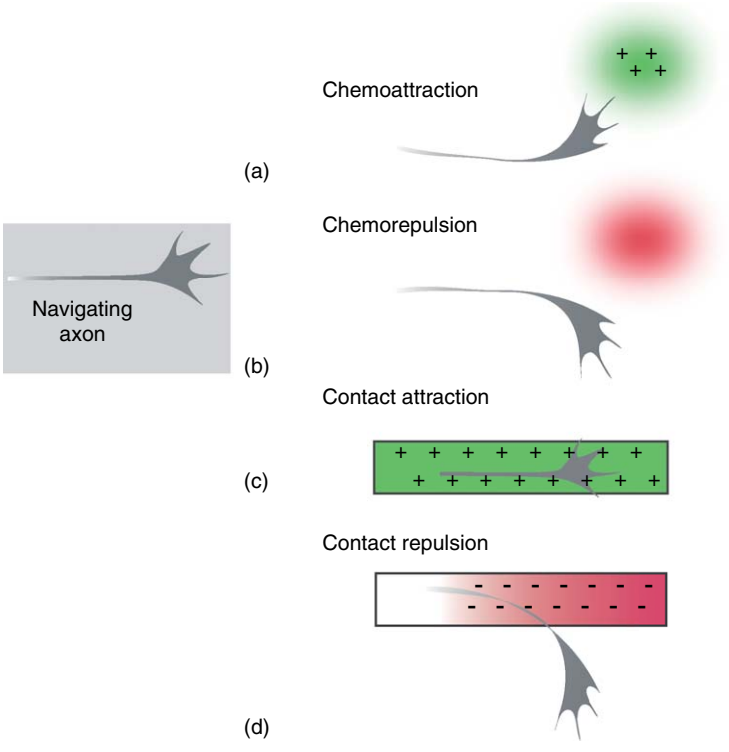

Figure 3 Mechanisms of growth cone guidance. Growth cone guidance is modulated by four main environmental stimuli: a, chemoattraction; b, chemorepulsion, mediated by soluble molecules; c, contact attraction; and d, contact repulsion, mediated by substrate-bound molecules.

time when axons meet with its region of expression; (2) it must be able to steer axons *in vitro* and *in vivo*; and (3) interfering with its function should result in axon guidance and targeting errors. The recent advent of powerful molecular and genetic techniques enabled these criteria to be met:

1. Analysis of the expression patterns of the protein of interest can be performed using antibody staining, application of tagged protein probes, or of RNA by *in situ* hybridization, screening through different developmental stages and target tissues.
2. To test for guidance activity *in vitro*, several experimental paradigms have been developed. One of them is called the stripe assay (Figure 4a). In this assay, axons are given a choice of growing on alternating lanes of guidance molecule versus control protein. If the guidance molecule tested is an attractive one, the axons will grow on the lanes containing the guidance molecule. If the guidance molecule tested acts as a repellent, then axons will avoid the lanes containing the guidance molecule and will grow in the control protein lanes.

Other *in vitro* guidance tests are also common. The growth cone collapse assay is a chemotropic assay for repulsive guidance cues, in which the protein of interest is applied globally to the growing axons for a certain amount of time (Raper and Kapfhammer, 1990). After application of the protein of interest, the percentage of collapsed growth cones is counted. Collapse is defined as a loss of the motile structures of the growth cone (the lamellipodia and the filopodia) and is often accompanied by cessation of growth and withdrawal of the growth cone (Figure 4b). Collapse *in vitro* is thought to be correlated with repulsion *in vivo*. An assay to test the guidance activity of substrate-adhered proteins, the bead assay, is also widely used. In this assay, a protein-coated latex bead is manipulated with the help of a laser tweezer (Kuhn *et al.*, 1995; Gallo *et al.*, 1997). The advantages of this system are that the concentration of the protein on the bead surface can be regulated, the beads can be immobilized accurately at the desired position, and the presentation on the bead surface may mimic the

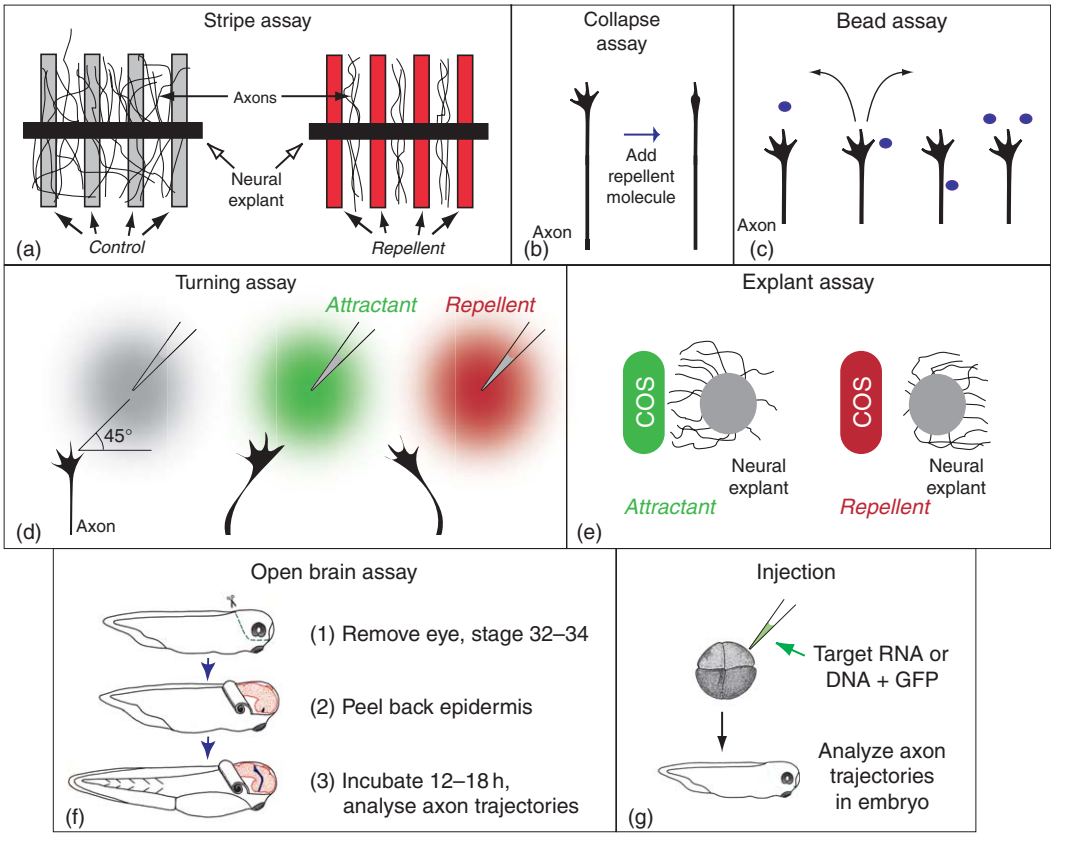

Figure 4 Common assays for axon guidance activity. A variety of *in vitro* and *in vivo* assays have been developed to assess the capacity of a molecule to influence axon guidance. Common *in vitro* assays include: a, the stripe assay; b, the collapse assay; c, the bead assay; d, the turning assay; and e, the explant assay. Two *in vivo* assays are: f, the open-brain assay; and g, the injection of RNA or DNA into blastomere-stage embryos (see text for details).

in vivo anchorage of certain proteins like the ephrins (Figure 4c).

Two techniques are also commonly used to analyze the activity of soluble guidance cues. In the turning assay soluble proteins are ejected out of a micropipette, resulting in stable diffusion gradient (Lohof *et al.*, 1992). An attractive cue will guide the growth cones toward the pipette, whereas a repellent molecule will result in turning away from the pipette (Figure 4d). A second test to the guidance activity of soluble proteins is the co-culture explant assay (Tessier-Lavigne *et al.*, 1988). Cultured cells expressing and secreting the protein of interest (for example, COS (cell line from African green monkey kidney) cells or the floorplate of the developing spinal cord) are grown near neural explants. Axons extending from the neural explant will grow toward the diffusible source if the protein secreted is an attractive one, and will grow away if the protein is exhibiting a repellent activity. Thus, there will be more axons on the side facing the cell explant in the case of an attractant and fewer axons in the case of a repellent molecule (Figure 4e).

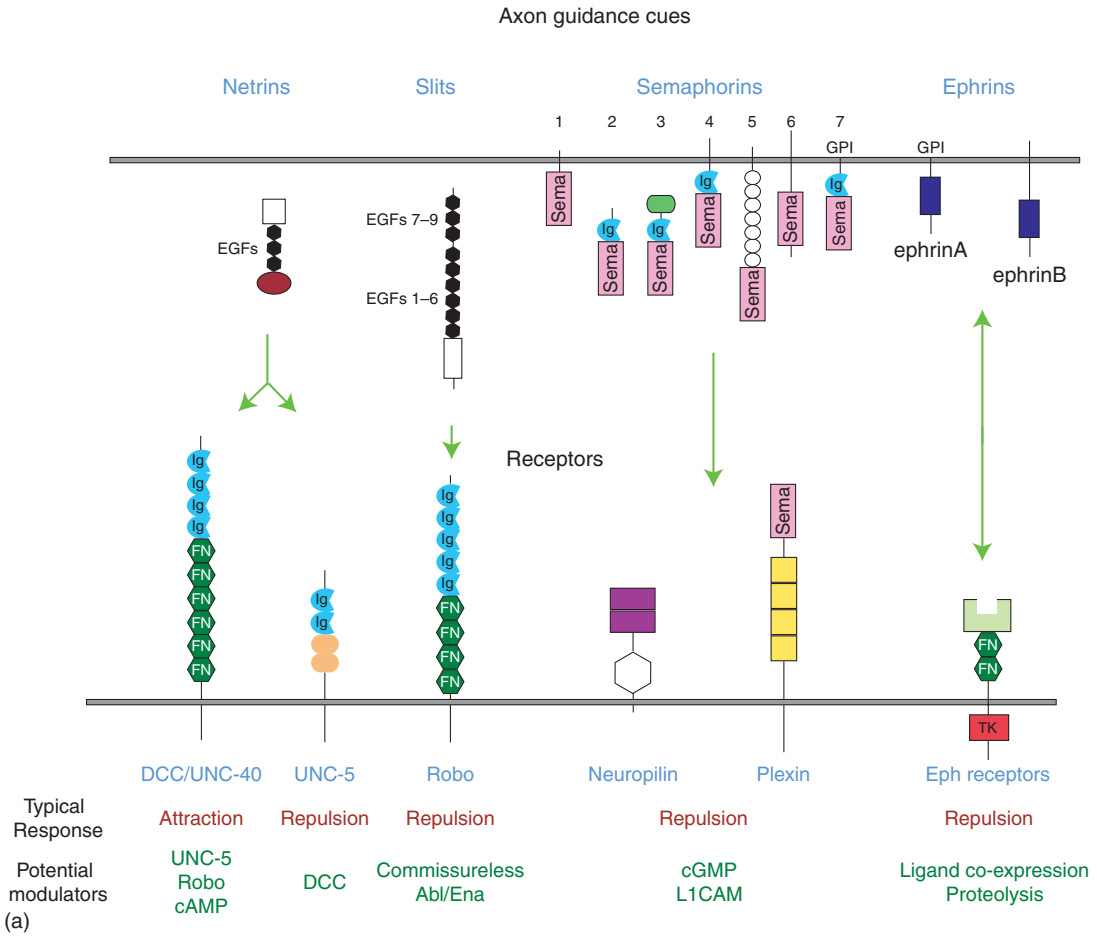
3. If the protein of interest is essential for axon pathfinding, then interfering with its function *in vivo* should result in pathfinding errors. Techniques to accomplish this include the overexpression or downregulation of proteins. For example, the recent development of knockin or knockout mice provides an elegant *in vivo* model for studying axon pathfinding and target-mapping defects. Other methods for studying axon pathfinding and target recognition in *Xenopus* are the open retina and open brain preparations (Figure 4f; McFarlane *et al.*, 1996). Either the retina or the tectum of living animals is exposed to the guidance cue of interest and the subsequent pathfinding of the axons is observed with *in vivo* time-lapse microscopy. Other methods for interfering with protein function are the use of siRNA or morpholino antisense oligonucleotides. These techniques are well established in *C. elegans*, *Xenopus,* and zebra fish model systems. RNA or DNA constructs interfering with the protein of interest are introduced by electroporation, injection, or lipofection into early blastomere or later-stage embryos along with the green fluorescent protein (GFP) to visualize the injected axons and to look for axon-pathfinding errors (Figure 4g).

1.12.3.2 Guidance Cue Families

Extracellular cues have long been postulated to provide positional information to axonal growth cones. Until recently the identity of the molecules responsible for this remained a mystery. However, in the last 10–15 years, the application of a variety of powerful genetic techniques in *Drosophila melanogaster* and *C. elegans* and the development of molecular and biochemical tools and assays to study axon growth in vertebrates have led to the identification of several families of axon guidance cues; the most prominent of them are the netrin-1s, semaphorins, Slits, and ephrins, which are discussed below (Figure 5). However, it should be noted that many other molecules have been implicated in axon guidance, such as the morphogens Wnt4 and Sonic Hedgehog, and growth factors like the fibroblast growth factor (FGF) and the glial cell line-derived neurotrophic factor (GDNF).

Perhaps the most remarkable aspect of the identification of these four families of molecules has been the extent to which their role in axon guidance has been conserved during evolution. For example, despite an evolutionary separation exceeding 600 million years, the netrin-1s have retained their role for attracting axons ventrally toward the midline in organisms as diverse as *C. elegans, Xenopus,* and human. A second interesting feature is the relatively small number of molecules that are used to generate the startling array of complexity found within the CNS. Here, we will describe the four major families of axon guidance molecules before discussing their multiple roles in axon pathfinding in the next section.

1.12.3.2.1 Netrin-1s and their receptors Chemoattractants are specifically expressed in the developing embryo to guide axons toward intermediate targets and to facilitate correct pathfinding to their ultimate destination. The netrin-1s ("one who guides," a derivation from Sanskrit) are the best-known chemoattractants, and have been implicated in the guidance of many developing axonal populations across a variety of species. Two studies, the first analyzing genes that regulate circumferential axon guidance in *C. elegans* and the second searching for secreted midline attractants involved in guiding spinal commissural axons in rodents, concurrently identified the first members of this family. Gene knockout studies in both these species have since verified the importance of this family of attractants in axon guidance. For example, one of the prominent phenotypes in mice lacking netrin-1 is a failure of the spinal commissural axons to reach the normally attractive floorplate (Serafini *et al.*, 1996). *C. elegans* and *Drosophila* contain one or two known members respectively (uncoordinated (UNC)-6 and netrin-1-A and netrin-1-B, reviewed in Tessier-Lavigne and



(a)

Nomenclature of guidance cues

	Netrins	Receptors	Slits	Receptors	Semaphorins	Receptors	Ephrins	Receptors
C.elegans	UNC-6	UNC-40	SLT-1	SAX-3	SMP-1, MAB-20	PLX-1,2	EFN1–4	VAB-1

Vertebrates	Netrin1–3	DCC, neogenin	Slit1–3	Robo1,2, Rig-1	Sema3–7	Plexin-A1-4, B1-3, C1, D1, neuropilin 1,2	ephrinA 1–5, ephrinB 1–3	EphA 1–8, EphB 1–6

(b)

Figure 5 a, Axon guidance cues. The four major families of axon guidance cues identified to date are: the netrins, Slits, semaphorins, and ephrins. These molecules interact with specific receptors on the surface of the growth cone to control axon pathfinding. Guidance responses can be modulated by other effectors within the growth cone. b, These guidance cues and their receptors have been highly conserved through evolution, and homologues of each are found in organisms as diverse as *C. elegans, Drosophila,* and vertebrates. EGF, epidermal growth factor repeat; Ig, immunoglobulin domain; FN, fibronectin type III domain; TK, tyrosine kinase domain; GPI, glycophosphatidylinositol linkage; Sema, Semaphorin domain.

Goodman, 1996). In vertebrates, two members were initially identified in chick (netrin-1 and netrin-2) and orthologues of netrin-1 have been reported in the mouse, human, frog, and zebra fish (reviewed in Meyerhardt *et al.*, 1999).

The netrin-1 receptors were also initially characterized in *C. elegans* by studying worm mutants with axon guidance defects. These proteins, UNC-40 and UNC-5, are transmembrane proteins that mediate different responses to netrin-1 *in vivo*. UNC-40, whose vertebrate homologue is DCC (deleted in colorectal cancer), mediates attraction. In some populations of axons, netrin-1s can also act as a repellent. The UNC-5 receptor, either on its own or in conjunction with UNC-40, mediates these effects (Chan *et al.*, 1996). This is important, as it shows that netrin-1s, though primarily attractants, can also be repulsive. Such bifunctionality is one

way in which neural complexity is created during nervous system development.

1.12.3.2.2 Semaphorins The first axonal chemorepellents to be thoroughly characterized were members of the Semaphorin (Sema) family. The identification of these proteins was the culmination of a study investigating a potent growth cone collapse-inducing molecule from the adult chick brain and another study in which the fascicle-specific expression of proteins was examined in the adult grasshopper CNS (Kolodkin *et al.*, 1992; Luo *et al.*, 1993). Many more Sema proteins have since been isolated, and members of this family are present in vertebrates, invertebrates, and even viruses. Although the Sema proteins form a large and heterogeneous group, they all share a common ~420 amino acid region at their NH_2-termini, called the Sema domain. Insects and nematodes share a small number of semaphorins that are divided in two subfamilies, transmembrane Semas (class 1) and secreted Semas (class 2). In contrast, vertebrates contain a large number of semaphorins that are divided into five subfamilies based on their common structure. An interesting point is that vertebrate semaphorins are not strict orthologues of invertebrate semaphorins, probably due to the existence of a duplication and a divergence of the semaphorin genes across evolution (reviewed in Chisholm and Tessier-Lavigne, 1999).

How does the growth cone respond to Sema proteins in the extracellular environment? Sema proteins bind to multimeric receptor complexes on the surface of the axonal growth cone. Although the exact makeup of these receptor complexes is in many cases unclear, they will often contain a transmembrane plexin protein. Another well-characterized component of the Sema receptor complex are the neuropilins, which act as receptors for class 3 Semas. Thus, Sema proteins in *Drosophila* and vertebrates generally act as repellents, with their spatiotemporal expression being used to channel axons through repulsive corridors or to prevent them from entering inappropriate areas, so enabling axons to navigate correctly within the developing CNS (see Section 1.12.4).

Although studies of netrin-1s have shown the remarkable molecular and functional conservation of guidance molecules in axon pathfinding, studies on the semaphorin receptors provide an example of a strong evolutionary divergence. Indeed, the neuropilin receptors are not conserved across species as they have not been found in *C. elegans* and *Drosophila*. It is thought that in invertebrates, instead of the neuropilin receptor, the plexin protein mediates the repulsive action of semaphorins. However, the reason why, during evolution, the plexin proteins present in invertebrates have been replaced by the neuropilin receptors functioning in vertebrates remains a mystery (reviewed in Chisholm and Tessier-Lavigne, 1999).

1.12.3.2.3 Slits and their receptors Another highly conserved family of guidance molecules are the Slits. In a screen for cuticular defects in *Drosophila* conducted over 20 years ago, one of the many mutations identified was dubbed *Slit*. In this mutation the longitudinal axon scaffold of the ventral midline collapsed into a single, fused tract, suggesting the absence of an unknown midline repellent in the mutant flies. This repellent was identified as the product of the *Slit* gene, a large, secreted protein with multiple protein–protein-binding motifs (Kidd *et al.*, 1999). Slit has three vertebrate homologues, which also primarily act as repellents during nervous system development. The Slits signal via interactions with the Roundabout (Robo) family of transmembrane receptors (in *Drosophila* Robo mutants, axons recross the midline multiple times, forming loops, hence Roundabout), which are expressed on the surface of the axon and growth cone. Like netrin-1s, Slits have been implicated in guiding axons from many developing neuronal populations. However, two developmental systems in particular have provided insights into the mechanisms underlying Slit-induced repulsion: the *Drosophila* ventral midline and the vertebrate optic chiasm (see Section 1.12.4).

1.12.3.2.4 Ephrins and Eph receptors Eph receptors were first found in a screen for tyrosine kinases in a cultured cell line, as their name reflects (erythropoietin-producing hematoma cell line). The ligands for these receptors, named ephrins, were identified using the extracellular domain of the Eph receptor for affinity chromatography, screening expression libraries, and in a search for axon guidance cues in the tectum. Based on their amino acid sequence similarities, both Eph receptors and ephrins are grouped into two subclasses: A- and B-type. There are eight EphA receptors (EphA1–EphA8) and six EphB receptors (EphB1–EphB6). The ephrinAs (ephrinA1–ephrinA6) are glycosylphosphatidyl (GPI)-anchored and ephrinBs are transmembrane-anchored proteins. Eph receptors and ephrins have been found in several species. The highest diversity of expression is found in chick, mouse, and human, followed by *Xenopus* and zebra fish, although family members have also

been identified in both flies and worms, indicating that the ephrins and their receptors are evolutionarily ancient. Indeed, the large diversity of vertebrate ephrins and their receptors and the high sequence homology of these proteins within vertebrate phyla suggest a major expansion of the Ephs and ephrins has occurred. This may have accompanied the evolution of vertebrates, which might have been critical in the construction of increasingly complex brains (reviewed in Flanagan and Vanderhaeghen, 1998; Wilkinson, 2000).

High-affinity binding usually occurs between ligands and receptors of the same subtype (ephrinA activating EphA, ephrinB activating EphB), although there is increasing evidence for a cross activation between subclasses (for example, EphA4 activated by ephrinB2, and recently it was found that ephrinA5 can activate EphB2; Himanen *et al.*, 2004). Ligand binding results in a clustering of the receptors, autophosphorylation, and activation of the intracellular pathways, finally leading to re-arrangements of the cytoskeleton. Both ligands and receptors are enriched in lipid rafts providing a platform for clustering and signaling. One interesting aspect of the signaling is the finding that both A- and B-type ephrins and Ephs can act as receptors and ligands, a fact described as bidirectional signaling. This signaling can occur in the forward (ephrin) or reverse (Eph) direction.

The most prominent role of this family is its role in cell contact repulsion. Eph receptors and their ligands act as stop signals at boundaries to prevent overshooting specific targets, or to channel axon growth. They are also involved in the formation of topographic maps in the retinotectal projection and in other pathfinding events, such as in the vomeronasal projection (critical for pheromone detection in rodents), in the hippocamposeptal projection (involved in learning and memory), and in the connection of motor neurons with their muscle targets.

1.12.4 The Retinal Projection and the Midline Choice Point: Model Systems to Study Axon Pathfinding

During the past decade, our understanding of axon-pathfinding mechanisms has been advanced through the use of invertebrate and vertebrate model systems. Two well-known model systems have provided many insights into the processes of axon pathfinding and we will confine our discussion to these examples: the vertebrate retinal projection and the midline of the developing CNS. Importantly, many of the guidance cues described in the previous section play integral roles in mediating axon guidance during development of these systems. Moreover, these two systems provide an introduction to the general processes that underlie axon guidance in other neuronal populations.

1.12.4.1 The Retinal Projection as a Model System

The retinal projection is the axonal pathway linking retinal ganglion cells (RGCs) of the eye to their primary target in the brain, the optic tectum (in lower vertebrates) or superior colliculus (in mammals) (Figures 6a–6d). The eye is a highly complex light-capturing organ which generates neuronal signals corresponding to external visual information and conveys them via the retinal projection to visual centers in the brain. To ensure that visual information is correctly relayed to the CNS, axons of embryonic RGCs must find their way from the eye to their CNS targets. The number of RGC axons that must navigate correctly from the eye is impressive. In mice, for example, more than 50 000 RGC axons exit from each developing eye, while in humans, over a million RGC axons must navigate accurately during embryonic development.

In this section, we will describe the different decisions that RGC axons make at various choice points during pathfinding to their targets in the brain. Although much remains unknown, it is clear that attractive and repulsive cues in the developing brain act in concert to guide RGC axons correctly. An important concept, shared by navigating axonal populations across a wide evolutionary distance, is that the retinal pathway is broken into smaller segments with distinct molecular characteristics. The subdivision into shorter distinct segments is used to simplify navigation, as well as allowing multiple regulatory check points.

1.12.4.1.1 General organization of the retinal pathway The first step in the journey of a RGC axon is to extend across the (vitreal) surface of the retina toward the optic nerve head (ONH), or future optic disk, where they form a bundle of axons that will exit the eye. Axons extend through the ONH toward the back of the eye (pigmented epithelium) where they emerge as a tightly fasciculated bundle to form the optic nerve. The optic nerve enters the brain at the ventral diencephalon and axons grow toward the optic chiasm at the midline. The chiasm is a key choice point as axons may cross to the other

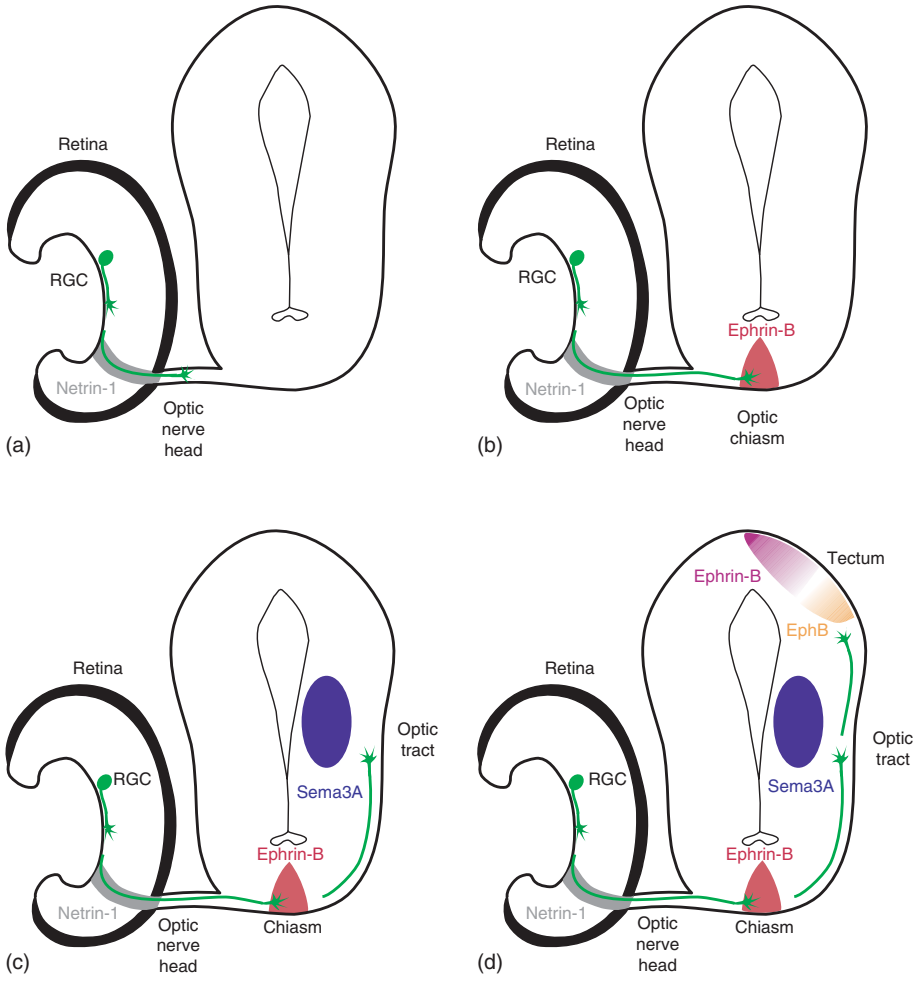

Figure 6 *Xenopus* retinotectal projection. In the *Xenopus* retinotectal projection, RGC axons navigate from the retina to the optic tectum in the brain. Guidance molecules are expressed at key choice points to ensure fidelity of pathfinding. Some of the major pathfinding decisions are made at: a, the optic nerve head; b, the optic chiasm; c, the optic tract; and d, the tectum itself (see text for details).

side of the brain or remain ipsilateral. After passing through the optic chiasm, RGC axons form the optic tract which courses dorsally along the lateral surface of the diencephalon. The final step in the retinal pathway involves the departure of RGC axons from the optic tract and entry into the main synaptic target, the optic tectum in lower vertebrates, the superior colliculus in mammals, in the midbrain. Within the target area, retinal axons terminate next to their retinal neighbors, thus forming a precise topographic map of visual space (Figures 6a–6d).

1.12.4.1.2 Pathfinding across and out of the retina In the first step of the retinal pathway, axons converge on the ONH. Remarkably, axons arising from all points of origin across the retinal surface orient immediately toward the ONH, suggesting that they receive directional information early in axonogenesis (reviewed in Oster *et al.*, 2004). The mechanisms responsible for this directed intraretinal growth, although not well understood, are beginning to be uncovered (reviewed in Mann *et al.*, 2004). For example, experimental studies that perturb the function of cell adhesion molecules (CAMs), such as L1, neural CAM (NCAM), and neurolin, that are expressed on both RGC axons and their substrate neuroepithelial cells, show that these molecules play a role in intraretinal growth (Brittis *et al.*, 1992; Ott *et al.*, 1998). In addition, chondroitin sulfate proteoglycans (CSPGs) have been proposed to play a role in directing axons toward the ONH. These extracellular matrix proteins, known to inhibit axon growth *in vitro* (Snow *et al.*, 1991), are expressed in a receding ring in the developing rat retina just peripheral to differentiating RGCs. Enzymatic removal of CSPGs causes defects in directional guidance with some axons

erroneously heading peripherally (Brittis *et al.*, 1992), suggesting that the ring of CSPG may serve to push growing axons centrally. However, a CSPG ring has only been observed in the rat retina, indicating that it may not represent a common guidance mechanism. Another class of molecule implicated in intraretinal guidance is the B-type family of Eph tyrosine kinases. Some members, such as EphB2, are expressed in a ventral-to-dorsal gradient in the retina and mutant mice lacking EphB2 and EphB3 display pathfinding errors within the retina (Birgbauer *et al.*, 2000).

When axons reach the ONH they make a sharp change in direction (approximately 90°) to enter the ONH, marking this as a critical decision point. This behavior is mediated by the chemoattractant netrin-1, which is localized to the ONH (de la Torre *et al.*, 1997; Deiner *et al.*, 1997). In netrin-1 and DCC-deficient mice, axon growth across the retinal surface to the ONH is unaffected, but many axons fail to enter the ONH, resulting in optic nerve hypoplasia (Deiner *et al.*, 1997). In this context, netrin-1 appears to be acting as a short-range attractant, guiding RGC axons that have arrived at the ONH into the optic nerve itself. This contrasts with its well-characterized long-range role in guiding commissural axons to the floorplate of the ventral spinal cord (Tessier-Lavigne *et al.*, 1988). Within the optic nerve, axons fasciculate into bundles through the action of homophilic binding of axonally expressed adhesion molecules. Sema5A, which is known to repel retinal axons *in vitro*, helps to confine the axons to the nerve bundle, as it is expressed as an inhibitory sheath around the nerve, preventing them from wandering off the defined path (Goldberg *et al.*, 2004).

1.12.4.1.3 Axon divergence at the chiasm From the optic nerve, RGC axons enter the brain and approach the midline, a key intermediate target. At this point, axons have to make the critical decision of whether to cross the CNS midline at the optic chiasm. At a functional level, the decision for RGC axons to cross or not cross at the chiasm correlates with the degree of binocular overlap. In species with eyes placed laterally there is no binocular overlap and the retinal projections are completely crossed (i.e., contralateral). Thus, the visual information from the left and the right eyes is processed independently. In species with forward-facing eyes and, hence, binocular vision, the visual fields of both eyes overlap to some extent. For example, a subset of RGCs in the left eye will receive stimuli that overlap with those in the right eye. To process such shared visual information, some RGC axons from the region of binocular overlap project ipsilaterally while others project contralaterally. This arrangement enables information about the same point in visual space from the two eyes to be brought together in the brain. Thus, in vertebrates with binocular vision, the ability to integrate shared visual information relies on the decision of RGC axons to cross or not to cross at the chiasm.

The first insights into the molecular regulation of crossing came from studies in the amphibian, *Xenopus*. In the filter-feeding tadpoles the eyes are placed laterally, so there is no binocular overlap as all the visual projections are crossed. During metamorphosis, the eyes migrate dorsally to the top of the head, creating binocular vision essential for the frog's new prey-catching lifestyle. Beginning at metamorphosis, axons arising from RGCs in the ventrotemporal binocular part of the retina extend ipsilaterally. What makes these axons alter their behavior? It turns out that ephrin-B expression is switched on during metamorphosis at the midline at the optic chiasm (Nakagawa *et al.*, 2000). Ephrin-B is the ligand for EphB receptors (Figure 5) and the ventrotemporal axons express high levels of EphB receptors. Since ephrin-B acts repulsively, the current working model is that ventrotemporal axons are deflected into the ipsilateral optic tract by the ephrin-B signal encountered at the midline chiasm in metamorphosing and postmetamorphic frogs. The same mechanism seems to play a role in other vertebrate species such as mice (reviewed in Mann *et al.*, 2004). Significantly, animals without binocular vision, such as zebra fish and chick, lack ephrin-B expression at the chiasm, suggesting that this mechanism has arisen during evolution to accommodate the development of binocular vision in vertebrates.

The determinant of regionalized EphB expression in the retina appears to be the transcription factor Zic-2, which is exclusively expressed in the ventrotemporal retina after the onset of metamorphosis in *Xenopus* and in the temporal retina in embryonic mice (Herrera *et al.*, 2003). As with ephrin-B expression at the chiasm, Zic-2 is not expressed in the retina of organisms without visual field overlap, such as the chick (Herrera *et al.*, 2003). In addition, the transcription factor Isl-2 is expressed only by RGCs that cross the chiasm and has been shown to repress the expression of Zic-2, preventing them projecting ipsilaterally (Pak *et al.*, 2004). Therefore, Zic-2 and Isl-2 transcription factors are expressed in mutually exclusive areas of the retina and are key regulators of an RGC's sensitivity to directional signals at the midline.

Finally, gene knockout studies in mice have shown that Slit1 and Slit2 are involved in the correct development of the chiasm. Mice deficient for both genes exhibit multiple retinal axon-pathfinding errors, including the formation of an ectopic chiasm (Plump *et al.*, 2002). Slit1 and Slit2 are expressed in complementary domains surrounding the path of the growing retinal axons, creating a repulsive barrier around the chiasm, which acts to channel the axons into a narrow corridor across the ventral diencephalon. Slits, therefore, unlike ephrin-B, are not involved in the decision to cross the midline but rather in the anterior–posterior positioning of the chiasm. Together these two complementary molecular systems help to determine the exact path of axons across the midline.

1.12.4.1.4 Pathfinding in the optic tract In the last segment of their journey, RGC axons have to elongate along the optic tract in the diencephalon and perform a 45° turn posteriorly in the mid-diencephalon to reach the anterior border of the tectum. Again, a variety of different cues work together to guide axons in the optic tract, and the expression of repulsive molecules stops them from leaving the optic tract and innervating inappropriate territories.

In vitro studies performed in *Xenopus* have highlighted a role for the netrin-1 and Sema3A cues in RGC axon pathfinding in the optic tract. In addition to its function at the ONH, netrin-1 is also expressed in the dorsal diencephalon in an area that is nonoverlapping with, but adjacent to, growing retinal axons, suggesting that it might act as a repellent cue to prevent RGC axons from leaving the optic tract (Shewan *et al.*, 2002). Sema3A is expressed along the boundary of a segment of the optic tract and may act as a repulsive cue forcing RGC axons to turn posteriorly (Campbell *et al.*, 2001).

A zebra fish mutant, called astray, corresponding to a mutation in the Robo2 gene has provided evidence that an interaction between Slit and Robo is essential for axon pathfinding in the optic tract. The astray mutant phenotype exhibits severe retinal axon-pathfinding defects, including defasciculation of axons in the optic tract and widespread invasion of inappropriate regions of the brain (Fricke *et al.*, 2001; Hutson and Chien, 2002). This suggests that Slit/Robo signaling may be required to prevent axons from leaving the optic tract. These results are also consistent with the finding that Slit2 controls RGC axon pathfinding and targeting *in vivo* within the rat diencephalon (Ringstedt *et al.*, 2000).

Slit/Robo signaling also seems to be implicated in the topographic sorting of axons in the optic tract. In this process, axons from the dorsal part of the retina are sorted into the ventral brachium of the optic tract, and axons from the ventral part of the retina axons are sorted into the dorsal brachium of the optic tract in fish (Scholes, 1979; Stuermer, 1988). In a screen for zebra fish mutants with retinal axon-pathfinding defects, two mutants were isolated, exhibiting optic tract-sorting defects: boxer (box), dackel (dak). Boxer and dackel were identified to encode for genes involved in heparan sulfate proteoglycan (HSPG) biosynthesis and therefore in both mutants the level of HSPG is dramatically reduced (Lee *et al.*, 2004). Remarkably, the dak box double mutant exhibits a severe phenotype similar to the astray zebra fish mutant, indicating that HSPG biosynthesis regulates Slit function. Indeed, there is accumulating evidence that heparan sulfate is essential for the function of Slit (Liang *et al.*, 1999; Hu, 2001; Ronca *et al.*, 2001). However, exactly how the HSPGs interact with Slit and regulate its function remains unknown.

Further evidence supports an essential role for HSPGs and CSPGs in axon navigation within the optic tract. Both are highly enriched in the *Xenopus* optic tract and enzymatic removal of HSPG during development results in abnormally short retinal projections, suggesting that HSPG plays a role in promoting growth. Addition of an HSPG-binding growth factor, FGF2, to such HSPG-free brains enables axons to continue growing but they then follow extremely aberrant trajectories, suggesting that HSPG is dually involved in guidance and growth (Walz *et al.*, 1997). Exogenous HSPG added *in vivo* to the embryonic diencephalon causes a highly penetrant mistargeting phenotype in which retinal axons avoid entering the tectum, suggesting that HSPG plays an important role in target recognition (Walz *et al.*, 1997). Exogenously applied CSPGs lead to defasciculation of the optic tract and axons invade inappropriate territories (Walz *et al.*, 2002). In addition, it has been found recently that both HSPGs and CSPGs interact with the guidance cue Sema5A and differentially modulate its action on axons in the developing rat brain (Kantor *et al.*, 2004).

At the end of their journey, RGC axons enter their target area, and are topographically sorted to ensure correct mapping of the retinal image. This topographic mapping mechanism involves the A- and B-type of ephrin guidance cues and their Eph receptors. Since mapping is not strictly part of the axon-pathfinding process, it is not included in this article (but is reviewed in McLaughlin *et al.*, 2003).

In conclusion, we have seen that a combination of molecules act as attractive and/or repulsive cues to guide RGC axons during their journey to innervate

their appropriate target in the brain. However, only a small part of this complex process has been elucidated so far, and we are just beginning to understand the mechanisms and the molecular determinants involved in each step of the retinal pathway.

1.12.4.2 The Midline Choice Point as a Model System

1.12.4.2.1 The *Drosophila* ventral nerve cord A second model system that has provided many important insights into the mechanisms underlying axon guidance has been the ventral nerve cord of *Drosophila*. Many neurons from this population are interneurons, that is, neurons that connect with other neurons. As with many other regions in the developing CNS of bilaterally symmetrical organisms, most (but not all) of these interneurons extend axons toward the midline. A brief synopsis of the development of the *Drosophila* ventral nerve cord is outlined in Figure 7a. In each segment of the ventral nerve cord, interneuron axons cross the midline at either of two defined points, known as the anterior and posterior commissures, and then project parallel to the midline in distinct longitudinal fascicles. Importantly, those axons that have crossed the midline never do so again in the wild-type situation.

Thus, the ventral midline represents an important choice point for interneuron growth cones. Decisions that need to be correctly made include: (1) whether to remain ipsilateral or to cross the midline and project contralaterally; (2) which commissure to cross in; and (3) which longitudinal fascicle to extend in postcrossing. How is this accomplished? A number of genetic and biochemical studies have led to the identification of many factors responsible for these decisions. Firstly, crossing axons are attracted to the midline by netrin-1-A and netrin-1-B expressed by midline cells (Harris *et al.*, 1996; Mitchell *et al.*, 1996). These axons must then leave the attractive midline to continue toward their targets.

Large-scale screens for *Drosophila* mutants that display guidance defects at the midline have isolated three key players involved in expelling crossing axons from the midline: Commissureless (Comm), Robo, and Slit (reviewed in Kaprielian *et al.*, 2001). Comm mutants lack all commissural tracts. Robo mutants exhibit a thickened midline, a result of ipsilateral axons crossing the midline and contralateral axons recrossing the midline several times. Slit mutants show a thickened midline, resulting from all spinal axons collapsing onto the midline. These observations led to the following model for axon guidance at the *Drosophila* ventral midline: Slit secreted by the midline glial cells acts as a short-range repellent. Axons that extend contralaterally repress the surface expression of Robo until past the midline, after which it is upregulated at the growth cone surface to ensure exit from the midline and to prevent recrossing. Axons that remain ipsilateral express Robo from the outset and so are repelled from the midline by Slit. A combination of Robo and the other two Slit receptors, Robo2 and Robo3, is then used to specify lateral positions within the longitudinal axon bundles (Rajagopalan *et al.*, 2000; Simpson *et al.*, 2000; Figure 7).

Comm regulates the surface expression of Robo, therefore being the switch mechanism between the contra- and ipsilateral decision (Keleman *et al.*, 2002). A recent study has resolved how this occurs (Keleman *et al.*, 2005). In commissural axons expressing Comm, Robo is sorted to the degradation machinery, so that no Robo reaches the growth cone surface and these axons can cross the midline. In postcrossing axons and ipsilateral neurons, which lack Comm, Robo is targeted to the growth cone membrane; therefore, these axons are repelled by the midline repellent Slit.

1.12.4.2.2 The vertebrate spinal cord The vertebrate spinal cord is another key model system for axon guidance and a comprehensive review of this area can be found elsewhere (reviewed in Kaprielian *et al.*, 2001). Importantly, the role of many of the molecules that regulate midline crossing has been strongly conserved during evolution. In the developing vertebrate CNS, commissural interneurons in the dorsal regions of the spinal cord extend axons ventrally toward the spinal cord floorplate (Figure 7b). This specialized area, considered to be functionally equivalent to the midline of the *Drosophila* ventral nerve cord, is where commissural axons cross the midline, and constitutes an important intermediate choice point for axon guidance. The way commissural axons are initially attracted to the floorplate is analogous to the situation in *Drosophila*. Both *in vitro* and *in vivo* studies have shown that netrin-1, expressed by the floorplate cells, attracts these axons to the midline (Kennedy *et al.*, 1994; Serafini *et al.*, 1994). The way in which these axons are compelled to leave the floorplate is also similar. Midline cells also express homologues of the Slit gene, namely Slit1, Slit2, and Slit3. After crossing, commissural axons gain sensitivity to these repellents, and exit the midline. Removal of all three Slit genes results in guidance errors indicative of axons no longer being repelled from the floorplate postcrossing (Long *et al.*, 2004).

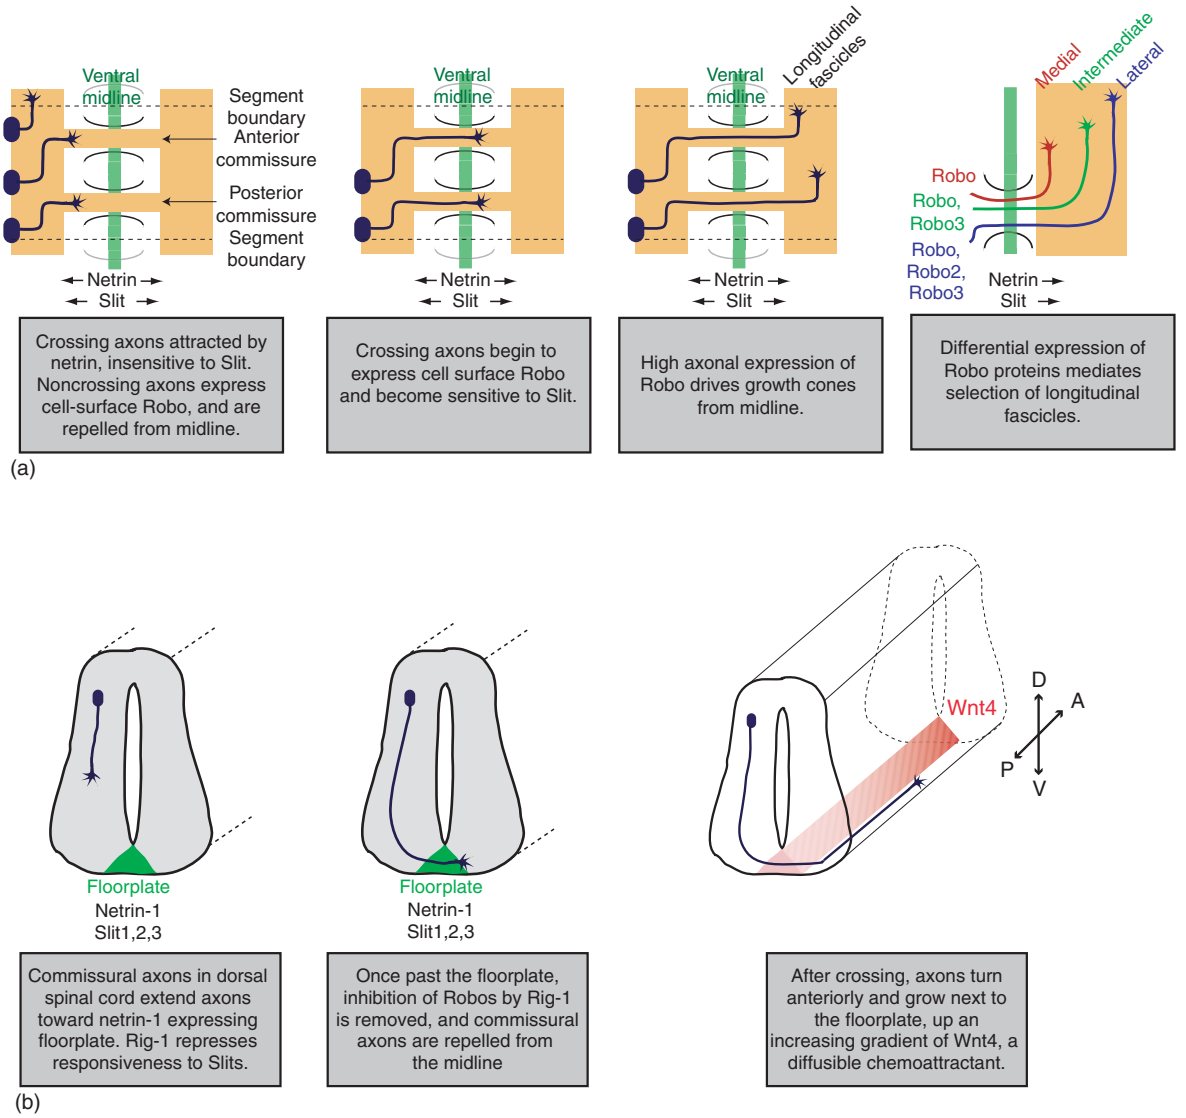

Figure 7 Axon navigation in the ventral nerve cord of *Drosophila* and in the vertebrate spinal cord. a, The ventral nerve cord of *Drosophila*. Within each segment of the *Drosophila* body, axons of the ventral nerve cord that project contralaterally cross the midline in either the anterior or posterior commissure. Expression of netrin and Slit by cells at the ventral midline mediates axonal navigation through the commissures. Precrossing axons are attracted by netrin-1. The insensitivity of these precrossing axons to Slit is mediated by Commissureless, a protein that sorts Robo away from the cell surface. As axons reach the midline, this repression is removed, and Robo is transported to the cell surface, rendering axons sensitive to the midline-derived Slit. Slit also controls selection of longitudinal fascicles once axons have exited the midline. b, The vertebrate spinal cord. In the developing vertebrate CNS, commissural interneurons in the dorsal regions of the spinal cord extend axons ventrally toward the netrin-1-expressing floorplate. The protein Rig-1 represses Slit responsiveness in precrossing axons. Once past the floorplate, the Slit inhibition is removed and axons are repelled from the midline. The chemoattractant Wnt4 is responsible for the anterior turn of axons which then grow next to the floorplate.

Interestingly, although precrossing commissural axons in the developing vertebrate spinal cord are not responsive to the Slit proteins, a Comm-independent mechanism seems to underlie this. Indeed, to date no Comm homologues have been identified in those vertebrate genomes sequenced. Instead, a divergent Robo homologue, Rig-1, has been shown to repress Slit responsiveness in precrossing axons (Sabatier *et al.*, 2004). How this occurs remains unclear, but it provides an illuminating example of evolution providing two different solutions to the problem of inhibiting repulsion of precrossing commissural axons.

After the midline, axons have another decision to make, namely whether to extend anteriorly or posteriorly parallel to the midline. Recently, another protein family was found to be involved in this aspect of axon guidance, the wingless proteins (Wnts) and their Frizzled (frz) receptors. The Wnts were originally identified as morphogens, which normally induce transcriptional changes by acting

inside the nucleus to pattern tissue and instructing cells to choose distinct cell fates. In contrast, axon guidance cues are defined to influence migration of motile cells or growth cones, primarily by inducing cytoskeletal changes and membrane dynamics. A surprising recent finding has been that the classical morphogens such as Wnts, Hedgehog (Hhs) and bone morphogenetic proteins (BMPs) can also act as guidance molecules in this context (reviewed in Schnorrer and Dickson, 2004). Indeed, in the rat spinal cord, a diffusible attractive gradient in the anterior–posterior direction was found to influence the guidance decision of commissural axons after crossing the midline to turn anteriorly. A search for candidates identified Wnt4. Application of Wnt function blocking SFRPs (secreted Frizzled-related proteins) resulted in stalling of axons after midline crossing. When Wnt4-expressing cell aggregates were ectopically positioned at a posterior position, these explants were able to reorient axon growth into a posterior turn. In fzd3 knockout mice, which lack the Wnt receptor, postcrossing axons exhibit random turning into anterior and posterior direction, suggesting that the signaling responsible for the anterior turn is impaired (Lyuksyutova *et al.*, 2003). Therefore, it has become clear that the Wnt family plays an important role in axon pathfinding and can also act as guidance cues to initiate signaling pathways involved in growth cone navigation.

1.12.5 Modulation of Axon Guidance

While additional axon guidance cues are known, and more surely remain to be identified, there is still only a small suite of factors in comparison to the high degree of complexity found in the nervous system. Importantly, members of the Slit, semaphoring, and netrin-1s families are multifunctional; their role in attraction or repulsion is defined by the axon population involved and developmental context in which pathfinding occurs. Indeed, some axons can switch responsiveness to a single cue dramatically over time. How is this plasticity achieved? Recently, a number of studies have begun to address how diverse outcomes are generated using the limited repertoire of guidance cues. It is becoming clear that both extrinsic and intrinsic factors modulate the behavior of developing axons, and that integration of signals from multiple guidance pathways is essential to coordinate directional pathfinding.

1.12.5.1 Regulated Gene Expression

Axon guidance cues and their receptors are dynamically expressed in the embryonic nervous system. By controlling when and where transcription occurs, axon guidance can be coordinated in a precise spatiotemporal fashion. Visual system development in the frog *Xenopus* provides one example. We have seen that in the tadpole, which has laterally placed eyes, all axons cross to the contralateral side of the brain at the optic chiasm. However, after metamorphosis, medialward movement of the eyes results in their visual fields having a degree of overlap. To integrate information from the overlapping visual field, some axons must project to the ipsilateral side of the brain. This is achieved by the expression of repulsive ephrin-B at the chiasm during metamorphosis. Thus, late-born ventrotemporal axons expressing the Eph-B receptor are repelled from the chiasm, and project ipsilaterally (Figure 8a).

1.12.5.2 Post-Transcriptional Control

The activity of guidance ligands and receptors is also controlled at the post-transcriptional level. For example, Slit2 can bind extracellular proteins including laminin and various proteoglycans, which may modulate its activity and presentation. Other instances of post-transcriptional control include alternative splicing, proteolytic cleavage and receptor shedding, receptor inactivation, and selective trafficking.

Selective trafficking of Robo at the midline crossing in *Drosophila* commissural axons provides a good example for the post-transcriptional control. As we have already mentioned, though these neurons express Robo from an early stage, it is not present on the surface of precrossing axons because of the presence of the Comm, an intracellular sorting receptor, that traffics Robo to lysosomes (Figure 8b; Keleman *et al.*, 2005).

1.12.5.3 Local Translational Control

The discovery of polyribosomes located beneath postsynaptic sites on dendrites (Steward and Levy, 1982; Steward and Fass, 1983) and the identification of various mRNA species specifically localized within dendrites (Garner *et al.*, 1988) suggest that compartmentalized synthesis of protein occurs in neurons. Altough the existence of local translation in dendrites has been widely accepted, the question of whether or not translation occurs in axons has remained more controversial. In invertebrate axons such as the squid giant axon and the marine gastropod *Aplysia*, all of the necessary components for RNA translation and a variety of mRNA species have been identified (reviewed in Alvarez *et al.*, 2000). *In vitro* experiments using fractions isolated from squid axons (Ingoglia *et al.*, 1983) and synaptosomes (Ingoglia *et al.*, 1983) have demonstrated that axonal protein can occur in axons. In vertebrates, ribosomes have

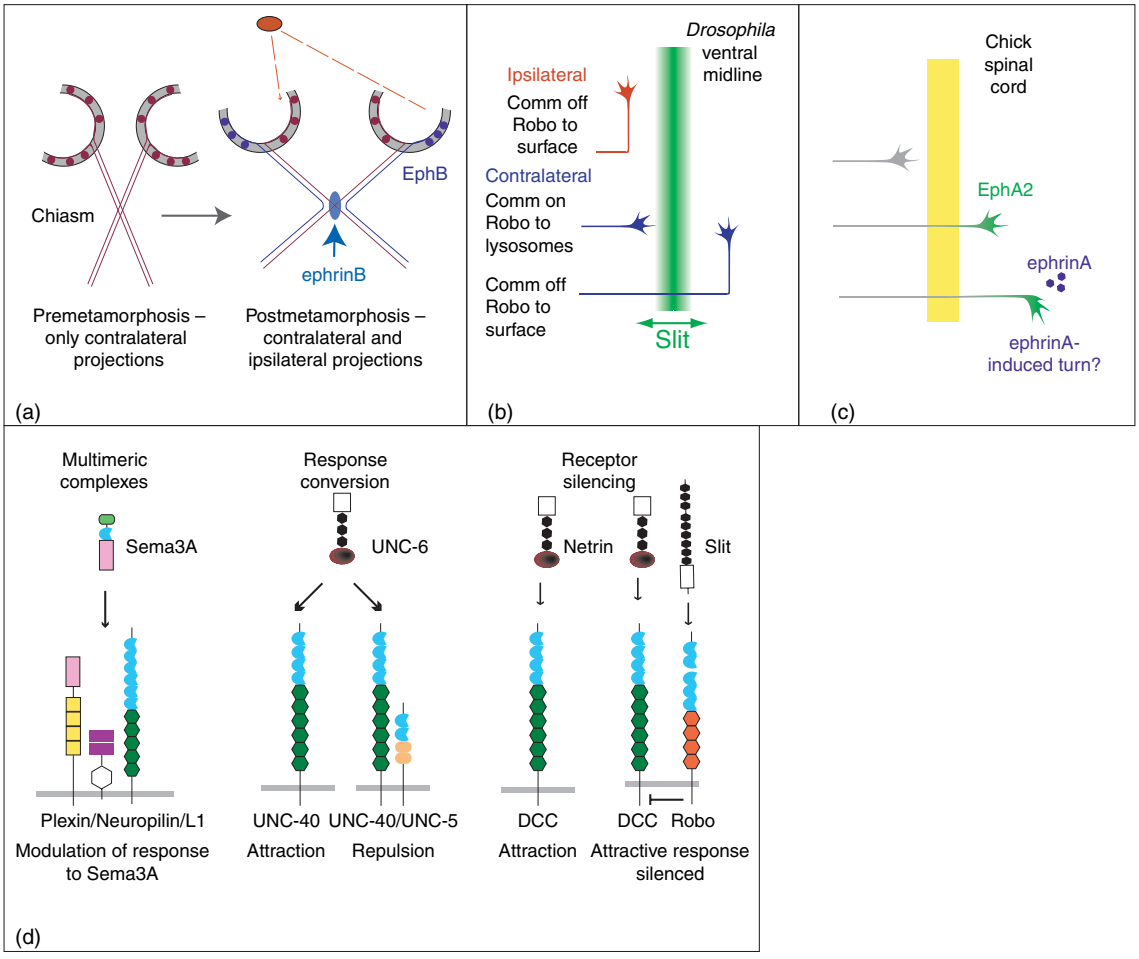

Figure 8 Modulators of axon navigation. Examples of ways in which responses of axons can be modulated during development (see text for description of each example): a, regulated gene expression; b, post-transcriptional control; c, local translation; and d, receptor interaction. Modulation of axon guidance using such methods allows for the generation of diverse outcomes using a small suite of guidance cues.

been identified in the initial axon segment (Steward and Ribak, 1986) and intermittently along the axon shaft (Pannese and Ledda, 1991; Koenig *et al.*, 2000) using both biochemical and immunohistochemical methods (Bassell *et al.*, 1998; Campbell and Holt, 2001). Other components necessary for translation have also been identified in vertebrate axons (reviewed in Alvarez *et al.*, 2000).

What is the role of protein synthesis in axons and does it play a role in aspects of axon guidance? A key finding with respect to these questions is that axon guidance molecules, like netrin-1 and semaphorin 3A, can trigger protein synthesis in retinal growth cones isolated from their cell bodies within 5–10 min. Moreover, inhibition of translation blocks the chemotropic responses of retinal growth cones to netrin-1 and Sema3A *in vitro* (Campbell *et al.*, 2001) and local protein synthesis is necessary for the normal turning responses of *Xenopus* retinal and spinal axons toward gradients of attractants *in vitro* (Ming *et al.*, 2002). By synthesizing specific receptor/effector proteins locally, an axon can potentially alter its responsiveness to previously encountered signals or gain responsiveness to cues expressed on its subsequent trajectory. Such a mechanism may be used by chick commissural axons, which express high levels of EphA2 on the postcrossing region of the axon. By linking mRNA for the marker protein GFP to the 3′ untranslated region (3′UTR) of EphA2 mRNA and driving its expression in commissural neurons, it has been shown that commissural axons specifically translate GFP only in the region extending beyond the midline. This suggests that a region in the EphA2 3′UTR promotes selective translation of EphA2 in distal axonal segments. EphA2 may be used later in guidance, conferring sensitivity to ephrinA ligands, though this remains to be shown (Brittis *et al.*, 2002). The key questions in all of these studies are: which proteins are translated in response to various axon guidance cues and how does their translation control the chemotactic turning behavior of a

growth cone? A local contact with a guidance cue, for example, through a single filopodium, may induce fast and specific change in protein levels (synthesis and/or degradation) within the growth cone, leading to asymmetric cytoskeletal rearrangements and turning, as has been shown in dendrites (Steward and Schuman, 2003). However, the role of local protein synthesis stimulated by guidance cues in the growth cone is still largely unknown (Figure 8c; reviewed in van Horck *et al.*, 2004).

1.12.5.4 Local Protein Degradation and Endocytosis at the Growth Cone

Xenopus retinal growth cones contain the machinery for proteosomal degradation (proteasome proteins, ubiquitin, and ubiquitinating enzymes). Moreover, inhibitors of proteasome function can block the chemotropic response of growth cone to guidance cues, such as netrin-1 and lysophosphatidic acid (LPA) (Campbell and Holt, 2001). An increase in ubiquitin-conjugated proteins within 5 min is induced by these guidance cues, indicating that they rapidly stimulate the degradation pathway. In addition, the protein caspase-3, a marker of the apoptotic pathway, has been found to be involved in chemotropic guidance in retinal axons (Campbell and Holt, 2003). Of interest is that one of the known cleavage targets of caspase-3 is the translation initiation factor eIF4G (Clemens *et al.*, 1998), raising the possibility that guidance cues, such as netrin-1 and brain-derived neurotrophic factor, which simultaneously activate both translation and caspase pathways, can downregulate the synthesis of proteins that they stimulate using a negative-feedback loop. Furthermore, in *Drosophila*, the pruning of the γ neuron axonal projections requires protein degradation. Indeed, mutations of an ubiquitin-activating enzyme or proteasome subunits prevent normal pruning (Watts *et al.*, 2003).

Another mechanism involved in growth cone guidance is the removal and/or inactivation of activated receptors. To advance along their way, growth cones have to break previous interactions with the surface. Several mechanisms are involved in this process, including proteolytic cleavage (Hattori *et al.*, 2000), transreceptor silencing (Stein and Tessier-Lavigne, 2001), and endocytosis. Recently, it has been shown that metalloproteases regulate *in vivo* the growth and guidance of retinal growth cones (Webber *et al.*, 2002). Moreover, it has been shown that endocytosis of functional ephrinB/EphB complexes promote cell detachment of the interacting cells *in vitro* (Marston *et al.*, 2003; Zimmer *et al.*, 2003). Together, these data suggest that endocytosis might be a fast mechanism for ending the adhesive contacts between growth cones and neighboring cells.

1.12.5.5 Receptor Interaction

Interaction between receptor proteins at the surface of the growth cone has been shown to be a remarkably efficient means by which the complexity of axonal responses to guidance cues can be magnified. The combinatorial assembly of heteromeric receptor complexes has a number of potential benefits, such as receptors with distinct signaling properties being used to potentiate the activity of other guidance ligands. The ability to modulate receptor activity via the expression of coreceptors is evident in instances of Semaphorin signaling. Sema receptors are often complexes of different proteins, and this confers the potential to modulate responses to a small number of cues with great subtlety. For example, the responses of dorsal root ganglion (DRG) neurons to Sema3A are modulated by the CAM, L1-CAM, which is also expressed on DRG axons (Castellani *et al.*, 2000).

As well as modulating axonal responses, coreceptor expression can directly convert responses to guidance cues. As mentioned previously, netrin-1s are bifunctional. When signaling via UNC40/DCC, netrin-1s act as attractants. However, when axons express UNC-5, this response is converted to repulsion. Netrin-1 can interact with UNC-5 directly to mediate repulsion, and UNC-5 can also bind DCC though its cytoplasmic domain, which essentially silences DCC-mediated attraction.

As a growth cone navigates through the terrain of the developing nervous system, it undoubtedly encounters multiple guidance cues simultaneously. At the choice point of the spinal cord floorplate, for example, a commissural growth cone will 'see' both netrin-1 and Slit, each of which is promoting a completely opposite reaction. How is such information successfully processed within the axon? Here too, interactions between receptors may be pivotal, as *in vitro* experiments with *Xenopus* spinal neurons suggest. Axons from these neurons turn and grow toward a local source of netrin-1 in culture. Application of Slit blocks netrin-1-mediated turning, yet axon growth mediated by netrin-1 is not affected. Silencing of attraction occurs via a direct interaction between the cytoplasmic domains of DCC and Robo. This specific silencing of netrin-1-mediated attraction by the Robo receptor is an elegant example of signal integration within the growth cone, demonstrating how encounters with concurrent signals may be ordered and prioritized to generate a directional response (Figure 8d; Stein and Tessier-Lavigne, 2001).

1.12.5.6 Implications for Axon Guidance

The degree of plasticity endowed by the above mechanisms enables developing axons to regulate their sensitivity to extrinsic guidance cues in a highly specific manner. Thus, in addition to responding in a stereotyped fashion to attractants or repellents, growth cones can navigate in environments which may not intuitively appear to be conducive for guidance, such as extending toward repulsive targets (e.g., Slit-expressing midline) or moving on from attractive intermediate targets (e.g., netrin-1-expressing ONH). Such changes in axon sensitivity to guidance cues have been described in many different neuronal populations (see above). Modulation of axonal responses has been particularly well documented for netrin-1. For instance, commissural axons from the rodent metencephalon lose responsiveness to this chemoattractant after crossing the midline (Shirasaki *et al.*, 1998), and *Xenopus* retinal axons advancing along the visual pathway switch netrin-1-responsiveness from attraction to repulsion over time (Shewan *et al.*, 2002).

As well as gaining (or losing) responsiveness to guidance molecules, growth cones can also adjust their sensitivity to changing concentrations of such cues. This process, known as adaptation, enables growth cones to navigate in gradients of chemotropic molecules. Adaptation has been described in *Xenopus* retinal (Piper *et al.*, 2005) and spinal (Ming *et al.*, 2002) growth cones *in vitro*, where exposure to a low level of a guidance cue elicits an initial desensitization to additional exposure to the cue, subsequently followed by resensitization and a resumption of responsiveness. Growth cone adaptation is thought to increase the sensitivity of axons when in gradients of guidance cues, allowing them to respond to subtle differences in the environmental concentration of the cue as they proceed. For example, retinal axons *in vitro* are able to grow further up a gradient of a repulsive guidance cue when initially exposed to the cue as compared to those axons not exposed to the cue at the start of the assay (Rosentreter *et al.*, 1998).

In summary, axon guidance cues can be modulated by a variety of intrinsic and extrinsic factors that ultimately regulate growth cone sensitivity and adaptation during development. Thus, by controlling the response of growth cones in a precise spatiotemporal fashion and by integrating and prioritizing coincidently encountered signals, the incredibly complex connections of the nervous system can be generated using a small repertoire of guidance molecules.

1.12.5.7 Axon Guidance and Evolution

In recent years, our understanding of the development and function of the CNS has expanded significantly. With respect to axon guidance, one of the most important advances in our knowledge has been the identification of the main molecular families responsible for navigation, patterning, and target innervation: the netrin-1s, semaphorins, Slits and ephrins. Remarkably, despite millions of years of evolutionary divergence, most of the key molecules that mediate axon guidance during formation of the nervous system in vertebrates and invertebrates are highly conserved, as are the intracellular signaling pathways they activate. For example, the netrins act as critical determinants controlling attraction of commissural axons toward the midline in both flies and mammals, despite an evolutionary separation exceeding 600 million years. The way in which pathfinding axons navigate to distant targets by sensing the molecular characteristics of the local environment, thereby breaking their journey into small segments, is also very similar across a broad range of species. For instance, to find their correct target, the pioneer Ti1 axons of the grasshopper limb are guided by local cues or guidepost cells, that are spaced short distances apart, while many developing vertebrate axon tracts, such as the retinal pathway, have multiple points at which axons receive directional information to simplify their navigation en route to their target. Such pathway subdivision is an extremely efficient method of enabling axons to navigate in an error-free way to their targets, and also endows the pathway with multiple regulatory checkpoints that can be altered during development to enable differing guidance decisions to be made over time.

However, there are a number of features of axon guidance that do reflect the evolutionary divergence of the vertebrate and invertebrate lineages. One example of this lies in the number of ligand and receptor molecules acting to control axon navigation. Vertebrates generally possess a greater number of axon guidance molecules, perhaps due to the genome and chromosomal duplications that have occurred in the vertebrate lineage. For instance, the Eph and ephrins form large, highly homologous families within the vertebrate phyla, suggesting that a major expansion of these genes has occurred. This expansion may have occurred in tandem with the evolution of the vertebrate lineage, and could have been a critical factor facilitating the construction of increasingly complex brains. The broad range of molecular components that can comprise semaphorin receptor complexes also provides an

example of strong evolutionary divergence, as these complexes differ widely between different species.

1.12.6 Concluding Remarks

In summary, we have presented a broad overview of the process of axon guidance, describing the fundamental tenets of axonal navigation shared by disparate species, as well as giving an insight into how different evolutionary advances, such as the development of more complex brains, has been accomplished using a limited suite of axon guidance cues. The growth cone, the tip of the growing axons, is the key structure in sensing and integrating the information provided by guidance cues within the environment. We have discussed some historical axon-pathfinding concepts and experimental techniques that provide insight in both the identification of guidance molecules and mechanisms. Two extensively studied model systems, the retinotectal projection and the midline choice point, have been used to identify the guidance cues and to study the mechanisms of attraction and repulsion induced by them. Finally, several mechanisms modulate the axonal responses at different levels of the signaling pathways, including receptor silencing, protein synthesis, degradation, and endocytosis. In the long term, understanding the mechanisms that underlie axon pathfinding during development will surely help us to determine the basis of many human syndromes with neurological deficits, and perhaps help us to elucidate the cause of neurodegenerative disorders. Encouragingly, studies of neural development have indeed begun to provide insight into neurological diseases and may eventually culminate in strategies for restoring neural connectivity following injury.

1.13 Evolution of the Action Potential

R H Pineda and A B Ribera, University of Colorado at Denver and Health Sciences Center, Aurora, CO, USA

Glossary

A-type current — A transient outward K^+ current that activates and inactivates rapidly. A-type currents are coded for by the Kv4 potassium channel gene subfamily. In addition, Kv1.4 and other Kv1 proteins can form A-type currents when complexed with accessory cytoplasmic proteins (e.g., β-subunits). A-type currents contribute to the resting potential, participate in repetitive firing and spike repolarization, and prevent back-propagation of dendritic APs.

absolute refractory period — The time interval during which a second AP cannot be elicited, regardless of stimuli intensity.

afterhyperpolarization (mV) — A temporal slow hyperpolarization observed after a train of APs. Often plays a role in the regulation of the neuron's firing rate.

amplitude (mV) — Property of an AP that refers to the mV difference between the RMP and peak.

anode break excitation — Generation of an AP at the end of a long-duration depolarization or hyperpolarizing pulse.

conductance — Property of a channel that characterizes its ability to conduct current.

delayed rectifier — Outward K^+ currents that activate slowly (delayed with respect to activation of voltage-gated sodium current). These channels show little, if any, inactivation in the range of seconds. These channels play a predominant role in AP repolarization.

depolarization — Change that results in a more positive (less negative) MP.

duration (ms) — A measure of the time that depolarization lasts during an AP (e.g., interval between threshold on the rising phase and recovering half of the AP amplitude on the falling phase).

hyperpolarization (mV) — Change that results in a more negative (less positive) MP.

inactivation — A process that leads to a nonconducting channel state that does not respond to depolarization by opening of the channel.

inward rectifier — Also known as anomalous rectifiers (as opposed to normal outward rectification), these potassium channels pass inward currents at potentials more negative than the K^+ equilibrium potential of (E_K). The Kir subfamily of voltage-gated ion channels (VGICs) codes for inward rectifiers. Inward rectifiers are strongly regulated by intracellular factors and second messengers and contribute to maintenance of the resting potential and K^+ homeostasis.

ionic dependence — Property of an AP that refers to the principal ion driving the depolarization.

outward rectifier — A channel that allows current to flow in an outward direction more easily than an inward direction.

peak (mV) — The voltage at which the maximum AP amplitude is reached.

permeability — Ion channel property that determines the rate at which ions pass through the pore.

potassium current (I_K) — Ion flux through a potassium-selective ion channel.

rate of fall ($mV\ ms^{-1}$) — Change in MP per unit time during the falling (repolarizing) phase of the AP. Used as an indirect measure of potassium current density.

rate of rise ($mV\ ms^{-1}$) — Change in MP per time unit during the rising (depolarizing) phase of the AP. Used as an indirect measure of sodium current density.

rectifier — In electronics, a circuit that converts bidirectional current (AC) to unidirectional current (DC). In physiology, a nonlinear I/V relationship produced when a membrane conductance is dependent upon the direction of traffic of the permeant ion. As a result, a rectifying current preferentially flows in one direction and not the other.

refractory period (ms) — A primary determinant of the maximal rate of firing of a neuron.

relative refractory period — The briefest interval after which a second AP can be elicited, albeit with diminished amplitude.

repolarization — Change that brings the MP back towards the resting value.

rheobase (nA) — The minimum amount of current needed to generate at least one AP.

sodium current (I_{Na}) — Ion flux through a sodium-selective ion channel.

threshold (mV) — The minimum value of the MP at which an AP is initiated. Threshold can also be defined as the absolute depolarization magnitude from the RP required to initiate an AP.

1.13.1 Introduction

The nervous system collects, coordinates, integrates, and disseminates diverse types of information regarding both the external and internal environments. Processing of this information leads to appropriate physiological and/or behavioral responses. In order for stimuli to produce accurate descriptions of the environment, a variety of neural codes and operations arose during evolution that allow information exchange within and between neurons (for review, see Perkel and Bullock, 1968; Gerstner *et al.*, 1997). One mechanism, the action potential (AP), arose early during evolution and is essential for rapid signaling in the nervous system.

In this article, we focus on how embryonic neurons acquire the ability to fire APs. AP generation represents a significant challenge because of the requirement for function of several different membrane proteins. Further, there are several examples of neurons that fire APs with developmentally regulated properties. Consequently, the roles of APs in emerging nervous systems are not static and depend upon developmental stage. We review mechanisms that lead to the developmental regulation of excitability. We conclude by identifying key issues that remain unresolved and warrant being the focus of future study (see Neuronal Migration, Axon Pathfinding, A Tale of Two CPGs: Phylogenetically Polymorphic Networks).

1.13.2 What Are Action Potentials?

Electrically excitable cells share in common the ability to generate APs. During an AP, the membrane potential (MP) of an electrically excitable cell displays dramatic, stereotypic, and rapid changes. In

muscle cells, AP generation quickly leads to muscle contraction. In neurons, APs allow rapid intra- and intercellular communication.

The classic work of Hodgkin and Huxley (1952; Hodgkin, 1958, 1964) demonstrated that time-dependent changes in the membrane conductance to specific ions underlie the generation of APs. For more detailed treatment of the ionic basis of the MP and AP, we refer the reader to any of several excellent books (Jack *et al.*, 1988; Johnston and Wu, 1994; Kandel *et al.*, 2000; Hille, 2001; Nicholls *et al.*, 2001). Below, we briefly review key aspects of AP generation. We have defined important terms in the glossary for readers who wish to read the primary literature.

Typically, all cells display an electrical difference across their membrane. This electrical difference, known as the MP, has values in the mV range. By convention, the inside of the cell is negative with respect to the outside. The predominant value of the MP is referred to as the resting MP (RMP).

Excitable cells generate APs (also referred to as spikes or impulses) in response to stimuli that bring the MP to a new, less negative value, known as threshold. Threshold values are not fixed and vary among excitable cells. Moreover, for any given cell, the value of threshold can change over time as a result of developmental regulation, activity, or cell–cell interactions. Stimuli that bring the MP to values less positive than threshold do not lead to AP generation and instead generate subthreshold responses. Thus, APs are not generated in a graded manner but rather as an all-or-none response of the membrane to stimuli of sufficient intensity (Hodgkin and Huxley, 1952).

Once threshold is achieved, the conductance to sodium and/or calcium ions increases, allowing rapid entry of positively charged sodium and/or calcium ions. The influx of positive charge results in a more positive MP. With further depolarization, more sodium channels open, resulting in greater sodium influx and even more positive MP values. When depolarization occurs, the membrane conductance to potassium ions also increases, but with a delay. The increased potassium conductance and inactivation of sodium channels repolarize the membrane to its original negative resting value, thereby terminating the AP.

In neurons, AP generation initiates near the cell body at a site known as the axon hillock (Coombs *et al.*, 1957a, 1957b). Subsequently, APs propagate down the axon at constant velocity and amplitude. The ability to propagate APs without diminution in amplitude is an essential feature of neuronal cell–cell communication and guarantees that signals will be transmitted faithfully without failure.

1.13.2.1 APs are Neuronal Signatures

Figure 1 presents an example of an AP fired by a mature neuron. Typically, adult neurons fire APs that are brief in duration and rely upon voltage-gated sodium channels for generation. However, APs fired by mature neurons vary significantly. Further, some neurons respond to stimulation by firing a single AP, while others fire multiple impulses in a characteristic pattern. Consequently, the type of AP or AP train fired in response to stimulation can serve as a signature of neuronal identity (for review, see Contreras, 2004).

1.13.2.2 AP Waveform Properties

The plot of the MP as a function of time during an AP is known as the AP waveform (Figure 1). Characterization of APs involves analysis of specific properties of the waveform that, in turn, reflect the complement of voltage-gated channels expressed by the cell (see 'Glossary').

During the AP, the MP achieves positive values near the equilibrium potential for sodium. The most positive MP achieved during an AP is known as the peak. The rapid depolarization leading to the peak reflects the activity of voltage-gated sodium channels. Thus, measuring the rate of rise provides an indication of sodium current density. In contrast, the activity of voltage-gated potassium channels contributes to the subsequent repolarization and the rate of fall.

After repolarization, the MP often becomes slightly more negative than the standard RMP,

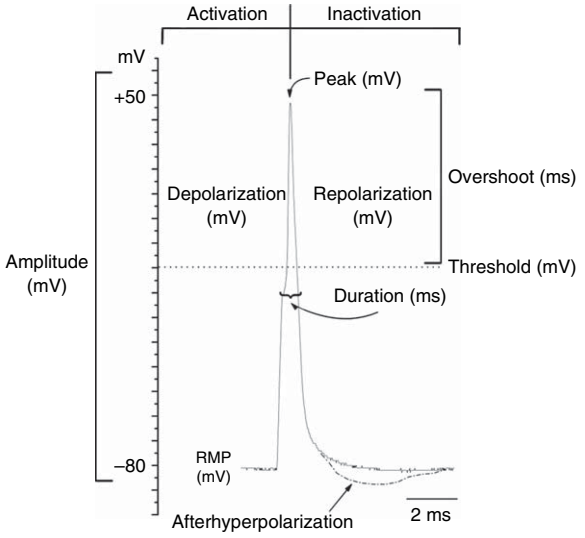

Figure 1 Stereotypic AP of a mature neuron: an AP recorded from a Rohon–Beard cell of a 2-day-old zebra fish embryo is shown (Pineda and Ribera, unpublished data). Several AP properties that are defined in 'Glossary' are illustrated in the figure.

resulting in an afterhyperpolarization. Afterhyperpolarizations play important roles in determining the frequency of AP firing. Because information is often encoded by AP frequency, afterhyperpolarizations can greatly influence processing of information in the nervous system.

One property of APs that varies greatly between excitable cells is the duration. In some neurons, the AP duration is extremely brief and barely 1 ms (Storm, 1987). In contrast, skeletal muscle fibers fire APs that have slightly longer durations (~5–10 ms; Kuriyama *et al.*, 1970). Cardiac myocytes fire strikingly different impulses with durations that are often as long as 500 ms (Cavalié *et al.*, 1985; Hume and Uehara, 1985). As discussed further below, the duration of neuronal APs often undergoes substantial developmental regulation.

1.13.3 Molecular Determinants of APs

The membrane conductances that underlie the AP reflect the activities of several members of the voltage-gated ion channel (VGIC) superfamily of membrane proteins (Figure 2). VGICs respond to membrane depolarization with conformational changes that reveal an ion-selective pore through which specific ions pass in a diffusion-limited manner. Members of the VGIC superfamily have a positively charged transmembrane domain known as the S4 helix, the structure of which depends upon the transmembrane voltage (for review, see Gandhi and Isacoff, 2002).

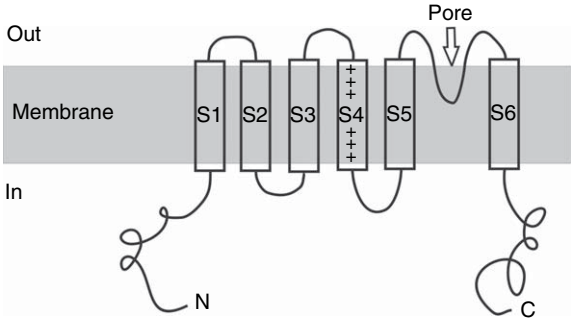

Figure 2 Proposed membrane topography of a voltage-gated potassium channel: the proposed disposition of a single voltage-gated potassium channel α-subunit in the membrane is shown. The S4 transmembrane domain, thought to be critical for voltage-dependent gating, is indicated. Similar S4 domains are also found in voltage-gated sodium and potassium channels and are a hallmark of the VGIC superfamily. 'N' and 'C' indicate the amino- and carboxyl-termini, respectively. Reprinted by permission from Macmillan Publishers Ltd: *Nature* (Yellen, G. 2002. The voltage-gated potassium channels and their relatives. *Nature* 419, 35–42), copyright (2002).

VGICs exist in species throughout the animal and plant kingdoms, including prokaryotes, protozoa, yeast, vascular plants, coelenterates, nematodes, arthropods, mollusks, teleosts, and tetrapods (for review, see Hille, 2001). Not surprisingly, APs have been recorded from cells in a range of species spanning the animal and plant kingdoms (for review, see Hille, 2001). During the last 20 years, many genes and transcripts for a large variety of VGIC proteins have been cloned and characterized. Noda *et al.* (1984) reported the cloning of a voltage-gated sodium channel from the electric organ of the electric eel, *Electrophorus electricus*. The cloning of a voltage-gated calcium channel from rabbit skeletal muscle followed in 1987 (Tanabe *et al.*, 1987). That same year, several groups reported cloning of the *Drosophila Shaker* potassium channel gene (Kamb *et al.*, 1987; Papazian *et al.*, 1987; Pongs *et al.*, 1988; Schwartz *et al.*, 1988). Comparisons of the primary sequences of cloned VGIC genes have revealed a high degree of conservation among species that are distantly related (for review, see Jan and Jan, 1990; Coetzee *et al.*, 1999; Moreno-Davila, 1999; Goldin, 2001; Yu and Catterall, 2003). Such findings suggest that the key structural and functional properties of VGICs have been conserved during evolution.

Molecular cloning has revealed an unexpectedly large number of VGIC genes, many more than might have been expected on the basis of physiological recording. Current research seeks to identify the specific roles of the many VGIC genes that have been identified. A common finding has been that VGIC gene subfamilies may have multiple members in vertebrates (e.g., Kv1 family: Kv1.1–Kv1.9; Nav1 family: Nav1.1–Nav1.9, respectively) but only a single orthologous gene in invertebrates (e.g., *Drosophila Shaker*; *Drosophila para*, respectively).

Phylogenetic analyses suggest that VGICs evolved from an ancestral voltage-gated potassium channel (for review, see Hille, 2001; Yu *et al.*, 2005). Further, voltage-gated calcium, but not sodium, channels have been detected in unicellular organisms (DeHertogh *et al.*, 2002). APs recorded from species lacking voltage-gated sodium channels rely upon voltage-gated calcium channels for their initiation and typically are much longer-lasting events that signal via changes in intracellular calcium ion concentrations.

Phylogenetic analyses indicate that voltage-gated sodium channels evolved later than did voltage-gated potassium and calcium channels. Voltage-gated sodium channel function also enlisted a sodium pump that establishes a transmembrane

sodium gradient (Stein, 2002). Voltage-gated sodium channels underlie the ability of the AP to be a rapid spike, occur in bursts, and propagate rapidly. Thus, the later evolution of voltage-gated sodium channels introduced important changes into the AP waveform, allowing it to be a rapid spike. Further, voltage-gated sodium channels allow APs to occur repetitively at high frequencies. Thus, voltage-gated sodium channels significantly expanded the roles that APs can play in information processing and behavior.

1.13.4 Roles in Information Coding

During development, the roles that APs play in the nervous system vary substantially (Figure 3; see below). Interestingly, many neurons fire APs prior to synapse formation. Several lines of evidence indicate that early-appearing APs play a developmental role. After synapse formation, APs take part in mechanisms that select and/or eliminate specific connections. In the mature nervous system, APs contribute to plasticity mechanisms in addition to being essential for the rapid processing of information.

1.13.4.1 Prior to Synapse Formation

Many aspects of neuronal differentiation begin prior to synapse formation. Importantly, many neurons acquire electrical excitability prior to synapse formation, thus allowing neuronal activity to influence subsequent aspects of differentiation (Holliday and Spitzer, 1990). For example, soon after neurons exit the cell cycle and initiate postmitotic differentiation, they often migrate long distances and take up residence at distant sites. Blocking electrical activity can affect migratory patterns of embryonic neurons for both invertebrates and vertebrates (Komuro and Rakic, 1992; Tam *et al.*, 2000). Neurons differentiate biochemically and often synthesize and secrete neurotransmitter prior to synapse formation. Perturbations of excitability alter biochemical differentiation of neurons, resulting in inappropriate neurotransmitter synthesis (Gu and Spitzer, 1995; Borodinsky *et al.*, 2004). Morphological differentiation also occurs during this period, notably axon outgrowth and initial contact of targets. Blockade of activity also perturbs this important aspect of neuronal differentiation (Cohan and Kater, 1986; Gu *et al.*, 1994). As discussed further below, electrical membrane properties are also developmentally regulated. Patterns of early activity influence acquisition of mature channel properties (Desarmenien and Spitzer, 1991; Gomez and Spitzer, 1999).

A common finding for effects of activity prior to synapse formation concerns its dependence on calcium ions. The majority of studies indicate that calcium ions act as intracellular messengers and participate in mechanisms that translate patterns of activity into developmental programs (for review, see Spitzer *et al.*, 2004). As we discuss below, many neurons fire long-duration calcium-dependent APs prior to synapse formation, thus accounting, at least in part, for the calcium dependence.

1.13.4.2 During Synapse Formation and Early Circuit Activity

Synapses can form in the absence of neural impulses (Verhage *et al.*, 2000; Trachtenberg *et al.*, 2002; De Paola *et al.*, 2003). However, the maintenance of synapses requires transmitter secretion that normally depends upon impulse propagation (for review, see Sanes and Lichtman, 2001). Moreover, in several instances, after synapses initially form,

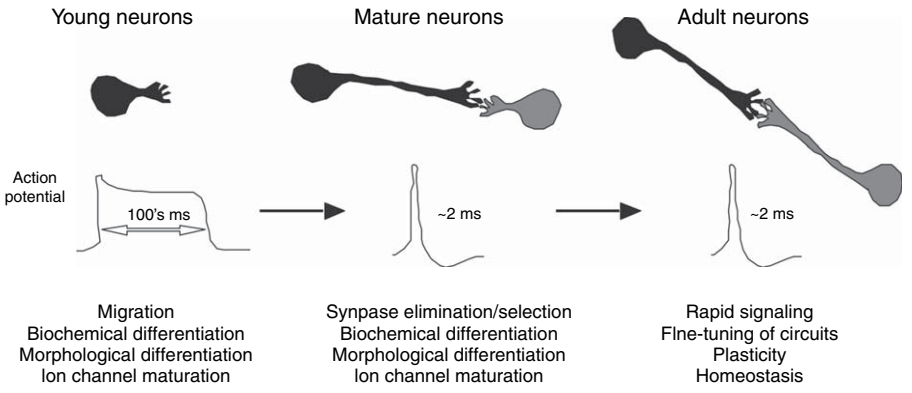

Figure 3 AP roles change during development. In neurons, APs play several roles in addition to rapid processing of information. Prior to synapse formation, APs play developmental roles. During the early stages of synapse formation, APs function in mechanisms that eliminate or stabilize specific connections. In the adult nervous system, APs contribute to plasticity mechanisms.

there is a period of pruning or synapse elimination. For example, at the neuromuscular junction, muscle fibers that receive inputs from multiple axons become singly innervated (for review, see Colman and Lichtman, 1993). Also, in the cerebellum, Purkinje cells are initially innervated by more than one climbing fiber but later respond to inputs from only one (Mariani and Changeux, 1981). Similar observations have been made for developing synapses in the visual, auditory, and autonomic nervous systems (Lichtman, 1977; Shatz and Stryker, 1988).

During development, activity regulates neuronal arbor growth by regulating branch lifetime in retinal ganglion cell axons and tectal dendrites of *Xenopus* and zebra fish larvae (Rajan and Cline, 1998; Rajan *et al.*, 1999; Lohmann *et al.*, 2002; Schmidt, 2004). Activity-dependent expression of structural proteins may also be involved in synapse stabilization and dendritic branch formation (Ziv and Smith, 1996; Lichtman, 2000; Star *et al.*, 2002; Fukazawa *et al.*, 2003; for review, see Steward and Schuman, 2001; Hua and Smith, 2004). Moreover, activity promotes secretion of neurotrophins that have multiple effects on synaptic development and function as well as ion channels (Nick and Ribera, 2000; for review, see Poo, 2001; Lu and Je, 2003; Figure 4).

1.13.4.3 Mature Nervous System

In the mature nervous system, a principal role of the AP is transduction, conduction, and processing of information (Eggermont, 1998; Sanger, 2003). However, even at these stages, AP generation contributes to mechanisms that alter the nervous system both structurally and functionally. For example, activity sculpts the time course of elimination of Rohon–Beard cells from the spinal cord of larval zebra fish (Svoboda *et al.*, 2001). Neural activity also promotes both short- and long-term synaptic changes and affects the maintenance, synthesis, and release of neurotrophins (Madison *et al.*, 1991; Poo, 2001; Lu and Je, 2003).

1.13.5 Regulation of Excitability during Embryogenesis

Developmental regulation of excitability occurs throughout embryogenesis. In the early 1970s, Takahashi and co-workers recorded the changes in electrical excitability that occur in the tunicate *Halocynthia roretzi* as it develops from an unfertilized egg to an adult with differentiated tissues (Takahashi, 1979; for review, see Takahashi and Okamura, 1998). Their results indicated that, in both the unfertilized and the newly fertilized egg, APs were generated. Further, AP generation required the function of voltage-gated sodium and/or calcium channels. In contrast, differentiated muscle fibers showed a predominantly calcium-dependent AP. These observations suggested that, during early embryonic differentiation: (1) some types of ion channels are eliminated; (2) some types of ion channels increase in density; and (3) new channel types appear.

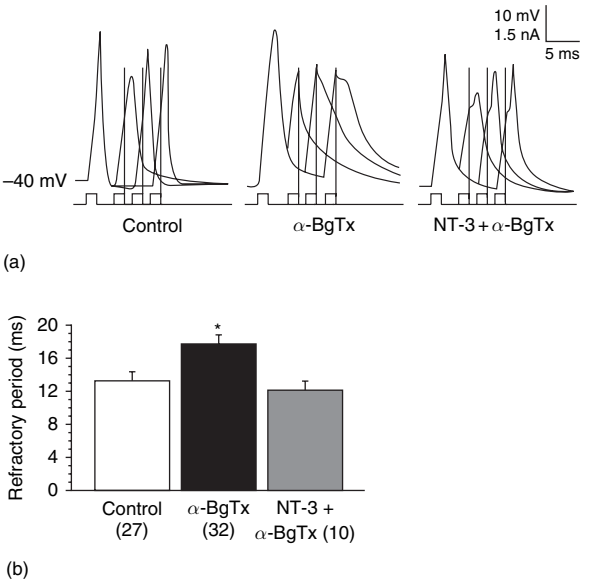

Figure 4 Synaptic activity regulates presynaptic excitablility. Muscle activation leads to release of retrograde factors that modulate excitability of the presynaptic neurons. These effects are mediated by the neurotrophin, NT-3. a, The refractory period was measured using a two-pulse protocol with a longer interpulse interval for each successive trial. Three trials are superimposed for each condition. In the presence of α-BgTX, APs did not overshoot the stimulus artifact. b, Co-application of NT-3 with α-BgTX rescued the effects of the toxin. Reprinted by permission from Macmillan Publishers Ltd: *Nat. Neurosci.* (Nick, T. A. and Ribera, A. B. 2000. Synaptic activity modulates presynaptic excitability. *Nat. Neurosci.* 3, 142–149), copyright (2000).

1.13.6 Developmental Regulation of the AP

The results of several studies reveal three general developmental patterns of APs (Figure 5). The first two patterns, classes 1 and 2, have been studied more frequently and are relevant to the vast majority of neurons that continue to fire APs in the nervous system. These two patterns are distinguished on the basis of the ionic dependence of the impulse initially fired by a differentiating excitable cell (for review, see

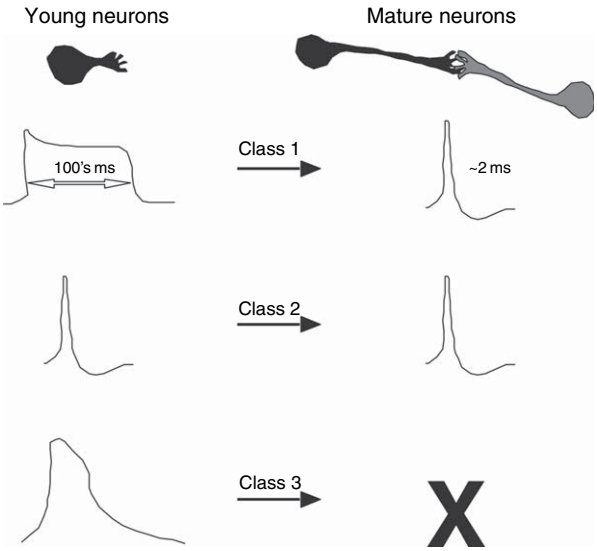

Figure 5 Patterns of AP development. Three patterns have been described. In the first, APs are of long duration when first present, but mature in time to the more stereotypic brief spikes, characteristic of mature neurons. The second pattern consists of APs that show little developmental regulation and are brief and sodium-dependent from the time of first appearance. The third pattern, characteristic of some sensory neurons, consists of APs at early stages followed by the loss of AP generation. At adult stages, neurons of the class 3 pattern respond with graded depolarization or hyperpolarizations to sensory stimuli.

Spitzer, 1991; Ribera and Spitzer, 1992; Spitzer *et al.*, 2000). We discuss these two patterns in more detail below.

The third developmental pattern consists of an early period of electrical activity followed by loss of AP generation. This pattern appears to be unique to sensory cells and consists of an early transient period of excitability followed by the generation of graded potentials in response to sensory stimuli (Beutner and Moser, 2001). Interestingly, the available evidence implicates the transiently appearing APs in proper development of sensory neurons (Beutner and Moser, 2001; Brandt *et al.*, 2003).

1.13.6.1 Class 1 Pattern of AP Development

The class 1 pattern of AP development consists of APs that are initially of long duration (5–500 ms; Spitzer and Lamborghini, 1976; Baccaglini and Spitzer, 1977). The early-appearing APs can be generated in the absence of extracellular sodium or in the presence of the sodium channel blocker tetrodotoxin and are eliminated by substitution of calcium in the extracellular media. Hence, these APs are described as calcium-dependent. In this respect, the class 1 pattern is similar to the third pattern mentioned above: the early APs that are transiently expressed by sensory neurons are calcium-dependent (Beutner and Moser, 2001).

As development proceeds, the AP duration becomes progressively briefer. In addition, the AP acquires sensitivity to blockers of voltage-gated sodium channels (e.g., tetrodotoxin) and insensitivity to calcium channel blockers (e.g., cobalt). The later-appearing APs are hence considered to be sodium-dependent. Examples of excitable cells displaying the class 1 pattern of development include amphibian primary spinal neurons, neurons of the rat dorsal nucleus of the vagus, chick motor neurons, ferret lateral geniculate neurons, and rat nucleus accumbens neurons (Spitzer, 1976; Spitzer and Lamborghini, 1976; Baccaglini and Spitzer, 1977; McCobb *et al.*, 1990; Ramoa and McCormick, 1994; Belleau and Warren, 2000; for review, see Spitzer, 1991; Moody, 1995).

1.13.6.2 Class 2 Pattern of AP Development

The class 2 pattern of AP development consists of APs that have brief durations from the time of their first appearance. The APs initially expressed are and remain sodium-dependent as differentiation proceeds. Further, the AP duration does not change significantly. Examples of cells displaying the class 2 pattern include chick ciliary ganglion neurons, quail mesencephalic neural crest cells, rat spinal and phrenic neurons, grasshopper interneurons, and amphibian myocytes (Goodman and Spitzer, 1981; Bader *et al.*, 1983, 1985; DeCino and Kidokoro, 1985; Henderson and Spitzer, 1986; Krieger and Sears, 1988; Ziskind-Conhaim, 1988a, 1988b).

1.13.6.3 General Principles

Even though several different types of ion channel underlie AP generation, the principal difference between the three patterns of AP development concerns developmental regulation of potassium current (Barish, 1986; Krieger and Sears, 1988; O'Dowd *et al.*, 1988; McCobb *et al.*, 1989; Nerbonne and Gurney, 1989; Ribera and Spitzer, 1989, 1990). The class 1 pattern reflects a program of ion channel regulation in which voltage-gated potassium channels are present at low density and have slow activation properties when APs are initially expressed and of long duration. The subsequent developmental shortening of the AP duration is due to a progressive increase in potassium channel density with concomitant changes in channel activation properties (Barish, 1986; O'Dowd *et al.*, 1988; Ribera and Spitzer, 1989; Lockery and Spitzer, 1992; Harris *et al.*, 1998).

Computer reconstructions of the APs recorded from *Xenopus* spinal neurons support the view that the delayed rectifier potassium current plays the predominant role during AP maturation in amphibian spinal neurons (Barish, 1986; Lockery and Spitzer, 1992).

Regardless of the developmental pattern, calcium and sodium currents appear early in neuronal differentiation (O'Dowd *et al.*, 1988; Alzheimer *et al.*, 1993; Albrieux *et al.*, 2004). Once present, calcium currents may increase in density but often remain stable (Barish, 1986; Gottmann *et al.*, 1988; McCobb *et al.*, 1989). In contrast, sodium currents typically increase in density and undergo kinetic changes (Huguenard *et al.*, 1988; O'Dowd *et al.*, 1988; McCobb *et al.*, 1990; Alzheimer *et al.*, 1993; Pineda *et al.*, 2005).

1.13.7 Myelination

In the nervous system, developmental regulation of ion channels is not unique to neurons. Glial cells also display developmentally regulated properties of excitability (Sontheimer *et al.*, 1992; Kressin *et al.*, 1995; Bordey and Sontheimer, 1997; Maric *et al.*, 1998; Bringmann *et al.*, 2000; Pannicke *et al.*, 2002; for review, see Waxman *et al.*, 1993). The distribution of specific sodium and potassium channel isoforms in myelinated axons provides one of the most interesting examples of developmental regulation of ion channels. Recent studies have revealed that interactions between axons and glia during development play key roles in sculpting the differential localization of VGICs in the axonal membrane.

1.13.7.1 Function

Glial cells wrap around axons and form several layers of membrane known as myelin (for review, see Sherman and Brophy, 2005). The identities of the glial cells that form myelin differ in the peripheral versus central nervous systems. In the central nervous system, oligodendrocytes form myelin. Schwann cells are the relevant glia for the peripheral nervous system.

Myelination of axons in both the peripheral and central nervous systems underlies the amazing ability of axons to propagate APs rapidly (for review, see Sherman and Brophy, 2005). Myelin provides insulation to the axon and current flow is restricted to nonmyelinated areas, known as nodes of Ranvier. Consequently, APs need not be conducted down the entire length of the axon but only to successive nodes of Ranvier, thereby accelerating AP conduction velocities. Further, the metabolic demands of transmitting APs over long distances are diminished because impulses are only generated at nodes and not throughout the entire length of the axon.

Morphological studies indicate that myelin is present in jawed vertebrates but not lamprey or hagfish (Bullock *et al.*, 1984). In addition, a few copepod crustacean species that display rapid escape behaviors necessary for life in predator-rich ocean waters also have myelin (Davis *et al.*, 1999). The copepods that display rapid behaviors and myelin-like sheaths are thought to have evolved later than other members of their species. Thus, myelin represents a relatively recent evolutionary adaptation that results in rapid behavioral responses.

1.13.7.2 Distribution of Ion Channels during Developmental Myelination

Toxin labeling studies indicated that axons have an overall low density of sodium channels, even though they can propagate APs (Waxman *et al.*, 1989). These studies raised the possibility that, in addition to myelin, the distributions of VGICs may be optimized for generation of APs at nodes of Ranvier. More recent immunocytochemical studies have demonstrated that sodium channels are maintained at high densities at nodes of Ranvier (for review, see Rasband and Trimmer, 2001; Figure 6). In contrast, specific potassium channel isotypes are maintained at high densities in nearby, non-nodal regions known as the juxtaparanodes. Moreover, the specific locations of the different ion channel types are specified during developmental myelination and require interactions between the axon and glia (Wu and Barish, 1994; Demerens *et al.*, 1996; Stevens *et al.*, 1998; Stevens and Fields, 2000).

In both the peripheral and central nervous systems, one sodium channel isoform, Nav1.2, appears early in unmyelinated zones (Westenbroek *et al.*, 1992; Gong *et al.*, 1999; Boiko *et al.*, 2001; for review, see Rasband and Trimmer, 2001). As nodes form, another isoform, Nav1.6, becomes the dominant sodium channel type (Caldwell *et al.*, 2000; Boiko *et al.*, 2001; for review, see Rasband and Trimmer, 2001).

Potassium channels also display stereotypic distributions in myelinated axons. Electrophysiological studies demonstrated that potassium current densities were not constant across the length of myelinated axons, suggesting nonhomogeneous, optimized distributions of potassium channels (Chiu and Ritchie, 1980; Chiu and Wilson, 1989; Roper and Schwarz, 1989). Immunocytochemical results have directly demonstrated the locations of specific potassium channel subtypes in myelinated axons. In myelinated axons, potassium channel

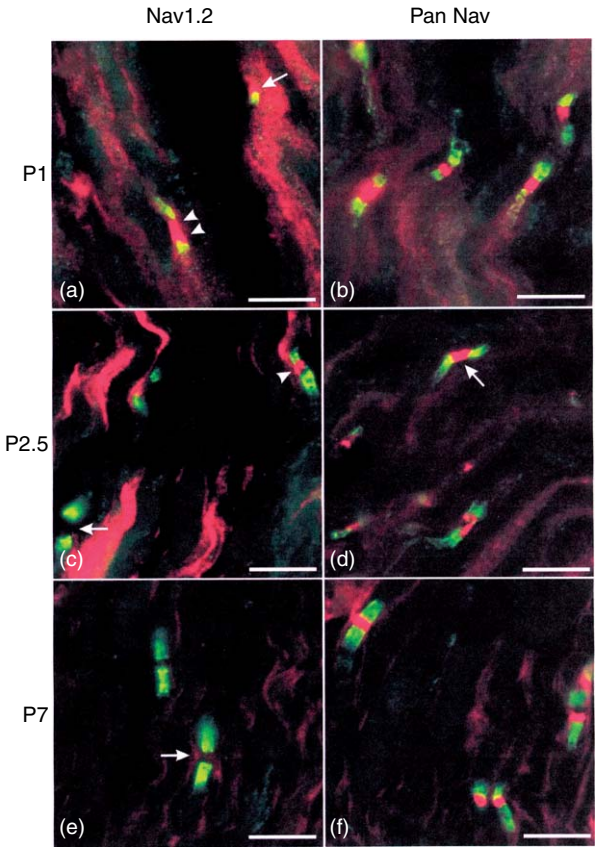

Figure 6 VGIC distributions in axons. At nodes of Ranvier, the identity of the sodium channel α-subunit changes during development in rat sciatic nerve. Panels (a), (c), and (e) present Nav1.2 immunoreactivity (red) data, whereas panels (b), (d), and (f) present pan-sodium channel immunoreactivity (red) data. Caspr immunoreactivity, a marker of the paranode, is shown in green. At all stages of development, nodes of Ranvier possess high densities of sodium channels (b, d, f). At early (a) but not late (e) stages, the predominant sodium channel isoform is Nav1.2. Scale bar: 10 μm. Reproduced from Rasband, M. N. and Trimmer, J. S. 2001. Developmental clustering of ion channels at and near the node of Ranvier. *Dev. Biol.* 236, 5–16, with permission from Elsevier.

densities are especially high in the juxtaparanodal regions (Wang *et al.*, 1993; Arroyo *et al.*, 1999; for review, see Rasband and Trimmer, 2001).

In sum, recent studies are revealing the molecular organization of nodal, paranodal, and juxtaparanodal regions of myelinated axons. It is clear that interactions between the axon and myelinating glia are required to form and maintain these regions and the concomitant distributions of ion channels. A better understanding of the underlying mechanisms will provide insights about how ion channel expression and distributions are regulated during development. Moreover, the information could potentially be useful for intervention and treatment of conditions associated with demyelination or axon regeneration.

1.13.8 Mechanisms of Developmental Regulation

Even though developmental changes in potassium currents typically drive maturation of the AP, most VGICs show developmental regulation. Analyses of mRNA and protein indicate that regulation of ion channel expression occurs across both temporal and spatial domains (Table 1). Electrophysiological analyses further indicate that the properties of voltage-gated currents expressed by a given cell are not constant over time but change during differentiation and in response to activity (Table 2).

Developmental regulation of channel function could occur at transcriptional, post-transcriptional, translational, and post-translational levels. These levels of control are not mutually exclusive and several could be operating simultaneously (Giraud *et al.*, 1998; Blaine *et al.*, 2004).

In some cases, developmental regulation of ion currents occurs in the absence of interactions with other cells or factors (Henderson and Spitzer, 1986). Additionally, cell–cell interactions, often apparent at the onset of synaptogenesis, play important roles (Okado and Takahashi, 1990a, 1990b; Okamura *et al.*, 1994; Subramony *et al.*, 1996; Bahls *et al.*, 1998; Nick and Ribera, 2000; Martin-Caraballo and Dryer, 2002a). Growth factors and neurotrophins often mediate the effects of activity or cell–cell interactions (Subramony *et al.*, 1996; Rothe *et al.*, 1999; Martin-Caraballo and Dryer, 2002a; for review, see Dryer *et al.*, 2003).

Further, extrinsic cues affect functional expression of VGICs differently depending upon the neuron type. For example, growth factors regulate expression of currents post-translationally in ciliary ganglion neurons but their effects require new protein synthesis in lumbar motor neurons (Subramony *et al.*, 1996; Martin-Caraballo and Dryer, 2002a). Thus, both intrinsic and extrinsic cues operate to regulate ion currents during development (for review, see Dryer, 1998; Ribera, 1998).

In Table 1, we review the molecular bases of developmental regulation of ion channel expression and function in the developing nervous system.

1.13.8.1 Transcriptional Regulation

Numerous stimuli, such as injury, electrical activity, growth factors, and development, modulate VGIC gene transcription (Beckh *et al.*, 1989; Ribera and Nguyen, 1993; Toledo-Aral *et al.*, 1995; Burger and Ribera, 1996; Gurantz *et al.*, 1996; Villeneuve *et al.*, 2000; Vega *et al.*, 2003; for review, see Levitan and Takimoto, 1998; Sashihara *et al.*, 1998; Black and Grabowski, 2003). Recent

Sodium	Nav1.3	Expression of Nav1.3 was linked to acquisition of electrical excitability.	Murine preplate and Cajal–Retzius cells (E12–13)	Albrieux *et al.* (2004)
Sodium and potassium	Nav1.1, Nav1.2, Nav1.3, Nav1.6; Kv1.3, Kv1.4, Kv1.6; Kv2.1; Kv3.1, Kv3.3; Kv4.2, Kv4.3	RT-PCR analyses indicated that full-length variants of Nav1.1 and Nav1.3 were expressed. In contrast, variants of Nav1.2 and Nav1.6 coding for truncated subunits were expressed. Several potassium channel subunits were already expressed at these early stages of differentiation.	Rat spinal motor neurons *in vitro*	Alessandri-Haber *et al.* (2002)
Sodium	Nav1.1, Nav1.2, Nav1.3	*In situ* hybridization studies showed that: (1) Nav1.1 was predominant at late postnatal stages; (2) Nav1.2 was expressed at all stages studied with regional variability; and (3) Nav1.3 was predominantly expressed at fetal and early postnatal stages.	Rat CNS, E10–P90	Beckh *et al.* (1989)
Potassium	Kv 1.1, Kv2.1, Kv2.2	*In situ* hybridization studies revealed Kv2.2 and Kv1.1 mRNA in ventral and dorsal spinal cord, respectively. Both Kv2 genes were detected in RNA of developing embryos by RNAase protection assays.	*Xenopus* spinal cord, 1–3 days	Burger and Ribera (1996)
Potassium	Kvβ1	*In situ* hybridization studies revealed developmentally and spatially regulated expression of the auxiliary subunit.	Mouse brain, E16–P7	Butler *et al.* (1998)
Potassium	Kvβ1, Kvβ2, Kvβ3	Kvβ1 expression was high at birth in all brain regions examined and decreased with age. Kvβ2 expression was low at birth and increased with age, reaching adult levels by the third postnatal week.	Mouse CNS, spinal cord and dorsal root ganglia, E16–adult	Downen *et al.* (1999)
Calcium	Calcium channel isotypes A, B, and E	Expression of Ca^{2+} channel transcripts are developmentally regulated *in vitro* and can be influenced differentially by transmembrane signaling via chronic depolarization and Ca^{2+} entry.	Rat cerebellar cortex	Falk *et al.* (1999)
Potassium	Kv3.1	Kv3.1 transcripts were upregulated *in vivo* and *in vitro* during the period of maturation of I_{Kv}.	*Xenopus* spinal neurons, 1–3 days	Gurantz *et al.* (1996)
Potassium	xKvβ2, xKvβ4	mRNA of both subunits is expressed during the period of impulse maturation in different neuronal populations.	*Xenopus* spinal neurons, 1–3 days	Lazaroff *et al.* (1999)
Sodium	TuNa I and TuNa II	Regional specific expression. Gene transcription is dependent on specific cellular contacts.	Ascidian embryo and neural cells (*Halocynthia roretzi*)	Okamura *et al.* (1997)
Calcium	N and L type	Immunocytochemical and physiological analyses demonstrated developmentally regulated expression of calcium channel isotypes.	Rat hippocampal neurons, *in vitro*	Pravettoni *et al.* (2000)
Potassium	XSha2 (Kv1.2)	RNAase protection assays demonstrated that Kv1.2 expression is neural-specific. Further, Kv1.2 transcripts were first detected at the time of neural induction.	*Xenopus* spinal neurons *in vivo* and *in vitro*	Ribera (1990)

Potassium	XSha1	mRNA detection in neural crest derivatives and in both CNS and PNS glia.	*Xenopus* embryo, 1–3 days	Ribera and Nguyen (1993)
Sodium	Navβ3	*In situ* hyridization studies revealed developmentally regulated expression of Navβ3.	Rat CNS, E10–P14 and adult	Shah *et al.* (2001)
Potassium, sodium	Kv1.1, Kv1.2, Kvβ2; Pan Nav1	Immunocytochemical analyses revealed progressive clustering of Kv subunits in axonal juxtaparanodes during developmental myelination. Nav1 subunits were in nodes of Ranvier.	Rat sciatic nerve, P3–21	Vabnick *et al.* (1996)
Calcium	P/Q, N, and R	Immunocytochemical analyses revealed cell-specific patterns of expression for calcium channel isotypes A, B, C, D, and E.	Adult rat spinal motor neurons, interneurons, and nerve terminals	Westenbroek *et al.* (1998)

RT-PCR, reverse transcriptase polymerase chain reaction; CNS, central nervous system; PNS, peripheral nervous system.

Table 2 Development and activity regulate VGIC properties

VGIC type	*VGIC molecular identity*	*Regulation*	*Neuron type*	*References*
Sodium	Nav1.3	Expression of Nav1.3 was linked to acquisition of electrical excitability.	Murine preplate and Cajal–Retzius cells (E12–13)	Albrieux *et al.* (2004)
Sodium	Persistent current	Persistent current density was upregulated during development.	Rat sensorimotor cortex, P2–21	Alzheimer *et al.* (1993)
Calcium, sodium, and potassium	ND	Potassium and sodium currents were detected at early stages. Calcium currents developed later. All were subsequently upregulated.	Quail embryonic mesencephalic neural crest cells *in vitro*	Bader *et al.* (1983)
Calcium, sodium, and potassium	ND	At the time of neurite appearance, functional Na^+, Ca^{2+}, and voltage-gated K^+ channels were present. However, I_{Kv} amplitude increased during neural development. Changes in kinetic parameters were observed. I_{Na} and I_{Ca} amplitudes were also increasing to a lesser extent during differentiation.	Amblystoma spinal neurons	Barish (1986)
Hyperpolarization-activated	HCN1, HCN2, HCN4	Febrile seizures differentially altered expression patterns of several HCN channel genes and proteins.	Rat hippocampus, E10–11	Brewster *et al.* (2002)
Potassium	Large-conductance K channels	Electrical recordings demonstrated developmental changes in calcium and voltage sensitivities.	Rat embryonic rat telencephalon cortical slices, E12–14 and E21	Bulan *et al.* (1994)
Potassium	A-type	Spontaneous electrical activity, but not target tissues, regulated the normal developmental increase in potassium current density.	Chick lumbar motoneurons, E6 and E11	Casavant *et al.* (2004)
Potassium	Large-conductance Ca-activated K channels	The developmental expression of functional K_{Ca} channels was regulated differentially in choroids versus ciliary cells.	Chick choroid and ciliary ganglion neurons, E9–13	Cameron and Dryer (2000)
Whole-cell conductance	ND	Development and hypergravity altered electrophysiological properties of hair cells.	Rat utricular hair cells, P0–8	Chabbert *et al.* (2003)

Table 2 (Continued)

VGIC type	*VGIC molecular identity*	*Regulation*	*Neuron type*	*References*
Calcium	LVA and HVA calcium channels	Large modifications in the expression of voltage-dependent calcium channels occurred during a developmental period associated with neuronal growth and the beginning of synaptogenesis.	Mouse vestibular ganglia, E14–17	Chambard *et al.* (1999)
Calcium and potassium	Calcium-dependent K current; inward rectifier; voltage-gated K current; Ca current	Spontaneous activity regulated functional expression of calcium-dependent K current. The effects were calcium-dependent and required *de novo* transcription.	Ascidian embryonic muscle	Dallman *et al.* (1998)
Potassium	Delayed rectifier	Calcium influx through voltage-dependent channels during early developmental stages regulated the differentiation of potassium current kinetics and modulated the ionic dependence of APs via a PKC-dependent pathway.	*Xenopus* embryonic spinal neurons *in vitro*	Desarmenien and Spitzer (1991)
Calcium	Calcium channel isotypes A, B, and E	Expression of Ca channel transcripts were developmentally regulated *in vitro* and modulated differentially by transmembrane signaling via chronic depolarization and calcium entry.	Rat embryonic cerebellar cortical neurons *in vitro*	Falk *et al.* (1999)
Calcium	LVA and HVA	Patterns of activity differentially regulated densities of LVA and HVA calcium currents.	Mouse dorsal root ganglion neurons *in vitro*	Li *et al.* (1996)
Calcium and potassium	Calcium-activated potassium current	A calcium-activated potassium current was not present in the cochlea of the chick embryo, although it is present at adult stages.	Chick cochlea, E14	Fuchs and Sokolowski (1990)
Several VGICs	Sodium, potassium, calcium, calcium-dependent potassium current	Developmental changes in APs waveforms and the onset of repetitive firing correlate with increase in the current density of existing VGICs.	Rat spinal motor neurons, E15–16 and P1–3	Gao and Ziskind-Conhaim (1998)
Potassium	Kv1 subfamily	Activity regulated the expression of some, but not all, Kv1 channel genes.	Mouse hippocampus *in vivo* and *in vitro*, E17, P2–6 and adult	Grosse *et al.* (2000)
Potassium	Delayed rectifier (single channels)	Single-channel recordings revealed three different potassium single-channel types. One type showed developmental changes in kinetic properties.	*Xenopus* spinal neurons *in vitro*	Harris *et al.* (1988)
Sodium	ND	Developmental changes in sodium current densities but not kinetic properties were observed.	Rat sensorimotor cortical neurons, E16–P50	Huguenard *et al.* (1988)
Potassium	BK (large-conductance) calcium-activated potassium (single-channel analysis)	Single channel analysis of large conductance calcium-activated potassium channels in neocortical pyramidal neurons indicated the presence of both fast- and slow-gating channels between P0 and P5. However, at later stages, only slow-gating channel was detected.	Neocortical pyramidal neurons, P1–28	Kang *et al.* (1996)
Sodium	Nav1.3, 1.8, and 1.9	Changes in neuronal activity altered the expression of sodium channel genes in a subtype-specific manner, via an NGF-independent mechanism.	Mice dorsal root ganglion neurons, E13.5 *in vitro*	Klein *et al.* (2003)

Table 2 (Continued)

VGIC type	*VGIC molecular identity*	*Regulation*	*Neuron type*	*References*
Potassium	ND	Developmental upregulation of potassium current occurred during acquisition of hearing.	Mouse hair cells	Kros *et al.* (1998)
Potassium	Kv1.5, Kv1.4, and Kv2.1	Membrane depolarization specifically inhibited Kv1.5 channel gene transcription.	Rat pituitary cell line	Levitan *et al.* (1995)
Potassium	Kv3.1	Elevated potassium induced increased Kv3.1 mRNA levels. The effect of the block was prevented by the addition of calcium channel blockers.	Rat inferior colliculus neurons, P3–30	Liu and Kaczmarek (1998)
Potassium	Kv1.1, Kv3.1	Perturbations of activity in the auditory system regulated the levels of Kv1.1 and K3.1 channel proteins in the nucleus magnocellularis. However, alterations in channel proteins did not linearly predict changes in current densities.	Chick auditory system neurons, P1–2 (electrophysiology) and P5–10 (immunocytochemistry)	Lu *et al.* (2004)
Sodium, calcium, and potassium	Sodium, calcium, and potassium	Developmental changes in voltage-gated currents led to the class 3 pattern of AP development. Initially, hair cells fired APs. However, at late stages, hair cells responded to stimulation with graded potentials.	Mouse cochlear inner hair cells, E14.5–P12	Marcotti and Kros (1999); Marcotti *et al.* (2003)
Potassium	Ca(v)1.3 and SK2	The appearance of the SK current coincided with their becoming responsive to acetylcholine. The transiently expressed SK channel was activated by Ca^{2+} influx through both $Ca_v1.3$ channels and nicotinic receptors.	Mouse inner and outer hair cells, E14.5–P18	Marcotti *et al.* (2004)
Potassium	ND	During early stages of neuronal differentiation, potentiometric dye studies revealed developmentally regulated changes in RMP.	Rat cortical cells, E11–22	Maric *et al.* (1998)
Potassium	Large-conductance Ca-activated K (BK); delayed rectifier; inactivating A-type	Two BK channel variants were described. One variant was preferentially expressed during embryonic development. In addition, there were quantitative changes in I_K expression, that underlied the overall increase in excitability of differentiating cells.	Embryonic rat telencephalic neuroepithelium, E12–21	Mienville and Barker (1996, 1997)
Potassium	rSlo and Kv3.1 transcripts; single-channel analysis	Molecular analyses revealed developmental upregulation of rSlo transcripts but uniform expression of Kv3.1. Upregulation required depolarization and calcium and occurred at the transcriptional level.	Rat cerebellum, E20 *in vitro* and P2–21 *in vivo*	Muller *et al.* (1998)
Calcium	ND	The density of HVA calcium current increases after cell death, during the period of synapse elimination.	Chick motor neurons	Mynlieff and Beam (1992)

Table 2 (Continued)

VGIC type	*VGIC molecular identity*	*Regulation*	*Neuron type*	*References*
Sodium and potassium	ND	Development of excitability in presynaptic motor neurons required synaptic activation of the postsynaptic muscle cells. The data suggested that muscle released a retrograde factor, perhaps NT-3.	*Xenopus* embryo spinal motor neurons *in vitro*	Nick and Ribera (2000)
Sodium, calcium, and potassium		During development, no changes in peak density or kinetics of I_{Ca} were noted. I_{Na} showed a twofold increase in its density with subtle changes in kinetics. In contrast, I_{Kv} increased threefold in density and displayed changes in kinetic properties.	*Xenopus* spinal neurons *in vitro*	O'Dowd *et al.* (1988)
Sodium	ND	During this early developmental period, most outer hair cells expressed sodium current, in contrast to the situation in the adult.	Rat outer hair cells, P0–11	Oliver *et al.* (1997)
Sodium and potassium	ND	During late embryonic and early postnatal periods, I_{Na} density was upregulated in cortical plate neurons. I_K density showed subtle changes. The AP acquired a larger amplitude, shorter duration, and more negative value of threshold.	Mouse cerebral cortex – intermediate zone and cortical plate, E14–P17	Picken-Bahrey and Moody (2003)
Sodium and potassium	Nav1.1 and Nav1.6	Sodium current was developmentally upregulated. Morpholino antisense knockdown indicated that Nav1.1 and channels were more prevalent at early and late stages, respec-tively. Action potentials acquired larger overshoots and briefer dura-tions as both sodium and potassium currents increased in density.	Zebra fish Rohon–Beard neurons, 16–48 h postfertilization	Ribera and Nüsslein-Volhard (1998); Pineda *et al.* (2005)
Potassium	Delayed rectifier and A-type currents	A critical period for the maturation of the delayed rectifier current required mRNA synthesis during a 9 h critical period. After transcriptional blockade, A-current development recovered but delayed rectified current did not.	*Xenopus* spinal neurons, *in vitro*	Ribera and Spitzer (1989)
Potassium	A-current	Maturation of A-current extended to times later than that for other voltage-dependent currents.	*Xenopus* spinal neurons, *in vitro*	Ribera and Spitzer (1990)
Potassium	ND	Extensive upregulation of I_K current density occurred with changes in activation kinetics.	*Xenopus* embryonic myocytes, *in vitro*	Ribera and Spitzer (1991)
Sodium	ND	Changes in sodium channel mRNA and protein levels were followed, beginning during embryonic development. Although there were dramatic increases in sodium channel mRNA levels postnatally, the increase did not fully account for protein levels, suggesting other levels of regulation (translational or post-translational). Increased gene transcription and channel mRNA. Kinetic analysis suggests a requirement for a developmentally regulated translational or post-translational step in brain sodium channel expression.	Rat forebrain, E16–adult	Scheinman *et al.* (1989)

Sodium	ND	During development, I_{Na} increased in density and displayed kinetic changes. These developmental changes were largely restricted to the period of axon ingrowth (E30–38).	Cat retinal ganglion cells, E30–E55	Skaliora *et al.* (1993)
Calcium	LVA and HVA	The density of LVA Ca^{2+} currents decreased during early stages of postnatal development, while the density of HVA increased.	Rat visual cortical neurons, P2–12	Tarasenko *et al.* (1998)

HVA, high-voltage-activated; LVA, low-voltage-activated; ND, not determined; E, embryonic; P, postnatal.

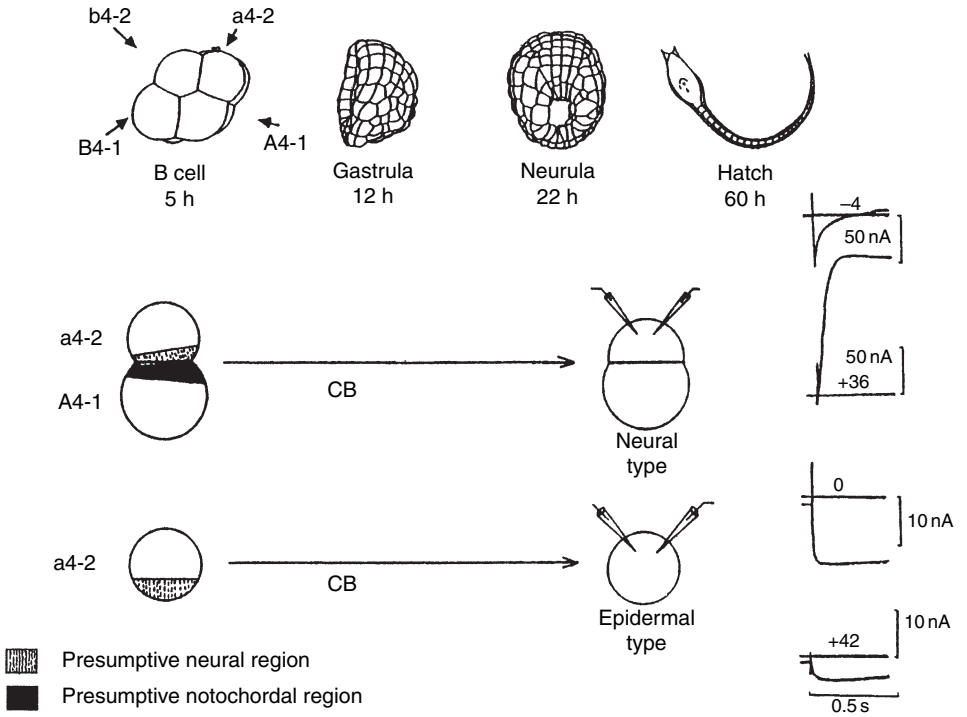

Figure 7 Neural induction activates VGIC gene transcription. Cell–cell interactions between appropriate blastomeres of the tunicate *H. auratum* induce expression of voltage-gated sodium current. When anterior animal blastomeres (a4-2) are cultured with anterior vegetal blastomeres (A4-1) as a two-cell system, the a4-2 blastomere develops normally and expresses sodium channels and tetraethylammonium (TEA)-sensitive delay-rectifier potassium channels. In contrast, when a4-2 blastomeres are cultured in isolation, each cell autonomously develops long-duration calcium-dependent APs. Reproduced from Takahashi, K. and Okamura, Y. 1998. Ion channels and early development of neural cells. *Physiol. Rev.* 78, 307–337, used with permission from The American Physiological Society.

studies are providing insights into how these stimuli are transduced into signals that regulate VGIC gene transcription (Mori *et al.*, 1993; Dolmetsch *et al.*, 2001; Tao *et al.*, 2002; Chen *et al.*, 2003). Less is known about the promoter regions that control VGIC transcription.

A series of interesting studies using cleavage-arrested blastomeres of the tunicate *Halocynthia roretzi* indicated that neural induction leads to the appearance of voltage-gated sodium current in the cell that adopts a neural fate (Takahashi and Yoshii, 1981; Takahashi and Okamura, 1998; for review, see Okamura *et al.*, 1993; Figure 7). More recent studies have characterized the effects at a molecular level and demonstrated that neural induction leads to the expression of a specific voltage-gated sodium channel isotype, TuNa1 (Okamura *et al.*, 1997). Transcription of TuNa1 is activated during neural induction by interactions between specific blastomeres of the animal and vegetal poles during a critical period of time (Okado and Takahashi, 1988, 1990a, 1990b; Okamura *et al.*, 1994).

Inappropriate cell contacts lead to differentiation of alternate cell types and the expression of different ion channels (Okado and Takahashi, 1990b). Similarly, a specific potassium channel transcript begins expression at the time of neural induction in embryonic spinal neurons of the frog *Xenopus laevis* (Ribera, 1990).

While it is clear that cell–cell interactions during development can activate transcription of specific ion channel genes, the underlying mechanisms are poorly understood. Moreover, depending upon its identity, a neuron will express a specific repertoire of ion channels. It is possible to accelerate the expression of one type of channel by premature expression of another (Linsdell and Moody, 1994). Future work needs to address how transcription of the subset of ion channel genes expressed in any individual neuron is coordinated. For example, co-regulation of transient potassium and hyperpolarization-activated inward currents has been observed in lobster stomatogastric ganglion neurons (Maclean *et al.*, 2003).

In comparison to the vast number of ion channel genes that have been identified by molecular cloning, little is known about their DNA regulatory elements or the transcription factors that regulate transcription. The best-studied transcription factor for an ion channel gene is REST, or repressor element silencing transcription factor (also known as neuron-restrictive silencing factor or NRSF, Kraner *et al.*, 1992; Mori *et al.*, 1992; Schoenherr and Anderson, 1995a, 1995b). REST specifically controls expression of the voltage-gated sodium channel α-subunit Nav1.2 (Chong *et al.*, 1995; Schade and Brown, 2000; Dallman *et al.*, 2004). REST binds to RE-1, a DNA element found in the regulatory region of many neuronal vertebrate genes (Kraner *et al.*, 1992; Schoenherr and Anderson, 1995b). Most non-neuronal tissues express REST. Overexpression of REST recombinant protein in neuronal cells prevents Nav1.2 expression (Huang *et al.*, 1999; Nadeau and Lester, 2002). Conversely, expression of a dominant negative REST in non-neuronal cells results in Nav1.2 transcription (Chong *et al.*, 1995). Thus, REST functions in a negative pathway and suppresses expression of Nav1.2 in non-neuronal cells.

Future work also needs to address what role transcriptional mechanisms play in the developmental upregulation of ion channels. For example, *Xenopus* spinal neurons display a threefold increase in potassium current density that underlies the developmental shortening of the AP duration (O'Dowd *et al.*, 1988; Lockery and Spitzer, 1992). A critical period of RNA synthesis is required for maturation of I_{Kv} (Ribera and Spitzer, 1989; Figure 8). Transient inhibition of RNA synthesis during a 9 h period prevents the normal threefold increase in density of I_{Kv}, even when a 48 h recovery period is allowed. Conversely, increasing the levels of potassium channel RNAs (e.g., Kv1.1 or Kv2.2) leads to premature maturation of I_{Kv} (Jones and Ribera, 1994; Blaine *et al.*, 2004). These findings are consistent with the notion that the critical RNA synthesized during the 9 h period codes for a potassium channel subunit.

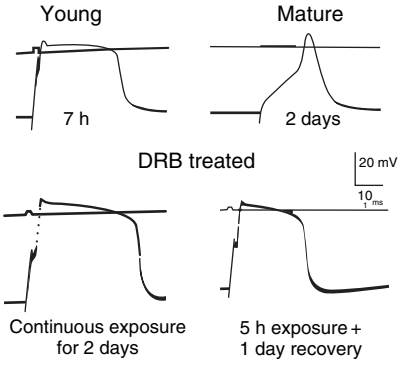

Figure 8 AP development requires a critical period of transcription. Blockade of transcription with an inhibitor of the RNA synthesis (DRB, 5,6-dichlorobenzimidazole 1-β-D-ribofuranoside) during a critical period of development prevents maturation of the AP and a voltage-gated potassium current. Reproduced from Ribera, A. B. and Spitzer, N. C. 1989. A critical period of transcription required for differentiation of the action potential of spinal neurons. *Neuron* 2, 1055–1062, with permission from Elsevier.

1.13.8.2 Post-Transcriptional

Post-transcriptional mechanisms, such as alternative splicing, editing, mRNA stability, and localization, influence ion channel function. Neural activity can activate post-transcriptional effects, as is the case for stabilization of transcripts coding for specific calcium channel isoforms (Schorge *et al.*, 1999). Moreover, recent studies indicate that post-transcriptional control of ion channel function occurs throughout development of the nervous system.

1.13.8.2.1 Alternative splicing Alternative splicing influences translational efficiency as well as protein stability, transport, and localization (Black, 2003; Stamm *et al.*, 2005). Alternative exon usage constitutes a major mechanism to increase functional diversity of VGICs. Almost all aspects of VGIC function can be affected by alternative splicing: channel activation and inactivation, gating, kinetic properties, and sensitivity to blockers and

modulators (Iverson *et al.*, 1997; Chemin *et al.*, 2001; Decher *et al.*, 2001; Tian *et al.*, 2001a, 2001b). The effects range from subtle ones to complete loss of function.

Alternative exon usage can change dynamically in response to diverse stimuli, including growth factors, pH, and neural activity. Of particular interest, development influences alternative exon usage (Kaufer *et al.*, 1998; Oh and Waxman, 1998; Stamm *et al.*, 2005). For example, multiple sites for alternative splicing usage have been identified in voltage-gated potassium and sodium channels. In *Drosophila*, the major class of sodium channel is encoded by a single gene known as *para*. Alternative splicing of *para* generates several different channel isoforms. The isoforms display temporally and spatially distinct expression patterns (Thackeray and Ganetzky, 1994; Lee *et al.*, 2002). Alternative splicing also regulates sodium channels in the cockroach and results in mRNA variants coding for proteins with different activation, inactivation, and gating characteristics (Song *et al.*, 2004). Further, several of the isoforms display tissue-specific distribution and developmental specificity. Similar results have been obtained by the study of *Drosophila* genes coding for voltage-gated (i.e., *Shaker*) or calcium-dependent (i.e., *Slo*) potassium channels (Atkinson *et al.*, 1991; Adelman *et al.*, 1992; Butler *et al.*, 1993).

Ion channel gene families that are represented by a single gene in invertebrates often have undergone duplications during evolution and exist as multigene families in vertebrates (i.e., *Shaker* gene vs. Kv1 gene family; *para* gene vs. Nav1 gene family). Despite the increased functional diversity created by gene duplication, alternative splicing still operates to create molecularly diverse channel transcripts. For example, the mammalian sodium channel α-subunit genes, Nav1.1, Nav1.2, Nav1.3, Nav1.6, and Nav1.9, are alternatively spliced (Sarao *et al.*, 1991; Gustafson *et al.*, 1993; Plummer *et al.*, 1997; Lu and Brown, 1998; Jeong *et al.*, 2000). Moreover, expression of specific splice variants is developmentally regulated. In *Xenopus*, alternative spicing of the *slo* (xSlo) gene generates variants that differ in their tissue and developmental expression patterns (Kukuljan *et al.*, 2003; Figure 9). Additionally, the variants code for channels that differ with respect to both voltage and calcium sensitivities.

Nav1.1, Nav1.2, and Nav1.6 genes display developmentally regulated patterns of alternative splicing (Sarao *et al.*, 1991; Plummer *et al.*, 1997; Alessandri-Haber *et al.*, 2002). Interestingly, the coding regions of neonatal variants of Nav1.2 and Nav1.6 genes predict truncated proteins. Whether or not the predicted truncated proteins are expressed and what their potential roles are remain unknown. However, the existence of these splice variants that are developmentally regulated raises the interesting possibility of negative-feedback mechanisms implemented by alternative splicing. Developmentally regulated variants of calcium channels that code for truncated ion channel proteins have also been observed (Okagaki *et al.*, 2001; Figure 10).

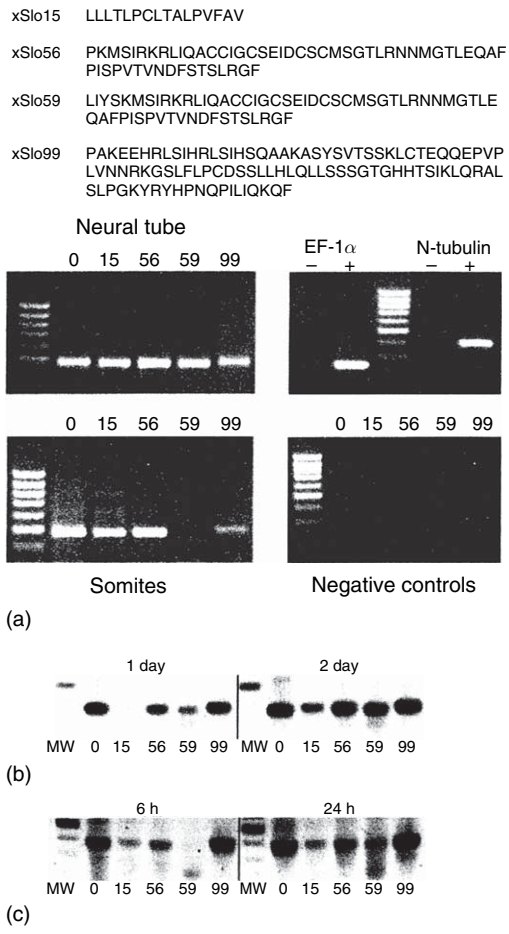

Figure 9 Development regulation of splicing of xSlo transcripts. The xSlo gene of *X. laevis* displays both tissue-specific and developmentally regulated splice variants. a, Four alternative splice variants – xSlo15, xSlo56, xSlo59, and xSlo99 – were detected by reverse transcriptase polymerase chain reaction (RT-PCR) analysis of RNA isolated from 2-day-old *Xenopus* embryos. Three of the alternatively spliced variants were expressed in both embryonic spinal cord and somites. One variant, xSLO59, was only detected in spinal cord. Constitutively expressed EF-1α and N-tubulin served as positive controls. Examination of 1- or 2-day-old embryo RNA indicated that the xSLO59 variant was developmentally upregulated (b) *in vivo* and (c) *in vitro*. Reproduced from Kukuljan, M., Taylor, A., Chouinard, H., Olguin, P., Rojas, C. V., and Ribera, A. B. 2003. Selective regulation of xSlo splice variants during *Xenopus* embryogenesis. *J. Neurophysiol.* 90, 3352–3360, used with permission from The American Physiological Society.

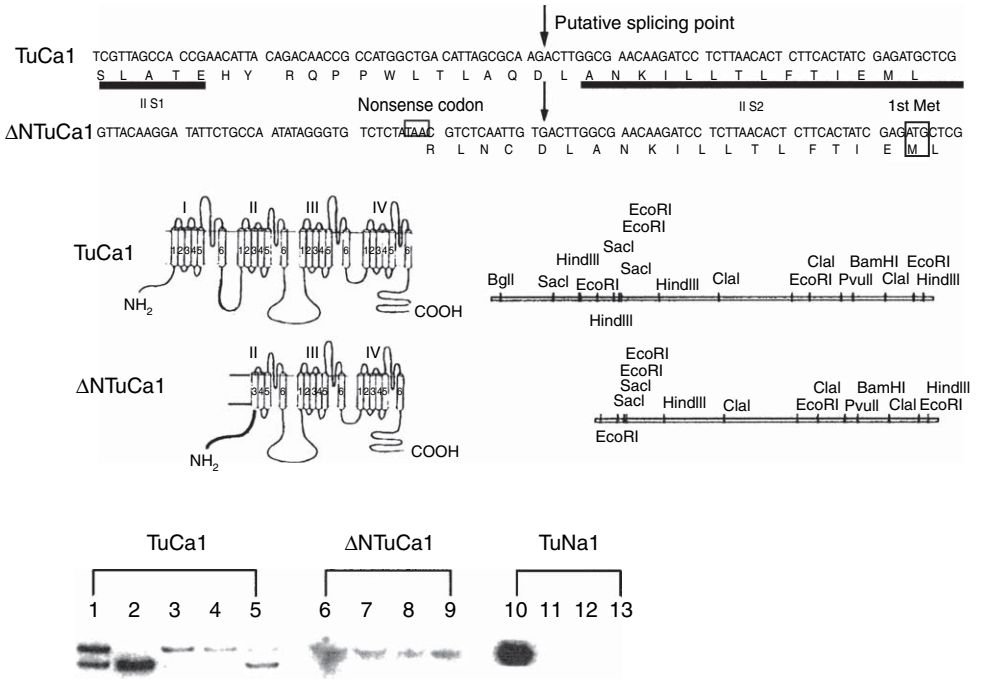

Figure 10 Alternative splicing generates transcripts for a voltage-gated calcium channel that code for truncated proteins. RT-PCR analyses indicate that the tunicate calcium channel gene expresses splice variants. One variant, TuCa1, codes for a full-length calcium channel α-subunit. In contrast, the other variant, ΔTuCa1, codes for a truncated subunit that lacks a substantial portion of the N-terminal region. Okagaki *et al.* (2001) demonstrate that the truncated subunit acts in a dominant-negative manner and inhibits function of the full-length protein. Lane 1 is a positive control with whole-tadpole RNA. RT-PCR analyses for a sodium channel gene TuNa1 are shown for comparison. Lanes 2, 6, and 10 present analyses done using neuronal RNA. Lanes 3, 7, and 11 present analyses done using RNA from epidermal (non-neuronal) cells. Lanes 4, 8, and 12 present analyses done using RNA from cells giving rise to motor neurons. Lanes 5, 9, and 11 present analyses done using muscle cell RNA. Reproduced from Okagaki, R., Izumi, H., Okada, T., Nagahora, H., Nakajo, K., and Okamura, Y. 2001. The maternal transcript for truncated voltage-dependent Ca^{2+} channels in the ascidian embryo: A potential suppressive role in Ca^{2+} channel expression. *Dev. Biol.* 230, 258–277, with permission from Elsevier.

1.13.8.2.2 Editing RNA editing leads to specific alterations in single nucleotides of mRNA transcripts (for review, see Simpson and Emerson, 1996). Selective mRNA editing of VGIC transcripts during development has been observed for sodium channels in invertebrates (Hanrahan *et al.*, 2000; Song *et al.*, 2004). The *Drosophila para* gene, in addition to being alternatively spliced, shows developmentally regulated patterns of RNA editing (Hanrahan *et al.*, 2000). In the German cockroach, editing of the sodium gene BgNav transcripts occurs in a developmentally specific manner (Song *et al.*, 2004). Furthermore, editing resulted in transcripts that coded for proteins that varied significantly in voltage-dependent activation and inactivation properties.

1.13.8.3 Translational/Post-Translational

Ion channels display many different types of post-translational modifications that are linked to specific functional consequences. Here, we summarize examples of developmentally regulated post-translational modifications. For many cases, however, the potential physiological roles of post-translational modifications during development are poorly understood (but see Misonou *et al.*, 2004). Post-translation mechanisms might be involved in setting current density levels in mature neurons (Blaine *et al.*, 2004; Figure 11).

1.13.8.3.1 Surface membrane insertion One of the best-studied examples of post-translational control of excitability concerns regulation of large-conductance calcium-activated potassium (K_{Ca}) channels of chick ciliary ganglion neurons (for review, see Dryer, 1998; Dryer *et al.*, 2003). Normal developmental upregulation of K_{Ca} channels requires interactions with both targets (iris) and inputs (afferent innervation provided by the Edinger–Westphal nucleus).

Transforming growth factor-β1 (TGF-β1) and β-neuregulin-1 mediate the effects of cell–cell interactions with targets and inputs, respectively, on K_{Ca} channels both *in vitro* and *in vivo* (Subramony *et al.*, 1996; Cameron *et al.*, 1998, 2001).

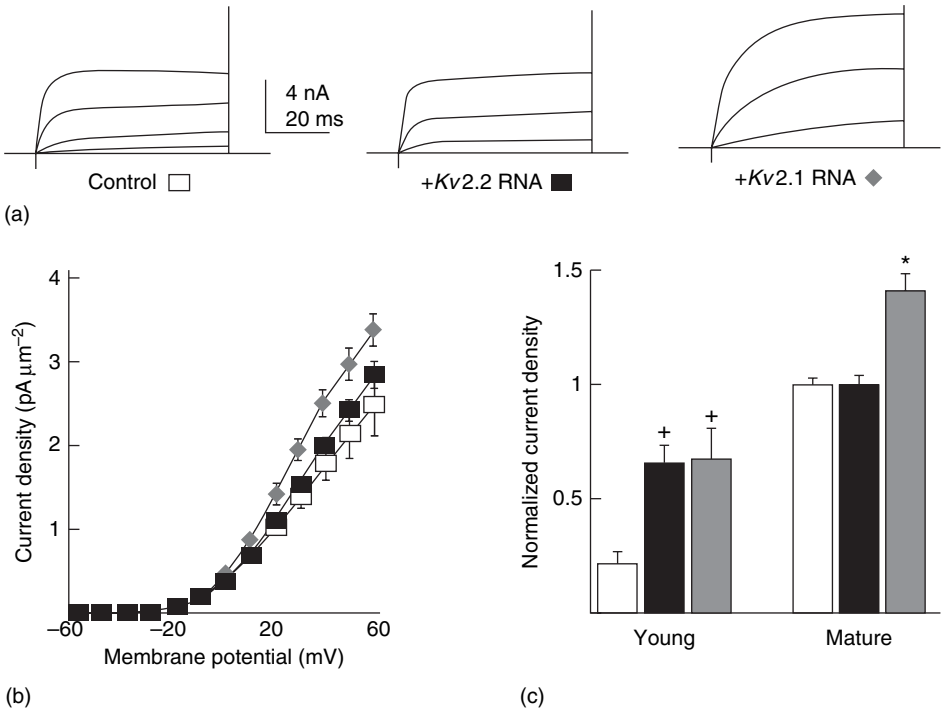

Figure 11 Post-translational control of potassium current density. a, Potassium current density of mature neurons can be increased by excess Kv2.1 mRNA but not by excess RNA from another Kv2 isoform, Kv2.2. b, The mean I_{Kv} densities of +Kv2.1 but not +Kv2.2 neurons were significantly larger than those of control neurons. c, Overexpression of Kv2.2 RNA increased current density in young but not in mature neurons. In contrast, overexpression of Kv2.1 RNA increased current density in both young and mature neurons. Blaine *et al.* (2004) demonstrated that regulation of potassium channel density induced by excess Kv2.2 RNA required a proximal region of the carboxyl terminal, known as *proxC*. These studies indicate that post-translational mechanisms can regulate VGIC current density in neurons. Reproduced from Blaine, J. T., Taylor, A. D., and Ribera, A. B. 2004. Carboxyl tail region of the Kv2.2 subunit mediates novel developmental regulation of channel density. *J. Neurophysiol.* 92, 3446–3454, used with permission from The American Physiological Society.

Importantly, the effects of TGF-β1 and β-neuregulin-1 persist in the presence of protein synthesis inhibitors (Subramony *et al.*, 1996). These studies indicate that new protein synthesis is not required for the developmental upregulation of K_{Ca} channel expression mediated by TGF-β1 and β-neuregulin-1 in chick ciliary neurons. Interestingly, the effects of extrinsic factors on developmental regulation of current in chick lumbar motor neurons do require new protein synthesis (Martin-Caraballo and Dryer, 2002a, 2002b).

More recent studies suggest that the effects of TGF-β1 on ciliary ganglion neurons lead to surface membrane insertion of presynthesized K_{Ca} channels (Lhuillier and Dryer, 2002). This finding is especially significant because large intracellular pools of several different types of VGICs have been observed. Thus, for several different types of ion channels, post-translational control of surface membrane insertion would be an effective and possible way to regulate functional expression of current (for review, see Misonou and Trimmer, 2004).

Conversely, post-translational regulation of ion channels in the surface membrane could result in their removal. For example, activation of sodium channels and sodium influx leads to removal of these channels from the surface membrane (Dargent and Couraud, 1990; Dargent *et al.*, 1994). This type of regulation might function after circuit formation as a homeostatic mechanism to keep channel densities and electrical activity in an optimal range (for review, see Turrigiano and Nelson, 2004).

1.13.8.3.2 Glycosylation In the adult nervous system, glycosylation promotes proper protein folding, function, stability, intracellular sorting, and membrane targeting (Bar-Sagi and Prives, 1983; West, 1986; Marban *et al.*, 1998; Tyrrell *et al.*, 2001). For some plasma membrane sodium channels, removal of glycosylation leads to changes in the voltage dependence of gating (Recio-Pinto *et al.*, 1990; Bennett *et al.*, 1997; Zhang *et al.*, 2003). Notably, depolarizing shifts in the steady-state activation and inactivation curves are produced (Recio-Pinto *et al.*,

1990; Bennett *et al.*, 1997; Zhang *et al.*, 2003). Of particular interest is the finding that the glycosylation levels of voltage-gated sodium channels are developmentally regulated and linked to modulation of voltage-dependent properties (Tyrrell *et al.*, 2001). Further, glycosylation of sodium channels has been linked to developmentally regulated changes in single-channel conductance and steady-state activation (Castillo *et al.*, 1997, 2003). In comparison to sodium channels, much less is known about developmental regulation of glycosylation for other VGICs.

1.13.8.3.3 Phosphorylation Protein phosphorylation and dephosphorylation underlie modulation of the activity of ion channels and modulate neuronal excitability (for review, see Levitan, 1999). VGIC α-subunits are common substrates for phosphorylation mediated by the major protein kinases, including cyclic adenosine monophosphate-dependent kinase (PKA), protein kinase C (PKC), calcium calmodulin kinase II (CAM kinase II), and tyrosine kinase. Moreover, electrophysiological studies indicate that key properties of VGIC can be modified by phosphorylation, at least in the mature nervous system (Brum *et al.*, 1983; Flockerzi *et al.*, 1983; Emerick and Agnew, 1989; Perozo and Bezanilla, 1990, 1991; Armstrong *et al.*, 1991; Hoger *et al.*, 1991; Murphy and Catterall, 1992; Covarrubias *et al.*, 1994; Cohen, 1996; Cohen *et al.*, 1996; Roeper *et al.*, 1997; Beck *et al.*, 1998). Comparatively little is known about the role of phosphorylation in developmental regulation of ion channel function. However, expression of kinases, such as CAM kinase II, is developmentally regulated (Hanson and Schulman, 1992; Menegon *et al.*, 2002). Further, this kinase participates in developmental regulation of synapse formation (Zou and Cline, 1996; Wu and Cline, 1998). These findings motivate further study of the potential role of phosphorylation in the developmental regulation of VGIC function.

1.13.8.3.4 Auxiliary subunits Auxiliary (also known as accessory) subunits form complexes with the pore-forming subunits of VGICs. Pore-forming subunits are typically designated as α whereas auxiliary ones are referred to by another Greek letter, such as β. Auxiliary subunits influence the kinetic properties and the voltage dependence of VGIC activation and inactivation (Isom *et al.*, 1992; Patton *et al.*, 1994; Rettig *et al.*, 1994; Morales *et al.*, 1995; Heinemann *et al.*, 1996) without major effects on ion conductance (for review, see Trimmer, 1998; Hanlon and Wallace, 2002). Further, auxiliary subunits have effects on the assembly and expression of VGICs (Patton *et al.*, 1994; Isom *et al.*, 1995a, 1995b; Qu *et al.*, 1995; Shi *et al.*, 1996; for review, see Isom *et al.*, 1994; Striessnig, 1999; Goldin, 2001). Because many of these properties are developmentally regulated, the role of auxiliary subunits during differentiation of excitability is of interest.

Spatial and developmental regulation of VGIC auxiliary subunit expression has been observed in several types of excitable tissue, including brain, muscle, and heart (Butler *et al.*, 1998; Downen *et al.*, 1999; Lazaroff *et al.*, 1999; Franco *et al.*, 2001; Falk *et al.*, 2003; Grande *et al.*, 2003). Very little evidence exists linking auxiliary subunits to developmental regulation of excitability (but see Falk *et al.*, 2003).

1.13.9 Future Studies

Electrophysiological analyses have indicated three general patterns of development of excitability in neurons. Each pattern is associated with specifc programs of development for underlying voltage-gated currents. Because ion channel genes have been and are being cloned, analyses of mechanisms can be approached at the molecular level. Regulation of excitability is complex and involves control of multiple VGIC genes at multiple levels.

Important issues for future research will be to identify transcription factors and DNA regulatory regions involved in the development control of VGIC gene transcription. It is likely that many VGIC genes will be coordinately controlled. At the other end of the spectrum, recent research suggests that an important post-translational mechanism for control of VGIC density involves regulation of plasma membrane insertion. This mechanism is not unique to VGICs as it is also crucial for regulation of postsynaptic function following periods of activity (for review, see Malinow, 2003).

1.14 Genetic Analysis of Neural and Non-Neural Co-Evolution

T F Schilling, University of California, Irvine, CA, USA

Glossary

agnathan Jawless vertebrates (also cyclostomes); living agnathans are lampreys and hagfish.

amphioxus Common name for the cephalochordate Branchiostoma (also lancelets).

bilaterians Taxa encompassing both the protostomes and deuterostomes.

cell commitment Irreversible restriction in potential, such that a cell will differentiate autonomously when placed into another region of the embryo.

cephalochordates Chordate group that includes genus *Branchiostoma* (also amphioxus or lancelet).

chordates Deuterostomes with a notochord – urochordates, cephalochordates, and vertebrates.

clade A monophyletic set of taxa, all derived from a common ancestor.

competence The ability of a cell to respond to an inductive signal.

deuterostome Coelomates with two mouths – echinoderms, hemichordates, and chordates.

encephalization Expansion of the head anteriorly to form the brain, skull, and sense organs.

floorplate Specialized ventral midline cells of the vertebrate neural tube.

Gastroneuralia Bilaterians with a ventral nerve cord – annelids and arthropods.

gnathostomes Jawed vertebrates.

hemichordates Deuterostomes related to chordates – acorn worms and pterobranchs.

heterochrony Shift in relative timing of developmental processes from one generation to the next.

homeotic gene Also called *Hom* or *Hox*. Genes containing a homeobox sequence involved in DNA binding and anterior–posterior patterning in vertebrates and invertebrates.

hypophysis Pituitary, including an anterior adenohypophysis and a posterior neurohypophysis.

lateral line Sensory system of mechanoreceptors and/or electroreceptors in aquatic vertebrates.

marsupials Metatherian mammals that have pouches – opossums in North America, kangaroos.

monophyletic Group of taxa all derived from a common ancestor.

monorhiny Single midline nostril, as seen in agnathans.

neural crest Cells that arise at dorsolateral edges of the neural tube in vertebrate embryos, adjacent to surface ectoderm. They form sensory neurons, glia, pigment cells, and cranial skeleton among other things.

neural ectoderm Embryonic subdivision that forms neurons and glia of the central nervous system.

non-neural ectoderm Subdivision that forms epidermis and peripheral nervous system.

Notoneuralia	Bilaterians with a dorsal nerve cord, including chordates.
orthologue	Related gene within a gene family between one generation and the next.
outgroup	Closest sister group to a monophyletic clade of interest.
Pedomorphism	Retention of juvenile characters in the adult.
paralogue	Equivalent gene within a duplicated gene cluster in the same organism.
pharyngeal arches	Segmental series of arches in the chordate head – form the jaw and gills in vertebrates (also visceral arches, or branchial arches if referring only to gills).
placode	Focal thickening of ectoderm in the embryonic chordate head that forms special sense organs including the olfactory, lens, hypophyseal, otic, lateral line, and epibranchials.
proprioception	Sense of position of body parts derived from sensory receptors in muscle.
protostome	Coelomates with one mouth – annelids, arthropods.
rhombomeres	Segments along the anterior–posterior axis of the hindbrain (rhombencephalon).
segment	One of a series of repeating morphological units along the anterior–posterior body axis.
specification	Reversible restriction in cell potential, such that the cell will differentiate autonomously when placed into a neutral environment.
tunicate	Common name for a type of urochordate (also sea squirt).
urochordates	Chordate group that includes tunicates (also sea squirt).

1.14.1 Introduction

Formation of the nervous system begins early during embryonic development in cells of the ectoderm. Comparative embryology has revolutionized our understanding of ectodermal evolution. Both protostomes and deuterostomes have a similar basic plan for patterning along the dorsal–ventral (DV) and anterior–posterior (AP) axes, and similar mechanisms of neurogenesis (Arendt and Nubler-Jung, 1999; see Basic Nervous System Types: One or Many?). However, the nervous system has become specialized within each group of animals, such as encephalization in vertebrates, in which the head expands anteriorly to form a large brain and sense organs (see The Evolution of Encephalization). In all cases, coordinated patterning of the neural ectoderm (NE) and non-neural ectoderm (NNE) has been an important developmental constraint during evolution. In this article, I discuss the genetic basis for this constraint, and the evolution of ectodermal cell fates.

Two crucial innovations that distinguish vertebrates from their invertebrate relatives are derived from ectoderm – neural crest and epidermal placodes. These may be key to understanding vertebrate origins and the coordinated development of the brain, skull, and sense organs (Gans and Northcutt, 1983; Northcutt and Gans, 1983; Northcutt, 2005). Neural crest cells form at the dorsolateral edges of the neural tube in the embryo and migrate throughout the body to give rise to neurons and glia, pigment cells, and bones of the skull as well as many other derivatives (LeDouarin and Kalcheim, 1999). Epidermal placodes are thickenings of the surface ectoderm that also migrate in some cases to join the cranial neural crest and form neurons and glia of the peripheral nervous system (PNS). Other placodes contribute to paired sense organs, including the olfactory, lens, pituitary, otic, acoustic, and lateral line (Begbie and Graham, 2001; Bhattacharyya and Bronner-Fraser, 2004; Streit, 2004; Schlosser, 2005). The locations of both neural crest and placodes are highly conserved between species and closely tied to development of the central nervous system (CNS).

Genetic studies in vertebrates have revealed critical pathways that control patterning of the ectoderm. Broader comparative studies across chordates are also leading to new ideas about gene functions and their ancestral roles. Here I consider the roles of genes known to act across both the NE and NNE and to mediate interactions between them during embryogenesis. Gene duplications may have provided some of the raw material for major evolutionary transitions, which I illustrate using several families of transcription factors and their functions in ectoderm.

1.14.2 Defining the Issues

1.14.2.1 Ectodermal Derivatives

Classical embryology identified two major subdivisions of the ectoderm, NE and NNE, in both protostomes and deuterostomes (Figure 1a). NE forms the CNS, and NNE forms an epidermal epithelium that covers the external surface. This so-called non-neural portion of the ectoderm, however, also gives rise to most or all of the PNS. Bilateralian animals can be divided into two large groups based on the location of the NE: (1) Gastroneuralia, such as annelids and arthropods with a ventral nerve cord; and (2) Notoneuralia,

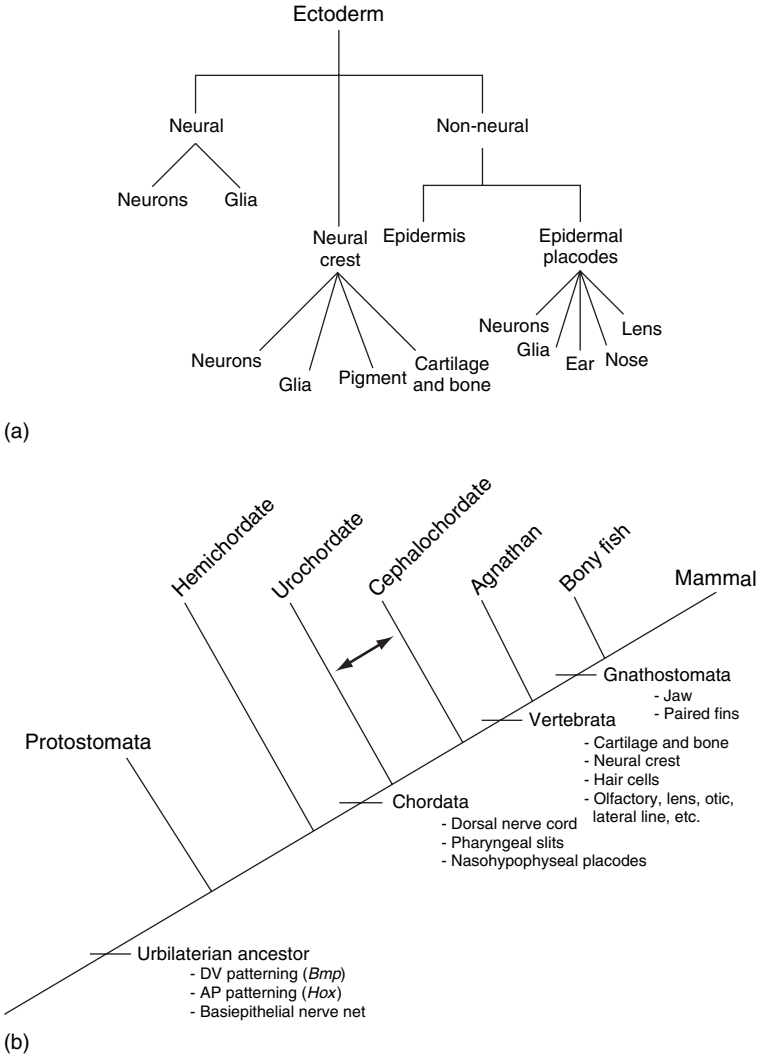

Figure 1 Ectodermal derivatives and their distribution among bilaterians. a, Some representative differentiated cell types of the ectoderm. Cell types are organized according to the ectodermal region from which they arise. b, Cladogram showing major branch points of groups that contain model developmental systems. Chordata comprises the Urochordata, one possible sister group to vertebrates, and the Cephalochordata, which is the other possible sister group. Both are characterized by the morphological features listed. Vertebrata includes the agnathans, sister group to the gnathostomes, characterized most notably by the lack of a jaw and paired appendages. Gnathostomata includes all of the jawed vertebrates.

such as chordates that have a dorsal cord (Hatschek, 1891; Nielsen, 1999). Despite this apparent inversion of the DV axis of the ectoderm, both share basic features of embryonic patterning that are under similar genetic control (Arendt and Nubler-Jung, 1999; Hirth *et al.*, 2003; see Origin and Evolution of the First Nervous System).

The NE in both groups initially consists of multipotent neural precursors that also form glial cells (Doe and Goodman, 1985; Temple and Qian, 1996). These arise in columns stretching the length of the NE and are further subdivided into distinct segments along the AP axis. In *Drosophila*, three bilateral columns of committed neural precursors flank midline glial cells that form the commissures connecting left and right sides (Figure 2e; Jimenez and Campos-Ortega, 1990; Skeath *et al.*, 1994). Similarly, the vertebrate NE thickens during gastrulation to form a neural plate in which neurons form in three longitudinal columns on either side of specialized ventral midline cells called floorplate (Figure 2f; Chitnis *et al.*, 1995; Haddon *et al.*, 1998). These also help guide commissure formation and create a hingepoint around which the neural plate rolls and fuses dorsally to form the neural tube (Schoenwolf and Alverez, 1989). In insects, the NE is more overtly segmented than in vertebrates. Neuroblasts coalesce to form large cephalic

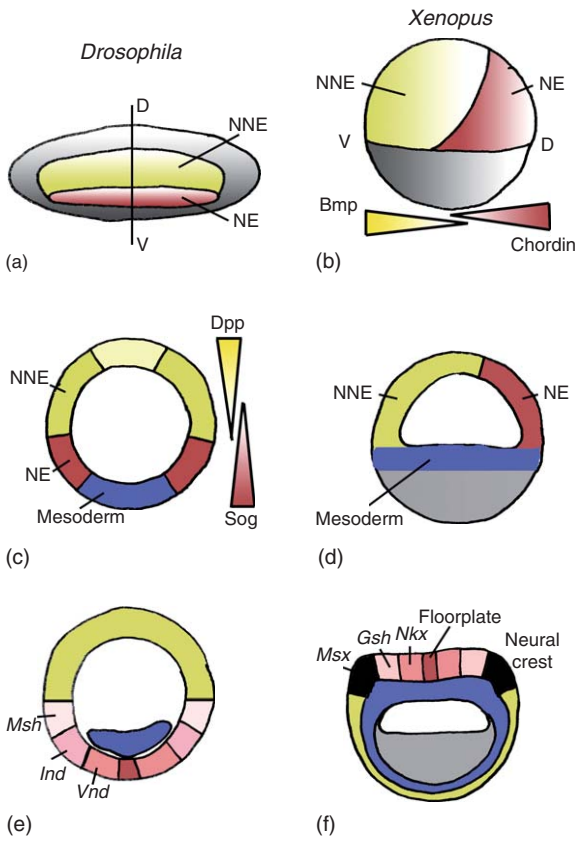

Figure 2 Conserved genetic control of DV patterning among bilaterians and specification of NE and NNE. a, Diagram illustrating a *Drosophila* embryo just prior to gastrulation in lateral view. NNE (yellow) lies dorsal to NE (red) on either side. b, *Xenopus* embryo prior to gastrulation in lateral view. NNE lies ventral to NE. Bone morphogenic proteins (bmps) are thought to form a gradient (triangle) from ventral to dorsal, which is opposed by a gradient of their inhibitor, Chordin. c, Transverse section of *Drosophila* pregastrula, showing DV organization of NNE, NE, and mesoderm and corresponding gradients of Dpp and Sog. d, Sagittal section of *Xenopus* pregastrula embryo. e and f, Transverse sections of *Drosophila* and *Xenopus* embryos after gastrulation. Domains of homeobox gene expression (Vnd, Ind, Msh) within the NE are indicated.

ganglia anteriorly and a ladder-like array of more posterior thoracic and abdominal segments. Segmentation of the vertebrate NE is most evident in the pattern of spinal motor and sensory nerves, as well as rhombomeres of the embryonic hindbrain (Figure 3; Lumsden and Keynes, 1989).

Similarities in the NNE between protostomes and deuterostomes are less clear (Figure 1a). In embryos of both groups NNE spreads to cover the body. However, vertebrate embryos also form neural crest cells at the NE/NNE boundary that are unlike any invertebrate ectodermal cell type (Horstadius, 1950; LeDouarin and Kalcheim, 1999). Neural crest cells have a broad range of possible fates, including cell types not found in invertebrates, such as cartilage and bone (Platt, 1893; Landacre, 1921; Stone, 1929). Neural crest cells also form a majority of the neurons and glia of the vertebrate PNS, unlike invertebrate sensory neurons, which develop within the epidermis (Teillet *et al.*, 1987; LeDouarin and Smith, 1988; Holland, 2005). Their origins from the dorsal neural tube and ability to form neurons suggests that neural crest cells constitute a subset of the NE, but in other respects they are more similar to NNE (Huang and Saint-Jeannet, 2004; Meulemans and Bronner-Fraser, 2004; Luo *et al.*, 2005). Thus, neural crest cells are uniquely poised to coordinate patterning between the CNS and PNS.

Epidermal placodes are also unique features of the vertebrate NNE that form near the NE/NNE boundary (Figure 1a). Placodes are thickenings within the surface ectoderm of the head that contribute to the special sense organs (Van Wijhe, 1883; Von Kupffer, 1891). Some placodes produce sensory neurons and glia within the PNS, similar to neural crest cells. Others form non-neural components of sense organs, such as surface cells of the lens, chemical-sensitive olfactory and taste receptors, motion-sensitive hair cells, and voltage-sensitive electroreceptors. Many of these sense organs connect to the CNS through sensory neurons of the PNS (cranial sensory ganglia) that are themselves descended from neural crest and placodes (Hamburger, 1961; D'Amico-Martel and Noden, 1983). Therefore, unlike invertebrates (Ghysen and Dambly Chaudiere, 1989), in vertebrates connectivity between special sense organs and their central targets in the brain are first established through interactions between NE, neural crest, and epidermal placodes during embryogenesis.

Genetic studies have identified several major steps in ectodermal development, including: (1) specification, in which cells acquire identities as NE or NNE; (2) inductive interactions, in which signals are passed between NE and NNE to coordinate patterning; and (3) circuit formation, when neurons within the CNS (derived from NE) and PNS (derived from NNE) connect to form a functional system. Each of these will be considered in the context of major transitions in ectodermal patterning and vertebrate head development.

1.14.2.2 Conserved Pathways and Evolutionary Transitions in Ectodermal Development

In some basal protostomes and deuterostomes neuronal cells are dispersed throughout the ectoderm in a basiepithelial nerve net, suggesting that this was the case for the common urbilaterian ancestor (Figure 1b). Support for this hypothesis in deuterostomes comes from the fact that echinoderms, a

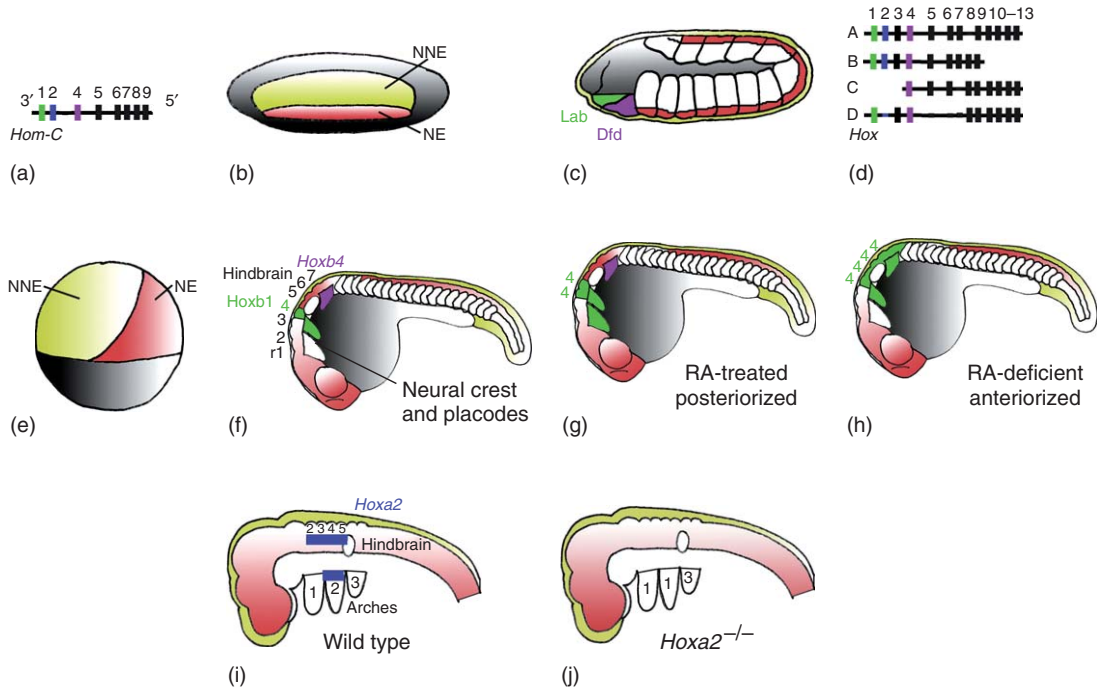

Figure 3 Conserved genetic control of AP patterning among bilaterians and coordinated patterning between NE and NNE. a, Eight genes of the single *Hom-C* cluster in *Drosophila* are numbered. b, Pregastrula fly embryo in lateral view, indicating NNE (yellow) and NE (red). c, Germ band extended-stage fly embryo in lateral view indicating body segments and expression domains of *Hox* group 1 (green) and 4 (purple) genes. d, Thirty-nine genes of the mammalian *Hox* clusters. e, Pregastrula fish/frog embryo. f, Wild-type fish embryo. *Hoxb1a* expression in rhombomere 4 and neural crest of pharyngeal arch 2. g, Fish or frog embryos soaked in RA show expansion of *Hox1* expression anteriorly, in both the NE and NNE. h, In RA-deficient fish, frogs, birds, or mice, *Hox1* expression expands posteriorly, in both the NE and NNE. i, Wild-type expression of *Hoxa2* in the anterior hindbrain (r2–5) and in the neural crest of pharyngeal arch 2. j, *Hoxa2* mutants exhibit a mirror-image duplication of arch 1 in place of arch 2.

chordate outgroup (i.e., their lineages branch at the base of the stem chordate lineage), and hemichordates have nerve nets (Brusca and Brusca, 1990; Adoutte *et al.*, 2000; Lowe *et al.*, 2003). In contrast, two basal chordates form a distinct neural plate. These are the ascidians or tunicates (Urochordata) and amphioxus (Cephalochordata), the closest living outgroups to the vertebrates (Garstang, 1894; Lacalli, 1994; Delsuc *et al.*, 2006). The ancestral chordate shared two major features of ectodermal patterning with its protostome relatives: (1) DV patterning involving transforming growth factor (TGF)-β signaling (Figure 2); and (2) AP patterning involving transcription factors related to the *Drosophila* homeotic (*Hom/Hox*) genes (Figure 3). Thus, the urbilaterian ancestor probably had both DV and AP coordinate systems in place, even if it did not develop distinct NE and NNE components.

1.14.2.2.1 Bmp signaling and DV inversion Dorsal expression of the TGF-β family member Decapentaplegic (Dpp) in *Drosophila* promotes NNE (Figures 2a and 2c). Vertebrate relatives of Dpp, the bone morphogenetic proteins (Bmps), also promote NNE but on the ventral side (Figure 2b), and this has revived the hypothesis that the DV axis is inverted in protostomes versus deuterostomes (Geoffroy-St. Hilaire, 1822; Arendt and Nubler-Jung, 1994; DeRobertis and Sasai, 1996). Ventral inhibition of Dpp in *Drosophila* is controlled by short gastrulation (Sog), which binds the Dpp ligand and prevents interactions with its receptor (Figure 2c). Similarly, in vertebrates Bmp4 is antagonized by inhibitors related to Sog, such as Chordin (Chd), expressed on the dorsal side (Figure 2b; Holley *et al.*, 1995). Vertebrate NE is induced by dorsal mesoderm (neural induction) through inhibition of Dpp/Bmp. Loss of inhibition leads to failure of neural induction and expansion of the NNE domain (Khokha *et al.*, 2005). Many other components of the Dpp/Bmp signal transduction pathway are also conserved in this process (DeRobertis and Kuroda, 2004).

Conservation in DV patterning extends further within the NE to patterning of neuronal fates along the medial–lateral (ML) axis (Figures 2e and 2f; see Basic Nervous System Types: One or Many?). Both *Drosophila* and vertebrates utilize the

transcription factors Vnd (Nkx-2), Ind (Gsh-1), and Msh (Msx) in distinct ML domains of the NE to specify the three longitudinal columns of early neuroblasts (McDonald *et al.*, 1998). These factors are, in turn, regulated by Dpp/Bmp and its inhibitors, thereby translating DV patterning into different ML domains of neurogenesis (Liem *et al.*, 1995). These results suggest that a conserved system of positional information patterns the NE in protostomes and deuterostomes.

In contrast, other upstream factors involved in NE development are less similar. Vertebrate ectoderm acquires the ability (competence) to respond to neuralizing signals by exposure to fibroblast growth factors (Fgfs), which in turn are inhibited by Wnts from the lateral ectoderm (Akai and Storey, 2004; Delaune *et al.*, 2005). Fgf, Bmp, and Wnt signaling also interact to position the NE/NNE boundary region (Streit, 2004; Litsiou *et al.*, 2005). These signals establish specialized precursors from which neural crest and placodes develop (Figure 2f; Ahrens and Schlosser, 2005). Yet, despite these crucial roles in vertebrates, Wnt and Fgf relatives in *Drosophila* do not regulate ectodermal competence or neural induction. Conversely, in flies the expression of Vnd, Ind, and Msh depends on the function of a critical transcription factor, Dorsal, but no such system exists for the vertebrate NE. Other similarities in neurogenesis between protostomes and deuterostomes only become apparent later when cells become neuroblasts (see Basic Nervous System Types: One or Many?).

1.14.2.2.2 *Hox* genes and AP Patterning *Hom/Hox* genes confer segmental identity in the ectoderm in both *Drosophila* and vertebrates (Figure 3). Mutations in many of these genes cause homeosis, in which one segment or structure is replaced by another (Bateson, 1894; Lewis, 1978). *Hox* genes are clustered, with more 3′ genes expressed earlier and further anteriorly than more 5′ genes (Figures 3a and 3d), and the temporal and spatial patterns of *Hox* expression are similar in all major bilaterian groups, including those (e.g., hemichordates) that do not form separate NE and NNE (Harding *et al.*, 1985; Lowe *et al.*, 2003). In some cases human *Hox* genes can functionally compensate for their relatives in flies (Malicki *et al.*, 1992). However, in contrast to the single homeotic complex (*Hom-C*) in *Drosophila* (Figure 3a), mammals have four *Hox* clusters (*HoxA–D*) located on different chromosomes and totaling 39 genes (Figure 3d; McGinnis and Krumlauf, 1992). Each of the clusters consists of up to 13 paralogues (*Hox1–13*), genes located in the same 3′–5′ position in different clusters and more similar to one another than to genes within the same cluster. Double mutant studies in mice have revealed redundancies between paralogues (Rossel and Capecchi, 1999; Greer *et al.*, 2000). Thus, differences in *Hox* gene number and expression, rather than distinct biochemical functions, are thought to underlie many aspects of morphological diversity along the AP axis.

Despite exhaustive studies, however, the tissue-specific roles for many *Hox* genes have remained unclear. In both *Drosophila* and vertebrates, *Hox* expression is generally strongest in the NE and sometimes difficult to detect in NNE and other tissues. Often the AP boundary of expression within the NNE aligns with that of the NE and is under similar genetic control (Couly and LeDouarin, 1990). For example, in vertebrates the vitamin A derivative retinoic acid (RA) promotes expression of *Hox1*-group genes in the posterior hindbrain (Figures 3f–3h; Marshall *et al.*, 1992; Schilling and Knight, 2001). *Hox1* expression shifts anteriorly both in the hindbrain and epidermal placodes upon treatment with RA (Figure 3g; Kolm and Sive, 1995). Conversely, inhibition of RA signaling causes placodes of the lateral line to expand posteriorly, and this coincides with a posterior expansion of the hindbrain rhombomeres that induce these placodes (Figure 3h; Gibbs and Northcutt, 2004). Amphioxus *Hox* genes (1, 3, 4, and 6) are also expressed in distinct AP domains in the NE and NNE that shift in response to changes in RA signaling (Holland and Holland, 1996; Escriva *et al.*, 2002; Schubert *et al.*, 2004). These results suggest that *Hox* genes are under common patterns of regulation in different ectodermal tissues that are highly conserved.

Hox expression is also regulated independently in NE and NNE in some instances. For example, vertebrate *Hoxa2* is expressed in rhombomeres 2–5 (r2–5) of the hindbrain but not in neural crest cells derived from r2–3 that form the first pharyngeal arch (mandibular; Figure 3i; Gavales *et al.*, 1997). Instead, expression is restricted to crest cells of the second pharyngeal arch (hyoid) derived from r4–5 (Hunt *et al.*, 1991), where *Hoxa2* function is required; loss-of-function mutations in *Hoxa2* cause homeotic transformations of the hyoid arch skeleton into a mirror-image duplicate of the mandibular (Figure 3j; Gendron-Maguire *et al.*, 1993; Rijli *et al.*, 1993). Distinct regulatory regions of the *Hoxa2* promoter control hindbrain and neural crest expression in transgenic mice (Maconochie *et al.*, 1999). Several *Hox* genes (*Hoxa2*, *Hoxa3*, *Hoxb4*) are also expressed in the surface ectoderm overlying the pharyngeal arches in avian embryos, and these

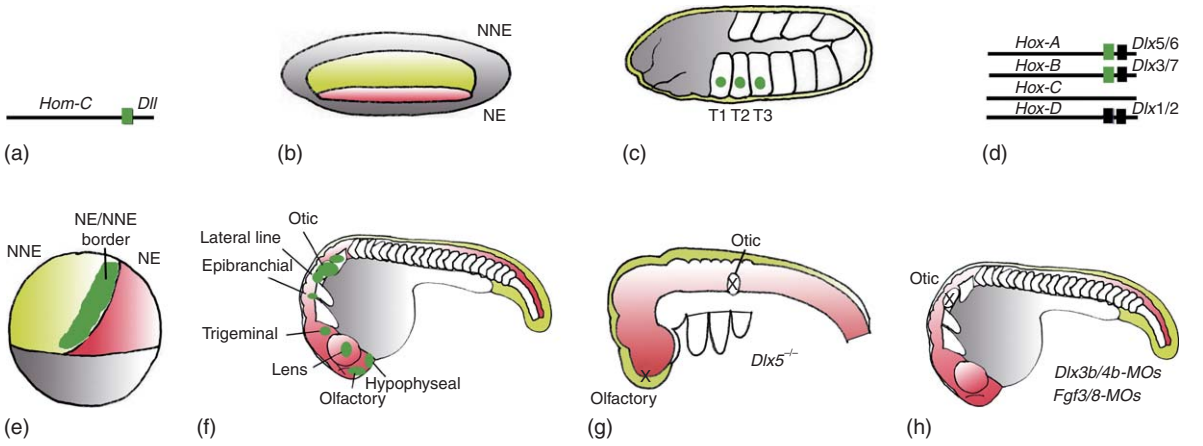

Figure 4 *Dlx* genes and patterning of the NNE. a, Single *Drosophila Dll* gene is linked to the *Hom-C* cluster. b, Pregastrula fly embryo indicating NNE (yellow) and NE (red). c, Germ band extended fly embryo indicating segments and expression of *Dll* (green) in cells of thoracic segments destined to develop legs. d, Three pairs of *Dlx* genes are linked to *Hox* clusters in vertebrates. e, *Dlx3* and/or *Dlx5* expression at the NE/NNE border of vertebrate embryos. f, Lateral view of zebra fish embryo showing positions of epidermal placodes. g, Olfactory and otic placodal defects in *Dlx5* mutant mice. h, Otic placodal defects in *Dlx3/4-* and *Fgf3/8*-deficient zebra fish.

patterns are regulated independently of the NE (Couly *et al.*, 1998). Other *Hox* genes (*Hoxa7*, *Hoxb8*) are expressed in the epidermis but at much later stages of embryogenesis. These results suggest a more complex system in which AP identities of NE and NNE cells can shift independently during evolution.

1.14.2.2.3 *Dlx* genes and non-neural patterning A third conserved system of positional information in the vertebrate ectoderm is encoded by homeobox genes of the *Dlx* family, relatives of *Drosophila Distal-less* (*Dll*; Figure 4a; Cohen *et al.*, 1989). *Dll* is a crucial regulator of appendage development in arthropods. It is only active in the thorax, because its expression is repressed in the abdomen by *Hox* genes such as *Ubx* and *AbdA* (Figure 4c; Vachon *et al.*, 1992). *Drosophila* has a single *Dll* gene, while vertebrates have at least six *Dlx* genes, organized into three pairs, each linked to one of the four *Hox* clusters (Figure 4d; Stock *et al.*, 1996; Panganiban and Rubenstein, 2002). *Dlx3* is expressed broadly throughout the NNE, and humans with *Dlx3* mutations have defects in hair, teeth, and craniofacial skeletal development (Price *et al.*, 1998). *Dlx5* expression in mice is restricted to the NE/NNE boundary and required for the development of olfactory and otic placodes, pharyngeal neural crest, and the dorsal midline of the neural tube (Figures 4e–4g; Acampora *et al.*, 1999; Depew *et al.*, 1999). *Dlx3b* and *Dlx4b* in zebra fish are essential for otic development (Figure 4h; Akimenko *et al.*, 1994; Solomon and Fritz, 2002). In each case, Dlx proteins appear to repress neural differentiation at the NE/NNE boundary, allowing cells to become competent to respond to placode inducers (Feledy *et al.*, 1999; McLarren *et al.*, 2003). This may have been an early ectodermal function for *Dll* that was co-opted during the evolution of the *Dlx* family to new vertebrate-specific functions in neural crest and placodes.

Roles for *Dlx* genes in NNE may have been inherited from a similar function in the protochordate ancestor. *Dlx* genes that have been identified in hemichordates and ascidians are expressed in anterior ectoderm, but not in domains associated with the NE/NNE boundary (Caracciolo *et al.*, 2000; Harada *et al.*, 2001). Amphioxus *Dll* (*AmphiDll*) is expressed throughout the NNE and anterior NE, similar to several *Dlx* family members in vertebrates (Holland *et al.*, 1996). Ectoderm in amphioxus embryos also expresses other relatives of genes characteristic of the NE/NNE boundary in vertebrates (*Pax3/7*, *Msx1/2*, *Zic*, *Slug/Snail*), but does not express transcriptional regulators that specify neural crest cells (*AP-2*, *SoxE*, *FoxD3*, *Id*, *Twist*; Meulemans and Bronner-Fraser, 2002, 2004), as discussed below.

1.14.3 Modularity in Ectodermal Evolution

An important conceptual framework for understanding ectodermal evolution involves the concept of a developmental module (Riedl, 1978; Wagner, 1996). Modules can be morphogenetic fields (i.e., germ layers, tissues, body segments, and organ rudiments), distinct cell lineages, or molecular

pathways. Genes themselves are clearly modular, as are their regulatory elements (promoters and enhancers). If a tissue or gene acquires or loses a module, different morphologies can develop. Modules can be dissociated, duplicated, or co-opted for different purposes at all levels of development (Raff, 1996).

1.14.3.1 Neural/Non-Neural Interactions

Changes in one developmental module will often affect other modules with which it interacts. Prime examples of this are interactions between NE and NNE that induce and pattern the olfactory, lens, otic, and hypophyseal placodes in vertebrates (Figure 5; Baker and Bronner-Fraser, 2001; Streit, 2004; Brugmann and Moody, 2005). Cells of the NNE initially express transcription factors with generic roles in placode formation such as *Six1*, *Eya1*, and *Dlx5/6*, and individual placodal domains are induced within this preplacodal primordium (Schlosser and Ahrens, 2004). Perhaps the best known of these is the induction of the lens by the anterior neural plate, which forms the optic cup (Figure 5a). The optic cup is both necessary and sufficient for lens formation in amphibians, and only certain regions of cranial ectoderm are competent to be induced (Lewis, 1904; Grainger, 1996; Grainger *et al.*, 1997). Both Bmps and Fgfs have been implicated in the inductive signal (Lang, 2004), and competence relies on transcriptional regulators such as *Pax6*, *Otx2*, and *Pitx3*, expressed in the prelens field (Zygar *et al.*, 1998; Khosrowshahian *et al.*, 2005). Lens-inducing signals may be largely permissive, rather than instructive, since in some species of amphibians the lens can develop independently of the optic cup (Balinsky, 1951).

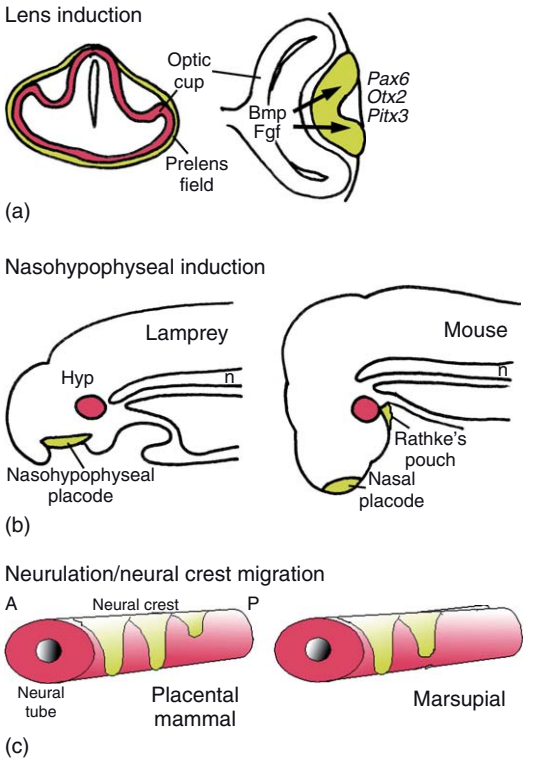

Figure 5 Heterochronic changes in ectodermal development. a, Lens induction. Diagrams illustrating transverse sections through the head of an early amphibian embryo (left panel) and the optic primordium at later stages (right panel). The optic cup secretes Bmp and Fgf that induce lens identities within a prelens field. b, Nasohypophyseal induction in agathans and gnathostomes. Lateral views, anterior to the left. Lampreys form a combined nasohypophyseal placode and a single nostril (left panel). In contrast, nasal placodes separate from Rathke's pouch, which forms the adenohypophysis, through a change in the timing of growth. c, Timing of neurulation and neural crest migration in placental and marsupial mammals. Diagrams illustrate transected segments of neural tube (red) with streams of migrating neural crest (yellow). Anterior to the left. n, notochord.

Similarly, development of the otic placode, which forms the inner ear and vestibuloacoustic ganglion, involves NE–NNE interactions. The otic vesicle is induced by two major steps in urodele amphibians (Yntema, 1933). Recent results in other species suggest that these include early signals from the cranial mesoderm during neurulation and later signals from the posterior hindbrain, both of which involve Fgfs (Ladher *et al.*, 2000, 2005; Barald and Kelley, 2004; Martin and Groves, 2006). The combination of Fgf3 and Fgf8 is required for otic induction in zebra fish (Figure 4h), while Fgf3 and Fgf10 in mice play similar, redundant roles (Solomon *et al.*, 2004). Like the lens placode, competence within the ectoderm to respond to Fgfs correlates with expression of the preplacodal state normally found at the NE/NNE boundary (Martin and Groves, 2006). Interestingly, in mammals and other amniotes with an external ear opening, the whole epidermis is involved, while in amphibians only the interior epidermal cells contribute to the otic vesicle, and no opening forms. Such differences could have evolved through changes in the competence of ectodermal cells to respond to Fgfs.

1.14.3.2 Heterochrony

Developmental modules can also become dissociated during evolution. When this involves changes in the relative timing of developmental events between an ancestor and its descendants, it is known as heterochrony. One tissue or organ system may develop at an accelerated or retarded pace relative to others or there may be a change in developmental sequence (Smith, 2002). For example,

heterochronic shifts in the timing of contact between the NE and adjacent hypophyseal placode underlie species-specific differences in morphology of the pituitary (Figure 5b). Where cells of the ventral hypothalamus contact the hypophyseal placode (i.e., Rathke's pouch) they fuse to form the neurohypophysis and adenohypophysis, respectively. In gnathostomes, the bilaterally symmetric nasal placodes develop adjacent to the hypophyseal placode but quickly become separated by anterior growth of the brain (Couly and LeDouarin, 1985; Glieberman *et al.*, 1999). In contrast, in agnathans such as the lamprey (Figure 1b), the olfactory epithelium and the hypophysis develop as a single median placode, the nasohypophyseal (Figure 5b; Gorbman and Tamarin, 1985; Kuratani *et al.*, 2001), and agnathan adults have a single nasal opening (monorhiny).

Early development of the hypophyseal placode is also intimately tied to the placodes that form the olfactory epithelia and lens, and changes in the timing of inductive signals from the hypothalamus may also play a crucial role in their specification. The secreted signaling molecule Sonic hedgehog (*Shh*), produced in the ventral midline of the neural tube, is both necessary and sufficient for the development of these placodes and may specify distinct placodal fates within a preplacodal field (Figure 5b; Herzog *et al.*, 2003). Recent studies in zebra fish have shown that *Pitx3* and *Dlx3b* define an equivalence domain for the lens and pituitary (Dutta *et al.*, 2005). Targeted gene knockdown studies suggest that *Pitx3* is required to form an early olfactory–lens–hypophyseal preplacode, while *Dlx3b* is required to determine placode size. Misexpression of *Shh* inhibits lens formation and expands the pituitary, but within a placodal domain of normal size. Mutants that reduce *Shh* signaling can, in some cases, result in the formation of a lens in the location of the adenohypophysis (Kondoh *et al.*, 2000). These results exemplify another fundamental feature of developmental modularity, namely, the progressive restriction of developmental potential, and heterochronic changes in the sequence of these restrictions may also underlie many evolutionary transitions in the ectoderm.

A common heterochronic change in both protostomes and deuterostomes has been in the maturation of different body segments along the AP axis. In short-germband insects, such as *Drosophila*, segmental domains are specified more or less simultaneously across a syncytial blastoderm. In contrast, long-germband insects form segments progressively from anterior to posterior, and this is the primitive mode in arthropods. Vertebrate segmentation more closely resembles this mode, with the sequential AP appearance of somites in the mesoderm, neural tube closure, and neural crest migration (Figure 5c). All three are under tightly coordinated genetic control. An interesting case of heterochrony in these processes occurs in marsupial mammals, which have an extremely short period of intrauterine development and are born as altricial neonates that suckle and develop outside the mother (Clark and Smith, 1993). Development of the jaws, tongue, and forelimbs is accelerated relative to other aspects of organogenesis, presumably to allow the neonate to attach and feed. To achieve this, neural crest migration is accelerated dramatically in the head as compared with placental mammals, revealing a shift in timing along the AP axis (Figure 5c; Vaglia and Smith, 2003). Neural crest migration and differentiation are also accelerated relative to closure of the neural tube in these animals. These results demonstrate the modular nature of neural and neural crest development.

Similar changes in the relative timing of neural crest migration may underlie other species-specific differences in vertebrate morphology. For example, neural crest migration in birds occurs largely after the neural tube has closed, while in zebra fish and mammals some cranial neural crest migration precedes tube formation (Nichols, 1981; Schilling and Kimmel, 1994; LeDouarin and Kalcheim, 1999). Thus, the rate of neural crest maturation can be locally regulated along the AP axis through mechanisms that are separate from other modules within the ectoderm.

1.14.3.3 Gene Duplication and Divergence in Ectodermal Patterning

Another fundamental feature of developmental modules is that they can be duplicated, and duplicates can evolve distinct functions. This has occurred at the level of single genes or gene clusters, as we have discussed for the *Hox* and *Dlx* genes (Figures 3 and 4), as well as at the level of gene networks that regulate whole fields of cells, as in the evolution of body segment number. It is now fairly well established that at least one major duplication event occurred on a broad scale in ancestral chordates involving whole-genome duplications, and that this accounts for the larger number of *Hox* clusters in vertebrates (Amores *et al.*, 1998; Holland, 1999). Functional redundancies between duplicates often obscure the roles of individual genes and this has made it difficult to clarify the functions of many Hox proteins. For example, double mutant analyses in mice have revealed

redundancies between *HoxA1* and *B1* in patterning of rhombomeres 4 and 5 (r4 and r5) of the hindbrain, as well as *HoxA3* and *D3* (Rossel and Capecchi, 1999; Greer *et al.*, 2000).

Determination of gene copy number in multiple species, combined with gene expression analysis, can give clues as to their roles in the most recent common ancestor. For example, one or more duplications of *Hox* clusters appears to have accompanied the chordate-to-vertebrate transition, since both ascidians and amphioxus have a single cluster like *Drosophila* (Figure 3; Garcia-Fernandez and Holland, 1994; DiGregorio *et al.*, 1995; Holland and Garcia-Fernandez, 1996; Delsuc *et al.*, 2006). Comparing the *Hox* clusters of chordates, arthropods, and mollusks suggests that there was a common set of seven *Hox* genes in the urbilaterian ancestor. It is attractive to postulate that duplication and divergence of *Hox* genes provided raw material for the more complex development of the brain and sense organs in the vertebrate ectoderm. However, duplications do not necessarily correlate with increased complexity, since additional whole-genome duplications have occurred in the lineages leading to teleost fishes, yielding seven *Hox* clusters, without a concomitant increase in complexity (Amores *et al.*, 1998; Postlethwait *et al.*, 1998).

The *Dlx* gene family has also undergone several rounds of gene duplication and divergence during chordate evolution (Figure 4). This family is represented by a single gene in protostomes, *Dll*, and amphioxus also has a single *Dll* gene, *AmphiDll* (Holland *et al.*, 1996). It appears, however, that the ancestral chordate *Dll* was duplicated in the deuterostome lineage prior to the divergence between urochordates and vertebrates into *DlxA* and *DlxB* (Di Gregorio *et al.*, 1995). Additional duplications of these led to two major classes of *Dlx* genes in gnathostomes, *Dlx-2,3,5* and *Dlx-1,6,7* (Stock *et al.*, 1996; Zerucha and Ekker, 2000; Sumimaya *et al.*, 2002). Since these are organized into three closely linked pairs (*Dlx1/2*, *Dlx5/6*, and *Dlx3/7*) associated with three of four *Hox* clusters in mammals, it seems likely that a pair of *Dlx* genes linked to *HoxC* existed following early whole-genome duplications, and was subsequently lost. Double mutant analyses of mice lacking the functions of linked pairs, *Dlx1* and *Dlx2*, as well as *Dlx5* and *Dlx6*, have revealed redundant functions in neural crest development (Qiu *et al.*, 1997; Depew *et al.*, 1999), as discussed below. In contrast, *Dlx3* and *Dlx5* have evolved distinct roles in placodal development (Price *et al.*, 1998; Acampora *et al.*, 1999; Depew *et al.*, 1999). Similar patterns of gene duplication and divergence have been described for many other vertebrate gene families.

1.14.4 Generating Evolutionary Novelty

1.14.4.1 Neural Crest and Vertebrate Origins

The appearance of neural crest cells was a crucial and seemingly abrupt step in vertebrate evolution (Gans and Northcutt, 1983; Northcutt and Gans, 1983; Northcutt, 2005). The closest chordate relatives do not form neural crest. However, all living vertebrates, including agnathans, have a full complement of neural crest and crest derivatives (Holland and Holland, 2001; Kuratani *et al.*, 2001). In both urochordates and cephalochordates, subsets of ectodermal cells express genes characteristic of the vertebrate NE/NNE boundary region, but these cells do not express relatives of the genes that specify neural crest cells and never migrate (Figure 1b; Meulemans and Bronner-Fraser, 2002, 2004). One exception to this was recently reported for one species of urochordate, in which labeled ectodermal cells were shown to migrate and form pigmented cells (Jeffery *et al.*, 2004). These results suggest that neural crest evolved from modifications of a pre-existing NE/NNE boundary region in an ancestral protochordate.

What cellular and molecular changes at the NE/NNE boundary led to the advent of neural crest? Genes expressed at the boundary (*Pax3/7, Msx1/2, Zic, Slug/Snail* – boundary-specific), and those specific to neural crest (*AP-2*α,β,γ, *Sox9/10, FoxD3, Id, Twist* – crest-specific), are likely candidates (Figure 6; Meulemans and Bronner-Fraser, 2004). Many of these genes are regulated by Bmp signaling in vertebrate DV patterning, which restricts their expression to the NE/NNE boundary. Ectoderm in amphioxus embryos expresses relatives of boundary-specific but not crest-specific genes (Baker and Bronner-Fraser, 1997; Langeland *et al.*, 1998). In larvaceans, which are urochordates, the cranial ectoderm expresses early boundary-specific genes in locations that resemble olfactory and hypophyseal placodes (Figure 4; Bassham and Postlethwait, 2005) and ascidian *Pitx* genes define a clear hypophyseal placode (Boorman and Shimeld, 2002; Christiaen *et al.*, 2002; Manni *et al.*, 2005). Thus, the NE/NNE boundary region may have arisen in ancestral chordates as part of a primitive olfactory/pituitary system (Mazet *et al.*, 2005; Schlosser, 2005).

Among the crest-specific genes, members of the activator protein (*AP-2*) family are notable in that they play ancient roles in NNE development in all

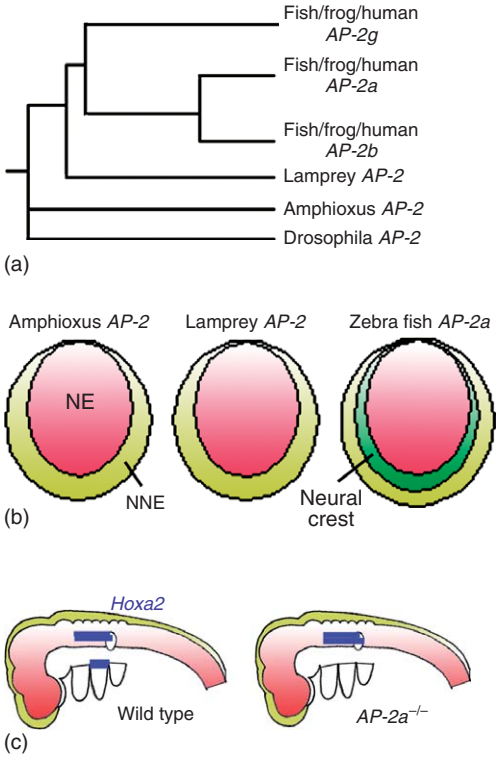

Figure 6 Evolution of the neural plate border, *AP-2* genes, and neural crest origins. a, Molecular phylogeny of AP-2 family members. b, Illustrations of expression of *AP-2* genes in cephalochordates, agnathans, and vertebrates in NNE (yellow) and neural crest (green), but not in NE (red). Views are from the anterior. c, Loss of *Hoxa2* activation in neural crest in *AP-2a* mutants. Lateral views. a, Modified from Meulemans, D. and Bronner-Fraser, M. 2002. Amphioxus and lamprey AP-2 genes: Implications for neural crest evolution and migration patterns. *Development* 129, 4953–4962.

chordates (Figure 6). *AP-2a* and its relatives in mammals (*AP-2b* and *AP-2g*) are among the earliest genes expressed specifically in ectoderm (Figure 6a; Hilger-Eversheim *et al.*, 2000). During gastrulation, AP-2a is expressed throughout the NNE, but is then upregulated in neural crest cells prior to and during their migration away from the NE (Williams *et al.*, 1988; Mitchell *et al.*, 1991). AP-2a is required for neural tube and body wall closure in mice and directly regulates keratin expression, indicating widespread roles in both NE and NNE. It also has specific roles in neural crest development, since null *AP-2a*$^{-/-}$ mutant zebra fish or mice lack neural, skeletal, and pigment cells derived from the cranial neural crest (Schorle *et al.*, 1996; Zhang *et al.*, 1996; Knight *et al.*, 2003, 2004). *AP-2a* is an essential activator of *Hoxa2* expression in neural crest that forms the second pharyngeal arch (Figure 6c), but not in the NE, indicating a direct role for *AP-2* genes in neural crest patterning (Maconochie *et al.*, 1999; Knight *et al.*, 2003). *AP-2b* mutations in humans cause Char syndrome, including craniofacial defects affecting skeletal derivatives of neural crest. Misexpression of *AP-2a* can restore neural crest and epidermal development in *Xenopus* embryos severely deficient in Bmp signaling, suggesting that they function in part as downstream mediators of this pathway (Luo *et al.*, 2002). Thus, multiple AP-2 proteins are thought to play essential roles in both neural crest and epidermal development.

A comparison of the expression patterns and functions of AP-2 proteins in invertebrates and vertebrates suggests that their ancestral roles were in epidermal development and that they were later co-opted in neural crest. This correlates with an increase in the number of *AP-2* genes in vertebrates, similar to the *Hox* and *Dlx* families discussed previously (Figure 6a). A single *Drosophila* AP-2 gene regulates proximal–distal (PD) patterning of appendages (Kerber *et al.*, 2001; Monge *et al.*, 2001). Amphioxus also appears to have a single *AP-2* gene family member, expressed throughout the NNE (Figure 6b; Meulemans and Bronner-Fraser, 2002). In contrast, fish, amphibians, and mammals all have at least three closely related *AP-2* family members (*AP-2a, b*, and *g*; Luo *et al.*, 2003, 2005; Zhang *et al.*, 2006; Javier and Schilling, 2004), which in mice are all expressed in neural crest (Figure 6a). Mammals have two additional family members (*AP-2d* and *e*) that are less well conserved. Zebra fish *AP-2b* is not expressed in neural crest, unlike its relatives in frog and mouse (Luo *et al.*, 2005; Moser *et al.*, 1997), and instead is confined to the pharyngeal ectoderm where it is required to induce skeletogenesis in the cranial neural crest (Knight *et al.*, 2005). This highlights another epithelial–mesenchymal interaction that occurs between the epidermis and underlying neural crest, and the divergence of tissue-specific roles of different members of a closely related family of duplicates.

1.14.4.2 Neural Crest and the Origins of Jaws and Middle-Ear Bones

Another major transition in vertebrate evolution was the appearance of a biting jaw. Ancestral vertebrates, like their chordate relatives, were initially jawless (agnathans) filter feeders with a segmented pharynx composed of gill arches (Figure 1b). Living agnathans, such as the lamprey, lack the distinct upper (proximal) and lower (distal) jaws found in gnathostomes (jawed vertebrates) (Figure 7). In urochordates and cephalochordates arches consist of reiterated folds in the pharyngeal ectoderm and endoderm. In contrast, vertebrate arches have a complex tissue composition, including skeletal

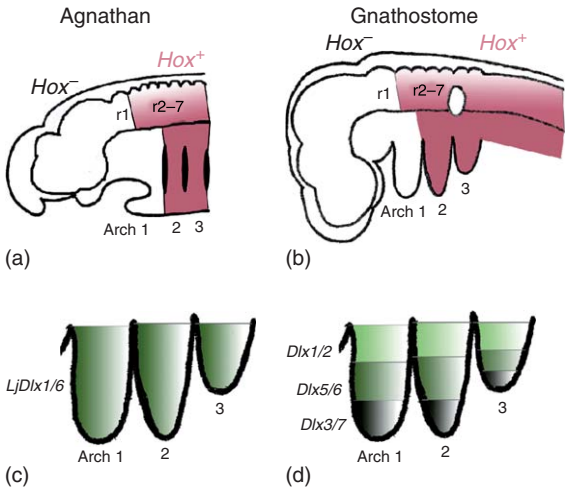

Figure 7 Evolution of pharyngeal arches and the origins of jaws. Left panels, lampreys; right panels, mice. a, Lamprey head showing *Hox*$^+$ region (red) emcompassing rhombomeres 2–7 and arches 2 and 3. b, Mouse head showing similar pattern of *Hox*$^+$ cells. c, Higher-magnification view of arches, lateral view, showing uniform expression of *LjDlx1/6* as compared with d, in which gnathostome *Dlx* genes are expressed in a nested pattern along the PD axis.

elements derived from cranial neural crest as well as muscles and blood vessels derived from mesoderm (Le Lievre, 1974; reviewed by LeDouarin and Kalcheim, 1999). The gnathostome jaw derives from arch 1 (mandibular), and classically has been thought to have evolved from a modified gill arch (Goodrich, 1958; DeBeer, 1937; reviewed in Mallatt, 1996). Comparative studies in lampreys are crucial in this case as they are one of the only living sister groups to the gnathostomes.

One unique molecular feature of the mandibular arch is the absence of *Hox* expression (Figure 7a). Mandibular neural crest cells emanate from *Hox*-negative regions of the neural tube (i.e., the midbrain and anterior hindbrain), while crest cells in more posterior arches are *Hox*-positive; cells in arch 2 (hyoid) express *Hoxa2* and *b2*, whereas cells in arch 3 express *Hoxa3* and *b3* (Hunt *et al.*, 1991). Kontges and Lumsden (1996) showed that *Hox*-positive connective tissue attachments of muscles in arch 2 are derived from neural crest cells that arise from the *Hox*-positive rhombomeres (r2–3) that innervate them. Thus, the skeletal elements, the muscles that move them, and the nerves that innervate the muscles form a developmental module that can be acted upon by evolution. Transformations of arch 2 into a mirror-image duplicate of arch 1 in *Hoxa2* mutants suggest that *Hox* genes function in part to suppress an arch 1 default state (Figure 3; Gendron-Maguire *et al.*, 1993; Rijli *et al.*, 1993). Thus, one attractive evolutionary hypothesis is that the loss of *Hox* expression in the mandibular arch in an ancestral agnathan allowed jaw evolution in gnathostomes. Recent evidence argues against this model, since *Hox* genes that have been described to date in the Japanese lamprey, *Lampetra japonica*, are largely excluded from the mandibular arch (Takio *et al.*, 2004; Kuratani, 2005).

Dlx genes are particularly interesting with regard to jaw evolution because they are expressed in distinct domains along the PD axis within each pharyngeal arch in gnathostomes (Figure 7b). This is reminiscent of *Drosophila* appendages, where *Dll* promotes distal cell identity (Panganiban *et al.*, 1997). All six *Dlx* genes are expressed along the PD axis in the neural crest of the mandibular arch. While *Dlx1* and *Dlx2* are expressed throughout the arch, *Dlx5* and *Dlx6* expression are confined further distally, and *Dlx3/7* expression domains are further distal still (Robinson and Mahon, 1994; Qiu *et al.*, 1995, 1997; Acampora *et al.*, 1999; Depew *et al.*, 1999). In *Dlx5/6* double mutants, distal cells of the lower jaw acquire dorsal characteristics typical of the upper jaw, revealing redundant functions in controlling distal cell identity (Depew *et al.*, 2002, 2005; Robledo *et al.*, 2002). Interestingly, a lamprey relative of *Dlx1* and *Dlx6* (*LjDlx1/6*) is expressed more broadly throughout the arches, and is not restricted to distinct P or D domains (Myojin *et al.*, 2001; Neidert *et al.*, 2001; Shigetani *et al.*, 2002; Kuratani, 2005). Thus, it is possible that a heterotopic (rather than heterochronic) shift in *Dlx1/6* gene regulation facilitated evolution of the lower jaw.

What might have caused such spatial shifts in *Dlx* expression? Epithelial–mesenchymal interactions between the epidermis and underlying neural crest in mice play central roles in *Dlx* regulation and PD patterning in the arches. *Dlx1* expression is induced in proximal neural crest cells by Fgf8, produced in the proximal surface ectoderm of the arch (Barlow and Francis-West, 1997; Neubuser *et al.*, 1997; Tucker *et al.*, 1998; Shigetani *et al.*, 2002), and ectodermal expression of Fgf8 is required for mandibular patterning (Trumpp *et al.*, 1999). *Dlx2* in mice is independently regulated in the arch epithelium and crest-derived mesenchyme (Thomas *et al.*, 2000). Similar to *LjDlx1/6*, a lamprey relative of Fgf8 is expressed widely in the oral ectoderm (Shigetani *et al.*, 2002). These results suggest that the biting jaw evolved from modifications of a preexisting system of interactions between the neural crest and epithelia in the pharyngeal arches of an ancestral agnathan.

PD domains within the arches have also been co-opted for entirely new functions. A famous case is the use of homologues of fish jawbones in the mammalian middle ear (Gould, 1990). Proximal bones of the mandibular and hyoid arches, which support the jaw in fish and attach to the wall of the otic capsule, are homologues of the malleus and incus bones that conduct sound.

1.14.5 Other Developmental Constraints

1.14.5.1 Morphology – Neural Crest and Neural Tube Morphogenesis

As we have seen, one consequence of modular development in the ectoderm is that it limits the possible phenotypes that can be created, and allows changes in some directions more easily than others. One such developmental constraint governs the production of sensory neurons in vertebrates from neural crest and placodes at the NE/NNE boundary. While all sensory neurons of the PNS are derived from these progenitors, a few are also found within the dorsal CNS, and these share many developmental features with neural crest cells (Figure 8a). These include the mesencephalic nucleus of the trigeminal (MesV), found within the midbrain of the CNS near the tectal commissure in all gnathostomes, that carries proprioceptive information from the jaw muscles (Gonzalez and Munoz, 1988). These cells appear to be absent in lampreys (Northcutt, 1979). In addition, Rohon–Beard (RB) neurons of embryonic fish and amphibians are sensory neurons located within the dorsal spinal cord (Figure 8b; Forehand and Farel, 1982). They function as a temporary sensory system in the larva that is subsequently replaced by neural crest-derived neurons of the dorsal root ganglia (DRGs) (Lamborghini, 1987). Both MesV and RB neurons may represent remnants of an earlier evolutionary state, in which such centrally located sensory neurons may have been common.

Sigmund Freud described RB neurons as unmigrated spinal ganglion cells, and recent studies indicate that they bear many similarities to neural crest. Extirpations of crest in urodeles also disrupts RB neurons (DuShane, 1938). In zebra fish, RB precursors share a lineage with neural crest cells, and interactions between these cells determine their fates inside or outside the CNS (Cornell and Eisen, 2000). Neuroblasts that produce RB cells inhibit their neighbors from forming neurons through lateral inhibition involving Delta-Notch

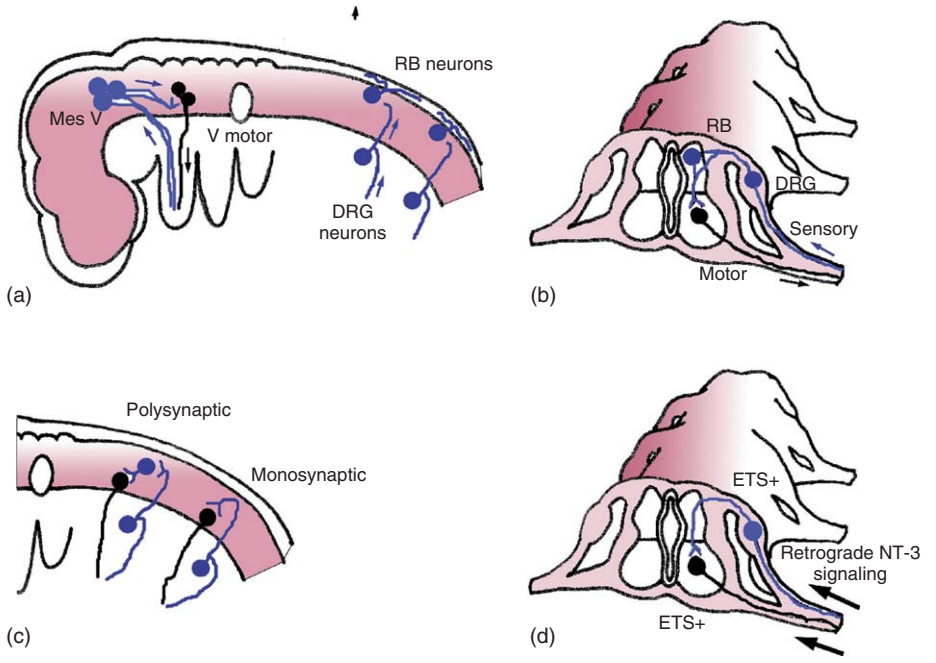

Figure 8 Developmental constraints in the formation of neural circuits. a and b, Morphological: MesV and RB neurons are neural crest cells trapped in the CNS. MesV cells are sensory neurons within the CNS that bring sensory information from the jaw and connect to trigeminal motor neurons (V motor). Similarly, RB neurons are sensory neurons in the trunk. a, Lateral view; b, transverse section. c, Physiological: establishing circuits between CNS and PNS. Polysynaptic and monosynaptic circuits involve information coming to (a) from a common peripheral target. d, NT-3 signals modulating ETS domain transcription factor form the basis of a target-mediated specification of sensory and motor neurons.

signaling, and these neighboring cells give rise to neural crest. Recent studies have also shown that *Dlx* genes in zebra fish are required in the development of RB neurons and in the trigeminal placodes, consistent with their origins at the NE/NNE boundary (Artinger *et al.*, 1999; Kaji and Artinger, 2004). Loss of *Dlx3b* and/or *Dlx4b* expression disrupts Bmp2b expression and this, in turn, regulates cell fate choices between RB neurons and neural crest cells at the boundary.

1.14.5.2 Physiology – Establishing Circuits between Central and Peripheral Neurons

The developing nervous system also has the functional constraint that its sense organs and PNS need ultimately to connect in an appropriate pattern to the CNS to establish circuits. The simplest circuit controls the monosynaptic reflex, in which an incoming axon of the PNS from a muscle receptor (derived from neural crest) enters through the dorsal root and terminates on a motor neuron in the ventral spinal cord (CNS) that innervates that same muscle (Figures 8c and 8d; Ariens Kappers *et al.*, 1960). These connections are established extremely early during embryogenesis. How do the neurons find their targets? Some evidence suggests that the targets of motor neurons are specified before their axons extend into the periphery (Lance-Jones and Landmesser, 1980). Innate neuronal identities are controlled by domains of expression of LIM transcription factors in different populations of motor neuron progenitors (Appel *et al.*, 1995).

Recent evidence suggests that connectivity between motor neurons and sensory neurons within a monosynaptic circuit is controlled by target-derived signals (Figure 8d; Chen *et al.*, 2003; Hippenmeyer *et al.*, 2004). Motor neurons within the ventral horn of the spinal cord receive monosynaptic input from Ia proprioceptive DRG sensory neurons. These two cell types establish peripheral connections with the same muscle targets. Two members of the ETS domain family of transcription factors, Pea3 and Er81 in mice, are expressed by distinct subpopulations of motor and sensory neurons that form such circuits (Lin *et al.*, 1998; Arber *et al.*, 2000; Livet *et al.*, 2002). Onset of Pea3 and Er81 expression coincides with the stages at which the axons of these cells begin to reach their target muscles. In the absence of Pea3 function, motor neurons project to the periphery but fail to innervate their targets. Er81, in contrast, is required in DRG sensory neurons to promote the establishment of axonal projections into the ventral horn of the spinal cord.

What is the nature of the target-derived signals? They must act retrogradely on the cell body to control the acquisition of cell identity and circuit assembly. Interestingly, a phenotype similar to that of Pea3 mutants is observed in mice lacking glial-derived neurotrophic factor (Haase *et al.*, 2002). These mice fail to induce Pea3 expression in motor neurons, and these motor neurons fail to migrate to their normal locations within the spinal cord, possibly due to defects in cell adhesion. Similarly, another neurotrophin called NT-3 induces Er81 expression in proprioceptive afferent neurons (Patel *et al.*, 2003). Thus, neurotrophins play a general role in the development of motor and sensory projections in a manner independent of their better-known roles in neuronal survival.

Generalizing from this example, it seems likely that other more complex neuronal circuits will involve similar processes in which neuronal subtypes are specified prior to the generation of postmitotic neurons. These define cell-autonomous competence to respond to target-derived signals which subsequently alter neuronal identities as their axons reach their targets. Such flexible systems help explain how cells derived from NE and NNE form appropriate connections with one another despite quite different developmental histories. The recent experiments have only begun to shed light on how this fine-tuned interplay between different ectodermal populations controls circuit formation.

1.14.6 Summary and Outlook

The mechanisms that pattern the nervous system in all bilaterian animals begin with signals that induce DV polarity within the ectoderm and combinatorial codes of transcription factors that define neurogenic and non-neurogenic territories. A common trend in ectodermal evolution is the loss of neurogenic potential from the NNE. Genetic studies in mice and zebra fish have begun to uncover mechanisms that coordinate patterning of the NE and NNE in vertebrates. Studies of neural crest and placodal development, in particular, have helped to define roles of Bmp, Hox, Dlx, and AP-2 proteins in ectodermal development. In this article, I have considered this new information in a comparative context to examine how changes in gene functions have co-evolved in the neural and non-neural components of the ectoderm.

All chordates share relatives of these gene families, though the families are typically three- to fourfold larger in vertebrates. Increases in gene copy number like this probably evolved through whole-genome duplications during and after the divergence

of vertebrate and invertebrate chordates, and they complicate comparisons between orthologous genes. However, we can infer ancestral functions for many genes based on their expression in amphioxus and ascidians, since they diverged from the vertebrate lineage prior to these gene duplications. These indicate that the primitive chordate ectoderm contained separate NE and NNE as well as an NE/NNE boundary region with characteristics of the olfactory and hypophyseal placodes in vertebrates. Future studies of the mechanisms controlling formation of this primitive placodal territory, including potential functional studies in ascidians, promise to reveal basic principles underlying specification of ectodermal fates.

1.15 The Role of Transient, Exuberant Axonal Structures in the Evolution of Cerebral Cortex

G M Innocenti, Karolinska Institutet, Stockholm, Sweden

Glossary

connection In this article, connection is used to refer to situations for which the existence of synapses was demonstrated or appears very probable on grounds of electron microscopic data or light-microscopic data with sufficient resolution.

projection This refers to situations where the demonstration is missing, for example due to the use of retrogradely transported tract-tracers. Notice that the distinction is justified for the developing brain, although it is often unclear whether a certain projection is actually forming synapses. In most of this article, the terms are synonymous.

1.15.1 Introduction

Developmental mechanisms, some of which have needed retuning while others have been maintained, have both permitted and constrained evolution. It is therefore legitimate to ask which developmental mechanisms were modified and which were maintained in the evolution of the cerebral cortex. Comparative studies suggest that two processes dominated the evolution of cerebral cortex: tangential expansion, and increased regional differentiation. The most commonly proposed scenario, accounting for the increased tangential expansion of the cerebral cortex, is an increased period of symmetrical divisions in the proliferative ventricular and subventricular zones. Regional differentiation, however, is multifaceted and the emergence of a new cortical area in the course of evolution must have required the coordination of several different developmental processes.

A primary cause of regional differences in the cortical mantle is probably the differential expressions of genes along tangential gradients. It is unclear, however, how the regionalization of the cortical mantle, presumably caused by gene expression, corresponds to the parcellation of cerebral cortex into structurally and functionally distinct areas, that is, into its arealization. Indeed, the identity of a cortical area is defined by a large set of morphological and functional criteria. The morphological criteria include not only cytoarchitectonics, myeloarchitectonics, and sometimes molecular differences, but also, most importantly, differences in connectivity with thalamic nuclei and with other cortical regions. The functional criteria include the sensory, motor, or cognitive consequences of lesions, the response properties of individual neurons, and the patterns of activation during specific tasks. Assuming that the patterns of genetic expression might be the primary determinants of cortical regionalization, the question is: which other changes in developmental processes were required to achieve the full set of local differentiations that characterize a cortical area?

As mentioned above, connectivity is a central feature in the definition of a cortical area. In addition, however, it also determines some of the other criteria that define a cortical area, in particular its architectonics, the response properties of its neurons, and their participation in specific functional neuronal assemblies and/or processing streams. Thus, the appearance of a new cortical area in

evolution required adjustments of cortical connectivity. These adjustments, in turn, were a major factor in determinning arealization.

This article illustrates how the development of cortical connectivity is based on the following mechanisms: (1) exuberant development, i.e., initial distribution of cortical axons to territories wider than in the adult; (2) selection, based on specific axon/pathway and axon/target recognition mechanisms, as well as on axoaxonal interactions; and (3) selection/validation of the connections by activity.

I claim that the algorithms of connectional development listed above, while maintaining a coherent Bauplan across the mammalian radiation, provided the degree of flexibility required to accommodate genetically based regionalization of the cerebral cortex and thus played a major role in the emergence of new cortical areas. The article is mainly restricted to data and concepts that appeared within the last 10–15 years, since the older literature has been reviewed previously (Innocenti, 1991; O'Leary, 1992; see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates, Cerebral Cortical Folding Patterns in Primates: Why They Vary and What They Signify).

1.15.2 Macroscopic versus Microscopic Exuberance in the Development of Connections

Structural exuberance in development includes the overproduction of neurons and non-neuronal cells, as well as that of cellular components, in particular axons and/or axon collaterals, synaptic boutons, dendritic branches, and spines. The common theme is that a part or all of the juvenile structures are eliminated at later stages of development.

Leaving overproduction of neurons aside, two kinds of developmental exuberance have been described over the last 30 years. Both are involved in the construction of neural circuits.

Macroscopic exuberance refers to the formation of transient projections (and/or connections) between macroscopic partitions of the brain; it includes transient afferent and efferent projections between a cortical site and other macroscopic subdivisions of the brain, such as cerebellum, subcortical nuclei, spinal cord, or cortical areas. Microscopic exuberance refers to the formation, within a restricted cortical territory, of transient structures involved in the communication between neurons; it includes the formation of transient axonal and dendritic branches and/or synapses. Some of the transient structures, but not all, are formed within layers and/or columns where they are no longer found in the adult.

The distinction between the two types of exuberance is not always sharp, and it is essentially based on the methods used. In particular, in studies of synaptic counts, performed at the electron microscopic level, the origin of the supernumerary synapses could not be determined. In some systems of connection there is a smooth transition from macroscopic to microscopic exuberance: the production of exuberant structures becomes progressively more topographically circumscribed, as if the target was reached by progressively refined approximations.

1.15.3 Methodological Issues

Neuronal connections are usually assessed by tracers that are either actively transported or diffuse along axons driven by concentration gradients. Nevertheless, the usage of most tracers in the developing brain can be problematic. Uptake, transport, and diffusion of tracers can vary with age. This is particularly true with the lipophilic tracers of the DiI-DiO family, which tend to mark better the young unmyelinated axons and much less, or not at all, the older and myelinated ones. The existence of tracer-permeable gap junctions and leaky membranes in the young brain raises the possibility of transneuronal diffusion of tracers, producing false-positive results. Finally, tracers tend to be less effectively taken up and/or transported in the young nerve tissue, therefore failing to visualize connections which, if more mature, can be readily visualized. In some of the studies summarized below, particularly for the callosal connections of the cat, the same projections were studied at different ages with different tracers (horseradish peroxidase (HRP), wheat germ agglutinin (WGA)-HRP, fluorescent tracers, including fast blue and diamidino yellow, fluorescent beads, lipophilic tracers, and biocytin). Unfortunately this is not the case for other projections. The possibility that some juvenile connections may have been missed due to insufficiently sensitive tracing conditions must be kept in mind in the interpretation of negative results.

Another difficulty in using tracers in the developing brain is that certain target structures can undergo complex reshaping due to displacement of neuronal populations. Thus, what might appear to be a transient projection could in fact be a projection to the appropriate target, but which has not yet reached its final location. A protection against the latter type of artifact is provided by tracers that can remain in the neurons for a long time, without

being metabolized or eliminated. Tracers of this kind, e.g., fast blue and fluorescent beads, allow us to take snapshots of the state of the same connection at different developmental stages (Innocenti, 1991; O'Leary, 1992). They also permit the differentiation of neuronal death from axonal elimination in the deletion of the transient connections.

While the magnitude of exuberance and elimination can be difficult to estimate, it is clear that some projections are fully eliminated. This is the case, for example, in the corticofugal projections to the spinal cord or to the cerebellum. The most satisfactory quantification, however, comes from electron microscopic studies. These studies have shown a loss of 70% of the callosal axons in both cat and monkey, although this figure might still underestimate the real loss (below).

1.15.4 Exuberant Projections/ Connections in Cortical Development

The first demonstration of macroscopic exuberance in development, i.e., of the formation of long/transient projections, came from the study of connections between the visual areas of the two hemispheres in the cat (Innocenti *et al.*, 1977; reviewed in Innocenti, 1991; O'Leary, 1992). Parts of areas 17 and 18 devoid of callosal connections in the adult exhibited transient projections to the contralateral hemisphere at birth. The elimination of the projections was fast, and was mostly terminated by postnatal day 21, although some elimination might have continued until day 30 and beyond. The elimination was due to selective loss of axons and the neurons, giving rise to the transient callosal projections, forming permanent connections in the ipsilateral hemisphere, by selection of collaterals. These findings were confirmed and extended by the demonstration of exuberant callosal connections between the somatosensory areas, and of projections from cerebral cortex to the spinal cord, cerebellum, and to other cortical areas. Particularly striking among the latter was the discovery of transient projections from the auditory to the visual cortex in both hemispheres in the cat (reviewed in Innocenti, 1991). Equally striking was the more recent demonstration of exuberant projections from the temporal cortex of the monkey into limbic structures (Webster *et al.*, 1991a, 1991b). Finally, the work of several groups focused attention on the microscopic aspects of exuberant connections by showing how elimination of axon collaterals of pyramidal neurons leads to the formation of local, clustered connections. Exuberant intra-areal axons were also described: within sublayers, in the monkey area 17, and as long tangential axons spanning the white matter under area 17 in the cat. In the cat, callosal axons, both those that are maintained and those that are later eliminated, initially form transient branches, first in the subplate and then in the gray matter (Aggoun-Zouaoui *et al.*, 1996; Bressoud and Innocenti, 1999). In addition, the number of synaptic boutons produced in the gray matter overshoots the adult number (Aggoun-Zouaoui *et al.*, 1996; Bressoud and Innocenti, 1999). As mentioned above, it appears that the production of exuberant axonal structures becomes progressively more topographically circumscribed, as if the target were reached by correspondingly more refined approximations. Similar events were described in the striate and extrastriate areas of the cat (Bressoud and Innocenti, 1999).

1.15.5 Exuberance and Selection versus Connectional Specificity

Developmental exuberance in no way excludes the existence of selectivity and order in the formation of the juvenile projections/connections. Both might be the expression of cellular specificities responsible for guiding growing axons along given pathways and determining their choice of a target. Most of the evidence has been gathered in studies of visual callosal connections in the cat.

First, the juvenile corticocortical connections, including the exuberant ones, are topographically organized from their early stages. Thus, injections of tracers spaced in the anteroposterior direction in one hemisphere label correspondingly spaced territories in the other hemisphere. Second, the cortical projections exhibit laminar specificity from the earliest stages in development. Corticocortical axons mainly originate from layers 3 and 6, although the relative contribution of the two layers to a given projection can change in development, due to the elimination of exuberant projections from layer 3. Third, from the earliest stages of their development, cortical axons can be classified into different types based on their pattern of projection to areas in the contralateral hemisphere. Interestingly, this targeting specificity includes axons that establish transient projections. This suggests that the whole projection, including both the transient and the permanent fractions, consists of a mosaic of cell types with different growth/targeting specificities (Bressoud and Innocenti, 1999). Finally, origin-to-target

selectivity is expressed at the time axons grow near, and into their terminal sites. Irrespective of their final fate, both callosal and intrahemispheric axons reach the white matter/gray matter border, which contains a largely transient neuronal population, the subplate, where they branch profusely. Then, the axons to be maintained invade the gray matter, where they develop terminal arbors and synapses, while the transient axons remain mainly in the white matter and are subsequently eliminated.

After entering the gray matter, axons exhibit further specific growth. Axonal branching and the formation of synapses are progressively focused on the sites of adult termination, although transient branches and synapses are also formed (Bressoud and Innocenti, 1999). The overproduction and elimination of synapses occur without noticeable changes in the topography of the connections, although presumably it modifies the strength of the connections.

1.15.6 Testing the Role of Exuberance in the Evolution of Cerebral Cortex

The hypothesis that exuberant development of connections could provide a permissive mechanism favoring cortical evolution can be tested against a number of potentially invalidating conditions. Exuberant development of connections should be found across species and systems. The fate of the juvenile connections, whether maintenance or elimination, should be modulated by factors that could have operated during the evolution. Finally, one might expect a greater developmental plasticity of cortical connections in areas that underwent the most massive evolution.

1.15.6.1 Exuberant Development Is Found across Phylogenetically Distant Species

Transient, exuberant projections/connections occur across all the mammalian species that have been studied (Table 1). Most of the studies have involved rodents, carnivores, and primates. However, exuberant corticocortical and/or corticofugal projections have also been demonstrated in rabbit and opossum. These findings can be mapped on to the evolutionary trees of the mammalian radiation (Figure 1). The fact that exuberant projections in development span widely across the mammalian radiation suggests that they were indeed present in the ancestors of most or all the extant mammals, as required by the hypothesis that they played a role in evolution.

1.15.6.2 Exuberant Development Is Found across Systems of Cortical Connections

Exuberant development occurs in several different types of cortical connections, including interhemispheric, intrahemispheric, and local connections, as well as the corticofugal connections. Sensory, motor, and association areas are involved. This is not to say that the magnitude of exuberance/elimination is the same for the different species, systems, and types of connection (Barone *et al.*, 1996), although cross-species comparisons must be made prudently, given the above-mentioned difficulties in the quantification of the transient projections. Furthermore, cross-species comparisons can be complicated by different speeds of axonal development. Interestingly, electron microscopic counts of callosal axons have provided similar estimates of elimination in cat and monkey (reviewed in Innocenti, 1991). However, this similarity might be fortuitous since both studies lack an estimate of the life span of individual axons. Obviously, if the life span of the transient axons differed in the two species, the quantitative estimates of axonal exuberance/elimination would have to be corrected.

The occurrence of developmental exuberance in the different kinds of cortical connections suggests that the newly emerging areas are able to establish an adequate complement of connections in evolution. However, different cortical territories might differ with respect to the type and/or amount of transient, exuberant projections they send and/or receive in development. These hypothetical differences might have favored the emergence of new cortical areas at some specific locations. Thus, precise estimates of the exuberant connectivity of the different cortical territories in a given species might hint at their evolutionary potential.

1.15.6.3 Multiple Factors Regulate the Maintenance/Elimination of Exuberant Connections

Transient connections can be maintained or eliminated by experimental manipulations of the developing cortex.

Although these conditions do not necessarily mimic the evolutionary history of the cerebral cortex, they highlight the mechanisms whose alteration in evolution could have affected the development of corticocortical connections. Particularly important is the evidence linking maintenance/elimination of the juvenile connections to information coming from the sensory periphery, since in evolution changes in body and brain

Table 1 Transient (exuberant) axonal projections in development cerebral cortex (1976–2004)

Species	*Thalamocortical*		*Callosal*		*Intrahemispheric/area*		*Corticofugals*	
	Macro	*Micro*	*Macro*	*Micro*	*Macro*	*Micro*	*Macro*	*Micro*
Rodents (rat, hamster, mouse)	38, 48, 51	61	30, 31, 38, 49, 52		38		1, 5, 14, 15, 29, 50, 54, 62	32, 47
Carnivores (cat, ferret)	7	33, 34, 35, 39	2, 6, 22, 24, 25, 26, 27, 28	2, 3, 6	4, 17, 19, 25, 56, 53	10, 11, 41, 42, 58	8, 40, 46, 63, 64	
Primates (rhesus)	16, 45	59	12, 18, 37		36, 65	60	23	
Others, (rabbit, opossum)			13				9, 20, 21	

Macroexuberance refers to situations where the projection is probably due to long axons.
Microexuberance refers to situations where the projection is due to local branches or synapses. In some cases, however (e.g., in the case of electron microscopic synaptic counts or anterograde transport data), the two conditions cannot be easily differentiated.
Dehay *et al.* (1988a) reported exuberant callosal projections from area 18 of the rhesus monkey but not from area 17.

had to be coordinated. Strong evidence has accumulated that maintenance and elimination of callosal connections may be under the control of thalamocortical input, conveying information originating more peripherally, in the retina, in the case of the visual system. Studies in the cat and in the rat have shown that callosal as well as corticocortical connections require retinal input for their maintenance (reviewed in Innocenti, 1991; Zufferey *et al.*, 1999). The first evidence of the role of peripheral input in shaping callosal connections came from the work of Shatz (1977), demonstrating abnormal callosal connections in the Siamese cat, as a consequence of the abnormal crossing of retinal axons in this species. The finding that visual callosal axons are either lost or altered in animals binocularly deprived of vision by eyelid suture or eye enucleation (reviewed in Innocenti, 1991) stressed the role of the periphery, mediated in part by activity, in selection of the juvenile axons. The fact that the axons surviving the binocular deprivation are stunted brought further support to the notion that the periphery controls the development of the connections (Zufferey *et al.*, 1999).

Perhaps the strongest argument indicating that evolution did indeed operate through a periphery-driven selection of exuberant connections in development is provided by the analysis of callosal connections at the border between visual areas 17 and 18 in different species. As reviewed by Olavarria (2001), the width of the callosally connected region near the 17/18 border varies across mammals. The callosally connected region near the 17/18 border represents portions of the visual field close to the representation of the visual field midline. It follows that in different species, different fractions of these areas, and consequently different extents of the visual field representations, ought to be callosally connected. Indeed, at comparable elevations, the portion of the visual field represented in the callosally connected portion of the visual areas appears to be wider in the ferret, where it includes azimuths well beyond 25° (Manger *et al.*, 2002a) than in the cat, where it seems not to exceed 15° (Payne and Siwek, 1991). Since in all mammals (including the ferret; Innocenti, unpublished observations) the visual callosal connections develop by exuberance, one can safely infer that some of the projections that are normally transient in one species are maintained in another.

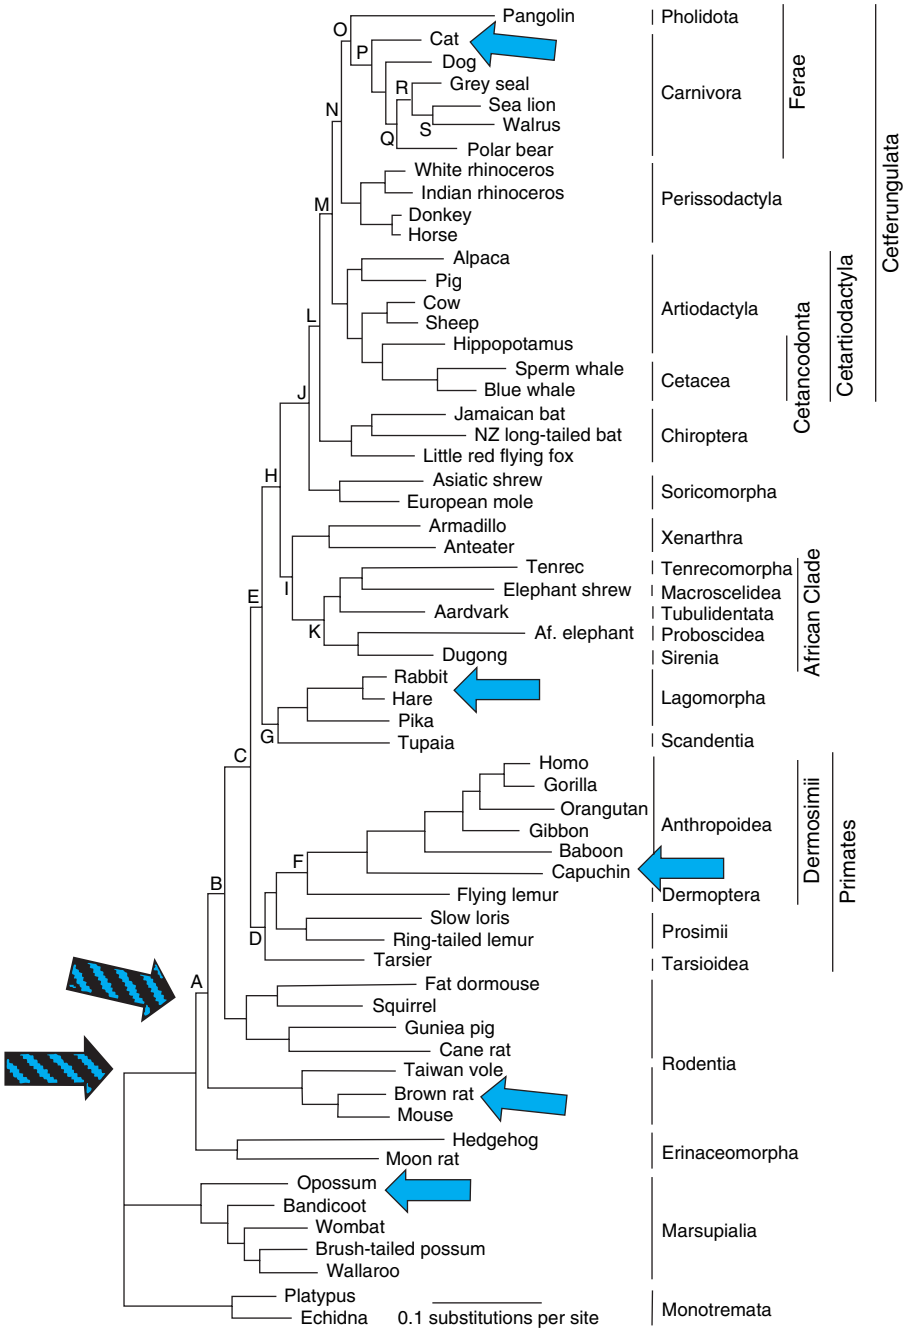

Figure 1 Exuberant connections in development were reported in a number of species (small arrows). This suggests that this mode of development appeared in the earliest ancestors of mammalian radiation (large hatched arrows) and was preserved in evolution. Adapted from Arnason, U., Adegoke, J. A., Bodin, K., *et al.* 2002. Mammalian mitogenomic relationships and the root of the eutherian tree. *Proc. Natl. Acad. Sci. USA* 99, 8151–8156. 1.15.6.4 More Developmental Plasticity in Cortical Areas Which Evolved More?

Any hint of developmental processes capable of channeling evolution might reveal a source of directedness in the otherwise haphazard emergence of the phenotype by trial and error, which is the legacy of classical Darwinism. Some hypotheses on directedness in the evolution of cortical areas can be derived from what has been discussed above. First, the emergence of cortical areas might have been favored at certain specific locations within the cortical surface. These locations should be those with the richest complement of afferent and efferent exuberant projections in

development. Second, areas at these locations might have evolved to a large extent under the pressure of information coming from the body periphery. Third, these newly emerged areas might also be endowed with the highest degree of developmental plasticity.

Large differences exist in the number of cortical areas across species, but they are probably greatest in the parietal, temporal, and prefrontal cortex. It is unknown whether developmental exuberance is largest in these areas, as would be required by the first of the hypotheses discussed above, although this would only be an approximation of the developmental differences in the ancestors. Consistently with the second hypothesis proposed above, only two areas seem to exist in the posterior parietal cortex of the ferret (Manger *et al.*, 2002b). This is far from the complexity found in the monkey, even taking into account the possibility that some areas might have been missed in the ferret. These differences can be tentatively ascribed to the much more complex repertoire of hand and eye movements, and eye–hand coordination in the monkey compared to the ferret.

Consistently with the third hypothesis mentioned above, experiments with early lesions have revealed an important reorganization of connections in the parietal cortex of the ferret (Restrepo *et al.*, 2003). Similarly, lesions in the temporal cortex of the newborn monkey led to the stabilization of otherwise transient connections (Webster *et al.*, 1991a, 1991b).

1.15.7 Conclusions

Language-related areas are among the most recent acquisitions of the mammalian brain. The integration of these areas into the cortical network, and more generally the functional and structural lateralization of the human brain, would not have been possible without a massive reorganization of corticocortical connectivity, in particular of callosal connections. In this article, I have developed some arguments in favor of the view that developmental exuberance, an interesting blend of directedness and groping around of axons in the formation of cortical connections, appeared early in evolution and was maintained through phyologenesis. Indeed, the exuberant juvenile axonal projections/connections provided the substrate from which new connections could be selected. At the same time, the rules underlying the selection, including information coming from the periphery, channeled evolution. Perhaps the maintenance of rule-driven but flexible developmental syntaxes might be the best key to apprehending how evolution, unlike human-directed mutagenesis, generated the multitude of viable brain architectures we know.

1.16 Neural Wiring Optimization

C Cherniak, Z Mokhtarzada, and R Rodriguez-Esteban, University of Maryland, College Park, MD, USA

Glossary

adjacency rule	"If components are connected, then they are adjacent." A wire-saving heuristic for laying out a system; also a simple wire-cost measure for such layouts.
component placement optimization	The positioning of a system of interconnected components to minimize total connection cost.
network optimization theory	The characterization of minimized use of limited connection resources (e.g., wire length) in a system.
NP-hard	A set of problems, each conjectured to require computation time typically on the order of a brute-force search of all possible solutions, and often therefore intractable.
size law	For some optimized systems, the smaller a subset, the poorer its optimization.
Steiner tree	A minimum-cost arbor connecting a set of terminal loci, which may include branch junctions not at terminals.

Long-range connections in the brain are a critically constrained resource, hence there may be strong selective pressure to finely optimize their deployment. The formalism of scarcity of interconnections is network optimization theory, which characterizes the efficient use of limited connection resources. The field matured in the 1970s for microcircuit design, typically to minimize the total length of wire needed to make a given set of connections among components. When this simple 'Save wire' idea is treated as a generative principle for nervous system organization, it turns out to have applicability: to an extent, 'instant brain structure – just add wire minimization'. The most salient caveat is that, in general, network optimization problems are easy to state, but enormously computationally costly to solve exactly; those reviewed here are NP-hard. We focus on the Steiner tree concept and on component placement optimization, with emphasis on the latter.

1.16.1 Neuron Arbor Optimization

The basic concept of an optimal tree is as follows: given a set of loci in 3-space, find the minimum-cost tree that interconnects them, e.g., the set of interconnections of least total volume. If branches are permitted to join at sites other than the given terminal loci (the leaves and root), the minimum tree is of the cheapest type, a Steiner tree. If the synapse sites and origin of a dendrite or axon are treated in this way, the optimization of the dendrite or axon can be evaluated. Approximately planar arbors in 2-space are easier to study. The most important feature of naturally occurring arbors – neuronal, vascular, plant, water drainage networks, etc. – is that, unlike much manufactured circuitry, for each internodal junction, trunk costs (e.g., diameter) are higher than the two branch costs. When such Y junctions are examined in isolation, positioning of the junction sites shows minimization of total volume cost to within approximately 5% of optimal (Cherniak, 1992). Furthermore, the relation of branch diameters to trunk diameter fits a simple fluid-dynamical model for minimization of wall drag of internal laminar flow: neuron arbors act like flowing water.

This Y-tree cost minimization constitutes local optimization. Only one interconnection pattern or topology is involved. Such small-scale optimization does not entail larger-scale optimization, where local trade-offs are often required. When more complex portions of a total arbor are analyzed, the optimization problem becomes a global problem, with an exponentially exploding number of alternative possible interconnection topologies. For example, a nine-terminal tree already has 135 135

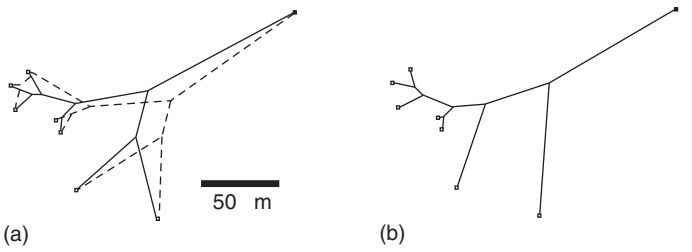

Figure 1 Actual vs. optimal neuron arbors, mouse thalamus extrinsic axon, ascending reticular formation (from data of Scheibel and Scheibel, 1966). The arbor best fits a minimized-volume model. a, Wire-frame representation of an eight-terminal subtree of an observed arbor. Actual tree, with actual topology in its actual embedding, appears as dashed lines. Optimal embedding with respect to volume minimization of the actual topology is superimposed as solid lines. The cost in volume of the actual arbor exceeds that of the optimized embedding of its topology by 2.20%. b, "Best of all possible topologies" connecting the given terminal loci: the optimal topology with respect to volume, optimally embedded. The volume cost of the actual arbor exceeds that of the optimal topology by 2.47%. Only 10 of the 10 395 possible alternative topologies here (approximately 0.14%) have lower total volume costs, when optimally embedded, than the actual topology (Cherniak *et al.*, 1999).

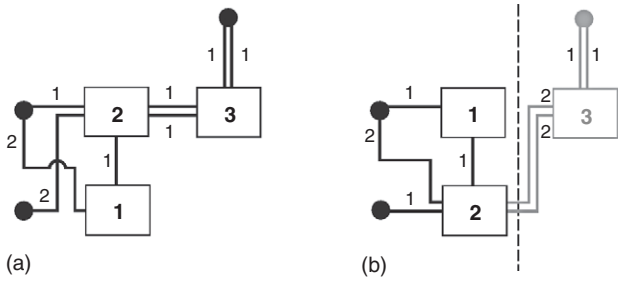

Figure 2 Simple illustration of component placement optimization: minimization of total length of connections. The complete system here consists of a 2-D array of movable components (1, 2, and 3) with given interconnections. All connections are of equal cost per unit length. Component 1 connects to a fixed edge terminal and also to 2; component 2 connects to two fixed edge terminals, and to 1, and also twice to 3; component 3 also connects twice to a fixed edge terminal. a, A globally optimal layout of the three components (cost: 10); cost includes a decussation (connection crossing). b, A complete layout that lacks the decussation, but now is suboptimal (cost: 11). Note also that if the system subset is restricted to only components 1 and 2, including connections to edge terminals, then their layout in (b) is cheaper than their layout in (a), with total connection length reduced from 6 to 5. Hence, these layouts also illustrate global optimization (a) at the trade-off expense of a locally suboptimal cost (b); connection minimization of a total system does not entail connection minimization of its subsets. (A similar pattern holds here for the simpler connection cost measure of adjacency-rule violations explained in text (Cherniak *et al.*, 2004).)

alternative topologies, each of which must be generated and costed to verify the best solution (see Figure 1). Neuron arbor samples, each with three internodal Y junctions, minimize their volume to within approximately 5% of optimal (Cherniak *et al.*, 1999). This optimality performance is consistent for dendrites (rabbit retina ganglion and amacrine cells, and cat retina ganglion cells) and also for some types of axons (intrinsic and extrinsic mouse thalamus).

1.16.2 Component Placement Optimization

Another key problem in microcircuit design is component placement optimization (also characterized as a quadratic assignment problem): given a set of interconnected components, find the placement of the components on a two-dimensional (2-D) surface that minimizes the total cost of connections (e.g., wire length). Again, this concept seems to account for aspects of neuroanatomy at multiple hierarchical levels.

"Why the brain is in the head" is a one-component placement problem. That is, given the positions of receptors and muscles, positioning the brain as far forward in the body axis as possible minimizes total nerve connection costs to and from the brain, because more sensory and motor connections go to the anterior than to the posterior of the body. This seems to hold for the vertebrate series (e.g., humans) and also for invertebrates with sufficient cephalization to possess a main nervous system concentration (e.g., nematodes).

Multiple-component problems again generally require exponentially exploding costs for exact solutions; for an n-component system, $n!$ alternative layouts must be searched (see Figure 2). One neural wiring optimization result is for placement of the 11 ganglionic components of the nervous system of the

roundworm *Caenorhabditis elegans*, with ~1000 interconnections. This nervous system is the first to be completely mapped (Wood, 1988), which enables fair approximation of wire lengths of connections. When all 39 916 800 alternative possible ganglion layouts are generated, the actual layout turns out in fact to be the minimum wire-length layout (Cherniak, 1994a). Some optimization mechanisms provide convergent support for this finding: a simple genetic algorithm, with wire cost as fitness measure, will rapidly and robustly converge on the actual optimal layout (Cherniak *et al.*, 2002). Also, a force-directed placement (mesh of springs) algorithm, with each connection approximated as a microspring acting between ganglion components, attains the actual layout as a minimum-energy state, without much trapping in local minima (Cherniak *et al.*, 2002).

There is statistical evidence that this brain as microchip framework also applies in the worm down to the level of clustering of individual neurons into ganglionic groups and to soma positioning within ganglia to reduce connection costs (Cherniak, 1994a).

Finally, the wiring-minimization approach can be applied to placement of functional areas of the mammalian cerebral cortex. Since wire lengths of intrinsic cortical connections are difficult to derive, one strategy is to explore a simpler measure of connection cost, conformance of a layout to an adjacency rule: if components *a* and *b* are connected, then *a* and *b* are adjacent. An exhaustive search of all possible layouts is still required to identify the cheapest one(s). One promising calibration is that the actual layout of the nematode ganglia is among the top layouts with fewest violations of this adjacency rule. For 17 core visual areas of macaque cortex, the actual layout of this subsystem ranks in the top 10^{-7} layouts best fitting this adjacency costing; for 15 visual areas of cat cortex, the actual layout ranks in the top 10^{-6} of all layouts (Cherniak *et al.*, 2004; see Figure 3) (see The Role of Vision in the Origin and Evolution of Primates, Primate Brain Evolution in Phylogenetic Context, Visual Cortex: Evolution of Maps and Mapping, Captured in the Net of Space and Time: Understanding Cortical Field Evolution, The Evolution of Visual Cortex and Visual Systems).

In general, a Size Law seems to apply to cases with such local–global trade-offs: the larger proportion of a total system the evaluated subsystem is, the better its optimization (see Figure 4). Similar findings have also been reported for rat olfactory cortex and for rat amygdala (Rodriguez-Esteban and Cherniak, 2005). For the largest systems studied (visual, auditory, and somatosensory areas of cat cortex), there is evidence of optimization approaching limits of current detectability by brute-force sampling techniques. A similar Size Law pattern also appears to hold for Steiner tree optimization of neuron arbor topologies (see Figure 1). The

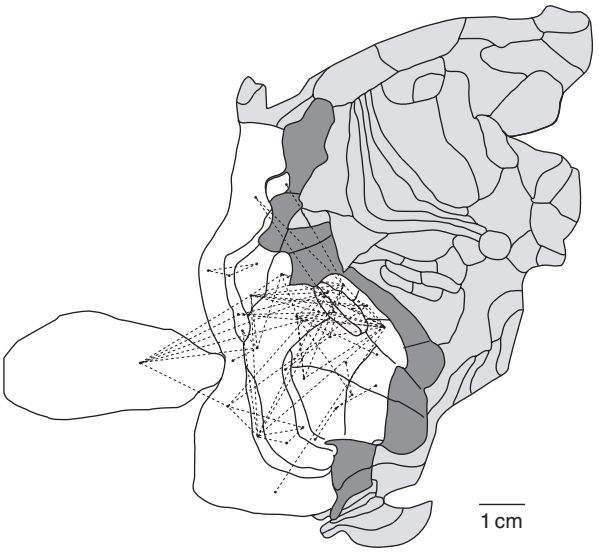

Figure 3 Parcellation of functional areas of macaque cerebral cortex (after Felleman and Van Essen, 1991). Component placement optimization analysis of a layout of 17 core areas (white) of visual cortex, along with immediately contiguous edge areas (dark gray). Reported interconnections among core areas are indicated by dotted lines. Rostral is to the right. In a connection cost analysis, this actual layout of the core visual system ranks in the top one-millionth of all alternative layouts (Cherniak *et al.*, 2004).

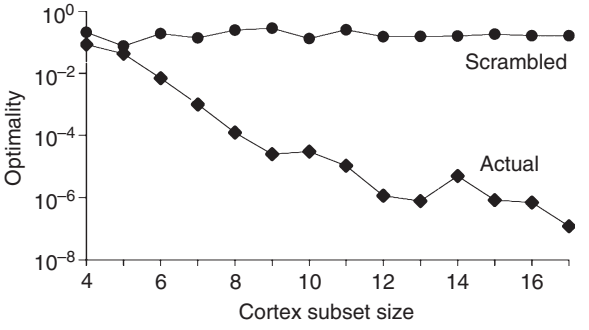

Figure 4 Size Law for macaque visual cortex areas. The system of components here consists of 17 contiguous visual areas of macaque cortex, as in Figure 3. A layout is scored in terms of its violations of the adjacency rule. A series of nested compact subsets of the set of visual areas was generated; each subset was compared with all possible alternative layouts of that subset for adjacency-rule optimality. As subset size increases, optimality ranking of the actual layout consistently improves (with two exceptions, $p < 0.02$). For comparison, the corresponding analysis for a layout of the 17 visual areas with their adjacencies randomly shuffled shows no trend toward improving optimality. Note that this analysis includes only 17 of the total 73 areas of macaque cortex.

picture then is of limited connections deployed very well, a predictive success story. The significance of ultrafine neural optimization remains an open question. Levels of connection optimization in the nervous system seem unlike levels of optimization elsewhere in organisms.

1.16.3 Optimization: Mechanisms and Functional Roles

Mechanisms of neural optimization are best understood against the background that the key problems of network optimization theory are NP-complete, hence exact solutions in general are computationally intractable. For example, blind trial and error exhaustive search for the minimum-wiring layout of a 50-component system (such as all areas of a mammalian cerebral cortex), even at a physically unrealistic rate of one layout per picosecond, would still require more than the age of the Universe (Cherniak, 1994b). Instead, even evolution must exploit quick and dirty approximation/probabilistic heuristics.

One such possible strategy discernible above is optimization for free, directly from physics. That is, as some structures develop, physical principles cause them automatically to be optimized. We reviewed above some evidence for arbor optimization via fluid dynamics, and for roundworm ganglion layout optimization via mesh of springs force-directed placement simulation. Although neuron arbors appear to optimize on an embryological timescale, component placement optimization appears to proceed much more slowly, on an evolutionary timescale. For component placement optimization, there is the chicken–egg question of whether components begin in particular loci and make connections, or instead start with their interconnections and then adjust their positions, or some mix of both causal directions. It is worth noting that both a force-directed placement algorithm for ganglion layout and genetic algorithms for layout of ganglia and of cortex areas suggest that simple 'connections → placement' optimization processes can suffice.

Wiring optimization is, of course, subject to many basic constraints and so cannot be ubiquitous in the nervous system; the question is where it does in fact occur and how good it is. Trade-offs of local optimality for better cost minimization of a total system (as Figure 2 illustrates) are one way in which global optimization can be obscured.

If the brain had unbounded connection resources, there would be no need or pressure to refine employment of wiring. Thus, to begin with, the very fact of neural resource limitations appears to drive 'Save wire' fine-grained minimization of connections. Another part of the functional role of such optimization may be the picture here of 'physics → optimization → neuroanatomy'. Perhaps such an economical means of self-organizing complex structure generation eases transmissibility through the information bottleneck of the genome. This constitutes a thesis of nongenomic nativism that some innate complex biological structure is not encoded in DNA, but instead derives from basic physical principles (Cherniak, 2005).

1.17 Principles of Brain Scaling

C F Stevens, The Salk Institute, La Jolla, CA, USA

Glossary

allometry A relationship between the sizes of two biological structures or other quantities that follows a power law. For example, suppose that L is the average length of an animal's life (a biological quantity) for a particular species, and W is the average weight for adults of that species (a measure of total animal size). Further suppose that, across species in some taxonomic group, the length of life is related to body weight by the equation $L = aW^b$ for some quantities a and b that are independent of both L and W. This relationship would constitute an allometry, and lifetime would be said to have an allometric relation to animal size. The constant a is called the scale factor and b is known as the allometric constant for the two quantities L and W.

grade shift If an allometric relationship holds for two different taxa with the same allometric constant but different scale factors, it is said that a grade shift has occurred. For example, there is an allometric relationship between brain size and body weight for both monkeys and teleost fish, but monkeys have larger brains; that is, a monkey always has a larger brain than a fish of the same weight, although a tiny monkey might have a smaller brain than a giant fish.

isometry An isometry is a special case of an allometry for which the allometric constant is unity. That is, two biological quantities are said to be isometric when they are related by a simple proportionality.

map Brain areas, like the thalamus or visual cortex, are said to have a map when the neurons are arranged in a way that preserves the neighbor relationships present in some reference structure. For example, the visual world is projected onto the retina, and the neighbor relations in the visual world are preserved in the projection of the retina to the visual thalamus, and from the visual thalamus to the visual cortex. Thus, both the visual thalamus and the visual cortex have a map of the visual world (the reference structure). Although a map must preserve neighbor relations, in general, other features may not be preserved: ordinary two-dimensional maps of the world keep things on the globe next to each other, but they change the size and shape of the continents. It is generally believed that all brain structures have maps but – as for language cortex or the olfactory cortex, for example – we do not know the reference structure for the map.

scalable architecture A term from computer science that refers to designs for computing circuits that can be made more powerful – that is, can carry out the computation for which they were intended more quickly or accurately – by simply increasing the size of the circuit (by, for example, increasing the number of computing elements) while keeping the same design. Familiar digital computers do not have a scalable architecture, which means that they must be redesigned each time their power is increased.

self-similar function A function that depends on parameters which change its size on a graph without changing its shape. A Gaussian is an example of a self-similar function because a plot of it still has the familiar bell-shape even when its parameters (its mean and standard deviation) are changed.

1.17.1 Introduction

The extent to which the brains of all mammals share a common design is striking: even though the brains of mammalian species vary in size by more than three orders of magnitude, the essential features of their design are unchanging (Butler and Hodos, 1996; Striedter, 2005; see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates, Primate Brain Evolution in Phylogenetic Context, The Evolution of Parallel Visual Pathways in the Brains of Primates, Brain Size in Primates as a Function of Behavioral Innovation, Constraints on Brain Size: The Radiator Hypothesis). This observation means, for example, that rodent, feline, and nonhuman primate brains can serve as model systems for studying principles of structure and function that apply to the human nervous system. From a computational perspective, then, one of the most remarkable features of the mammalian brain is that it has a scalable architecture (Comer, 2005). That is, the computational power of a brain can be increased continuously and gracefully by adding more components while adhering to a single basic design.

Understanding the scalable architecture of the mammalian brain is clearly important for determining how neuronal circuits are designed and how they compute (see The Evolution of Encephalization). And to elucidate scalability, one must learn the rules followed when brain size and computing power are increased. An important quantitative tool for investigating scalability is allometry (Huxley, 1932; Schmidt-Nielsen, 1984), the study of how the size of one part of the brain scales up with the size of another part as the entire brain is enlarged. The rules that describe the relationship between the sizes of two different structures in brains of different sizes are called allometries, or allometric relations, or scaling relations. Two examples of allometric (or, equivalently, scaling) relations are illustrated in Figure 1, where the size of primary visual cortex (V1) – the first cortical processing center for visual information – in various primates is compared with the size of the lateral geniculate nucleus (LGN), the immediate source of the cortex's visual information. Two different measures of size are used here. In Figure 1a, the volume of V1 for a range of primate species is plotted, on double logarithmic axes, as a function of the volume of the LGN (Stephan *et al.*, 1981; Frahm *et al.*, 1984). The relationship is linear on this double logarithmic plot with a slope of 1.125. The sizes of the same two structures are compared again (for the same primate species) in Figure 1b, this time with size being measured by the number of neurons present in each structure rather than by volume; that is, Figure 1b presents the logarithm of the number of cortical neurons processing visual information (the number of neurons in V1) as a function of the logarithm of the number of neurons providing that information (the number of neurons in the LGN) (Stevens, 2001). As before, the data points fall along a straight line, but this time the slope of the line is $3/2 = 1.5$, not 1.125. Here, then, are two scaling laws – allometric relationships – that describe aspects of visual system scalability, and any theory of how the visual system processes information must account for these scaling relationships.

1.17.2 The Interpretation of Scaling Laws

The relationships in Figure 1 have a particular functional form; they are power laws

$$S = as^b,$$

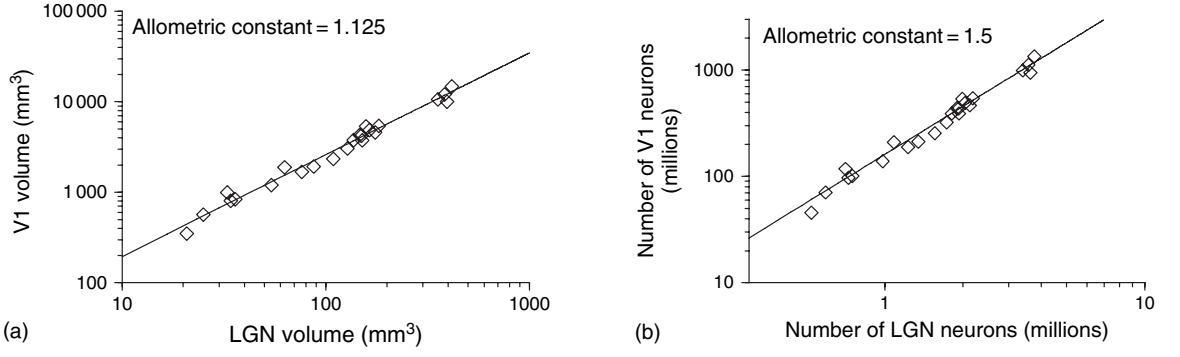

Figure 1 Relationship between the size of primary visual cortex (V1) and the lateral geniculate nucleus (LGN) for 23 primates (haplorhines). a, Size of the two structures is measured as volume (mm^3). The allometric constant is 1.125. b, Size of the two structures is measured in numbers of neurons in each. The allometric constant is 1.5.

with S being the size of the cortex, s the size of the LGN, and a and b constants ($b = 1.125$ in Figure 1a and 1.5 in Figure 1b). Taking the logarithm of this equation, one finds that

$$\log S = b \log s + \log a,$$

an equation with the form

$$y = bx + c$$

if one defines $y = \log S$, $x = \log s$, and $c = \log a$. This means that, on a double logarithmic plot like the ones in Figure 1, a power law results in a straight line with slope b and intercept of $c = \log a$. The constant a is called the scale factor, and the constant b is known as the exponent or the allometric constant. Note that if the exponent $b = 1$, the allometric relationship becomes a simple proportionality

$$S = as.$$

Clearly, although power laws result with either measure of structure size (structure volume in Figure 1a as opposed to number of neurons in Figure 1b), the values of the allometric constants differ (1.125 vs. 1.5 in Figure 1) according to how size is measured.

The relationship displayed in Figure 1 is a power law, but the functional form might, in general, be some other type of function. For example, one could imagine that there might be some pair of variables R and r, representing the sizes of two hypothetical structures, for which the relationship is

$$R = a(1 - e^{-br}),$$

with constants a and b; this is an exponential rather than a power law. Although this exponential equation does relate the sizes of two structures, it would not count as an allometric relationship because the term allometry is reserved for just those pairs of structures whose sizes are related by a power law. Power laws arise in many situations, and their study has been particularly important in various areas of physics (Barenblatt, 1996).

Empirically, many pairs of brain structures have been found to follow power laws with various different allometric constants (Huxley, 1932; Schmidt-Nielsen, 1984; Striedter, 2005). In some of these cases, the actual functional form of the relationship is indeed a power law and, in other cases, the functional form is not really a power law but can be approximated as one over some restricted range of sizes. In general, just as almost any equation can be approximated over a limited range by a linear equation, so can almost any relationship describing the sizes of a pair of structures be approximated, on a double logarithmic plot, as a straight line (which is equivalent to a power law). I am concerned here with those situations that produce actual power laws – that is, true allometric relationships – and I will not consider (except for one case) why functional forms other than power law might occur.

In the following, I give three different ways that true allometric relations can arise. The first is the original interpretation, due to Julian Huxley, of differential growth; Huxley's view was that allometries arose when one structure grew faster than another (Huxley, 1932). If, on the other hand, the growth rate of two structures were always exactly the same, then the relative size of the structures would be constant and they would be said to have an isometric (as opposed to allometric) relationship to one another; this is a special case of the allometric relationship with the allometric constant $b = 1$.

A second way in which allometric relations can be generated is through the preservation of the form of structures. Often, one has the idea that structure and function are intimately related so that form must be evolutionarily preserved in order to preserve function. For example, the hand is a structure beautifully designed for fine manipulations of elements in the environment, and a single species keeps the same form of the hand for small and large individuals by changing hand size and also by altering some dimensions more than others (long, thin fingers as opposed to thick, stubby fingers). Allometric relations can be generated when the basic form of structures is maintained but is stretched in some directions more than in others as the organism is made larger. The production of allometric relationships in this way differs from Huxley's because it does not consider growth of structures but just properties of the final products. This idea is made more precise in an example below by considering what are called self-similar functions (Barenblatt, 1996).

A third possibility for generating allometric relations depends on the unfamiliar notion of changing dimensions in going from one structure to another (Stevens, 2001). For an example of how dimensionality can be changed by an operation, imagine illuminating a three-dimensional object from one direction so that it casts a shadow on a screen. This object (a three-dimensional first structure) casts a two-dimensional shadow on the screen (the second structure) and so one can say that, in some sense, a shadow forms a two-dimensional representation on the screen of a three-dimensional object in space as this object is made smaller and larger. The size of the shadow is related to the size of the object casting the shadow: for example, the area of the shadow will scale as the 2/3 power of the volume

of the object casting the shadow; the size of the two-dimensional shadow, then, will bear an allometric relationship to the size of the original three-dimensional object. As will be described below, certain types of computation can change the dimensions of the space used to represent the input and output of a computation, and this change in dimension can lead to allometric relations between the numbers of neurons in one structure and another.

1.17.3 Huxley's Allometry

How are the scaling laws in Figure 1 to be interpreted? As noted above, the linear relationships of the double logarithmic plots are equivalent to power laws. That is, if S is the size of V1 and s is the size of the LGN, these quantities are related by the power law equation

$$S = as^b,$$

where a and b are constants.

Huxley (1932) discovered a number of scaling relations – it was Huxley who coined the name allometric relation – and attributed them to the differential growth of the two structures being compared. To see how a power law can result from differential growth rates, suppose that one structure (for example, V1), whose size is $S(t)$, grows exponentially with a rate m for a growth duration t. At the end of the growth period, the cortical size would be

$$S = S_0 e^{mt},$$

where S_0 is the size of the structure at the start of the exponential period of growth. The actual final size of S would, of course, depend on the length of the growth period t. Suppose further that another structure (LGN, for example) with size $s(t)$ follows the same exponential growth law for the same growth duration t except this structure has a growth rate n and an initial size s_0; the size s of this second structure, then, is

$$s = s_0 e^{nt}$$

and it also depends on the growth duration t. If one takes the natural logarithm of these two equations and combines them by eliminating the growth duration t (which is assumed to have the same value in both equations), the result is

$$\log S = (m/n)\log s + [\log S_0 - (m/n)\log s_0].$$

That is, S is related to s by a power law whose exponent (or allometric constant) is $b = (m/n)$ and for which the scale factor a above is given by

$$\log a = [\log S_0 - (m/n)\log s_0].$$

For each growth duration, then, different sizes S and s will result, and these sizes are related by a power law. Thus, differential growth rates can lead naturally to scaling relations that are power laws.

1.17.3.1 Detail

The example just given assumed that the growth rate of the structures is constant throughout development and that structure size therefore increases exponentially. A power law results, however, from less restrictive assumptions. Specifically, the growth rate can vary with time during development for two structures and a power law will still result if the two growth rates vary the same way so one is always proportional to the other one.

Let $S_1(t)$ be the size of structure 1 at time t during development, and $S_2(t)$ be the size of a second structure at that time. These structures grow according to the equations

$$dS_1/dt = g(t)S_1(t) \quad \text{or} \quad dS_1/S_1 = g(t)\,dt$$

and

$$dS_2/dt = h(t)S_2(t) \quad \text{or} \quad dS_2/S_2 = h(t)\,dt,$$

where $g(t)$ and $h(t)$ are the growth rates at time t during development; note that the growth rate can vary over the course of development. Eliminate dt between these equations to give a growth equation for the pair of structures:

$$dS_1/S_1 = [g(t)/h(t)]\,dS_2/S_2.$$

If we suppose that the ratio $g(t)/h(t) = b$, where b is a constant – that is, if we suppose that $g(t)$ is proportional to $h(t)$ at all times with the proportionality constant b, even if the growth rates vary over time during development – then the growth equation becomes

$$dS_1/S_1 = b\,dS_2/S_2$$

and integrating this equation one finds that

$$\log(S_1) = b\log(S_2) + c$$

where c is a constant of integration. Thus, even if the growth rates change during development and the growth is not exponential (because growth rate is not constant), as long as the growth rates remain proportional to one another through the time of development, a power law relates the sizes of the two structures (S_1 and S_2) generated by different growth periods.

The problem with this differential-growth explanation for scaling is that one does not know why the growth rates should be different or by how much. A more complete explanation for the scaling relation,

then, would require either some notion of the mechanisms that lead to differential growth rates for two structures or for a reason why having differential growth rates suits the structures to their function. Two alternative explanations for allometric relations are considered below.

1.17.4 When Form Follows Function

Often in biology, the function of a structure and its form are intimately related. If the function is to be preserved as the size of the structure is changed, then the form must also be preserved in order to maintain the form/function connection. This sort of situation can give rise to allometric relations.

To illustrate how preserving form can yield scaling laws, picture a hypothetical axon, much like a retinal axon in the tectum, whose terminal branches form a flat, round disk-like arbor. For this illustration I imagine that all axons in a particular species have arbors of the same size. Suppose we wish to describe how this type of axon distributes synapses in the target structure (the tectum, for example) in a range of comparable species with different brain sizes. The job of this arbor is to distribute information over a map in the target brain area, and the way synapses are distributed should be preserved as the size of the arbor is increased. For example, the computations carried out by the circuit might require that an arbor produce an approximately Gaussian density of synapses over space, and so the form must always be one that will give a Gaussian distribution of synapses for any arbor size (Figure 2). I will denote the size of the target for a particular species by the variable s; this might be, for example, the average lateral length of the tectum, or its average surface area for that species, and I pick some particular species as a reference, for which I choose $s = 1$.

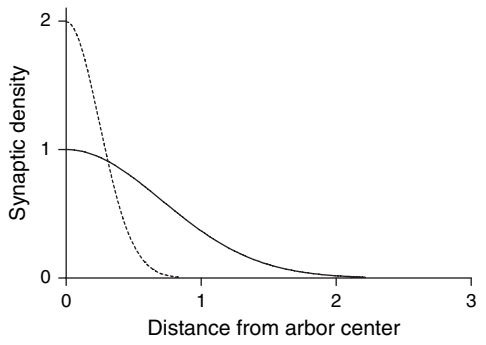

Figure 2 Hypothetical density of synapses formed by an axonal arbor as a function of the distance from the center of the arbor. Two different-sized arbors are depicted, a larger one (solid line) and a smaller, more compact one (dotted line). Both functions are Gaussians.

The size of target structure, then, is measured relative to the size in our reference species, so that, if $s = 3$, the target structure in that species would be three times the size in the reference species.

The average spatial distribution of synapses provided by the arbor will be given by the function $f(r,s)$, where r is the radial distance from the center of the arbor, s is the target size, and the value of the function f gives the average density of synapses in a circular annulus at a distance r from the arbor center. For example, $f(r,s)$ might be a Gaussian whose variance depends on s, as shown by the pair of functions in Figure 2. What does it mean to preserve the form of this arbor? The usual idea for maintaining form is to have the function f be self-similar, which means that its shape is unchanged when s is varied (Barenblatt, 1996); that is, the function might be stretched or compressed in the vertical (y) and horizontal (r) directions, and the amount of the stretching or compression would depend on s. But even when a Gaussian function is stretched in this way, it still is a Gaussian. For example, the function (dotted line) in Figure 2 results when the function presented in a solid line in Figure 2 is stretched vertically by 2 and horizontally by 1/4.

Now suppose we wish to compare the distribution of synapses in the target structure (tectum, for example) across a range of different species. If we take $f(r,1)$ to describe the density of synapses for an axon arbor in the target structure in our reference species (see Figure 2, for example) and if we want to preserve the shape of the function f, then the spatial distribution of synapses for the general target of size s is given by the relation

$$f(r,s) = u(s)f(r/v(s),1).$$

What this means is that, when the target size is s, you can find the spatial distribution of synapses by vertically stretching the distribution of synapses for the reference target by the amount $u(s)$ ($u(s) = 2$ in going from the solid to dotted function in Figure 2), and stretching horizontally by the amount $v(s)$ ($v(s) = 1/4$ in going from the solid to dotted function in Figure 2).

It is easy to see that the vertical stretch is specified by $u(s)$, but perhaps a little harder to understand how $v(s)$ determines the horizontal stretch (in the r-direction). The key is to observe that the value of a function (f in our example) depends on whatever is inside the parentheses $f(\ )$. When r is divided by $v(s)$, the function f decides its value based on the ratio $r/v(s)$ (not just on r), and if $v(s) > 1$, r has to be larger to get the same value of f as when $v(s) = 1$; this stretches the function out along the r-axis.

A remarkable feature of self-similar functions, which has been shown by mathematicians (Aczel, 1969), is that both the vertical and horizontal stretches must have a power law dependence on the size s. Specifically, $u(s)$ and $v(s)$ must both have the form

$$u(s) = as^b$$

and

$$v(s) = As^B$$

for some constants a, b, A, and B if the shape of the function $f(r,s)$ does not change with brain size and if $u(s)$ and $v(s)$ depend smoothly on the size s. Now go back to the synaptic distribution $f(r,s)$, make use of the power law form of $u(s)$ and $v(s)$, and add up the number of synapses in the arbor (integrate $f(r,s)$ over all values of r) to give the total number of synapses $n(s)$ made by each arbor in a target structure of size s. The result can be shown to be the scaling law for synapses per arbor as a function of target size given by

$$n(s) = n(1)s^k$$

for some constant k; here, $n(s)$ is the number of synapses made by an arbor in a brain with target size s and $n(1)$ is the number of synapses made by the reference arbor (whose target size is taken as 1). Thus, preserving the shape of an arbor's distribution of synapses as the target structure is increased or decreased in size results in an allometric relation; often, it is possible to interpret allometric relations in this way. Here I supposed for simplicity that there is only a single variable (r above) and a single parameter (s above for the size of the target structure), but the same sort of argument can be used when more variables are involved.

1.17.5 Changing the Number of Dimensions from One Map to the Next

In addition to differential growth and preserving the form of structures to maintain form/function relations, power laws can also result from certain types of computations and mappings that change the dimension of what is being represented. For example, a two-dimensional map can be transformed into a three-dimensional map, and this can lead to a 3/2 power-scaling law, as will be described below; this happens in the mammalian visual system between the LGN (with a two-dimensional map) and the V1 (which contains a three-dimensional map) (Stevens, 2001).

How can the dimension change in going from one map to another? Describing a curve in a plane – like a circle drawn on a piece of paper – requires two dimensions with an x- and y-coordinate for each point on the curve; Figure 3 (dashed line) illustrates, in perspective, a circle in the x–y plane. This two-dimensional circle can be mapped into three dimensions in a natural way by appending a third number to the (x, y) pair for each point on the circle. For example, each (x, y) pair can be made into an (x, y, z) triplet by setting z equal to the slope of a tangent to the curve at point (x, y). This is seen in Figure 3 (solid line), in which the circle has been 'lifted' into a three-dimensional curve by plotting the orientation of the tangent to the circle at each (x, y) point. Thus, the two-dimensional circle on a plane (dotted line in Figure 3) is transformed into a curve (solid line in Figure 3) in three-dimensional space. The three-dimensional curve can be changed back into the two-dimensional circle by projecting the three-dimensional curve on a plane (for example, by casting its shadow with illumination from above). The three-dimensional space depicted in Figure 3 is called the tangent space of the x–y plane because it not only specifies the position of the curve in the plane (from the (x, y) in each (x, y, z) triplet), but it also give the slope of the tangent to each point along the curve (the z in the (x, y, z) triplet).

When it comes to the brain, it may be slightly difficult to understand what one means by the dimension of maps – say a map of the visual world – represented in some brain region. For example, the visual cortex is essentially a two-dimensional sheet, so how can it contain a representation of the world that is other than two-dimensional? To explain this, I need to consider the essential idea behind the dimensionality of something. The critical notion is: the dimensionality of a space is determined by how many numbers are necessary to specify a point in

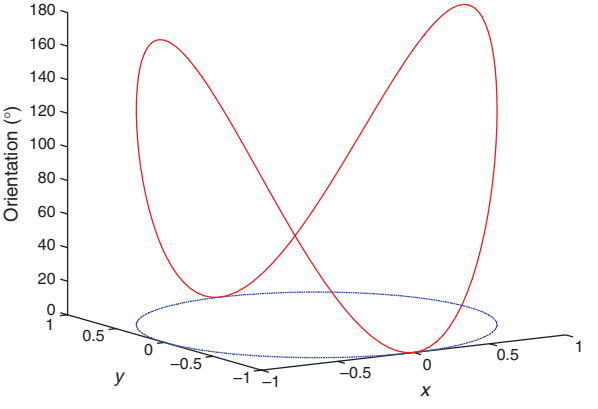

Figure 3 Illustration of how a two-dimensional figure, the circle (dotted blue line) in the x–y plane, might be extended into a three-dimensional volume (solid red line). The vertical axis is the orientation of a tangent to each point on the circle.

that space. For example, because a pair of numbers (x, y) is required to determine the position of any point in a plane, a plane is two-dimensional. Similarly, three numbers (x, y, z) are needed to determine the location of any point in a three-dimensional volume. In the same way, one can imagine (although not picture) a four-dimensional space in which four numbers are required to characterize a point. In physics, it is common to talk about a four-dimensional space, called spacetime, in which the position of a person, for example, is specified by four numbers, three (x, y, z) to define the person's location in space and a fourth number (t) to specify the time at which the person occupied that location. Of course, abstract spaces of any dimension can be constructed.

To understand how a three-dimensional space is represented in the brain, it is convenient to consider a specific example provided by V1. Neurons in V1 respond preferentially to lines or edges, but the response of the neurons depends not only on the location of the line or edge in space but also on its orientation (Hubel and Wiesel, 1959). Thus, if an animal looks at a house at the center of a picture, a particular V1 cell would respond only to a line that is in some specific place in that picture (for example, the line that defines the edge of a tree to the right of the house). But this cell would not respond to just any line there, but only to a line that is, say, vertically rather than horizontally oriented. For each location on the retina, then, there is a population of neurons in V1 that respond only to lines whose images cross that retinal location and, among cells in this population, there are distinct V1 neurons that respond best to each possible direction of the line. This means that each neuron in V1 requires three numbers to characterize its behavior: two numbers to specify the (x, y) position on the retina to which the V1 neuron is assigned, and a third number to give the orientation (from 0° to 180°) of a line that the neuron prefers. Because three numbers (x, y, and orientation) are needed to determine if a particular neuron in V1 is responding, the V1 can be said to have a three-dimensional representation of the visual scene. And because only a pair of numbers are needed to characterize the response of retinal cells, the dimensionality of the retinal representation of the visual scene is two. The visual cortex, then, carries out computations to map a two-dimensional image on the retina into a three-dimensional space in V1. In a similar way, the dimensionality of the representation in any brain area can be described: the dimensionality is determined by how many numbers are needed to characterize the response properties of neurons in that region. As an aside, I should note that the representation of maps in cortical areas is actually greater than three because more than three parameters are needed to characterize completely the response properties of cortical neurons.

How would a scaling law result from such a two-into three-dimensional transformation? To answer this question, one has to recognize that neural representations are grainy because only a relatively small number of neurons are available. Just as the pixel size – and, therefore, the resolution – of a digital camera is determined by the number of pixels available, so is the resolution of a neural map, like the retina or V1, determined by the number of neurons available. If the number of neurons in a hypothetical retina were increased from $1000 \times 1000 = 1$ million to $2000 \times 2000 = 4$ million (a 1-megapixel retina upgraded to a 4-megapixel one), the linear resolution of the retinal image would be doubled because the number of neurons (pixels) would be doubled in each direction. Going from the retina to the LGN (where the image is also represented as two-dimensional), the number of neurons in each direction would also have to be doubled for the LGN to keep up with the resolution available from the retina; there would be no point in making a larger eye, and a larger retina with more neurons, if the increased resolution were just thrown away at the next stage. Going from the LGN to V1, the number of neurons in each direction would also have to be doubled if the resolution in the cortical representation is to keep pace with that available from the eye. The cortex, however, not only has x- and y-directions, each of which must have the number of neurons doubled, but also a z-direction (line orientation) which would also have to double its neurons to make use of the improved resolution available in the image from the larger eye.

To see what happens in general, suppose that the linear resolution in the retina is increased a-fold (doubled in each direction in the example above) so that the total number of retinal neurons is increased by $a \times a = a^2$. For the cortex resolution to keep pace with the resolution available from the retina, the number of cortical neurons would have to be increased a-fold in the x-, y-, and z-directions, so the number of cortical neurons would become $a \times a \times a = a^3$ larger. If n_0 is the initial number of retinal neurons, and n is the number after the increase in size, n would be $n = n_0 a^2$. And if N_0 is the initial number of cortical neurons, and N is the number after the increase in size, N would be $N = N_0 a^3$. Now eliminate a between these two equations to give the result

$$N = (N_0 / n_0^{3/2}) n^{3/2}.$$

Thus, the number of cortical neurons (N) is related to the number of retinal ganglion cells (n) by a power law whose exponent is the ratio of the number of dimensions in the visual cortical representation (3) to the number of dimensions in the retinal representation (2). Such a power law will result whenever the number of dimensions changes in going from one area to another and the resolution in each dimension is increased in parallel.

Certain kinds of computation do not change dimensions whereas others do (Stevens, 2004). For example, if an image is simply filtered – by blurring or sharpening edges, for example – the number of dimensions in the original representation of the image and its filtered versions is the same. This is the sort of operation performed in going, for example, from retina to LGN. On the other hand, some operations do change the number of dimensions. For example, a sonogram of a birdsong takes a one-dimensional function (the sound pressure produced by the bird as a function of time; time is the single independent variable) and displays it as sound intensity of pitches produced as a function of time, a two-dimensional representation of the bird song (the two independent variables are pitch and time). The common image compression schemes, like the modern jpeg format used by digital cameras, also increase the number of dimensions but save space by limiting the resolution.

A widely used class of computations, known as wavelet transforms, always change the dimension of a map. For example, a two-dimensional image becomes four-dimensional after it is wavelet-transformed and it has been argued that V1 carries out such a transform with the firing rate of each neuron representing the magnitude of one coefficient of the transformed image (Stevens, 2004).

In summary, then, allometric relations can arise in different ways and can potentially give information about various underlying mechanisms. According to the original Huxley interpretation, the allometric constant tells you the relative growth rates of two structures. The interpretation of the allometric constant when the allometry arises from self-similarity of structures is more complex, and depends on the details of the situation. Finally, when an allometric relation arises because a computation alters the dimension of the neural representation of a map, the allometric constant specifies the ratio of the number of dimensions in the original representation to the number of dimensions needed for the result. For example, going from a two- to three-dimensional map, the allometric constant would be 3/2.

1.17.6 Some Limitations

Although allometric relations are very important as a tool for describing how brain structures change in size as the brain is made smaller or larger, drawing meaningful conclusions from them requires care. Here I indicate three potential problem areas.

1.17.6.1 Selecting the Appropriate Measures of Size

Figure 1 presents allometric relations between the size of the LGN and V1 with two different measures of size that give two different allometric constants (1.125 and 1.5). Which allometric constant is correct? Both may be correct but not necessarily equally easy to interpret. To decide on the appropriate measure for a structure's size, one must decide, based on the function of the structure, what measure is most natural. For example, number of neurons is an appropriate size measure if one believes that neurons are the computational units of the brain, and volume would be a less natural measure because the essential function does not depend on the volume of the structure (unlike, for example, the liver, where volume is presumably the relevant variable) but rather on the number of computational units.

The volume of a brain structure is related to the number of neurons it contains by the neuronal density (number of neurons per cubic millimeter), and neuronal density is known to decrease as the volume of the structure increases. For the LGN and V1, for example, the neuronal density is related to the structure's volume by power laws (Stevens, 2001), and so the power law for cell numbers, together with the power laws for neuronal densities, dictates that a power law should also result when structure sizes are measured by volumes. To account for the Figure 1a allometric relation, then, one would have to combine the Figure 1b allometric relation and the allometries that relate structure volumes to neuronal densities. The determination of what size measures are relevant for allometric relations depends, then, on one's ideas about how the structures function.

1.17.6.2 Internal Consistency

Figure 4 (open circles) shows an allometric relation between the neocortical volume and the subcortical gray-matter volume for 24 primates (Stephan *et al.*, 1981; Frahm *et al.*, 1982); the allometric constant is 0.73. The subcortical gray matter comprises a number of nuclei, like the thalamus, hypothalamus, and striatum, and each of these structures also obeys a scaling law. For example, Figure 4 (open squares) plots, on a double logarithmic scale, the volume of the striatum as a function of the neocortical volume

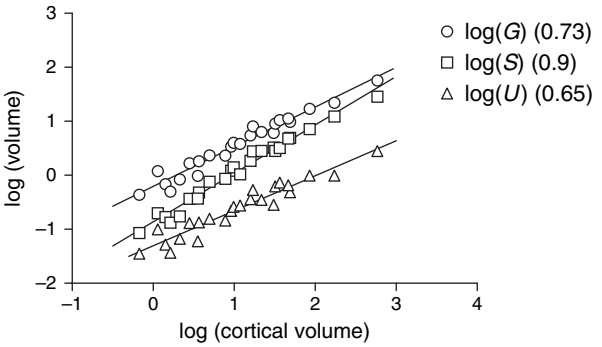

Figure 4 Double logarithmic plots of the volume (mm^3) of subcortical gray-matter structures as a function of the volume of the cortical gray-matter volume for 24 primates. Open circles represent the total volume of the subcortical gray matter, open squares the volume of the striatum, and open triangles the volume of the total subcortical gray matter except for the striatum. Note that the open triangles have been shifted vertically down 10-fold (1 log unit) for clarity.

for the same primate species, and a power law with the allometric constant = 0.9 appears to hold for this pair of structures. The remainder of the subcortical gray-matter volume – including everything except the striatum – is plotted as a function of neocortical volume in Figure 4 as open triangles and the least-squares fitted power function gives an allometric constant of 0.65. Thus, two components whose volume adds together to give the entire subcortical gray-matter volume (striatum and all subcortical structures other than the striatum) each are related to the neocortical volume by power laws with different allometric constants (0.65 and 0.9), and the entire subcortical gray-matter volume is itself related to the neocortical volume by a third power law with an allometric constant of 0.73.

The problem with these allometric relations is that they are internally inconsistent and cannot all be right. The reason is that the sum of power laws with different exponents is not again a power law; for example, there is no value of the constant a that makes $x^2 + x^3$ equal to x^a. Thus, if the striatial volume and the nonstriatal subcortical gray matter are both proportional to different powers of the cortical volume, the total subcortical gray-matter volume (= striatal + nonstriatal) cannot also be proportional to a power of the neocortical volume, as it appears to be from the graph. The sum of power laws with different exponents often can, over some range of values, be approximated by a power law (as illustrated by the data in Figure 4), but the allometric constant for this approximate allometry is not simply related to the allometric constants of the two constituent allometries. This means that the allometric constant for the combined case is difficult or impossible to interpret.

In summary, then, what appears on a double logarithmic plot to be an allometric relation may not, in fact, be one but only an approximation. If it is an approximation that consists of the sum of power laws with different exponents, the allometric constants are not easily interpreted, and may not be useful except as descriptive parameters.

1.17.6.3 Grade Shifts

Allometric relations usually do not hold across all vertebrates or all mammals but rather are restricted to specific taxa. An example is shown in Figure 5a for hominoids (family Hominindae, the great apes and humans) and for monkeys (families Platyrrhini and Ceercopithecoidea), where the volume of the cerebellar hemispheres is plotted, double logarithmically, as a function of the volume of the cerebellar vermis (MacLeod *et al.*, 2003); the allometric constants (the slopes of the lines on the plots) for these hominoids and monkeys are the same (1.4), but the scale factors (determined from the intercepts) are about threefold different (the hominoid curve is displaced vertically from the monkey curve). Allometric relations that differ by their scale factors for different taxa (here, hominoids versus monkeys) are known as grade shifts, and they are very common (Pagel and Harvey, 1989).

The points plotted in Figure 5a are derived from measurements on several specimens from each species, but frequently one uses data that are averaged across all specimens from a given species (for example, the values for all human cerebella are averaged together). The family Hominindae contains only five species, and one generally wishes to seek allometric relations across a larger sample than this. In Figure 5b, data points that appear in Figure 5a have been averaged across species, and the hominoids and monkeys have been plotted together (one point for each species; i.e., one human point, one chimp point, etc.). In Figure 5b, the cerebellar hemisphere volume appears to be related to the vermis volume by a power law with an allometric constant of 1.9 but, from Figure 5a, we know this value for the allometric constant is an artifact that arises from combining allometric data with different scale factors. Ignoring grade shifts in determining allometric constants can therefore lead to incorrect values, and consequently to misinterpretations of the meaning of scaling laws.

In summary, allometric relations reveal orderly rules used by brains when their sizes are increased. These scaling laws can be interpreted in different ways – three have been given here – but these

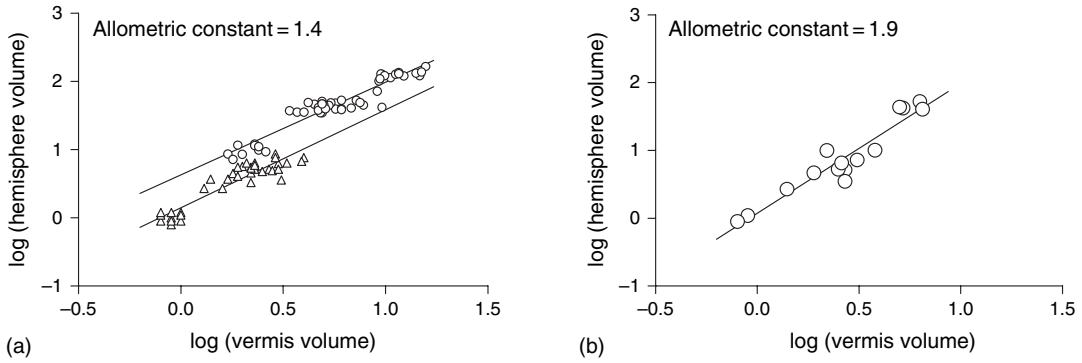

Figure 5 Double logarithmic plot of volume (mm^3) of the cerebellar hemispheres as a function of the volume of the vermis of the cerebellum for five hominoids and 10 species of monkey. a, Each data point represents an individual specimen. b, Each data point is the average of all of the specimens for a particular species.

interpretations are the start, not the end, of the job of understanding the scalable architecture of the brain. For each allometric relation, one must determine the mechanisms that generated it and understand why evolution has chosen a particular value for an allometric constant.

1.18 Relevance of Understanding Brain Evolution

T H Bullock[†], University of California at San Diego, La Jolla, CA, USA

Glossary

afferent Arriving input; said of nerve fibers carrying impulses into the brain or any center.

EEG Electroencephalogram; used to embrace the electrical activity seen by electrodes on the scalp or on the brain or in the brain including the compound field potentials of many cells from unknown but presumably multiple sources and generartors. Normally understood to have been filtered by amplifiers that pass only activity above about 0.2 Hz and up to several hundred hertz.

efferent Output leaving the brain or any reference center; said of nerve fibers carrying impulses away.

EP Evoked potential; electrical activity responding to some stimulus; used for the compound local field potentials recorded with EEG electrodes as passed by specified filters, generally used with 'adequate' = normal stimuli delivered at a known moment.

ERP Event-related potential; electrical activity, usually a slow wave attributable to an event which in humans would be called mental and is well defined in time of onset.

glia Neuroglia; non-neuronal cells of the central nervous system, other than cells of the vascular system; normally used to include astrocytes, oligodendroglia, and microglia.

PTP Post-tetanic potentiation; a term referring to a physiological phenomenon where, following the end of a period of tetanus (a series of imposed stimuli such as electrical shocks at a frequency and strength causing sustained contraction of muscle), there is a period of enhanced effectiveness of single test shocks.

rebound A physiological phenomenon where excitability changes for a period in the opposite direction from whatever effect imposed stimuli cause; for example, rebound excitation would follow the end of a period of imposed inhibition.

rhythmicity The degree to which a time series of more or less wide band nature (in terms of the Fourier or frequency/power spectrum) consists of rhythms defined as periodicities within some limit of irregularity of period, sustained for more than some arbitrary number of cycles without major phase shift.

taxon A scientifically defined category of animal populations at a defined level of species, genus, family, order, class or phylumor other groupings, relatedness such as intermediates.

trait A character or feature of structure or function, whether behavioral, anatomical, or physiological.

A case can be made for the proposition that the most neglected aspect of biology is the evolution of complexity and for the assertion that the evolution of complex nervous systems – in short, of the brain – is an outstanding fact, manifesting a span of difference in grade of complexity from the simplest exemplars to the most advanced, far greater than any other systems known except systems made up of many brains. The aim of this article is not to make this case, which I take to be self-evident, but to point out how little studied are the specifics that manifest and define the grades of complexity, in other words, the consequences of neural evolution. A major step in opening this field of study would be to recognize some way of measuring complexity, relevant to animal biology.

It seems feasible, in principle, to attempt to measure neurological complexity by the number of kinds of (1) elementary cellular units, neurons and neuroglia cells and (2) anatomical and physiological interrelationships among groupings of units at each integrative level from single, whole cells and pairs of pre- and postsynaptic cells to organized assemblies, both smaller and larger, plus (3) their resulting repertoire of alternative discriminations and behaviors. Obviously, real numbers would be unavailable in practice and educated guesses as to relative numbers must suffice. Even with relatively

[†] Deceased.

simple animals, it is clear that there are many variables underlying the recognition of repertoire of responses, self-initiated acts, and distinguishable sensory stimuli.

Instead of merely multiplying numbers of like neurons, nature has differentiated them at least with respect to their receptive fields and effector fields (input and output connectivity) with decisive consequences for the animal so that the number of kinds of cells becomes the number of essentially distinct connectivities, afferent and efferent, allowing for overlap. Behind this anatomically basic differentiation is a rich domain of dynamic differentiation in functional properties. We know a great deal about these at the neuronal and subcellular levels but much less at levels of assemblies and functional groupings. At the neuronal level, more than 48 traits or variable properties have been listed (Bullock *et al*., 1977), within each of which there can be a spread from high to low degree of expression; e.g., the threshold of a given neuron can be relatively high or low or intermediate.

Evolution has operated mainly at the higher levels of the brain. Some examples are familiar, particularly in anatomical and connectivity features. Among invertebrates, it is commonly observed that otherwise more advanced taxa have parts of the brain composed of many small, chromatin-rich, tightly packed cells called globuli cells, principally connected intrinsically, among themselves. More advanced or higher brains are also frequently laminated in their more rostral regions and may have a cortex of cells overlying a subcortex of fiber tracts instead of the more primitive condition in which a fiber- and terminal-rich core is surrounded by a rind of somata (cell bodies). The subcortex or fiber core tends to segregate into regions of pure fibers and regions with many terminals – axonal, dendritic, or both – so that more advanced taxa show more differentiated textures of neural tissue and neuropil, with many terminal ramifications and synapses, confined to certain areas. Such areas are likely, in advanced taxa, to be defined or delimited by texture boundaries into nuclei, centers, or laminae, which are more numerous, more distinct, and more subdivided in the most evolved animals. Structures such as commissures and the highly specialized corpus callosum exemplify what I am advocating. We should discover and characterize, even list, the features that distinguish grades of complexity with the estimated degree of differentiation and the names of the taxa displaying them. Conspicuous examples such as the corpus callosum and the cerebral cortex are relatively well known but I assert that others are not yet familiar or even known, especially semiquantitatively in estimated degree of differentiation. Comparative hodological study is likely to uncover differences in the prevalence of reciprocal connections, in marked asymmetries of afferent and efferent connections or in the mapping of either, or in the proportion of cells that respond bimodally or multimodally to two or more kinds of stimulation.

These are only some of the possible innovations that might have evolved in some taxa, probably at the level of order or class. As long as we do not know where such characters appear, we will not appreciate what evolution has brought about or what intermediate stages the brain has had between the simplest and the most evolved brains. A real challenge for new research is to identify specific traits that distinguish grades of brains and behavior.

Even more relevant than anatomical traits are dynamic physiological processes – an area that is much less known and studied. Basic neural mechanisms are still poorly known, e.g., the relative roles of spikes and slow and infraslow potentials, of oscillations, both intracellular and circuit-dependent, of degrees of synchrony, and of correlation dimensions greater than 3 or 4, among other dynamic features. Our understanding even of the occurrence and distribution of slow waves, of synchrony, and of correlated activity among organized assemblies of cells is based on too little comparative data from animal groups that are widely different in complexity.

What we know of such signs of complexity (Bullock and Horridge, 1965) strongly suggests that they are commonly more prominent in the taxa that evolved later and that this is true between and within invertebrate phyla, classes, and orders and between and within vertebrate classes and orders commonly though far from inevitably – long before there were primates or mammals or vertebrates – so that it is not an anthropomorphic bias.

To this writer it is not at all obvious what the selective advantage or survival value was for the stepwise advances in grade of complexity. Vague references to improved discrimination and adaptability are not convincing and plausibility by itself is a treacherous guide. Lacking a satisfactory selective value, it is all the more important to investigate just what evolution has brought to pass, in specific detail, structurally, biochemically, and functionally as well as in susceptibility to viral attacks, immunological disorders, and degenerative diseases. Survival value should support the less complex animals that have passed the test of survival convincingly again and again.

I have elsewhere argued (Bullock, 1992) that most neural evolution has been horizontal adaptation by specialization within the same general grade of

complexity and that vertical differences in grade of complexity are relatively rare, being clear only when one compares taxa sufficiently far apart, rarely at the level of families or orders. This use of grade is therefore quite distinct from the usual use in phylogenetic literature.

In some quarters, there is a lingering prejudice against the terms higher and lower and equivalent words. I take it as *prima facie* that the nervous system of corals is simpler than that of polyclad flatworms and that these are simpler than those of many polychaete annelids, which in turn are not as complex as those of many insects. Higher simply means more complex. Nothing is implied about phylogenetic relationship, moral value, or engineering efficiency.

I will consider cephalopods more complex than gastropod mollusks and polychaete annelids more complex than oligochaetes, at least when comparing the more advanced families in each class. With this proviso, I find it difficult to arrange Chelicerata, Insecta, and Crustacea in order of complexity of their respective most advanced members. Among the vertebrates, the best teleosts are more complex than elasmobranchs, which are in turn more complex than agnathans, although the brain of hagfish is quite advanced histologically. Advanced reptiles are higher than the best amphibians but not much more so than the most advanced teleosts, according to my impression (see Evolution of the Nervous System in Fishes, Evolution of the Amphibian Nervous System, Evolution of the Nervous System in Reptiles). Gallinaceous birds are probably less complex than psittacines and corvines, which are approximately equal to some mammalian orders (see The Evolution of Neuron Classes in the Neocortex of Mammals). Some orders of Mammalia seem more complex than others and this, like all the foregoing cases, was true long before the advent of higher primates. Zoologically and giving due weight to behavior, considered as a broad congeries more than a specialized modality, I place the human species a large step in complexity beyond the next nearest taxon. No doubt some of these assertions are arguable and all suffer from an extreme lack of even semiquantitative data for our definition of complexity. The interest and importance of the question, however, justify our best guessing, as I have attempted to do, beginning with an estimate of the number of distinct (only partially overlapping) kinds of neurons and ending with the above summary, based mainly on the predicted length of the complete ethogram with all the discriminable stimuli and responses, especially the subtler social stimuli and responses. Whatever the arrangement or sequencing, I am willing to assume that the separable grades are different in more than a few traits of brain anatomy or physiology. It is these upon which I am focusing in this article; we should be searching for them at each grade level, particularly for the dynamic physiological properties.

I must stretch to name examples; this is the domain I am advocating for new research. We know little about the comparative physiology of kindling, a well-studied phenomenon in laboratory mammals, in which brain stimulation subthreshold for eliciting seizure discharges reveals a sensitization such that weak stimuli delivered 10 or more hours later trigger full seizures, but not if delivered too soon. Frogs are said to be triggered after mere minutes (Morrell and Tsuru, 1975; Ono *et al*., 1980). It seems likely that the presence or absence of a six-layered cortex would make still further differences in such physiological properties as post-tetanic potentiation or inhibition or in rebound excitation or inhibition (Bullock, 1986b). We have tentatively reported that ongoing local field potentials such as the electroencephalogram (EEG) can show more or less coherence, on average, between electrodes a short distance apart (Bullock, 1991). Coherence is the fraction of the energy at each frequency that maintains the same phase in two electrode loci for the chosen duration of sampling. The regression with distance is a measure of volume synchrony (Bullock and McClune, 1989) of the slow fluctuations (usually *c*. 1–25 Hz, at better than 1 Hz resolution). We believe, from a small number of tectum opticum samples in teleost (catfish and electric fish) and elasmobranch fish, that there is less coherence in these than in mammals and that geckos and turtles may have an intermediate level of coherence. Synchronization of subthreshold slow waves may have evolved from more stochastic activity in lower vertebrates. Invertebrates may have still less, based on a single study of ongoing spontaneous background activity in ganglia of the gastropod, *Aplysia*, with microelectrodes less than a millimeter apart in loci not dominated by large unit spikes (Bullock and Basar, 1986).

Bicoherence is a variable that measures the quadratic phase coupling between any two frequencies in the same or different sites and is a nonlinear higher moment of an ongoing wideband time series (Bullock *et al*., 1996, 1998). It can be low or high for different pairs of frequencies if there is enough nonrandom structure mixed with a stochastic component. We do not have enough data as yet to make comparisons but this property might show evolution between major taxa.

Among other variables that might show evolution, such as mutual information or correlation dimensions, a new variable has been pointed out: an estimate of the rhythmicity. Among the wide band of the EEG, some bands show more than a coincidental degree of repetitive pattern in some samples some of the time, whereas many individuals show no significant rhythmicity much of the time (Bullock, 2003). When a good rhythm appears, it is usually unaccompanied by others, but exceptionally a second rhythm at another frequency is seen. Again, we have insufficient experience to assert any comparative statements at present.

In the very early stage of understanding we are in, it seems that we should not worry about finding principles or ranking emergent traits in importance or defending proposals for selective survival value. We should act as naturalists and attempt simply to list differences and estimate their degree of expression in taxa well separated in overall advancement. In how many ways are the brains of the best (most complex) reptiles different from those of the best amphibians? (see Evolution of the Amphibian Nervous System, Evolution of the Nervous System in Reptiles). Once we have reasonably representative lists, interpretive propositions will be in order and, it may be hoped, insightful. It is to be expected that some comparisons will be ambiguous with respect to which taxon is more complex. Special adaptations, such as echolocation and electrosensory processing, add complexity but in a particular modality. Traits often evolve independently and perhaps the taxa I am calling more complex are in fact those with many more independent traits, especially behavioral traits.

One category of dynamic property is reflected in the compound field potentials of ongoing spontaneous activity frequently called the EEG (which I will use not only for the human scalp-recording, but also for that derived from microelectrodes on or in the brain, also called the local field potential). The EEG is not well understood in origin or causation but manifests spontaneity and volume conduction of algebraically summed activity of neurons and, probably, neuroglia and other sources. Usually described in terms of the Fast Fourier Transform as so much energy at each of the frequency components between chosen limits at a chosen resolution (commonly from <1 to >50 Hz at 1 Hz or finer resolution), we are puzzled by the finding that all classes of vertebrates are much alike (Bullock and McClune, 1989), whether they possess a cerebral cortex or not! The only difference between the EEGs of lower vertebrates and mammals is in amplitude, which is markedly higher in the latter class practically independent of species and brain size (Bullock, 2004).

Another part of the puzzle, in addition to the great similarity of the EEG power spectra in elasmobranchs, teleosts, amphibians, reptiles, and mammals, is the great difference between these and the EEGs of most invertebrates. Despite large differences in anatomy and ethology, the ongoing, spontaneous electrical recordings from the brains of insects, crustaceans, snails and other gastropods, and earthworms and other annelids are all much alike but strikingly different from those of all the vertebrates (Basar and Bullock, 1986; Bullock, 1986a). The invertebrate activity is very spikey with much energy above 100 Hz and very little below 25 Hz, whereas the activity of any vertebrate is mainly below 25 Hz with very little above 100 Hz. Spikes can be found by searching with suitable electrodes but they contribute little energy. The exception is the cephalopod EEG, which is vertebrate-like but, inexplicably, can be switched on or off (Bullock, 1984)!

Beyond the realm of spontaneous, ongoing background activity, such as the EEG, many features and traits are available in the evoked potential (EP) and the event-related potential (ERP), time-locked to the instant of stimulation or of an event that we would consider a mental event in humans (such as "There's one!" or "What's that?"). I prefer to maintain the distinction of earlier literature, between these two categories, one more exogenous, dependent on the stimulus parameters, such as intensity, linearity, and rate of onset, and the other more endogenous and cognitive – dependent on brain state and recent history. We (my associates and I) have much experience with EPs in different taxa and modalities (sharks, rays, bony fish, amphibians, lizards, snakes, turtles, doves, penguins, rats, rabbits, cats, sloths, seals, sea lions, dolphins, manatees, and bats) and invertebrates (earthworms, polychaetes, insects, crayfish, crabs, mantis, shrimp, lobsters, *Limulus*, snails, slugs, *Aplysia*, octopus, squid, and cuttlefish) and some experience with ERPs in a few species of vertebrates.

The main finding relevant to the present topic is that EPs have evolved very little (Basar and Bullock, 1986; Bullock and Basar, 1986). ERPs have been represented by the omitted stimulus potential (OSP), a wave emitted by the eye or brain at a characteristic delay after the due time of a missing stimulus from a regular train at *c.* 2–15 s^{-1}. It is quite dependent on brain state, is barely sensitive to the intensity, placement, or physics of the stimulus, and can be considered a sign of expectation unmet. The defining feature is that, for different

interstimulus intervals in the conditioning train, a fixed and consistent latency is found in each individual, measured from the due time of the omitted stimulus (Bullock *et al*., 1990). Humans have two kinds of OSP: (1) a short-latency, fast one that does not depend on attention and (2) a long-latency, slow one that requires the subject's focused attention (Karamürsel and Bullock, 2000). The other species studied thus far have the fast kind but we have not yet controlled the animal's attention to look for the slow kind except by eliminating it with sleep during which the crayfish show no OSP. The surprise is that a very similar OSP occurs in humans, cats, turtles, rays, and crayfish; i.e., no evolution has thus far been detected. In some taxa, it has been shown that this wave arises in the retina, even after the optic nerve is cut to prevent efferent activity from the brain. This suggests that the OSP can be a relatively low-level phenomenon, cognitively.

I expect the ongoing EEG in nonmammalian species to be less complex than that of mammals (Bullock, 2002a), in correlation with the anatomy of the cerebrum and the evolution of a laminated cortex but thus far have not identified the differences in complexity of electrical activity (Bullock, 2002b, 2003). Also correlated with the anatomy, I expect the ethogram, including discriminable social situations, degrees of danger or attraction, and range of emotional responses, to be longer, more detailed, and hence more complex but thus far cannot cite convincing authors or quotations to support this assumption. The vast difference in complexity between clearly simpler and more advanced phyla, classes, and orders in brain anatomy and behavior remains little studied and a pregnant reservoir of explanatory traits.

1.19 Origin and Evolution of the First Nervous System

R Lichtneckert and H Reichert, University of Basel, Basel, Switzerland

Glossary

anterior class Hox *genes* — Group of *Hox* genes that are involved in the specification of the anterior-most part of the anteroposterior body axis of bilaterians. The bilaterian Hox cluster genes are believed to be descended from an ancestral ProtoHox cluster which included four genes, the ancestor of the present-day Hox classes (anterior, group-3, central, and posterior).

basal Metazoa — Here used to refer to Porifera, Cnidaria, Ctenophora, and Placozoa. Other authors include the Platyhelminthes (flatworms).

Bilateria — A monophyletic group of metazoan animals that is characterized by bilateral symmetry. Traditionally, this group includes deuterostomes (e.g., chordates, echinoderms, and hemichordates), and protostomes (e.g., arthropods, nematodes, annelids, and mollusks).

Coelenterata — Cnidaria and Ctenophora were traditionally joined together as Coelenterata based on the presence of a single gastrovascular system serving both nutrient supply and gas exchange.

deuterostome — A bilaterian animal whose mouth forms embryonically as a secondary opening, separate from the blastopore. Deuterostomes include chordates, hemichordates, and echinoderms.

effector cell/organ — Single cells or group of specialized cells transducing external stimulation or neuronal signals into a specific response like contraction, secretion, bioluminescence, or electricity.

Eumetazoa — A monophyletic group of animals including all metazoans except the phylum Porifera.

excitable epithelia — Epithelia which can conduct electrical signals over wide areas without decrement.

expressed sequence tag (EST) — A nucleic acid sequence that is derived from cDNA as part of sequencing projects.

four-domain Na^+ channel — A single protein ion channel composed of four linked domains, each of which consists of six transmembrane segments. The whole protein folds up into a channel forming a pore that is selective for Na^+ ions. The four-domain Na^+ channels are believed to have evolved from structurally similar Ca^{2+} channels.

gap junctions — Membrane protein complexes (connexons) that join the plasma membranes of two neighboring cells creating a communication between the cytoplasm of the two cells. This allows the exchange of molecules and the direct propagation of electrical signals.

higher Metazoa — We use these terms as a synonym of Bilateria.

homologue — A gene related to a second gene by descent from a common ancestral DNA sequence. The term, homologue, may apply to the relationship between genes separated by the event of speciation (see orthologue) or to the relationship between genes separated by the event of genetic duplication (see paralogue).

hypostome — The terminal region of a polyp, on which the mouth is situated.

low resistance pathway — A tract of multiple cells which are cytoplasmically connected through specialized pores in the cell membranes allowing the fast conduction of electrical signals.

medusa — Mobile form (jellyfish) of life history in the cnidarian classes Hydrozoa, Scyphozoa, and Cubozoa (Medusozoa).

Medusozoa — Comprises three of the four cnidarian classes (Hydrozoa, Scyphozoa, and Cubozoa), which produce a sexually reproducing medusa (jellyfish) as part of the life cycle.

mesenteries — Longitudinal sheets of tissues that extend radially from the body wall of polyps into the body cavity.

mesogloea (also known as mesoglea) — The body layer between ectoderm and endoderm in cnidarians, ctenophores and acoelomates, which is traditionally distinguished from mesoderm on the basis of the former being acellular and the latter cellular.

myoepithelium — A single-layered tissue of contractile cells.

orthologue — Orthologues are genes in different species that evolved from a common ancestral gene by speciation. Orthologues often retain the same function in the course of evolution.

pacemaker — Single cell or group of cells (neuronal or muscular) that spontaneously drive rhythmic activity in neighboring cells.

paralogue — Paralogues are genes related by duplication within a genome. Paralogues may evolve new functions.

planula — The free-swimming, ciliated larva of a cnidarian.

polyp — The sessile form of life history in cnidarians; for example, the freshwater *Hydra*.

posterior class Hox *gene* — Group of *Hox* genes that is involved in the specification of the posterior part of the anteroposterior body axis of bilaterians. The bilaterian Hox cluster genes are believed to be descended from an ancestral ProtoHox cluster which included four genes, the ancestor of the present day Hox classes (anterior, group-3, central, and posterior).

protomyocyte — An evolutionary antecedent of muscle cells.

protoneuron — Term coined by Parker (1919) for the type of nervous cell from which modern ganglionic neurons evolved.

protostome — A bilaterian animal whose mouth and anus develop embryonically from the same invagination (the blastopore) during embryogenesis.

Radiata — Animals that are traditionally considered to have radial symmetry. This group includes the Ctenophora and the Cnidaria.

Siphonophora — Cnidarian order of marine colonial hydrozoans.

statocyst — The statocyst is a balance organ and consists of a pouch lined with sensory hairs, within which sits a heavy granule called the statolith. The sensory hair cells are connected by nerve fibers to the animal's nervous system. The sensed motion of the statolith in response to gravity allows the animal to orientate itself.

1.19.1 Introduction

1.19.1.1 Tracing Back the First Nervous System

By definition, the first nervous system evolved after the evolutionary shift from unicellular to multicellular life forms. Complex, coordinated behavior controlled by a primitive nervous system in early metazoan animals must have conferred strong selective advantages and thus contributed significantly to the evolutionary success of nervous systems within metazoan animals. Ultimately, more advanced nervous systems, including our own, evolved into the most complex structures found in living matter. In order to learn more about the origins of complex nervous systems in highly evolved animal species, research on the more simple nervous systems that characterize basal metazoan phyla was initiated more than two centuries ago. Then, as today, understanding the origin and early evolution of these simple nervous systems may lead to more profound insight into fundamental principles of development, organization, and function of modern nervous systems.

It is highly likely that the emergence of the first nervous system predated the evolutionary divergence of Bilateria and Radiata 600–630 Mya (Peterson *et al.*, 2004) given the fact that neurons and nervous systems are present in both animal groups. However, the independent evolution of the Bilateria and Radiata during this long period of time implies that most extant animals cannot be regarded as primitive in terms of the organization of their nervous systems. Moreover, for the Radiata, which are generally considered to be basal eumetazoan groups, the fossil record is poor and does not allow reconstruction of fossil nervous systems (Chen *et al.*, 2002). Thus, in the quest to understand the origin of the first nervous systems, it seems best to pursue a comparative approach, in which the structure, function, and development of nervous systems in several basal metazoan phyla are considered and compared in terms of key molecular, cellular, and morphological aspects.

In this review, we will begin by defining what neurons and nervous systems are and then present a current version of the phylogenetic relationships that characterize the systematic groups that are relevant for subsequent considerations. Following this, we will give a brief historical overview of the ideas concerning the origin and evolution of the first nervous system. The main part of the review will then present a detailed comparative analysis of nervous systems in the basal metazoan phyla which may have participated in the origin of the nervous system. Here the main emphasis will be on Cnidaria, but Porifera, Ctenophora, and Placozoa will also be presented, and electrical conduction outside of the animal kingdom will be considered. Finally, we will discuss the implications of recent molecular genetic findings on neurogenesis and axial patterning in cnidarians and bilaterians for our current understanding of the origin of the first nervous system.

1.19.1.2 Definition of the Nervous System

All living cells respond to stimuli and engage in signal processing. Thus, even in the absence of a nervous system, reactions to external stimuli do occur. In most metazoans however, a discrete subset of specialized somatic cells form an interconnected network, called the nervous system, in which multiple sensory stimuli can be processed and conducted to specific effector organs, achieving coordination of complex behaviors. A useful general definition of nervous systems has been given by Bullock and Horridge (1965): "A nervous system is an organized constellation of cells (neurons) specialized for the repeated conduction of an excited state from receptor sites or from other neurons to effectors or to other neurons." An additional aspect was put forward by Passano (1963), who pointed out that the ability to generate activity endogenously is as much a part of the definition of a nervous system as is the ability to respond to stimulation. It follows, from these considerations, that connectivity, specialization for propagating an excited state, and spontaneous generation of activity are important anatomical and physiological criteria for a true nervous system.

The functional units of nervous systems are nerve cells or neurons, which are specialized for the reception of stimuli, conduction of excitation, and signal transmission to other cells. Neurons appear in the most simple animals as specialized conducting, secreting, and spontaneously active cells within epithelia which themselves may show sensory, conducting, and pacemaker features. Given their role in conduction, a key point about neurons is that they are elongated, which enables them to transmit beyond their immediate neighbors without exciting all the interspersed cells (Horridge, 1968).

Some extant animals have a diffuse nerve net representing either an ancestral organization or a secondary loss of centralized structures as often observed in parasitic or sedentary life forms. A nerve net has been defined by Bullock and Horridge (1965) as "a system of functionally connected nerve cells and fibers anatomically

dispersed through some considerable portion of an animal and so arranged as to permit diffuse conduction of nervous excitation, that is, in relatively direct paths between many points. The paths, as opposed to indirect routing through a distant ganglion or central structure, are multiple and confer a tolerance of incomplete cuts."

1.19.1.3 Basal Metazoan Phylogeny

A comparative approach to nervous system structure, function, and origin requires an understanding of the phylogeny that underlies the animal groups considered. It is now commonly agreed that all metazoan phyla including Porifera have a monophyletic origin (reviewed in Müller, 2001; Müller *et al.*, 2004). In this section the phylogenetic relationships of major extant taxonomic groups at the stem of bilaterian animals will be presented (Figure 1).

Choanoflagellata, which show a striking structural resemblance to the choanocytes found in sponges, have been hypothesized to be the closest relative to multicellular animals, and Porifera have been proposed to derive from a colonial form of choanoflagellates (James-Clark, 1867). Recent molecular phylogenetic data provide further support for this hypothesis, indicating that choanoflagellates are indeed more closely related to animals than are fungi and, thus, form a monophyletic sister group of metazoans (Medina *et al.*, 2001; Brooke and Holland, 2003).

Porifera represent the earliest known metazoan phylum and consist of three major taxa: Hexactinellida, Demospongiae, and Calcarea. The molecular sequence analysis of key proteins from these three poriferan classes, suggest that Hexactinellida are the phylogenetically oldest taxon, while Calcarea represent the class most closely related to higher metazoan phyla (Medina *et al.*, 2001; Müller *et al.*, 2004).

The relative positions of the potential sister groups to the bilaterians, namely Cnidaria, Ctenophora, and Placozoa are controversial. Classically the Cnidaria and Ctenophora have been grouped together as the sister group to bilaterians. Together, they are also referred to as the Radiata based on their radially symmetrical appearance (this term may be inappropriate given that biradial and even bilateral symmetry are also common among these animals). On morphological and embryological grounds, such as the presence of mesoderm as a third germ layer, multiciliated cells or a simplified through gut, Ctenophora have been suggested to be the closest relative to Bilateria (Nielsen, 1997; Martindale and Henry, 1999). However, recent molecular phylogenetic analyses support the notion that Cnidaria are more closely related to Bilateria than are Ctenophora, and Cnidaria are therefore often considered as the true sister group of Bilateria (Collins, 1998; Kim *et al.*, 1999; Medina *et al.*, 2001; Martindale *et al.*, 2002). Within Cnidaria recent molecular data based on ribosomal

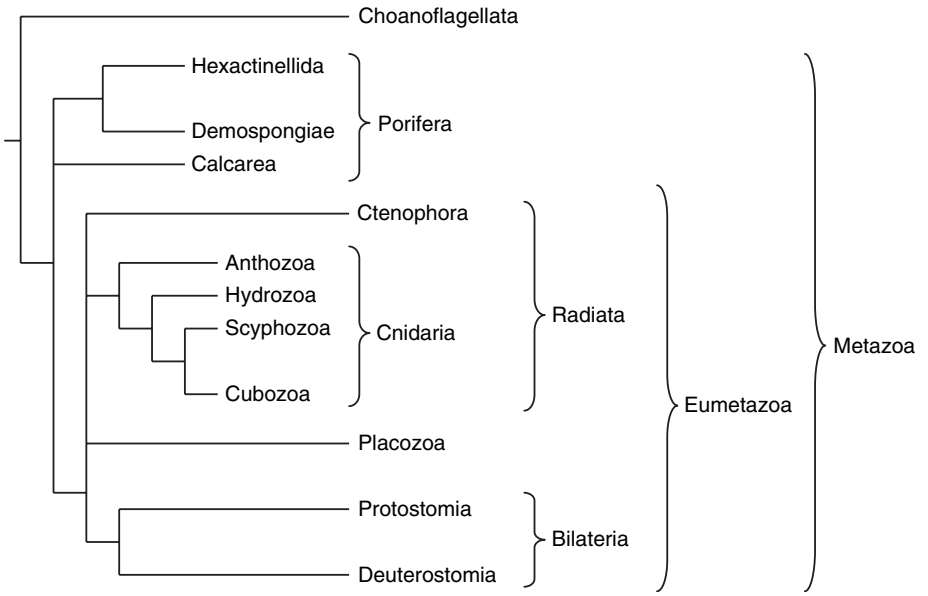

Figure 1 Phylogeny of metazoan animals at the stem of Bilateria. Choanoflagellata have been included as the closest unicellular relatives to the metazoans. The phylogeny is based on widely accepted molecular data and the currently uncertain relationships between the different sponge classes as well as among the potential bilaterian sister groups (Ctenophora, Cnidaria, and Placozoa) have been left open. Terms used in the text for higher classification of animal phyla are indicated on the right-hand side.

DNA sequence analysis and mitochondrial genome organization are in agreement with the view that the Anthozoa, which have only a polyp stage, are basal to the other three classes, Hydrozoa, Scyphozoa, and Cubozoa, which are characterized by an additional medusa stage in their life cycle (Medusozoa; Petersen, 1979).

The Placozoa, represented by a single known species, *Trichoplax adhaerens*, were long believed to be cnidarians with a simple organization as the result of secondary reduction (Bridge *et al.*, 1995). Analysis of molecular data, however, has shown that Placozoa are not derived cnidarians (Ender and Schierwater, 2003). Furthermore, Bilateria and Placozoa may have a more recent common ancestor than either does to Cnidaria (Collins, 2002).

The rapidly increasing amount of molecular data from basal metazoans such as sponges, ctenophorans, cnidarians, placozoans are expected to further clarify the phylogenic relationships among these groups in the coming years (see Metazoan Phylogeny). A robust phylogeny based on different sets of molecular data and, importantly, including a large number of representing species for each taxonomic group will be essential to understand early metazoan evolution and, thus, gain more insight into the origin of the first nervous system.

1.19.2 Historical Concepts and Theories about the Evolutionary Origin of Nervous Systems

1.19.2.1 The Elementary Nervous System

The cornerstone for studies of the evolution of nervous systems at the cellular level was the application of the cell theory (Schleiden, 1838; Schwann, 1839) to the anatomical units of the nervous system in the neuron doctrine which was put forward by Cajal, Kölliker, Waldeyer, and others at the end of the nineteenth century (reviewed in Shepherd, 1991). Subsequently, with improved anatomical staining methods, it became possible to specifically label nervous structures in basal metazoan organisms. With experimental access to the neurons and nervous systems of basal metazoans, it became conceivable to address the question of which cell lineages originally gave rise to nerve cells and how the first nervous system was organized at the cellular level. Hypothetical considerations were initially based on the conceptual model of an elementary nervous system, defined as "a group of nerve cells with the minimal number of specializations required to perform the basic functions of nervous tissue" (Lentz, 1968). However, Lentz pointed out that this simplified conceptual approach does not necessarily determine the actual characteristics of an evolutionarily early, simple system.

Nerve cells are likely to have arisen in multicellular organisms from epithelial cells that turned out to become able to transduce external information (pressure, light, and chemicals) into chemical and electric signals, and then transmit these signals to neighboring cells (Mackie, 1970; Anderson, 1989). Assuming an epithelial layer of equivalent cells, all having the potential of receiving stimuli and producing some form of effector response, different evolutionary theories on the origin of specialized sensory cells, nerve cells, and muscle cells have been proposed. In the following, a brief historical overview of the most influential theories about the evolution of the first nervous system will be given.

1.19.2.2 Proposals for the Evolution of the First Nervous System

One of the earliest theories on the origin of the nervous system was that of Kleinenberg (1872), which he based on the discovery of 'neuromuscular cells' in the freshwater hydrozoan *Hydra*. He viewed this cell type as a combination of receptor, conductor, and effector cell. The apical ends of the described cells were exposed on the surface of the epithelium and were believed to act as nervous receptors. Their basal ends were drawn out into muscular extensions and supposedly served as effectors which received signals from the cell bodies. Kleinenberg postulated that comparable 'neuromuscular cells' gave rise to nerve and muscle cells in the course of evolution. In 1878 the Hertwig brothers described sensory cells, ganglionic cells, and muscular cells in Cnidaria, and postulated that each element was differentiated from a separate epithelial cell but still in a physiologically interdependent way (Hertwig and Hertwig, 1878). In contrast to this notion, Claus (1878) and Chun (1880) suggested that nerve and muscle cells arose independently and became associated only secondarily.

The theory of the Hertwigs in which nerve and muscle were thought to have evolved simultaneously was generally accepted until Parker's publication of *The Elementary Nervous System* in 1919. In this influential publication, Parker proposed a succession of three major evolutionary stages in the organization of the neuromuscular system (Figure 2; Parker, 1919). In sponges, which Parker considered as extant representatives of the first evolutionary stage, muscle is present at the absence of nerve cells. This stage is characterized by the appearance of 'independent effectors' such

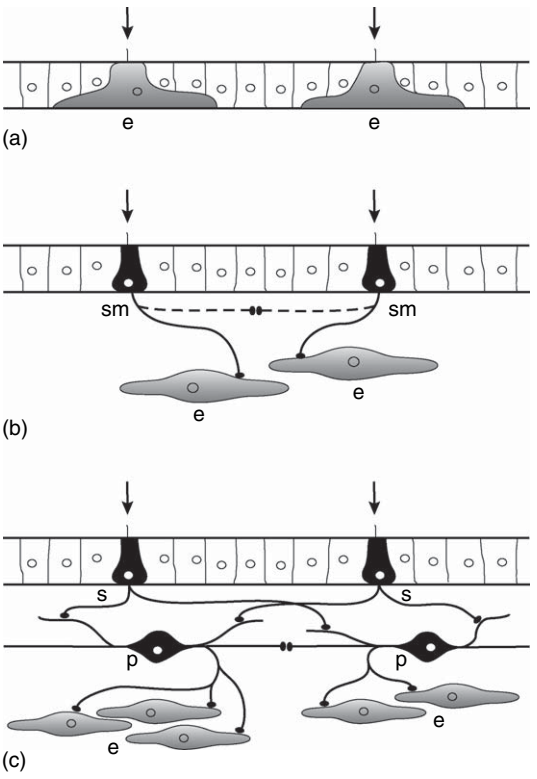

Figure 2 Succession of three evolutionary stages of neuromuscular organization according to Parker (1919). a, Independent effectors. Single contractile effector cells surrounded by epithelial cells are directly stimulated, which leads to a response in the cell. b, Receptor–effector system. Sensory motor neurons directly conduct external stimuli to the underlying muscle cells. In a more complex form, sensory motor neurons can be interconnected among each other (dashed lines). c, Nerve net. A second type of neuronal cell termed "protoneuron" by Parker intercalates between the sensory cells and the muscle cells and forms a highly interconnected neuronal network. Parker proposed that nerve cells of higher animals had their origin in protoneurons. e, effector/muscle cell; p, protoneuron; s, sensory cell; sm, sensory-motor neuron. Arrows indicate the site of stimulation.

as the contractile cells of the oscula sphincters in sponges, which respond directly to environmental stimuli. Although sponges lack nerves, Parker pointed out that they do have a slow type of conduction due to elementary protoplasmic transmission, and he suggested that this 'neuroid transmission' might be considered the forerunner of nervous activity. The second stage of evolution was postulated to be a receptor–effector system such as that believed to exist "in the tentacles of many cnidarians" (Parker, 1919). Receptors were thought to arise from epithelial cells that were in close proximity to the already differentiated muscle cells and, in its simplest form, directly connected to the subjacent muscle cells. However, the separate existence of this type of receptor–effector system has never been directly observed and even Parker admitted that this organizational level might frequently be complicated by the fact that receptor cells not only innervate muscle cells but are also interconnected among each other. In the final stage of early nervous system evolution, a third type of cell, termed "protoneuron" by Parker, was intercalated between the sensory and effector cells forming a true nerve net. This stage was thought to be represented by the nerve nets of extant Cnidaria, and Parker suggested that nerve cells of higher animals were derived from this third type of protoneuronal cell. In a nutshell, Parker proposed that the first nervous system evolved as a consequence of the selective advantage obtained by coordinating independent effectors.

In the second half of the twentieth century, a number of alternative theories for the evolutionary origin of the nervous system were put forward. Based on morphological and physiological studies on sea anemone nerve nets, Pantin (1956) proposed that nervous systems functioned from the beginning to coordinate the behavior of the whole animal. He argued that the nervous system did not evolve on the basis of single cells, but rather originated as whole networks innervating multicellular motor units. Only later would specific conducting tracts have become associated with specific reflexes in the nerve net and given rise to the reflex arc, which according to this view, is not primitive. Pantin's major objection to Parker's theory was the lack of evidence for the independent existence of a receptor–effector system. Based on studies of *Hydra* and scyphomedusae, Passano (1963) postulated that the nervous system evolved from specialized pacemaker cells whose function was to generate contractions within groups of protomyocytes from which they derived. In this view, nerve cells would have derived from pacemaker cells, retaining rhythm generation as their primary function, and only later becoming specialized for conduction over long distances and as sensory receptors. Grundfest (1959, 1965) postulated that the ancestral neuron was derived from a secretory cell that developed a conducting segment between its receptive and secretory poles. Accordingly, true neurons were originally formed when the secretory activity became confined to the terminations of the cells' processes. Thus, this theory is based on the notion that secretion is a primitive feature of the nervous system (Figure 3). A few years earlier, Haldane (1954) proposed that signaling by means of neurotransmitters and hormones had its origin in chemical signaling in protists exemplified by the chemical signals involved in the control of conjugation among different mating types in ciliates. Lentz (1968) noted that protists

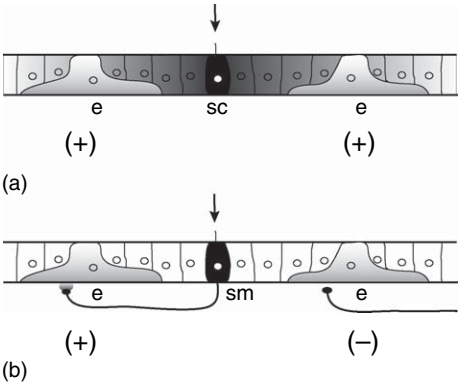

Figure 3 Cell signaling by diffuse secretion preceded synaptic innervation according to Grundfest (1959, 1965). a, Ancestral state. Single cells secrete biologically active substances upon stimulation, which diffuse throughout the epithelium and activate all surrounding effector cells. b, Emergence of neurons. Upon stimulation, sensory neurons specifically activate their target cells by local synaptic release of neurotransmitters. e, effector cell; sc, secretory cell; sm, sensory-motor neuron. Arrows indicate the site of stimulation, (+) stands for an active state and (–) for an inactive state of the effector cell.

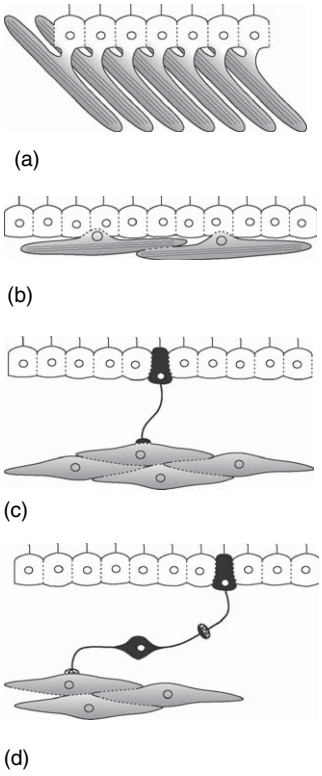

Figure 4 The evolution of nerve and muscle cells from electrically coupled myoepithelial cells according to Mackie (1970). a, Primordial myoepithelium. b, Protomyocytes start to leave the epithelium and move into the interior. c, Protoneurons evolve, conveying excitation to the myocytes from the exterior. All cells are still shown as electrically coupled. d, Neurosensory cells and neurons evolve. They are connected to one another and to the myocytes by chemically transmitting, polarized synapses. Electrical coupling persists in many epithelia and muscles. However, conduction of impulses becomes increasingly a property of the nervous system. Dashed lines at junctions between cells indicate low resistance pathways through which electrical currents can flow. Modified from Mackie, G. O. 1970. Neuroid conduction and the evolution of conducting tissues. *Q. Rev. Biol.* 45, 319–332, Copyright 1970, The University of Chicago Press.

as well as many non-nervous cells have excitable and conductile properties and, furthermore, that 'neurohumors' occur in protists, indicating that these substances could have evolved before the appearance of neurons. He therefore suggested "that the nerve cell arose by the coupling of electrical activity with secretion of biologically active substances so that a chain of events in response to stimuli resulted in alteration of effector activity." In contrast to Grundfest's proposal that the ancestral neuron was a secretory cell which developed specialized receptive surfaces and a conductile intermediate component, Lentz proposed that both neuronal functions evolved simultaneously.

Horridge (1968) and Mackie (1970) described excitable epithelia in hydromedusae and siphonophores, which conduct action potentials and serve as pathways mediating certain types of behavior. Based on this discovery, they proposed that nerves evolved from tissue whose cells were already interconnected by pathways for metabolic exchange and electrical current flow, thus making cell-to-cell propagation of action potentials possible. According to Horridge, the primary function of neurons was neurosecretory or growth regulatory and only later did their elongated axons become effective in impulse propagation. Nerve cells, with their elongated form and functional isolation from surrounding tissues, would have arisen in response to a need for a more selective type of excitation within conductile epithelia in which effector subgroups could be controlled independently (Horridge, 1968). Mackie proposed that the starting point for a metazoan nervous conducting system resembled a myoepithelial tissue sheet in coelenterates. The cells in the tissue capable of reception, transmission, and contraction were connected by cytoplasmic pathways, which also served metabolic exchange among the cells (Figure 4). Specialized muscle cells arose by segregation from the primordial epithelium, whereas cells that lost their contractile component but retained their conducting ability gave rise to nerve cells (Mackie, 1970). Westfall propagated the idea that receptive, electrogenic, and neurosecretory functions co-evolved in primitive protoneurons. This proposal was based on his demonstration with

electron microscopic resolution that nerve cells in *Hydra* not only have receptor poles with a sensory cilium and basal neurites making synaptic contact with effectors but also contain neurosecretory material (Westfall, 1973; Westfall and Kinnamon, 1978). He further proposed that specialized neurons found in modern higher animals derived from multifunctional neuronal ancestors comparable to those found in *Hydra* (e.g., Grimmelikhuijzen, 1996).

In more recent studies, Seipel *et al.* (2004), working on the development of the hydrozoan *Podocoryne carnea*, have found molecular evidence supporting the hypothesis that muscle and nerve cells derive from a common myoepithelial precursor. In bilaterian animals, neuronal determination and differentiation is controlled by genes encoding basic-helix-loop-helix (bHLH) transcription factors and among these are the genes of the Atonal gene family (reviewed in Lee, 1997; Dambly-Chaudiere and Vervoort, 1998). In *Podocoryne*, the cnidarian Atonal-like 1 (Atl1) gene is expressed in a subset of nerve cell precursors of the medusa and additionally in developing striated muscle cells. Simlarly, the neuronal marker gene coding for the cnidarian RFamide neuropeptide is expressed not only in mature nerve cells but also transiently in the developing muscle of *Podocoryne* (Seipel *et al.*, 2004). Based on these developmental genetic similarities, the authors propose that nerve and muscle cells are likely to have been linked closely in evolution and share a common ancestor. In contrast, Miljkovic-Licina *et al.* (2004) studying regulatory genes involved in differentiation of neuronal cell lineages in *Hydra* have proposed a scenario in which mechanoreceptor cells would have preceded neuronal cell types in evolution. Their work shows that the nematocyte and neuronal cell differentiation pathways share regulatory genes that exhibit a high level of conservation during metazoan evolution (Miljkovic-Licina *et al.*, 2004). Nematocytes can sense chemical and mechanical stimuli, transduce these signals, and react to them through nematocyst discharge. The authors propose that this type of fast and cell-autonomous response was a hallmark of very primitive nerve cells and that nematocytes were a derived cnidarian byproduct of these ancestral 'neuro-epithelial' cells. In subsequent evolutionary steps, the 'neuro-epithelial' cells could have differentiated into neuronal cells with elongated processes that began to establish connections with myoepithelial cells and involve them in the response to the stimulus. During later stages, neuronal cells would have become progressively more interconnected with each other in a nervous system allowing coordinated behavior.

In summary, a variety of alternative theories implying different origins of the nervous system have been suggested in the last 150 years. Most of these theories are based on extrapolations of observations made on extant protists, sponges, and cnidarians. The origin of neurons is generally attributed to epithelial cells; however, the characteristics of these ancestral cells are variously considered to have been contractile, neurosecretory, conductile, chemoreceptive, or mechanoreceptive, and each theory emphasizes one or several of these features as being driving force for the evolution of the nervous system. While many of these proposals appear plausible and inspiring for further discussion, it seems impossible to rate one of the theories as more relevant than the others. However, all of the proposed scenarios for the evolution of the nervous system do focus attention on the cell biology of excitable cells in the basal animal groups, and this focus will be explored in more depth in the following pages.

1.19.3 Origin of the First Nervous System: A Comparative Phylogenetic Approach

1.19.3.1 Introduction

Although the nervous system must have arisen in a multicellular organism, unicellular organisms such as protists show a variety of behavioral programs in response to their environment. In protists, behavioral responses to external stimuli are achieved at a subcellular level by organelles specialized for signal reception, signal conduction, and effector response (Deitmer, 1989; Febvre-Chevalier *et al.*, 1989; Hennessey, 1989). Thus, molecular machineries capable of reception of chemical, mechanical, or light stimuli, secretion of biologically active substances, propagation of electrical potentials along membranes, and conversion of stimuli into effector responses were probably already present in the ancestor of metazoans. Assuming colonial protists with equivalent cells as an intermediate form between unicellular protists and early metazoans, an increasing specialization of subgroups of cells must have occurred during evolution. Porifera represent the most basal extant metazoan phylum and are thought to have derived from a colonial form of choanoflagellates. Although a variety of different cell types can be found in sponges, no nerve cells could be identified so far (Jones, 1962; Pavans de Ceccatty, 1974; Mackie, 1979). Nevertheless, contractile cells encircling the oscular openings in sponges are able to react upon mechanical stimulation. In cnidarians and

ctenophores, the closest metazoan relatives of sponges, nerve cells are present and can form sophisticated nervous systems capable of solving complex behavioral tasks. This evolutionary step from poriferan to cnidarian or ctenophoran organization may harbor the emergence of nerve cells and nervous systems.

1.19.3.2 Non-Nervous Conduction Outside of the Animal Kingdom

Many key characteristics of nerve cells can be found in non-nervous cells of metazoans, plants, fungi as well as in unicellular organisms like protists and even prokaryotic bacteria. These characteristics include reception and transmission of signals to other cells, intercellular communication by secretion of biologically active substances, and the propagation of electrical potentials. Nevertheless, the combined appearance of these features in morphologically and functionally specialized nerve cells is unique to the nervous systems of metazoan animals.

Ion channels, which can be gated by ligands, voltage, or mechanical forces and are permeable to specific ions, such as K^+, Ca^{2+}, Na^+, and Cl^-, play a major role in the generation of neuronal excitability in higher animals. Moreover, ionic fluxes across cellular membranes mediate a great variety of biological processes that are essential for viability of most life forms. A large number of genes presumably coding for ion channels have been identified in prokaryotes, but although structural or electrophysiological information has been obtained for some of these proteins, their biological roles are mostly unknown. Presumably, prokaryote channels are involved in metabolic function, osmoregulation, and motility (Ranganathan, 1994; Kung and Blount, 2004). In the bacterium *Escherichia coli*, genome sequencing suggests the presence of six putative mechanosensitive channels, one putative voltage-gated K^+ channel, and two Cl^- channel-like structures. Three of the mechanically gated channels are involved in osmoregulation and release solutes upon osmotic down-shock, whereas Cl^- channels apparently function in short-term acid tolerance. Although, the function of the K^+ channel is still unknown, its protein shares extensive topological and structural similarity with eukaryotic K^+ channels suggesting a common ancestral origin from which K^+ and later probably Ca^{2+} and Na^+ channels evolved (Milkman, 1994; Ranganathan, 1994; Kung and Blount, 2004). Voltage-dependent and stretch-activated ion channels have been found in the plasma membrane of yeast (Gustin *et al.*, 1986, 1988; Zhou *et al.*, 1995). In addition, the yeast genes involved in the pheromone response show high similarity to signal transduction genes of higher animals. For example, the mating factor receptor STE2 of *Saccharomyces cerevisiae* belongs to the rhodopsin/beta-adrenergic receptor gene family (Marsh and Herskowitz, 1988), and the alpha-type mating factor shows amino acid sequence similarities with the vertebrate reproductive gonadotropin-releasing hormone (Loumaye *et al.*, 1982).

In addition to the transmission of information through substrate flux, plants have electrical and hormonal signaling systems. Action potentials in plants were described for the first time in 1873 by Burdon-Sanderson. He recorded electrical signals from a specimen of the Venus's flytrap, *Dionaea muscipula*, which he received from Charles Darwin (Burdon-Sanderson, 1873; Sibaoka, 1966). The leaves of *Dionaea* are divided into two lobes, each of which carries three tactile sense hairs functioning as trigger for an all-or-nothing electrical signal that is followed by the fast closing of the lobes entrapping the prey. In plants like the Venus's flytrap, action potentials are part of a signaling system that responds to mechanical stimulation by changing cell turgor, which leads to relatively rapid movements. Propagation of action potentials from the site of stimulation to the effector cells has been studied in the seismonastic movements of the leaves of *Mimosa pudica* (Sibaoka, 1966; Simons, 1992). Non-nervous electrical conduction in plants involves low-resistance pathways (plasmodesmata) between the phloem cells, comparable with gap junctions that electrically couple cells in excitable epithelia and muscles in animals. Action potentials in plants have been studied in detail in the giant internodial cells of the freshwater algae *Chara* and *Nitella*. In these large cells, a motility system based on actin and myosin drives cytoplasmic streaming, which serves to equally distribute organelles and nutrients around the central vacuole. Upon mechanical or electrical stimulation, an action potential is generated, which spreads in both directions along the shoot and immediately stops the cytoplasmic streaming probably to avoid leakage of the cell in case of injury. In contrast to the action potentials of higher animals where the influx of Na^+ and Ca^{2+} supports the depolarizing phase, in *Chara* and *Nitella* Ca^{2+} and Cl^- are the key components of depolarization, a situation which is typical for plant action potentials. A fast initial influx of Ca^{2+} ions is followed by the efflux of Cl^- through Ca^{2+} activated Cl^- channels across the vacuolar and plasma membranes. The falling phase of the action

potential is due to an increase in K^+ permeability, similarly to what occurs in nervous cells of higher animals (Sibaoka, 1966; Simons, 1992; Wayne, 1994; Kikuyama, 2001). Although molecules that act as neurotransmitters in higher animals such as glycine, GABA, glutamate, and acetylcholine have been isolated from plants, no chemical transmission of electrical signals between cells of plants has been observed. Rather, these substances are involved in a variety of functions related to metabolism, circadian rhythm, or light response of plants (Simons, 1992; Mackie, 1990; Hille, 1984).

A number of neuroactive substances including adrenalin, noradrenalin, 5-HT, DOPA, dopamine, and beta-endorphin as well as receptors for acetylcholine, catecholamines, and opiates have been reported in protists (Zipser *et al.*, 1988; Carr *et al.*, 1989; Görtz *et al.*, 1999). Furthermore, receptor tyrosine kinase genes, known to be involved in cell–cell signaling in metazoans, have been recently isolated from choanoflagellates, suggesting that this family of signal receptor molecules evolved before the origin of multicellular animals (King and Carroll, 2001; Brooke and Holland, 2003; King *et al.*, 2003). Some protists can respond to mechanical stimulation with depolarizing or hyperpolarizing membrane potentials. Their membranes are equipped with ion channels gated mechanically, or by ligand or voltage, and in some cases, action potentials are elicited when the cell membrane is depolarized up to a threshold level by receptor potentials. In most protists, Ca^{2+} ions are responsible for carrying ionic currents and coupling membrane excitation to motile response or contractile activity (Febvre-Chevalier *et al.*, 1989). In some ciliates, ion channels are not distributed uniformly over the cell membrane; this is reminiscent of neuronal cell membranes that have distinct channel populations in dendrites, soma, axon, and presynaptic terminals. For example, in *Paramecium* and *Stylonychia*, different ion channels can be found at the front and back poles of the cell generating different ion currents, which lead to opposed escape behaviors away from the source of mechanical stimulation (Kung, 1989; Deitmer, 1989; Kung and Blount, 2004). Behavioral responses in protists elicited by action potentials often involve changes of cell shape or alterations in the pattern of ciliary or flagellar beating (Febvre-Chevalier *et al.*, 1989; Hennessey, 1989). The complexity of effector responses driven by different types of electrical potentials within a unicellular organism is nicely illustrated by the dinoflagellate *Noctiluca*. Two different kinds of flagellar movements and a bioluminescent light response are controlled through different action potentials involving different ion currents across the cytoplasmic and vacuolar membrane. In this manner, multiple bioelectric activities in *Noctiluca* are able to control altered effector responses within a single cell (Oami, 2004). Thus, in the absence of a nervous system, protists exhibit complex behaviors which incorporate features of sensory receptors and effectors into a single, highly structured eukaryotic cell.

1.19.3.3 Porifera: Specialized Cells and Electrical Conduction

Sponges, the most basal extant metazoans, probably evolved from a colonial choanoflagellate. At this stage of phylogeny a number of specialized cell types including muscle-like contractile cells has made its appearance, however, nerve cells are lacking (Jones, 1962; Pavans de Ceccatty, 1974; Mackie, 1979). Some of the actin-containing contractile cells (myocytes) are concentrated as sphincters around the osculum and pore canals of sponges. To contract, the sphincters have to be directly stimulated and they thus represent "independent effectors" as proposed by Parker (1919). Slow contractile responses that spread over short distances have been described in several sponge species, but the responsible cells do not seem to be electrically excitable, and there is no evidence of associated changes in membrane potentials (Mackie, 1979). Thus, some form of mechanical interaction between neighboring cells seems likely. The sponge epithelial cells that build the external and internal boundary of the mesenchyme are not joined together with occluding junctions and, therefore, the internal milieu may not be very well isolated from the external. Nevertheless, the mesenchyme provides an environment in which electrical and chemical gradients could be generated and nutrients and hormones diffuse without excessive leakage through the body wall (Mackie, 1990). Acetylcholinesterase, catecholamines, and serotonin have been shown, by histochemical techniques, to be present in sponges (Lentz, 1968). Further, some neuroactive substances have been demonstrated to influence the water circulation in the sponge *Cliona celata* (Emson, 1966), but so far there is no clear evidence that they are involved in intercellular signaling processes. Interestingly, a recent finding has shown that cells isolated from the marine sponge *Geodia cydonium* (Demospongiae) react to the excitatory amino acid glutamate with an increase in intracellular calcium concentration (Perovic *et al.*, 1999). Extracellular agonists as well as antagonists known from metabotropic glutamate/GABA-like

receptors in mammalian nerve cells were found to elicit similar effects in these sponge cells. In addition, a cDNA coding for a seven-transmembrane receptor was isolated from *Geodia*, which has high sequence similarity to metabotropic glutamate/GABA-like receptors in mammals. Although these findings suggest that Porifera possess a sophisticated intercellular communication and signaling system, so far there is no evidence for the type of specialized intercellular signal transmission in sponges that might foreshadow the evolutionary origin of nervous systems.

The tissue of glass sponges (Hexactinellida) is syncytial, allowing the rapid propagation of electrical events, which is a fundamental difference between this class and the other two cellular sponge classes, Demospongiae and Calcarea (Müller, 2001). All-or-nothing electrical impulses were recorded from the glass sponge *Rhabdocalyptus dawsoni*. Tactile and electrical stimuli evoke impulses, which lead to the abrupt arrest of water flow through the body wall, presumably due to the coordinated cessation of beating of the flagella in the flagellated chambers. From the superficial pinacoderm, impulses are conducted through the trabecular reticulum, a multinucleate syncytial tissue draped around the spicules of the sponge skeleton, to the flagellated chambers. Impulses are propagated diffusely at 0.27 ± 0.1 cm s^{-1}, a value that falls within the lower range of action potential conduction velocities in non-nervous tissues. It is assumed that signal propagation through the syncytium depends on Ca^{2+} influx and that Ca^{2+} channels may also mediate the flagellar arrest (Leys *et al.*, 1999). The trabecular syncytium seems to be a derived feature specific to the most ancient sponge class Hexactinellida. Since calcareous sponges and demosponges lack comparable syncytial tissue, they would require low-resistance pathways equivalent to eumetazoan gap junctions to conduct electrical signals from cell to cell, but no similar structures have been found so far (Leys *et al.*, 1999; Müller, 2001).

Larvae of many sponge species exhibit rapid responses to external stimuli including light, gravity, and current (reviewed in Wapstra and van Soest, 1987). Demosponge larvae have a spheroid body shape and consist of an outer epithelial layer of monociliated cells and a solid center of amoeboid cells in an extracellular matrix of collagen. The spheroid-shaped body is polarized anteroposteriorly with respect to the swimming movement of the larvae, and a ring of pigmented cells that gives rise to long cilia is located at the posterior end. In the demosponge *Reneira*, directional swimming is mediated by the long cilia of the posterior pigmented cells and incorporates an asymmetric response of these cells to different light intensities (Figure 5). Increased light intensity causes a bending of the cilia such that they shield the pigment vesicles, whereas decreased light intensity reverses this process. This results in steering the larva away from bright light (Leys and Degnan, 2001). Interestingly, re-analysis of the action spectrum of the ciliary response to light reveals that the photoreceptive pigment in the sponge larva has the characteristics of rhodopsin, similar to the situation in other metazoans that have a rhodopsin-like protein as their primary photoreceptive pigment (Leys *et al.*, 2002; Leys and Meech, 2006). In *Reneira* the light response of the posterior cells has been suggested to depend on the depolarization of the membrane potential and the influx of Ca^{2+} into the cilium. Since sponge larvae lack neurons or gap junctions that would allow coordination of signals among cells with long cilia, each posterior cell appears to respond independently to changes in light intensity. On the other hand, no intercellular coordination seems to be required, given the inherent photokinetic

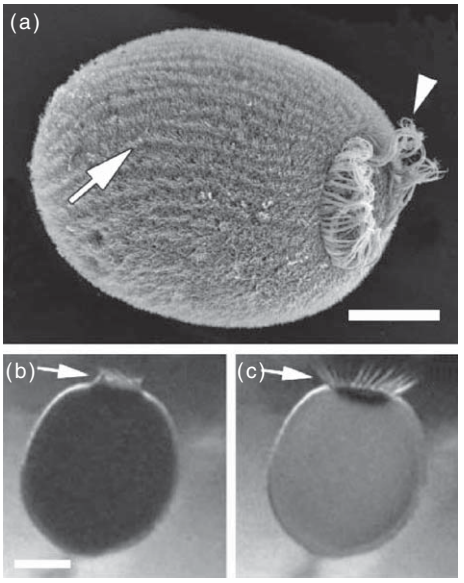

Figure 5 Photosensitive cells and ciliary light response of the sponge *Reneira* larva. a, Scanning electron micrograph showing the structure of the demosponge larva. Monociliated epithelial cells form most of the outer layer (arrow). The posterior pole is circumscribed by a ring of long cilia (arrowhead). Video recording of bending (b) and straightening (c) of the long posterior cilia (arrows) in response to shutting and opening of a shutter in front of the light source. Scale bars: 100 μm. Reproduced from *J. Comp. Physiol. A*, vol. 188, 2002, pp. 199–202, Spectral sensitivity in a sponge larva, Leys, S. P., Cronin, T. W., Degnan, B. M., and Marshall, J. N., figures 1a and 2b (I + II). responses of each ciliated cell depending on its position relative to the light source (Leys and Degnan, 2001). Therefore, in some cases 'independent effectors' in sponges may mediate coordinated behavior. Although sponges emerged at an early level in multicellular animal evolution when nervous systems had not yet evolved, they do represent the oldest extant metazoans with specialized cells responding to different stimuli and performing behavioral tasks.

1.19.3.4 Ctenophora and Cnidaria: The Oldest Extant Nervous Systems

Ctenophora and Cnidaria are the lowest animal phyla that have a nervous system. The two phyla were traditionally joined together in one group, termed Coelenterata, based on the presence of a single gastrovascular system serving both nutrient supply and gas exchange among the body parts. Molecular phylogenetic data, however, suggest an independent origin of the two phyla in the prebilaterian line, and their relative position in early metazoan phylogeny is controversial (Martindale and Henry, 1999; Medina *et al.*, 2001; Podar *et al.*, 2001; Ball *et al.*, 2004). Whereas most molecular data support the more basal position of ctenophores with cnidarians forming the sister group to bilaterians, other evidence, including the presence of true subepithelial muscles and multiciliated cells, supports the view that ctenophores are more closely related to bilaterians than cnidarians (Nielsen, 1997). Thus, it is presently not clear whether Ctenophora or Cnidaria are the closest extant metazoan relatives of Porifera. Nevertheless, it is likely that the first nervous system evolved at the evolutionary step from Porifera to either of the two coelenterate phyla.

Ctenophores are medusoid gelatinous animals, which generally have two tentacles for capturing prey and eight ciliary comb rows on their outer surface for locomotion. The nervous systems of ctenophores are organized into diffuse nerve nets, which show some local tract-like accumulations below the ciliary comb rows and around the mouth and pharynx. At the ultrastructural level, polarized as well as symmetrical chemical synapses have been shown to be present in these nerve nets. Sensory nerve cells are interspersed among the epithelial cells, except at the aboral pole where sensory and nerve cells constitute, together with a statocyst, the apical organ. Locomotory movements of ctenophores involve metachronal beating of eight comb plate rows radiating from the aboral region. The apical organ serves as pacemaker of the comb plate rows and coordinates geotactic responses (Satterlie and Spencer, 1987). Transmission of ciliary activity among comb plate cells is non-nervous by mechanical coupling (Tamm, 1982). In addition, comb cells are electrically coupled through gap junctions, probably allowing the synchronous response of neighboring cells to modulatory synaptic input (Hernandez-Nicaise *et al.*, 1989). In *Pleurobrachia* different inhibitory and excitatory pathways coordinate the electromotor behavior of comb plate cells with tentacle movements during prey capture and ingestion (Moss and Tamm, 1993). In their basic elements the ctenophoran nervous systems already share many features with nervous systems of higher animals, thus allowing well-coordinated behavioral programs in a basal metazoan animal.

1.19.3.5 Cnidarian Nervous Systems: Multiple Levels of Organization

It is often assumed that nervous systems probably evolved first in Cnidaria or a closely related ancestor, and their nervous systems are, thus, often considered to be among the simplest forms and reflect an early stage of evolution. This view prevailed until few decades ago and is still present in many textbooks (Brusca and Brusca, 1990; Ruppert and Barnes, 1994). However, cnidarians have been evolving independently for some 600–630 million years, and have therefore had plenty of time to develop sophisticated solutions for comparable behavioral tasks and under similar conditions as have many higher animals. During this long evolutionary time period, a wide spectrum in nervous system complexity emerged within the cnidarian phylum, ranging from the diffuse nerve nets of sessile polypoid species to the multiple ring-shaped nerve tracts, giant axons, and highly specialized sensory organs in actively swimming medusoid species. Thus, in some cases, the complexity of nervous systems in modern cnidarians may reflect more the behavior tasks of the species considered than any ancestral organization. Many physiological and structural solutions found exclusively in the nervous systems of cnidarians deal with the problem of generating coordinated behavior in a radially symmetrical animal (Mackie, 1990). Ring-shaped nerve nets or diffuse epithelial conduction may, therefore, represent adequate systems for specific behavioral functions rather than remnants of a primitive nervous system. Nevertheless, many basic features of bilaterian nervous systems can be found in cnidarian nervous systems and consequently are likely to have been present in their common ancestors in which the first nervous system probably

evolved. These features, which have been the subject of considerable research, are considered in more detail below.

Different levels of nervous system organization are encountered in the phylum Cnidaria and often even in the same animal. The spectrum of levels ranges from independent effector cells, as already found in sponges, to the first trends of centralization of integrative and coordinative functions in the nerve rings of some medusae (Bullock and Horridge, 1965; Mackie, 2004). In many aspects, the cnidarian nematocytes can be considered as 'independent effectors' (Miljkovic-Licina *et al.*, 2004). Nematocytes are mechanoreceptor cells found in the ectodermal tissue of cnidarian tentacles that discharge the toxic content of a highly specialized capsule named the cnidocyst upon contact with the prey. Although most nematocytes are innervated, they are still able to discharge in the absence of nerve cells (Aerne *et al.*, 1991) and thus respond to direct stimulation. Another example of an 'independent effector' in cnidarians are the photoreceptor cells of the cubozoan *Tripedalia* planula. These unicellular photoreceptors contain the photoreceptor and shielding pigment granules within the same cell, which in addition carries a motor cilium that enables the larva to perform phototactic behavior. Ultrastructural analysis further reveals that there is no nervous system to which these photosensitive cells transmit visual information. These cells are thus self-contained sensory-motor entities that respond directly without a coordinating nervous system (Nordström *et al.*, 2003). The unicellular photoreceptors of the *Tripedalia* larva represents an interesting parallel to the photosensitive ciliated cells of sponge larvae in that each cell has a well-developed motor-cilium, which directly responds to light stimulation (Leys and Degnan, 2001; Leys *et al.*, 2002; Nordström *et al.*, 2003). However, since no similar autonomous photosensory motor cells have been described in more basal cnidarian larvae, the homology of these two structures can be most likely excluded.

Excitable epithelia are another non-nervous element involved in signal conduction that can be found in Cnidaria side by side with highly specialized nervous conduction pathways. Excitable epithelia are present in the endodermal radial canals of hydrozoan medusae where they conduct signals involved in motor control of behavioral responses such as 'crumpling' (protective involution), feeding, or swimming. In the pelagic jellyfish *Aglantha*, this epithelial pathway is preserved despite the presence of a highly complex nervous system consisting of several neuronal conduction systems that include diffuse nerve nets, nerve rings, and giant axons (Mackie, 2004). Thus, relatively slow, non-nervous signal conduction of the type known from sponges and even plants can offer alternative pathways in parallel to highly specific, fast nervous conduction. Epithelial conduction consisting of electrically coupled equivalent cells, from which more specific pathways evolved with the emergence of elongated nerve cells, has been proposed as a characteristic of the hypothetical metazoan ancestor (Horridge, 1968; Mackie, 1970). Whether epithelial conduction is indeed an ancient feature or rather arose several times during evolution is unclear. Nevertheless, this mode of conduction can be found throughout the animal kingdom, from ctenophores to the early tadpole larvae of amphibians (Roberts, 1969; Mackie, 1970).

A diffuse, two-dimensional nerve net formed by bi- or multipolar neurons is considered to be a simple form of nervous system organization. A classical example of this simple type of neural ground plan is found in *Hydra*. This cnidarian has a network of multifunctional nerve cells, which combine sensory and motor tasks and have processes that conduct impulses bidirectionally. Traditionally, the nervous system of *Hydra* has been illustrated with a simple meshwork of equally spaced neurons, as it is still the case in many textbooks (e.g., Brusca and Brusca, 1990). However, detailed neuroanatomical analysis of the *Hydra oligactis* nerve net shows that its neurons are not equally distributed throughout the polyp body wall but rather form a ring-shaped area between tentacles and mouth opening and local concentrations in the peduncle suggesting a level of regional specialization (Figure 6a; Grimmelikhuijzen and Graff, 1985). Furthermore, distinct neuronal subsets can be distinguished morphologically or neurocytochemically based on neuropeptide expression (Grimmelikhuijzen *et al.*, 1996). In *Hydra*, new nerve cells are constantly generated by interstitial cells in a specific zone of the polyp body column and migrate toward the body extremities where old nerve cells are lost. As they migrate, nerve cells can undergo morphological and neurochemical transformations and give rise to the different neuronal subsets (Bode *et al.*, 1988; Grimmelikhuijzen *et al.*, 1996). In addition to their roles in behavior, nerve cells in *Hydra* are directly involved in the regulation of growth and in the production of chemical morphogenetic gradients (Schaller *et al.*, 1996). Thus, the nervous system of *Hydra* is not a simple, diffuse meshwork of interconnected nerve cells and it is unlikely to represent an ancestral situation within the Cnidaria. In the sea pansy, *Renilla koellikeri*, belonging to the

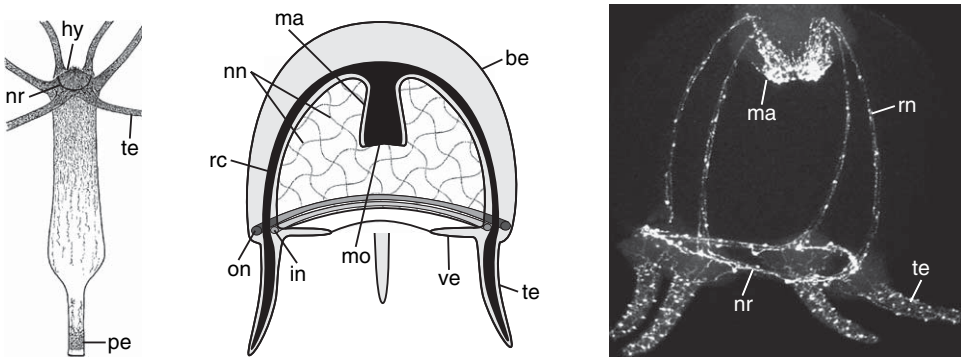

Figure 6 Nervous system organization of hydrozoan polyps and medusae. a, Drawing showing the RFamide-positive nervous system in *Hydra oligactis*. This species has a dense plexus of immunoreactive neurites in the hypostome and a nerve ring between hypostome and tentacle bases. A collar of neurons can be found in the peduncle. b, Nerve net and nerve rings in a hydromedusa. Nerve nets underlying the ectodermal and endodermal tissues span the inner surface of the bell. An inner and an outer nerve ring encircle the bell near the margin. These nerve rings connect with fibers innervating the tentacles, muscles, and sensory organs. c, Fluorescent RFamide staining of the hydromedusa *Podocoryne carnea*. Nerve cells expressing RFamide can be detected in the nerve ring around the margin of the bell and the radial nerves which line the four radial canals. In addition many RFamide positive cells are found around the mouth opening at the tip of the manubrium and scattered over the surface of the tentacles. be, bell; hy, hypostome; in, inner nerve ring; ma, manubrium; mo, mouth; nn, nerve net; nr, nerve ring; on, outer nerve ring; pe, peduncle; rc, radial canal; rn, radial nerve; te, tentacle; ve, velum. a, Reproduced from *Cell Tissue Res.*, vol. 241, 1985, pp. 171–182, Antisera to the sequence Arg-Phe-amide visualize neuronal centralization in hydroid polyps, Grimmelikhuijzen, C. phylogenetically basal cnidarian class of Anthozoa, the nervous system is also found to consist of multiple interconnected nerve nets with local concentrations at specific organs involved in feeding or reproduction (Pernet *et al.*, 2004; Umbriaco *et al.*, 1990). Indeed, it appears that the simplest form of nervous system organization found in extant cnidarians is that of multiple interconnected nerve nets formed by different neuronal subtypes and showing local concentrations.

An important feature of nerve nets is diffuse conduction, characterized by the spreading of an impulse in all directions from the site of stimulation. Symmetric synapses are frequently seen in cnidarian nerve nets, especially in Scyphomedusae, where they can transmit excitation bidirectionally (Anderson and Spencer, 1989). Although, bidirectionality can often account for diffuse conduction, symmetrical synapses are apparently not an absolute requirement for this and diffuse conduction can also be obtained by the distributed arrangement of many unidirectional pathways (Bullock and Horridge, 1965). Asymmetrical as well as symmetrical chemical synapses have been identified in all cnidarian classes, whereas electrical synapses have been demonstrated only in hydrozoans by electrical and dye coupling and by the presence of conventional gap junctions (Anderson and Mackie, 1977; Spencer and Satterlie, 1980; Westfall *et al.*, 1980). In the multiple nerve net system of hydrozoans, neurons belonging to the same nerve net are generally electrically coupled by gap junctions or even represent true syncytia, whereas chemical synapses are restricted to the interfaces between different nerve nets or utilized for excitation of epithelia, including myoepithelia (Satterlie and Spencer, 1987; Mackie, 2004). The restriction of gap junctions within the phylum Cnidaria to Hydrozoa raises the question of whether electrical signaling between neighboring cells via gap junctions could have preceded the evolution of true nervous conduction. If gap junctions evolved before neurons did, the ancestors of Anthozoa and Scyphomedusae must have independently lost their gap junctions secondarily during evolution, which is rather unlikely. Alternatively, gap junctions arose *de novo* in the ancestor of Hydrozoa after nervous cells had already evolved (Mackie, 1990).

Cnidarian nerve rings and nerve tracts have been proposed to correspond to 'compressed nerve nets' (Spencer and Schwab, 1982), although nerves consisting of parallel axon bundles, which are not interconnected by synapses have also been described (Mackie, 2004). A nerve ring, which has been taken as a simple example of neuronal centralization in Cnidaria, is located near the oral pole of the polyp *Hydra oligactis* (Figure 6a; Grimmelikhuijzen and Graff, 1985). Even more obvious is the presence of nerve rings in medusae at the margin of the bell (Figures 6b and 6c). These nerve rings are

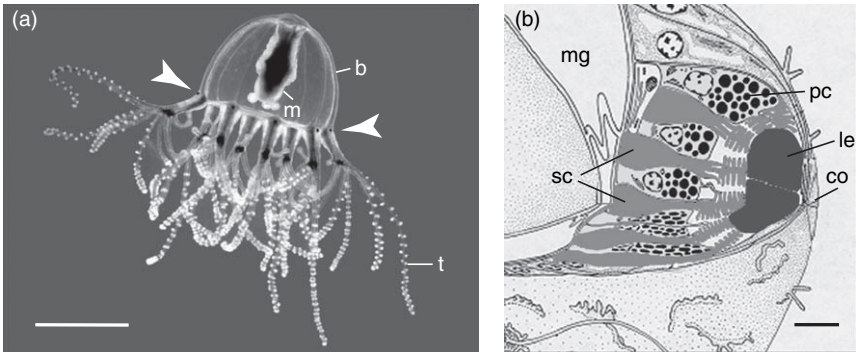

Figure 7 Photosensitive organs in the hydromedusa *Cladonema radiatum*. a, Photograph of an adult medusa with lens eyes located at the base of the tentacles at the margin of the bell (arrowheads). b, Structure of the lens eye in a schematic cross section. integrative centers, where different peripheral pathways from sensory organs converge and where activity patterns that result in coordinated behavior are generated. A further striking example is found in the two marginal nerve rings of *Aglantha*, a pelagic hydrozoan medusa. In these interconnected nerve rings, information from 14 conduction systems, including multiple nerve nets, giant axons, and two epithelial pathways, are processed and result in the generation of complex behavioral patterns (Mackie, 2004). A ring-shaped central nervous system (CNS) has been proposed to be appropriate for a radially symmetrical organism, where the term 'central' is not meant morphologically but rather in terms of the functions carried on within it (Spencer and Arkett, 1984; Mackie, 1990). Cnidarian nerve rings may therefore represent the first integrating concentrations of nervous tissue in the animal kingdom (Bullock and Horridge, 1965).

Ganglionic centers, which contain a variety of sensory structures including statocysts, ocelli, or even, lens eyes, can be found spaced around the bell margin at the base of the tentacles of many medusae (Figure 7a). The occurrence of photosensitive structures in Cnidaria includes a wide range of complexity and specializations. The sessile polyps of all cnidarian classes respond to light (Tardent and Frei, 1969) but until now no photoreceptive structures or specialized cells for light detection have been identified in polyps. The free-swimming medusa stage, however, can have differentiated photoreceptor organs, which range from simple ocelli to highly evolved lens eyes (Figure 7b; Land and Fernald, 1992; Stierwald *et al.*, 2004; Piatigorsky and Kozmik, 2004; Gehring, 2005). The diversity of photosensitive structures is illustrated by the cubozoan *Tripedalia cystophora*, where the planula develops unicellular photoreceptors scattered over the posterior epidermis of the larva, whereas the adult jellyfish forms elaborate multicellular lens eyes (Nordström *et al.*, 2003).

The presence of giant axons is another feature of nervous systems that is common to cnidarians and higher invertebrates. Giant axons are distinguishable from normal axons by their large diameter and relatively high speed of signal conduction. Indeed, the first intracellular neuronal recordings in Cnidaria have been carried out from the giant axons in the stem of the siphonophoran *Nanomia*, a colonial hydrozoan (Mackie, 1973). Giant axons may have evolved independently in different cnidarian groups, most probably by axonal fusion within nerve nets or endomitotic polyploidy (Mackie, 1989). In the hydromedusa *Aglantha*, several giant axons have been shown to be involved in rapid escape behavior. Interestingly, motor giant axons of *Aglantha*, which synapse onto swimming muscles, can conduct two types of action potentials. Rapidly conducted Na^{+}-dependent action potentials result in fast swimming associated with escape behavior, whereas slow swimming movements depend on low-amplitude Ca^{2+} action potentials. Thus, two kinds of impulse propagation within the same giant axon subserve different behavioral responses in *Aglantha* (Mackie and Meech, 1985), showing that structural simplicity does not allow inference of functional simplicity in Cnidaria.

1.19.3.6 Cnidarian Nervous Systems: Ion Channels and Neuroactive Substances

Cnidarian nervous systems have electrophysiological properties which are similar to those of higher

animals. Neurons exhibit conventional action potentials with Na^+ inward currents and K^+ outward currents, miniature end-plate potentials, Ca^{2+}-dependent quantal transmitter release, and with spatial and temporal synaptic summation and facilitation (Spencer, 1989). Typical four-domain Na^+ channels are found in Cnidaria, although these channels are not tetrodotoxin sensitive as in higher metazoans (Mackie, 1990). Whereas most protists use Ca^{2+} as the inward charge carrier, purely Na^+-dependent action potentials are common to metazoans, including cnidarians. This prompted Hille (1984) to speculate that Na^+ channels evolved from Ca^{2+} channels in parallel with the evolution of the first nervous system. With the emergence of voltage gated Na^+-selective channels, neurons that generate action potentials at high frequency would have become possible; if Ca^{2+} were the only positive charge carrier, high-frequency discharges would probably cause intracellular Ca^{2+} to accumulate to toxic levels (Anderson and Greenberg, 2001). Hille further suggested that oubain-sesitive Na^+–K^+ ATPase molecules, involved in maintaining the electroosmotic gradient of these two ions, evolved coincidentally with Na^+ channels (Hille, 1984).

Two different classes of neuroactive substances, classical neurotransmitters and neuropeptides, have been detected in cnidarian tissues. The major difference between these two classes is their mode of synthesis. While classical transmitters are synthesized in nerve terminals, neuropeptides are synthesized in neuronal cell bodies, processed within vesicles and then transported along the axons to the nerve terminals. A large percentage of cnidarian neurons show immunoreactivity with antisera against neuropeptides that have either an Arg-Phe-NH2 or Arg-Trp-NH2 carboxyterminus (LWamide, RFamide). Furthermore, from a single anthozoan species, *Anthopleura elegantissima*, 17 different neuropeptides have been isolated so far, some of which are specifically expressed in at least six identified neuronal subpopulations (Grimmelikhuijzen *et al.*, 1996). Cnidarian neuropeptides occur only in neurons and have been shown to have behavioral effects in several species. Interestingly, some of these neuropeptides also play an important role in growth regulation, morphogenesis, and the induction of metamorphosis (Schaller *et al.*, 1996). This dual role is exemplified in the planula of the hydrozoan *Hydractinia echinata*, where LWamide and RFamide neuropeptides form an antagonistic system that influences both planula migratory behavior and initiation of larval metamorphosis in response to environmental cues (Katsukura *et al.*, 2003, 2004; Plickert *et al.*, 2003). Although, the cnidarian nervous system is primarily peptidergic, there is growing evidence for the involvement of classical neurotransmitters in signal transmission. This is supported by the presence of biogenic amines and acetylcholine in the tissues of several cnidarian species and the role of these substances in modulating behavior. Furthermore, serotonin-immunoreactive neurons have been described in the colonial anthozoan *Renilla*, and GABA and glutamate receptors mediate a modulatory function of pacemaker activity and feeding response in *Hydra* (Umbriaco *et al.*, 1990; Concas *et al.*, 1998; Kass-Simon *et al.*, 2003; Pierobon *et al.*, 2004). However, it remains controversial to what extent neuronal signal transmission in Cnidaria is accomplished by the use of classical transmitters since their action at the synaptic level has not yet been demonstrated (Mackie, 1990; Grimmelikhuijzen *et al.*, 1996; Anctil, 1989). Nevertheless, the presence of both aminergic and peptidergic neurotransmitters in cnidarians indicates a parallel evolution of the two transmitter systems (Prosser, 1989).

1.19.3.7 Placozoa versus Cnidaria

The phylogenetic position of Placozoa, which is currently represented by a single-known species, *T. adhaerens*, is controversial. Recent evidence, however, favors the localization of Placozoa between Cnidaria and Bilateria, rather than within medusozoan cnidarians. Placozoa have a low level of tissue organization consisting of only four different somatic cell types arranged in a functional lower and upper side enfolding a number of intermediate cells (Grell and Ruthman, 1991). Although *Trichoplax* apparently lacks nerve cells, some cells react with antibodies raised against the neuropeptide RFamide (Schuchert, 1993). The possible presence of neuropeptides in *Trichoplax* may indicate a secondary loss of a nervous system, in accordance with the notion that placozoans are reduced derivatives of an early metazoan. Alternatively, RFamides could have a primitive pre-nervous role in growth regulation or differentiation. Be that as it may, extant placozoans do not have neurons and do not have nervous systems. Thus, we are left with the Cnidaria.

The analysis of signal conducting systems in cnidarians representing the most basal extant phyla with nervous systems, leads to the conclusion that many basic features characterizing nervous systems of higher animals were already present in the last common ancestor of cnidarians and bilaterians. Cnidarian neurons structurally resemble those of higher animals. Furthermore, the biophysical basis of electrogenesis in

neurons is conventional, and chemical and electrical synapses are similar to those found in all higher metazoans, although the common use of bidirectional synapses in cnidarians is somewhat unusual. Therefore, the 'simplicity' of the cnidarian nervous system does not lie at the level of individual neurons, but rather in the organization of such cells into conducting systems, such as nerve nets. The evolutionary origin of the neuron remains elusive.

1.19.4 Origin of the First Nervous System: A Comparative Developmental Genetic Approach

1.19.4.1 Conserved Genes in Neuronal Development

In 1990, Mackie relaunched Parker's discussion of the elementary nervous system and proposed that the evolutionary origin of the nervous system should be reconsidered in the light of recent results form molecular biology and developmental genetics (Mackie, 1990). Indeed, over 80 years after Parker first put forward his theoretical views, it seems appropriate to consider not only the origin of the cell lineages that initially gave rise to neurons, but also the origin of the genes involved in neurogenesis and neuronal differentiation. Ideally this type of molecular evolutionary developmental approach should allow identification of a basal set of genes that are likely to have been involved in generating the first nervous system. Thus, a novel and promising approach to nervous system evolution is the comparative analysis of the genes that control neuronal proliferation and differentiation in key metazoan phyla. Which key phyla should be subjected to such a molecular genetic analysis? Although, impulse conduction and sensitivity to neuromodulatory substances have been shown in different Porifera, extant sponges lack nerve cells and a nervous system and are therefore not ideal for studies on the molecular genetics of neuronal development. In contrast, true neurons as well as different levels of nervous system organization can be found in the Cnidaria, and, in consequence, a comparative developmental genetic analysis of cnidarian versus bilaterian nervous systems is likely to be useful. In the following, the evolution and origin of the first nervous system will be considered in light of the molecular genetic control elements for neurogenesis, axial patterning, and eye development that are conserved between Cnidaria and Bilateria. A caveat for all of these considerations is, however, the fact that functional analyses of key control genes are still lacking in the Cnidaria.

1.19.4.2 Genetic Control of Neurogenesis in Cnidaria and Bilateria

Key genetic regulators of neurogenesis have been studied in a number of vertebrate (mouse, chick, frog, zebra fish) and invertebrate (*Drosophila, C. elegans*) model organisms. Several transcription factors involved in early neurogenesis events have been identified that are structurally and functionally conserved among protostome and deuterostome phyla (Arendt and Nübler-Jung, 1999; Bertrand *et al.*, 2002; Reichert and Simeone, 2001). This suggests that similar transcription factors might already have been involved in neurogenesis of the common ancestor of all bilaterians. Different classes of regulatory genes involved in neurogenesis have been isolated and their expression patterns studied in the cnidarian model organism *Hydra*, and homologues of regulatory genes expressed during neurogenesis in deuterostomes and protostomes have been found.

Two homeobox genes *prdl-a* and *prdl-b* are expressed in nerve cell precursors and neurons in the body column of the *Hydra* polyp (Gauchat *et al.*, 1998, 2004; Miljkovic-Licina *et al.*, 2004). They are both related to the paired-like *aristaless* family, members of which have been shown to be important for normal forebrain development in vertebrates (Seufert *et al.*, 2005). The *COUP-TF* genes which encode orphan nuclear receptors are implicated both in neurogenesis and in CNS patterning during embryogenesis as well as in the adult nervous system of vertebrates and *Drosophila* (Gauchat *et al.*, 2004). The *Hydra* homologue *hyCOUP-TF*, was found to be expressed in a subset of neurons and in the nematocyte lineage (Miljkovic-Licina *et al.*, 2004). The bHLH transcription factor *CnASH* is related to the *achaete-scute* gene family in *Drosophila*, which has proneural activity (Grens *et al.*, 1995). *CnASH* is expressed in the differentiation of sensory neurons in the tentacles of *Hydra* (Hayakawa *et al.*, 2004). Another bHLH transcription factor *Atonal-like1* (*Atl1*), which belongs to the Atonal gene family, has been isolated in the hydrozoan *Podocoryne*. Atonal homologues are responsible for the determination of neural fate in sense organs as well as in the peripheral system and CNS of bilaterian model organisms (reviewed in Hassan and Bellen, 2000). In the medusa of *Podocoryne, Atl1* is expressed in subsets of presumed nerve cells of the tentacle and the feeding organ (Seipel *et al.*, 2004). These findings suggest that some elements of the genetic network underlying neuronal development may be conserved from cnidarians to vertebrates, implying that the

molecular genetic control of neuronal development evolved only once.

1.19.4.3 Genetic Control of Anteroposterior Patterning in Cnidaria and Bilateria

The bilateral symmetry of bilaterian animals is achieved by the orthogonal intersection of an anteroposterior and a dorsoventral body axis. Different genetic mechanisms are responsible for patterning each axis and the underlying gene networks are widely conserved between Protostomia and Deuterostomia. Thus, *Hox* genes play an evolutionary conserved role in patterning the anteroposterior axis of all bilaterians studied to date (Slack *et al.*, 1993). Interestingly, Hox genes are also responsible for the anteroposterior patterning of bilaterian nervous systems as has been shown in genetic experiments carried out for arthropods and vertebrate model systems. The anteroposterior expression pattern of the *Hox* genes during nervous system development largely reflects their pattern of expression in the embryonic body and corresponds to the spatial arrangement of the *Hox* genes in their chromosomal clusters (spatial colinearity). Similarly, the homeobox transcription factors of the *orthodenticle* (*otd/Otx*) and *empty spiracles* (*ems/Emx*) families have evolutionarily conserved expression domains in the anterior cephalic regions of all bilaterian animals studied to date. Moreover, both gene families are known to play an important role in the development of the most anterior part of the nervous system, the anterior brain, in arthropods and vertebrates. Mutations in these genes lead to severe brain phenotypes such as the absence of large neurogenic regions of the brains of both insects and vertebrates. Thus, bilaterian brains are universally characterized by a rostral region specified by genes of the *otd/Otx* and *ems/Emx* family and a caudal region specified by genes of the *Hox* family (Figure 8a; Shankland and Bruce, 1998; Sharman and Brand, 1998; Arendt and Nübler-Jung, 1999; Hirth and Reichert, 1999; Reichert and Simeone, 2001; Lowe *et al.*, 2003; Lichtneckert and Reichert, 2005).

Homologous genes involved in anteroposterior patterning of the body wall and nervous systems of bilaterians have been isolated from different cnidarian species. *otd/Otx* family genes have been cloned from two hydrozoans, *Hydra* (Smith *et al.*, 1999) and *Podocoryne* (Müller *et al.*, 1999). Whereas *Podocoryne Otx* is only expressed in the striated muscle of the developing medusa, which seems unrelated to *otd/Otx* function in Bilateria, *Hydra Otx* expression can be found in ectodermal epithelial cells throughout the body column. In addition, *Hydra Otx* expression has been detected in nerve cells by cell type Northern; however the *Otx*-positive neural subpopulation has not yet been identified. In gastrozooid polyps of the hydrozoan *Hydractinia symbiolongicarpus*, expression of *Emx* is detected at the oral 'head' end of the oral–aboral axis, specifically in endodermal epithelial cells of the hypostome (Mokady *et al.*, 1998). No *Emx* expression in nervous systems of cnidarians has been described so far.

The question whether true *Hox* genes are present in cnidarians is controversial (reviewed in Galliot, 2000; Ball *et al.*, 2004; Finnerty, 2003). Based on sequence analysis, several authors have argued for the presence of anterior class and posterior class *Hox* genes in cnidarians. The chromosomal linkage of these genes in clusters is still a matter of debate. The expression data from hydrozoans and anthozoans show that different *Hox* genes are expressed in specific regions along the oral–aboral body axis. Five *Hox* genes were recovered from the sea anemone *Nematostella vectensis*; their expression was studied during larval development (Finnerty *et al.*, 2004). Two cnidarian-specific gene duplications appear to have produced two pairs of sister genes *anthox1-anthox1a* which are homologous to bilaterian posterior group *Hox* genes, and *anthox7-anthox8*, which are homologous to the anterior *pb/Hox2* genes in vertebrates and flies (Figure 8b). Whereas expression of *anthox1* is restricted to the ectoderm at the aboral tip of the polyp, a nested expression of *anthox1a, anthox7*, and *anthox8* is found in the endoderm layer all along the body column. The *lab/Hox1* homologue, *anthox6* is expressed in the endodermal body layer of the pharynx, the oral-most part of the polyp. Therefore, during development *Nematosella Hox* gene expression spans nearly the entire oral–aboral axis, which is similar to the situation in the body of bilaterian animals. Whether expression of anthozoan *Hox* genes is present in the nerve cells of *Nematosella* is currently unknown. Cnidarian *Hox* gene expression has also been reported in larval development of the hydrozoan *P. carnea* (Masuda-Nakagawa *et al.*, 2000; Yanze *et al.*, 2001). Three *Hox* genes, *cnox1-Pc, cnox2-Pc*, and *cnox4-Pc* are expressed in restricted domains along the oral–aboral axis in ectodermal and endodermal germ layers of the planula larva. Although, an anteroposteriorly polarized nerve net has been described in the planula larva of *Podocoryne* (Gröger and Schmid, 2001), the presence of the *Hox* genes in the cells of this nerve net has not been investigated yet. Interestingly, comparison of orthologous *Hox* genes between *Nematostella* and *Podocoryne* reveals that their axial expression patterns in the planula are reversed.

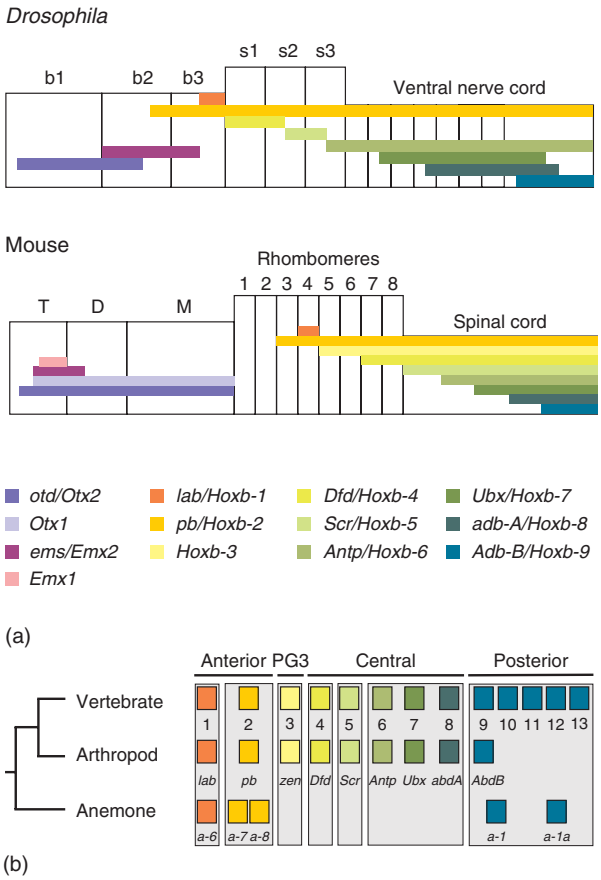

Figure 8 Conserved anteroposterior order of gene expression in embryonic CNS development of bilaterians and occurrence of Hox genes in bilaterians and anthozoans. a, Schematic of *otd/Otx, ems/Emx*, and *Hox* gene expression patterns in the developing CNS of *Drosophila* (stage 14 embryo) and mouse (stage 9.5–12.5 embryo). b, Homology of *Nematostella vectensis Hox* genes to vertebrate and arthropod orthologues based on phylogenetic analysis of homeodomains. Vertebrate *Hox* paralogues are numbered from 1 to 13. Arthropod *Hox* paralogues are named with *Drosophila* terminology (*lab, labial; pb, proboscipedia; zen, zerknüllt; Dfd, Deformed; Scr, Sex combs reduced; Antp, Antennapedia; Ubx, Ultrabithorax; abd-A, abdominal-A; Abd-B, Abdominal-B*). Paralogue groups are classified as anterior, paralogue group 3 (PG3), central, and posterior *Hox* genes. *a-1, anthox1; a-1a, anthox1a; a-6, anthox6; a-7, anthox7; a-8, anthox8;* b1–b3, segments in the *Drosophila* brain (proto-, deuto-, and trito-cerebrum, respectively); s1–s3, mandibular, maxillary, and labial segments, respectively, of the fly subesophageal ganglion; T, telencephalon; D, diencephalon; M, mesencephalon. a, Reproduced from Sharman, A. C. and Brand, M. 1998. Evolution and homology of the nervous system: Cross-phylum rescues of otd/Otx genes. *Trends Genet.* 14(6), 211–214, with permission from Elsevier. b, Reprinted with permission from Finnerty, J. R., Pang, K., Burton, P., Paulson, D., and Martindale, M. Q. 2004. Origins of bilateral symmetry: *Hox* and *dpp* expression in a sea anemone. *Science* 304, 1335–1337. Copyright 2004 AAAS.

For example, the anterior *Hox* gene, *cnox1-Pc* is expressed at the apical end of the planula in *Podocoryne*, while the *Nematostella* homologue, *anthox6* is expressed at the blastoporal end of the planula. This apparent contradiction may be attributed to a developmental reversal of spatial polarity that has been described for *Hox* expression in *Podocoryne* during metamorphosis (Masuda-Nakagawa *et al.*, 2000). Thus, while clear homologues of bilaterian anterior and posterior class *Hox* genes are present in cnidarians, the correlation between cnidarian and bilaterian *Hox* gene expression patterns remains ambiguous. Moreover, the expression and function of cnidarian *Hox* genes in nerve cells has not been explicitly investigated so far, leaving the question of their involvement in nervous system patterning unanswered.

1.19.4.4 Genetic Control of Dorsoventral Specification in Cnidaria and Bilateria

A hallmark of dorsoventral polarity in many bilaterians is the dorsoventral location of the CNS. Whereas in vertebrates the CNS is located dorsally, in arthropods the CNS is located ventrally. This reversal in the relative position of the CNS led Geoffroy Saint-Hilaire to propose that the dorsoventral axes of vertebrates and arthropods are inverted with respect to the position of their mouth openings (Geoffroy

Saint-Hilaire, 1822). This 'dorsoventral inversion' hypothesis has gained strong support in recent years, since homologous, but spatially inverted patterning mechanisms were found to be operating in vertebrates and insects (Holley *et al.*, 1995). The *transforming growth factor-β* (*TGF-β*) superfamily members *decapentaplegic/Bone Morphogenetic Protein 4 (dpp/BMP4)* are required for patterning the dorsal region in arthropods and for promoting ventral fates in vertebrates (Figures 9a and 9b). In both animal groups *dpp/BMP4* have strong anti-neurogenic properties, and therefore, the nerve cord can only develop where *dpp/BMP4* activity is inhibited or absent. In *Drosophila*, the ventral expression of the *dpp* antagonist *short gastrulation* (*sog*) allows the development of the ventral neuroectoderm, whereas in vertebrates, the same effect is achieved dorsally by the *sog*-related *Chordin* gene (Reichert and Simeone, 2001; Lichtneckert and Reichert, 2005).

Although textbooks usually characterize cnidarians as radially symmetrical (Brusca and Brusca, 1990; Campbell *et al.*, 2004; Johnson, 2003), it has long been recognized that many anthozoan cnidarians exhibit bilateral symmetry (Stephenson, 1926; Hyman, 1940). In many sea anemones a secondary body axis, referred to as the directive axis, crosses the pharynx orthogonally to the primary oral–aboral body axis. For example, a cross section through the sea anemone *N. vectensis* reveals that the mesenteries and their associated retractor muscle fibers exhibit a bilateral symmetry in their orientation around the pharynx. Genes involved in specifying the dorsoventral axis in Bilateria have recently been found to be expressed asymmetrically along the directive axis of anthozoans. In the gastrulating embryo of *Acropora millepora*, expression of *bmp2/4-Am* (a *dpp/BMP4* homologue) is not symmetrical about the primary body axis, which runs through the blastopore. Rather *bmp2/4-Am* mRNA is concentrated in one quadrant of the surface ectoderm next to the blastopore (Hayward *et al.*, 2002). This suggests that the *bmp2/4-Am* expression domain defines a second polarized axis, in addition to the one defined by the blastopore. A similar distribution of *dpp/BMP* mRNA has been reported during early embryogenesis of the sea anemone *N. vectensis* (Finnerty *et al.*, 2004); at later developmental stages of *Nematostella, dpp/Bmp4* is expressed in the pharynx and the mesenteries in a bilaterally symmetrical fashion relative to the directive axis (Figure 9c). Within the Cnidaria, bilateral symmetry is a characteristic of anthozoans and thus probably represents an ancestral trait of the phylum that might have been lost

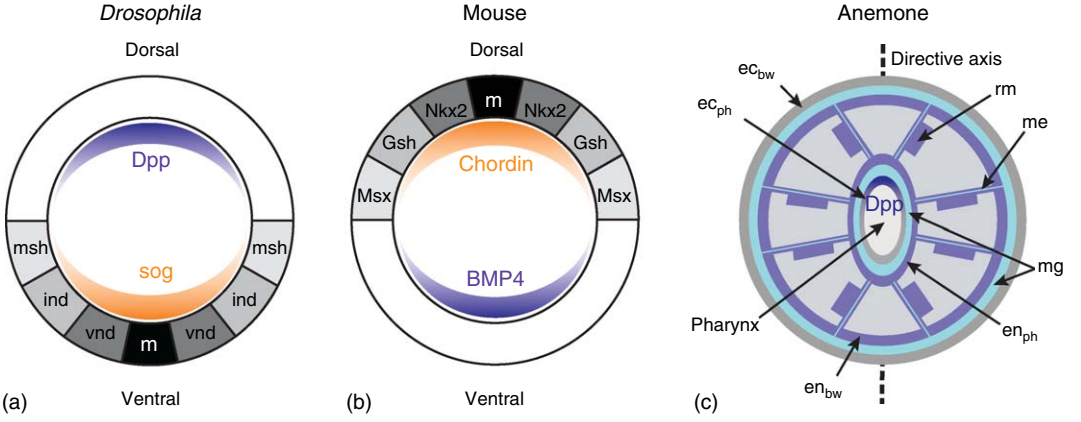

Figure 9 Asymmetric Dpp/BMP4 signaling along the dorsoventral and directive axis of bilaterians and anthozoans. a and b, The secreted products of the homologous genes *dpp/Bmp4* form a dorsoventrally inverted gradient in mouse (Deuterostomia) with respect to *Drosophila* (Protostomia). Sog/Chordin act from opposing dorsoventral poles in both insect and vertebrate embryos antagonizing the antineurogenic effect of Dpp/BMP4. The neuroepithelium is further subdivided by a set of homeobox genes into medial (*vnd/Nkx2*), intermediate (*ind/Gsh*), and lateral (*msh/Msx*) neurogenic domains in *Drosophila* and mouse. c, Cross section through the pharyngeal region of the anemone *Nematostella* reveals bilateral symmetry about the directive axis. The pharynx is attached to the outer body wall via eight endodermal mesenteries. Each mesentery bears a retractor muscle on one face. The only plane of mirror symmetry passes through the directive axis. During development, Dpp is expressed throughout the endoderm. In addition, Dpp expression is transiently found in the pharynx ectoderm in an asymmetric distribution relative to the directive axis. ec_{bw}, body wall ectoderm; ec_{ph}, pharyngeal ectoderm; en_{bw}, body wall endoderm; en_{ph}, pharyngeal endoderm; m, midline; me, mesentery; mg, mesogloea; rm, retractor muscle. a and b, Modified from Reichert, H. and Simeone, A. 2001. Developmental genetic evidence for a monophyletic origin of the bilaterian brain. *Philos. Trans. R. Soc. Lond. B* 356, 1533–1544, Copyright 2001, The Royal Society. c, Reprinted with permission from Finnerty, J. R., Pang, K., Burton, P., Paulson, D., and Martindale, M. Q. 2004. Origins of bilateral symmetry: *Hox* and *dpp* expression in a sea anemone. *Science* 304, 1335–1337. Copyright 2004 AAAS.

secondarily in medusozoans due to the emergence of a clearly radial symmetric medusoid life stage. Although at least part of the dorsoventral patterning system that has antineural function in bilaterians is present in anthozoan polyps, no morphological regionalization of the nervous system along the directive axis of polyps has yet been observed.

In arthropods and vertebrates, initial regionalization of the dorsoventral axis by *dpp/Bmp4* and their antagonists is followed by further patterning of the neuroectoderm along its dorsoventral axis by a group of conserved homeobox genes. In *Drosophila*, *vnd* (*ventral neuroblasts defective*), *ind* (*intermediate neuroblasts defective*), and *msh* (*muscle segment homeobox*) are involved in the dorsoventral specification of a ventral, intermediate, and lateral column of neuroblasts in the developing ventral neuroectoderm (Figures 9a and 9b). During vertebrate neurogenesis, genes closely related to *Drosophila msh* (*Msx*), *ind* (*Gsh*), and *vnd* (*Nkx2*) are expressed in domains corresponding to those in *Drosophila* along the dorsoventral axis of the developing CNS suggesting that this system was conserved throughout evolution (reviewed in Arendt and Nübler-Jung, 1999; Reichert and Simeone, 2001; Lichtneckert and Reichert, 2005).

All three of these dorsoventral patterning genes (*vnd/Nkx2, ind/Gsh, msh/Msx*) are present in cnidarians (Schummer *et al.*, 1992; Grens *et al.*, 1996; Hayward *et al.*, 2001). In the anthozoan *A. millepora, cnox-2Am*, the orthologue of the vertebrate *Gsh* gene, is expressed in scattered ectodermal cells of the larva with a restricted distribution along the oral–aboral body axis. Based on morphology, these cells have been characterized as transectodermal neurons (Hayward *et al.*, 2001). The expression of *cnox-2Am* in a subset of neurons is consistent with the restricted expression of *Gsh* orthologues in bilaterians. The presence of all three dorsoventral patterning homeobox genes in Cnidaria, together with the spatially restricted neuronal expression of *cnox-2Am* along the anteroposterior axis of the planula larva, suggests that the *msh/ind/vnd* system may have had an ancient evolutionary origin that predated the Cnidaria/Bilateria split, and thus might represent an ancient nervous system patterning process. It remains to be shown, however, if the cnidarian orthologues of *vnd/Nkx2* and *msh/Msx* are also expressed in nerve cells and if their expression specifies different neuronal subsets located on a secondary body axis, as in bilaterians.

1.19.4.5 Genes Involved in Eye Development in Cnidaria and Bilateria

A conserved gene regulatory network including members of the *Pax6, six, dachshund*, and *eyesabsent* families has been shown to orchestrate eye development in a wide range of bilaterian animals. *Pax6* mutations in the mouse or fly cause a reduction or absence of eyes. On the other hand, ectopic expression of *Pax6* from various bilaterian species induces ectopic eyes in *Drosophila*, implying that *Pax6* might represent a 'master control' gene for eye development (reviewed in Piatigorsky and Kozmik, 2004; Gehring, 2005). The fundamental, evolutionarily conserved role of the genetic network underlying eye development led to the suggestion of a monophyletic origin of the eye (Gehring and Ikeo, 1999). The *Pax2/5/8* family comprises one single *D-Pax2* gene in *Drosophila* (Fu and Noll, 1997), whereas in mammals three genes, *Pax2, Pax5, and Pax8*, arose by duplications at the onset of the vertebrate lineage (Pfeffer *et al.*, 1998). The *Pax2/5/8* genes play an important role in brain patterning and are also implicated in eye development.

In cnidarians, eyes are found sporadically in some hydrozoan (see Figure 7b) and cubozoan medusae, and it is not known whether other jellyfish have lost their eyes in the course of evolution or whether they never acquired them (Piatigorsky and Kozmik, 2004; Gehring, 2005). Four *Pax* genes (*PaxA, PaxB, PaxC,* and *PaxD*) have been isolated from anthozoans (Miller *et al.*, 2000) and a number of other cnidarian species (Sun *et al.*, 1997, 2001; Gröger *et al.*, 2000; Kozmik *et al.*, 2003), but none of these have a protein domain structure that corresponds of bilaterian *Pax6*. In the cubomedusa *T. cystophora, PaxB* is expressed in the lens and the retina of the complex eyes as well as in the statocyst. Interestingly, it has been shown that *PaxB* is structurally a mosaic between *Pax2* and *Pax6*. This is further supported by functional studies in *Drosophila*, where *PaxB* complements *Pax2* mutants (*sparkling*) and also induces ectopic eyes like *Pax6* (Kozmik *et al.*, 2003). Therefore, *PaxB* of *Tripedalia* might resemble an ancestral gene of the *Pax6* and *Pax2/5/8* subfamilies, which arose by duplication of the ancestral form in the bilaterian line (Kozmik *et al.*, 2003; Piatigorsky and Kozmik, 2004). Thus, the competence to regulate eye development was either inherited from the ancestral *PaxB*-like gene by cnidarian *PaxB* and bilaterian *Pax6*, which would support the monophyletic origin of eyes (Gehring and Ikeo, 1999; Gehring, 2005), or it emerged parallely during the evolution of the two *Pax* genes following the cnidarian bilaterian split (Piatigorsky and Kozmik, 2004). Interestingly, a *PaxB* orthologue has been isolated from sponges (Hoshiyama *et al.*, 1998); however, it is not known whether the expression of this gene is associated with the photoreceptive cells in sponge larva. Additional support for the monophyletic origin

of the eyes was obtained from the hydrozoan *Cladonema*. Orthologues of two *Six* family members, which are known to control eye development in vertebrates and arthropods, are expressed in the lens eyes of the hydromedusa and are involved in eye regeneration (Stierwald *et al.*, 2004). This implies that the common ancestor of Cnidaria and Bilateria may already have possessed some kind of photoreceptive organ. Moreover, it suggests that at least part of the gene regulatory network used for the development of eyes by modern species, was already used by the eumetazoan ancestor. Taken together, the presence of photosensitive cells, probably autonomous receptor–effector cells, in multicellular animals, as exemplified by certain sponge larvae, may have anticipated the emergence of a nervous system. If this were the case, then the sensory input from these photoreceptors might have had a strong influence on the early evolution of the nervous system.

1.19.5 Conclusions and Outlook

The origin and evolution of the first nervous system remains elusive. Over the last 150 years, the evolution of the first nervous system has been a central issue in notions about the emergence of eumetazoan animals, and a variety of theories have been proposed. The main question has been the identification of the primordial cell lineage from which nerve cells might have been derived. During the last decade, however, advances in molecular genetic techniques have focussed our interest on the genes that might have been involved in the generation of the first nervous system. In terms of comparative developmental genetics, it appears that genes involved in patterning of the anteroposterior axis in bilaterians, such as the *Hox* genes, are also expressed in restricted domains along the main body axis during cnidarian larval development as well as in the adult polyp. However, the validity of comparing gene expression patterns along the oral–aboral axis of cnidarians to those found along the anteroposterior axis of bilaterians is questionable. Moreover, in contrast to bilaterians, *Hox* gene expression in cnidarian nerve cells has not yet been unequivocally demonstrated. Similar considerations apply to most of the genes involved in dorsoventral patterning in cnidarians and bilaterians. Thus, although there is morphological and genetic evidence for bilateral symmetry with respect to the directive axis in anthozoans, no regional restriction of neurogenesis in the cnidarian body has been reported to date. Does this mean that the restriction of nervous tissue to one side of the dorsoventral body axis by early genetic pattering mechanism evolved only in bilaterian animals?

One of the most intriguing findings to emerge from preliminary expressed sequence tag (EST) projects on several cnidarian species is that the gene sets of cnidarians and, by implication, the common metazoan ancestor, are surprisingly rich and complex (Kortschak *et al.*, 2003). A long-held assumption is that fewer genes should be required to build a sea anemone than a fly, but this seems not to be true. This paradox is exemplified by the fact that, whereas anthozoan cnidarians have the simplest extant nervous systems, the *A. millepora* genome contains many of the genes known to specify and patterns the much more sophisticated nervous systems of vertebrates and insects. It has been proposed that the first major wave of gene duplications in metazoans predated the Parazoa and Eumetazoa split ~940 Mya resulting in large genomes in basal metazoans (Nikoh *et al.*, 1997; Suga *et al.*, 1999). Gene number seems to be a poor indicator of the sophistication of gene use; it is now widely accepted that alternative splicing and transcriptional regulation are generally more complex in mammals than in insects and that this difference accounts for the execution of more complex molecular programs in complex animals (Ball *et al.*, 2004).

A comparative genetic approach including Cnidaria and Ctenophora as well as different bilaterian groups may help to reconstruct different aspects of the nervous system of the last common ancestor, which might have resembled the first nervous system in evolution. Moreover, the availability of genomic data from Porifera in the near future (Leys *et al.*, 2005), should pave the way for the identification and analysis of further sponge homologues to genes involved in neurogenesis or in sensory organ development in Eumetazoa, thus providing more information about the origin and the evolution of the first nervous system.

1.20 The Evolution of Arthropod Nervous Systems: Insights from Neural Development in the Onychophora and Myriapoda

P M Whitington, University of Melbourne, Parkville, VIC, Australia

Glossary

anlage(n)	Embryonic primordium or rudiment of an organ.
apomorphy	A character that has been derived from, but differs from, the ancestral condition.
commissure	Axon pathways that connect right and left sides of the central nervous system.
basal	At the base of an evolutionary lineage.
efferent	Axons that exit the central nervous system, i.e., motor axons.
fascicle	A bundle of axons.
invagination	Folding of an epithelial sheet to produce a depression, which may separate from the overlying sheet as a vesicle or tube.
monophyletic	Derivation of a taxonomic group from a single ancestral lineage.
neuroblast	A neural stem cell, whose progeny develop either as neural precursors or neurons.
neurogenesis	Developmental processes underlying the generation of an immature, postmitotic neuron. This excludes processes associated with neuron differentiation, e.g., axon growth, neurotransmitter production.
neuromere	A segmental unit of the nervous system.
paraphyletic	A taxonomic grouping that includes some, but not all, of the descendants of a single common ancestor.
polyphyletic	Derivation of a single taxonomic group from two or more different ancestral lineages.
synapomorphy	A character present in two or more related lineages that is derived from a character present in an ancestor shared by only those lineages.

1.20.1 Introduction

Comparative studies of neural development in living animal groups can provide insights into both the evolutionary origins of those groups and how their nervous systems have been modified in the course of evolution. The arthropods are a natural choice for such an analysis, as we know more about cellular and molecular mechanisms of neural development for one arthropod, the fruitfly *Drosophila melanogaster*, than for any other animal. Other representatives of the Hexapoda and the remaining arthropod taxa – Chelicerata, Crustacea, and Myriapoda – have, in comparison, received much less attention. However, insights into developmental mechanisms provided by studies in *Drosophila* have generated a renewed interest in these groups. Each has been the subject of several recent studies, which have employed a range of modern molecular and cellular tools supplementing the classical histological methods used in

descriptions of arthropod embryology dating back to the late nineteenth century.

This article reviews the literature concerning neural development in Myriapoda and a group generally held to be closely related to the Arthropoda, the Onychophora. These taxa have long held a special interest for those seeking to understand the evolution of the Arthropoda and their relationships to other metazoans (Heymons, 1901; Sedgwick, 1888). For example, similarities in the functional morphology (Manton, 1973) and early embryology (Anderson, 1973) of these groups were central to the development of a long-standing model for arthropod evolution, the Uniramian hypothesis (see Origin and Evolution of the First Nervous System, Adult Neurogenesis and Neuronal Regeneration in the Teleost Fish Brain: Implications for the Evolution of a Primitive Vertebrate Trait).

1.20.2 Evolutionary Relationships between Onychophora, Myriapoda, and Other Arthropods

To understand how nervous systems have been modified during the course of evolution, it is necessary to have some knowledge of the phylogenetic relationships between the animal groups in question. I will therefore briefly review our current understanding of the position of the Onychophora and Myriapoda with respect to other arthropods as a prelude to reviewing neural development in these groups. This issue has been a long-standing one in biology and remains a lively topic of debate.

1.20.2.1 Onychophora

Onychophora were originally considered to be a transitional group between the Annelida and the Arthropoda (Sedgwick, 1884; Snodgrass, 1938). Annelidan-like features of their body plan include a soft body and metameric segmentation, while arthropod affinities include presence of a cuticle, dorsal blood vessel, hemocoel, and appendages with extrinsic and intrinsic muscles.

Recent phylogenetic analyses using a range of gene sequences place the Onychophora close to the Arthropoda: either as one of a number of taxa, including Tardigrada, closely related to the Euarthropoda – a taxon comprising the Hexapoda, Myriapoda, Crustacea, and Chelicerata (Figure 1a; Boore *et al.*, 1995; Aguinaldo *et al.*, 1997; Mallatt *et al.*, 2004); as the sister group to the Euarthropoda (Figure 1b; Wheeler *et al.*, 1993); or as a sister group to chelicerates and crustaceans plus hexapods (Figure 1c; Ballard *et al.*, 1992). A parsimony analysis employing a suite of 100 brain morphological features supports a sister group relationship between Onychophora and Arthropoda (Strausfeld, 1998).

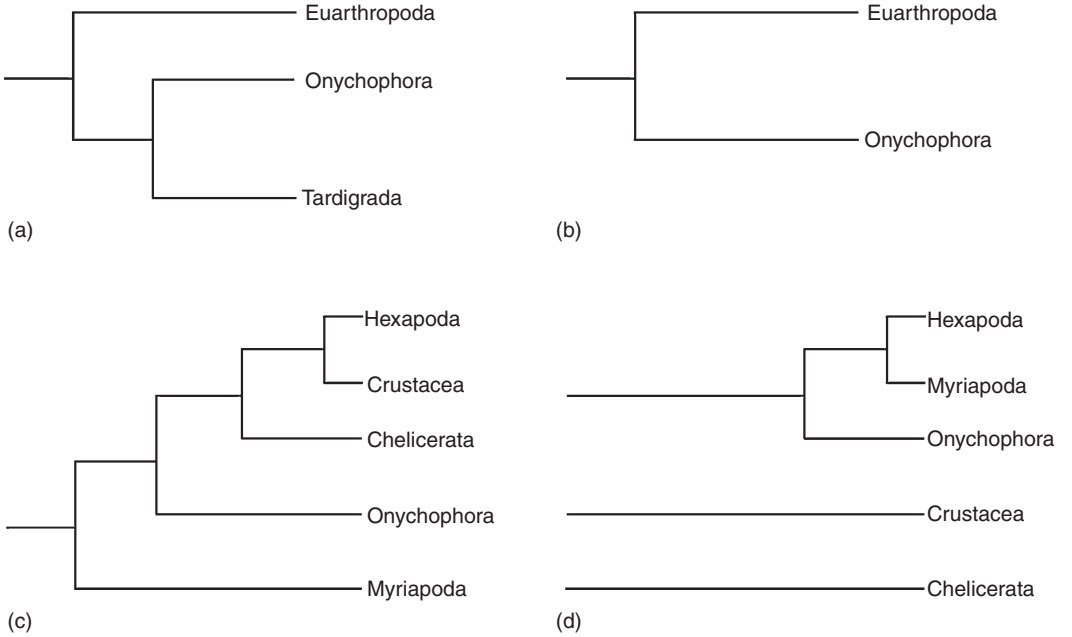

Figure 1 Four alternative views of the phylogenetic relationships between the Onychophora and Euarthropoda (Hexapoda + Crustacea + Chelicerata + Myriapoda). Part a has the Onychophora as one of a number of taxa, including Tardigrada, closely related to the Euarthropoda. Part b has the Onychophora as a sister group to the Euarthropoda. Part c has the Onychophora as a sister group to the chelicerates and crustaceans plus hexapods. Part d depicts the Uniramian hypothesis, which postulates a polyphyletic origin of the arthropods, with Onychophora being most closely allied to the Myriapoda and Hexapoda.

The Uniramian hypothesis (Tiegs and Manton, 1958; Anderson, 1973) placed the Onychophora with the Myriapoda and the Hexapoda in a separate phylum to the other arthropods – the Crustacea and Chelicerata (Figure 1d). The methodology used in the construction of the Uniramian hypothesis has been criticized by several authors and it is no longer widely accepted.

1.20.2.2 Myriapoda

The Myriapoda consists of four classes of terrestrial arthropods (Chilopoda, Diplopoda, Symphyla, and Pauropoda) that share a number of morphological features. However, the status of the Myriapoda as a monophyletic group is controversial. The traditional view of monophyly, based on morphology (Ax, 1987; Boudreaux, 1987), is supported by several recent molecular analyses (Friedrich and Tautz, 1995; Regier and Schultz, 1997; Mallatt *et al.*, 2004). In contrast, Dohle (1997), Kraus (1997), and Shear (1997) maintain that there are no positive morphological characters shared by all of the myriapod classes that can be regarded as genuine synapomorphies – only the absence of characters such as median eyes, scolopidia, and typical ommatidia. Cladistic analyses led them to the conclusion that Myriapoda is a paraphyletic group, with Chilopoda being more closely related to the Hexapoda than to the other three classes of myriapods, which they group together in a taxon called the Progoneata.

Leaving aside the question of monophyly of the Myriapoda, what is the likely sister group of these arthropods? Until recently, the favored view (Figure 2a) was to group the Myriapoda and the Hexapoda in a taxon known as the Antennata (Kristensen, 1991). Morphological characters supporting this division include absence of second antennas and presence of Malpighian tubules, organs of Tömösvary and tracheae in Myriapoda and Hexapoda. A plausible evolutionary scenario for the evolution of the insects from a myriapod-like ancestor involves tagmatization of trunk segments, with loss of limbs on posterior segments to form the abdomen and gain of wings on the two thoracic segments adjacent to the abdomen. This idea seems particularly attractive given the existence of homeotic mutations in *Drosophila* and other insects that result in a transformation from abdominal to thoracic or metathoracic to mesothoracic segmental identity.

In recent years the concept of an Antennata taxon has come under attack and an increasing amount of morphological, developmental, and molecular evidence now points to the malacostracan crustaceans, rather than the Myriapoda, as being the sister group to the Hexapoda (Figures 2b and 2c). Several of the characters supporting this case involve the structure and development of the nervous system. Some of this evidence is detailed below and has been reviewed elsewhere (Strausfeld, 1998; Dohle, 2001; Whitington, 2004; Harzsch *et al.*, 2005). In brief, several aspects of the organization of the compound eyes, the brain, and the ventral nerve cord (VNC) in adult insects show much closer affinities to malacostracan crustaceans than to myriapods. The mode of generation of neurons in the central nervous system (CNS) and the pattern of early axonogenesis in insect embryos are more closely related to malacostracans than to myriapods.

In addition, analyses of several rRNA gene sequences have led to the conclusion that Crustacea, not Myriapoda, is the sister group to Hexapoda. These molecular studies have either grouped the Myriapoda with the Chelicerata (Figure 2b; Friedrich and Tautz, 1995; Hwang *et al.*, 2001; Mallatt *et al.*, 2004; Pisani *et al.*, 2004) or have placed them basal to the rest of the Arthropoda (Figure 2c; Ballard *et al.*, 1992). Similarities between Myriapoda and Arachnida in the pattern of neurogenesis (see Section 1.20.4.1.2) provide support for the former view. In any event, the weight of evidence now speaks against the

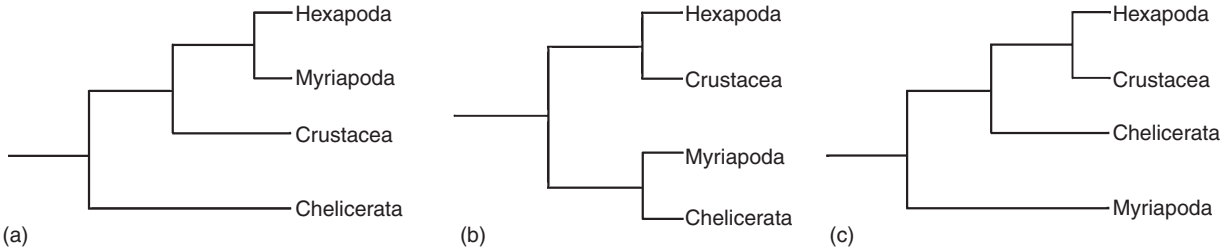

Figure 2 Three alternative views of phylogenetic relationships between the arthropods. Part a has the Myriapoda as the sister group to the Hexapoda, while (b) and (c) depict the more widely held recent view that Crustacea is the sister group to the Hexapoda. Part b has Chelicerata and Myriapoda as sister groups, while (c) has the Myriapoda basal to the other arthropods.

traditional view (Figure 2a) of a sister group relationship between the myriapods and insects.

1.20.3 Neural Development in the Onychophora

Studies of neural development in Onychophora are almost exclusively restricted to morphological descriptions using classical histological techniques (Balfour, 1883; Sedgwick, 1885, 1887; Evans, 1902; Pflugfelder, 1948; Manton and Harding, 1949). A recent study (Eriksson *et al.*, 2003) has supplemented these methods with an immunohistochemical staining procedure that reveals developing axon tracts. These studies, on species from a wide geographical range and including both ovoviviparous and viviparous groups, provide a consistent view of neural development, which is likely to reflect an ancestral mode.

1.20.3.1 Neurogenesis

Neurogenesis in Onychophora commences at an early embryonic stage, when the first segmental borders are beginning to appear in the head and 7–9 pairs of somites are evident (Figure 3; stage 1 according to the staging system of Eriksson *et al.*, 2003).

The region of the ventral ectoderm from which the CNS arises – the neuroectoderm – consists of a simple stratified layer of epithelial cells, whose nuclei are elongated in the apical–basal axis. Scattered mitotic divisions are seen in enlarged cells in this layer. Further internally, a layer of smaller, more rounded cells with heterochromatic nuclei is present – presumably the products of these divisions (Figures 3 and 4). Sedgwick (1887) and later Eriksson *et al.* (2003) suggest that these darker cells are neuron precursors. However, the manner in which they arise from the outer cells remains unclear, as is their distribution over the neuroectodermal cell sheet.

At stage 1 the left and right sides of the neuroectoderm are separated, in all but the most anterior and posterior regions of the embryo, by a medial layer of thin, extraembryonic ectoderm (Figure 3).

Slightly older embryos, in which antennas are just beginning to form (stage 2), show an additional layer internal to the two layers described above, which consists of small cells with strongly heterochromatic nuclei (Figures 4 and 5). Some of these

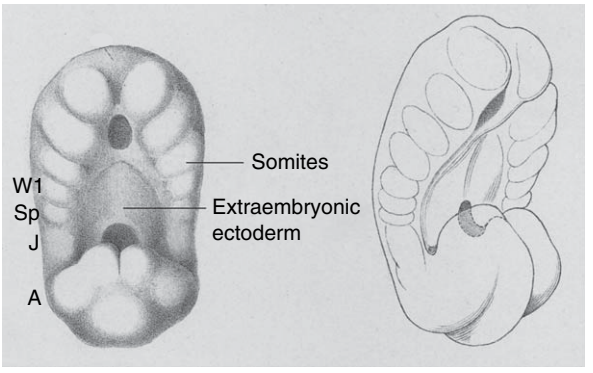

Figure 3 *Peripatus capensis* embryo at stage 1 of Eriksson *et al.* (2003). A, antennal segment; J, jaw; Sp, slime papilla; W1, walking leg 1. Reproduced from Sedgwick, A. 1885. The development of *Peripatus capensis*. *Q. J. Microsc. Sci.* 25, 449–468, with permission from The Company of Biologists.

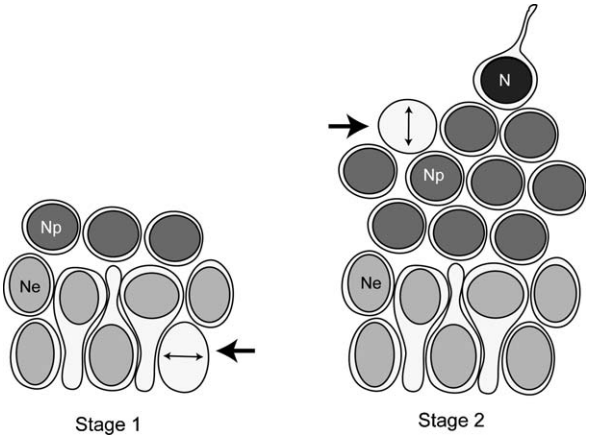

Figure 4 Schematic representations of the neuroectoderm and ganglion anlagen of stage 1 and 2 onychophoran embryos. Ne, neuroectodermal cells; Np, neural precursor cells; N, neurons. Arrows indicate regions of mitotic activity. Lines with double arrowheads indicate orientation of long axis of mitotic spindle within the dividing cells. Neural precursor cells are presumed to arise from divisions of cells in the outer neuroectodermal layer. Mitotic divisions of these neural precursor cells are thought to generate neurons in the ganglion anlage.

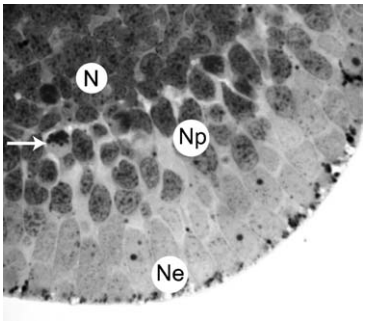

Figure 5 Cross section of a stage 4 *Euperipatoides kanangrensis* embryo showing neuroectoderm and ganglion anlage. Ne, neuroectodermal cells; Np, neural precursor cells; N, neurons. Arrow indicates a dividing cell at the border between the neural precursor and neuron layer. Reproduced from 'Head development in the onychophoran *Euperipatoides kanagrensis* with particular reference to the central nervous system', *J. Morphol.*; Eriksson, B. J., Tait, N. N., and Budd, G. E.; Copyright © 2003, Wiley-Liss. Reprinted with permission of Wiley-Liss Inc., a subsidiary of John Wiley & Sons, Inc.

cells are apparently early-differentiating neurons as they possess small axon-like protrusions (Eriksson *et al.*, 2003). These cells are even more rounded than the cells in the neural precursor layer. There is a rapid increase in the number of these cells and the thickness of the innermost layer over the following developmental period, during which time the outer two layers remain relatively constant in thickness. How the innermost cells are generated from the presumed neural precursor cells in the second layer is unclear. While mitotic activity is evident in the second layer (Figure 5), there is no indication that these cells undergo the asymmetrical, stem cell divisions typical of neuroblasts of insects and malacostracan crustaceans. Nor is there any sign of the internal nuclear migration characteristic of neurogenesis in the Myriapoda (see Section 1.20.4.1.2). Pflugfelder (1948) describes asymmetrical divisions in the neuroectodermal layer that produce neurons, but this is not apparent in his figures. He also describes an internal movement of these immature neurons through a thick basement membrane that separates the neuroectoderm from the ganglion anlagen. Mayer (2005) presents a series of cross sections of the onychophoran neuroectoderm at different developmental stages which provide additional support for the sequence of cellular events described above.

It is unclear whether there is a segregation of neural precursor and epidermal precursor cell fates within the neuroectoderm of the onychophoran embryo. It seems likely that cells remaining in the outer neuroectodermal layer after neurogenesis has slowed down develop into epidermal cells, although this has not been definitively shown. There is no indication from classical histological studies that the epidermis arises by a migration of ectodermal cells from lateral or medial positions, as occurs in myriapod (see Section 1.20.4.1.3), crustacean, and chelicerate embryos.

A stereotypic pattern of early-differentiating, individually identified neurons, such as is seen in insect and crustacean embryos, cannot be readily discerned in the VNC of onychophoran embryos. Large numbers of neurons are rapidly produced soon after neurogenesis commences. Neuromeres in the VNC of adult onychophorans contain much larger numbers of neurons (Schürmann, 1995, estimates 20000–40000 neurons per neuromere) than in insect and crustacean VNC ganglia (approximately 700 neurons per neuromere). The majority of these neurons are small cells (nuclei of diameter 5–9 μm), which cannot be individually identified. While small cells of this type are found in certain regions of the brain in insects and crustaceans (Strausfeld, 1976, 1998; Strausfeld *et al.*, 1995), they are not a feature of ventral ganglia in these groups.

1.20.3.2 Development of Central Axon Tracts

The pattern of axon growth in the embryonic onychophoran CNS is summarized diagrammatically in Figure 6. This schema is based largely on data presented in Eriksson *et al.* (2003), where antiacetylated tubulin immunohistochemistry was used to reveal axons in the developing CNS of *E. kanangrensis*.

1.20.3.2.1 Brain Axon growth within the developing CNS commences when the ganglion anlage already contains many neurons (stage 5). The first axon tract to appear is the antennal commissure, which links left and right sides of the developing antennal hemispheres. Efferent axons linking the first neuromere to the base of the antenna – the

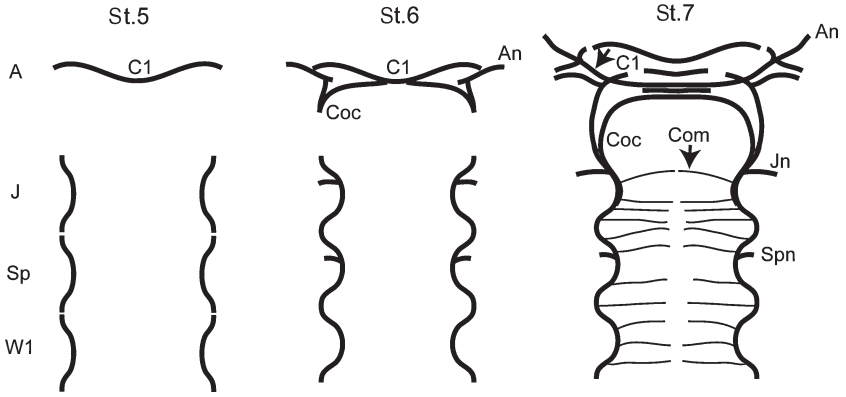

Figure 6 Schematic representation of formation of major axon tracts in the brain and VNC of the onychophoran embryo from stages 5–7. E.; Copyright © 2003, Wiley-Liss. Reprinted with permission of Wiley-Liss Inc., a subsidiary of John Wiley & Sons, Inc.

antennal nerve – appear shortly thereafter, as do posteriorly projecting axons (Figure 7a). The brain becomes much more complex from stage 7 onwards, as many more neurons contribute axons to the neuropile, antennal glomeruli develop, and additional commissural tracts appear (Figure 7b). During this period, the antennal nerve becomes redirected, projecting in an anterior rather than a lateral direction.

1.20.3.2.2 Ventral nerve cord Axons begin to appear in the neuromeres that innervate the jaws, the slime papillae, and the most anterior legs at the same time as the antennal commissure begins to form. Most of these axons project longitudinally, meeting axons from adjacent neuromeres during stage 5 (Figure 6). Axonal connection between the brain and the VNC is delayed as a thin ectodermal sheet initially separates the antennal and jaw segments. By stage 7, when the connection between the brain and the VNC is established, a broad, continuous bundle of axons runs longitudinally down each side of the VNC (Figures 6 and 7b). These longitudinal connectives, which are widely separated and lie lateroventrally, are joined by commissural axon bundles.

Commissure formation in trunk segments is retarded with respect to the antennal neuromere, presumably because of the split in the germ band in the trunk. Pioneering axons do not begin projecting towards the ventral midline in trunk segments until late stage 6 to early stage 7 (Figures 6 and 7b). By this stage the left and right sides of the germ band have begun to move towards the ventral midline and are separated by only a narrow strip of thin, extraembryonic ectoderm. In contrast, the antennal commissure is strongly developed at this stage. Growth of efferent axons from trunk neuromeres is well under way by stage 6–7.

The pattern of commissural growth in trunk segments of Onychophora, as revealed by antiacetylated tubulin staining of *E. kanangrensis* (Eriksson *et al.*, 2003) and antihorseradish peroxidase (anti-HRP) immunostaining of *Acanthokara kaputensis* embryos (P. M. Whitington and D. Leach, unpublished) is quite irregular, contrasting with the stereotypic mode of commissure formation in crustaceans and insects (Klämbt *et al.*, 1991; Whitington *et al.*, 1993, 1996). A relatively large and variable number of separate axon fascicles (between five and nine, compared to two in insects and crustaceans) make up the commissural pathways in an individual trunk neuromere (Figure 8a). These fascicles are unevenly spaced in the anteroposterior axis and the course taken by single fascicles, at least during early stages of commissure formation, can be quite irregular. Fascicles often do not grow directly across the midline, but may wander in the anteroposterior axis, sometimes fusing with other fascicles (Figure 8b). Some of the irregularity in the pattern of commissural axon tracts is maintained into late embryonic stages.

Unlike the situation in most arthropod embryos, the developing VNC comprises a continuous mass of neural tissue – at no stage is a morphological separation of individual neuromeres into distinct ganglia linked by connectives evident. The leg nerves are the only gross structures in the CNS that show a clear metameric organization.

The above description of the final structure of the embryonic onychophoran nervous system closely matches the organization of the adult onychophoran nerve cord, as described in several early studies (reviewed in Schürmann, 1995). One difference is

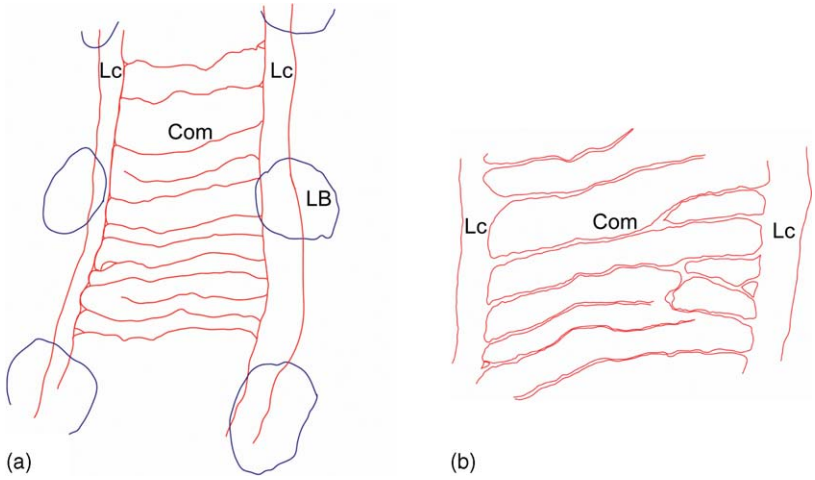

Figure 8 Camera lucida drawings of axons in the VNC of whole-mount stage 7 *A. kaputensis* embryos immuno-stained with anti-HRP antibody (P. M. Whitington and D. Leach, unpublished). a, The axon pattern in two adjacent neuromeres; b, higher-power view of a single neuromere. Lc, longitudinal connectives; Com, commissural axons; LB, base of limb bud.

that the adult shows a more regular arrangement of commissures, with either 9 or 10 being found per neuromere (Balfour, 1883; Feodorow, 1926).

1.20.3.3 Ventral Organ Formation

A pair of prominent structures, called ventral organs, forms in close association with the developing brain of the onychophoran embryo. Their first appearance is at stage 7, when the neuroectoderm just lateral to the ventral midline invaginates to form a pair of grooves (Figure 9a). Eventually, these invaginations detach from the surface to form two vesicles – so-called hypocerebral organs – at the ventral base of the brain (Figure 9b). The function of these organs is unclear, although the ultrastructure of the cells facing their lumen suggests a glandular role (Eriksson *et al.*, 2003, 2005).

Structures called ventral organs have been described in a number of myriapod embryos (e.g., in Symphyla (Tiegs, 1940), Pauropoda (Tiegs, 1947), and Chilopoda (Heymons, 1901)), raising the question of whether these are homologous to the onychophoran ventral organ. Indeed, possession of ventral organs has been claimed to be a synapomorphy of Onychophora and Myriapoda (Anderson, 1973). This issue is complicated by the fact that the term ventral organ has been used to refer to two quite different structures in myriapod embryos (see Sections 1.20.4.1.2 and 1.20.4.1.3).

One clear difference between myriapod and onychophoran ventral organs is that these structures are segmentally repeated in the former group and not in the latter. Pflugfelder (1948) has claimed that ventral organs form in every body segment of onychophoran embryos. However, he uses the term more broadly to refer to the more medial portion of the ventral neuroectoderm. While invagination does takes place within this region in the antennal neuromere, there is no clear indication that the medial neuroectodermal region in other segments undergoes this morphogenetic change or has a different fate to the rest of the neuroectoderm. There would therefore appear to be little justification in claiming that ventral organs exist in segments other than the antennal segment in Onychophora.

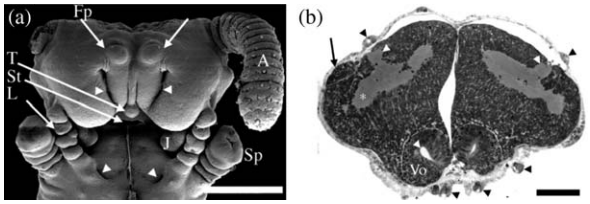

Figure 9 a, Scanning electron microscopy (SEM) micrograph of a stage 7 *E. kanangrensis* embryo. Upper arrowheads show the sites of invagination of the ventral organs. Lower arrowheads show salivary duct openings. A, antenna; L, lips; Sp, slime papillae; St, stomodeum; T, tongue; Fp, frontal process. Scale bar: 200 μm. b, Cross section of a stage 9 *E. kanangrensis* embryo at the axial level of the anterior part of the brain, anterior to the mouth. Ventral organs (Vo) have completely invaginated. Lower white arrowhead indicates the lumen of the ventral organs. Asterisk, antennal glomeruli; upper white arrowheads, antennal tracts; black arrowheads, dermal papillae. Scale bar: 100 μm. 1.20.4 Neural Development in the Myriapoda

As noted above, there is some debate about the evolutionary relationships between the different myriapod taxa – Symphyla, Pauropoda, Chilopoda, and Diplopoda. Nonetheless, I have chosen to discuss their neural development as a group as the pattern of neurogenesis shows similarities in all of these groups. Accounts of myriapod embryology employing classical histological methods (Heymons, 1901; Tiegs, 1940, 1947; Dohle, 1964; Knoll, 1974b; Hertzel, 1984) have been augmented in recent years by a number of studies that have used more modern techniques to examine cell morphology and patterns of cell division within the neuroectoderm, the expression of genes involved in neurogenesis, and the axon morphology of individual neurons (Whitington *et al.*, 1991; Hughes and Kaufman, 2002b; Dove and Stollewerk, 2003; Kadner and Stollewerk, 2004).

1.20.4.1 Neurogenesis

1.20.4.1.1 Thickening of the neuroectoderm In all of the myriapod groups, development of the VNC begins at an early stage, when the first limb buds are just beginning to form. The onset of neurogenesis is marked by a thickening of the ventral ectoderm on either side of the midline, associated with proliferative divisions of the surface ectodermal cells (Figures 10a and 10b). The inner layer of ectodermal cells may retain cytoplasmic connections with the surface (Tiegs, 1940).

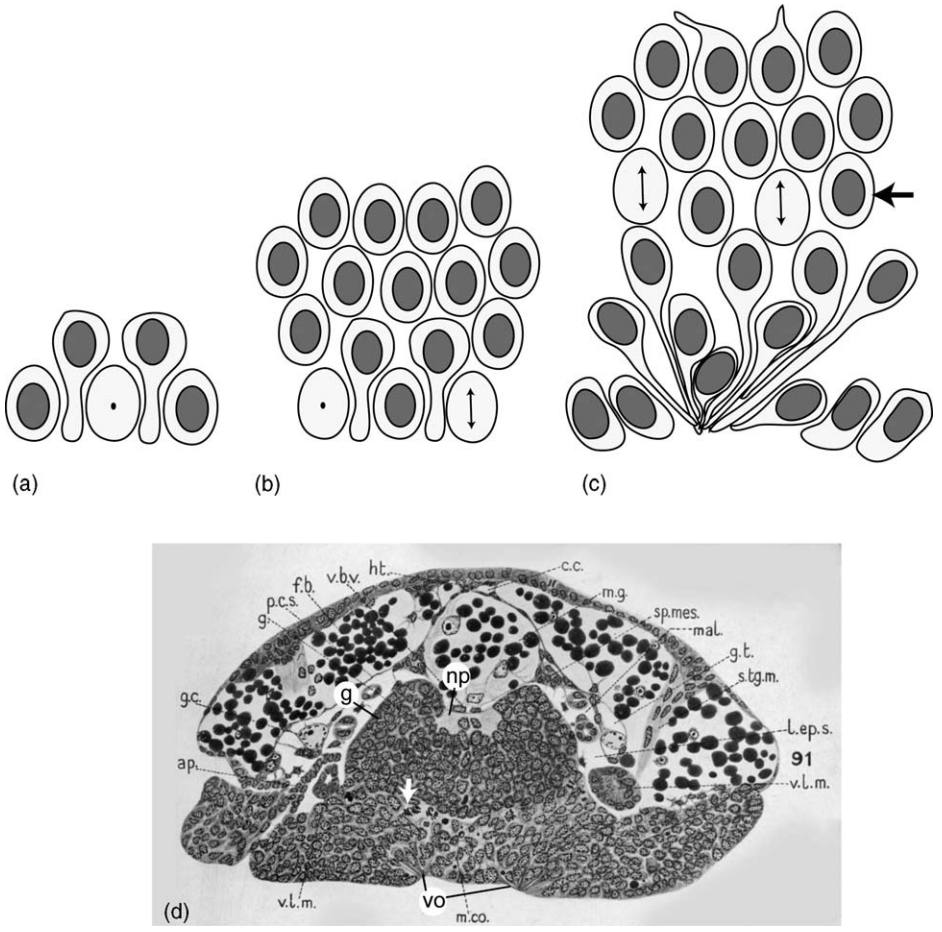

Figure 10 Schematic representations of the neuroectoderm and ganglion anlage of a generalized myriapod embryo at different developmental stages. Lines with double arrowheads indicate orientation of long axis of mitotic spindle within dividing cells. a and b, The neuroectoderm thickens as a result of cell divisions. c, The nuclei of groups of superficial ectodermal cells migrate internally and their apical processes converge at a site or sites on the surface of the neuroectoderm. A mitotically active zone of cells internal to the cells with apical processes (arrow) generates immature neurons. These neurons subsequently send axonal processes to the dorsal surface of the ganglion anlage to form the neuropile. d, Cross-sectional view of the ventral region of an embryo of *Hanseniella agilis* at a somewhat later stage (9 day) to that shown in (c). Vo, ventral organs; g, ganglion anlage; np, neuropile; white arrow indicates the zone of high mitotic activity that lies just external to the ganglion anlage. d, Reproduced from Tiegs, O. W. 1947. The development and affinities of the Pauropoda, based on a study of *Pauropus silvaticus*. *Q. J. Microsc. Sci.* 88, 165–336, with permission from The Company of Biologists.

1.20.4.1.2 Nuclear migration and origin of neural stem cells The second major event of neurogenesis is a migration of nuclei from a superficial to an internal, basal position in certain ventral ectodermal cells (Figures 10c and 10d). These cells retain a connection to the surface by a thin cellular process. The extensions of groups of cells converge at a point on the surface, which is immunoreactive for the anti-HRP antigen (Whitington *et al.*, 1991; Kadner and Stollewerk, 2004) and which stains with rhodamine-phalloidin, presumably because of a high concentration of F-actin in those apical processes (Dove and Stollewerk, 2003; Kadner and Stollewerk, 2004). The surface of the ectoderm flattens at the site of convergence of the cell processes. However, there is no sign of invagination of the ectoderm at this time. This process of nuclear migration has been reported in all myriapod groups: Diplopoda (Dohle, 1964; Dove and Stollewerk, 2003); Chilopoda (Heymons, 1901; Knoll, 1974b; Hertzel, 1984; Whitington *et al.*, 1991; Kadner and Stollewerk, 2004); Symphyla (Tiegs, 1940); and Pauropoda (Tiegs, 1947). It is therefore highly likely to represent a basal character for the Myriapoda.

Earlier studies reported a single site of convergence of cell processes per hemisegment: the group of cells with converging apical processes were referred to as a ventral organ (Figure 10d) (Heymons, 1901; Tiegs, 1940, 1947; Knoll, 1974a; Hertzel, 1984) . More recent studies using anti-HRP and rhodamine-phalloidin staining in Chilopoda and Diplopoda reveal that there are multiple sites of convergence of apical cell processes per hemisegment in these groups. These techniques have not yet been applied to symphylan and pauropodan embryos to clarify the number of sites in these groups.

In the diplopod *Glomeris marginata* a stereotypic pattern of 30–32 sites, arranged in seven rows with four to five sites per row, appears in each head and trunk hemisegment (Figure 11a) (Dove and Stollewerk, 2003). Up to 11 cells contribute processes to each site (Figures 11b and 11c). Individual sites appear in a precise sequence during four waves of production. Somewhat confusingly, Dove and Stollewerk (2003) refer to this process of basal nuclear migration as invagination. There is, however, no evidence from this or other studies that a true invagination of the ectoderm takes place at this stage.

A very similar arrangement of 30 sites per hemisegment is seen in the chilopods *Lithobius forficatus* (Kolbe, 2001; Kadner and Stollewerk, 2004; Figure 11d), *Ethmostigmus rubripes* (Whitington *et al.*, 1991), and *Strigamia maritima* (Chipman and Stollewerk, 2006). However, fewer cells (five to nine) contribute processes to each site in *Lithobius* than in the diplopod *Glomeris* and in *Strigamia* the cellular processes converge on one of the cells in the group, rather than on the apical surface of the ectoderm. A strikingly similar pattern of phalloidin-positive sites is seen in the neuroectoderm of the spider *Cupiennius salei* (Stollewerk *et al.*, 2001). This has been advanced as evidence for a close phylogenetic relationship between the Myriapoda and the Chelicerata (Kadner and Stollewerk, 2004).

It is tempting to conclude that this striking, evolutionary-conserved morphological event is related to the specification of neural fate within the ventral ectoderm. What is the fate of the groups of cells whose nuclei undergo internal migration? Some early workers claimed that these cells are neural stem cells, with the properties of insect neuroblasts, i.e., cells that divide repeatedly in an asymmetric

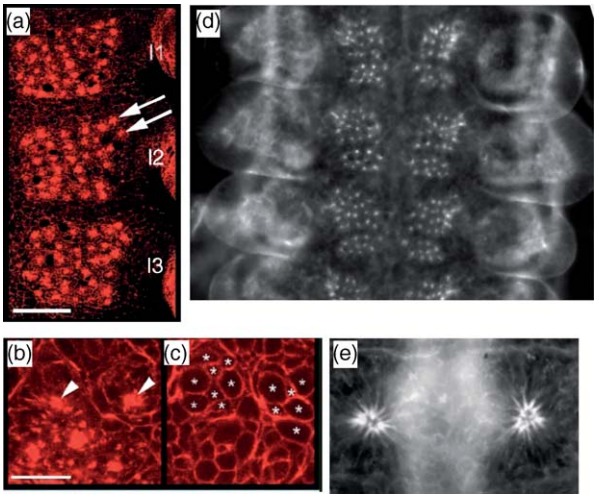

Figure 11 Rhodamine-phalloidin staining of myriapod embryos reveals sites of convergence of apical processes of neuroectodermal cells. a, The regular pattern of these sites (arrows) in three adjacent trunk neuromeres of the diplopod *G. marginata*. b, A higher-magnification view of an apical optical section showing several sites (arrowheads). c, A basal optical section at the level of the nuclei of the cells with apical processes (asterisks). fashion to produce a chain of ganglion mother cells, each of which divides symmetrically to produce a pair of neurons. However, the histological evidence advanced for this idea is not convincing (see figures 37, 48, and 49 in Dohle, 1964). Tieg's detailed histological studies of symphylan (Tiegs, 1940) and pauropodan (Tiegs, 1947) embryos provide no evidence for enlarged cells with the characteristics of insect neuroblasts in the ventral ectoderm of these groups. Nor do they indicate that the cells whose nuclei have migrated internally are a particular focus of mitotic activity. Rather, divisions are concentrated in a layer internal to these cells (Figures 10c and 10d), which abuts the developing ganglion.

To determine the relationship between the sites of phalloidin staining and mitosis in the diplopod embryo, Dove and Stollewerk (2003) employed antiphosphohistone 3 staining. They found that mitotic cells are found adjacent to sites of phalloidin staining or in regions where such staining is later seen (Figures 12a–12c). These dividing nuclei are mainly located at the surface of the ectoderm, rather than internally. They observed that the dividing cells are significantly larger than surrounding cells and suggested that these are neuronal stem cells.

If this presumption is correct, then these observations would argue for a stereotypic pattern of neural stem cells in the neuroectoderm of diplopodan embryos. What remains unclear however is whether the dividing superficial ectodermal cells identified in the Dove and Stollewerk (2003) study generate the nearby cells with convergent apical processes. It is also unclear whether these internal groups of cells are undifferentiated neurons, neural progenitors, or some other cell type. The reported positive anti-HRP immunoreactivity of the sites where the processes of these cells converge is not conclusive evidence for a neural identity, since anti-HRP is not expressed in axons in the centipede CNS later in embryonic development (Whitington *et al.*, 1991).

Confusingly, Dove and Stollewerk (2003) refer to the cells with basal nuclei and convergent cytoplasmic processes as neural precursors, a term normally reserved for progenitor cells that divide to produce neurons. However, it is clear that these authors use the term neural precursors to mean postmitotic, undifferentiated neurons (Stollewerk, 2004, p. 4). Whitington *et al.* (1991) used a different method – BrdU incorporation – to determine patterns of cell division within the neuroectoderm of the scolopendromorph centipede *Ethmostigmus*. They found labeled cells at all positions in the internal–external axis of the neuroectoderm, not just on the apical ectodermal surface (Figure 12d). This observation concurs with Tiegs' observations in Pauropoda and Symphyla. Strongly labeled cells were not conspicuously larger than their presumed, more weakly stained progeny. The latter were also not oriented

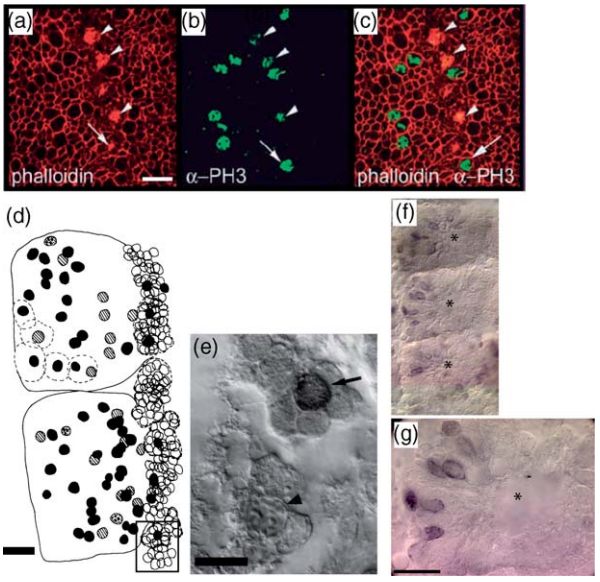

Figure 12 Patterns of cell division in the neuroectoderm of Diplopoda and Chilopoda. a–c, Confocal micrographs of a millipede (*G. marginata*) hemineuromere showing the close relationship between mitotic cells, stained with antiphosphohistone 3 antibody, and rhodamine-phalloidin-stained sites. The arrowheads in the single (a, b) and merged images (c) show where mitotic cells correspond to stained sites, while the arrows show where a mitosis occurs near a stained site. Scale bar: 10 μm. d, Camera lucida drawing of BrdU-labeled nuclei within two adjacent trunk hemineuromeres of a centipede (*E. rubripes*) embryo. Black nuclei are internal, hatched nuclei external, and dotted nuclei in intermediate positions. Medial is to the right and anterior is up. Dashed lines show the borders of clusters of neurons. These clusters are particularly obvious along the medial edge of the ganglion anlage. Scale bar: 20 μm. e, Photomicrograph of the region within the rectangle in (d). A BrdU-labeled nucleus (arrow) and a labeled nucleus in mitosis (arrowhead) are found in the center of the two most posterior clusters in this hemisegment. Scale bar: 20 μm. f, Photomicrograph of three trunk hemineuromeres in a centipede (*L. forficatus*) embryo, showing BrdU-labeled nuclei in purple. This embryo is older than the *Ethmostigmus* embryo shown in (d) as the central region of neuroectoderm has begun to invaginate (asterisks). The neuroectodermal cells lie in clusters, which radiate out from the rim of the invagination. The strongest BrdU-labeled cell within each cluster tends to lie towards the outer edge of the cluster. g, Enlargement of the middle neuromere in (f). Scale bar: 20 μm. a–c, Reproduced from Dove, H. and Stollewerk, A. 2003. Comparative analysis of neurogenesis in the myriapod *Glomeris marginata* (Diplopoda) suggests more similarities to chelicerates than to insects. *Development* 130, 2161–2171, with permission from The Company of Biologists. d and e, Reproduced from *Roux's Arch. M., Meier, T., and King, P., figure 3, with kind permission of Springer Science and Business Media. f and g, Reproduced from Kolbe, S. 2001. Comparisons of Central Nervous System Development in a Centipede and a Spider. Honours thesis, University of Melbourne.

in internally directed columns. These observations argue against the presence of insect-like neuroblasts in this centipede.

However, cells were found to lie in clusters in the developing ganglia, often with a strongly labeled BrdU-positive cell near the center or towards the dorsal side of the cluster (Figures 12d and 12e). A longitudinal column of four to five prominent clusters was found on the medial border of each hemineuromere (Figure 12d). Injections of the dye Lucifer yellow into a single cell in one of these clusters revealed that all of its cells are dye-coupled. These observations are consistent with the idea that each of these clusters represents a clone of progeny arising from a single, central stem cell, although this is yet to be confirmed by direct lineage-tracing methods. It is tempting to conclude that these clusters are equivalent to the groups of internal cells whose processes converge on phalloidin-stained ectodermal sites, but direct evidence for this is also lacking.

To shed further light on neurogenic mechanisms in the Myriapoda, Dove and Stollewerk (2003) examined the expression pattern within the diplopod neuroectoderm of orthologues of the *Drosophila achaete-scute* complex (*asc*) proneural genes and neurogenic genes *Delta* (*Dl*) and *Notch* (*N*). In *Drosophila*, proneural genes define regions within the neuroectoderm where cells acquire the potential to differentiate into neuroblasts. Subsequent cell–cell signaling mediated by *N* and *Dl* causes a single cell within each proneural cluster to adopt a neuroblast fate, while the rest acquire an epidermal progenitor fate (Baker, 2000).

Dove and Stollewerk (2003) found that the *Glomeris achaete-scute* homologue (*GmASH*) is expressed in neuroectodermal cells at the same locations as phalloidin-stained sites, just prior to the appearance of those sites. It is also transiently expressed in the groups of cells whose processes converge on those sites, as is the *Glomeris Delta* homologue (*GmDelta*). Similar observations have been made for homologues of *achaete-scute* (*LfASH*) and *Delta* (*LfDelta*) in the centipede *L. forficatus* (Kadner and Stollewerk, 2004). Assuming that *GmASH*, *LfASH*, *GmDelta,* and *LfDelta* are involved in specification of neural stem cell fate, these findings would support the view that the apical ectodermal cells that express these genes belong to this lineage, but leave unresolved the identity of the internal groups of cells. Direct lineage-tracing experiments are called for to establish the relationship between dividing superficial ectodermal cells, the groups of cells with basal nuclei and post-mitotic neurons.

While the chilopod and diplopod homologues of insect proneural and neurogenic genes are expressed in the neuroectoderm, it is clear that these genes must play different roles in insects and myriapods. In insects, the action of these genes leads to a segregation of neuroblasts from epidermal progenitor cells within the neuroectoderm. In myriapods, epidermis arises from ectodermal cells lateral or medial to the neuroectoderm (see Section 1.20.4.1.3). The role of the proneural and neurogenic genes in the latter groups may be to specify the timing of commitment of a stem cell to the neural lineage and the subsequent divisions of this cell to form neurons, rather than a segregation of neural and epidermal fates.

1.20.4.1.3 Ganglion formation Following the process of internal nuclear migration in myriapod embryos, the neuroectoderm thickens rapidly, and the anlagen of the segmental ganglia begin to take shape. This phase of neurogenesis must involve the production of large numbers of neurons from progenitor cells in the neuroectoderm. However, little is known about the location of the neural stem cells or the nature of the divisions that generate these neurons.

It would seem clear that some neuron progenitor cells are not restricted to the most superficial neuroectodermal layer, but are located quite internally. In Symphyla (Tiegs, 1940) and Pauropoda (Tiegs, 1947), two distinct zones can be recognized in the developing neuroectoderm: the ganglion rudiment and the ventral portion of the neuroectoderm (Figure 10d). Based on the distribution of mitotic figures, the zone of ventral ectoderm that abuts the developing ganglion appears to be a major site of generation of neurons, although divisions also occur at other levels of the neuroectoderm and within the ganglion. This zone is internal to the neuroectodermal cells with basal nuclei and apical processes, which appear to be relatively mitotically inactive.

A distinctive morphogenetic event takes place in the ganglion rudiment of diplopod (Dohle, 1964) and chilopod (Heymons, 1901; Whitington *et al.,* 1991; Kolbe, 2001) embryos: the surface of the ganglion rudiment invaginates to form a vesicle, which becomes trapped inside the ganglion (Figures 12f and 12g). During this process, the superficial phalloidin/anti-HRP-stained sites become drawn into a circle in the middle of the hemiganglion (Figure 11e).

Invagination occurs after the process of internal nuclear migration described in Section 1.20.4.1.2. This fact, and the observation that invagination does not occur in symphylan or pauropodan embryos,

which do show nuclear migration, would suggest that the two processes are not coupled. Confusingly, the vesicle arising from invagination has also been called a ventral organ by some authors (Heymons, 1901). The functional significance of ganglionic invagination is unclear: the vesicle is a transitory structure which becomes flattened and disappears late in embryogenesis (Heymons, 1901). Heymons (1901) claimed that these invaginations are the seat of production (Bildungsstätte) of neurons in *Scolopendra dalmatica*. In *Ethmostigmus* (Whitington *et al.*, 1991) and *Lithobius* (Kolbe, 2001), BrdU-labeled nuclei are often found on the outer edge of clusters of cells that radiate out from the invagination site in the ganglion (Figures 12f and 12g). However, the fact that invagination takes place well after the clusters have begun to form indicates that it is probably incidental to neural generation.

The invagination process described above for diplopodan and chilopodan embryos bears some similarities to the process of ventral organ formation in the antennal segment of onychophoran embryos. However, in the latter group, the invaginated tissue develops into a structure, the hypocerebral organ, which remains separate from the CNS.

The separation of the ganglion rudiment from the ventral surface takes place in different ways in different myriapod groups. As noted above for Symphyla and Pauropoda (Tiegs, 1940, 1947), a mass of tissue lies ventral to the ganglion rudiment from an early stage. Some of these ventral cells contribute to the formation of distinctive organs called eversible sacs, located at the limb bases. A similar organ is formed in the collum segment of pauropod embryos, while in other segments the ventral cells are either absorbed into the ganglion or become incorporated into the epidermis. In leg-bearing segments of pauropod embryos, medial ectodermal cells spread laterally to form the ventral epidermis (Tiegs, 1947). In Chilopoda and Diplopoda, the ventral epidermis arises by the medial migration of ectodermal cells that initially lie lateral to the neuroectoderm. These cells eventually form a continuous epithelium which overgrows and internalizes the ganglia (Dove and Stollewerk, 2003; Kadner and Stollewerk, 2004).

Differences are also seen between different myriapod groups in the degree of separation of left and right sides of the developing ganglia. In scolopendromorph centipedes, there is a wide separation between hemiganglia from the earliest stages of neurogenesis (Heymons, 1901; Whitington *et al.*, 1991), which is maintained for a considerable period of embryogenesis (Figure 13a). The eventual fusion of the hemiganglia in the ventral midline is accompanied by apoptosis of the ventral extraembryonic ectodermal cells.

In other Chilopoda and all other myriapod groups, the hemiganglia are quite close together from the outset of neural development, separated by, at most, a narrow band of midline cells. The split of the germ band in scolopendromorph centipedes therefore appears to be a derived character of this group, perhaps associated with the large size of the egg. It is certainly not a shared-derived (synapomorphic) character of Myriapoda and Onychophora.

1.20.4.2 Formation of Central Axon Tracts

Studies of myriapod embryology using standard histological techniques provide some information about the timing of axon growth (Heymons, 1901; Tiegs, 1940, 1947; Dohle, 1964). The first axons appear on the dorsal surface of the ganglion anlagen following internal nuclear migration and the onset of mitotic activity within the thickened neuroectoderm (Figure 10c). There are no neural cell bodies overlying these dorsal axons. In all groups, axonogenesis, as with other developmental processes, takes place in a rostrocaudal sequence, beginning in head neuromeres, then progressing to more posterior segments (Figure 14a).

The order of formation of different axonal tracts has been revealed in the centipedes *Ethmostigmus* and *Lithobius* by a combination of single-neuron dye injections, 1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate (DiI) axonal labeling, and rhodamine-phalloidin staining (Whitington *et al.*, 1991; Kolbe, 2001). In *Ethmostigmus*, a wide bundle of caudally directed axons – the primary tract – descends from the brain to posterior segments well before axon growth begins in any of the trunk neuromeres (Figures 13a–13c). This tract becomes progressively wider as development ensues. Heymon's description of axon growth in *Scolopendra* (Heymons, 1901) suggests that a primary tract also forms in this embryo. A similar tract appears to form in *Lithobius*, but axon growth has been initiated in trunk neuromeres by the time the axons of the primary tract arrive in those segments (Kolbe, 2001).

Within trunk segments of the *Lithobius* embryo, longitudinal, peripheral, and commissural axons all begin outgrowth at around the same time (Figure 13a). In contrast, commissural axon outgrowth in *Ethmostigmus* lags behind longitudinal and peripheral axon growth. Commissural axons only cross the midline when the hemiganglia, which are widely separated when the first neurons send out axons, have come into close proximity

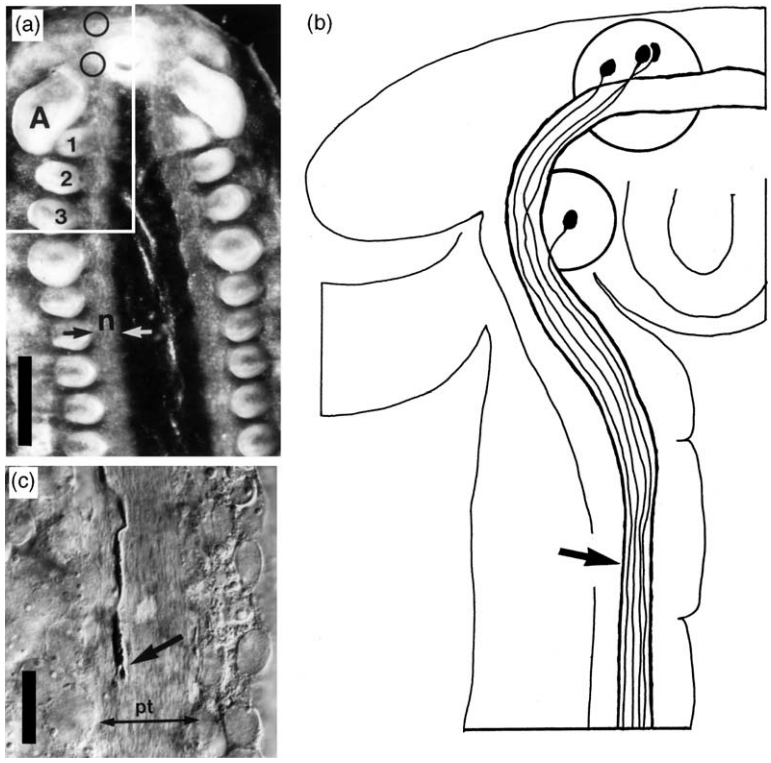

Figure 13 Primary tract formation in the embryo of *E. rubripes*. a, Photomicrograph showing separation of left and right sides of the germ band. Scale bar: 200 μm. b, Schematic diagram of the region within the white rectangle in (a). Descending axons from neurons located in the circled brain regions form the primary tract (arrow). c, The growth cone (arrow) of a single axon within the primary tract (pt) that has been injected with Lucifer yellow. Scale bar: 20 μm. Reproduced from *Roux's Arch. Dev. Biol.*, vol. 199, 1991, pp. 349–363, Segmentation, neurogenesis and formation of early axonal pathways in the centipede, *Ethmostigmus rubripes* (Brandt), Whitington, P. M., Meier, T., and King, P. figure 6, with kind permission of Springer Science and Business Media.

(Figure 15d). A regular pattern of commissural tracts eventually develops in each trunk neuromere of both *Ethmostigmus* and *Lithobius* (Figures 14b and 14c) embryos (P. M. Whitington unpublished; Kolbe, 2001).

The pattern of axon growth from several early-differentiating neurons in the *Ethmostigmus* CNS has been determined by single-neuron dye-filling (Whitington *et al.*, 1991) (Figures 15 and 16). At early stages, many of these neurons can be individually identified, allowing a comparison with the detailed descriptions of axon growth from identified neurons in insects (Goodman *et al.*, 1984; Thomas *et al.*, 1984; Whitington *et al.*, 1996) and malacostracan crustaceans (Whitington *et al.*, 1993) embryos.

The pattern of axon growth in the centipede appears to be substantially different to that seen in insects and malacostracan crustaceans (Figure 16). However, a caveat to this conclusion is that the axon morphology of only a subset of early differentiating centipede neurons has been determined to date. The large number of cells present in centipede neuromeres at even the earliest stages of axon growth will make an exhaustive description of the pattern of central axon growth a challenging goal. Access to probes for myriapod homologues of *Drosophila* genes that are expressed in specific subsets of neurons would greatly facilitate a comparison between the myriapods and the insects. As an illustration of the potential of this approach, Duman-Scheel and Patel (1999) have used molecular probes to identify putatively homologous neurons in hexapods and crustaceans.

Centipede homologues to several *Drosophila* genes have now been cloned: these include *even-skipped*, *engrailed*, and *wingless* (Hughes and Kaufman, 2002b) and the 10 *Hox* genes (Hughes and Kaufman, 2002a). Unfortunately, mRNA probes have not yet provided the resolution necessary to determine the expression of these genes at the level of single neurons. Nonetheless, examination of figure 4d from Hughes and Kaufman (2002b) suggests that *even-skipped* may be expressed in a small subset of neurons located close to the midline in each hemineuromere, a

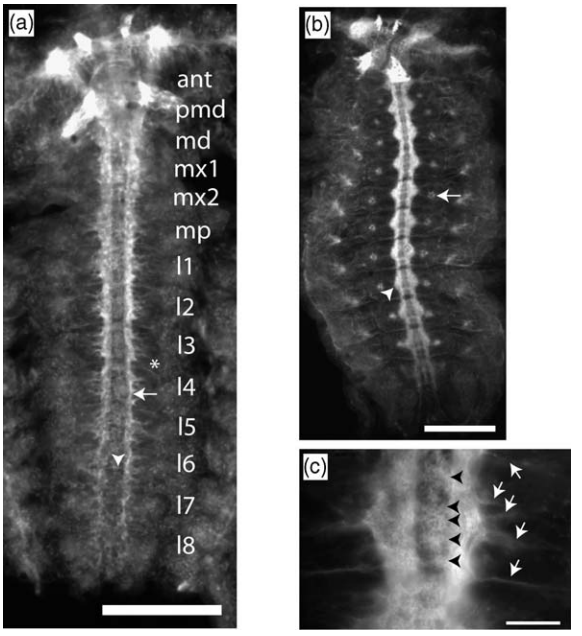

Figure 14 Rhodamine-phalloidin staining reveals patterns of axon growth in *Lithobius* embryos. a, Stage 5 embryo (according to staging scheme of Hertzel, 1984). Axon growth has just begun in the most posterior segments, l7/8, while longitudinal (arrow), commissural (arrowhead), and peripheral (asterisk) axons are present in every neuromere anterior to l6. Segment abbreviations: ant, antennal; pmd, premandibular; md, mandibular; mx1, maxillary 1; mx2, maxillary 2; mp, maxilliped; l1–8, leg-bearing 1–8. Scale bar: 200 μm. b, Late-stage embryo. Each neuromere shows a well-developed neuropile, which stains strongly with rhodamine-phalloidin (arrowhead). The arrow shows the ring of phalloidin staining marking the site of the vesicle that forms by invagination in every hemiganglion. Scale bar: 200 μm. c, Magnified view of a neuromere from the embryo in (b). Arrowheads show the position of commissures. Arrows indicate peripheral nerves. Scale bar: 30 μm. Reproduced from Kolbe, S. 2001. Comparisons of Central Nervous System Development in a Centipede and a Spider. Honours thesis, University of Melbourne.

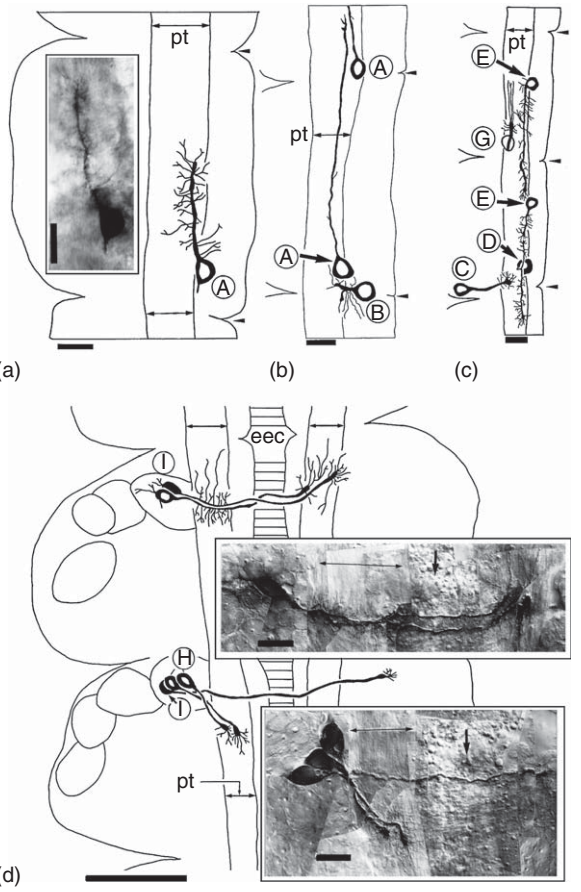

Figure 15 Pattern of axon growth from early-differentiating neurons in trunk neuromeres of stage 5 (a), 6 (b), and 7 (c) *Ethmostigmus* embryos (staging after Whitington *et al.*, 1991). Camera lucida drawings and photomicrographs of neurons injected with Lucifer yellow. Each of the labeled neurons can be individually identified based on soma position and pattern of axon growth. Most of the early axons run longitudinally, fasciculating with axons in the primary tract (pt). The medial edge of the hemineuromere is on the right and anterior is up in each case. Scale bars: 25 μm for the line drawings in (a–c), 20 μm for the micrograph in (a). d, Commissural axon growth in trunk neuromeres of a stage 7 *Ethmostigmus* embryo. The left and right hemineuromeres have approached the midline and are separated by only a thin band of extraembryonic ectoderm (eec). The axon of neuron I has crossed the midline. Scale bars: 100 μm for the line drawings, 20 μm for the micrographs. Reproduced from *Roux's Arch. Dev. Biol.*, vol. 199, 1991, pp. 349–363, Segmentation, neurogenesis and formation of early axonal pathways in the centipede, *Ethmostigmus rubripes* (Brandt), Whitington, P. M., Meier, T., and King, P., figures 7 and 9, with kind permission of Springer Science and Business Media.

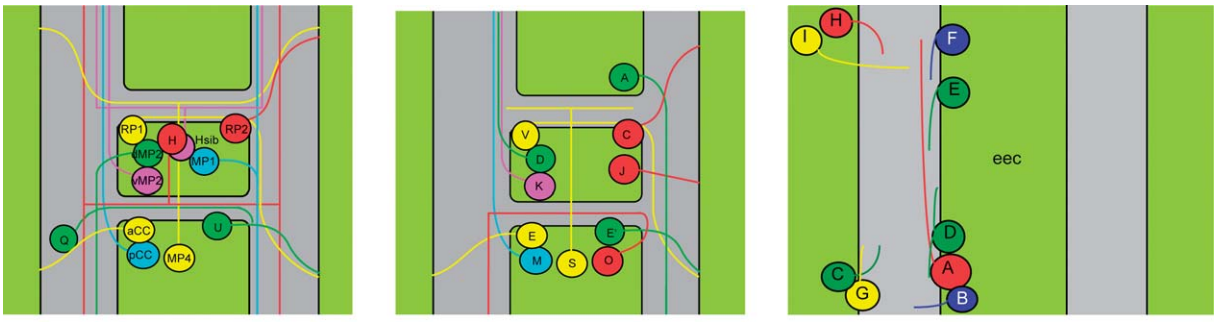
pattern that bears some similarities to insects and crustaceans (Duman-Scheel and Patel, 1999).

1.20.5 Summary and Evolutionary Insights Gained from Studies of Neural Development

While several recent studies have contributed significantly to our understanding of mechanisms for neural development in the Onychophora and Myriapoda, many questions remain. In this final section I will summarize key findings that provide insights into the evolution of the nervous system in these groups and their relationships to other arthropods. In addition, I will highlight some of the unresolved issues in this field and point to future directions for research.

1.20.5.1 Mechanisms for Neurogenesis

Mechanisms for neurogenesis in insects are well understood at cellular and molecular levels, due largely to an extensive body of research in the fly *Drosophila* (reviewed in Goodman and Doe, 1993; Skeath and Thor, 2003). The neural stem cells in



Insect (*Drosophila*, Grasshopper) Malacostracan (crayfish, woodlouse) Centipede (*Ethmostigmus*)

Figure 16 Diagrammatic summary of patterns of early axon growth from identified neurons in the CNS of insect (*Drosophila* and grasshopper), malacostracan crustacean (crayfish *Cherax*, woodlouse *Porcellio*), and centipede (*E. rubripes*) embryos.

this group are neuroblasts, which are formed from the neuroectoderm in a stereotypic pattern due to the action of the proneural and neurogenic genes. This process involves a segregation of neural and epidermal progenitor cell fates from a common sheet of neuroectodermal cells. After delaminating from the surface ectoderm, each neuroblast undergoes several rounds of internal, asymmetric divisions to produce a column of ganglion mother cells, each of which subsequently divides symmetrically to produce a pair of neurons (or in some cases glial progeny). Patterns of neuroblast division are highly stereotypic and result in the production of invariant populations of individually identifiable neurons. Malacostracan crustaceans show a superficially similar mode of neurogenesis, although it is not yet clear whether this represents a synapomorphic character shared by these two groups or an example of evolutionary convergence (Whitington, 1996, 2004; Dohle *et al.*, 2004).

A key issue is to what extent this hexapod/crustacean mode of neurogenesis is shared with other arthropods. It seems clear from the studies reviewed in Sections 1.20.3.1 and 1.20.4.1 that neural stem cells with the morphological features of insect and crustacean neuroblasts are not present in either onychophoran or myriapod embryos. How then are neurons generated in these groups? Is there any evidence that they possess a population of neural stem cells with the functional, if not morphological, properties of neuroblasts?

1.20.5.1.1 Evidence from onychophoran neurogenesis Few answers to these questions can be gleaned from current descriptions of neurogenesis in the Onychophora. The lack of data in this group is especially disappointing as Onychophora might be expected to reveal the basal mode of neurogenesis for the Euarthropoda. Virtually no information is available concerning patterns of cell division in the neuroectoderm of these embryos. We do not know whether cell divisions are randomly distributed across the neuroectoderm or whether they cluster at defined sites: a BrdU or antiphosphohistone study should clarify these issues. Nor is it clear whether neurogenesis involves a segregation of neural and epidermal cell fates within the neuroectoderm.

It seems unlikely that Onychophora display the phenomenon of basal nuclear migration and convergence of apical cellular processes as seen in Myriapoda: even classical histological techniques would have revealed this process, if it were present. Tiegs claimed that a ventral organ is a common feature of neural development in Onychophora, Pauropoda, and Symphyla (Tiegs, 1947). However, this claim does not stand up to close scrutiny as the onychophoran ventral organ is only present in antennal segments and is formed by ectodermal invagination rather than by basal nuclear migration, as in Myriapoda. A similar process of invagination of the neuroectoderm takes place later in certain myriapod groups, but is probably incidental to neural generation (see Section 1.20.4.1.3). One can surmise that the myriapodan mode of neurogenesis was not basal for the Euarthropoda or, alternatively, that it has been modified during onychophoran evolution.

The presence of very large numbers of small globuli cells in the onychophoran nerve cord and the apparent absence of individually identifiable neurons points to a fundamental difference between Onychophora and Hexapoda/Crustacea in mechanisms for neurogenesis. Harzsch *et al.* (2005) have pointed out a trend during arthropod evolution for variably sized groups of neurons with a particular phenotype (e.g., serotonergic) to be replaced with small and stereotypic numbers of individually

identifiable neurons. They suggest that this may be linked to differing modes of neurogenesis in different arthropod groups, with production of neural stem cells by generalized mitotic divisions in the neuroectoderm in basal groups being replaced by segregation of a stereotypic pattern of neuroblasts in more derived groups. An analysis of patterns of cell division and cell lineages within the neuroectoderm of the onychophoran embryo will help to test this hypothesis.

1.20.5.1.2 Evidence from myriapod neurogenesis
Considerably more information is available regarding mechanisms for neurogenesis in the Myriapoda than in the Onychophora. As noted in Section 1.20.4.1.2, all myriapod groups display a basal migration of nuclei in clusters of ectodermal cells, and the convergence of apical extensions from these cells to sites on the ectodermal surface (termed invagination sites by Dove and Stollewerk, 2003; Kadner and Stollewerk, 2004).

The pattern of these apical ectodermal sites is highly stereotypic and conserved between Diplopoda and Chilopoda. It is not clear whether the other two myriapod groups, Symphyla and Pauropoda, show the same pattern of sites. This is a key issue as it would help to clarify whether the presence of the same pattern of ectodermal sites in spider embryos represents a synapomorphy of the Chelicerata and Myriapoda or a convergent character. As noted above, the absence of these ectodermal sites in onychophoran embryos may speak against the idea that this is a basal character of the Euarthropoda.

The stereotypic and evolutionary conserved pattern of phalloidin/anti-HRP-positive sites on the surface of the diplopodan and chilopodan neuroectoderm suggests that this process plays an important role in the specification of neural fate. However, the nature of that role is not entirely clear. The positions of these sites correspond to the location of apical cell divisions as well as the expression of proneural and neurogenic genes. This has led Kadner and Stollewerk (2004) and Dove and Stollewerk (2003) to propose a model in which apical neuroectodermal cells at stereotypic positions become committed to a neural lineage. Repeated divisions of each of those stem cells generate a clone of daughter cells (neural precursors, in their terminology). The nuclei of these daughter cells move to a basal position in the neuroectoderm and these cells later differentiate into neurons. These apical stem cells would therefore have similar properties to insect/crustacean neuroblasts.

While this model is attractive, we currently lack some key data to assess its validity. The identity, spatial pattern, and mode of division of these apical stem cells have not been demonstrated directly. Nor has it been definitively shown that their presumed progeny, the cells with basal nuclei, are indeed immature, postmitotic neurons. Cell lineage studies in the diplopodan or chilopodan neuroectoderm, similar to those carried out in insect and crustacean embryos (Bossing *et al.*, 1996; Schmidt *et al.*, 1997; Gerberding and Scholtz, 2001), are needed to resolve these issues.

Whether or not neural stem cells are located in the apical ectodermal layer, it would seem clear from observations of mitotic figures in Symphyla and Pauropoda and of BrdU-labeled cells in Chilopoda, that more internal regions of the neuroectoderm are additional important zones of cell production. There is some evidence for the existence of neural stem cells in scolopendromorph centipedes. Neurons are found in discrete clusters which generally contain a mitotically active cell in the center or towards one side. All cells in a cluster are dye-coupled, as seen in the clone of cells arising from an individual neuroblast in the grasshopper embryo (Goodman *et al.*, 1979). Whether these mitotically active cells have stem cell properties like insect neuroblasts and whether they generate invariant sets of individually identifiable neural progeny remain to be determined in future lineage-tracing experiments. Certainly, some neurons in the embryonic (Whitington *et al.*, 1991) and adult (Harzsch, 2004; Harzsch *et al.*, 2005) centipede VNC can be identified as individuals, unlike the situation in Onychophora.

As noted in Section 1.20.4.1.2, there is an important difference between myriapods and insects in at least one aspect of neurogenesis: specification of neural fate in the myriapod neuroectoderm does not involve a segregation of neural precursor versus epidermal precursor fate because the ventral epidermis forms from cells originally located medial or lateral to the neuroectoderm.

1.20.5.2 Mode of Formation of Central Axon Pathways

Detailed descriptions at the level of individually identified neurons of the pattern of central axon growth have been carried out in a variety of insect and crustacean embryos. This knowledge provides a solid base for comparative studies in other arthropod groups. Such comparisons are particularly interesting because of the many striking similarities between insects and malacostracan crustaceans in the pattern of pioneering axon growth (Whitington *et al.*, 1993; Whitington, 1995). These similarities, together with

a similar pattern of neural expression of the genes *even-skipped* and *engrailed* (Duman-Scheel and Patel, 1999), suggest that these two groups of arthropod share a common evolutionary Bauplan for the formation of early axon pathways in the CNS. They also raise the question of the extent of conservation of this Bauplan among the Arthropoda. For example, does the insect/crustacean pattern resemble the basal pattern for the Euarthropoda?

1.20.5.2.1 Axon growth in onychophoran embryos

As noted in Section 1.20.5.1.1, the large number and small size of neurons in the onychophoran CNS, even at early stages of ganglion development, make it difficult, if not impossible, to identify cells as individuals. This precludes a comparison with the pattern of axon growth in insect and crustacean embryos at this level. Nevertheless, staining of axon tracts in the CNS of onychophoran embryos using antiacetylated tubulin or anti-HRP antibodies does point to a number of significant differences to the insect/crustacean pattern of axon growth (see Section 1.20.3.2.2). First, axons first appear in the onychophoran embryo at a stage when the ganglion anlage contains large numbers of neurons. Second, commissural axon growth in trunk segments of the onychophoran embryo is quite irregular, contrasting with the stereotypic pattern in insects and crustaceans. Third, the commissural connection in Onychophora is made up of a large number (up to nine) of separate axon fascicles that cover the entire anteroposterior extent of each trunk neuromere, whereas in insects and crustaceans a pair of commissures is found towards the central region of each neuromere. Finally, commissural axon growth in trunk segments of the onychophoran embryo is delayed with respect to longitudinal and peripheral axon growth, whereas commissural axons are among the first to form in insect and crustacean neuromeres. This difference is presumably a consequence of the early separation of hemiganglia in Onychophora.

Given the extent of these differences, further insights into the relationship between the onychophoran and insect/crustacean patterns of axon growth will probably have to await the development of molecular probes that label subsets of neurons expressing homologous genes in these different groups. Such studies will hopefully provide clues as to which aspects of early axon growth reflect the basal pattern for the Euarthropoda and which represent onychophoran specializations.

1.20.5.2.2 Axon growth in myriapod embryos

Classic histological studies show that axon growth begins in all myriapod embryos when there is a relatively large population of cells in the ganglion primordium. In this respect, the Myriapoda resemble the Onychophora and differ from the Hexapoda and Crustacea. Information about the pattern of early axon growth that can be usefully compared to the insect/crustacean pattern is only available for one group of myriapods – the Chilopoda. The best-studied representative, the scolopendromorph centipede *Ethmostigmus*, shows a number of differences to the insect/crustacean pattern.

First, commissural axon growth is delayed with respect to longitudinal and efferent axon growth. As for the Onychophora, this delay can be attributed to the wide separation of hemiganglia at early developmental stages and is therefore likely to be an apomorphic character of the scolopendromorpha: no such delay is evident in the lithobiomorph *Lithobius*, which does not possess a split germ band.

Second, the pioneering axon population in the VNC of *Ethmostigmus* is a bundle of longitudinally projecting axons – the primary tract – which originates from neuron cell bodies in the brain and descends through all segmental neuromeres to the posterior end of the embryo well before axon growth commences in trunk segments. In contrast, the first longitudinal axons to appear in embryonic insect and crustacean neuromeres arise from local, segmental neurons. The precocious development of this primary tract appears to be another specialization of the scolopendromorph centipedes as it is not seen in *Lithobius*. It is certainly not present in onychophoran embryos, since the axonal connection between the brain and the VNC in that group is only made after longitudinal connectives have formed between the trunk neuromeres (see Section 1.20.3.2.2).

Finally, the pattern of pioneering axons in the *Ethmostigmus* embryo, as determined by dye-filling of individual neurons that have begun to enlarge, shows few similarities to the conserved insect/crustacean plan (Whitington *et al.*, 1991). However, it is possible that a population of pioneering neurons with a similar pattern of axon growth to the insects and crustaceans has been overlooked in studies to date. A resolution of this issue is likely to be close at hand now that centipede homologues to *even-skipped* and *engrailed*, genes that show a conserved pattern of expression in insects and malacostracan crustaceans, have been cloned. Existing data on the pattern of expression of transcripts of these genes (Hughes and Kaufman, 2002b) should soon be supplemented by descriptions of expression of their protein products, extending resolution to the level of single neurons.

As should be clear from the above discussions, there is an urgent need for studies of the pattern of early axon growth to be extended to the other myriapod groups, employing modern techniques such as antiacetylated tubulin and anti-HRP immunohistochemistry, labeling of single neurons by dye injection and DiI, and rhodamine-phalloidin labeling of axon tracts.

1.20.5.3 Overall Conclusions

While the picture is still incomplete, it seems clear that neural development in myriapods – including both mechanisms for neurogenesis and patterns of early axon growth – differs substantially from insect and crustacean embryos. The differences in neurogenesis take on a special significance, given the recently described similarities between spider and centipede/millipede embryos in the pattern of putative neural progenitor cells.

On the other hand, there are also considerable differences between the Myriapoda and the Onychophora in both mechanisms for neurogenesis and in patterns of axon growth. One of the challenges for the future will be to determine which, if either, of these modes of development most closely resembles the basal plan for the Arthropoda.

1.21 Segmental Organization of Cephalic Ganglia in Arthropods

R Urbach and G M Technau, University of Mainz, Mainz, Germany

Glossary

antennal lobes Deutocerebral glomerular neuropils receiving sensory inputs from the antennas.

central complex Prominent median unpaired neuropils in the protocerebrum implicated in locomotor control.

deutocerebrum Neuromere of the (first) antennal segment in mandibulates, which comprises the antennal lobes.

engrailed Segment polarity gene involved in the formation of segmental compartments.

head Anterior-most body part, which in insects encompasses three gnathal and three to four pregnathal segments.

Hox *genes* Homeotic genes that confer segmental identities.

labrum Preoral ectodermal outgrowth of the body wall, probably of appendicular nature.

mushroom bodies Prominent paired neuropil structures in the protocerebrum, each consisting of distinct lobes (alpha-, beta-, and gamma-lobe), the peduncle, and the calyx; these structures are involved in olfactory memory and learning.

neuroblast Neural stem cell.

neuromere Segmental unit of the central nervous system.

ophistosoma Posterior part of the body in certain chelicerates (i.e., arachnids).

orthodenticle Head gap gene involved in the specification and formation of the anterior-most head segments.

prosoma Anterior part of the body in certain chelicerates (i.e., arachnids), including the head segments.

protocerebrum Anterior-most and largest part of the brain comprising several distinct areas of neuropil, among which are the paired optic lobes (visual processing centers), the median central complex, and, in most arthropods, the paired mushroom bodies.

subesophageal ganglion Fused neuromeres of the gnathal (labial, maxillary, and mandibular) segments located below the esophagus.

supraesopahgeal ganglion Fused neuromeres of the pregnathal segments located above the esophagus.

tritocerebrum Neuromere of the intercalary or second antennal segment in mandibulates, which constitutes the posterior-most and smallest part of the brain.

1.21.1 Introduction

Along the anteroposterior (AP) axis cephalic ganglia encompass the supraesophageal ganglion (i.e., the brain) and the subesophageal ganglion. Although (adult) cephalic ganglia are usually morphologically distinct units, condensation of ganglia varies considerably in different arthropods; in certain chelicerates (arachnids), brain and all ventral ganglia (including the subesophageal) are fused to form

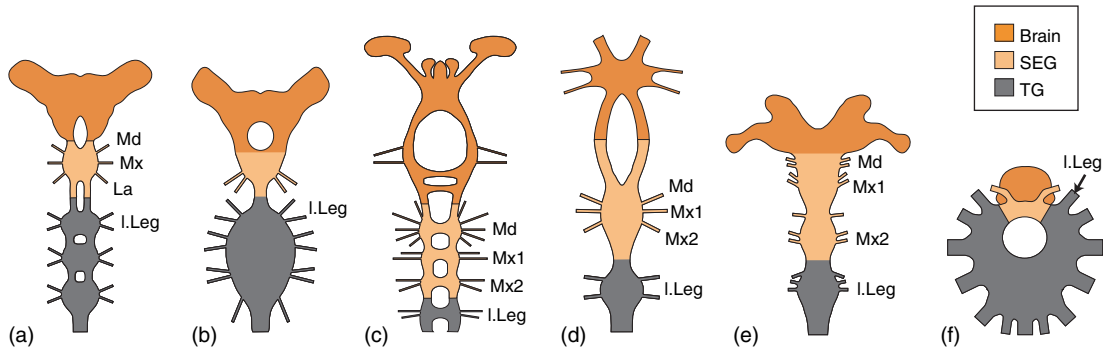

Figure 1 Schematic representations of the gross morphology of the anterior central nervous system (CNS) in different arthropods displaying various degrees of condensation in cephalic ganglia. Brain, subesophageal ganglion (SEG), and thoracic ganglion (TG) are indicated by color code. Insects: a, *Locusta* (Orthoptera); b, *Musca* (Diptera). Crustaceans: c, *Triops* (Notostraca); d, *Homarus* (Decapoda). e, *Thereupoda* (Myriapoda). f, *Limulus* (acquatic chelicerata). Drawings are not to scale. Md, Mx (1, 2), La: mandibular, maxillary (first, secondary), labial neuromere, respectively; I. Leg, neuromere innervating the first leg. Reprinted with permission of John Wiley & Sons, Inc.

a single nerve mass (Bullock and Horridge, 1965) (Figure 1). The ground pattern of the brain in most arthropods distinguishes three main regions, the relative size and pattern of which differ between arthropod taxa (Bullock and Horridge, 1965; Strausfeld, 1998; Mittmann and Scholtz, 2003):

1. The protocerebrum, which generally represents the anterior-most and largest part of the brain and in the adult consists of several distinct areas of neuropils. Among them are the prominent structures of the paired optic lobes (visual processing centers), the median central complex (implicated in locomotor control), and, in most arthropods (except crustaceans), the paired mushroom bodies (involved in olfactory memory and learning).
2. The deutocerebrum, the neuromere of the (first) antennal segment in mandibulates, which contains the antennal lobes, the olfactory processing centers of antennal input.
3. The tritocerebrum, the neuromere of the intercalary/second antennal segment in mandibulates, which constitutes the posterior-most and smallest part of the brain.

The subesophageal ganglion arises from the fusion of the neuromeres of the gnathal segments which innervate the mouth parts: in mandibulates, from anterior to posterior, usually the mandibular, (first) maxillary, and labial/second maxillary neuromere. However, the number of neuromeres fused into the subesophageal ganglion can vary in certain arthropods (Figure 1), especially in crustaceans (e.g., up to six in amphipods; reviewed in Bullock and Horridge, 1965). Whereas segments of the gnathal part of the head and corresponding neuromeres of the subesophageal ganglion are clearly addressable in all arthropods, the segmental pattern of the pregnathal part of the head is highly derived. The segmental organization of the arthropod head is one of the most enigmatic issues and there are numerous theories concerning it (reviewed in Rempel, 1975; Scholtz, 1998; Haas *et al.*, 2001; Urbach and Technau, 2003c). One of the most reliable criteria in defining a body segment is the presence of a corresponding neuromere (Rempel, 1975). Therefore, a key towards an understanding of the segmental organization of the arthropod head lies in the segmental composition of its (embryonic) ganglia, and in particular in that of the brain. This article provides a review of the current status of a long-lasting debate on the segmental pattern of the arthropod head and brain. Embryonic morphological data as well as recent molecular data on key developmental genes (such as *Hox* genes, head gap gene *orthodenticle*, segment polarity gene *engrailed* (*en*), and dorsoventral (DV) patterning genes) will be discussed (see A History of Ideas in Evolutionary Neuroscience, Field Homologies, Metazoan Phylogeny, Basic Nervous System Types: One or Many?, Commissural Organization and Brain Segmentation in Insects, The Evolution of Arthropod Nervous Systems: Insights from Neural Development in the Onychophora and Myriapoda, Origin and Evolution of the First Nervous System).

1.21.2 Identification of Homologous Head (and Brain) Regions in Different Arthropods by the Expression of *Hox* Genes and *orthodenticle*

Analysis of gene expression during embryonic development provides useful tools for a phylogenetic comparison and has contributed significantly to

our understanding of arthropod relationships. Data on the expression of *Hox* genes have recently accumulated, which reliably allow us to deduce homologies between head segments and brain neuromeres among different arthropod groups (insects, crustaceans, myriapods, and chelicerates).

Hox genes of the *Antennapedia* complex (Antp-C; i.e., *labial* (*lab*), *proboscipedia* (*pb*), *deformed* (*dfd*), and *sex comb reduced* (*scr*), *Antp*) define the identities of posterior head segments. The extent of the expression domains of head *Hox* genes varies considerably among different arthropod groups (reviewed in Hughes and Kaufman, 2002a). In the insect and crustacean head, *Hox* expression domains are distinct (segment-specific), usually nonoverlapping, and restricted to one or two segments (at least those of *lab*, *pb*, *dfd*, and *scr*) (Figure 2) (Abzhanov and Kaufman, 1999a, 1999b). In chelicerates, *Hox* domains encompass several segments and are broadly overlapping, probably representing an ancestral state (which is reminiscent of homologous *Hox* genes in vertebrates, although it is not yet known whether this represents conservation or convergence) (Damen *et al.*, 1998; Telford and Thomas, 1998). In myriapods (centipedes), the extent of *Hox* domains appears to reflect an intermediate state between that of insects/crustaceans and chelicerates (Hughes and Kaufman, 2002b) (Figure 2). According to these observations, it seems that evolution of head *Hox* genes involves shrinkage of their expression domains from chelicerates to the insect/crustacean clade. However, the relative positions of anterior boundaries of *Hox* gene expression appear to be evolutionarily stable (in accordance with spatial co-linearity of genes on the chromosome) and therefore are good positional markers.

Some of the results of such a comparison of *Hox* gene expression in different arthropod classes are summarized in Figure 2. Expression of head *Hox* genes in mandibulates (which include the insect/crustacean clade and myriapods) unambiguously supports homology of the three gnathal segments (mandibular, maxillary, and labial), the existence of which has never been seriously questioned. In all arthropods *lab* is the most anteriorly expressed *Hox* gene. In mandibulates, *lab* specifically indicates a head segment anterior to the mandibular one, the intercalary/second antennal segment, as well as a corresponding brain neuromere, the tritocerebrum (Diederich *et al.*, 1991; Rogers and Kaufman, 1997; Abzhanov *et al.*, 1999; Peterson *et al.*, 1999; Urbach and Technau, 2003b). Chelicerates represent the only arthropod class without a distinct head region. Their body exhibits only two major tagmata, the anterior prosoma which includes head segments and a posterior ophistosoma (Figure 2). A homology at least of anterior head segments with those in other arthropods

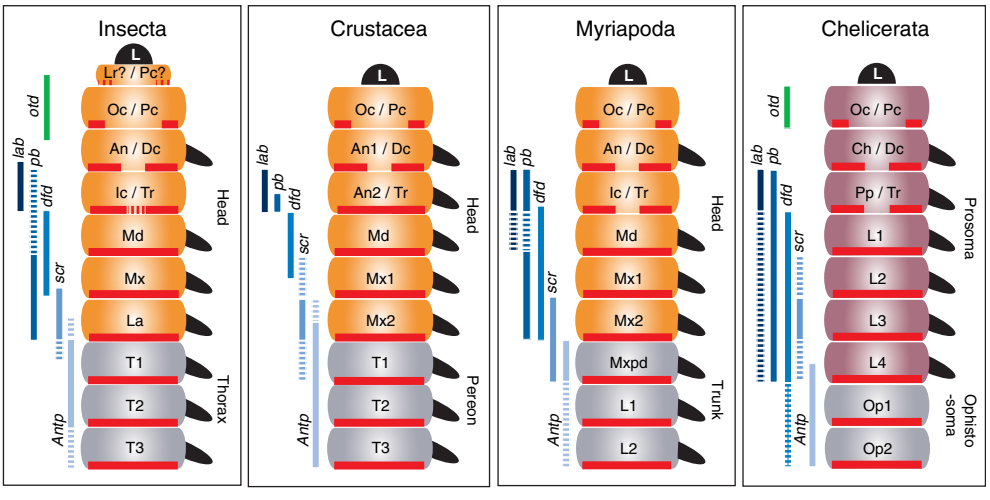

Figure 2 Alignment and proposed homologies between anterior body segments across the arthropod lineages as deduced from expression of *Hox* genes, *otd* and *en*. Schematic presentations of head segments (and corresponding parts of the brain) in mandibulates are highlighted in orange. The prosoma in chelicerates, which includes head segments, is indicated in purple. *en* expression is illustrated as red horizontal bars within the body segments. For each arthropod group, expression domains of *orthodenticle* (*otd*; green vertical bar) and *Hox* genes of the Antp complex (blue vertical bars: *labial* (*lab*), *proboscipedia* (*pb*), *deformed* (*dfd*), and *sex combs reduced* (*scr*)) are indicated on the left, and segmental appendages are indicated on the right. For all genes, regions of weak, transient, or variable expression are indicated by broken bars.

Data on *Hox* gene expression in insects are from Diederich *et al.* (1991), Rogers and Kaufman (1997), Peterson *et al.* (1999), Rogers *et al.* (2002); in crustaceans from Abzhanov and Kaufman (1999a, 1999b, 2000); in myriapods from Hughes and Kaufman (2002b); in chelicerates from Damen *et al.* (1998), Telford and Thomas (1998), Abzhanov *et al.* (1999), Damen and Tautz (1999); for a detailed review and further references on *Hox* gene expression, see Hughes and Kaufman (2002a).

appeared problematic, since it was traditionally thought that they are lacking a homologue of the (mandibulate) first antennal segment (including a deutocerebral part of the brain) (Remane *et al.*, 1975; Weygoldt, 1985). A major conclusion from *Hox* gene expression is that they reveal a conserved mode of head segmentation: expression of *lab*, supported by the anterior extension of *dfd*, suggests that: (1) the pedipalpal segment is homologous to the intercalary/second antennal segment in mandibulates; and (2) the mandibulate (first) antennal segment (and deutocerebrum) is not missing but homologous to the cheliceral segment (Damen *et al.*, 1998; Telford and Thomas, 1998) (Figure 2). Notably, the existence of a chelicerate deutocerebrum has been confirmed by morphological studies (Mittmann and Scholtz, 2003).

Since in all arthropods *Hox* genes are usually not expressed in or anterior to the antennal segment (Hughes and Kaufman, 2002a) (Figure 2), it is useful to include other marker genes in such a phylogenetic analysis, such as the conserved head gap genes. In *Drosophila*, head gap genes have been shown to be directly involved in the metamerization of the anterior head and, in addition, are assumed to confer segmental identity (Cohen and Jürgens, 1990; Schöck *et al.*, 2000). For example, at the blastodermal stage *orthodenticle* (*otd*) is expressed in the ocular and antennal segmental primordia (Cohen and Jürgens, 1990), and later in the part of the protocerebrum deriving from the ocular segment and in a small adjacent part of the deutocerebrum (Younossi-Hartenstein *et al.*, 1997; Urbach and Technau, 2003b). Two *otd* genes have been identified in the beetle *Tribolium*; the expression of *Tc otd-1* closely resembles that of *otd* in *Drosophila* (Li *et al.*, 1996). Interestingly, *otd* expression has also been found in the ocular segment of a chelicerate, the mite *Archegozetes* (Telford and Thomas, 1998). These findings provide evidence that the segmental organization of the anterior head is closely related among arthropods. Further studies will have to show how far the expression (and perhaps function) of other head gap genes, such as *empty spiracles* and *buttonhead* (Younossi-Hartenstein *et al.*, 1997), are evolutionarily conserved.

1.21.3 *engrailed* Expression in the Arthropod Head and Its Implication for the Segmental Organization of the Brain

The segment polarity gene *en* shows a highly conserved pattern of expression in the posterior compartment of each segment (Kornberg *et al.*, 1985), where it determines posterior cell fates. *en* expression has permitted fundamental insights into the segmental composition of the head in a wide variety of arthropods (for review, see Rogers and Kaufman, 1997; Scholtz, 2001; Urbach and Technau, 2003c).

1.21.3.1 Insects

Mainly based on the expression of *en*, it has been suggested that in insects the pregnathal head consists of at least three segments (intercalary, antennal, and ocular), each contributing a neuromere (tritocerebrum, deutocerebrum, and ocular neuromere, respectively) to the brain, a view that is widely accepted (reviewed in Rogers and Kaufman, 1997; Urbach and Technau, 2003c). Some of these studies not only focus on the peripheral head ectoderm, but also embrace structures of the developing embryonic brain, such as neuroblasts (Figure 3) (reviewed in Urbach and Technau, 2003c). Neuroblasts (NBs) are neural stem cells, which delaminate from a specialized ectodermal region, the neuroectoderm. Each NB produces a certain number of progeny cells, which differentiate into specific neuronal and/or glial cell types. The principal pattern of *en*-expressing ectodermal head domains and descending brain NBs appears to be strongly conserved among different insects (except *en* expression in the anterior-most part of the head; see below). The extent of the embryonic primordia of the trito- and deutocerebrum is clearly indicated by small numbers of *en*-expressing NBs deriving from ectodermal *en* stripes at the posterior border of each segment (the intercalary and antennal stripe, respectively) (Figure 3). Sizes of the tritocerebral and deutocerebral primordia are reduced compared with truncal neuromeres. In most insects the number of NBs forming the tritocerebrum is less than half of a truncal neuromere (Figure 3; total numbers of brain NBs in different insects are reviewed in Urbach and Technau, 2003c). In all insects, the ocular neuromere encompasses the largest fraction of brain NBs. Its posterior border (at least partially) is indicated by *en*-expressing NBs detaching from the *en* head spot (Figure 3). In the ocular segment the second head spot, an additional cluster of *en*-expressing neural cells, becomes visible later on. However, the clonal origin of these cells may be different among insects. Expression of *en* has been found in the (clypeo-) labral region of several insects (although absent in others). In *Drosophila*, *en* expression in the dorsal hemispheres and descending brain NBs lends support

for an additional neuromere, the labral neuromere (Schmidt-Ott and Technau, 1992; Urbach and Technau, 2003a). However, its existence and identity are controversial issues, and will be discussed later.

1.21.3.2 Other Arthropods

Unfortunately, *en* expression in the embryonic brain had not been investigated in arthropods other than insects. So far *en* data in other arthropods are limited to the peripheral head ectoderm. The spatial pattern of *en* head domains seems to be largely conserved among mandibulates (crustaceans: Patel *et al.*, 1989; Scholtz, 1995; Abzhanov and Kaufman, 2000; myriapods: Hughes and Kaufman, 2002c). It comprises three segmental gnathal *en* stripes: (1) a continuous intercalary *en* stripe (similar to basal insects); (2) a discontinuous antennal *en* stripe (separated at the midline); and (3) a smaller *en* domain in the central part of each preantennal head hemisphere. The latter presumably represents the counterpart of the *en* head spot in insects. In malacostracan crustaceans, the equivalent *en* domain (the ocular-protocerebral *en* stripe) seems to be enlarged and surrounds the preantennal head ectoderm (including the visual anlagen). Therefore, in crustaceans it is not clear whether this *en* domain indicates the ocular segment or the posterior border of the unsegmented acron (which is traditionally referred to as the eye-bearing part of the head) (Scholtz, 1998). *en* expression in chelicerates, with a mid-stage embryonic head morphology very similar to that of mandibulates, exhibits close correspondences to mandibulates: an *en* stripe exists in each gnathal and in the intercalary segment. Furthermore, the next *en* stripe demarcates the cheliceral segment (which supports homology to the (first) antennal segment), and more anteriorly, a head spot-like *en* domain has been identified, which might indicate a preantennal segment (Damen *et al.*, 1998; Abzhanov *et al.*, 1999), most likely the ocular segment. However, this *en* spot has not been detected in another chelicerate, the mite *Archegozetes*. This has been interpreted as being due to the lack of eyes, since in insects the size of the *en* head spot appears to be correlated with that of the eye (Telford and Thomas, 1998). Taken together, in line with the data from *Hox* gene and *otd* expression (Figure 2), many aspects of the *en* pattern support the existence of at least six head segments to be conserved among arthropods.

1.21.3.3 The Labrum – Insights into an Endless Dispute

Still enigmatic and the subject of ongoing debate is the status of the labrum, and the existence of or affiliation to a corresponding segment and neuromere (Rempel, 1975; Schmidt-Ott and Technau, 1992; Schmidt-Ott *et al.*, 1994; Rogers and Kaufman, 1996, 1997; Popadic *et al.*, 1998b; Scholtz, 1998, 2001; Haas *et al.*, 2001; Urbach and Technau, 2003c). It has not yet been determined whether the labrum represents a metameric appendage, serially homologous to other body appendages, or simply a nonappendicular preoral outgrowth of the body wall. The following body of evidence argues in favor of the labrum being homologous to a segmental appendage.

1. The labrum is often composed of secondarily fused, paired appendages, and labral coelomic sacks have been identified (reviewed in Haas *et al.*, 2001; Urbach and Technau, 2003c).
2. A homeotic transformation of the labrum into a gnathal limb has been reported in a coleopteran (Haas *et al.*, 2001), although this could not be induced in *Drosophila* (Rogers and Kaufman, 1996).
3. Expression of *distal-less* (*dll*) (Panganiban *et al.*, 1995; Popadic *et al.*, 1998b; Thomas and Telford, 1999; Schoppmeier and Damen, 2001) and *dachshund (dac)* (Prpic *et al.*, 2001), usually found in segmental appendages, has been reported in the labrum of several arthropod groups and might support homology (Scholtz, 1998; Thomas and Telford, 1999; Prpic *et al.*, 2001); however, *dll* is likewise expressed in nonappendicular structures (Panganiban *et al.*, 1997; Scholtz, 2001).
4. Support for the appendicular nature of the labrum might come from motoneuronal innervation and pattern of glial and sensory cells (Boyan *et al.*, 2002).

Assuming that the labrum represents a true appendage, a central issue is the question: to which segment does it belong? (For a review of theories on head segmentation and the labral discussion in the older literature, see Rempel, 1975.) One current model of head segmentation (the L-/bent-Y model) suggests that the (insect) labrum represents the appendage of a labro-intercalary segment (Figure 4a) (for details, see Haas *et al.*, 2001). Considering that each segment has only one pair of limblike appendages (Manton, 1977), this view appears to be contradicted by the fact that during embryonic development several insect species

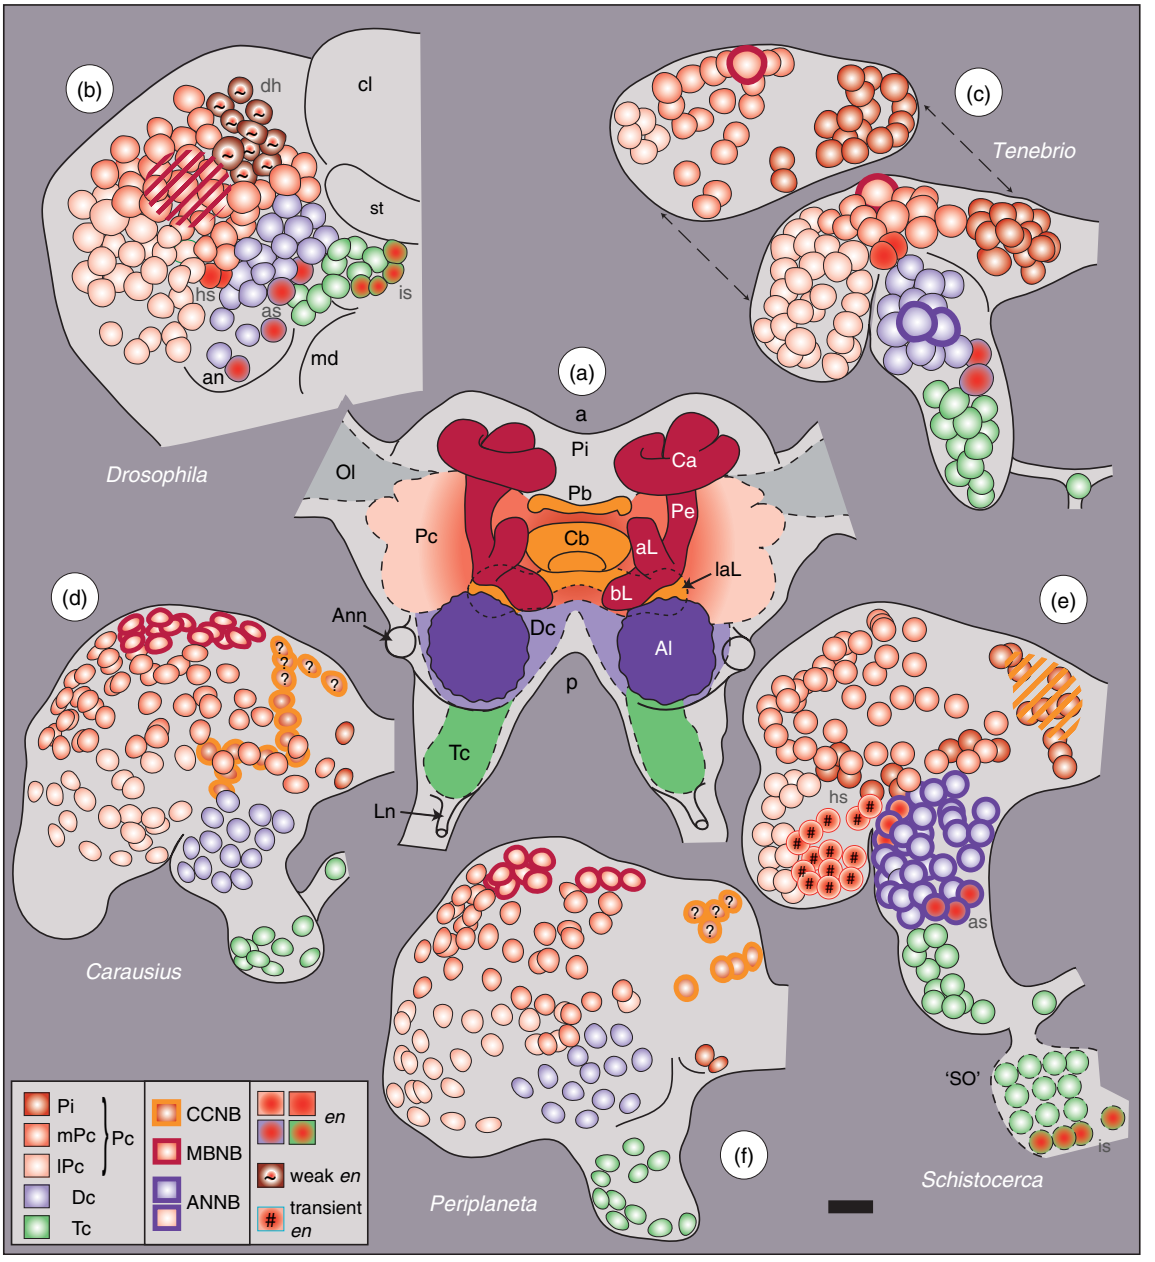

Figure 3 Comparison between different insect species of the spatial arrangement and *engrailed* expression in embryonic brain NBs, and their assignment to specific brain neuropil structures. a, The scheme depicts major neuropil structures of the protocerebrum (mushroom bodies, central complex) and deutocerebrum (antennal lobe, Al) in an adult insect brain. The mushroom body neuropils are built by the axons of thousands of Kenyon cell fibers, which project through the peduncle (Pe) into distinct lobes (aL, alpha-lobe; bL, beta/gamma-lobe). The calyces (Ca) of the mushroom bodies are mainly formed by dendrites of the Kenyon cells. The unpaired median neuropil structures include the central complex (Cc) and the protocerebral bridge (Pb), which are mainly formed by neurons from the pars intercerebralis (Pi). The central complex shows massive connections to the lateral accessory lobes (laL). The optic lobes (Ol) and nerves innervating the ocelli (which occur in some insects) are not shown. Anterior (a) is top and posterior (p) is bottom.

b–f, Semischematic presentations of the NB pattern disclosing the left half of an embryonic brain primordium in a ventral view. The color code indicates the distribution of NBs in the trito- (Tc), deuto- (Dc), and protocerebrum (Pc); the protocerebral NBs are further subdivided into a lateral (lateral protocerebrum, lPc), central (median protocerebrum, mPc), and mediodorsal population (pars intercerebralis, Pi). In embryonic brains of species in (b), (c), and (e) NBs expressing *engrailed* (*en*) are highlighted (see color code, which also distinguishes between strong, weak, and transient *en* expression). NBs that have been assigned to the mushroom bodies (MBNB; encircled in dark red), the central complex (CCNB; encircled in orange), and the antennal lobe (ANNB; encircled in blue) have been indicated. Hatching marks populations of NBs, which include putative progenitors of the respective neuropils (purple hatching indicates putative MBNBs, orange hatching, CCNBs). b, *Drosophila* (Diptera): entire population of brain NBs at about 35% embryogenesis (corresponding to late stage 11; data according to Urbach and Technau, 2003a). The four progenitors of the mushroom bodies in each hemisphere (Noveen *et al.*, 2000) are part of the protocerebral NB (mPC) population which is covered by dark red hatching (unpublished data).

(*Continued*)

Figure 3 (Continued) c, *Tenebrio* (Coleoptera): entire population of brain NBs at 40% embryogenesis. For clarity, the ventral and dorsal half of the brain primordium is shown separately. Data according to Urbach *et al.* (2003). In each hemisphere two NBs of the median protocerebrum form the larval mushroom bodies (encircled in dark red), and two deutocerebral NBs contribute to the larval antennal lobe (encircled in blue). It is not yet known if other deutocerebral NBs also contribute to the antennal lobe.

d, *Carausius* (Orthoptera) (stage D2, adapted from Malzacher, 1968); NB map includes almost all brain NBs; however, progenitors of the mushroom bodies might also form later. According to Malzacher (1968), the mushroom bodies descend from a population of about 15 NBs (group Od; encircled in dark red); NB group 1Ac is suggested to contribute to the central complex (encircled in orange); NBs of group 1Aa (indicated with ?) might additionally participate in the formation of the central complex.

e, *Schistocerca* (Orthoptera); entire population of brain NBs at about 45% embryogenesis. Each NB is indicated by a sphere of equal size with its center corresponding to the position of the NB *in situ*. Data on the NB pattern are according to Zacharias *et al.* (1993).

en expression data are according to Zacharias *et al.* (1993) and Boyan and Williams (2000). A large population of protocerebral NBs expresses *en* (albeit most of them only transiently), which all derive from a *en* hs-like domain. Three *en*-expressing NBs separate from the lPc to join the Dc. Note that the tritocerebral NBs are split in an anterior and posterior group. According to Doe and Goodman (1985), the NBs of the posterior group were first assigned to a fourth gnathal neuromere, the 'SO' neuromere, but have been reassigned to the TC (Boyan and Williams, 2000). Orange hatching indicates population of pars intercerebralis NBs; of these, a subset of four NBs contributes to the central complex (Boyan and Williams, 1997). Apparently all deutocerebral and three (*en*-expressing) protocerebral NBs form the antennal lobe (encircled in blue; Boyan and Williams, 2000).

f, *Periplaneta* (Orthoptera) (stage E2; adapted from Malzacher, 1968). The map encompasses most brain NBs, although at later stages there might be some more (e.g., NBs of the mushroom bodies might form during the second half of embryogenesis).

According to Malzacher (1968), the mushroom bodies derive from NBs including group Od (encircled in dark red); the central complex is argued to derive from group 1Ac (encircled in orange) and perhaps from group 1Aa (indicated by ?). an, cl, md, antennal, clypeolabral, and mandibular appendage, respectively; Ann, antennal nerve; as, antennal *en* stripe; dh, *en* expression in the dorsal hemispheres; hs, *en* head spot; is, intercalary *en* stripe; Ln, labral nerve. Scale bar: b, 18 μm; c, 25 μm; d–f, about 50 μm. Modified from Urbach, R. and Technau, G. M. 2003c. Early steps in building the insect brain: neuroblast formation and segmental patterning in the developing brain of different insect species. *Arthropod Struct. Dev.* 32, 103–123.

transiently exhibit rudiments of intercalary appendages (homologous to the crustacean second antennas) (Malzacher, 1968; Tamarelle, 1984; Fleig and Sander, 1986). However, since in *Tribolium* the labrum has been considered to be composed only of the proximal portions of an appendage (Haas *et al.*, 2001), it has been suggested that the transitory intercalary appendage (due to lack of *dll* expression) represents the distal part of an appendage, which together with the labral part originally formed one complete appendage of a labro-intercalary segment (Hass *et al.*, 2001). Conflicting with this model is that, based on *dac* expression, the labrum represents the distal rather than the proximal part of an appendage (Prpic *et al.*, 2001). Expression of *lab* in the labrum as well as in the second antennal/intercalary segment of a crustacean (Abzhanov and Kaufman, 1999a) and a myriapod (Hughes and Kaufman, 2002b) might support an origin of the labrum from the second antennal segment. However, the crustacean second antenna appears to represent a complete appendage. Moreover, *lab* has not been found in the labrum of the more basal chelicerates, but instead in the pedipalps and all four pairs of walking legs (Damen *et al.*, 1998). In *Drosophila*, another model of head segmentation has been favored (the S-model; Figures 4a and 4b). The expression of segment polarity genes indicates the existence of remnants of four pregnathal segments arranged in an S-shaped loop, the intercalary, antennal, ocular, and labral segment, with the latter at the anterior tip of the head. The labrum is part of the labral segment, and the ocular segment (see also Rogers and Kaufman, 1996; Sharov, 1966) is located between the antennal and labral segments (Schmidt-Ott and Technau, 1992; Urbach and Technau, 2003a, 2003b). Additional evidence provides the deletion pattern of sensory organs in head gap mutants (Schmidt-Ott *et al.*, 1994). Furthermore, this analysis suggests that the optic lobes are of segmental origin, deriving from the ocular segment (Schmidt-Ott *et al.*, 1995). In this model, the ocular segment (including the anlagen of the visual system) covers that part of the head which in the linear model of head segments (Rempel, 1975) represents the unsegmented acron (traditionally referred to as the eye-bearing part of the arthropod head) (Figure 4a). As a consequence, an ocular segment excludes the existence of a nonsegmental acron.

1.21.4 A Neuromeric Model of the Brain in *Drosophila*

As described above, *en* domains in the pregnathal head, in contrast to the trunk, are discontinuous, and thus leave substantial parts of the segmental boundaries in the head and brain unlabeled (Figure 2). A reconstruction of these boundaries in the procephalic ectoderm and in the array of brain NBs deriving from this region was achieved by

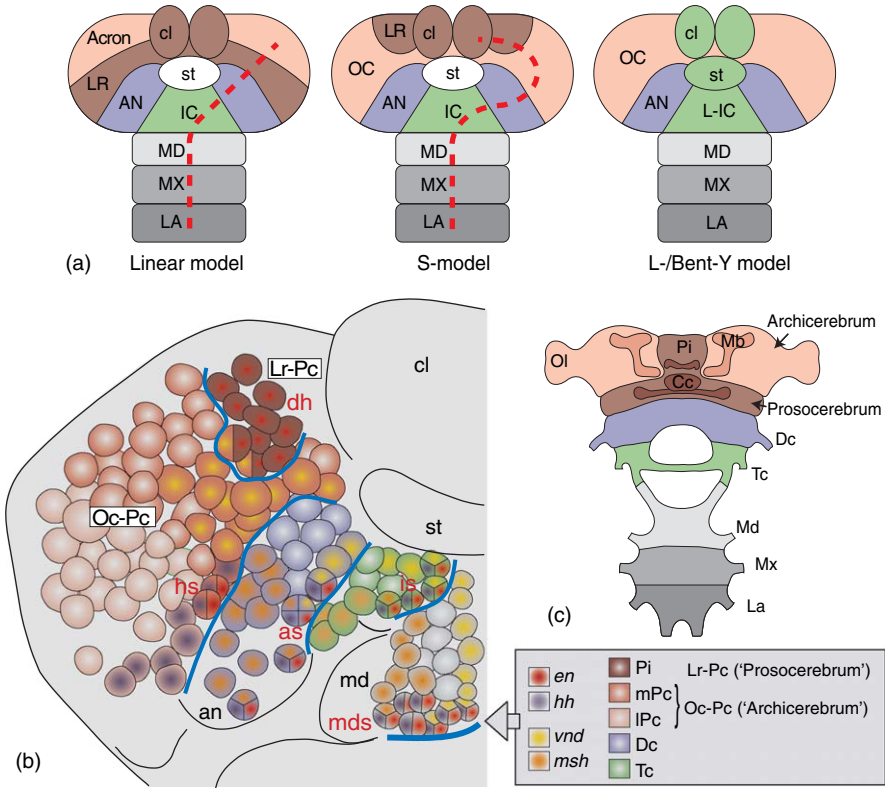

Figure 4 a, Current models on head segmentation in insects. Schemes disclose in a ventral view the different numbers, orientations, and identities of segments in the embryonic insect head.

In the linear model (after Rempel, 1975), six head segments and an acron are arranged rather straight along the anteroposterior axis (as indicated by the red broken line); the labral segment (LR) represents the preantennal segment, and the acron the anterior tip of the head.

In the S-model (after Schmidt-Ott and Technau, 1992), the arrangement of seven head segments follows an S-like loop (as indicated by the red broken line); the ocular segment (OC) represents the preantennal segment, and the labral segment is at the anterior tip of the head. Here, the ocular segment replaces the acron. Compare with the segmental model of the embryonic brain proposed in (b).

The L-/bent-Y model (after Haas *et al.*, 2001) proposes six head segments and reinterprets the ventral territory spanning the intercalary segment (IC), the stomodaeum (st), and the (clypeo-) labral appendages (cl) as the labro-intercalary segment (L-IC). AN, antennal; IC, intercalary; L-IC, labro-intercalary; LA, labial; LR, labral; OC, ocular; MD, mandibular; MX, maxillary segment.

b, Segmental model of the early embryonic brain in *Drososphila*. Semischematic presentation of the brain NB map at about 35% embryogenesis (late stage 11, orientation as in Figure 3). Based on the expression of segment polarity genes (*en*, *hedgehog* (*hh*)) and DV patterning genes (*muscle segment homeobox* (*msh*), *ventral nervous system defective* (*vnd*); as indicated by the color code), the embryonic brain is proposed to consist of four neuromeres (data for pregnathal NBs according to Urbach and Technau, 2003a). Blue lines indicate the borders between the respective neuromeres. As indicated in the color code, from posterior to anterior the brain anlagen encompass the tritocerebrum (Tc), the deutocerebrum (Dc), the ocular (Oc-Pc) and labral (Lr-Pc) part of the protocerebrum. The ocular part comprises the largest fraction of brain NBs (including NBs of the median (mPc) and lateral protocerebrum (lPc), which may correspond to the archicerebrum; the much smaller labral part of the protocerebrum (consisting of NBs of the pars intercerebralis (Pi)) may correspond to the prosocerebrum.

as, is, mds, antennal, intercalary and mandibular *en* stripe, respectively; dh, *en* expression in the dorsal hemispheres; hs, *en* head spot; an, cl, md, antennal, clypeolabral, and mandibular appendage, respectively; st, stomodaeum. a, Modified from Haas, M. S., Brown, S. J., and Beeman, R. W. 2001. Pondering the procephalon: The segmental origin of the labrum. *Dev. Genes Evol.* 211, 89–95.

c, Model of the segmental composition of the adult insect brain and subesophageal ganglion after Rempel. According to this model, the archicerebrum encompasses the optic lobes (Ol) and mushroom bodies (Mb), and the prosocerebum (in Rempel's view, the preantennal neuromer) encompasses the neurosecretory cells of the pars intercerebralis (Pi), and the components of the central complex (Cc). Dc, Tc; deuto-, tritocerebrum; Md, Mx, La, mandibular, maxillary, and labial neuromere, respectively. Modified from Rempel, J. G. 1975. The evolution of the insect head: An endless dispute. *Quaest. Entomol.* 11, 7–25.

analysis of the expression of a large collection of molecular markers, including segment polarity genes and DV patterning genes, which are differentially expressed along the DV as well as the AP axis (Urbach and Technau, 2003a, 2003b). These data support the view that the pregnathal *Drosophila* head is composed of four segments, each contributing a neuromere to the brain. The expression

patterns define the boundaries between trito-, deuto-, and protocerebrum, and provide indications that the protocerebrum is composed of two neuromeres belonging to the ocular and labral segment (Schmidt-Ott and Technau, 1992; Urbach and Technau, 2003a) (Figure 4b). The ocular neuromere comprises more than 50% of all brain NBs. By contrast, the putative labral neuromere consists of a small fraction of about 10 *en*-expressing NBs, thus, being confined to its posterior segmental compartment. These NBs derive from the anterior-most part of the procephalic neuroectoderm (*en*-expressing domain of the dorsal hemispheres) which has been suggested to coincide with the posterior boundary of the labral segment (Schmidt-Ott and Technau, 1992; Urbach and Technau, 2003a). The segmental character of both protocerebral neuromeres seems to be less conserved compared with the trito- and deutocerebrum. This is reflected by the orthogonal expression of segment polarity and DV patterning genes, which is principally conserved in the posterior segments of the pregnathal head and brain, but becomes obscure towards anterior sites. It is further reflected by the identification of NBs in the trito- and deutocerebrum which have serially homologous counterparts in the neuromeres of the ventral nerve cord (reviewed in Urbach and Technau, 2004).

1.21.5 Clues to the Segmental Origin of Some Major Neuropil Centers

1.21.5.1 Mushroom Bodies

Mushroom bodies have been described in all arthropods, except crustaceans (reviewed in Strausfeld *et al.*, 1998). They represent a paired protocerebral brain structure involved in higher brain function, like olfactory learning and memory (reviewed in Heisenberg, 1998; Menzel, 2001). In insects, they consist of a large number of neurons (Kenyon cells), whose fibers form typical substructures, the calyx, peduncle, and lobes (Figure 3a). Mushroom bodies derive from specific NBs (MBNBs) which are already formed in the embryo (Figure 3). The number, arrangement, and proliferation behavior of embryonic (and postembryonic) MBNBs, as well as the final size and complexity of the adult mushroom bodies, show enormous variabilities among insects (reviewed in Strausfeld, 1998; Farris and Sinakevitch, 2003; Urbach and Technau, 2003c). MBNBs reside in the posterior dorsal brain cortex either in small numbers (e.g., two in coleopterans; Figure 3c), or in larger groups (up to 100, e.g., in certain Blattoidea). In *Drosophila*, molecular markers specifically expressed in MBNBs (Noveen *et al.*, 2000) indicate that these NBs are part of the ocular neuromere (Urbach and Technau, 2003c) (Figure 3b).

A traditional view is that the protocerebrum in arthropods consists of the archicerebrum and prosocerebrum (Remane *et al.*, 1975). The archicerebrum is argued to be that part of the brain that derives from the acron, comprising the optic lobes and mushroom bodies (Figure 4c) (reviewed in Rempel, 1975). Since the acron has been regarded as equivalent to the ocular segment (as discussed above), the ocular neuromere would be equivalent to the archicerebrum (Schmidt-Ott and Technau, 1992; Urbach and Technau, 2003a). This would be in agreement with the view that the mushroom bodies are part of the ocular neuromere (or archicerebrum).

1.21.5.2 Central Complex

Another conserved protocerebral neuropil center associated with higher brain function in arthropods is the central complex (Figure 3a) (Utting *et al.*, 2000; Loesel *et al.* 2002; reviewed in Strauss, 2002). In most insects this prominent unpaired structure develops its typical shape during postembryonic stages. Information about the embryonic origin of the central complex is still lacking, except in orthopteran insects, in which the central complex is formed by about 13–20 NBs on either side in the pars intercerebralis (Figures 3d–3f) (Malzacher, 1968; Boyan and Williams, 1997). In *Drosophila*, likely counterparts might be the *en*-expressing labral NBs deriving from the dorsal hemispheres (Figures 3a and 4a). Similar to the situation in orthopterans, their progeny is later found in the larval pars intercerebralis and might participate in the formation of the central complex (Urbach and Technau, 2003a, 2003c). Under the assumption that a labral neuromere remnant is existent, this would be in harmony with the traditional view that the prosocerebrum, corresponding to the labral part of the protocerebrum, includes the central complex and cells of the pars intercerebralis (Figure 4b) (reviewed in Rempel, 1975).

1.21.5.3 Antennal Lobes

The antennal lobes in insects are important centers in the olfactory pathway (reviewed in Stocker, 2001; Jefferis *et al.*, 2002). Similar olfactory deutocerebral centers have been reported in crustaceans (reviewed in Strausfeld and Hildebrand, 1999). Specialized deutocerebral precursor cells of enlarged size and/or specific proliferation behavior have been identified in insects (Figure 3) and crustaceans, the progeny of which contribute to the developing antennal/olfactory lobes (reviewed in Beltz and

Sandeman, 2003; Urbach and Technau, 2003c). These olfactory centers have been traditionally attributed to the deutocerebrum, although not much is known about their embryonic segmental origin. In insects, antennal lobes derive from embryonic deutocerebral NBs (Figure 3) (Nordlander and Edwards, 1970; Truman and Bate, 1988; Stocker *et al.*, 1995; reviewed in Urbach and Technau, 2003c). However, at least in orthopteran insects there are indications that the antennal lobes may not be pure deutocerebral derivatives but also include components descending from the protocerebrum (Boyan and Williams, 2000) (Figure 3e).

1.21.6 Conclusions

Comparison of the expression of key developmental control genes provides fundamental insight into the development and phylogeny of the arthropod head and its ganglia. *en*, *otd*, and *Hox* gene expression data suggest that the sister groups of insects and crustaceans share the same mode of head segmentation with the more basic myriapods and chelicerates, and might further emphasize the monophyletic origin of arthropods (Damen *et al.*, 1998; Popadic *et al.*, 1998a; Abzhanov and Kaufman, 1999; Hughes and Kaufman, 2002a, 2002b). In all arthropods the head appears to consist of at least six segments. Nevertheless, the metameric organization of the anterior head, including the ocular/acronal and labral region (as well as of the descending protocerebrum), is not yet clear and remains open to ongoing discussions. A subdivision of the brain into three main regions, the trito-, deuto-, and protocerebrum, appears to be conserved among insects and crustaceans, but this is less clear in other arthropod taxa (Bullock and Horridge, 1965; Damen *et al.*, 1998; Telford and Thomas, 1998; Eriksson and Budd, 2000; Mittmann and Scholtz, 2003). Moreover, it is uncertain how far particular brain centers in insects have homologous counterparts in other arthropods: homology of the central body in mandibulates and chelicerates has been suggested. Mushroom bodies are missing in crustaceans, but may be homologous to structures found in chelicerates, and homology of the antennal lobes in different arthropods is unresolved (e.g., Breidbach and Wegerhoff, 1993; Strausfeld *et al.* 1993, 1998; Strausfeld, 1998; Strausfeld and Hildebrand, 1999; Utting *et al.*, 2000; Harzsch and Glötzner, 2002; Loesel *et al.*, 2002). In the brain of onychophorans (which are proposed to be very basal to arthropods), several neuropils with similarities to brain structures in euarthropods have been described (Loesel, 2004), but it is not yet known if they represent homologous structures. A study on the cephalic nerves in onychophorans points out that the relationship of head segments in onychophorans and other arthropods is far from clear (Eriksson and Budd, 2000). The key towards solving these and other questions related to brain evolution in arthropods lies in the comparative analysis of embryonic brain development, including a growing array of (evolutionary conserved) developmental control genes, which will be a challenging task for further research.

1.22 Commissural Organization and Brain Segmentation in Insects

G S Boyan and J L D Williams, University of Munich, Martinsried-Planegg, Germany
F Hirth, University of Basel, Basel, Switzerland

Glossary

Abd-B, *Abd-B*	Abdominal B gene, protein.
Antp, *Antp*	Antennapedia gene, protein.
cell adhesion glycoprotein	A member of the immunoglobulin superfamily of cell adhesion molecules which promote adhesivity between cells. Such molecules have an extracellular (N-terminal) gobular domain held in place by disulfide bonds and a C-terminal domain anchored in the cell membrane via either a transmembrane amino acid sequence in the protein itself or a lipid. Such molecules promote cell–cell adhesion by binding to one another (homophilic binding) without requiring calcium.
CNS	Central nervous system.
Com, *Com*	Commissureless gene, protein.
conserved	A structure, molecule, or amino acid sequence which is maintained in a recognizable form between different species throughout evolution.
DC	Deutocerebrum.
Dfd, *Dfd*	Deformed gene, protein.
DUM	Dorsal unpaired median
ems, *EMS*	Empty spiracles gene, protein.
expression	Gene activity resulting in the production of its protein (and detectable for example via an antibody against the protein).
gmc	Glial cells missing gene.
homeobox gene	A gene which contains a homeobox, a 180-basepair region, which codes for the homeodomain of about 60 amino acids that is able to bind to DNA and therefore can act as a transcription factor.
homo	Homothorax gene.
HRP	Horseradish peroxidase.
inductive factor	A molecule which is produced by one group of cells and acts as a signal in that it influences the development of a second, neighboring, group of cells.
jing	*jing* gene.
lab, *Labial*	Labial gene, protein.
MaC	Mandibular commissure.
mutational analyses	Deduction of gene function in development by studying possible phenotypes caused by the mutation of a gene. Mutation of a gene can be the result of either its absence (deletion) or the inactivation/malfunction of its encoded protein (mutation).
Mx	Maxillary neuromere.
neuromere	The nervous system component of an embryonic segment.
null mutant background	The genotype in which both alleles of a gene are absent or inactivated.
otd, *Otd*	Orthodenticle gene, protein.
PC	Protocerebrum.
PCC	Protocerebral commissure.
pcXX, XXI	Posterior commissures XX, XXI of the brain.
pioneer (neuron)	A neuron and its axonal projection which together are responsible for guiding subsequent neuronal processes to their targets in the developing nervous system.
repo	Reversed polarity gene.
stomodeum	The mouthlike modification of the anterior end of the gut (in embryos) formed by an invagination of the ectoderm.
TC	Tritocerebrum.
TCC	Tritocerebral commissure.
temporal dynamic	Time-dependent morphological changes in the nervous system.
transcription factor	A protein that is able to bind to DNA and therefore can either activate or suppress the function of a gene.

Ubx, *Ubx*	Ultrabithorax gene, protein.
VG 1,3	Ventral giant cells 1, 3 of the deutocerebrum.
VNC	Ventral nerve cord.

1.22.1 Commissural Organization and the Segmental Body Plan

The evolution of a bilateral body form and bilaterally coordinated behavior required the development of a central nervous system (CNS) in which information could be exchanged across the midline. The most obvious neural adaptation in this regard is the presence of serially iterative transverse commissures linking the left and right hemispheres of all bilateral nervous systems (Bullock and Horridge, 1965). Many cellular and molecular studies have focused on the proper establishment of such commissures during development (Kaprielian *et al.*, 2001), often in conjunction with the expression patterns of genes which identify specific brain regions or segment borders (Hirth and Reichert, 1999). One such marker is the segment polarity gene *Engrailed* which encodes a transcription factor and is expressed in cells located within the posterior compartment of a given body segment (Nüsslein-Volhard and Wieschaus, 1980; Hidalgo, 1996). Its role in positional specification is remarkably conserved in both invertebrates and vertebrates (Patel *et al.*, 1989a, 1989b; Lans *et al.*, 1993; Eizema *et al.*, 1994; Fleig, 1994; Scholtz, 1995; Wray *et al.*, 1995; Itasaki and Nakamura, 1996; Rétaux and Harris, 1996; Rogers and Kaufman, 1996; Marie and Bacon, 2000; see Segmental Organization of Cephalic Ganglia in Arthropods, Cognition in Invertebrates, Aggression in Invertebrates: The Emergence and Nature of Agonistic Behavioral Patterns).

Recent molecular data, including *Engrailed* expression in grasshopper (Figure 1a) and *Drosophila* (Figure 1b), suggest that the insect brain comprises three neuromeres: (1) the proto cerebrum (PC), corresponding to the ocular and preantennal segments; (2) the deuto cerebrum (DC), corresponding to the antennal segment; and (3) the tritocerebrum (TC), corresponding to the intercalary segment (Diederich *et al.*, 1991; Rogers and Kaufman, 1996; Hartmann and Reichert, 1998; Hirth *et al.*, 1998; Peterson *et al.*, 1998; Haas *et al.*, 2001a, 2001b; Boyan and Williams, 2002). In the early embryonic ventral nerve cord (VNC) of insects, *Engrailed* expression has the appearance of a regular series of stripes which extend into the posterior epithelium of the associated appendage (Figure 1a; Patel *et al.*, 1989a). In the brain, this regular pattern is broken by the presence of the foregut (or stomodeum), which bisects the head anteroposteriorly and bilaterally (Figure 1a). Traditionally, the stomodeum has been held to divide the brain between the deutocerebral and tritocerebral neuromeres (Snodgrass, 1935; Bullock and Horridge, 1965). PC and DC have been considered the preoral neuromeres, while the TC has been considered postoral in its anatomical organization. New molecular data discussed below suggest that this interpretation requires revision. The most obvious evidence that the foregut affects the organization of head neuromeres is seen in the pattern of *Engrailed* expression, which in the brain is highly irregular compared to that in the VNC in that it comprises a mix of partial stripes and spots bearing a pronounced temporal dynamic (Patel *et al.*, 1989a; Cohen and Jürgens, 1991; Fleig, 1994; Boyan *et al.*, 1995; Rogers and Kaufman, 1996; Marie and Bacon, 2000; Boyan and Williams, 2002).

The foregut appears to have a profound influence not only on the gross morphology of the brain, but also as an inductive factor on the organization of axons within it (Page, 2002). Whereas in the VNC each ganglion possesses a transverse anterior (a-type) and a posterior (b-type) commissure (Figure 1c; Goodman and Bastiani, 1984; Thomas *et al.*, 1984; Whitington, 1995), in the head, the early embryonic mandibular, tritocerebral, and protocerebral neuromeres contain only a single commissure. More extreme still, the embryonic DC appears not to possess a commissure at all (Figures 1d and 1e). These differences in axonal organization may relate to where, topologically, the stomodeum bisects the brain. Molecular data provide an insight into this problem, and into the identity (a-type or b-type) of the various cephalic commissures.

The Fasciclin (Fas) I antigen belongs to the family of cell adhesion glycoproteins and is primarily expressed by pioneer axons early in the embryonic development of the insect nervous system (Snow *et al.*, 1987, 1988). Immunocytochemical data show that the expression of Fasciclin I in commissural fibers is segmentally iterative along the VNC (Figure 1f; Bastiani *et al.*, 1987). Careful inspection reveals that this expression appears to be consistently stronger in the a-type commissure than in the b-type commissure of each neuromere (Figure 1f). More interestingly, this strong Fasciclin I expression within the a-type commissure appears to be consistently localized to a single fascicle at this embryonic stage (Figure 1g). With regard to the tritocerebral commissure (TCC), only a single clearly defined Fasciclin I immunoreactive fascicle is observed (Figure 1h). Preorally, and at the equivalent stage of embryogenesis, double immunolabeling with anti-horseradish peroxidase

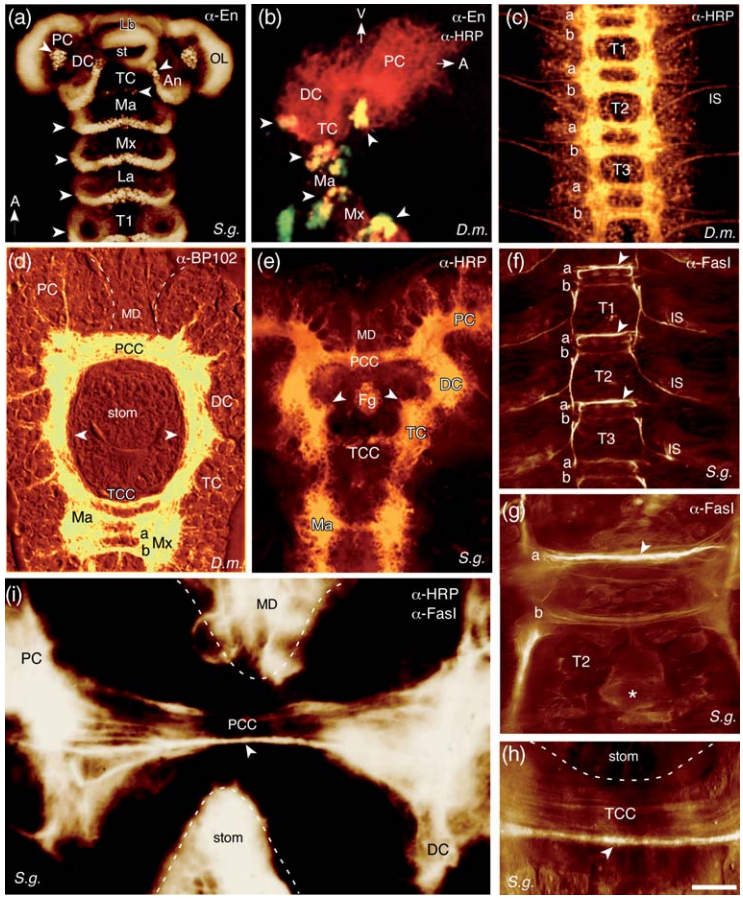

Figure 1 Segmental organization of commissures in the embryonic insect nervous system. a, Immunocytochemical labeling with the anti-En antibody reveals pattern of *Engrailed* expression in the head of the grasshopper *Schistocerca gregaria* (*S. g.*) at 28% of embryogenesis. Wholemount embryo, ventral view. *Engrailed* expression (white arrowheads) is present in stripes which extend into the posterior epithelium of the appendage associated with each segment. The brain comprises three neuromeres: (1) in the PC, *Engrailed* expression in neuroblasts is associated with the optic lobe (OL); (2) in the deutocerebrum (DC), *Engrailed* expression extends into the posterior antennal (An) epithelium; and (3) in the tritocerebrum (TC), *Engrailed* expression is associated with the labrum (Lb). Anterior (A) is to the top in all figures except (b). b, Laser confocal image of the anterior CNS of a wild-type stage 12 *Drosophila melanogaster* (*D. m.*) embryo viewed laterally following double labeling with anti-*Engrailed* antibody (yellow/green) and neuron-specific anti-HRP antibody (red/orange). En-expressing cells appear as clusters (white arrowheads) in lateral view. Ventral (v) is to the top. c, Laser confocal image following neuron-specific anti-HRP immunostaining reveals the structure of the ventral nerve cord in wild-type stage-15 *Drosophila* embryo. Ventral view. Ladder-like axonal tracts with anterior (a-type) and posterior (b-type) commissures and longitudinal connectives, along with the serially iterated intersegmental nerves (IS) are seen. Prothorax = T1; mesothorax = T2; metathorax = T3. d, Section through a stage-16 brain of *Drosophila melanogaster* (*D. m.*) embryo stained with the axon-specific Mab BP 102 reveals the orthogonal scaffold of fibers around the stomodeum (stom). Anteriorly (preorally) lies the protocerebral commissure (PCC); posteriorly (postorally), lies the tritocerebral commissure (TCC) and three commissures (S1, mandibular; S2a, anterior maxillary; S2b, posterior maxillary) of the subesophageal ganglion. White arrowheads indicate the location where a deutocerebral commissure would be expected. e, Confocal image of the brain of the grasshopper at 40% of embryogenesis following neuron-specific anti-HRP immunocytochemistry. Note the prominent PCC preorally and the TCC postorally. White arrowheads indicate the location where a deutocerebral commissure would be expected. f, Segmental organization of axon pathways in thoracic neuromeres of the ventral nerve cord of the grasshopper viewed ventrally and in wholemount following anti-Fasciclin I immunocytochemistry at 40% of embryogenesis. Each neuromere possesses an anterior (a-type) and posterior (b-type) commissure, longitudinal tracts, and an intersegmental nerve (IS) to the periphery. Note that the antibody staining appears consistently stronger in the anterior commissure (white arrowheads). g, Higher-power micrograph of the mesothoracic neuromere from another preparation to that in (c) reveals that Fasciclin I expression in the anterior commissure (a) is restricted to a single fascicle (white arrowhead). The immunoreaction in the b-type commissure is much weaker. The lineage (white asterisk) of the dorsal unpaired median (DUM) neuroblast of T2 is visible posteriorly. h, Photomicrograph of the tritocerebral commissure in the embryonic grasshopper (40% stage) following anti-Fasciclin I immunocytochemistry. A single strongly immunoreactive fascicle (white arrowhead) is visible within the commissure. i, Photomicrograph of the brain of the grasshopper at 40% of embryogenesis as seen in wholemount and viewed ventrally following double immunolabeling with neuron-specific anti-HRP and anti-FasI antibodies. Note the single prominent Fasciclin I-positive fascicle (white arrowhead) within the PCC. MD, median domain; Fg, frontal ganglion. Scale bar (in h): 400 μm (a); 10 μm (b, c); 20 μm (d); 200 μm (e, f); 50 μm (g, h); 100 μm (i). b, Modified from Hirth, F., Therianos, S., Loop, T., Gehring, W. J., Reichert, H., and Furukubo-Tokunaga, K. 1995. Developmental defects in brain segmentation caused by mutations of the homeobox genes *orthodenticle* and *empty spiracles* in *Drosophila*. *Neuron* 15, 769–778, Elsevier. c, Modified from Leutzinger, S., Hirth, F., Gerlich, D., *et al.* 1998. (anti-HRP) and anti-FasI shows (Figure 1i) that the protocerebral commissure (PCC) is already well developed, comprising over 100 axons (Boyan *et al.*, 1995). Within the PCC, a single large fascicle can be seen expressing the FasI antigen. The pattern in both PCC and TCC is therefore identical to that found in the a-type commissure of each neuromere in the VNC (Figures 1f and 1g) implying that the protocerebral and tritocerebral neuromeres have, like the mandibular neuromere (Figure 1d), 'lost' a specific b commissural component, whether via fusion, splitting, or axonal redirection.

1.22.2 Genes, Commissures, and Segments

1.22.2.1 The Preoral Brain

Developmental genetic analyses have so far identified three genes that are involved in the formation of the preoral brain commissure (PCC). These are *orthodenticle* (*otd*), *commissureless*, and *jing*. The homeobox gene, *otd*, has been shown to play a major role in anterior brain development in insects and vertebrates alike (Hirth *et al.*, 1995; Acampora *et al.*, 1998; Hirth and Reichert, 1999; Reichert and Simeone, 1999). In *otd* null mutants of *Drosophila*, the entire protocerebral neuromere is missing (Figures 3a and 3c; Hirth *et al.*, 1995). The mutation appears to have no gross morphological defects in DC and TC development, but disruption of anterior brain structures leads to the complete absence of all protocerebral commissural axons. In addition, the *otd* mutant phenotype implies that commissural axons from other neuromeres of the brain fail to cross the preoral midline in the mutant brain, probably due to missing pioneer cells which have been shown to be of protocerebral origin (Boyan *et al.*, 2003). In the VNC, the *otd* null mutant is characterized by a condensation of ganglia and a failure to form discrete metameric commissures (Figure 3c). Overexpression of the *otd* gene rescues the commissural organization of the PC and re-establishes the wild-type plan of a-type and b-type commissures in the VNC (Leutzinger *et al.*, 1998).

In *commissureless* mutants, commissures in the VNC do not form (Figures 2a, 2b, 3a, and 3b; Seeger *et al.*, 1993; Tear *et al.*, 1996). Also missing are the tritocerebral (TCC) and mandibular (MaC) commissures. However, the preoral PCC, though reduced, is still present in the brain (Therianos *et al.*, 1995). The Commissureless protein might therefore not be necessary for the initial pioneering of the PCC. The survival of the PCC in the *commissureless* null mutant points to additional molecular mechanism(s) to those acting in the VNC as being responsible for pioneering this commissure. The foremost candidate is probably the *jing* zinc finger transcription factor. In homozygous *jing* mutant embryos the PCC is not pioneered and never forms, while the TCC is pioneered but subsequently does not form properly (Figure 3f). *jing* appears to be essential for the formation of the primary axon scaffold of the brain by regulating the differentiation of Repo-, Castor-, and Sim-positive cells such as midline glia (Sedaghat and Sonnenfeld, 2002). These findings are consistent with the data from *otd* and *com* mutants in pointing to molecularly distinct mechanisms underlying PCC and TCC formation, respectively.

The *commissureless* mutants provide important additional information as to the origin of the pioneering fibers contributing to the PCC. Pioneer axons early in embryogenesis express Fasciclin II, a member of the NCAM family of glycoproteins (Bastiani *et al.*, 1987; Grenningloh *et al.*, 1991). FasII immunocytochemistry in the *commissureless* mutant reveals that fibers from the PC and two locations within the DC contribute to the PCC (Figure 2c), indicating that not only protocerebral but also deutocerebral commissural axons survive the mutation. These data provide evidence that in the wild type, embryonic deutocerebral fibers cross the midline in association with the PCC, thereby contributing to preoral axon pathways in the developing *Drosophila* brain. This appears to also be the case in the early embryonic nervous system of the grasshopper. Examination of axon pathways following Lazarillo immunocytochemistry shows that pioneer neurons from the DC project growth cones anteriorly to the PC where they fasciculate with axons of identified Lazarillo immunoreactive cells (the LC cells) (Figure 2d). These embryonic deutocerebral cells subsequently direct axons across the midline via fascicle XX (Figure 2e) which develops into posterior commissure XX (pcXX) of the adult brain (Figure 2f).

1.22.2.2 The Postoral Brain

In the grasshopper, the DC is also the origin of pioneer neurons which project axonal growth cones posteriorly toward the TC (Figure 2d). En route they fasciculate with the anteriorly directed growth cones of tritocerebral neurons. Further investigation at a later developmental stage identifies the deutocerebral cells as being a bilaterally symmetrical pair of Fasciclin I-immunoreactive neurons with axonal growth cones that pioneer a fascicle within the TCC (Figure 2g). The growth

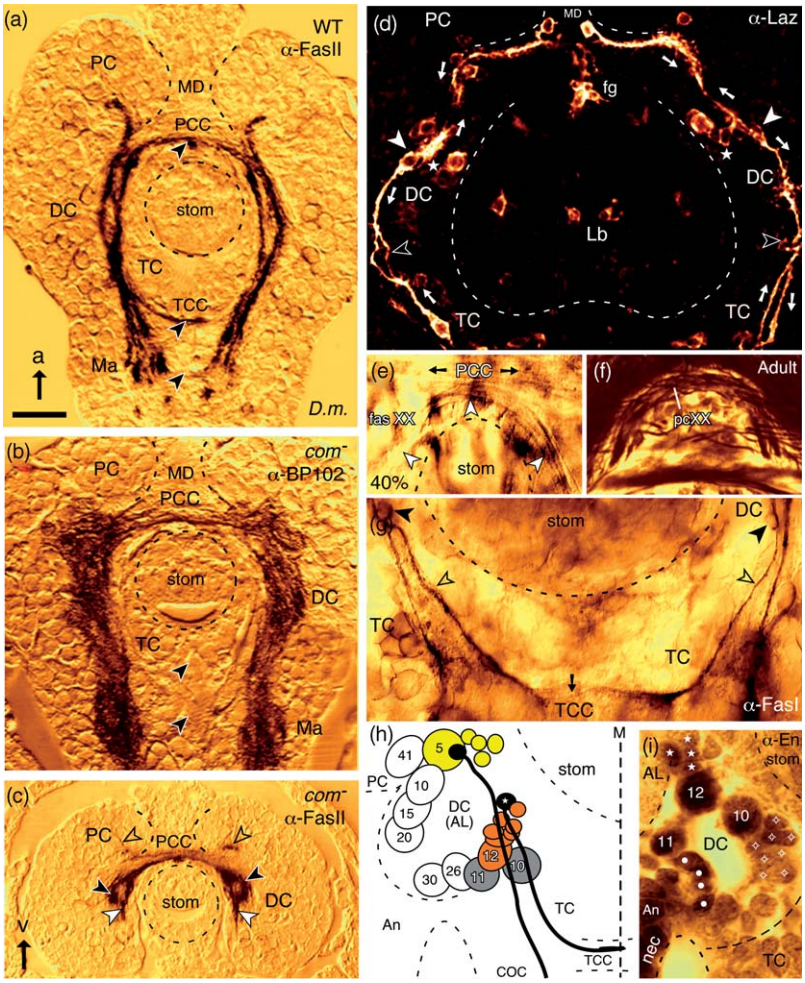

Figure 2 Pathway choices made by pioneering deutocerebral cells in the brain of *Drosophila* (a–c) and grasshopper (d–i). a, Section through the brain of a stage 16 wild-type (WT) *Drosophila* embryo in the plane of both circumesophageal connectives following Fasciclin II immunocytochemistry. Fasciclin II-expressing axons are seen in preoral (PCC) and postoral (TCC, MaC) commissural fascicles (black arrowheads), as well as in longitudinal circumoesophageal fascicles. Arrow points to anterior and applies to all figures. b, Section through the brain of a *Drosophila commissureless* mutant embryo following axon-specific anti-BP 102 immunocytochemistry. Note that the PCC is reduced but still present, while all other postoral commissures, such as the TCC and MaC, are missing (black arrowheads indicate normal location of TCC, MaC). c, Section through the brain of a stage-16 *Drosophila commissureless* mutant embryo following Fasciclin II immunocytochemistry reveals the segmental origin of fibers contributing to the reduced PCC. A single fascicle from the PC (open black arrowhead), and two from the DC (black and white arrowheads), cross in the PCC in this particular section. No fibers from the DC project across the postoral midline in this section and the TCC itself is missing. d, Confocal image following anti-Lazarillo immunocytochemistry at 32% of embryogenesis reveals direction of axonal outgrowth of pioneer neurons in the brain. Some deutocerebral pioneers (white stars) grow out anteriorly toward the PC, while others differentiating at the same site (white arrowheads) grow posteriorly toward the tritocerebrum where they fasciculate with anterior-growing TC pioneers. Sites of fasciculation are indicated by open white arrowheads, while the direction of axogenesis is indicated by white arrows. e, Photomicrograph from wholemount showing commissural axons of deutocerebral origin in embryonic axon fascicle XX (white arrowheads) at 40% of embryogenesis. Note that fas XX joins the PCC at the brain midline. f, Photomicrograph from frontal section through an adult brain showing posterior commissure XX following Bielschowsky histology. pcXX contains axons of deutocerebral origin. Its location and shape suggest it is the adult equivalent of embryonic fas XX. g, Photomicrograph of the medial tritocerebrum viewed dorsally and in wholemount at 34% of embryogenesis following anti-FasI immunocytochemistry. Deutocerebral Fasciclin I immunoreactive pioneers (black arrowheads) from the border of the antennal lobe direct axons (open arrowheads) posteriorly and medially toward the midline of the tritocerebral neuromere where they fasciculate (black arrow) and so pioneer a fascicle of the TCC. h, Ontogeny of deutocerebral pioneer neurons. Lineage analysis (semischematic not to scale) reveals that the bilaterally symmetrical Fas I-expressing pioneer neurons of the TCC shown in (g) above derive from neuroblast 12 of the deutocerebrum. At 34% of embryogenesis the lineage (brown) of NB12 comprises a ganglion mother cell (GMC) and six progeny, one of which (white star) directs an axon posteriorly and medially into the TCC. i, Pioneer neurons and their mother cells express the Engrailed protein, proving their deutocerebral origin. Photomicrograph at 30% of embryogenesis reveals that neuroblast 12 of the deutocerebrum is Engrailed immunoreactive, as are all its progeny (white stars). Neighboring neuroblasts 10, 11 of the DC along with their progeny are also Engrailed immunoreactive. Axogenesis has not yet commenced in these lineages. AL, antennal lobe; An, antenna; coc, circumesophageal connective; nec, neuroepithelial cells. Scale bar (in a): 12 μm (a); 15 μm (b); 8 μm (c); 70 μm (d); 10 μm (e); 50 μm (f); 70 μm (g); 20 μm in (h, i). Reproduced from Boyan, G. S., Reichert, H., and Hirth, F. 2003. Commissure formation in the embryonic insect brain. *Arthropod Struct. Dev.* 32, 61–77, with permission from Elsevier.

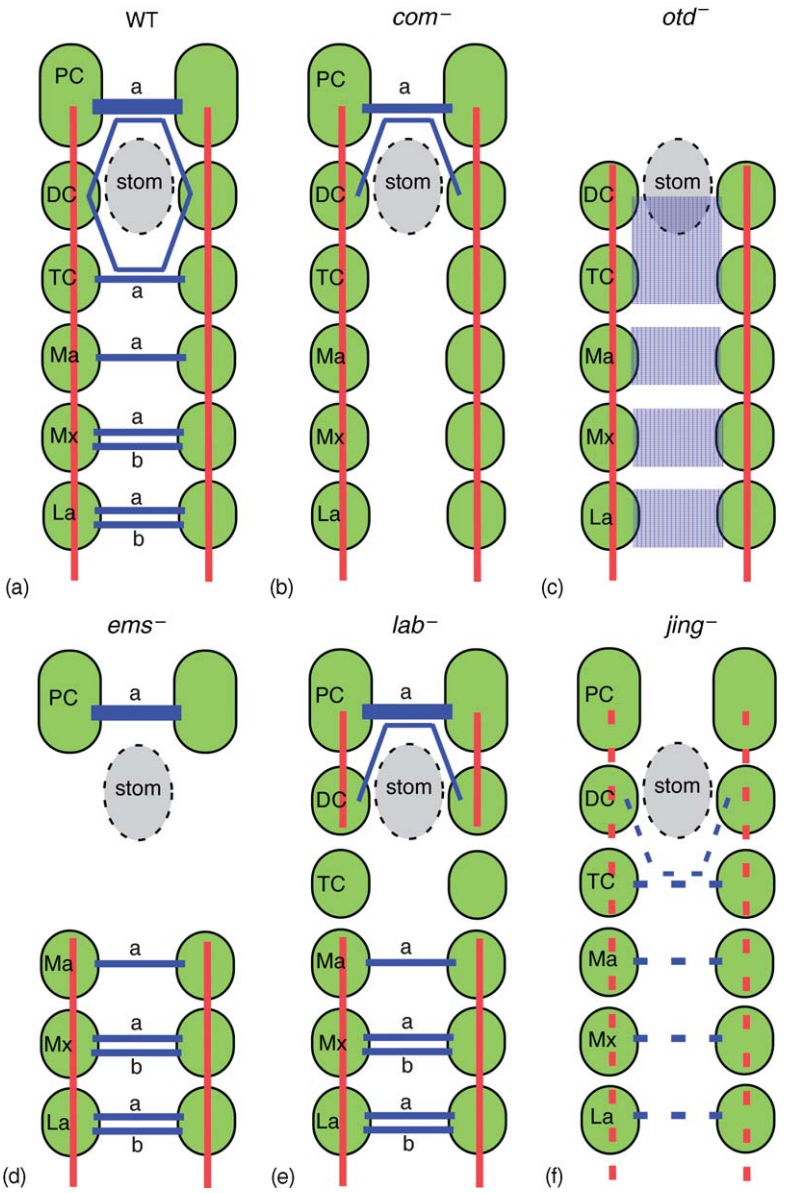

Figure 3 Summary diagrams illustrating the *Drosophila* primary axon scaffold of the embryonic wild type and *com, otd, ems, lab,* and *jing* mutant brains. Commissures are blue; longitudinal fiber tracts are red; neuromeres are green. a, In the wild-type (WT) nervous system, anterior head neuromeres PC, TC, and Ma possess a single a-type commissure, while posterior Mx and La head neuromeres possess two commissures like those neuromeres of the VNC (a-type, b-type). The commissural fibers of the DC utilize the preoral PCC and the postoral TCC to cross the midline. The stomodeum therefore bisects the brain within the DC itself. b, In the *commissureless* (*com*) mutant, all commissures of the VNC are missing, but the PCC survives in reduced form, as does the preoral contribution from the DC. c, In the *orthodenticle* (*otd*) mutant, the entire PC, including the PCC, is missing. Remaining neuromeres are fused along the midline and discrete commissures cannot be discerned (blue hatching). d, In the *empty spiracles* (*ems*) mutant, the DC and TC including the TCC are missing, leading to a gap between the PC and the postoral CNS. The commissural organization in the remaining neuromeres is intact. e, In the *labial* (*lab*) mutant, the tritocerebral commissure, commissural fibers of the DC normally utilizing the TCC, as well as tritocerebral longitudinal connectives, are missing. f, In the *jing* mutant, the protocerebral commissure is missing as well as commissural fibers of the DC utilizing the preoral PCC. Remaining commissures are partially present but malformed (dashes), as are the longitudinal fiber tracts.

cones from each bilateral homologue subsequently meet at the midline of the CNS. Lineage analysis confirms these cells as deriving from deutocerebral neuroblast 12 at the posterior border of the antennal lobe (Figure 2h). This neuroblast is one of three prominent Engrailed-expressing neuroblasts making up the posterior compartment of the grasshopper DC (Figure 2i); its progeny, including the TCC pioneers, are also Engrailed immunoreactive at this stage.

The data thus far show that deutocerebral fibers pioneer commissural fascicles of the preoral (PCC) and postoral (TCC) brain, implying that the stomodeum lies topologically within the deutocerebral neuromere itself. These findings are supported by analyses carried out in *Drosophila* mutants. Thus, mutational inactivation of the *empty spiracles* (*ems*) gene affects the formation of the DC and TC. In *ems* mutants no gross morphological defects are observed in the protocerebral neuromere, and the PCC itself is preserved (Figure 3d), but the TCC does not form and the longitudinal connectives between brain and VNC are interrupted (i.e., not continuous) (Hirth *et al.*, 1995). Mutations in homeobox genes such as *extradenticle* (*exd*) and *homothorax* (*hth*), also strongly perturb the formation of the primary axon scaffold of the brain (Nagao *et al.*, 2000). In *exd* null mutants the formation of the PCC is normal, but delayed, and subsequently shifted (topologically) posteriorly according to neuraxis. While the PCC still forms in the *exd* mutant, the TCC is missing (Nagao *et al.*, 2000). The absence of the TCC in *exd* mutants may be attributed to the fact that *exd* appears to be involved in the regulation of *labial (lab)*, which itself is required for the formation of the TCC (Figure 3e; Hirth *et al.*, 2001; Boyan *et al.*, 2003). *labial* belongs to the Hox gene family of transcription factors whose spatial and temporal expression domains show striking similarities along the anteroposterior axis of the CNS in flies and mice (Hirth and Reichert, 1999; Reichert and Simeone, 1999). Expression of the *labial* gene is restricted to the developing TC and functional analyses have shown that the Lab protein is required for the specification of segmental neuronal identity during embryonic brain development in *Drosophila* (Hirth *et al.*, 1998, 2001). Thus, in *labial* null mutants, tritocerebral cells are generated and positioned correctly, however these cells fail to express neuronal markers and marked axogenesis defects occur leading to the absence of the commissure (TCC) and connectives in this neuromere (Hirth *et al.*, 1998). Indeed, *lab*::Gal4 driven UAS::*taulacZ* reporter gene expression which mimics normal Labial expression in wild type and *lab* null mutant *Drosophila* embryos (Figure 4a), demonstrates that the *labial* gene is essential for the formation of the TCC (Hirth *et al.*, 2001).

Interestingly, in addition to the expression in the endogenous labial domain, ectopic *lab*::Gal4 driven UAS::*taulacZ* reporter gene expression can also be seen in putative deutocerebral cells which direct axons posteriorly into the TCC. These molecularly ectopic deutocerebral cells occupy an equivalent location to the identified deutocerebral pioneers of the TCC in the grasshopper (Figure 2g), and provide additional evidence that the foregut bisects the brain within the DC itself. Neuron specific anti-HRP immunolabelling reveals that the TCC is missing in the *lab* loss-of-function mutant embryonic brain (Figures 3e and 4b), suggesting that the Labial protein is essential for the formation of the TCC. This is further supported by the fact that the TCC can be rescued by transgenic expression of the Lab protein in a *lab* null mutant ($lab^{-/-}$) background (Hirth *et al.*, 2001). Moreover, *lablacZ* reporter gene expression together with anti-β-tubulin immunoreactivity reveals that commissural fibers in the TCC originate from two sources: (1) from the labial domain in the TC, and (2) from ectopic neurons of the labial domain located in the DC (Figure 4c). The axon projections from these putative deutocerebral neurons bear a striking similarity to those of the Fasciclin I expressing pioneers of the TCC in the grasshopper (cf. Figure 2g). These cells are missing in the *lab* null mutant (Figure 4d), as is the TCC (Figure 3e). UAS::*taulacZ* reporter gene expression in combination with anti-β-Gal and anti-Fasciclin II immunolabelling in the *lab* null mutant showed that these pioneers require the Labial protein in order to cross the midline and form the TCC (Hirth *et al.*, 2001). Thus, in addition to the data obtained from otd^{-} and com^{-} mutant analyses, the *exd* and *lab* mutant phenotypes provide further genetic evidence for distinct molecular mechanisms underlying PCC and TCC formation, respectively.

Does the TCC, then, develop like other postoral commissures of the suboesophageal ganglion and the VNC? Recently, it has been shown that genes of the Hox group such as *Dfd*, *Antp*, and *Ubx* whose expression domains are restricted to neuromeres posterior to the TC, are capable of rescuing the TCC in the *lab* null mutant (Hirth *et al.*, 2001 and reviewed in Boyan *et al.*, 2003). Only the most posteriorly expressed *Abd-B* could not rescue the TCC. Nevertheless, there appears to be a molecular distinction between postoral commissures within the head such as TCC and MaC and the commissures of the VNC. The distinction lies in the fact that only in the tritocerebral (via *labial*) and mandibular (via *Deformed*) cephalic neuromeres is commissure formation itself regulated by Hox genes. The TCC and the MaC are in this respect molecularly more akin to one another than they are to the more posteriorly situated commissures of the VNC. An interesting study in this regard proposes that the TCC and MaC, which are ultimately unitary in their respective neuromeres in the grasshopper and in *Drosophila* (Figures 1d and 1e) actually derive from a single

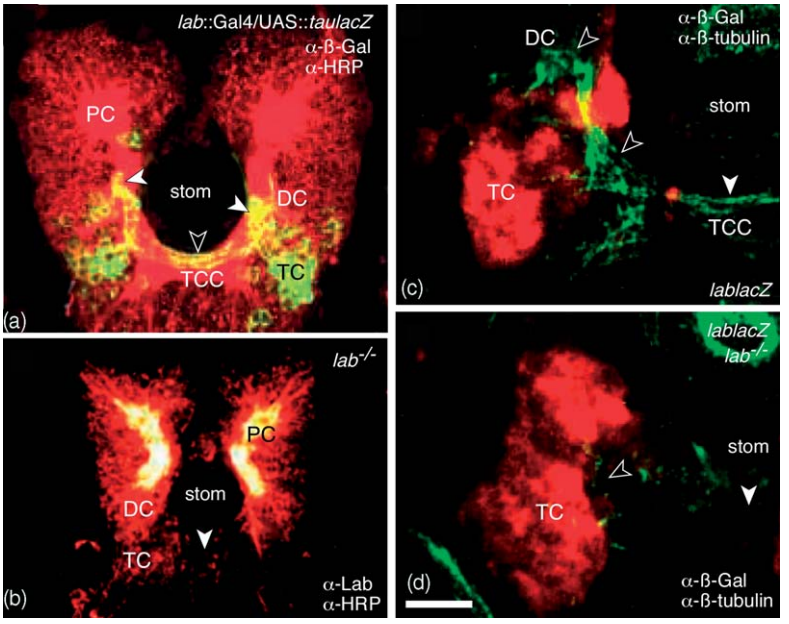

Figure 4 Genetic regulation of tritocerebral commissure (TCC) formation in the embryonic *Drosophila* brain. Reporter gene expression reveals dependence on the Lab protein for the formation of commissural axons in the TCC. a, Laser confocal reconstruction of a stage-15 embryo in frontal view reveals P{w$^+$ *lab*::Gal4}K5J2- driven UAS::*taulacZ* reporter gene expression in the wild-type brain. Double immunolabeling with anti-HRP (red) and anti-β-Gal (green). Co-expression is yellow. UAS::*tauLacZ* reporter gene expression is seen in axons of cells from the TC (the endogenous tritocerebral Lab expression domain) which project into the TCC, as well as ectopic reporter gene expression in deutocerebral cells (white arrowheads) which direct axons (open arrowhead) into the TCC. b, Laser confocal microscopy of stage-15 *lab* loss-of-function mutant embryonic brain following anti-HRP immunolabeling. White arrowhead indicates missing tritocerebral commissure. c, Laser confocal reconstruction of a stage-14 wild-type brain with a *lab-lacZ* reporter construct following double labeling with anti-β-Gal (red) and anti-β-tubulin (yellow/green). Commissural fibers (white arrowhead) in the TCC originate from the labial domain in the TC, and from β-tubulin-expressing neurons of the DC (open arrowheads). d, Laser confocal reconstruction from a stage 14 of a *lab* mutant brain with *lab-lacZ* reporter construct. The TCC (white arrowhead indicates normal location) is absent, as are the axon projections from deutocerebral cells (open white arrowhead; cf. (d)). Scale bar (in d): 10 μm (a, b); 4 μm (c); 5 μm (d). Modified from Hirth, F., Loop, T., Egger, B., Miller, D. F. B., Kaufman, T. C., and Reichert, H. 2001. Functional equivalence of Hox gene products in the specification of the tritocerebrum during embryonic brain development of *Drosophila*. *Development* 128, 4781–4788; Boyan, G. S., Reichert, H., and Hirth, F. 2003. Commissure formation in the embryonic insect brain. *Arthropod Struct. Dev.* 32, 61–77.

commissure that subsequently splits into an anterior a-type and a posterior b-type fascicle (Page, 2004). According to this hypothesis, the TCC can be considered as equivalent to an a-type commissure, and the MaC as equivalent to a b-type commissure, of a given VNC neuromere. The splitting of the commissure is proposed to be a function of Repo-expressing glia cells which appear between the diverging axon fascicles. However, the proposed role of these glial cells in *Drosophila* awaits further confirmation, for example by examining TCC and MaC formation in embryos mutant for glial cell formation like the *glial cells missing* (Hosoya *et al.*, 1995) or *repo* (Halter *et al.*, 1995) mutants. In the grasshopper, no evidence for a splitting of a common commissure in the formation of the TCC and MaC is seen. Nevertheless, both our data (Figures 1f–1h) and those of Page (2004) suggest that the TCC at least develops like an a-type commissure of the VNC.

1.22.3 The Split Deutocerebrum: Evidence from Identified Neurons of the Adult Brain

Several lines of evidence suggest that deutocerebral neurons project commissural axons along pre- and postoral routes to cross the embryonic brain midline (Figure 3a). These are supported by histological data and cobalt backfills from the circumoesophageal connectives in the adult grasshopper brain (Figures 5a–5f) which show populations of identified deutocerebral cells, some with axons in preoral, others with axons in postoral, commissures. The bilateral ventral giant 3 (VG3) cells of the posterior deutocerebral midline direct axons into commissure pcXXI of the preoral adult brain (Figures 5b, 5e, and see Boyan *et al.*, 1993, for an atlas of brain commissures). Each neuron projects an axon into the respective contralateral

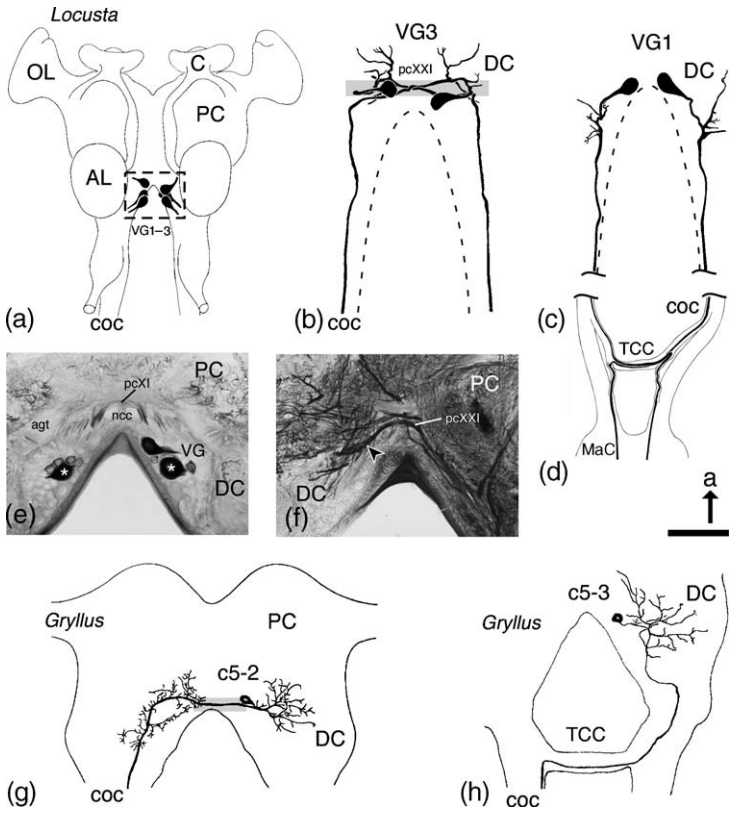

Figure 5 Commissural interneurons of the deutocerebrum in the adult brain of the grasshopper, *Schistocerca gregaria* (a–e), and cricket, *Gryllus bimaculatus* (f and g). a, Semi-schematic drawing (not to scale) showing the ventral cluster of cell bodies (VG1–3) at the posterior midline of the deutocerebrum in the adult locust. Dashed rectangle indicates the cell body group investigated in (b–e). b, Drawing from sections following Wigglesworth histology shows the bilaterally paired VG3 interneurons of the deutocerebrum with crossing segments in posterior commissure XXI (pcXXI), and axons descending contralaterally via the circumoesophageal connectives (coc) to the ventral nerve cord. Note that pcXXI is located preorally in the brain. Dashed outline indicates 'crotch' of the brain as in (a). c, Drawing from sections following Wigglesworth histology shows the bilaterally paired VG1 interneurons of the deutocerebrum with axons descending ipsilaterally into the circumoesophageal connectives, but (d) then crossing the midline postorally via the tritocerebral commissure (TCC) of the TC. e, Photomicrograph from section following cobalt backfilling from a circumoesophageal connective shows cell bodies of the VG cell cluster in the deutocerebral brain midline of the locust. White asterisks label the bilaterally paired VG1 cell bodies. One of the commissures (pcXI) containing axons of deutocerebral origin is indicated. agt, antennal glomerular tract; ncc, nerve roots of the corpora cardiaca. f, Photomicrograph (as in (e)) shows axons (black arrowhead) of deutocerebral origin crossing the brain midline preorally in pcXXI. g, Drawing of identified contralateral descending interneuron c5-2 in the brain of the cricket, *G. bimaculatus*, following retrograde labeling via the cervical connective (see Staudacher, 1998 for details). This neuron has its cell body in the equivalent ventral cluster to that described for the locust above, and the crossing segment is probably also in a preoral posterior commissure (shaded gray). h, As for (g) but of ipsilateral descender c5-3. This neuron is equivalent to VG1 in the locust (see (c)) and crosses the midline postorally via the TCC. Anterior is to the top in all figures. Scale bar: 100 μm (b–e); 270 μm (f, g). a–f, Modified from Williams, J. L. D. 1975. Anatomical studies of the insect central nervous system: A ground-plan of the midbrain and an introduction to the central complex in the locust, *Schistocerca gregaria* (Orthoptera). *J. Zool.* (*Lond.*) 176, 67–86. g and h, Reproduced from *Cell Tissue Res.*, vol. 294, 1998, pp.187–202, Distribution and morphology of descending brain neurons in the cricket *Gryllus bimaculatus*, Staudacher, E. With kind permission of Springer Science and Business Media.

circumoesophageal connective and then into the VNC. The VG1 cells of the same deutocerebral cluster (Figures 5a, 5c, and 5d), by contrast, first project axons ipsilaterally into the circumoesophageal connectives, and these axons then cross the midline postorally in the commissure of the tritocerebral neuromere (Figure 5c).

These data are supported by studies undertaken in other insects. In the cricket, for example, an identified interneuron of the deutocerebral neuromere projects a commissural process preorally across the brain midline (Figure 5f), while another interneuron projects an axon contralaterally via the postoral TCC (Figure 5g). These neurons may well be homologues of those described in the grasshopper (Figures 5b and 5c; see Staudacher, 1998). Consistent with these findings, Strausfeld (1976) describes deutocerebral B interneurons and CentP

neurons in Diptera which project dendrites into antennal glomeruli via a preoral commissure.

1.22.4 Conclusions

1. The commissures of the insect CNS are organized as an iterative array as far anteriorly as the maxillary (Mx) neuromere of the head. In more anterior neuromeres (mandibular, tritocerebral, deurocerebral, and protocerebral), the typical pattern of anterior and posterior commissures breaks down: PC, TC, and mandible possess only single commissures (Figure 1) which might represent the anterior or a-type commissure of a typical neuromere in the VNC (Figure 3a).
2. In the grasshopper embryo, pioneers from the DC project growth cones anteriorly where they cross in a preoral posterior fascicle XX (Figure 2d). Other deutocerebral pioneers project growth cones posteriorly where they fasciculate with tritocerebral ascending axons before pioneering a fascicle of the TCC (Figures 2g and 4c). In the adult (Figure 5), some identified deutocerebral interneurons in grasshopper, cricket, and fly contribute to preoral (e.g., grasshopper pcXXI), others postoral (TCC), commissures. The foregut therefore bisects the brain topologically within the DC itself and not, as traditionally thought, between DC and TC (Figure 3a).
3. Genetic experiments in *Drosophila* provide further evidence for a molecular distinction between the commissures in the head and VNC (Figures 3b–3f). In *otd* (Figure 3c) and *jing* (Figure 3f) mutants the PCC is missing, as are axons from deutocerebral neurons which normally contribute to the preoral brain commissure. Pre- and postoral deutocerebral axons are also missing in the *ems* mutant which specifically affects the formation of the DC and the TC (Figure 3d). In *lab* and *exd* mutants the TCC is absent (Figures 3e and 4b) due to missing tritocerebral, and postoral deutocerebral, commissural axons (Figures 4c and 4d). In *com* mutants, only part of the PCC and preoral fibers from the DC survive (Figures 2c and 3b). The *com*, *otd*, *jing*, *lab*, and *exd* mutant phenotypes suggest that distinct molecular genetic mechanisms underlie commissure formation in the anterior insect brain as opposed to the VNC.

1.23 Evolution of Color Vision and Visual Pigments in Invertebrates

T W Cronin, University of Maryland, Baltimore, MD, USA

Glossary

color vision	The ability to discriminate among stimuli on the basis of hue, independently of brightness or any other cue.
microspectrophotometry	Measuring absorption spectra of very small objects, typically of single photoreceptor cells. The technique is useful for finding the spectra of visual pigments *in situ*.
opsin	The protein on which all visual pigments are based.
trichromatic	Based on three spectrally different photoreceptor classes.
visual pigment	The molecules used in all animals that absorb light and begin the process of seeing.

1.23.1 Introduction

1.23.1.1 Visual Pigments: Definition and Properties

Vision in all animals is based on the same set of molecules, light-absorbing compounds called visual pigments. These pigments capture incoming photons of light, transducing light's energy into the biochemical language of cells and thereby beginning the process of seeing. Although visual pigments are homologous across all animals, even occurring in some plants, their diversity among invertebrates is bewildering and leads in many cases to visual capabilities and systems of color vision quite unlike those of humans.

All visual pigments are built by combining a protein, opsin, with one of four different chromophores, each an aldehyde of a molecule in the vitamin A family. Opsins vary greatly in their amino acid sequences, and this, together with the potential to bind different chromophores, produces an enormous range of different visual pigment types. The primary influence that visual pigments have on visual sensitivity and color vision is via the spectral region in which each pigment absorbs light. The shapes of the spectral absorption curves of all visual pigments are similar, so it is possible to characterize each pigment by specifying the wavelength at which it absorbs light most effectively. Spectral properties of visual pigments are measured either in solution, using classical spectrophotometric techniques, or in individual photoreceptor cells using microspectrophotometry. Figure 1 shows an example of the absorption spectrum of a visual pigment within an invertebrate photoreceptor, illustrating both typical data and the fit of these data to an idealized visual pigment spectral template. As with all visual pigments, this spectrum has a smooth, nearly symmetrical peak dropping to complete transparency on the long-wavelength limb and to a shoulder on the short-wavelength side.

1.23.1.2 Color Vision: Definition and Properties

Color vision is the ability to discriminate among stimuli on the basis of hue, independently of

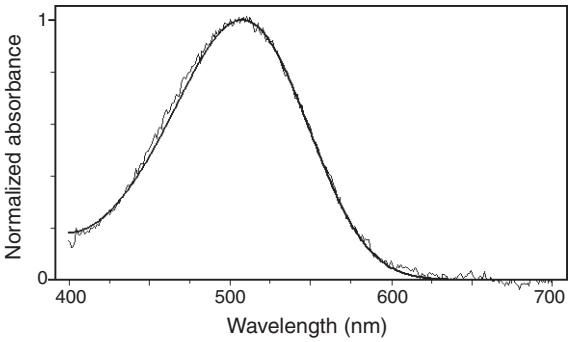

Figure 1 The major visual pigment in photoreceptors of the hermit crab, *Petrochirus diogenes*. The jagged, thin curve is the original data, collected using microspectrophotometry, and the smooth, dark curve is the ideal visual pigment template curve that best fits the data. The best-fit curve peaks at 508 nm, drops to near transparency by ~625 nm on the long-wavelength limb, and decreases more gradually at shorter wavelengths.

brightness or any other cue. To do this, at least two receptor classes differing in their spectral sensitivities must contribute to vision in an animal. By sampling two separate spectral regions, and with the assistance of appropriate neural processing, a visual system can extract spectral (i.e., color) differences from stimuli. The great benefit of color vision is that it adds both visibility and perceptual uniqueness to visualized objects, making it easier both to discriminate them (i.e., distinguish them from surrounding objects or backgrounds) and to identify them (i.e., know what they are, based on their color). Color vision is important for orientation and navigation, for identifying conspecifics, for detecting predators and/or prey, and for recognizing visual signals produced by other organisms.

The simplest, and by far the most common, technique for producing multiple spectral classes of receptors is to use different visual pigments in independent receptor types. Thus, like humans – whose color vision is based on sets of red-, green-, and blue-sensitive cones, each with a different visual pigment – most species of invertebrates have color-vision systems founded on two or more visual pigments with different absorption maxima (see The Comparative Biology of Photopigments and Color Vision in Primates).

1.23.1.3 Establishing the Presence of Color Vision in a Species

1.23.1.3.1 Genetic and physiological approaches It is rarely easy to know whether or not a given animal species possesses color vision. Typically, one first determines the number of receptor classes that are present in the retina. Often a screen of the genome provides a first estimate of the number of visual pigment genes, but this is often misleading for estimating the diversity of potential color receptors for several reasons. Different visual pigments may be devoted to different visual tasks (e.g., in receptors specialized for use in bright or dim light). Also, not all opsin genes may be expressed, or they may be expressed at different life stages. To avoid some of these problems, retinal mRNAs encoding for opsins can be analyzed, but this still does not discriminate color from non-color receptor classes. At higher levels of inquiry, receptor types can be classified by their structure or by their physiological properties (e.g., using single-cell recording techniques), or they can be characterized using microspectrophotometry.

1.23.1.3.2 Behavioral approaches All these molecular biological or physiological approaches assess only the potential of the visual system, not its actual performance. Different receptors may operate in different light regimes (analogously to vertebrate rods and cones), or they may exist in different regions of the eye and provide no input to a color-vision system. They could also contribute to what are known as 'wavelength-specific behaviors', wherein different spectral receptor classes mediate different behaviors, but there is no recognition of color as such. For example, water fleas (*Daphnia*) swim differently depending on the predominant wavelength of light in the environment, producing color-specific 'dances' that rely on the excitation of particular receptor types but do not apparently involve hue discrimination by comparing receptor inputs (Smith and Baylor, 1953). Therefore, the presence of color vision in a given species must ultimately be established by using behavioral tests, challenging an animal to learn to associate a given color with a reward. This approach has been used successfully with a number of invertebrate species, often revealing surprisingly sophisticated capacities (see Cognition in Invertebrates). Unfortunately, the failure to train an animal to color cues can never disprove that it has color vision, but if the species has only a single visual pigment class, it is generally safe to infer its absence.

1.23.2 Survey of Visual Pigment Type and Color Vision in Invertebrates

1.23.2.1 General Principles

With the existence of millions of invertebrate species, it is impossible to generalize or to cover all possible invertebrate visual systems. More importantly, there are almost certainly visual systems with extremely odd or unique properties that have not even been discovered yet. However, since at this point all known visual pigments are homologous and have similar absorption properties, little needs to be said about their diversity other than that it

exists. Spectral differences among species are evidenced primarily as shifts in the wavelength of maximum absorption, although secondary effects produced by the identity of the chromophore that is bound to the opsin also play a role in the shape and position of the absorption spectrum. Visual pigments also vary among species and across phyla in their interactions with the biochemical machinery of the receptor cell, but these properties are not thought to affect color vision.

1.23.2.2 Invertebrates other than Arthropods

The simplest metazoans, hydras, have at least one opsin-based visual pigment (Musio *et al.*, 2001), but, lacking eyes, they do not 'see' and thus could not possibly have color vision (though color-specific behavior remains possible). It is an unfortunate fact that, with the exception of the arthropods and cephalopod mollusks, little is known about the visual systems of most invertebrate phyla other than the basics of eye structure. Color vision has arisen repeatedly in well-studied phyla, so it probably exists widely throughout the invertebrates. Molecular techniques, combined with physiological and behavioral approaches, will hopefully be employed to address some of the gaps in our knowledge of the huge diversity of animals that remain virtual mysteries (see Gene Expression in the Honeybee Mushroom Body and Its Gene Orthologues).

Cephalopod mollusks (octopus, cuttlefish, and squid) have large and well-developed eyes and sophisticated visual behavior, making them major invertebrate model systems in vision science. Opsin genes of several species have been sequenced and visual pigments have been spectrally characterized. Unexpectedly, cephalopods in general are color-blind, having vision based on a single visual pigment class (see Figure 2, *Sepia officinalis* – the common cuttlefish). There is indirect evidence that one nocturnal, deep-sea species, the Japanese firefly squid *Watasenia scintillans*, has multiple visual pigments and receptor types (Seidou *et al.*, 1990), but this is a difficult species to study behaviorally; having color vision certainly could be useful to such a species for recognizing bioluminescent signals in the dark of the sea. In general, though, cephalopods may be the only animals with highly complex eyes that have bypassed color vision, probably in favor of other systems of visual analysis.

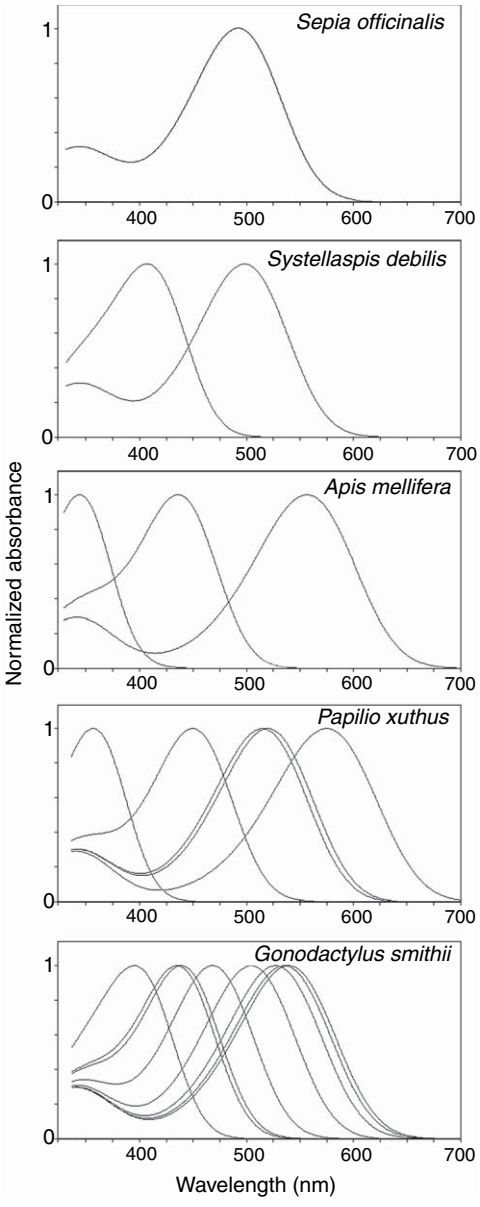

Figure 2 Spectra of visual pigments in representative color-vision systems of a variety of invertebrates, mostly arthropods. The top panel shows the single-receptor system of the cuttlefish, *Sepia officinalis*, with one visual pigment peaking at 492 nm. Next is the visual system of a deep-sea shrimp, *Systellaspis debilis*, with two pigment classes, peaking at 410 and 498 nm. The center panel illustrates the trichromatic system of the honeybee (pigments at 344, 436, and 556 nm). Complex color vision in the Japanese swallowtail butterfly, *Papilio xuthus*, is illustrated in the fourth panel (pigment peaks at 360, 450, 515, 520, and 575 nm). The bottom panel shows the eight-receptor color system of the mantis shrimp, *Gonodactylus smithii* (pigments at 400, 424, 454, 474, 496, 521, 541, and 546 nm).

1.23.2.3 Arthropods

By far the greatest diversity of visual pigment classes exists in arthropods. Their pigments peak at wavelengths from deep in the ultraviolet (<340 nm) to well into the red (600 nm or longer), and the visual pigments of some species (e.g., the horseshoe crab *Limulus polyphemus* and the crayfish *Procambarus clarkii*) have historical significance for understanding visual pigment function. More impressively, arthropods have the greatest diversity in systems of color vision among animals. The insects and

crustaceans in particular have taken color vision to its most complex forms yet described, with at least eight primary color classes present in some species. The honeybee, *Apis mellifera*, has served as a major model system for studying the principles of color vision, and in fact bees have the best-known system next to that of humans.

Examples of arthropod sets of visual pigments that contribute to color-vision systems are illustrated in the lower four panels of Figure 2. The simplest possible system includes two receptor types, each with its own pigment; this is exemplified in the deep-sea shrimp *Systellaspis debilis* (Cronin and Frank, 1996). It is present in many common crustaceans, including most crabs, lobsters, and shrimps. The central panel illustrates the trichromatic (literally, 'three-color') color-vision system of the bee, with ultraviolet-, blue-, and green-sensitive receptor types. Next is the five-receptor system of a swallowtail butterfly, which differs from that of the bee primarily by adding two receptor types with visual pigments absorbing maximally near 500–520 nm (in the green). Finally, the most elaborate color systems known exist in the mantis shrimps. An example from *Gonodactylus smithii* is illustrated in the bottom panel of Figure 2, with eight classes of color receptors present peaking at wavelengths from 400 to near 560 nm. Like other mantis shrimps, this species also has five spectral classes of ultraviolet photoreceptors, which may also play roles in color vision, and other receptor classes devoted to spatial, motion, and other aspects of vision; altogether this species and its relatives have at least 16 visual pigment classes used in vision, the largest number known among animals (Cronin and Marshall, 2004).

Increasing the number of visual pigments, however, does not by itself lead automatically to improved color vision. Visual pigment spectra are broad, and packing many of these spectra into a restricted range simply leads to lots of overlap with no increased ability to discriminate colors. This is well illustrated at the bottom of Figure 2, where many spectra of pigments in the retina of a mantis shrimp are piled on top of one another. Mantis shrimps, as well as many other arthropods, deal with this complication using filters lying directly in the path of incoming light or placed alongside the receptor, that modify the light traveling inside it. All these consist of some sort of photostable pigment, often a carotenoid, that generally transmits only in a restricted spectral range. The pigment trims the spectrum of light, sharpening the sensitivity of the underlying visual pigment and improving spectral discrimination. Figure 3 shows an example of receptors containing two different visual pigments that are tuned with different filters, producing a pair of receptor classes with very narrow spectral sensitivities. This tactic for improving color vision is seen in butterflies, fireflies, click beetles, crabs, locusts, and no doubt many other insects and crustaceans.

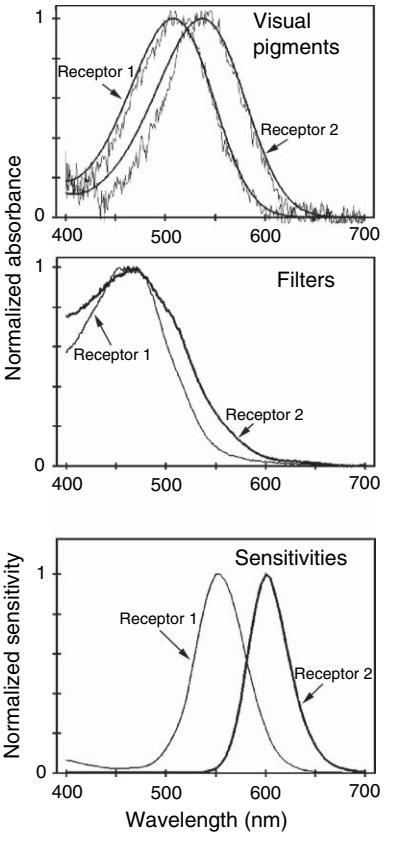

Figure 3 The use of filter pigments to sharpen spectral sensitivities, here showing an example from the mantis shrimp *Haptosquilla trispinosa*. In the illustrated receptor pair, visual pigments (the thin, jagged lines show original data, while the thick, smooth lines are idealized visual pigment spectra) in two receptors, peaking at 508 nm ('receptor 1') and 537 nm ('receptor 2'), are tuned by overlying filter pigments with absorption spectra illustrated in the center panel. The filters absorb short-wavelength light, producing a pair of receptors with spectral sensitivities that are much narrower and shifted to long wavelengths. The presence of these and other filters allows many similar visual pigments (as in the lower panel of Figure 2) to produce a series of separately tuned photoreceptors, providing multidimensional color vision. Many invertebrates use similar filters to tune photoreceptor sensitivities.

1.23.3 Theories of Evolution of Visual Pigments and Color Vision

1.23.3.1 Visual Pigment Tuning: Sensitivity and Contrast Hypotheses

Spectral properties of visual pigments are sensitive to the presence of specific amino acids at critical locations in the opsin molecule; consequently, evolutionary alterations can produce highly diverse sets

of pigments. How visual pigments are optimally tuned has long been of interest to vision scientists. To be effective, the visual system should allow important objects to stand out against their backgrounds, and two hypotheses have been advanced to predict how this might be done. The 'sensitivity hypothesis' predicts that visual pigments should be tuned to match the light present in an animal's environment, thereby providing the greatest possible response to any illumination. The 'contrast hypothesis' predicts that vision should be tuned to maximize the stimulation difference between object and background. The hypotheses are related, in that in many dim-light environments, the only difference between foreground and background is in their brightness, favoring sensitivity. Nevertheless, in colorful environments, it is not always obvious how contrast should be optimized, especially for a color-vision system. Thus, while these hypotheses can predict the spectral properties of visual pigments that evolve in animals with a single photoreceptor class, they are not very useful for explaining how color vision evolves.

1.23.3.2 Visual Ecology and Natural Scenes

A second approach to understanding the evolution of color vision is to model how visual systems should adapt to the scenes that animals view. Each species uses its eyes in a limited selection of all possible visual environments, whether in forests, meadows, lakes, coral reefs, the deep ocean, or wherever it is found; thus, its visual system should be adapted for optimal function in the scenes it is most likely to view. This approach requires careful documentation of environmental illuminants and colors (spectral reflectances) and heavy mathematical treatment of how these interact with each other and with a selection of visual systems. Nevertheless, it has been very successful for predicting how simple color-vision systems, based on two or three color receptor classes, can be optimized.

1.23.3.3 Role of Color Vision in Object Identification, Feeding, and Signal Detection

Animals use their visual systems both for general tasks like orientation and object avoidance and for species-specific needs like food finding, predator detection, and signal interpretation. Thus, while there could be overall environmental control (via lighting, natural scenes) of the evolution of visual pigments and color vision, there must also be special evolutionary significance for specific tasks directly related to survival, like seeing food and early recognition of the presence of a predator (see Evolutionary Neuroethology – A Case Study: Origins and Evolution of Novel Forms of Locomotion in Hippid Sand Crabs (Malacostraca, Decapoda, Anomala). Furthermore, there must be co-evolution of signals and visual systems, so that signals are effective. Several studies, based on different models of visual function, have demonstrated how flower colors and honeybee color vision have co-evolved. Here, however, it appears that it is the evolution of flower colors, rather than of the receptors of the bees, that optimizes signaling. Our current understanding of visual evolution and the evolutionary tuning of color vision suggests that visual systems evolve under the influence of environments, and signals evolve under the influence of visual systems.

1.23.4 Summary and Conclusions

The invertebrates, with their enormous phyletic diversity, make it nearly impossible to generalize except to say that nearly any conceivable method of visual pigment tuning or system of seeing and analyzing color is likely to be found among them. Consequently, the greatest advantage that these animals offer to vision scientists is the chance to explore well-selected questions concerning visual evolution in a well-suited biological system. Invertebrates will continue to serve as means of answering new questions as they arise and as sources for finding unexpected evolutionary directions of visual systems.

1.24 A Tale of Two CPGs: Phylogenetically Polymorphic Networks

P S Katz and J M Newcomb, Georgia State University, Atlanta, GA, USA

Glossary

central pattern generator	An ensemble of neurons that generates a rhythmic motor pattern.
notaspid	Marine gastropod in the order Notaspidea, a sister order to the nudibranchs.
nudibranch	Marine gastropod in the order Nudibranchia, characterized by a lack of a shell.
Nudipleura	Clade consisting of Nudibranchia and Notaspidea.
opisthobranch	Marine gastropod in the subclass Opisthobranchia, characterized by a reduced shell, mantle, and gills.

1.24.1 Introduction

> It was the best of times, it was the worst of times, it was the age of wisdom. . .(Charles Dickens)

It is the best of times for understanding neural circuits from a functional perspective; much has been gained from the approach of studying specialized neural circuits in invertebrate species with large neurons and simple behaviors. With this approach, neuroscientists have had tremendous success in unraveling neural circuits and mechanisms underlying behaviors. Invertebrate circuits, and in particular opisthobranch nervous systems, have provided important insights into motor pattern generation (Getting, 1989a), and learning and memory (Pittenger and Kandel, 2003). Thanks to work on invertebrate circuits, there is now a recognition that individual neurons and the circuits that they form can be multifunctional; that is, a single anatomically defined group of neurons can be dynamically reconfigured to serve multiple functions (Harris-Warrick and Marder, 1991; Kupfermann and Weiss, 2001; Marder, 1994; Marder and Calabrese, 1996).

It is the worst of times because success in understanding neural circuits has occurred in the absence of understanding their origins. It has been noted previously that the architecture of modern neural circuits may not reflect functional optimization, but may be the result of historical circumstances (Arbas *et al.*, 1991; Dumont and Robertson, 1986). Despite the new awareness that neural circuits are multifunctional within a given animal, there is little known about how phylogenetically plastic central circuits are. Is it possible that species-specific behaviors arise from the same circuit being differentially modulated or are there species-specific neural circuits? If there are different circuits underlying different behaviors, how did they orginate?

This tale of two central pattern generators (CPGs) in two nudibranch mollusks, serves to illustrate some concepts related to the evolution of species-specific behaviors. The two species of this tale are *Tritonia diomedea* and *Melibe leonina* (Figures 1a and 1f). Both of these sea slugs swim using whole body flexions. Their nervous systems contain homologous neurons, yet they use different groups of neurons to produce their respective swimming behaviors. Comparing the behaviors and their neural mechanisms in these two species shows that distinct functional neural circuits arose through a differential partitioning of a common nervous system to produce species-specific behaviors. Further comparisons with a third species, *Pleurobranchaea californica*, suggest that analogous behaviors can be controlled by

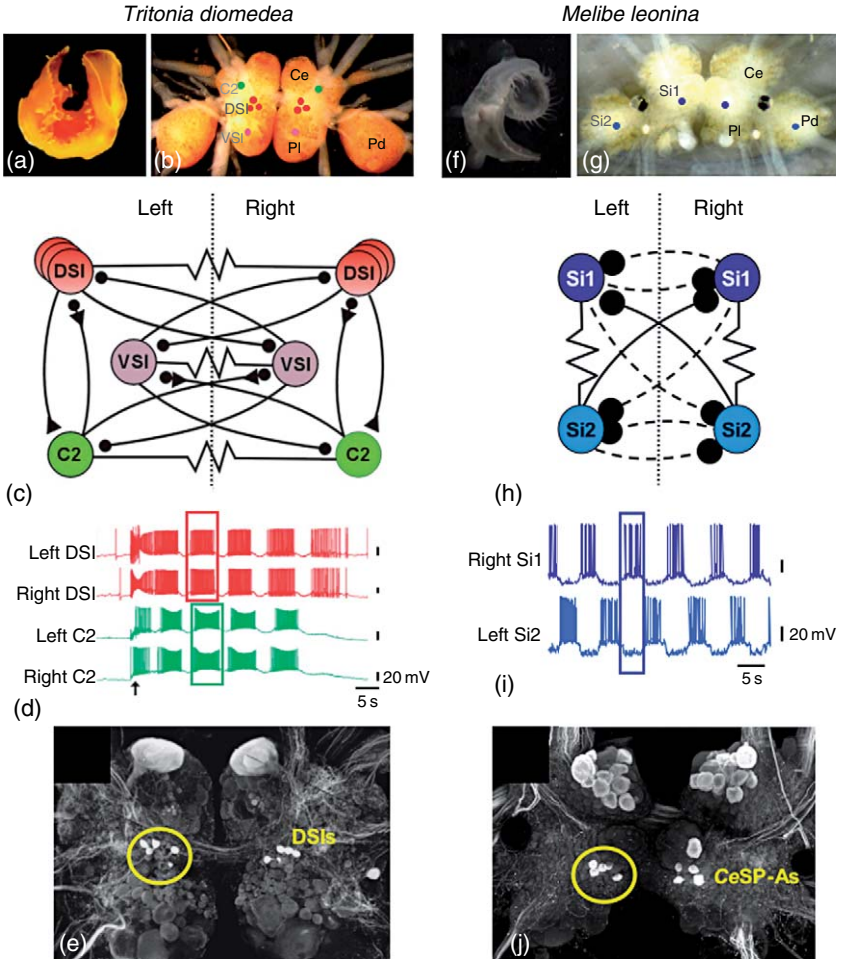

Figure 1 Comparison of the swim central pattern generators (CPGs) in two nudibranchs: *T. diomedea* (a–e) and *Melibe leonina* (f–j). a, *Tritonia* swims by flexing its body in the dorsal and ventral directions. b, A photomicrograph of a *Tritonia* brain, which consists of the cerebral (Ce), pleural (Pl), and pedal (Pd) ganglia. The locations of the three CPG neurons are indicated: cerebral neuron 2 (C2), the three dorsal swim interneurons (DSIs), and ventral swim interneuron-B (VSI). c, The synaptic connectivity of the swim CPG. Excitatory synapses are indicated as triangles, inhibitory synapses are balls, and electrical synapses are shown as resistors. All neurons are electrically coupled to their contralateral counterparts. d, Simultaneous intracellular microelectrode recordings from the left and right DSIs and C2s show that the contralateral counterparts burst in phase with each other during the swim motor pattern, which was elicited at the arrow by brief electrical stimulation of a peripheral nerve. e, Serotonin immunohistochemistry shows the locations of the three DSIs as part of a group of five serotonergic neurons in the posterior portion of the cerebral ganglion. f, *Melibe leonina* swims by flexing from side to side. g, The locations of the swim CPG neurons are superimposed on a photomicrograph of a *Melibe* brain. Swim interneuron 1 (Si1) is located in the cerebral ganglion and swim interneuron 2 (Si2) is in the pedal ganglion. h, The synaptic connectivity of the *Melibe* swim CPG shows that there is mutual inhibition of the contralateral Si2s. i, Simultaneous intracellular microelectrode recordings of the right Si1 and left Si2 show the alternation in firing between the left and right sides that is characteristic of the swim motor pattern. j, Serotonin immunohistochemistry shows the location of the cerebral serotonergic posterior (CeSP-A) neurons, which are homologous to the DSIs in *Tritonia*. a, Reproduced with permission from William Frost. f, Reproduced with permission from Win Watson.

homologous neurons, indicating that a similar partition of the common nervous system could have arisen independently. In other words, similarity in behavior may have arisen through parallel evolution.

1.24.2 The Behaviors

Although the swimming behaviors of *Tritonia* and *Melibe* are both whole body flexions, they differ in several important respects. First, *Tritonia* rarely swims; it is a benthic nudibranch that uses swimming as an escape response to contact with a predatory sea star, *Pycnopodia helianthoides* (Willows and Hoyle, 1968; Willows, 1968). In contrast, *Melibe* swims more readily than *Tritonia*; simply displacing it from the substrate is a sufficient stimulus to cause the animal to swim, although the animal will also swim in response to contact with

seastar tubefeet (Lawrence and Watson, 2002). The animals also have different postures during swimming; *Tritonia* flattens its body in the coronal plane and flexes its body rhythmically in the dorsal and ventral directions, whereas *Melibe* flattens its body in the sagittal plane and rhythmically flexes in the lateral directions (side-to-side) (Willows, 2001). There are other important differences in these swimming behaviors. *Tritonia* swims for relatively short bouts (2–10 flexion cycles, lasting up to a minute), but *Melibe* can swim for extended periods of time (many minutes). There does not appear to be any directionality to the *Tritonia* swim; the primary objective seems to be to cause the animal to rise off the bottom to allow it to be swept away by water currents. For *Melibe*, the swim has some directionality; the animal proceeds in a foot-first direction (Lawrence and Watson, 2002). Clearly, these behaviors, although analogous in being whole body flexions, are species-specific in many ways.

1.24.3 Polymorphic Neural Circuits

1.24.3.1 The *Tritonia* Swim CPG

The CPG underlying the *Tritonia* swim motor pattern represents one of the earliest success stories in research on functional neural circuits. In the mid-1960s, researchers were looking for invertebrates with large neurons that performed simple behaviors so that the neural circuits underlying those behaviors could be deciphered. During this period, Kandel *et al.* (1967) began working on the gill and siphon withdrawal circuit of *Aplysia* and Willows and Hoyle (1969) began studying the *Tritonia* swim response. Willows was the first to show that behavioral acts could be correlated with the activity of single neurons and that stimulation of single neurons could elicit behaviors (Willows and Hoyle, 1968; Willows, 1968). Over the course of several years, Willows, Peter Getting, and colleagues determined the basic components and synaptic connections of the *Tritonia* swim CPG (Taghert and Willows, 1978; Getting, 1976, 1977, 1981; Getting *et al.*, 1980) (Figure 1c). Getting created one of the earliest realistic simulations of a CPG using the components of the *Tritonia* swim circuit and demonstrated the feasibility that the known network components could produce the behavioral output (Getting, 1983, 1989b).

Later work added to the knowledge about the *Tritonia* swim CPG. The trigger and gating elements were identified (Frost and Katz, 1996; Frost *et al.*, 2001) and mechanisms of intrinsic neuromodulation were uncovered (Katz *et al.*, 1994; Katz and Frost, 1996; Sakurai and Katz, 2003). Thus, studying the functions of neurons in the *Tritonia* swim CPG as a dedicated circuit has proved to be very fruitful.

1.24.3.2 Multifunctional Neuronal Circuits

Although the early work was guided by the principle of determining the functions of neurons in dedicated circuits, the work in *Tritonia* was the first to uncover the idea that neurons could be multifunctional. The names given to the neurons that comprise the CPG and the motor system in general reflect the bias that these neurons were part of a dedicated circuit: dorsal swim interneuron (DSI) and ventral swim interneuron (VSI) (Figures 1b and 1c). Subsequently, however, it was suggested that the neurons might have roles in other behaviors such as defensive withdrawal. Thus, the concept of 'polymorphic' or multifunctional networks was originated (Getting and Dekin, 1985). It was later shown, for example, that the DSIs, which are part of the swim CPG and fire rhythmic bursts of action potentials during the swim motor pattern (Figure 1d), also play a role in accelerating crawling when the animal is not swimming (Popescu and Frost, 2002). It is now clear that neurons in other neuronal circuits also can serve many different functions and that neuronal circuits can be reconfigured to produce different behavioral variations (Lieske *et al.*, 2000; Marder and Calabrese, 1996; Meyrand *et al.*, 1994).

It has been suggested that the multifunctionality of neuronal circuits could aid the evolution of species-specific behaviors (Arbas *et al.*, 1991; Katz, 1991; Katz and Harris-Warrick, 1999; Tierney, 1995). If a single neural circuit can produce many outputs, then evolution of species-specific behaviors could arise by differential modulation of a generic circuit.

This has been hypothesized to occur in the feeding circuit of gastropods. It was suggested that homologous neurons form a circuit that is differentially modulated or controlled to produce either stereotyped biting or more variable bite patterns (Benjamin, 1983). In such a case, the same neurons would participate, but their roles would change. For example, there is a giant serotonergic cerebral cell in all gastropods that is involved in feeding, but this neuron has different roles in different species (Pentreath *et al.*, 1982; Rosen *et al.*, 1989; Yeoman *et al.*, 1994a, 1994b).

1.24.3.3 Comparing the *Melibe* and *Tritonia* Swim CPGs

Because the swimming behaviors of *Tritonia* and *Melibe* are so different, they could serve as a test of

the hypothesis that species-specific behaviors arise from the same neural network producing a different output. The architectures of the circuits reflect the fundamental difference between the swimming behaviors in the two animals. *Melibe* swims by alternately flexing from side to side, so the left and right CPG counterparts are mutually inhibitory, assuring alternation (Thompson and Watson, 2005) (Figures 1h and 1i). In *Tritonia*, the left and right sides are co-active, so each CPG neuron is electrically coupled to its contralateral counterpart (Getting, 1981) (Figures 1c and 1d).

The neurons that comprise the *Melibe* swim CPG are not homologous to the neurons in the *Tritonia* swim CPG. The *Melibe* CPG consists of two cell types: swim interneuron 1 (Si1) and swim interneuron 2 (Si2) (Thompson and Watson, 2005). Si2 is located in the pedal ganglion (Figure 1g). It interacts with its contralateral counterpart through one of the pedal–pedal connectives. Thus, if this connective is cut, the swim motor pattern is halted. In contrast, none of the *Tritonia* CPG neurons is found in the pedal ganglion (Figure 1b) and the swim motor pattern in this animal can continue with the pedal–pedal connectives cut. These observations suggest that the two behaviors, although roughly analogous because they involve whole body flexions, evolved independently and have a different neural basis. They do not share a neural circuit that is differentially modulated. Therefore, in this case, species-specific behaviors are not produced by differential modulation of a common neuronal circuit.

1.24.3.4 A Common Nervous System

Although the neurons that comprise the swim CPGs in *Tritonia* and *Melibe* are not homologous, there are homologous neurons in each nervous system. For example, homologues of the serotonergic DSIs in the *Tritonia* swim CPG have been identified in all opisthobranchs that have been examined so far, based on their soma location and serotonin immunoreactivity (Katz *et al.*, 2001) (Figure 1e). We recently identified DSI homologues in *Melibe* (Newcomb and Katz, 2003) (Figure 1j). Because *Melibe* does not swim with dorsal–ventral flexions, we could not name these neurons DSIs, so we chose an anatomical descriptor, the cerebral serotonergic posterior (CeSP-A) neurons. It is likely that homologues of all of the neurons in the *Tritonia* swim CPG will be found in *Melibe* and, conversely, Si1 and Si2 homologues will be found in *Tritonia*. These animals, by virtue of their common descent in the nudibranch lineage share a common nervous system design.

Despite the common neurons, are the nervous systems partitioned differently to produce different functional circuits? The CeSP-As resemble the DSIs in their physiological properties and synaptic connectivity; however, they are not rhythmically active during the *Melibe* swim motor pattern and are not members of the swim CPG in this animal (Newcomb and Katz, 2003). Thus, the same neurons have come to serve different functions and participate in different functional circuits.

Despite the differential partitioning of homologous neurons, there may be common functions that reflect the common heritage of these nervous systems. Although the CeSP-As are not rhythmically active during the *Melibe* swim motor pattern, spiking activity in a CeSP-As is sufficient to elicit a swim motor pattern in a quiescent preparation. Similarly, in *Tritonia*, spiking in a DSI is sufficient to elicit a swim motor pattern (Fickbohm and Katz, 2000; Katz *et al.*, 2004). Thus, the CeSP-As, although not part of the swim CPG in *Melibe*, are able to activate it, suggesting a conserved aspect of their function.

These observations suggest that different functional circuits were partitioned from a common nervous system to produce species-specific circuits that underlie species-specific swimming behaviors (Figure 2). The changes that underlie the differential partitioning could be as subtle as differences in the properties of neurons or strengths of synapses as has

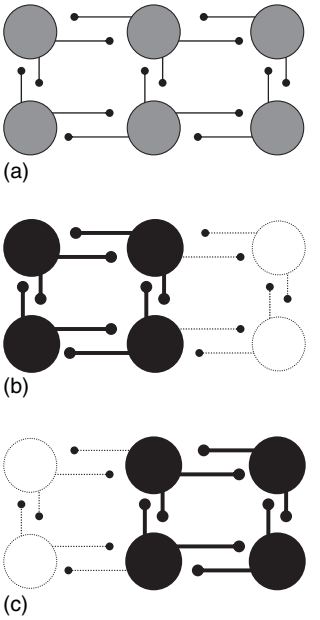

Figure 2 A polymorphic nervous system (a) can be differentially partitioned into different functional circuits (b and c) by changes in cellular and synaptic properties.

been observed in the multifunctional circuits of the crustacean stomatogastric ganglion (Combes *et al.*, 1999; Meyrand *et al.*, 1991, 1994).

1.24.4 Homoplasy and Parallel Evolution

1.24.4.1 Pleurobranchaea

Although the functional circuits for the swim CPGs in *Tritonia* and *Melibe* are different, the hypothesis that they were partitioned from a common nervous system can be tested by examining the neural basis of swimming in closely related species. This has been approached in only one animal that is closely related to the nudibranchs, *Pleurobranchaea californica* (Gillette and Jing, 2001; Jing and Gillette, 1999, 2000). *Pleurobranchaea* is in the order Notaspidea, which together with Nudibranchia, forms a monophyletic clade that has been called 'Nudipleura' (Waegele and Willan, 2000; Wollscheid-Lengeling *et al.*, 2001) (Figure 3). Like *Tritonia*, *Pleurobranchaea* swims with dorsal–ventral body flexions. The swim CPG in *Pleurobranchaea* contains homologues of the DSIs and cerebral neuron 2 (C2), as well other neurons not identified in *Tritonia*. Furthermore, the DSI homologues (called As1–3) and the C2 homologue (called A1) behave the same as they do in *Tritonia* (Jing and Gillette, 1999). Thus, the CPGs of these animals with similar behaviors are also similar.

The similarities in the behavior and the neural circuit underlying swimming in *Pleurobranchaea* and *Tritonia* led Jing and Gillette (1999) to hypothesize that dorsal–ventral (DV) swimming was the ancestral condition for nudibranchs. However, examining the rest of the nudibranch lineage reveals that DV swimming is rare and that some of the intermediary lineages lack this behavior (Figure 3). Thus, a more conservative hypothesis is that DV swimming in *Tritonia* and *Pleurobranchaea* arose independently (homoplasy).

1.24.4.2 Parallel Evolution

Homoplasy can result from convergent or parallel evolution (see The Evolution of Parallel Visual Pathways in the Brains of Primates). Convergent evolution is when nonhomologous structures come to have analogous functions. If the two behaviors arose independently, yet still share a common neural basis, then it would suggest that homologous neurons independently came to have the same functions in these animals: parallel evolution.

Parallel evolution is well recognized in genetics. For example, parallel changes in genes have been shown to play a role in the evolution of plumage patterns in birds (Mundy *et al.*, 2004) and loss of

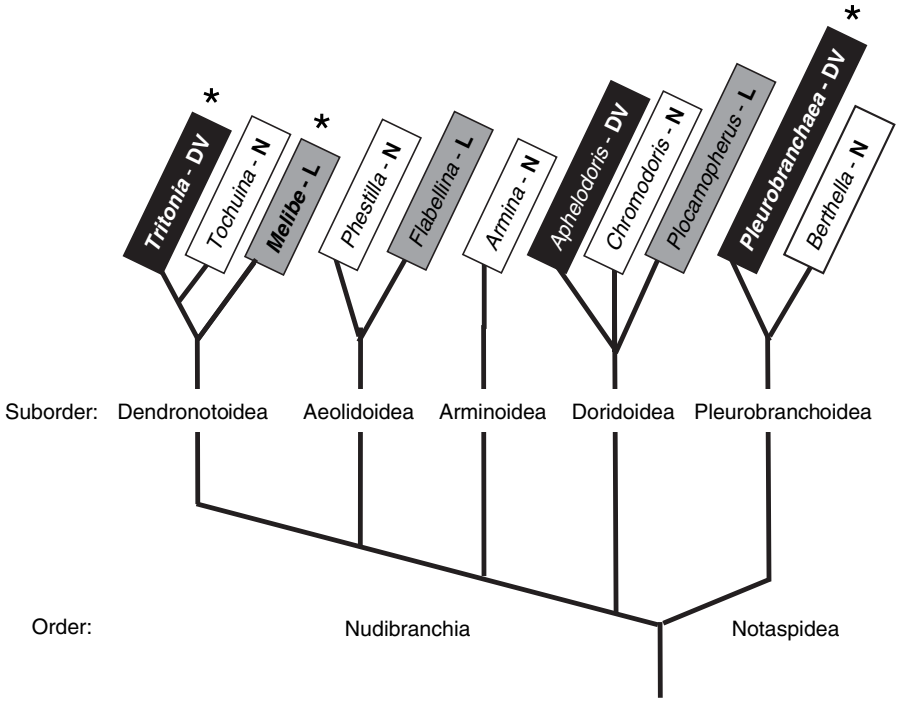

Figure 3 A dendrogram of the Nudipleura clade showing representative species with different modes of swimming. *Tritonia*, *Pleurobranchaea*, and *Aphelodoris* are dorsal–ventral (DV) swimmers. *Melibe*, *Flabellina*, and *Plocamopherus* are lateral swimmers (L). There are nonswimmers (N) in each of the lineages. The species discussed in this article are indicated by an asterisk (*).

armor in stickleback fish (Cresko *et al.*, 2004). However, there is less awareness of the potential for parallel evolution in the nervous system.

The implications of parallel evolution are very important. If the same components of the nervous system can come to serve the same function independently, it means that it is easier to evolve species-specific behaviors from phylogenetically polymorphic nervous systems than if the circuits had to be constructed *de novo* (see Primate Brain Evolution in Phylogenetic Context). There may be many stable configurations of multifunctional circuits that can be selected for, allowing an array of different species-specific behaviors to evolve from a generic network of neurons.

The importance of parallel evolution can be illustrated with the example of pair-bonding behavior in mammals. It has been shown that vole species that pair-bond have vasopressin receptors in the nucleus accumbens, whereas promiscuous vole species do not (Wang *et al.*, 1997; Young and Wang, 2004). The same pattern of receptor distribution occurs in pair-bonding species in other rodent lineages and in primate lineages (Young, 1999), suggesting independent evolution. This demonstrates that the same neural circuitry has come to have the same function in social interactions in disparate species through similar changes in receptor distribution. Thus, the evolution of pair bonding required just a small change in the promoter region of the vasopressin gene to cause species-specific behavior, yet the basic neural circuitry is shared with all mammals and is repeatedly reused for the same function in different lineages.

1.24.5 Conclusions

There is good evidence that neural circuits within an animal are multifunctional; a single circuit can produce different outputs and individual neurons can switch their functions at different times. This has led to the idea that evolution of species-specific behaviors can occur through differential modulation of a common circuit. However, examination of the *Tritonia* and *Melibe* swim CPGs shows that these circuits are not composed of homologous neurons. Thus, in this case, species-specific behaviors are performed by different sets of neurons. However, homologous neurons are present in both species. Therefore, we suggest that evolution of species-specific behaviors occurred through a differential partitioning of a polymorphic common nervous system (Figure 2). Furthermore, the neural circuits underlying swimming in *Tritonia* and *Pleurobranchaea* are remarkably similar despite the phylogenetic distance between these lineages. Rather than this being due to an incredible coincidence, it seems more likely that the same partitioning of the polymorphic network arose twice. Such parallel evolution has important implications for understanding the evolution of species-specific behaviors. To end this tale of two (or three) CPGs and to paraphrase Dickens poorly: it is a far, far better circuit that can evolve from a polymorphic network, than could arise alone.

1.25 Evolution of Visceral Control in Invertebrates

A I Selverston, University of California at San Diego, La Jolla, CA, USA

Glossary

chemosensory	Neurons that respond to chemicals.
conditional burster	A neuron that requires the presence of a neuromodulatory substance in order to produce bursting activity.
fictive pattern	The pattern recorded in *in vitro* preparation that mimics the pattern recorded in the intact animal.
immunohistochemical	A general histological technique for staining a protein by making an antibody to it and then reacting that antibody with another one made from a different host that has a fluorescent marker attached to it.
intrinsic burster	A neuron that can produce bursting–spiking activity when completely isolated from other neurons.
ligand	A chemical substance that binds and activates a postsynaptic membrane.
myogenic	The ability of muscle tissue to contract without innervation.
neurogenic	Requiring input from neurons.
neuromodulator	A chemical that binds to specialized postsynaptic receptors and activates a second messenger system.
neuropile	The central part of an invertebrate ganglion, location of synaptic connections.
neurosecretory	Release of a chemical transmitter or modulator by a neuron into the blood.
pacemaker	A neuron that fires regular periodic bursts that can entrain other nerves or muscles.
plateau potentials	Membrane potentials that are maintained at a depolarized level.
soma	The cell body of a neuron containing the nucleus.
trophic	Supplying nutrient or growth factors to a cell.
voltage-gated channel	An ionic channel in the membrane that is sensitive to the transmembrane voltage.

1.25.1 Introduction

The evolution of visceral control in invertebrates is a specially useful topic because it not only helps illuminate the evolution of nervous systems in general, but also is particularly important to the field of comparative neurophysiology. This is because the neural circuits that have evolved to control the viscera are among the most fully described neural circuits available – and therefore of great heuristic value. These circuits are different from those investigated in the vertebrate central nervous system (CNS) because they describe detailed synaptic connectivity among identified neurons. From a neurophysiological viewpoint, it is likely that the general principles underlying the function of neural

circuits in mammals will be drawn from invertebrate studies. Given the small number of neurons involved in controlling invertebrate behavior including the viscera, this may seem somewhat surprising. However, it is reasonable because the basic elements or 'building blocks' (Getting, 1989) of small circuits – voltage- and ligand-gated ionic channels, chemical and electrical synapses, neuromodulatory environment, etc. – are also present in the brains of higher animals where the principal difference is the pattern and massive increase of synaptic connectivity. The unresolved question, that applies to comparative neurological studies and that bear on the question of evolution, is how exactly does the increased numerical and synaptic complexity that occurs during evolution give rise to behavioral events that cannot be explained by a simple scaling-up of circuits found in invertebrate nervous systems? Or put another way, does the massive increase in numbers of neurons give rise to special computational processes that are fundamentally different from invertebrate computational processes?

How have the basic functional components of the circuits controlling invertebrate viscera evolved? It is commonly assumed that selection acts on behavior and that alterations in cell or circuit properties that occur by random mutation and which act to enhance behavior, will become permanently incorporated into the genome. For example, consider a small change in a single membrane conductance, say a minor shift in the activation or inactivation curve for that conductance in a particular neuron. Or perhaps the strengthening of a synaptic connection that alters a behavior in an almost imperceptible way can over time become permanent if the behavioral change confers a selective advantage. However, these changes are rather obvious and the effects of evolution on the nervous system are in fact more complicated. Dumont and Robertson (1986) have suggested four fundamental factors that are involved:

- adaptive effects that optimize behavior,
- developmental constraints,
- historical influences, and
- architecture imposed by the design of the organism.

All of these will determine what the final evolutionary outcome will be and these factors are constantly changing.

One way to study evolutionary change is to compare homologous systems (and the behaviors they produce) between species. Generally we consider the changes in behavior to be overt and measurable. However, new cell properties or connection patterns may also be covert. For example, changes may occur that increase the stability or robustness of a circuit without directly affecting behavioral performance. In addition, some alterations may lead to an increase in behavioral flexibility in response to transient or permanent sensory perturbations. Other changes may provide the necessary connectivity for multifunctionality, allowing a single circuit to generate various stable spatiotemporal patterns when exposed to different neuromodulators. This ensures that entirely *de novo* circuits need not be constructed and only new neuromodulators can be made available.

Since the evolution of ion channel proteins, neurotransmitters, gap junctions, etc., have produced common phyla-spanning functional elements. I will briefly consider the evolution of those elemental factors that are used by all regions of the nervous system including visceral components. These include neuronal structure and function, voltage and chemically sensitive ion channels, gap junctions, neuromodulators and receptors, second messenger systems, and finally muscle and neuromuscular connections. I will illustrate how these independent elements have been incorporated into functional visceral mechanisms; in particular, how different circuits have been constructed to ensure reliability and flexibility for the viscera they control. Finally, I will discuss five highly specialized visceral control systems in their present form, which exemplify the evolutionary culmination of processes that have assembled the available components into reliable circuits. These pathways and species are indicated in red in the invertebrate cladogram (Figure 1), which also gives the reader some indication of the very large number of invertebrate classes for which virtually nothing is known in terms of visceral control mechanisms.

Note that the arthropod, annelid, and molluskan groups represent very divergent evolutionary relationships that nevertheless utilize remarkably similar cellular and biochemical mechanisms. In one, the stomatogastric system of crustaceans, which has led to detailed studies on a large number of species, it is possible to compare the relationships between structural and neural analogues involved in control mechanisms in some detail.

The main visceral functions of all animals are responsible for the physiological processes that sustain life – respiration, circulation, and digestion. Processes such as the control of heart pumping and digestive processing must work reliably and constantly throughout the life of the animal. The control of the heart rhythm in the leech and lobster and the control of feeding and digestion in the marine mollusk *Aplysia*, the snail, and the lobster have been examined in great detail. All of these have visceral control systems that use fundamental feedback

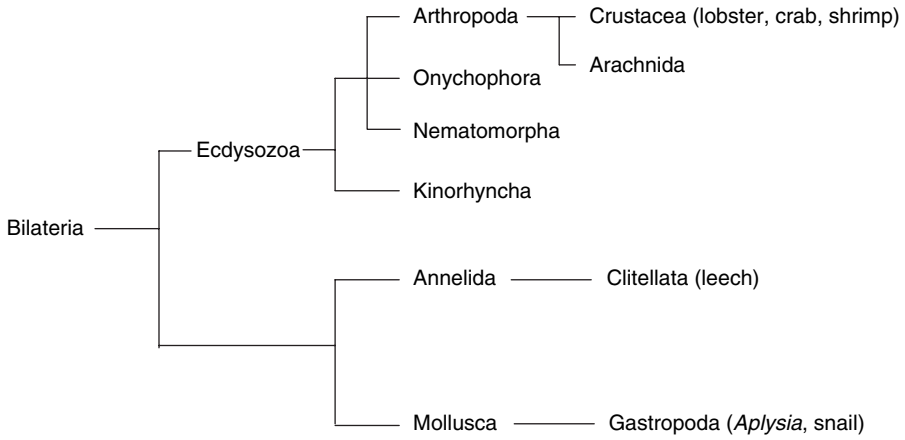

Figure 1 Summary of relationships between Bilateria summarized for the Tree of Life Web Project indicating one current scheme for tracing lineages.

principles to maintain homeostasis. Control over rhythm-generating neural networks is by local and descending inputs that integrate sensory information and issue the proper motor commands. Nervous systems involved in visceral control have to produce rhythmic patterns that are made up of similar design elements. These elements have evolved at very early stages of evolution but have been assembled much differently under a variety of selective environmental pressures (see Evolution of Color Vision and Visual Pigments in Invertebrates, Cognition in Invertebrates, Aggression in Invertebrates: The Emergence and Nature of Agonistic Behavioral Patterns).

1.25.2 Evolution of the Functional Components

A remarkable feature of the invertebrate nervous systems, which have been studied most intensively over the last 50 years or so, has been the recognition that all use the same general 'building blocks', a term suggested by Getting (1989). This term meant that all of the components – ion channels, synaptic mechanisms, and basic patterns of connectivity, are found in all of the nervous systems that have been described thus far, but through evolutionary processes have become arranged differently so as to meet the particular demands of each animal. If so many diverse metazoa, from coelenterates to arthropods, use the same basic components, then these elements must have evolved in their basic form prior to their appearance in functional circuits. It is clear that the similarity between particular channels, for example, spans phyla and although they all could have evolved in parallel to meet the same needs, it is probable that they at least started with the same basic protein structure.

1.25.2.1 Neuron Structure and Physiology – Identified Neurons

Neurons that are contained within visceral neuronal circuits are typical of invertebrate neurons found throughout all animal phyla. Each neuron can be organized into soma, dendritic, and axonal compartments that are electrically contiguous (Figure 2). Neuronal somata in invertebrates can be quite large. In some molluska, they can be close to 1 mm in diameter and be observed with the naked eye. Because their numbers are considerably fewer than the numbers estimated to be present in the 'higher' nervous systems of vertebrates, it has been suggested that they may perform more complicated functions. However, this does not appear to be the case. In general, invertebrate neurons are almost as computationally complicated as their vertebrate counterparts, and their large size probably has a different explanation. The cell somata are usually heavily wrapped in glia and free of synaptic contacts. Their role appears to be largely trophic and from an integrative viewpoint they act mainly as an electrical sink. A large neurite connects the soma to a heavily branched neuritic tree that contains both pre- and postsynaptic terminals and where connections to other neurons are made. Depending on the electrical properties of the principal neurite connecting soma to neuritic tree, some of the subthreshold currents generated in minor processes can be observed in the soma. More importantly, however, these currents will be summed at the spike initiation zone and propagated down the neuron's axon to an effector organ or to a neuron at some distant location. Many invertebrate neurons have been shown to have local circuit interactions with synaptic transmission occurring without spikes, that is, with transmitters being released as a function of

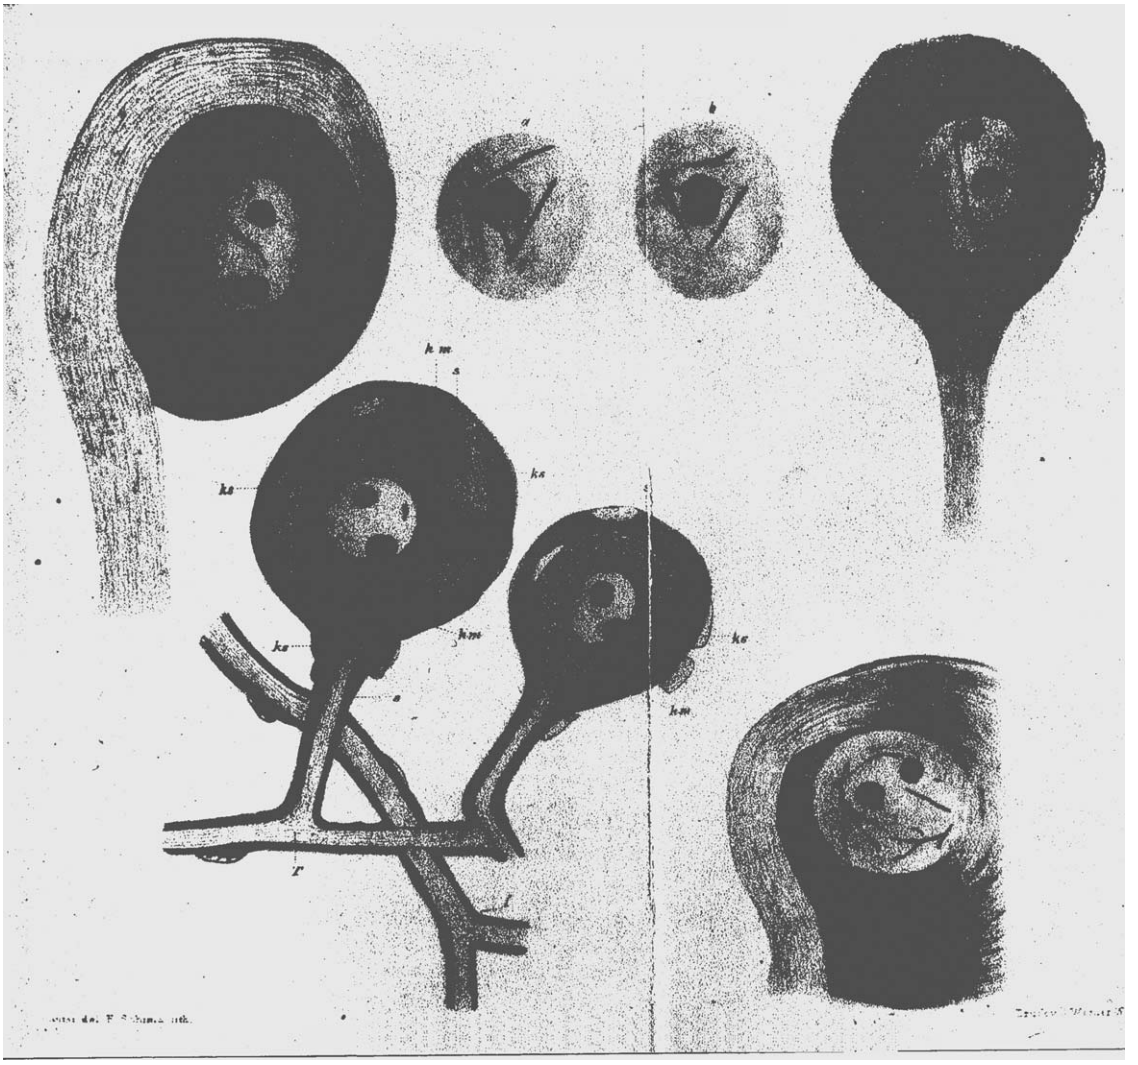

Figure 2 Drawings of visceral neurons from the STG of crayfish by Sigmund Freud illustrating cell somata and primary neurites.

presynaptic depolarization (Roberts and Bush, 1981). Starting from the primitive condition in which single neurons had both sensory and motor functions (Parker, 1919), neurons have evolved in both functional and structural complexity. Neurons have been deleted by degenerative mechanisms as a result of a missing target and their trophic influence suggests that trophic factors played a major role in keeping neurons intact over time. Changes in neuronal shape or function were likely due to evolutionary changes in gene expression (Arbas *et al.*, 1991). Segmental homologues were likely influenced by segmentation genes that tailored cell functions to organs that differed from one segment to another. The study of segmental homologues (Mittenthal and Wine, 1978; Shafer and Calabrese, 1981) has been specially useful in suggesting the range of transformations that might have occurred over the evolution of a particular species.

Of all of the criteria that confer identifiability to invertebrate neurons, the three-dimensional arrangement of neuronal branches is the least consistent (Glasser *et al.*, 1977). Nevertheless, the function of identified neurons is constant from animal to animal, which suggests that mechanisms exist that balance channel and other biophysical properties so as to insure functional consistency. In addition, mechanisms must exist to insure constant function despite membrane protein turnover and changes resulting from synaptic plasticity. These mechanisms have only recently begun to be explored.

1.25.2.2 Voltage-Gated Ion Channels

Many of the same ionic channels present in neurons today are found in protists, life forms that began

their evolutionary history millions of years ago. The simplest of these are the mechanosensitive channels found in bacteria and eukaryotes. Their simplicity lies in the fact that they open and close in response to pressure and do not require voltage sensors or ligand-binding sites. Among the K, Na, and Ca channels, K appears to be the oldest. The K channel is made up of a tetramer of identical subunits while Na and Ca channels are made up of four K-like domains. The evolution of these channels therefore probably began with a K channel structure but Na channels have recently been cloned from a jellyfish, the most primitive organism with nerves.

Which voltage-gated channels were the first to evolve, K, Cl, or Ca? One might suspect Ca because of its role as a second messenger. Studies on unicellular organisms however suggest K channels that are stretch-activated in bacteria and yeast came first. There are seven channels found in paramecia alone including a Ca-activated K channel as well as a voltage-activated Ca channel similar to those found in mollusks, annelids, and chordates. No Na channels have been found in unicellular animals and apparently did not arise until the metazoa. The Na channel genes probably diverged early, before the branching off of arthropods and vertebrates. The K channels became the most diverse functionally and could be gated by depolarization, hyperpolarization, and divalent cations as well as being modulated by second messengers.

As nervous systems evolved to control the viscera, a large palette of channels was already available to control the intrinsic properties of individual neurons and the properties of their synaptic connections. That is why the different channel types are ubiquitous in different phyla and in different specific circuits. Their expression probably became fixed as selective pressures gave advantage to behaviors that had circuits with the best combination of conductances to ensure the success of each animal.

A fundamental concept is that for voltage-gated ion channels, it is the membrane voltage that affects the performance of a neuron in a circuit. One can trace the molecular evolution of channel proteins in a systematic way, but it is the effect of the different channels or combination of channels on neuronal behavior that is selected for. It is therefore likely that the expression of the proteins making up the net conductance characteristics of each identifiable neuron be highly specified and controlled by the genome. For the rhythmicity observed in invertebrate viscera, neuronal properties are quite similar to those found in other parts of the invertebrate nervous system and vertebrate nervous system as well. Certainly inward Na and Ca currents were necessary for depolarization and outward K currents necessary for repolarization of the membrane. Additional currents that could fine-tune neuronal membrane electrical activity could add to the effectiveness of each neuron as a component in a system of neurons. For example, the $I_{K–Ca}$ channel will increase membrane repolarization and add to the effects of the delayed rectifier action of I_K. If it was advantageous to have a neuron repolarize even faster, then I_H would prove effective. If it was necessary to delay the onset of firing, then the transient I_A current would have a selective advantage. All of these currents have been described for neurons in visceral nervous systems and have started to be employed at the molecular level to study the role of each channel in circuit function (Baro *et al.*, 1997).

1.25.2.3 Neuromodulators and Receptors

The large role of neuromodulation in determining behavior has become increasingly apparent with the development of techniques to locate putative neuromodulatory substances within visceral nervous systems. In particular, the ability to make antibodies against particular peptides, amines, etc., and their subsequent amplification and visualization by immunohistochemistry has demonstrated a large array of neuromodulators for even small ganglia. The anatomical localization can suggest experiments with agonists and antagonists of these substances when applied directly to the nervous tissue or when released by stimulation of the appropriate nerves to further characterize the physiological role these substances might have. The effects, which can be observed in *in vitro* experiments, in many cases appear to be more numerous than the particular visceral structure actually requires. For example, the pyloric system of the crustacean stomatogastric system has over 30 neuromodulatory substances associated with it despite the fact that its function is limited to a rather straightforward pumping and filtering action. Because the synaptic connectivity has been conserved during evolution, it has been suggested that neuromodulators had a greater effect on producing variability of motor programs than has change to the neural circuits (Katz and Tazaki, 1992).

1.25.2.4 Muscle and Neuromuscular Factors

The control of invertebrate viscera is mainly comprised of intrinsic and extrinsic neural mechanisms

along with neuromodulatory agents acting either as hormones or local transmitters. The visceral organs we consider are those involved in alimentation and circulation. Both utilize various muscle cell types that evolved from specialized cells containing contractile proteins and strongly resembling the myocytes found in today's sponges. These cells were not innervated and each acted independently under local contact, stretch, or chemical control and would not be considered true muscle by most. The first true muscle probably evolved independently in ancestors of today's coelenterates and whose contractile fibers were arranged in parallel to form longitudinal muscle or at right angles to form circular muscle. The two could act antagonistically to cause shape changes or bending so that if coordinated could cause pumping or peristaltic gut movements (Figure 3). This type of musculature has been retained by most soft-bodied animals including Colenterata, Platyhelminthes, Annelida, and Mollusca.

We can consider, as a starting point for all muscles, a soft-bodied tubular animal similar to present-day *Hydra* with a pair of antagonistic sheets of fine nonstriated contractile cells. Over time we can postulate that these were arranged into locally organized clusters with intrinsic activity and superimposed reflex actions mediated by local neurons. One can also suggest that they could function cooperatively because of the development of connections between the local neurons and through-conducting giant neurons innervating them collectively. The local connections eventually formed a nerve net but their connections with axons of larger and larger diameter permitted the synchronous activity of the whole when necessary. The gut has today retained many of these early features as did other organs that evolved out of the body tube by being pinched off when necessary to provide other functions such as storage, churning, secretion, and transport of blood or other body fluids. Each has its own local nervous system in the form of a nerve net, a plexus, or a ganglion (or some combination thereof).

The gut muscle cells of invertebrates other than arthropods are nonstriated, resemble vertebrate smooth muscle, and are assembled in a similar manner (Hoyle, 1983). Arthropod gut muscle, however, is striated although it has some properties of vertebrate smooth muscle as well. In insects there appears to be a direct innervation of gut musculature, so if there is a peripheral innervation as well, this suggests multiple innervation of individual muscle cells (Cook and Holman, 1979). The anterior parts of the guts, crops, gizzards, etc. are innervated by a medial nerve that is connected to a frontal ganglion that is

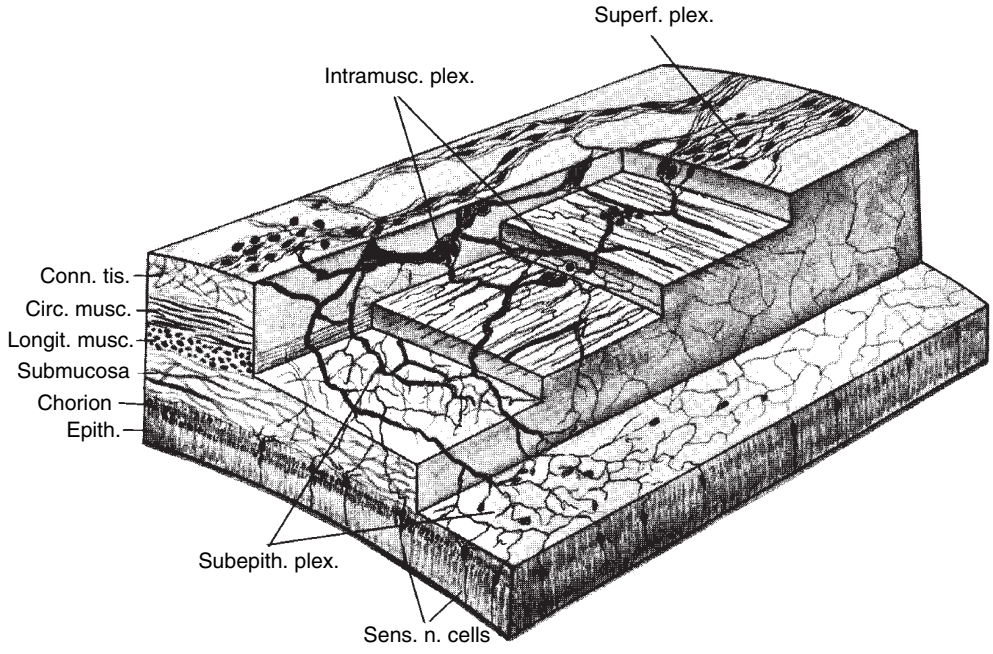

Figure 3 Localized visceral control exemplified by this semischematic drawing of the arrangement of nerves and muscles in the wall of the intestine of *Sepia* (Mollusca) (Alexandrowicz, 1928). Intramusc. plex., intramuscular plexus; Superf. plex., superficial plexus; Conn. tis., connective tissue; Circ. musc., circular muscle; Longit. musc., longitudinal muscle; Epith., epithelium; Subepith. plex., subepithelial plexus; Sens. n. cells, sensory nerve cells.

at the junction of two nerves from the forebrain. In crustacea, a small stomatogastric ganglion (STG) forms along the medial nerve that supplies patterned input to the striated muscles of the stomach. Gut physiology in phyla other than arthropod varies enormously. All show a basic tonus and for some this is all that is observed. In many others one can observe peristaltic and longitudinal slow waves that are in general somewhat slower than their vertebrate counterparts. Prosser *et al.* (1965) described gut activity in a variety of invertebrates and found that actional potentials occurred spontaneously in the esophagus at a mean frequency of ~1 Hz. However, these were highly erratic and asynchronous, and fluctuating tension measurements could not be correlated with the electrical activity. Occasionally, waves, spikes, and tension become synchronized, which indicates that there is an overall control mechanism that can superimpose itself on local activity. Blocking the intrinsic nerves with a local anesthetic led to a tendency toward synchronization of spikes and waves, suggesting that it was local neural inhibition that led to the asynchrony.

In all of the invertebrate guts that have been investigated, a local stimulus causes a contraction that is conducted decrementally away from the point where it is elicited and is reduced significantly after only a few centimeters of conduction. The range of velocities of propagation is narrow, from 4 to 6 cm s^{-1} for *Thyone* to 12 cm s^{-1} for *Loligo* (Prosser *et al.*, 1965). Procaine blocks conduction in all animals tested except for the echinoderm *Thyone*, which suggests that, like vertebrates, conduction is along muscle cells. Since chordates are closely related to echinoderms, intestinal cell-to-cell conductance is characteristic of the echinoderm–chordate line and phylogenetically very old.

1.25.2.5 Generation of Functional Patterns by Defined Circuits

In most primitive invertebrates, neurons that participate in controlling rhythmic visceral activity are arranged in diffuse nerve networks in which neurons are interconnected close to their effector organs and in a position to respond quickly to sensory stimuli (Figure 4). But a phylogenically early step was the clustering of neurons into ganglia that controlled segmental functions or visceral organs (Figures 5 and 6). Generally, but not always, sensory neurons remained peripherally located while ganglia contained interneurons and motorneurons. All invertebrate phyla except for Cnidaria and Ctenophora (Field *et al.*, 1988) have developed

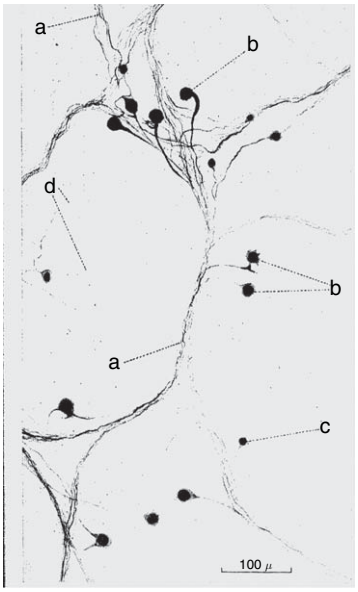

Figure 4 A peripheral nerve plexus in the wall of the posterior stomach of the snail *Helix*. a, nerves; b, cell bodies; c, small cells; d, plexus. Modified from Abraham, A. 1940. Die innervation des darmkanals der gastropoden. *Z. Zellforsch.* 30, 273–296.

formal ganglionic structures, that is, condensations of neurons and their processes into discrete structures (ganglia) linked by axon tracts (connectives) (Leise, 1991). Individual neuron cell bodies, often identifiable, surround a dense neuropile core made up of the neurites of each cell (Figure 7). Synaptic connections are made within the neuropile, often on small varicosities distributed along on the fine neurite processes (King, 1976).

The control of visceral structures became concentrated within these distributed ganglia and because they represented individual local circuits that could be studied independently of the rest of the CNS, they represent the best-described neural circuits in existence. The architecture of each ganglion varies considerably from species to species. The neuropiles of some ganglia have distinct morphological boundaries for separate sensory and motor control purposes (Altman, 1981). Where the neuropile has been investigated more fully, for example, in the case of the STG, some of the motor neuron arborizations do appear to be compartmentalized (Christie *et al.*, 1997).

The condensation of neural functions into larger and larger ganglia appeared to be an evolutionary trend in invertebrates for good reason. Advanced arthropods and mollusks evolved massive brains but seem to have done so independently (Bullock and Horridge, 1965). The condensation of neurons would of course have a significant effect on

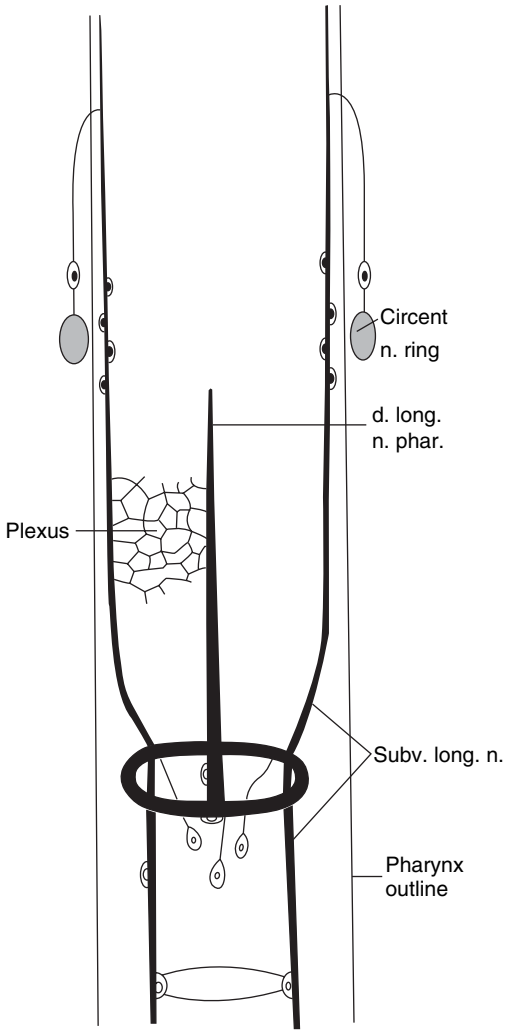

Figure 5 Schematic representation of the visceral nervous system of the nematode. Note the start of clustering of neurons and nerve fibers in addition to the pharyngeal plexus. the arrangements of commissures, tracts, and neuropile and would have positive effects on reduced conduction times, elimination of relay interneurons and the increased availability of sensory input to individual neurons and networks (Altman and Kien, 1987).

However, it was quite common for abdominal visceral ganglia to remain independent of the condensation of the rest of the nervous system but nevertheless incorporating neurons for the control of more than one visceral organ. Why this distributed processing remained a viable method for organizing the abdominal nervous system probably had more to do with achieving redundancy and therefore reliability than integrating sensory and motor functions. Interestingly, even in mammals, the autononomic nervous system, a system largely devoted to the control of the viscera, evolved as individual discreet ganglia.

1.25.3 Examples of Visceral Control Systems

1.25.3.1 Crustacean Cardiac Ganglion

One of the simplest invertebrate systems for the control of a particular visceral organ is the nine-cell lobster cardiac ganglion. A muscular heart aspirates blood from the thoracic cavity using passive elastic forces and pumps it out via blood vessels to various parts of the body with neurogenic heart contractions. The heart muscle itself has lost all intrinsic burst activity and therefore requires synchronized bursts of neural input in order to produce its synchronized rhythmic contractions.

Because the cardiac ganglion has proved to be a robust preparation for the study of small neural networks, particularly how endogenous bursting can be produced in nerve cells, it has been examined in many species. Anatomically, the nine neurons that make up the lobster cardiac ganglion contain five large neurons (54–84 μm) located anteriorly and a (22–43 μm) group of four smaller posteriorly located neurons (Figure 8). In the spiny lobster *Panulirus*, all of the neurons are arranged linearly, while in the clawed lobster *Homarus*, the posterior part of the ganglion bifurcates and two small neurons are found in each branch (Hartline, 1967). In crabs, two of the large cells are clustered with the small cells at the posterior end of the ganglion. The meaning of the different clustering is unknown and why this particular cell arrangement has evolved differently is not known. More interesting from an evolutionary perspective is

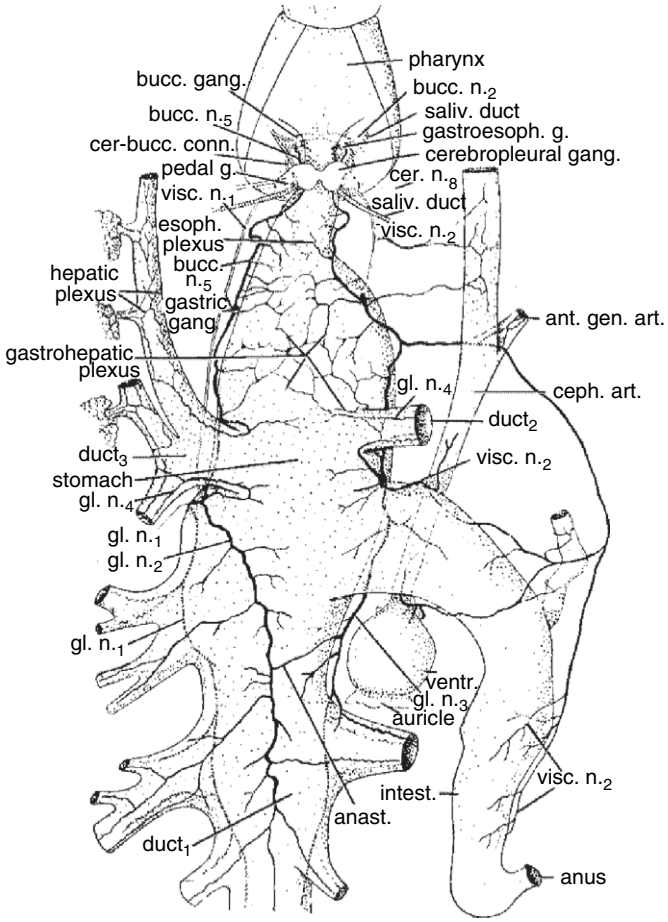

Figure 7 Stomatogastric nervous system of *Acolidia papillosa* (Opisthobranchia, Nudibranchia). Important features are: anast., anastomasis; ant. gen. art., anterior genital artery; bucc. n., buccal nerve; bucc. gang., buccal ganglion; ceph. art., cephalic artery; cer. n., cerebral nerve; cer-bucc. conn., cerebro-buccal connective; gastroesoph. g., gastroesophageal ganglion; gl. n., gland nerve; intest., intestine; saliv. duct., salivary duct; ventr. gl. n., ventral gland nerve; visc. n., visceral nerve. Lond.* 1, 197–233.

why all species have nine cells and why some are larger than others.

The burst-generating mechanism appears to reside within the small cells since cutting or blocking results in continued small cell bursting but termination of bursts in the large cells (Mayeri, 1973; Cooke and Tazaki, 1979). Trying to unravel the synaptic connectivity of this small system was hampered for many years by the size of the small cells. Early recordings from large cells suggested that their bursts were triggered by the small cells. It is now known that the small cells produce a slow driver potential endogenously that leads to a burst of spikes. These spikes then activate the large cells synaptically to fire a burst. In Panulirus, it has been found that all small cells synaptically drive all large cells (Friesen, 1975). Because all of the cells are connected to each other electrically, all of the cells, small and large, fire synchronously (Figure 9). Cell 6 elicits a particularly powerful and rapidly antifacilitating EPSP onto cells 1–4, accounting for the abrupt onset of their burst depolarization. The EPSPs from cells 7–9 are smaller but antifacilitate less and often commence prior to the motor burst onset (Friesen, 1975). The synaptic connections between the small cells has been very hard to measure because of their small size, but it has been shown that cell 6 could be correlated with firing of cells 7–9 and of excitation of cell 7 by cell 8 and of cell 8 by cell 9 in a completely feed-forward manner (Friesen, 1975). The key feature in this system is the synchronization of the intrinsically bursting small cells by their electrical and chemical synapses to produce periodic bursts of activity to drive the heart muscle. Such circuits

are extremely robust to perturbations and reliable for the life of the animal. This form of pacemaker evolved to specialized tissue in the hearts of higher animals as exemplified by the sino-atrial node of the mammalian heart. Similarly, other rhythms that consist of periodic discharges with only a single phase per cycle can be generated by neural connectivity with this degree connectivity. For example, each hemisegment of the lamprey is thought to contain a central pattern generator (CPG) in which an indeterminate number of interneurons are synaptically connected with fast and

slow excitatory synapses that synchronize the bursting for each hemisegment (Cangiano and Grillner, 2005).

When the large cells and small cells are considered together, the data suggest the entire network is more that feed-forward. When the large cells are depolarized by injected current, the succeeding small cell burst is accelerated and hyperpolarization has the opposite effect (Watanabe and Bullock, 1960; Tazaki, 1971). This suggests that electrotonic connections between the small and large cells, usually thought of as a way to provide synchronization between neurons, have a more complicated function. Similarly, antidromic spike trains generated in the large cells can elicit spikes or hasten bursts in the small cells (Mayeri, 1973) proving that the large cells also have a feedback onto the small cells.

The mechanism for producing rhythmicity in the cardiac ganglion system illustrates one of the several ways in which bursting behavior has evolved in neural networks that control the viscera. In most rhythm-generating networks, there is almost always one or more neurons capable of generating bursting pacemaker potentials. This type of neuron incorporates a panel of conductances that can generate slow oscillatory potentials entirely autonomously. That such neurons exist was demonstrated conclusively in molluskan neurons by physically isolating them from an *Aplysia* ganglion (Alving, 1968). While these neurons burst in isolation in a saline-containing Petridish, similarly isolated neurons do not burst unless exposed to some modulatory substance such as an amine or peptide. Neurons in this category are termed conditional bursters, that is, conditional upon the presence of a pharmacological agent. This type of bursting cell is common to many phyla and has been studied rigorously in the STG, where both the cellular and functional aspects of the phenomena have been described in detail (Harris-Warrick *et al.*, 1992).

1.25.3.1.1 Bursting pacemaker potentials The ion channels responsible for generating bursting pacemaker potentials had probably already evolved by the time metazoa required neuronally generated rhythmic activity and it was likely that different combinations of channels were employed initially to achieve this goal. Basically there had to be a self-generating mechanism for depolarizing the neuron, a mechanism for the generation of spikes at maximal levels of depolarization although in some cases the neurons could act without spiking, and a third mechanism for terminating the depolarization. These currents have been studied successfully in mollusca using the voltage clamp method due to the fact that the pacemaker potentials are generated near the soma which is itself electrogenic. Between bursts, there is a high resting electrical conductivity corresponding to Na ions, (G_{Na}), which is persistent and voltage independent (Smith *et al.*, 1975; Carpenter and Gunn, 1970). This current gradually depolarizes the membrane as K currents from the preceding burst recede. This slow depolarization activates a persistent voltage-dependent slow G_{Na} and in some cases a parallel Ca current that initiates the burst. The burst is terminated and the membrane is repolarized by activation of a slow G_K and a G_{K-Ca} (Thompson, 1977). During the depolarizing phase, spikes are produced by fast inward Na/Ca currents and delayed rectifier K currents. A third K current was also described that was activated by hyperpolarization and helps control the duration of the interburst interval (Neher, 1971).

Similar mechanisms for bursting in lobster pyloric neurons have also been described. Unlike some of the truly endogenous molluskan bursting pacemaker neurons, the pyloric neurons are conditionally bursting neurons, which must be activated by neuromodulators from 'higher' ganglia. The ionic mechanisms seem to be approximately the same, except that the initial slow pacemaker potential is the result of a decrease in the resting leak G_K (Gola and Selverston, 1981). Pyloric neurons also have a pronounced plateau potential when given a short depolarizing pulse and this potential appears to determine the overall burst length. Finally, bursting pyloric neurons have varying amounts of an I_H that helps control the speed with which the bursting neuron repolarizes and can therefore determine at what phase in the cycle the neuron will fire its burst.

1.25.3.1.2 Modulation of heart rhythmicity There are several mechanisms used to modulate the heart's rhythmicity. Intrinsic reflexes are present that can accelerate and strengthen the heartbeat when the cardiac ganglion is stretched (Maynard, 1961). There also appear to be dendritic processes of some neurons embedded directly in the heart muscle that likely serve a sensory function (Alexandrowitz, 1932). Neuromodulators from the pericardial organ, a neurosecretory structure near the heart, were among the first chemical control substances studied that had distinct effects on the viscera. These modulators, thought to be mainly peptides and amines (Cooke, 1966), when extracted from the pericardial organ and applied topically to the proximal axonal regions of the small cells generally increased burst frequency (Cooke and Hartline, 1975). In the blue

crab *Callinectes sapidus*, a neuron in the commissural ganglion (CG; L-neuron) that was shown to contain dopamine by immunohistochemical staining for its synthetic enzyme tyrosine hydroxolase, innervates the pericardial organ and the cardiac ganglion (Fort *et al.*, 2004). The cardiac ganglion also receives direct innervation from the CNS (Figure 10) that controls its activity in tandem with the neurohormonal innervation (Delgado *et al.*, 2000; Field and Larimer, 1975; Maynard, 1960.)

1.25.3.2 Leech Heart

A key characteristic of annelids is their segmental nature, which in some cases is reflected in the morphology of their viscera and the innervation of these structures. In the gut, neurons innervating the musculature are embedded in the gut wall (Figures 11 and 12). However, the leech heart is also controlled by patterned neural input from CPGs in the segmental ganglia. One of the most well-examined annelid neural systems is the heart CPG network in the leech (Calabrese and Peterson, 1983). The hearts consist of long laterally placed muscular tubes extending the length of the animal. The contractions are in

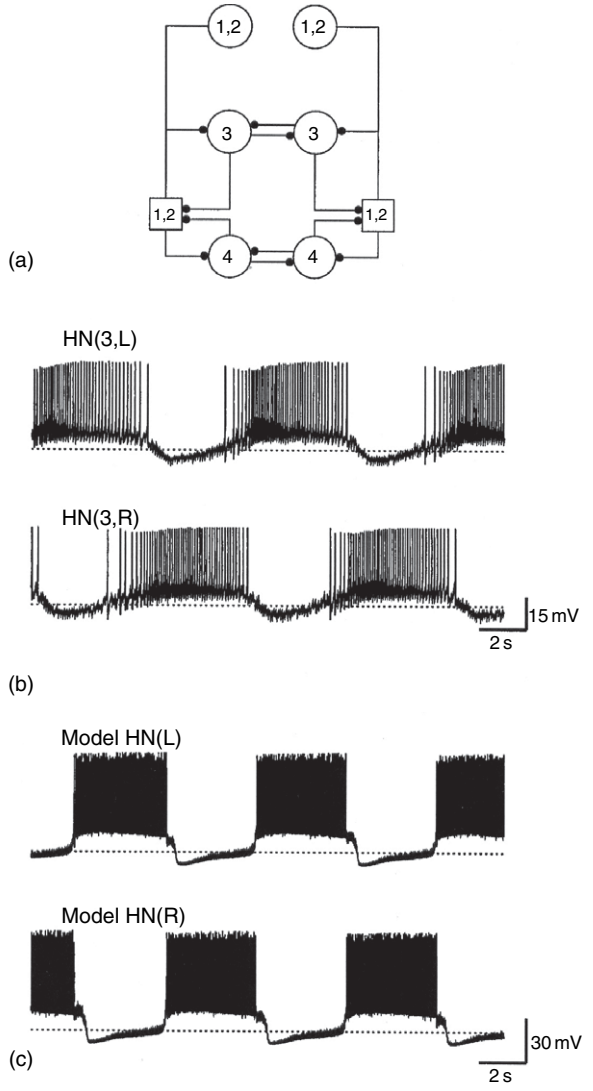

Figure 13 a, Circuit diagram showing inhibitory connections among heart (HN) interneurons that produce pacemaker activity during leech fictive heartbeat activity. Cells are indexed by ganglion and body side. The HN cells of the third and fourth segmental ganglia make reciprocal inhibitory connections across the ganglion midline with each pair constituting an independent neural oscillator. The oscillations are coordinated through their connections with the HN(1) and HN(2) interneurons, which are lumped together here because they are functionally equivalent. b, Typical alternate bursting activity of a pair of oscillator interneurons in an isolated ganglion. c, A model of the same two neurons displaying similar activity. Modified from Calabrese, R. L. and Feldman, J. L. 1997. Intrinsic membrane properties and synaptic mechanisms in motor rhythm generators. In: Neurons, Networks and Motor Behavior (*eds.* P. S. G. Stein, S. Grillner, A. Selverston and D. Stwart), pp. 119–130. MIT Press.

part myogenic, but the rhythm is entrained and controlled by motor neurons in segmental ganglia. These neurons fire rhythmically due to cyclic periodic inhibition from a CPG comprised of seven bilateral pairs of neurons (HN neurons) that occur in the first seven segmental ganglia (Figure 13). The rhythmicity is generated by the first four pairs of interneurons (Peterson and Calabrese, 1982) and is the result of synaptic interactions (reciprocal inhibition) and intrinsic membrane properties. The spiral muscles that make up the heart wall also have intrinsic rhythmicity and continue to contract when the nervous system is removed, although at a much slower rate. The ability for gut or vascular tubes to generate intrinsic rhythms probably evolved early with superimposed neural control coming only in later stages of animal complexity. The normal behavior of the leech heart tubes is rather complicated and represents a condition where the organizing influence of a nervous system is required. Each tube constricts in a coordinated longitudinal pattern, one in a rear-to-front peristaltic wave and the other approximately synchronously (Thompson and Stent, 1976). About every 20 heartbeats, the two tubes trade roles and these changes in

coordination are always reciprocal and occur with remarkable regularity. The heartbeat pattern generator comprises two different oscillators: a timing oscillator composed of the HN(1)–HN(4) interneurons (Figure 13) responsible for the beat timing; and the switching oscillator which is responsible for the coordination state. Each of these two oscillators is autonomous but they connect to two HN(5) nonautonomous neurons. These two neurons are able to blend the periods of the two oscillators and connect them to the variable phase neurons HN(6) and HN(7). The pattern generator produces the correct phases of activity in the HE motorneurons through direct inhibitory connections from a subset of the HN interneurons that includes members of both the timing oscillator cells and the variable phase interneurons. The HE motor neurons therefore entrain the intrinsic rhythm of the heart muscle very effectively.

Initially, the explanation for the operation of the CPG relied on inhibitory synapses between the reciprocally connected pairs of HN neurons in the third and fourth segmental ganglia. Subsequent studies, which successfully blocked the inhibitory synapses without interfering with currents in the HN cells, demonstrated that these neurons were capable of intrinsic bursting (Cymbalyuk *et al.*, 2002). Both mechanisms, endogenous bursting and synaptic interactions, work synergistically to produce a reliable yet flexible rhythm. The coexistence of bursting using pacemaker potentials and bursting being generated by network properties are found throughout invertebrate CPGs.

The period of the heartbeat is controlled by neuromodulators from a variety of sensory neurosecretory and motor pathways (Arbas and Calabrese, 1990). A family of endogenous RFamide peptides has been shown to modulate the rhythm and these substances have been localized to particular neurons. The target for this central modulation was shown to be the oscillator neurons in the third and fourth ganglion.

The peptide FMRFamide in particular is effective in slowing the heart rate by acting on I_K channels and by decreasing the amplitude of inhibitory synaptic transmission (Simon *et al.*, 1992). As already noted, the use of neuromodulators to control visceral networks is ubiquitous and a general solution used by all animals.

1.25.3.3 Snail Feeding CPG

Considerably more complicated than either the single-phase crustacean heart rhythm or the alternating peristaltic and synchronous leech heart rhythm is the molluskan feeding rhythm. We can consider two different feeding rhythms that have evolved parallel mechanisms for operation of the feeding apparatus. Motoneurons controlling the feeding rhythm of the snail *Lymnaea stagnalis* receive synaptic inputs from a CPG located in the cerebrobuccal ganglion. The CPG controls a structure called the radula, which undergoes protraction and rasping movements when the animal feeds. The CPG neurons (Figure 14a) are activated by chemosensory inputs from the lips that strongly depolarize a set of protraction phase interneurons called N1Ms, and trigger the production of endogenous plateau potentials that maintain protraction phase activity (Kemenes *et al.*, 2001). This activation is further supported by synaptic excitation from N1L and the SO. The combined N1M and N1L activity has a biphasic effect on the rasp phase interneurons that consists of an initial hyperpolarization followed by a slow depolarization that activates and triggers plateau potentials in the N2v and by electrical connections to N2d rasp phase interneurons. This activity terminates the plateau potentials in N1M and ends the protraction phase by increased inhibition from N2v and N2d on all of the protraction phase interneurons and the SO neuron. The rasp phase ends when the plateaus in N2v and N2d terminate spontaneously. This releases another set of interneurons, N3t and N3p, which generate swallowing, from inhibition by both protraction and rasp phase interneurons. Because N3t has a strong postinhibitory rebound (PIR), it rebounds from its inhibition and fires strongly, pulling the N3p interneurons along with them because of electrical connections. Once the swallowing phase stops, continued sensory stimulation starts a new cycle (Straub *et al.*, 2002).

The three consecutive phases that are produced by the CPG control the firing sequences of the motoneurons and subsequent muscle contractions (Figure 14b). The sequence of firing in this system derives from the synaptic interactions and the intrinsic properties of the interneurons in the CPG. This pattern can be demonstrated *in vitro* by stimulating the SO neuron which starts a sequence of bursts from N1 to N2 to N3 in that order. By stimulating SO, EPSPs are produced in the approximately 10 N1 neurons which then burst together and in so doing inhibit the SO, N2, and N3 neurons simultaneously. When the N1 burst terminates, N2 fires and continues to inhibit N3 and when N2 stops firing, N3 is free to fire. When the three N3 neurons fire, they turn off the SO and the N1 neurons. As with many mollusks, there is some degree of myogenic activity in the feeding muscles

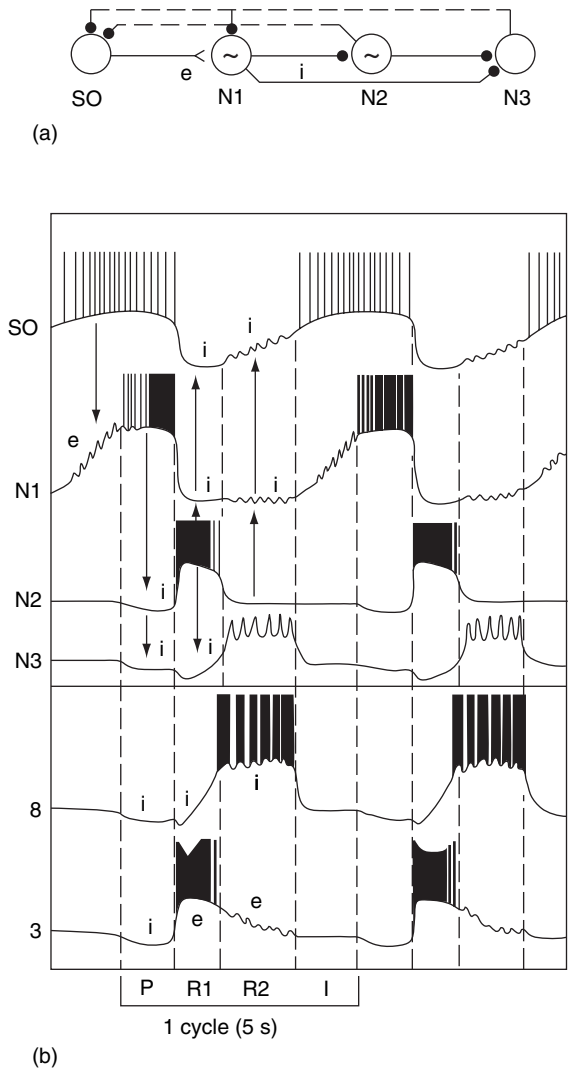

Figure 14 Summary of the CPG in the *Lymnaea* feeding system. a, The hypothetical wiring diagram showing the minimum number of connections required to produce the activity pattern shown in (b). b, Output pattern of the four interneuronal types and two examples (8 and 3) of motoneuron output when the SO is on either spontaneously or as a result of steady depolarization. Arrows indicate synaptic connections, e for excitatory and i for inhibitory. Reproduced from Rose, R. M. and Benjamin, P.R. 1981. Biol.* 92, 203–228, with permission from The Company of Bilogists Ltd.

but not enough to insure the coordination of the muscles for different behaviors.

Isolation of the neurons making up the CPG by placing them in tissue culture has revealed the intrinsic cellular properties of the constituent neurons. The N1 interneurons were able to generate intrinsic plateau properties when properly stimulated while the N2 interneurons could only generate plateau potentials in the presence of acetylcholine. Other isolated neurons in the feeding CPG circuit had no significant intrinsic properties relative to the feeding rhythm. The lateral N1, the dorsal N2, the phasic N3, and the slow oscillator neuron had their firing patterns determined by cholinergic and glutamatergic synaptic inputs from other CPG interneurons, which could be mimicked in culture by pharmacological agonists. In addition to the SO neuron, stimulation of the cerebral ventral 1a neuron (CV1a) was shown to produce a fictive feeding pattern in isolated ganglia.

The control over the feeding rhythm, as in the cardiac and leech heart, consists of both synaptic and neuromodulatory inputs to the feeding CPG. Direct stimulation of the cerebral ventral neuron (CV1a) and SO leads to a strong CPG-driven fictive feeding pattern (Kemenes *et al.*, 2001). However, when the lips are stimulated with a natural stimulus such as sugar, neither CV1a nor SO1 is involved in the initial activation of the rhythm. Once the behavior begins, CV1a has effects on motor neuron burst duration and SO in setting the overall frequency. Cerebral to buccal interneurons that may be homologous to CV1 in *Lymnaea* have been identified in many other molluskan species, including *Aplysia* (CB12; Rosen *et al.*, 1991), *Limax* (CB1; Delaney and Gelperin, 1990), *Pleurobranchia* (phasic paracerebral neurons; Gillette *et al.*, 1982), and *Achatina* (C1; Yoshida and Kobayashi, 1992). As with *Lymnaea*, all of these can drive feeding rhythms when stimulated intracellularly, can respond to food stimuli but are not necessary to activate the rhythym when chemosensory fibers are stimulated. Similar homologies exist between the SO and other buccal neurons that can drive feeding rhythms. In *Aplysia*, which we will consider separately, several buccal neurons can drive the rhythm (Susswein and Byrne, 1988; Kabotyanski *et al.*, 1998). Similar but not homologous neurons have also been found in *Helisoma* (Quinlan *et al.*, 1997), *Clione* (Arshavsky *et al.*, 1989), and *Planorbis* (Arshavsky *et al.*, 1988).

The amine 5-HT contained in the cerebral giant cells acts on motor neurons that are part of feeding CPG including B4, B8, and B4CL (Straub and Benjamin, 2001). All of these neurons were depolarized past firing threshold for prolonged periods of time by 5-HT. Conditional bursting occurred in the B4 and B8 cells but not in the B4CL neurons and the bursting frequency was increased by CCG tonic firing. 5-HT also increased PIR in all three neuron types. As will be the case in all of the systems discussed however, how these modulators are used during the actual behavior of the animal is difficult to ascertain.

1.25.3.4 *Aplysia* Feeding

A similar mechanism for the control of the feeding apparatus occurs in the marine mollusk *Aplysia californica*. Despite the fact that the muscles themselves still have some intrinsic rhythmicity, the evolution of multifunctional circuits operating the radula and the other mouth parts led to a new level of complexity including a heavy reliance on neuromodulation. As in other circuits, the predominant role of reciprocal inhibitory synapses has evolved to insure that antagonists do not fire at the same time, no matter what specific behavior occurs, and to be the sole or supportive mechanism for generating alternate bursts. Similarly, many of the neurons in the circuit are intrinsic or conditional bursters – conditional on the presence of neuromodulatory input. The particular circuitry shown here has been useful in illustrating how a small ensemble of neurons can perform several different functions by making only small changes to the circuit (Jing *et al.*, 2004). The basic kernel of the motor circuit is comprised of two reciprocally inhibitory neurons B63 and B64 (Figure 15). Depending on which higher-order neurons are activated, the kernel circuit along with other neurons will form both behavior-specific (used only for one behavior) and behavior-independent (that is capable of multiple behaviors) modules. Behavior-specific modules such as biting, swallowing, and rejection are encoded by combinations of output from CBI-2 and CBI-4 which are higher-order interneurons in the cerebral ganglion (Figure 15a). Encoding of behavior-independent modules for swallowing or rejection is achieved by adding neuron B51 to the circuit (Figure 15b).

The radula has also been used as a model system with which to study the co-evolution of the nervous system and the biomechanical plant it controls (Sutton *et al.*, 2004). Sutton *et al.* make the assumption that evolutionary adaption acts on behavior and that the most intimate causal factor is the biomechanical plant, the muscles, and parts of the body moved by the muscles. The evolution of the nervous system must therefore be seen in the context of the unity between all three elements – behavior, musculosketal plant, and nervous system (see also Dumont and Robertson, 1986).

1.25.3.5 The Crustacean Stomatogastric System

The crustacean stomatogastric system is one of the best characterized invertebrate visceral nervous systems but very little is known about it in terms of evolutionary development. Like lobsters and crabs, insects also have a stomatogastric nervous system that has been described as an invertebrate homologue of the vertebrate visceral autonomic nervous system (Hartenstein, 1997). In crustaceans, nerve cells are located on the fore and hindgut which supply motor nerves to the stomach (Figure 16). The neurons are connected to a large ganglion in the head (supra-esophageal) and to commisures which circle the esophagus and supply the stomatogastric ganglion (STG) with various kinds of descending input.

It is not known when the crustacean digestive tract evolved from producing simple peristaltic movements to become capable of complicated food maceration and filtering behaviors. One can speculate that the ability to reduce feeding time in the open, where animals could easily be preyed upon, conferred some selective advantage to storing food in a large cardiac sac for later maceration and digestion. This would require the stomach to have not

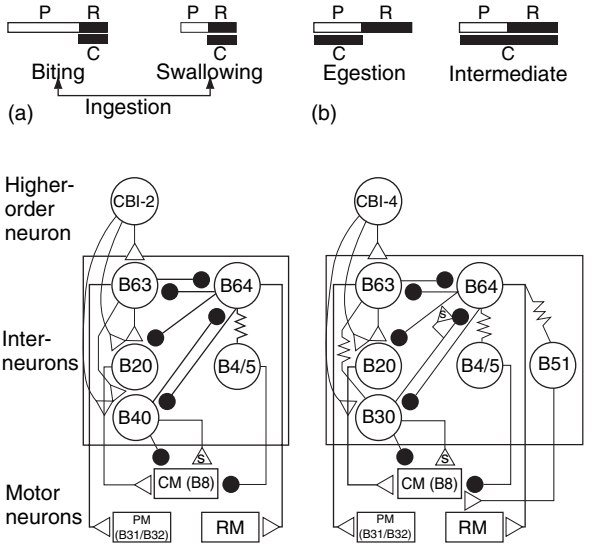

Figure 15 Fictive motor programs elicited in the isolated CNS by stimulation of the CBIs (Rosen *et al.*, 1991). The multiple motor patterns and the circuits that underlie them are shown here diagrammatically. a, Classification of the motor programs and their relation to behavior. Each cycle of the program comprises a protraction (P) phase that is followed by a retraction (R) phase. Motor programs can be classified into four types depending on the phasing of the radula closer (C) motor neuron. b, Schematic diagrams of the feeding circuits that produce the multiple motor outputs. On the left, the circuit that is activated by CBI-2 mediates ingestive-biting-like, egestive, and intermediate programs. On the right, the circuit that is mediated by CBI-4 and mediates ingestive-swallowing-like, egestive, and intermediate programs is shown for comparison. Adapted from Jing, J., Cropper, E. C., Hurwitz, I., and Weiss, K. R. 2004. The construction of movement with behavior-specific and behavior-independent modules. *J. Neurosci.* 24, 6315–6325, with permission from Society of Neuroscience.

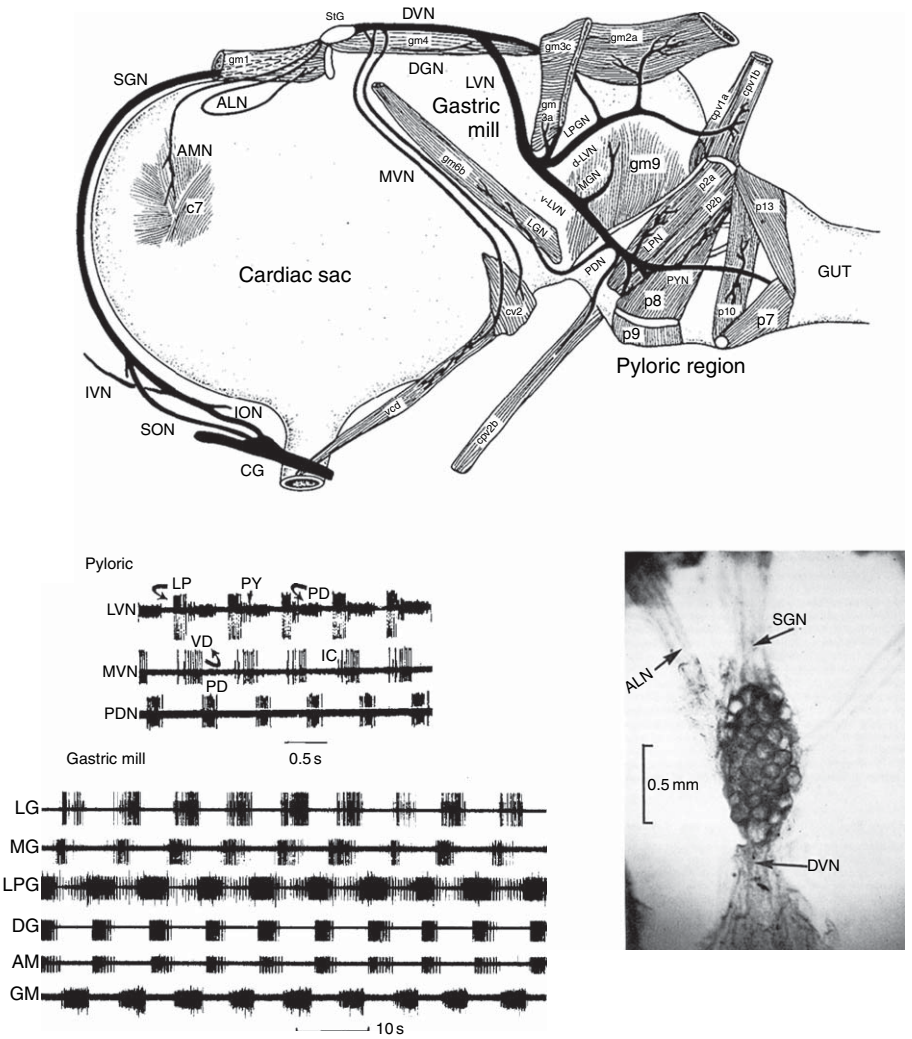

Figure 16 Diagram of the lobster stomach illustrating the four basic divisions: esophagus, cardiac sac, gastric mill, and pylorus. The STG lying on top of the stomach contains about 30 neurons. The axons of these neurons pass out the ganglion via the dorsal ventricular nerve (DVN) to innervate the striated muscles controlling constriction and dilation of the pyloric filter and gastric mill. Beneath the diagram of the stomach are extracellular recordings of the pyloric and gastric rhythms as recorded from the different motor nerves shown in the diagram in a preparation with commissural ganglia attached. To the right of the recordings is a picture of the STG as it appears in the dissecting microscope.

only a simple storage and mixing function but also the ability to macerate and filter the food. Neural control over these processes would lead to the organization of local CPGs in the stomatogastric system that in turn would be under the influence of higher centers. In addition, this system evolved the membrane receptor proteins and second messenger systems necessary to enable the stomach to respond to neuromodulatory substances in complex ways.

1.25.3.5.1 The stomatogastric CPGs The STG, located in the ophthalmic artery just above the stomach, contains the complete neuronal infrastructure for the generation of two visceral behaviors – the gastric mill and the pyloric. The isolated STG can be observed in Figure 16. The gastric rhythm, produced by 11 neurons, is for 'chewing' the food that has been swallowed and stored in the cardiac sac division of the stomach (Figure 16). Contractions of the cardiac sac force coarsely shredded food into the gastric mill. Here the three teeth of the gastric mill move in a more or less periodic pattern which grinds the food but are heavily modulated by sensory feedback which adjusts the pattern to the consistency of the material in the stomach. The pyloric rhythm controls a pump – filter apparatus at the caudal end of the stomach (Figure 16) – and while it can adjust its speed, appears to work almost continuously (Rezer and Moulins, 1983). The neurons in

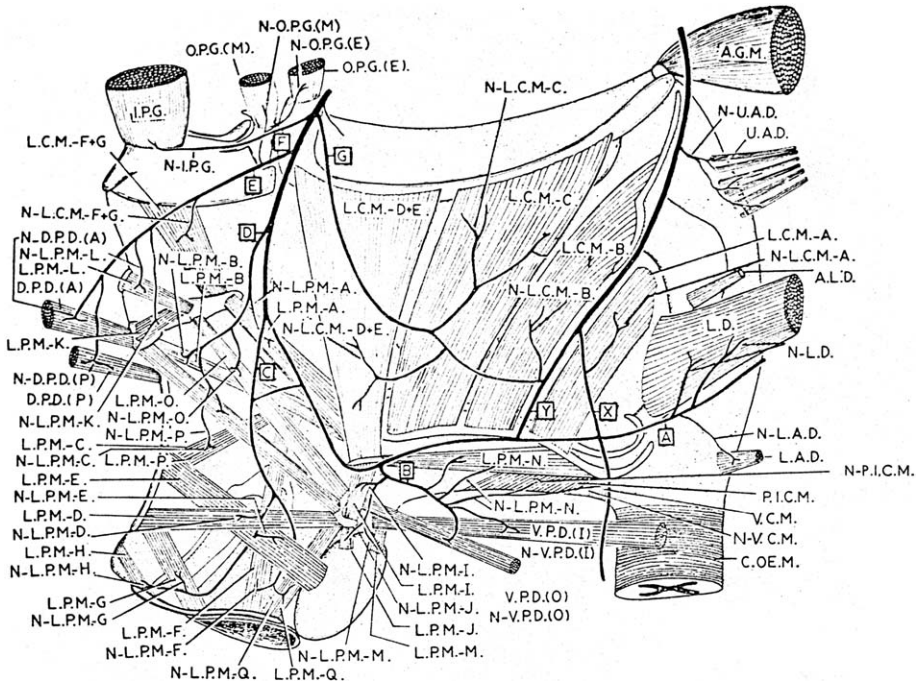

Figure 17 Diagramatic lateral view of the foregut of the crab *Paratelphusa guerinii* (Milne-Edwards) showing the muscles and their innervation.

both CPGs have dual functions. With the exception of two that are interneurons, the remainder have evolved specific biophysical and synaptic properties to not only produce coherent synchronized patterns as a result of their cellular properties and synaptic interconnectivity, but to also act as motor neurons transmitting spike potentials to the appropriate neuromuscular junctions. The distribution of the motor nerves supplying muscles in the lobster and crab are illustrated diagrammatically in Figures 16 and 17. Unlike the molluskan examples that have been discussed, the crustacean stomach muscles are striated and are morphologically and functionally identical to all other 'voluntary' muscles such as those in the limbs and therefore require neural input for contraction. The neurons therefore have dual functions: to generate the motor pattern within the ganglion and to signal the muscles outside the ganglion (shown for both rhythms in Figure 16). The synapses use both acetylcholine and glutamate but interestingly produce mainly inhibitory connections within the ganglion and exclusively excitatory connections at the neuromuscular junction. In addition, like some synapses in vertebrates, for example, in the retina, the stomatogastric neurons can release their neurotransmitters without a spike invading the presynaptic terminal, that is, as a graded function of membrane voltage at the synapse. At the neuromuscular junction, however, the release is pulsatile.

1.25.3.5.2 Inputs from higher centers The STG is connected to other parts of the CNS by a single input nerve, the stomatogastric nerve (SGN). This nerve is made up of four separate nerves that emerge from the paired CGs, the superior and inferior esophageal nerves (SONs and IONs). In addition, an unpaired nerve, the inferior ventricular nerve (IVN in Figure 16), emerges from the base of the supraesophageal ganglion and enters the esophageal ganglion at the point where the SONs and IONs come together to form the SGN. Two histaminergic fibers in the IONs synapse directly onto specific neurons in the STG. Other neurons with cell bodies in the esophageal ganglion turn on the gastric mill rhythm and strongly affects the pyloric rhythm by binding to muscarinic receptors (Nagy and Dickinson, 1983). Another neuron, the pyloric suppressor (PS) terminates the pyloric rhythm (Cazalets *et al.*, 1990). The types of descending neurons appear to differ among species and has by no means been worked on in comparative terms. For example, the European lobster *Hommarus gammarus* has two pairs of neurons, CGs and GIs, which act as command fibers for the gastric

mill (Combes *et al.*, 1999). The CG neurons excite the LPGs and GMs, while the GI neurons inhibit the LG, MG, and DG neurons. Each pair of neurons produces a different pattern and the combined action of the two determine the actual output.

1.25.3.5.3 The canonical STG circuit Although the stomatogastric system had been described anatomically in the 1800s (Mocquard, 1883), it was not until the advent of intracellular recording that detailed functional circuitry within the STG was described. There are four separate CPGs in the stomatogastric system – the gastric and pyloric CPGs are entirely contained in the STG, while the cardiac sac and esophageal CPGs have some neurons in the STG but the location of the other neurons has not been localized. The connections for some of the cardiac sac and esophageal neurons have been described but the complete CPG circuits are not known. However, the pyloric and gastric CPG circuitry has been fully described from work on many different species and although there is some variation in cell numbers (Tazaki and Tazaki, 1997), the overall 'canonical' circuitry (Figure 18) has been known for many years.

The pyloric and gastric mill neural circuits are shown in Figure 18. The pyloric circuit is comprised of two PD cells, eight PY cells, and one each of VD, LP, IC, and AB cells. The circuit was originally described by Maynard (1972) and completed in 1975 (Maynard and Selverston, 1975). In a combined preparation with the two CGs and the single esophageal ganglion intact, all of the neurons in the pyloric network burst intrinsically. Because they require neuromodulatory inputs from the commissurals, however, they are sometimes referred to as 'conditional' bursters. Without this modulatory input, the intrinsic conductances underlying bursting are not sufficiently activated and the cells are

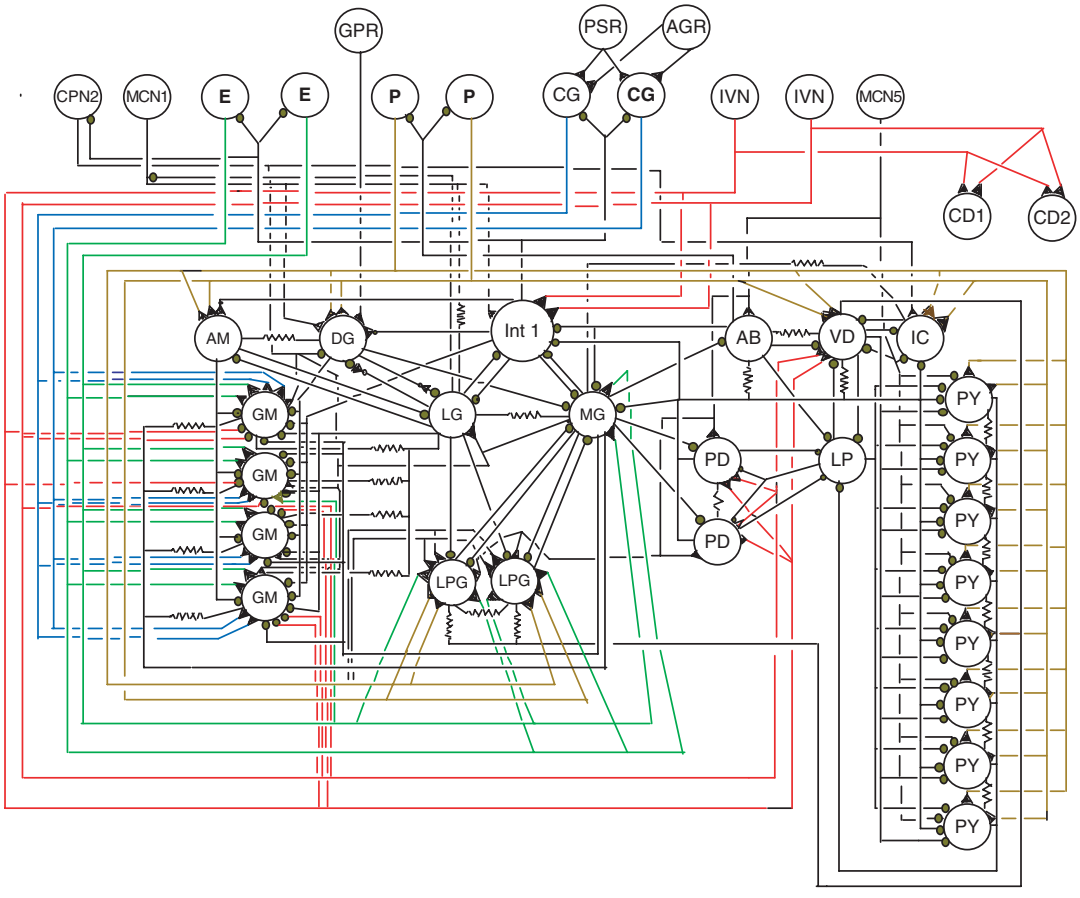

Figure 18 Canonical circuit for the lobster stomatogastric system. The left cluster containing the LG, MG, int 1, LPGs, GMs, and AM (11 neurons) make up the gastric mill CPG. The right cluster, PDs, AB, VD, IC, LP, and PYs (14 neurons), comprise the neurons of the pyloric CPG. Both pyloric and gastric CPG neurons are located in the STG. The E and P neurons are located in the CGs. Other neurons shown represent various sensory and neuromodulatory inputs to the STG and are discussed in the text.

either silent or fire slowly but not in bursts. The AB neuron occasionally bursts when isolated from neuromodulatory input and when inputs are present it has the fastest rhythm, thus acting as a pacemaker for the other pyloric cells. Simultaneous intracellular recordings can be obtained from all of the pyloric neurons. By deleting single neurons from the circuit sequentially, it has been shown how the synaptic connectivity and the intrinsic ability to burst combine to produce a robust three-phase burst pattern (Miller and Selverston, 1982). The ionic mechanism for bursting is different from that described for molluskan neurons. Basically a decrease in the K leak current depolarizes the neuron until a voltage-gated Ca and Na current is activated (Gola and Selverston, 1981). This increases the rate of the depolarization and activates the fast spiking and plateau currents. Inactivation of the Na and Ca currents combined with Ca-activated K current brings the cell back to its resting potential. Other currents, particularly I_A and I_H play an important role in burst timing and will be considered later.

The circuitry of the gastric mill CPG was established in 1974 (Mulloney and Selverston, 1974a, 1974b; Selverston and Mulloney, 1974) and has undergone only minor revision since then. The gastric mill CPG appears to work entirely as a result of the synaptic interactions with no single neuron or group of neurons acting as the pacemaker for the rhythm. The idea that within one ganglion there coexists two fundamentally different mechanisms (the other being intrinsically bursting cells) for generating motor patterns is unique but is logical if one considers the behaviors involved, the constant pumping of the pylorus and the intermittent grinding of the gastric mill.

The inhibitory synapses in the gastric mill play the determining role in pattern formation. The key LG and DG neurons evoke two types of IPSPs in follower neurons (Elson and Selverston, 1995). The fast type rises rapidly (100–300 ms), is mediated by an increased chloride and K conductance and resembles the glutamatergic IPSPs described for the pyloric CPG. The second, slow type of IPSP, has a long rise time (1–2 s) and is mediated by an increased conductance to K. The fast inhibition occurs alone at connections from DG and LG to power stroke motor neurons (MG and GM). Slow inhibition occurs in parallel with fast inhibition (producing dual component responses) at LG to LPG and Int 1. DG evokes a pure slow IPSP onto the LPG neurons.

While the two CPGs control separate stomach musculature, there are many direct synaptic and electrotonic connections between neurons belonging to each circuit (Figure 18). In addition, several neurons that are located in the CGs receive synaptic inputs from the neurons in each CPG and feedback timed inputs to neurons in both CPGs. This is most apparent in intracellular recordings from the DG and AM neurons, which show bursts of EPSPs that originate from P cells which are modulated by the AB neuron. Since each CPG operates at different frequencies, the possible functions of these connections has been investigated (Bartos *et al.*, 1999).

1.25.3.5.4 Ion channels in STG neurons As already mentioned, several voltage-gated channels are responsible for the intrinsic burst-generating mechanisms found in STG neurons. Several other channels are particularly important in controlling various aspects of the bursting behavior and therefore properties of the behavior itself. The somata of STG neurons contain only outward ion channels and are inexcitable (Graubard and Hartline, 1991; Golowasch and Marder, 1992). Two of the other important currents located on the processes in the neuropile are I_H and I_A – both found to a greater or lesser extent in all STG neurons. I_H is activated by hyperpolarized voltages and plays an important role in determining the extent of PIR which occurs after inhibition. I_A is a transient depolarization-activated K current which delays the onset of bursting. Voltage clamp studies on individual pyloric neurons have shown that the distribution of I_A channels differs between cells. It is largest in PD and PY cells, smaller in AB, LP, and IC cells and not detectable in the VD cell (Tierney and Harris-Warrick, 1992). When I_A currents are blocked with 4-AP, the cycle period is decreased by ~20%; there is a general enhancement of activity in all of the cells and there is a change in phasing of follower cells with respect to the PD/AB pacemaker group.

1.25.3.5.5 Chemical modulation The cells of the STG require modulatory input from the CGs in order for rhythmic activity to take place. The CGs release an as yet unknown mixture of neuromodulatory substances into the neuropile of the STG thus enabling the gastric and pyloric CPGs to operate. The modifications to the cellular conductances are due to phosphorylation mechanisms following the activation of kinases by second messenger systems, the concentrations of which have been raised by G-protein/membrane receptor interaction with the neuromodulators. The ionic conductances have kinetic profiles which are directly responsible for establishing burst periods in isolated cells by acting on slow conductances and this along with the

synaptic strengths of the faster ionotropic synapses determine the temporal and spatial characteristics of the motor pattern. So if we consider the isolated STG, we see that there have evolved a large number of overlapping mechanisms that are present which control the output patterns driving the gastric and pyloric regions of the stomach. The CPGs, with neuromodulatory input from the two higher ganglia generate the basic autonomous pattern. Various combinations of other modulatory substances, mostly amines and peptides, can also be released into the ganglion to produce many different patterns by:

- reconfiguring the gastric or pyloric circuit to generate different variations of the main pattern;
- switching one or more neurons from one pattern to another;
- combining a subset of neurons from several CPGs to form an entirely new circuit; or
- fusing two complete CPGs to form a new combined circuit generating a new and novel pattern.

The modulators can be released from the terminals of neurons or be carried to the neuropil in the blood after being released from neurohemal structures such as the pericardial organ. Together, these mechanisms allow the neural circuits controlling the viscera to produce many more motor patterns than are required to process food. Since it has not been experimentally tractable to record both rhythms while at the same time monitoring the levels and types of neuromodulators present in the STG neuropil, the reason for all this flexibility is not known. Nevertheless, it is unlikely that all of these mechanisms were selected for without their having some function, at least some of the time, but at present one can only speculate whether or not they are historical leftovers or really have a clear purpose.

1.25.3.5.6 Sensory control The stomach wall and the striated muscles that operate the gastric mill and pyloric pump contain sensory receptor cells sensitive to stretch (mechanoreceptors) and others inside the gut that respond to chemical stimuli. Not all of these have been investigated in the stomatogastric system but single sensory fibers have been shown to be able to affect the pattern on a cycle-by-cycle basis. Receptors in the posterior part of the stomach (PSRs) are stimulated by rhythmic movements and their action, via the CGs, is to activate both the gastric and pyloric rhythms (Nagy and Moulins, 1981). One feedback mechanism that has been described is a sensory neuron (AGR) close to the STG that receives stretch receptor innervation from the powerful GM muscles. The AGR can either enhance or restrain the output to these muscles depending upon the amount of force being sensed (Simmers and Moulins, 1988). In this sense, the AGRs act like both the Golgi tendon organs and muscle spindles of vertebrates which evolved quite separately to perform similar functions. The AGRs in the European rock lobster *Hommarus gammarus* synapse onto two pairs of command neurons called CG and GI which are located in the CG. When the gastric mill is active *in vitro* weak firing of the AGR occurs in time with the gastric mill rhythm, when all the power stroke neurons are synchronously active. However, with strong AGR firing, the phase relationships switch to a different pattern in which lateral and medial teeth motor neurons fire in antiphase (Combes *et al.*, 1999). In this case, the feedback from a single mechanosensory neuron is able to specify two different motor pathways in an activity-dependent manner.

Another set of stretch receptors call the gastropyloric receptors (GPRs) do not act via the CGs but instead form a closed loop system in which the GPRs display endogenous rhythmicity (Katz and Harris-Warrick, 1990a). The GPRs found in crabs activate the pyloric rhythm via cholinergic mechanisms and cause some of the gastric mill neurons to fire in pyloric time. The later result appears to be due to the co-release of serotonin (Katz and Harris-Warrick, 1990a, 1990b). Finally, bilateral sensory neurons in the cardiac gutter of the crab stomach project to both the gastric and pyloric feeding circuits (Beenhakker *et al.*, 2004). When stretched artificially, these neurons initiate chewing movements and modify the pyloric filtering movements via projection neurons in the CGs.

1.25.3.5.7 Evolution of the stomatogastric system The question of how visceral nervous systems evolved is complicated by the fact that a comparative study of the systems described in this chapter (leech heart, snail, and aplysia feeding, etc.) has not been undertaken. That is understandable since most of them were investigated with other goals in mind – generally a mechanistic description of how rhythmic patterns are generated in animal models. However, in order to understand how these systems evolved, we have to look at the same system in a variety of different species that have evolved at different times based on phylogenic descriptions. Commonalities and differences between species can suggest hypotheses for how the system evolved to its present form. The stomatogastric system is probably the only one of these systems that has been studied in sufficient detail and at enough different levels to attempt this comparison. An excellent description of the evolution of the stomatogastric system has been put forward by Katz

(1991) and by Katz and Tazaki (1992). One principal outcome of these studies has been the suggestion that while the neural circuits have remained stable over time, enormous variations in neuromodulators and external structures have evolved to meet the needs of animals living in different environments and utilizing different food sources.

The phylogenetic tree for the decapod crustaceans shown in Figure 19 is a compilation of various phylogenetic classification schemes (Burkenroad, 1983; Bowman and Abele, 1982; Schram, 1986; Kim and Abele, 1990) that have been suggested by Katz and Tazaki (1992). Such an analysis is important in tracing the evolution of the nervous system since there is no fossil record and the only possible approach is a phylogenic tree.

The Katz–Tazaki formulation makes it quite clear that the changes which have occurred in the stomatogastric system over evolutionary time can be studied by examining various decapod classes and though incomplete, is probably better than any other analysis of neural systems. Figure 20 shows three stomatogastric systems from the clawed lobster *Homarus*. The Caribbean spiny lobster *Panulirus argus* and the crab *Callinectes* are illustrated diagrammatically. The organization at the level of the major ganglia is similar, with the subesophageal ganglion connecting to the paired CGs which in turn connects to the esophageal ganglion (og) via the paired SONs and IONs (son and ion). These four nerves coalesce to form the SGN, the principal input to the pattern generators in the STG. The principal variation between these three species appears in the arrangement of motor nerves leaving the ganglion. This is due to the different size and position of ossicles within the gastric mill (Figure 21) and the different arrangement of muscles in both the gastric mill and pyloric regions of the stomach (see also Figure 17).

The anatomical differences that have evolved extend to the arrangement of neurons in the CPGs as can be observed in Table 1, which is a

compilation of elements making up five different crustacean pyloric systems (Tazaki and Tazaki, 1997). As a result, there are also differences in the motor output patterns and synaptic connectivity between pyloric neurons (Figure 22).

The constancy in structure and CNS topology lends some credence to the idea that overall the principal features of decapod visceral control evolved in a similar way and that fine-tuning of these circuits may be more the result of neuromodulator variation than the rearrangement of neurons and synapses.

1.25.4 Some General Conclusions Regarding the Evolution of Visceral Nervous Systems

- Using the same components – neurons, synapses ion channels, etc. – all visceral nervous systems have evolved rhythmic central pattern-generating networks with which to control automatic functions such as digestion, circulation, and respiration.
- These CPGs are robust and sensitive due to their intrinsic dynamics.
- Cellular and synaptic properties are stable despite channel turnover and plastic changes due to homeostatic mechanisms.
- Neuromodulators provide multifunctionality to circuits by altering their cellular and synaptic properties via second messenger-induced phosphorylation mechanisms.
- Neurons forming visceral control mechanisms are generally located in ganglia near the structures being controlled. Within the ganglia, neurons can be identified based on location, physiological properties, connections with other neurons and effector organs, molecular properties, and many other criteria.

1.26 Cognition in Invertebrates

R Menzel and B Brembs, Freie Universität Berlin, Berlin, Germany
M Giurfa, Université Paul Sabatier, Toulouse, France

Glossary

classical conditioning Learning about relationships in the environment.

cognition The use and handling of knowledge.

episodic memory In humans the consciously recollected memory for facts and events as they are characterized by their contents (what), their time of occurrence (when), and their locations (where). Episodic-like memory in animals stores the what, when, and where for important events (food). (See Section 1.26.6.)

explicit knowledge Knowledge encoded as representations, such as places, facts, and events.

habituation Reduction of responsiveness after multiple application of the same stimulus. Habituation is discriminated from sensory adaptation and motor fatigue by its stimulus specificity, spontaneous recovery, dishabituation by a strong stimulus, and by a saving effect (stronger response decrement after multiple sessions of habituation).

implicit knowledge Knowledge encoded in actions and associations, for example, acquired through predictive learning.

innate preferences, innate stereotypy Simple forms of behavior based on phylogenetic memory.

nonelemental learning Associative forms of learning in which individual events are ambiguous and only logical combinations of them can be used to solve the problem. Examples are described in Section 1.26.4.

occasion setting A learning situation in which a stimulus, the occasion setter, sets the occasion for when a predictive

	relationship applies. Contextual learning is closely related to occasion setting (see Section 1.26.5.3).
operant conditioning	Learning about the consequences of one's own behavior.
phylogenetic memory	The species' memory. The information stored in the genome as acquired by mutation and selection during evolution.
predictive learning	Using operant and classical conditioning to predict future events.
rule learning	The ability of an animal to infer rule information from a number of different examples connected by a common feature (see Section 1.26.5).
search image	Animals searching for a target the knowledge about which has either been learned or is known on the basis of innate information (phylogenetic memory).
sensitization	Increase of responsiveness after the experience of a strong stimulus.
working memory	A transient form of active memory that combines both information retrieved from a permanent store and actual incoming information (see Sections 1.26.6.1 and 1.26.6.2)

1.26.1 Introduction

Animals are characterized at all levels of neural complexity by a continuous flow of energy, material, and information. Behavior is an animal's means for surviving the destructive forces of entropy on both long and short timescales. Evolution maintains and in most cases improves complexity over multiple reproductive life cycles. To achieve this goal the environment evaluates stochastic changes in the material inheriting the organism's organizational information, and the information thus selected is transmitted from one generation to the next. Thus, evolution is in essence an information-creating (in some cases information-destructing) process, and the inherited information characterizing each organism may be called the species-specific phylogenetic memory.

Animals also collect and store individual memories on a short timescale through learning by experience. Information based on repeated experience gathered by an individual organism in attempts to cope with the immediate demands of the environment is evaluated through environmental feedback, either reinforcing or reducing the impact of the underlying cellular mechanisms on the organism's future responses. Individual memory is therefore based on learning, which is the capacity to modify the individual's behavior on a relatively permanent basis through the acquisition of new information based on individual experience. Both kinds of memory, phylogenetic and individual memory, can be understood as organismic devices to predict the future and to reduce the environment's uncertainty. They are thus instantiations that link the past with the future, creating a present that is better adapted to the organism's requirements. Individual memory is incorporated into the framework provided by the phylogenetic memory, facilitating and shaping individual learning processes. Thus, the framework within which experience-based learning occurs is tuned to the demands expected during the individual organism's lifetime.

Cognition can be viewed as the integrating process that utilizes both forms of memory, creates an internal representation of the world and a basis for expecting the future of the animal's own actions within the experienced environment. It thus allows the animal to decide between different options in reference to the expected outcome of its potential actions. All these processes occur as intrinsic properties of the nervous system and provide an implicit form of knowledge for controlling behavior. None of these processes need to – and certainly will not – become explicit within the nervous systems of most invertebrates, but, as this review will show, such processes must be assumed to also exist in invertebrates with proper nervous systems (albeit over a large range of levels of complexity) to account for their behavior.

The results of these integrating cognitive processes are manifold and can span a gradient of possibilities. In such a gradient, at one extreme, one can find organisms dominated by their inherited information and having minimal experience-based adaptation; at the other extreme, phylogenetic memory may merely provide a broad framework, and experience-based memory will dominate. The factors determining the specific combination and weights of inherited and experience-dependent memories in an individual are not yet well understood. A short individual lifetime, few environmental changes during a lifetime, and highly specialized living conditions will favor the dominance of inherited information; a longer individual lifetime, less adaptation to particular environmental niches, and rapid environmental changes relative to the life span reduce the impact of phylogenetic memory and increase the role of individual learning. Social living style also seems to be a defining factor for the balance between these different forms of memory. In social animals, learning has to play an important role, because the species' genome must equip the individuals for acting under much

more variable environmental conditions because of the society's longer lifetime, and because the communicative processes within the society demand a larger range of cognitive processes.

It has also been suspected that the complexity and size of the nervous system may be related to the dominance of inherited or experience-dependent memories, in the sense that individual learning demands a larger nervous system having greater complexity. However, the primary parameter determining the size of the nervous system is body size, and secondary parameters such as richness of the sensory world, cognitive capacities, and abundance of motor patterns are difficult to relate to brain size, because such parameters cannot be adequately measured, and thus a comparison based on them is practically impossible between animals adapted to different environments. Although the relationship between brain size and cognitive capacity is still unclear, it is obvious that animals differ with respect to their sensory, motor, and cognitive capacities (see Evolution of the Elephant Brain: A Paradox between Brain Size and Cognitive Behavior). Individual learning within the species-specific sensory and motor domains will lead to more flexible behavior, and thus to more advanced cognitive functions. Predicting the future will therefore be less constrained, and more options will enrich the animal's present state.

Although we do not attempt to strictly define the cognitive components of behavior, the essential characteristics of cognition are: (1) rich and cross-linked forms of sensory and motor processing; (2) flexibility and experience-dependent plasticity in choice performance; and (3) long-term (on the timescale of the respective animal's life span) adaptation of behavioral routines. These three features allow the creation of novel behavior through different forms of learning and memory processing. Among them, we can cite (1) rule learning, (2) observatory learning during navigation and imitation, and (3) recognition of group members and individuals in a society. All these characteristics are based on implicit forms of knowledge and do not require any explicit (or conscious) processing. However, internal processing at the level of working memory (or representation) as an indication of rudimentary forms of explicit processing may exist in invertebrates within the context of observatory learning and social communication, and will be discussed.

We shall first consider forms of behavior that are dominated by innate components, and raise the questions of how innate and learned behavior are related and whether innate behavior involves cognitive components. The following sections focus on experience-dependent forms of behavior and follow in the order of ascending complexity: from elemental forms of associative learning to rule learning and observatory learning in navigation and communication. A key component in cognition is memory, not only as a storing device, but also in the form of working memory, the implicit form of representation which may provide the substrate for neural operations underlying decision making in relation to the expected outcome of the animal's actions. Both aspects of memory will be discussed.

1.26.2 Dominance of Innate Behavior

Invertebrates are dominated to a great extent by innate behavior, and some researchers have gone so far as to characterize insects and crustacea as "mindless machines" (Gould and Gould, 1982). Historically, innate preferences for biologically relevant sensory cues were used to characterize innate behavior. This view, which is still represented in ecological approaches to invertebrate behavior, assumes that invertebrates are irresistibly attracted to some sensory cues, which act as magnets on different phases of invertebrate behavior. At the origin of this notion, one can certainly find the preconception that invertebrates are essentially reflex machines with limited forms of experience-dependent plasticity. Although we shall focus on learning-related flexibility as a characteristic of invertebrate cognition, it is worthwhile to first recognize the complexity and richness of innate sensory–motor routines and their relationship to learned behavior.

1.26.2.1 Selection of Habitat, Feeding, and Foraging

Earthworms not only eat their way through the soil, swallowing the dirt they encounter, but feed selectively in many ways, as described by Darwin (1882). They leave unsuitable ground and select more productive soil, and they crawl out of their burrows at night to feed on the leaves of certain plant species. The earthworm grasps the tapered tip opposite the petiole, and then pulls the leaf back into the burrow to be eaten underground (Edwards and Lofty, 1972). Selection of habitat and food sources is commonly based on 'search images', innate sensory–neural filters that inform the animal about the desired food. Innate preferences are difficult to demonstrate because they require an absolute control of the animal's experience prior to the experiments in which it is confronted with the stimuli to be tested. If such control is absent, it is practically impossible to conclude anything about potential innate preferences, because the animal's

choice may simply reflect its previous experience with natural stimuli in its environment. Despite the difficulty of achieving such a control, some studies have appropriately addressed the question of innate preferences and showed that such preferences do indeed exist. However, they have also pointed out that choice behavior driven by this programmed signal responding is subjected to dramatic modifications based on first experiences. Thus, although such preferences may exist, they seem to be essentially useful in guiding the animals' behavior in their first confrontations with the external world.

A clear example of changes in innate preferences due to previous experiences is provided by the cuttlefish *Sepia officinalis*. In this animal, Darmaillacq *et al.* (2004a) recently showed that on the third day post-eclosion, when the young cuttlefish have consumed their vitellogenic resources, they exhibit clear preference for shrimps over crabs and young fish of comparable sizes. However, by making the preferred prey distasteful with quinine, it is possible to induce a preference for an originally nonpreferred prey item in 3-day-old and naïve cuttlefish, demonstrating the flexibility of this initial behavioral preference in response to previous individual experience. Such a learning is extremely fast (Darmaillacq *et al.*, 2004b), a fact that indicates to what extent innate preferences may be easily modified.

In insects, several studies have addressed the question of appetitive choice behavior as driven by innate preferences. In the moth *Helicoverpa armigera*, for instance, Cunningham *et al.* (2004) have shown that experience-deprived adult moths raised in isolation exhibit innate preferences for phenylacetaldehyde when tested in dual-choice wind tunnel tests. Again, this preference changes rapidly if a nonpreferred volatile substance is paired with a feeding stimulus (sucrose solution). In honeybees, a similar result was found with respect to color preferences. Honeybees whose visual experience was strictly controlled in a flight cage in which no rewards were provided on colored targets showed consistent preferences for some dominant wavelengths when presented with such targets in their first active foraging flight (Giurfa *et al.*, 1995). Colors preferred by naïve bees were human-blue and human-yellow, which correspond to those hues that experienced bees learn faster and better when trained with a single color/sucrose reward association (Menzel, 1967). However, all other hues which are originally not chosen rapidly become preferred if they are explicitly paired with sucrose reward (Giurfa *et al.*, 1995).

The intimate connection between innate and learned behaviors and their mutual replacement for behavioral control also becomes obvious in host selection by the two species of the stem-borer parasitoids *Cotesia glomerata* and *Cotesia flavipes* (Hymenoptera, Braconidae) (Geervliet *et al.*, 1998; Potting *et al.*, 1997; Vet, 1996; Vet *et al.*, 1995). While *C. flavipes* exhibits innate preference for its host's odors, the larvae of *Pieris brassica* (Lepidoptera), the closely related *C. glomerata*, learns the varying odor profiles of its Pieris host larvae, which depend on the plants it feeds on. No other differences in behavior between these two species were found, indicating that experience-dependent adjustment and innate stereotypy are two close strategies and are not related to any great differences between the neural systems involved.

The interesting question of whether innate preferences are deleted or inhibited by experience (and thus available at different moments of an invertebrate's life) has been addressed in bumblebees (Gumbert, 2000). Naïve bumblebees show color preferences that are similar to those exhibited by honeybees. After being trained to a given colored target by pairing it with sucrose reward, the bees chose novel test colors according to their similarity to the trained color. Thus, bees generalized their choice from the trained to novel, similar colors; however, if the trained and the test colors were perceptually dissimilar to the bees such that generalization did not occur, the original innate color preferences reappeared and guided the bees' choices. Thus, bumblebees show innate preferences for certain colors not only prior to color learning but also after intensive learning when choosing among very different novel colors (Gumbert, 2000).

These chosen examples among many similar ones from other invertebrates allow us to conclude that (1) invertebrates exhibit innate preferences for signals allowing to rapidly and efficiently detect biologically relevant stimuli in their first encounters with them; (2) such preferences can be drastically modified by the animals' experience such that plasticity and not rigidity of behavior should be underlined in the case of innate preferences; and (3) such preferences can be available in experienced adults such that they can be retrieved under particular circumstances, when the learned information is no longer useful. It is still unknown how these preferences can be hard-wired in the naïve invertebrate nervous system, but they have been selected through the species' evolutionary history and thus belong to its phylogenetic memory.

1.26.2.2 Early Programmed Learning

Early programmed learning occurs in young animals exposed to particular stimuli during a critical period. As a consequence of this process, also called imprinting, the animal later prefers the 'imprinted' stimuli. This kind of programmed learning has also been documented in invertebrates, particularly in insects. For instance, mosquitoes *Culex quinquefasciatus* use chemical cues to locate suitable water pools for oviposition. An individual mosquito's preferences for these odors can be altered greatly by prior experience (McCall and Eaton, 2001). In particular, change in odor preferences could be demonstrated following exposure to the odor during development or pupal eclosion, suggesting that some form of larval or early adult imprinting occurred.

In social Hymenoptera, parental relationships involve the use of specific signals, some emitted by the young animals, and others by the adults. Some of the signals are learned during an early experience (Dobson, 1989). The behavioral responses of parasitic wasps to chemical cues from their hosts and host plants are known to be affected by genetic and environmental components. Gandolfi *et al.* (2003) have shown that true pre-imaginal learning of olfactory cues occurs in the parasitic wasp *Hyssopus pallidus*. While parasitoids are not able to learn the fruit cues in the adult stage, exposure to fruit odor at early pre-imaginal stages significantly increases the adult response to frass from fruit-fed caterpillars (Gandolfi *et al.*, 2003). The olfactory memory persisted through metamorphosis, with a retention time of 14 days. Pre-imaginal learning was not confined to fruit cues, but was also demonstrated for menthol, an olfactory host- and fruit-independent cue.

A fascinating case of imprinting in insects is provided by studies on slave-making ants, which are characterized by socially parasitic founding of colonies (i.e., colonies in which two species of social insects coexist, one of which is parasitically dependent on the other) and the pillage of broods from neighboring host colonies during slave raids. Slave-making ants invade colonies of other ant species and transport the pupae back to their own nest. Adults emerging from these pupae react and work for the slave-making species as if it were its own species (Isingrini *et al.*, 1985; Carlin and Schwartz, 1989). The basis for such phenomenon may be olfactory imprinting processes by which the slave ants learn to recognize the slave makers as members of their own species. This hypothesis is subject to debate because it has been argued, for instance, that the capacity of larvae to imprint on the odor of their natal nest might make an ant species unsuitable for slave makers. An ant worker pillaged as pupa after pre-imaginal imprinting might identify slave-maker brood as alien and refuse to care for them (D'Ettorre and Heinze, 2001). However, the problem is solved if the hydrocarbon cuticular profiles, the distinctive olfactory mark of each species, of both the slaves and the slave makers are similar. This seems to indeed be the case (Lenoir *et al.*, 2001; D'Ettorre *et al.*, 2002).

The mechanistic basis of early olfactory learning has been studied in some insects. In the fruit fly *Drosophila melanogaster*, Devaud *et al.* (2003) showed that synaptogenesis in the antennal lobe, the primary olfactory neuropile in the insect brain, starts in late pupa and continues during the first days of adult life, at the same time as the behavioral response to odors matures. The antennal lobe is made up of functional units with a globular structure called the glomeruli, which can be recurrently identified due to their position and morphology. Individual olfactory glomeruli (DM6, DM2, and V) in *Drosophila* display specific growth patterns between days 1 and 12 of adult life. Experience can modify the olfactory pathway both structurally and functionally, as shown by adaptation experiments. The modifications associated with this form of learning seem to take place at a critical age. Exposure to benzaldehyde at days 2–5 of adult life, but not at 8–11, causes behavioral adaptation as well as structural changes in DM2 and V glomeruli. Taken together, these data demonstrate an imprinting-like phenomenon in the olfactory pathway of young *Drosophila* adults, and illustrate its glomerulus-specific dynamics.

1.26.3 Elemental Forms of Associative Learning

Rapid changes in environmental contingencies require flexible capacities with which organisms can come to expect biologically significant events and modify their behavior in anticipation of those events if behavior is to remain adaptive; that is, increase the probability of obtaining beneficial consequences and avoiding harmful ones (Reif, 1998; Sutton and Barto, 1998; Dickinson and Balleine, 2002). The acquisition of such anticipatory behavior relies on simple associative principles.

These principles are centered on computing error signals: whenever the current expectation is violated, error signals trigger processes in the brain which serve to both keep the animal's expectation

up-to-date and minimize such errors. The most potent error signals are generated by unexpected situations or events with biological relevance (i.e., an unconditioned stimulus, US): upon first perceiving such an unexpected US, coincidence detectors evaluate any neural activity preceding or overlapping with the error signal generated by the US. *A priori* it is irrelevant if this neural activity stems from the animal's behavior (abbreviated: BH) and/or from any environmental stimulation (i.e., a conditioned stimulus, CS). The preceding events can serve as predictors of the US, if their temporal connection with the US is consistent enough. Depending on the state of the animal and the nature of the environment, several more encounters with the US and its preceding events are required for a reliable memory to form. A reliable memory means that fully expected USs no longer generate any error signals, and hence the animal does not need to update its expectations any further. In such a state, the animal can behave adaptively: it expects the consequences of any behavior or situation.

There are two basic ways in which such memories can be acquired. In operant (or instrumental) conditioning the behavior (BH) of the animal is essential for these memories to form; indeed, it is the predictor by which the animal controls the occurrence of the US. If, on the other hand, the animal's behavior is dispensable for learning to occur, the situation is termed classical (or Pavlovian) conditioning. In freely moving animals, these two systems work together to guide adaptive behavior; Pavlovian learning often provides information to guide the selection of a particular behavioral strategy. But these systems can also work independently and even in opposition to one another (Ellison and Konorski, 1964; Balleine, 2001).

1.26.3.1 Invertebrate Classical Conditioning

The main associative principle for the conceptual understanding of classical conditioning is the notion of stimulus substitution (Pavlov, 1927). In the naïve animal, the CS initially triggers no or little response, that is, there is a transmission block from the sensory pathway to the motor circuits. If this CS is paired consistently enough with an initially unexpected US, the locations in the nervous system where the sensory information about the two events converge are modified such that the CS now comes to elicit a behavioral response, often mimicking the response to the US. The pairing has created new connections or removed transmission blocks so that the sensory circuitry processing the CS can now access some of the response-producing motor circuits that were previously engaged only by the US. By acquiring some of the response-eliciting properties of the US, the CS prepares the animal for the US and minimizes the error signals that future USs generate.

For instance, in *Aplysia* skin, sensory neurons make direct synapses onto motor neurons that control the defensive gill withdrawal reflex. Upon a light touch to the naïve animal's siphon, these sensorimotor synapses fail to conduct and the gills are not withdrawn. However, if the touch is repeatedly paired with a noxious stimulus (such as an electric shock) which does elicit gill withdrawal, the light touch alone eventually comes to elicit a gill withdrawal, whereas before such training it did not (see, e.g., Kandel *et al.*, 1979, 1983; Walters *et al.*, 1979, 1981; Carew *et al.*, 1981, 1983, 1984; Kandel and Schwartz, 1982; Hawkins *et al.*, 1983, 1986, 1989, 1998; Walters and Byrne, 1983a, 1983b; Abrams and Kandel, 1988; Byrne *et al.*, 1990). This increase in synaptic efficacy (facilitation) is brought about by the action of the neuromodulator serotonin released by modulatory interneurons during the electric shock. The sea slug *Aplysia* was most helpful for identifying synaptic facilitation as an instance of stimulus substitution and thus establishing a neurobiological basis for a psychological concept.

The discovery of such simple biological processes was of tremendous importance for the study of classical conditioning in more complex invertebrate brains such as those of insects. This can be exemplified in olfactory learning. The similar structure of the first few processing stages of smell in vertebrates and invertebrates is intriguing. Sensory neurons expressing the same olfactory receptor converge on aggregates of glomerular neuropil structures, where they synapse onto local interneurons and projecting neurons. In both vertebrates and invertebrates the pattern of neural activity in the glomeruli is odor specific. In insects, the projection neurons transmit this pattern to the next synapse in the calyces of the mushroom bodies. Evidence from aversive conditioning in *Drosophila* and from appetitive conditioning in *Apis* points toward an initial CS conduction failure either at the input synapse, or the output synapse of the mushroom body Kenyon cells, or suggests additive effects at both (Heisenberg, 2003). In *Drosophila*, a group of animals is exposed to one of two initially equivalent odors at a time in a vial coated with an electried grid (e.g., Tully and Quinn, 1985; Tully, 1991; Tully *et al.*, 1994). One of the odors is paired with an electric shock. After a few such odor–shock pairings, the animals are exposed to each of the odors

from opposing vials in a decision chamber and have to make a choice between the odors. In a successful conditioning experiment, the large majority of flies will avoid the odor associated with the shock. In the honeybee, individually harnessed hungry animals initially rarely respond to an odor presentation with an extension of their mouthparts (proboscis), whereas they will almost invariably do so if a sugar solution touches their antennas (e.g., Menzel, 1990; Menzel and Müller, 1996). If the odor is paired with the sucrose stimulation even only once, a stable memory of this association is formed and the animal will exhibit the conditioned proboscis extension response (PER) to future presentations of the odor alone. In both insects, the information about the identity of the odors is relayed to the behavior-initiating centers deep in the brain via the glomerular olfactory lobes and the mushroom bodies. Neurons containing the neuromodulators octopamine and dopamine have been found which could modulate any of the synapses in this pathway (Hammer, 1993, 1997; Schwaerzel *et al.*, 2003). Interestingly for the notion of expectation and anticipation, the octopaminergic neuron VUM_{mx1} exhibits activity paralleling the animal's expectation: it responds to unexpected sucrose presentations, but not to expected ones (Hammer, 1993, 1997). While there is evidence in vertebrates of how this reduction in the error signal may be implemented biologically, such evidence is still lacking in invertebrates. Conditioning using the PER has been so successful that it has been established in other insects such as moths and flies (Medioni and Vaysse, 1975; DeJianne *et al.*, 1985; Holliday and Hirsch, 1986; Brigui *et al.*, 1990; Fan *et al.*, 1997; Fresquet, 1999; Hartlieb *et al.*, 1999; Daly and Smith, 2000; Fan and Hansson, 2001; Skiri *et al.*, 2005) and for use with mechanosensory stimuli (Giurfa and Malun, 2004).

There is another advantageous snail model system for predictive learning, the pond snail *Lymnaea*. Its feeding behavior can be classically and its respiratory behavior operantly conditioned. Appetitive classical conditioning of *Lymnaea* feeding behavior involves either a tactile (touch to the lips) or a chemical (amylacetate) CS and a sucrose US (Kemenes *et al.*, 2002; Jones *et al.*, 2003; Staras *et al.*, 2003; Straub *et al.*, 2004; Fulton *et al.*, 2005; Korneev *et al.*, 2005). A single presentation of either CS with a sucrose solution will enhance *Lymnaea*'s bititing frequency in the presence of future CSs presented without the sucrose. Changes in neuronal activity and cellular properties that were recorded following tactile conditioning occur at all levels of the system, including central sensory pathways, modulatory interneurons, central pattern generator (CPG) interneurons, and motoneurons involving several possible plasticity sites. *Aplysia* biting behavior can be conditioned similarly (Lechner *et al.*, 2000a, 2000b). A brief touch to the lips with a small brush (CS) does not usually elicit a bite. But when this touch is consistently paired with a food reward (US), the touch alone suffices to elicit the bite. This procedure has been transferred to a reduced preparation, where peripheral nerve stimulation replaces the CS and US and motor nerve recordings monitor the behavior (Mozzachiodi *et al.*, 2003).

A third molluskan model system, the predatory snail *Hermissenda*, has revealed principal aspects of classical conditioning. The conditioning procedure consists of pairing light CS with high-speed rotation, or orbital shaking (US) which are aversive stimuli for the snail (Crow, 2004). Two responses are elicited by rotation, a reduced rate of forward locomotion and foot shortening. The two sensory structures mediating the CS and US are central, and thus their synaptic projections remain intact after isolation of the nervous system. Because the neurons that contribute to the neural circuitry controlling the unconditioned responses (URs) and conditioned responses (CRs) are identified, and can be studied in semi-intact nervous systems, an explanation is within reach of how conditioning is expressed in behavior generation.

Recently, earthworms have also been classically conditioned to anticipate potentially dangerous illumination after a brief vibration by longitudinally contracting their body (Watanabe *et al.*, 2005). Other invertebrate model systems for classical conditioning include cockroaches and crickets (Matsumoto and Mizunami, 2002, 2004; Matsumoto *et al.*, 2003; Watanabe *et al.*, 2003; Kwon *et al.*, 2004; Lent and Kwon, 2004; Pinter *et al.*, 2005).

The notion of predictability and error signal minimization developed mainly from classical conditioning experiments. In the course of these experiments, a number of paradigms were developed which now can be used to probe invertebrate preparations for the biological substrate underlying these learning phenomena. The first hint at predictability at the chore of classical conditioning came from its strict dependence on the relative timing of CS and US. In order for classical conditioning to occur, the onset of the CS has to occur before the onset of the US. Simultaneous or reverse (backward) pairings yield very little to no learning (Hellstern *et al.*, 1998). This result also contradicts the notion that simple pairings were sufficient for conditioning to occur. The next challenge to the simple pairing

hypothesis was to randomly add US-alone presentations, so as to render the CS nonpredictive, but to preserve the total number of paired CS–US presentations from successful experiments. Strengthening the predictability hypothesis, a US that is presented equally often with or without the CS prevents any CS–US conditioning that would normally have occurred (Rescorla, 1968). More sophisticated experiments included a second CS. In sensory preconditioning (Brogden, 1939; Kimmel, 1977), CS1 and CS2 are first presented together, without any US. In a second training phase, one of them (CS1) is paired with the US until the CS1–US association is formed. In the test phase, CS2 is tested alone. Successful sensory preconditioning experiments also contradict the simple pairing hypothesis, since CS2 was never paired with the US (Brembs and Heisenberg, 2001; Guo and Guo, 2005; for the honeybee, Müller *et al.*, 2000). In blocking experiments (Kamin, 1968), a first training phase consists of CS1–US pairings. In the second training phase, CS2 is added, so that the compound CS1–CS2 is paired with the US. The idea behind this experiment is that the prediction error signal for the US is zero after the first training phase (CS1 fully predicts every US occurrence) and as such nothing will be learned about the 'redundant' CS2. Hence the term 'blocking': the learning about CS1 blocks any learning about CS2, even though it was paired with the US sufficiently to produce classical conditioning had the first training not occurred (see Brembs and Heisenberg, 2001 for invertebrate literature on blocking). In the honeybee, the data on blocking are controversial (Smith and Cobey, 1994; Gerber and Ullrich, 1999). It is yet to be resolved whether the kind of odor stimulus (Linster and Smith, 1997) or the adequate control group will help to determine that blocking is a reliable phenomenon.

Perhaps not very surprisingly, all mechanisms and changes found to subserve classical conditioning in any of the above-mentioned model systems affect the CS pathway, emphasizing the universal role stimulus substitution plays in classical conditioning.

The relationship between classical conditioning procedures and predictive learning has often provided the justification for using this paradigm to study the neural bases of animals' basic cognitive or representational capacities. Nevertheless, it is rarely recognized that, at an adaptive level, cognitive capacities, such as those involved in encoding the predictive relations between stimuli, can be of little functional value to the purely Pavlovian organism. The sensitivity of cognitive systems to sources of information would seem more likely to provide the basis for modifying, even withholding or reversing, the direction of behavior in response to that information, something that demands greater behavioral flexibility than the system mediating classical conditioning provides. Hence, through developing an understanding of operant conditioning, one may actually come closer to establishing the functional role of cognitive processes in behavior.

1.26.3.2 Invertebrate Operant Conditioning

Just as in classical conditioning, error signals from unexpected events drive operant conditioning. The main associative principles using these signals are the concepts of initiating and gating behavioral activity. In the naïve animal, a behavior initially without a biologically relevant consequence is suddenly followed by the perception of an unexpected US. In sufficiently ambiguous situations, the animal has to first initiate a number of behavioral programs in order for the coincidence detectors to successfully cross-correlate this behavior with the novel US ('trying out'): any of its behaviors around the given time may have triggered the US. The significant cross-correlation between behavior and US eventually leads to modifications that act as a gate, letting only the behaviors pass that will maximize reward or minimize punishment (operant behavior). It is hypothesized that during operant conditioning separate processes modify the subsequent, more persistent initiation of behavior (operant memory). In contrast to classical conditioning, there is evidence from invertebrates on how the error signals may be generated in the brain. Whenever an action is initiated, a corollary discharge (or efference copy) is fed forward as a control signal to be compared with the sensory input. The difference between this control signal (expectation) and the actual sensory input generates the error signal (for a review, see Webb, 2004).

Isolating a behavior from any consequences other than a single biologically significant one (i.e., a US) is difficult. Hence, it is not surprising that there are only a few operant conditioning experiments which have demonstrated a reduction analogous to classical conditioning (one predictor – one consequence, BH → US).

Drosophila suspended at the torque meter is probably as isolated from operant feedback as technically possible in an intact animal (Heisenberg *et al.*, 2001). Glued at head and thorax to a copper wire hook, it is clamped to a device that measures the fly's yaw torque (yt) (i.e., the force the fly generates when it attempts to turn about its vertical axis). The animal is tethered completely motionless

and its visual environment is entirely homogeneous (since the head is fixed). In such a constant stimulus situation the animal may beat it wings, move its legs, bend the abdomen, or extend the proboscis with no consequences at all. The experimenter may choose to make a biologically relevant stimulus (e.g., an unpleasant heat beam, US) contingent on one of the behaviors the animal generates. For the fly, it means that without any warning from the environment, temperatures suddenly rise to an unpleasant level. The animal has to find out how to switch the heat off. There is no way the animal can know that the experimenter coupled the heat with yt values that correspond roughly to, say, right turns. The animal has to find this correlation by trying out different behaviors until it finds the correct flight control maneuvers that eventually lead to more tolerable temperatures. This is a completely arbitrary situation in which the animal has to spontaneously produce a range of behaviors. This array of different motor outputs must then be cross-correlated with the sensory input. Only behaviors with significant cross-correlations are to be maintained (gating). In principle, such a gating mechanism is neurobiologically straightforward: the neurons generating the relevant behaviors are active when the neuromodulators signaling the heat on- and offset are being released. These neurons will be modified by activity-dependent plasticity to bias any future behavior toward the behaviors controlling the heat. Such a process has been found in a similarly isolated behavioral preparation, that is physiologically much more accessible, the operant conditioning of feeding behavior in *Aplysia* (Nargeot *et al.*, 1997, 1999a, 1999b, 1999c; Brembs *et al.*, 2002, 2004; Brembs, 2003a, 2003b). In this paradigm, spontaneous bites (or the corresponding neural patterns in the reduced preparation) are rewarded by dopamine-releasing nerve stimulation. A series of experiments suggests that dopamine-dependent modifications in the biophysical properties of a neuron that is active late during the rewarded behavior (and is critical for the type of behavior – biting) are partly responsible for the increased probability of emitting biting behavior in contingently reinforced animals as compared to control animals.

Thus, similar to classical conditioning, the psychological concept of behavior selection in operant conditioning could be related to a neurobiological mechanism.

However, it is more difficult to imagine the neurobiological mechanism which modifies behavior initiation during operant conditioning. After all, the initiation of the behavior may take place quite some time before the US is perceived and therefore the neurons initiating behavior may have been silent for any amount of time. At the time of this writing, there is only one hint as to whether behavior-initiating neurons actually are modified, but there is no data about any possible mechanisms by which such modification may occur. One is tempted to draw from the concept of the efference copy to hypothesize about how this gap may be closed. Efference copies are corollary discharges during behavior that allow the animal to discern self-motion from passive motion. The connection of this neural activity with the sensory organs and the motor circuits make efference copies suitable candidates for the memorization of potential consequences of their respective actions and thus the link between behavior selection and initiation (Webb, 2004).

While there is no data confirming or falsifying these speculations to date, there are more operant conditioning paradigms which may be helpful in understanding the biological implementation of cognitive concepts in invertebrates.

The honeybee antennae can be operantly conditioned to assume a certain posture (Kisch and Erber, 1999). In a more reduced preparation, the activity of the fast flagellum flexor muscle is recorded extracellularly from the scapus of the antenna (Erber *et al.*, 2000). Whenever the muscle activity exceeds a defined reward threshold, the animal is rewarded with a drop of sucrose solution. After several US deliveries, the frequency of the muscle potentials increases significantly over the spontaneous frequency. The conditioned changes of frequency can be observed for 30 min after conditioning and do not occur in yoked controls, which were rewarded independent of nerve activity.

Aversive operant conditioning of *Lymnaea*'s aerial respiratory behavior involves stimulating the animal's pneumostome when it surfaces and attempts to breathe (Lukowiak *et al.*, 1996, 1998, 2000, 2003; Lukowiak and Syed, 1999; Spencer *et al.*, 1999; Haney and Lukowiak, 2001; McComb *et al.*, 2002, 2003; Sangha *et al.*, 2002, 2003; Scheibenstock *et al.*, 2002; Spencer *et al.*, 2002). The stimulation is aversive, which leads to the animal closing the pneumostome and learning as training progresses to reduce its attempts to open the pneumostome. Instead of aerial respiration, the animals rely on cutaneous respiration for oxygen and hence it could be shown that the decrease in pneumostome openings was not due to a generally detrimental effect of the procedure. The neural network mediating the behavior is simple and well studied, making *Lymnaea* a very promising model system for the understanding of behavior initiation and selection.

1.26.3.3 Invertebrate Composite Operant Conditioning

Of course, in freely moving animals, a CS rarely occurs independent of all the animal's behaviors, just as a US will very rarely be contingent on a behavior independent of any other stimulus present. Such situations (i.e., with a BH, a CS, and an US present) are called composite operant conditioning. *Drosophila*, *Aplysia*, and the honeybee are also the most widely used model systems for studying composite operant conditioning. Exploiting their unique technical advantages, one paradigm each in both *Drosophila* and *Aplysia* has been explicitly developed to combine operant and classical components in a single preparation. If one adds coloration of the (unpatterned) arena as a CS to the operant yaw torque learning paradigm described above for *Drosophila*, one creates an instance of composite operant conditioning (Heisenberg *et al.*, 2001). Whenever the yaw torque of the fly is in one of the two domains (roughly corresponding to left or right turns, respectively), the arena surrounding the animal is illuminated in one color; if the yaw torque moves into the other domain, the coloration changes as well. Thus, yaw torque and color become equivalent predictors of the punishing heat. This switch (sw)-mode learning causes a larger aftereffect than yaw torque learning. This increased effectiveness of composite over purely operant or classical conditioning was observed previously, comparing classical conditioning to flight-simulator (fs) mode (Brembs and Heisenberg, 2000). In this setup, the angular velocity is calculated from the online torque signal that this momentum would give the fly. But instead of turning the fly, the yaw torque is made to turn the patterned arena around the fly in the opposite direction. This arrangement enables the fly to stabilize the arena, that is to fly straight with respect to the patterns on the arena wall, and to choose 'flight directions' with respect to these patterns. Before the training, the fly shows a moderate fixation of the patterns without a striking preference for one or the other. During training, the punishing heat beam is applied whenever the fly chooses a flight direction toward one of the pattern types. If after a few minutes of training the heat is permanently switched off the fly still prefers flight directions toward the previously 'cold' patterns.

Is visual pattern discrimination learning operant? The fly learns to associate the patterns (CS) with heat and 'no-heat' (US), meeting the definition of classical (Pavlovian) conditioning. Could the operant behavior in fs-learning merely accompany a learning process which in essence is classical? The standard experiment to answer this question is a 'yoked' control (Brembs and Heisenberg, 2000). Exact sequences of pattern position and heating periods are recorded during operant training and are played back to a naïve fly. The replay control is a purely classical conditioning experiment, since the fly has no influence on the stimuli presentation. This kind of training is considerably less effective than the training operantly controlled by the fly. Thus, just as the sw-mode learning is more effective than the yt-learning, the training in fs-learning is more effective than in replay control. In other words, in both cases the three-term contingency (CS → US, BH → US) is more efficient than the two-term contingency (BH → US in yt-learning; CS → US in the yoked control of fs-learning). The interesting difference is that in fs-learning the behavior is not directly modified (Brembs and Heisenberg, 2000), whereas in sw-learning the spontaneous yt-distribution is altered just as in yt-learning. This allowed investigating which of the components are learned in the three-term contingency (Heisenberg *et al.*, 2001). These studies showed that in both fs- and sw-learning only the classical but not the operant association is separately accessible, ruling out that the two act additively. Not summation but rather interaction between the operant and classical components characterizes the three-term contingency. Apparently, composite conditioning is so effective because learning about sensory stimuli is enhanced once the fly can control them by its own behavior, whereas behavioral modifications tend to be avoided (Heisenberg *et al.*, 2001). Experiments with robots have yielded similar results, supporting the notion of a general synergistic mechanism (Verschure *et al.*, 2003).

Similar questions can now be asked in a newly developed preparation in *Aplysia*. It was described above how the feeding behavior of *Aplysia* can be conditioned classically and operantly (Nargeot *et al.*, 1997, 1999a, 1999b, 1999c; Lechner *et al.*, 2000a, 2000b; Brembs *et al.*, 2002, 2004; Brembs, 2003a, 2003b; Mozzachiodi *et al.*, 2003). Taking advantage of the greater physiological accessibility, a reduced preparation of the isolated buccal and cerebral ganglia was used. This preparation still produces spontaneous nervous activity, which can be recorded as patterned motor output at selected motor nerves. These neuronal patterns can be related to feeding behavior in the intact animal. Stimulation of sensory nerves serves as CS and US input. Thus, all elements of the three-term contingency are present: BH, CS, and US. The preparation has been shown to produce robust learning effects; it

will be interesting to see if results can be found that are analogous to those in *Drosophila* and, if so, what their neural basis is (Brembs *et al.*, 2004).

Susswein and colleagues have developed another promising composite paradigm using *Aplysia* feeding behavior (Susswein and Schwarz, 1983; Schwarz and Susswein, 1984, 1986, 1992; Susswein *et al.*, 1986; Schwarz *et al.*, 1991; Chiel and Susswein, 1993; Botzer *et al.*, 1998; Katzoff *et al.*, 2002). Food touching the lips of *Aplysia* initiates biting, which causes food to enter the mouth. Swallowing is triggered by food within the mouth. Food or nonfood objects in the mouth can also trigger rejection (Kupfermann, 1974). In this aversive procedure, animals learn to avoid biting on inedible food items. Food is made inedible by wrapping it in a plastic net that the animals can neither swallow nor break. During training, the netted food touches the lips and the animal tastes the food through holes in the net. The animal bites, food enters the mouth and elicits swallows, which fail to convey the tough food to the gut. The food eventually is rejected. The food continues to stimulate the lips and elicit bites, which again lead to failed swallows. As training proceeds, the response of the animal to the food gradually changes. Food stays within the mouth for progressively shorter periods, eliciting fewer swallows and more rejections. Animals eventually stop responding to the food (Susswein *et al.*, 1986).

An instrument more suitable than the fs for using the powerful genetic techniques in *Drosophila* for operant conditioning is the heat box (Wustmann *et al.*, 1996; Wustmann and Heisenberg, 1997; Putz and Heisenberg, 2002). In the tiny, dark chamber, every time the fly walks into a designated half, the whole chamber is heated. As soon as the animal leaves the punished half, the chamber temperature reverts to normal. Even if the heat is switched off after a few minutes, the animals still restrict their movements to only one half of the chamber. Because it is completely dark in the chamber, the animal most likely relies on idiothetic cues to orient itself, thus minimizing the contamination with potential classical predictors. It can be shown that the operant memory consists of two components, a spatial component and a "stay-where-you-are" component (Putz and Heisenberg, 2002). One of the mutants found using the heat box is the 'ignorant' gene (Putz, 2003; Putz *et al.*, 2004). Interestingly, it appears that 'ignorant' has very different effects on operant and classical conditioning. The original mutant allele (ignP1) shows a sexual dimorphism in the heat box, where males are impaired but females appear normal (Putz, 2003; Putz *et al.*, 2004). Both males and females of that line are statistically indistinguishable from the wild-type controls in olfactory classical conditioning (Bertolucci, 2003). The null mutant ($ign^{58/1}$) shows decreased learning and memory in the classical case (Bertolucci, 2003), but is normal in the heat box (Putz, 2003; Putz *et al.*, 2004). Finally, several partial deletions of the *ignorant* gene are defective in the heat box (Putz, 2003; Putz *et al.*, 2004), but these lines have not yet been tested for classical conditioning. Apparently, different mutations of the 'ignorant' gene have different effects on operant and classical conditioning, indicating fairly well-separated mechanisms for both forms of learning.

Another composite paradigm in honeybees and bumblebees is visual discrimination learning in the Y-maze. The freely flying bees enter a triangular decision chamber on one side and can see two target objects at the ends of the two arms of the 'Y' attached to the other two sides of the triangular chamber. Only one of the two targets contains a sucrose reward and thus animals can be trained to associate one of the two targets with the reward. Repeating the procedure with the targets at both arms in random sequence establishes a visual discrimination memory that is independent of the location of the target and hence of the turning maneuvers needed to reach it. In this situation, bees learn to associate a given target with reward and the alternative target with the absence of reward such that the former is excitatory and the latter inhibitory (Giurfa *et al.*, 1999). Furthermore, bees are rewarded for every correct choice such that operant and classical associations certainly drive their choice within the maze. Several variants are known of this kind of visual learning in bees: from the simple visual target conditioning in which a bee has to land on a single rewarded stimulus, to training with a complex maze made from several connected boxes, at the end of which they get rewarded with sucrose solution (Zhang *et al.*, 1999), bees efficiently learn this kind of task which has allowed further insights into higher-order forms of learning (see Section 1.26.4).

1.26.4 Nonelemental Forms of Associative Learning

In previous sections we reviewed different forms of associative learning that can be described as elemental forms of learning. These forms have in common that they can be formalized as links that connect specific stimuli (in the case of Pavlovian conditioning), or a stimulus and a response (in the case of

operant conditioning). In most of the paradigms described, such links are established in such a way that they connect directly and unambiguously well-defined events in the animal's environment (Rescorla and Wagner, 1972). Simple links between an event (A or B) and reinforcement (+) (or its absence: –) allow solving elemental problems such as absolute conditioning (A+) and differential conditioning (A+ vs. B−). In the former, an animal has to learn to respond to A, which is unambiguously associated with reinforcement; in the latter, it has to learn to respond to A and not to B because A is unambiguously associated with reinforcement and B is unambiguously associated with the absence of reinforcement.

However, invertebrates are also capable of more complex forms of associative learning, which can be described as nonelemental forms of learning, and which in contraposition to elemental ones, do not rely on simple links between events. In the study of nonelemental learning, paradigms have been developed for which the associative strength of a specific event, stimulus or reaction, is ambiguous and therefore cannot be predictive for solving a problem. Such problems cannot be formalized, therefore, in terms of simple connectivity between events and their respective outcomes, because one or various events involved in the problem usually allow opposed outcomes (Pearce, 1994). For example: if a given stimulus, A, is rewarded as often as not rewarded, and the key for solving the problem is that it is rewarded whenever it is presented together with a different stimulus B, whereas it is nonrewarded when presented together with a third stimulus C (AB+ vs. AC−), the animal cannot rely on the pure associative strength of A to solve the problem. Two possibilities appear: (1) the nonelemental one, in which the animal learns that it is the configuration (AB or AC) which counts and which has to be learned, independent of the associative strength of the elemental stimuli A, B, C; and (2) the elemental one in which the animal learns to focus on B, which is always rewarded, and/or on C, which is always nonrewarded. This example, and its two possible interpretations which differ drastically, show that in studying whether animals exhibit nonelemental forms of learning, experiments must be carefully designed in order to avoid dual interpretations for the same behavioral outcome.

Standard paradigms have been developed by experimental psychologists to address this problem in an efficient manner (Rudy and Sutherland, 1992, 1995). Simple links between a stimulus and reinforcement do not allow solving nonelemental problems like negative patterning, biconditional discrimination, and the neutral discrimination feature (see discussion below). In these problems, each stimulus appears rewarded as often as nonrewarded such that linear solutions do not apply. In negative patterning, for instance, the subject has to learn to respond to the single stimuli A and B but not to their compound AB (A+, B+, AB−). This problem does not admit elemental solutions, since the animals learn that AB has to be different from the linear sum of A and B. In biconditional discrimination, the subject has to learn to respond to the compounds AB and CD and not to the compounds AC and BD (AB+, CD+, AC−, BD−). As in the previous problem, each element A, B, C, or D appears rewarded as often as nonrewarded such that it is impossible to rely on the associative strength of a given stimulus to solve the task. Finally, in feature neutral discrimination, the animal has to learn to respond to B and to the compound AC but not to C and the compound AB (B+, AC+, C−, AB−). In this case, each element is again ambiguous such that the animal has to learn the predictive value of the compounds AB and AC, independent of its composing elements, and the fact that B and C alone produce different outcomes than when in compound. These examples show to which extent more elaborated computational strategies are necessary in the case of nonelemental discrimination problems. In Section 1.26.6, other elaborated forms of nonelemental learning are discussed such as contextual learning, or rule learning, but here we focus on more formalized problems such as the ones just introduced, which allow discerning between linear and nonlinear problem solving. This distinction is pertinent not only with respect to the nature of established associations, but also with respect to the neural substrate subtending these different forms of learning (Rudy and Sutherland, 1995; Sutherland and Rudy, 1989). It has been suggested that different neuronal circuits and structures underlie elemental versus nonelemental learning in vertebrates, with a particular role assigned to the hippocampus and the cortical circuitry associated to it in the formation of nonelemental stimulus representations (Lachnit *et al.*, 2004; Rudy and Sutherland, 1995).

Lobsters placed in an aquarium can be aversively conditioned to stop searching in it by pairing an olfactory stimulus delivered in water with a mechanosensory disturbance produced by the experimenter (Livermore *et al.*, 1997). Lobsters were trained in this way with an olfactory compound AX reinforced (AX+). Conditioning was either absolute (AX+) or differential (AX+ vs. AY−). Both conditioning procedures yielded different results, thus showing that depending on the

conditioning schedule, lobsters treated and learned the compound differently (Livermore *et al.*, 1997). After absolute conditioning, lobsters inhibited their searching behavior when presented with AX but still searched when presented with A, X or with a novel odor Y. Similarly, a novel compound AY did not inhibit searching behavior. This result is consistent with learning the compound AX as an entity different from its components A and X (the configural view; Pearce, 1994). After differential conditioning, lobsters inhibited their searching behavior when presented with AX but not with AY. Interestingly, they also inhibited search when presented with the element X but not with the element Y. A was not useful as it was common to the reinforced and the nonreinforced compounds AX+ and AY−, respectively (Livermore *et al.*, 1997). In this case, lobsters seem to have learned the compounds AX and AY in elemental terms, thus being able to fully generalize their respective responses to X and Y.

In the honeybee, several recent studies have addressed the issue of elemental versus nonelemental learning, using visual training of free-flying animals or olfactory conditioning of harnessed animals. In both modalities, bees are able to solve a biconditional discrimination (AB+, CD+, AC−, BD−) – visual (Schubert *et al.*, 2005); olfactory (Chandra and Smith, 1998; Hellstern *et al.*, 1995). This capacity demonstrates that both visual and olfactory compounds are learned under certain circumstances as entities different from the simple sum of their elements. Similarly, negative patterning experiments (A+, B+, AB−) have also been performed both in the visual (Schubert *et al.*, 2005) and the olfactory modality (Deisig *et al.*, 2001, 2002). Such discrimination can only be explained if the compound AB is treated as being different from the simple sum of its elements. Two essential theories can be invoked for explaining this result; both are different from a purely linear approach based solely on the elements of a compound: the configural theory, mentioned above, which proposes that a mixture constitutes an entity different from its components ($AB = X \neq A + B$) (Pearce, 1994); and the unique-cue theory, which proposes that a mixture is processed as the lineal sum of its components plus a stimulus (u) that is unique to the joint presentation of the elements in the mixture ($AB = A + B + u$) (Whitlow and Wagner, 1972). In the latter case, the unique cue supports the inhibitory strength assigned to the compound. In the case of honeybee olfactory learning, computer simulations and experiments such as negative patterning and its variants (Deisig *et al.*, 2001, 2002, 2003) showed that olfactory compound learning and processing in bees was consistent with the unique-cue theory. A unique cue is generated when bees receive olfactory input to both brain sides, since bilateral olfactory input is required to solve a negative patterning task (Komischke *et al.*, 2003). Assuming that the elements interfered with each other is implied in a modified unique-cue theory (Redhead and Pearce, 1995), which provided the best account for all the behavioral results available (Deisig *et al.*, 2003; Lachnit *et al.*, 2004).

Another paradigm used to study nonelemental olfactory learning in bees is the side-specific olfactory conditioning (Sandoz and Menzel, 2001). In this case, a thin plastic wall separates the honeybee's antennas during olfactory stimulation. Bees were differentially conditioned using two odors: A and B. Bees were conditioned with A+ versus B− on one antenna and with A− versus B+ on the other. This discrimination resembles a form of contextual learning (see next section), since the context of each antennal side (left vs. right) determines the contingency of the stimuli. Bees learned to respond appropriately to the rewarded odor and to inhibit their reaction to the nonrewarded odor on each side (Sandoz and Menzel, 2001). They thus solved this side-specific, nonelemental discrimination.

This and two other paradigms were recently used to test mushroom body (MB)-ablated honeybees and to determine whether intact MBs are necessary to solve nonelemental olfactory discriminations (Komischke *et al.*, 2005). Bees with unilateral lesions of the MBs generated by larval treatment with hydroxyurea (Malun, 1998) were trained under different olfactory conditioning designs. When odorants were delivered in a side-specific manner, bees with unilateral MB lesions could not solve an unambiguous double discrimination (paradigm 1: A+, B− on one antenna, C+, D− on the other; $A + B-/C + D-$), whereas they could solve at least one of both discriminations of an ambiguous problem (paradigm 2: A+, B− on one antenna , A−, B+ on the other; $A + B-/A - B+$). In the latter case, they solved the discrimination proposed to their intact brain side. Nonablated bees could learn both side-specific discriminations. When odorants were delivered simultaneously to both antennas (paradigm 3: $A + B - C + D-$), ablated bees learned slower than normal bees. Thus, in all three cases, the unilateral loss of a median calyx affected olfactory learning (Komischke *et al.*, 2005). It was proposed that MBs are required for solving elemental olfactory tasks whose complexity is enhanced by virtue of the number of stimuli involved (paradigms 1

and 3: four stimuli) and that MB ablations could have an effect on the inhibition of information exchange between brain hemispheres. This exchange may or may not occur in normal circumstances, depending on the information stored in each brain side. MB lesions would impede the ablated side to block the transfer of information from the intact side in the side-specific ambiguous problem (paradigm 2).

Interestingly, cumulative experience seems to play a critical role for adopting elemental or nonelemental learning strategies (Giurfa *et al.*, 2003). Giurfa *et al.* (2003) trained free-flying bees to fly into a Y-maze to collect sucrose solution on a rewarded stimulus presented in one of the arms of the maze. Stimuli were color disks, violet (V), green (G), or yellow (Y), which were of equal perceptual salience for honeybees. Training followed an A+, BC+ design, followed by an AC versus BC test. Training consisted of 6 (3 A+ and 3 BC+), 20 (10 A+ and 10 BC+), or 40 (20 A+ and 20 BC+) acquisition trials. Elemental models of compound processing predict that in the test, a preference for the nontrained stimulus AC should occur while configural models predict a preference for the trained stimulus BC. After six training trials, bees favored an elemental strategy and preferred AC to BC during the tests. Increasing the number of training trials resulted in an increase of the choice of BC. Thus, short training favored processing the compound as the sum of its elements (elemental account) while long training favored its processing as being different from the sum of its elements (configural account). Additionally, it was observed that the change in stimulus processing was also influenced by stimulus similarity. Color perceptual similarity favored configural processing with increasing experience (Giurfa *et al.*, 2003), a result that was consistent with the results of honeybee olfactory compound conditioning (Deisig *et al.*, 2002).

It thus seems that some invertebrates, at least lobsters and honeybees, are capable of nonelemental forms of learning in the strict sense, and that such forms of learning are highly dependent on the way in which animals are trained, on the number of trials, and on the similarity between elements in a compound. Further factors favoring nonelemental compound processing and learning could be the spatial and temporal proximity of elements and the animals' previous experience. Further research should ask whether or not other invertebrate models can solve such nonlinear discrimination problems and determine the kind of processing underlying this problem solving.

1.26.5 Integration Across Sensory Modalities and Rule Learning

Animals, including invertebrates, can sometimes respond to novel stimuli that they have never before encountered or can generate novel responses that are adaptive given the context in which they are produced. In doing this, the animals exhibit a positive transfer of learning (Robertson, 2001), a capacity that cannot be referred to as an elemental form of learning because the responses are aimed toward stimuli that do not predict a specific outcome *per se* based on the animals' past experience. Moreover, animals can also learn to inhibit such a transfer in order to produce adaptive responses that can be linked to a specific context. They learn that, given a certain stimulus or condition, a particular response is appropriate, whereas, given a different stimulus or condition, the same response is no longer appropriate. This form of learning, usually referred as conditional learning or occasion setting, cannot be viewed as elemental learning, since a given stimulus may or not be predictive of a certain outcome, depending on the particular environment. Relying on its elemental outcome alone therefore does not help solving this kind of problem. In this section, we focus on these forms of nonelemental learning. We therefore deal with three main capacities: (1) selective attention, (2) rule learning, and (3) contextual learning. We start with selective attention, as it seems to be a necessary requisite for extracting the information that allows solving the other two problems.

1.26.5.1 Selective Attention

Selective attention consists of the ability to focus perceptual mechanisms on a particular stimulus and to actively process this information while ignoring nonrelevant stimuli (Zentall, 2005). It implies that the representation of the stimulus has been filtered or modified, presumably so that it can be processed or responded to more efficiently. Different approaches have been proposed to the notion of selective attention. Here we focus on the ecological notion of 'search image' (Tinbergen, 1960) and on the more traditional approach of discriminative learning to selective attention (Zentall and Riley, 2000).

Selective attention could be related to the notion of search image, since such images are assumed to exist in cruising animals in order to facilitate detection of relevant stimuli in the environment. Search images, which could be innate (see Section 1.26.2) or acquired through experience in the field, have been proposed to be a specific means for filtering

out sensory information and focusing perception on specific stimulus configurations as a way to more efficiently forage and avoid predation. Innate search images driving the first foraging flights are assumed in insect pollinators, in order to facilitate the detection of flower sources (Menzel, 1985). Indeed, naïve bees exhibit innate preferences for biologically relevant floral cues such as colors (Giurfa *et al.*, 1995; Gumbert, 2000) or bilateral symmetry (Rodriguez *et al.*, 2004). Salticid spiders have also an innate predisposition to form search images for preferred preys (spiders) rather than for nonpreferred preys (insects) (Jackson and Li, 2004).

Traditionally, selective attention has been studied through a discriminative learning approach. Such an approach posits that through selective attention animals gradually learn to attend to the dimension along which discriminative stimuli differ (Mackintosh, 1975). Honeybees (Giurfa, 2004) and bumblebees (Dyer and Chittka, 2004) discriminate differently a given color after absolute (training with a single reinforced color) and differential conditioning (training with a reinforced color and nonreinforced alternatives). They become progressively better in discriminating the trained color from colors that are perceptually close after prolonged differential conditioning while they are incapable of such discrimination after the same amount of absolute conditioning These results can be interpreted along the selective attention hypothesis such that insects gradually learned to attend to the spectral dimension along which discriminative stimuli differed. An alternative interpretation posits that differentially conditioned animals form positive and negative generalization gradients to the rewarded and the unrewarded stimulus, respectively, and thus develop a sharper generalization profile for the learned stimulus. An attentional account may also apply to pattern discrimination experiments in which bees do or do not discriminate the same two patterns depending on the kind of training used, absolute or differential conditioning (Giurfa *et al.*, 1999). Absolute conditioning promoted recognition based on local cues (the lower half of a disk made of different sectors) while differential conditioning expanded it to the whole pattern.

Arguments in favor of selective attention in invertebrates come from research on the fruit fly *D. melanogaster* (van Swinderen and Greenspan, 2003). A fly flying stationary within a circular arena and tracking a visual moving object (a vertical black bar) exhibits behavioral and neural processes consistent with selective attention for visual stimuli. Local field potentials recorded in the central brain of these flies show that activity in the 20–30 Hz range increases as a response to the moving bar when it appears in the visual field of the fly and before the insect initiates tracking. This neural response, which is interpreted as being related to the perceptual event occurring at the onset of stimulus tracking, can be retraced to the mushroom bodies. It increases by novelty and odor-evoked salience, it is anticipatory, and it is reduced when the fly is in a sleep-like state. These results suggest that selective attention underlies visual tracking in flies.

1.26.5.2 Rule Learning

Selective attention constitutes the very basis of rule learning, because in such a process animals learn to focus attention on the relevant information that allows detecting the rule underlying the problem to be solved. Rule learning presupposes positive transfer of an appropriate response from a known set to a novel set of stimuli. In this case, the animal bases its choice not on the perceptual similarity between the novel and the known stimuli, which might not share any common feature, but on a rule which transcends the stimuli used to train it. Examples of such rules are 'larger than', or 'on top of', which may apply to stimuli which do not share any common feature but which can nevertheless be classified according to the rule. Other examples are the so-called principles of sameness and of difference. These rules are uncovered through delayed matching to sample (DMTS) and the delayed nonmatching to sample (DNMTS) experiments, respectively. In DMTS, animals are presented with a sample and then with a set of stimuli, one of which is identical to the sample and which is reinforced. Since the sample is regularly changed, they must learn the sameness rule 'always choose what is shown to you (the sample), independent of what else is shown to you'. In DNMTS, the animal has to learn the opposite, that is 'always choose the opposite of what is shown to you (the sample)'.

Honeybees foraging in a Y-maze learn both rules (Giurfa *et al.*, 2001). Bees were trained in a DMTS problem in which they were presented with a changing nonrewarded sample (i.e., one of two different color disks or one of two different black-and-white gratings, vertical or horizontal) at the entrance of a maze. The bees were rewarded only if they chose the stimulus identical to the sample once within the maze. Bees trained with colors and presented in transfer tests with gratings that they have not experienced before solved the problem and chose the grating identical to the sample at the entrance of the maze. Similarly, bees trained with the gratings

and tested with colors in transfer tests also solved the problem and chose the novel color corresponding to that of the sample grating at the maze entrance. Transfer was not limited to different kinds of modalities (pattern vs. color) within the visual domain, but could also operate between drastically different domains such as olfaction and vision (Giurfa *et al.*, 2001). Furthermore, bees also mastered a DNMTS task, thus showing that they also learned a principle of difference between stimuli (Giurfa *et al.*, 2001). These results document that bees learn rules relating stimuli in their environment. The capacity of honeybees to solve DMTS tasks has recently been verified (Zhang *et al.*, 2004, 2005). It was found that the working memory for the sample underlying the solving of DMTS is ~5 s (Zhang *et al.*, 2005) and thus coincides with the duration of other visual and olfactory short-term memories characterized in simpler forms of associative learning in honeybees (see Section 1.26.6). Moreover, bees trained in a DMTS task can learn to pay attention to one of two different samples presented successively in a flight tunnel (either to the first or to the second) and can transfer the learning of this sequence weight to novel samples (Zhang *et al.*, 2005).

Despite the honeybees' evident capacity to solve relational problems such as the DMTS or the DNMTS tasks, such capacities are not unlimited. In some cases, biological constraints may impede the solving of a particular problem for which rule extraction is necessary. It is therefore interesting to focus on a different example of rule learning which bees could not master, the transitive inference problem (Benard and Giurfa, 2004). In this problem, animals have to learn a transitive rule, that is, A > B, B > C, then A > C. Preference for A over C in this context can be explained by two strategies: (1) deductive reasoning (Fersen *et al.*, 1990) in which the experimental subjects construct and manipulate a unitary and linear representation of the implicit hierarchy A > B > C; or (2) responding as a function of reinforced and not reinforced experiences (Terrace and McGonigle, 1994), in which case animals choose among stimuli based on their associative strength, that is, on the effective number of reinforced and nonreinforced experiences with the stimuli.

To determine whether bees learn the transitive rule, they were trained using five different visual stimuli A, B, C, D, and E in a multiple discrimination task A+ versus B−, B+ versus C−, C+ versus D−, and D+ versus E− (Benard and Giurfa, 2004). Training therefore involved overlapping of adjacent premise pairs (A > B, B > C, C > D, D > E), which underlie a linear hierarchy A > B > C > D > E. After training, bees were tested with B versus D, a nonadjacent pair of stimuli that were never explicitly trained together. In theory, B and D have equivalent associative strengths because they are, in principle, equally associated with reinforcement or absence of it during training. Thus, if bees were guided by the stimulus' associative strength, they should choose randomly between B and D. If, however, bees used a transitive rule, they should prefer B to D.

Honeybees learned the premise pairs as long as these were trained as uninterrupted, consecutive blocks of trials (Benard and Giurfa, 2004). But if shorter and interspersed blocks of trials were used, such that bees had to master all pairs practically simultaneously, performance collapsed and bees did not learn the premise pairs. The bees' choice was significantly influenced by their experience with the last pair of stimuli (D+ vs. E−) such that they preferred D and avoided E. In the tests, no preference for B to D was found. Although this result agrees with an evaluation of stimuli in terms of their associative strength (see above), during training bees visited more B when it was rewarding than D, such that a preference for B should have been expected if only the associative strength were guiding the bees' choices. It was then concluded that bees do not establish transitive inferences between stimuli but rather guide their choices by the joint action of a recency effect (preference of the last rewarded stimulus, D) and by an evaluation of the associative strength of the stimuli (in which case preference for B should be evident). As the former supports choice of D while the latter supports choice of B, equal choice of B and D in the tests could be explained (Benard and Giurfa, 2004). In any case, memory constraints (in this case the fact that simultaneous mastering of the different premise pairs was not possible and the fact that the last excitatory memory seems to predominate over previous memories) impeded learning the transitive rule.

1.26.5.3 Conditional Discriminations: Occasion Setting and Contextual Learning

Contextual learning is a term widely used for describing conditional discriminations which can be subsumed in the so-called occasion setting problem (Schmajuk and Holland, 1998). In this problem, a given stimulus, the occasion setter, informs the animal about the outcome of its choice (for instance, given stimulus C, the occasion setter, the animal has to choose A and not B because the former but not the latter is rewarded). This basic

form of conditional learning admits different variants depending on the number of occasion setters and discriminations involved, which have received different names. For instance, another form of occasion setting involving two occasion setters is the so-called transwitching problem. In this problem, an animal is trained differentially with two stimuli, A and B, and with two different occasion setters, C1 and C2. When C1 is available, stimulus A is rewarded while stimulus B is not (A+ vs. B−), while it is the opposite (A− vs. B+) with C2. Focusing on the elements alone does not allow solving the problem as each element (A, B) appears equally as often rewarded and nonrewarded. Each occasion setter (C1, C2) is, in the same way, simultaneously rewarded and nonrewarded, depending on its association with A or B. Animals have, therefore, to learn that C1 and C2 define the valid contingency. The transwitching problem is considered a form of contextual learning because the occasion setters C1 and C2 can be viewed as contexts determining the appropriateness of each choice. Note that a problem like the biconditional discrimination (AB+, CD+, BC−, AD−; see Section 1.26.4) is amenable to a transwitching problem, and thus to an occasion-setting problem, if one assumes that A and C act as occasion setters for B and D (i.e., given A, B+ vs. D−, and given C, B− vs. D+). This is so because all these problems are forms of conditional learning in which a stimulus can have different associates depending on the conditions in which it is presented.

Despite semantic confusions, conditional discriminations viewed as contextual learning have been studied in several invertebrate models. We will keep the term 'contextual learning' as it appears recurrently in the works that we will discuss from here on. In the nematode *Caenorhabditis elegans*, retention of habituation of an escape response is aided by contextual associations formed during training (Rankin, 2000; see also Section 1.26.6). Nematodes were trained and tested in the presence of a chemosensory cue ($NaCH_3COO$) which was used as the general context surrounding the animals. Animals trained and tested in different chemosensory environments showed lower retention than animals that stayed in the same context. In the same animal, Law *et al.* (2004) used taste cues to create distinct contexts for olfactory adaptation assays and showed that performance in this associative learning paradigm is sensitive to context manipulations. In *Aplysia californica*, Colwill *et al.* (1988) showed that animals exposed to two different contexts, a smooth, round bowl containing lemon-flavored seawater and a rectangular chamber with a ridged surface containing unscented seawater that was gently vibrated by an aerator located in one corner, and receiving a series of moderate electric shocks (US) in one of these two contexts, established an association between the context and the shock. The context alone elicited a defensive reaction which was exclusive for the reinforced context. In the freshwater pond snail *Lymnaea stagnalis*, aerial respiratory behavior was operantly conditioned so that the animals performed aerial respiration significantly less often (Lukowiak *et al.*, 1996; see also Section 1.26.3). Recall of the learned behavior was dependent on the context in which memory was established. Animals trained in water containing food odorant (the contextual cue) exhibited recall only in the presence of such food odorant context (Haney and Lukowiak, 2001).

Arthropods have provided reliable evidence of contextual learning. Hermitte *et al.* (1999) found that in the crab *Chasmagnathus*, spaced and massed training with an opaque screen moving overhead produced different forms of long-term habituation (LTH) of an escape response: LTH acquired by spaced but not by massed training was affected negatively by a change in context, provided by different visual cues around the bowl in which animals are kept. In the fruit fly *D. melanogaster*, the incidence of context on visual learning was analyzed using the flight simulator (see Section 1.26.3) in which a fly has to learn to fly stationary toward surrounding T-shaped patterns (upright and inverted) used as landmarks and presented on a surrounding screen. Context variation in this aversive learning paradigm was provided by a change in the color of the illuminating light (Liu *et al.*, 1999). Normal flies transferred appropriate responses toward patterns from a trained to a new context providing that the chromatic differences between the two contextual lights were not too large (Liu *et al.*, 1999). MB defective flies were unable to realize such a transfer and could not therefore remember the information learned in one context in a different one. These results suggest that the MBs help to stabilize visual memory with respect to context changes and thus allow the memory of an event to be stored and then retrieved in different situations (Liu *et al.*, 1999).

Matsumoto and Mizunami (2004) have shown that crickets *Gryllus bimaculatus* associate one of a pair of odors with water reward (appetitive US) and another odor with saline solution (aversive US) under illumination, and learn the reversed contingency in the dark. Thus, crickets solved this variant of the transwitching problem (see above) and the visual context affected learning performance only

when crickets were requested to use it to disambiguate the meaning of stimuli and to predict the nature of reinforcement.

Bumblebees have also been trained in a trans-switching problem to choose a 45° grating and to avoid a 135° grating to reach a feeder, and to do the opposite to reach their nest (Fauria *et al.*, 2002). They can also learn that an annular or a radial disk must be chosen, depending on the disk's association with a 45° or a 135° grating either at the feeder or the nest entrance: in one context, the nest, access to it was allowed by the combinations 45° + radial disk and 135° + annular disk, but not by the combinations 45° + annular disk and 135° + radial disk; at the feeder, the opposite was true (Fauria *et al.*, 2000). In both cases, the potentially competing visuomotor associations were insulated from each other because they were set in different contexts. Comparable behavior was found in honeybees where distinct odors or times of the day (Menzel *et al.*, 1998) were the occasion setters for a given flight vector.

Further examples for contextual learning in honeybees could be provided (e.g., Gerber and Menzel, 2000). The rich Russian literature on this subject is summarized in Kartsev (1996) and Mazokhin-Porschnyakov and Kartsev (1994), but they would be redundant for the main conclusion of this section which is that there is abundant evidence of conditional learning in invertebrates, which can be described as occasion setting or contextual learning. However, the nature of the associations underlying this kind of learning and its neural substrates remain unclear.

1.26.6 Memory Systems

Memories exist in multiple forms and functions. They are categorized according to their physiological substrates along a timescale as short-term, mid-term, and long-term memory (STM, MTM, LTM), referring to ongoing neural activity as the storage device of STM, intercellular signaling cascades leading to MTM, and gene activation, protein synthesis, and new structures underlying LTM. The transitions between these memory stages or phases can be sequential or parallel, processes referred to as physiological correlates of consolidation, a phenomenon originally known from human psychological studies (see Human Cognitive Specializations) capturing the fact that over time early, vulnerable forms of memory are converted into more stable and long-lasting forms (Ebbinghaus, 1964; Müller and Pilzecker, 1900).

Two processes of memory formation have already been introduced: the distinction between phylogenetic (the species' memory) and individually acquired memory (memory from learning). The relationship between these two forms of memory concerning their different molecular and cellular substrates – but also their corresponding mechanisms of expression (Fox *et al.*, 1998) – is of utmost importance in the study of behavior and cognition, but is poorly understood. Here we focus on experience-dependent memory.

The term experience-dependent memory subsumes two processes in the brain, storing and retrieving information. A content of memory that is potentially retrievable but not actually retrieved is often referred to as 'remote memory', whereas 'working memory' captures the fact that retrieved and updated information exists in an active form that allows predictions to be made about potential outcomes of actions. Working memory is probably the most important concept in describing cognitive processes, since it is considered the interface between evaluated earlier events and future events in the context of the animal's current needs and motivations. Memory systems are also categorized according to their contents, and in vertebrates particular brain structures are related to it, for example procedural memory (e.g., cerebellum), episodic memory (hippocampus, prefrontal cortex), and emotional memory (amygdala). Whereas procedural memory certainly exists in invertebrates and may be distributed over their ganglionic nervous systems, it is debatable whether any animal possesses episodic memory, the ability to carry out long-term recall of sequences of events or narratives (see, for instance, Suddendorf and Busby, 2003, and reply by Clayton *et al.*, 2003a). In humans, this property is intimately related to the functions of the hippocampus and cerebral cortex. It is argued that food-storing birds may develop an episodic-like memory about a kind of food stored at a certain place and at a certain time. Pollinating insects certainly control their foraging activities according to the kind of food they collect at a particular place and at a specific time of day, but it is unknown whether they make decisions between options integrating the what, where, and when of potential food sites (see Section 1.26.7).

Memory systems are highly dynamic and content sensitive. Any retrieval from the memory store will change its content due to the updating process in working memory. It is this updating process that may lead to extracting rules which underlie generalization, categorization, and implicit forms of abstraction (see Section 1.26.7). Furthermore, retrieval from memory store also induces new learning, and consequently consolidation into new

memory, a process referred to as 'reconsolidation' (see discussion below).

It may be expected that the structure and dynamics of memory systems have been shaped by the evolutionary history of the species, and may thus reflect species-specific adaptations to the requirements posed by the environment. Little is known about these ecological adaptations of the memory system, because animal models of memory are rarely studied with respect to their natural behavior in order to detect possible correlates between behavioral and memory dynamics. However, appetitive learning in the honeybee provides certain insights into this question (see discussion below).

1.26.6.1 Physiological Correlates of Memory Systems

In bacteria and ciliates the memory for sensory adaptation and habituation of innate responses lies in the temporal dynamics of second messengers and their targets (see Section 1.26.2). The nematode *C. elegans* habituates to mechanical stimulation, and the duration of the memory depends on the number and intervals of the stimuli. Since retention of habituation differs for different chemical context conditions, it has been proposed that some form of associative learning may be involved (Steidl and Rankin, 2002). The 24 h memory, but not an early memory, depends on protein synthesis, thus indicating an early and a late memory phases. *C. elegans* provides excellent opportunities to study the molecular, cellular, and network properties of learning and memory, but since associative learning and its memory phases have not yet been convincingly documented, this model system awaits further progress before it will become useful for such studies (see Rankin, 2004 for further discussion).

The memories of various forms of learning have been intensively studied in several species of mollusks (*Tritonia diomedea, Hermissenda crassicornis, Limax maximus, L. stagnalis, Helix pomatia, Pleurobranchaea californica, A. californica*; Byrne, 2002). The focus in these studies lies on nonassociative forms of learning such as habituation and sensitization and on their physiological correlates, depression and facilitation. Pavlovian conditioning was studied in *Hermissenda, Limax*, and *Lymnaea*, and as in nonassociative learning, two major phases of memory were found, STM and LTM. The cellular correlates of short-term and long-term sensitization have been studied in greatest detail in *Aplysia* (Kandel, 2001). Short-term sensitization lasts for seconds and minutes and involves the modification of neuronal membrane properties and synaptic efficacy, often through the alteration of the phosphorylation state of existing proteins. Long-term sensitization lasts from days to weeks, depending on the training protocol (spaced trials lead to longer memory than massed trials). It requires synthesis of new macromolecules, since the inhibition of either gene transcription into mRNA or translation of mRNA into protein blocks long-term sensitization. In its most persistent form, long-term sensitization involves morphological changes and neuronal growth. In all these respects, the studies of *Aplysia* sensitization are exemplary and paradigmatic for any research on the cellular basis of learning and memory (Milner *et al.*, 1998). In the context of the relationship between phylogenetic and experience-dependent memory, studies on the mechanistic relationship between development and learning are particularly interesting (Carew, 2002). In *Aplysia*, the nonassociative forms of plasticity in the sensory–motor connection of the siphon withdrawal response appear sequentially during early development: first habituation, then dishabituation, and then sensitization, indicating that the two facilitatory processes dishabituation and sensitization are mechanistically different. This interpretation is supported by the finding that the sequential appearance of plasticity phenomena at the sensory motor synapses corresponds to these forms of plasticity. Synaptic decrement of the sensory–motor synapse appears first in development, then facilitation of the decremented EPSPs, then facilitation of the nondecremented EPSPs, and, finally, an inhibition of nondecremented EPSPs appears in stage 12 of *Aplysia* development. The development of the inhibitory process can be nicely related to a maturation effect of sensitization in which strong stimuli become less effective in later developmental stages. Follow-up studies (Nolen and Carew, 1988) also demonstrated in adult *Aplysia* that dishabituation and sensitization are two different forms of facilitatory plasticity, at both the behavioral and the neural levels. Furthermore, it was found that long-term forms of sensitization emerge at the same time of development as short-term forms (stage 12), indicating that STM and LTM memory are mechanistically interrelated (Wright *et al.*, 1996). These studies are of general importance because they document that the nonassociative forms of learning (habituation, sensitization) reflect not only two opposing processes but rather are composed of four behavioral processes, two decrementing (habituation, inhibition) and two facilitatory.

Using molecular genetic tools in *Drosophila*, four distinct memory stages have been found following

aversive olfactory conditioning: STM, MTM, anesthesia-resistant memory (ARM), and LTM (Tully *et al.*, 1994). Among the several mutants that have been analyzed with respect to their memories, rutabaga (rut) and amnesiac (amn) yielded the most information about their cellular mechanisms and the localization of STM and LTM in the *Drosophila* brain (Heisenberg, 2003; Isabel *et al.*, 2004). Rut encodes a calcium-sensitive adenylylcyclase, and amnesiac encodes a neuropeptide similar to vertebrate PACAP (pituitary adenylylcyclase-activating peptide). Rut mutants learn normally, but suffer from reduced STM that can be rescued in transgenic flies expressing the gene in a subpopulation of mushroom body neurons (γ-lobe neurons; Zars *et al.*, 2000). Amn mutants lack PACAP-expressing neurons, and two of these neurons extrinsic to the mushroom body are essential for the transition to LTM (Feany and Quinn, 1995). Structural mutants with lesions restricted to the alpha lobe of the mushroom body specifically abolish LTM (Pascual and Preat, 2001; Dubnau *et al.*, 2001). Taken together with the analysis of several other single-gene mutants, these observations suggest that olfactory learning and memory depend, at least in part, on the activity of MB neurons. Different MB neurons may be involved in storing different memories, but currently nothing is known about how the transfer occurs between these neurons during consolidation from STM to LTM. So far only very few of the many neurons certainly involved in memory formation in *Drosophila* have been studied. It is estimated that more than 1000 genes are transcriptionally regulated during olfactory LTM formation (Dudai, 2002).

Reward learning in honeybees initiates a sequence of memory phases which lead to long-lasting memory passing through at least four forms of memory (Menzel and Müller, 1996; Menzel, 1999). An associative-learning trial induces an early form of short-term memory (eSTM) in the seconds range. This memory is highly dominated by appetitive arousal and sensitization, is rather unspecific, and is quickly converted into a late STM (lSTM). At the cellular level, stimulus association is reflected in the convergence of excitation of the conditioned stimulus pathway of the (odor) via nicotinic acetylcholine receptors (nAChRs) in the antennal lobe and the MB, and the pathway for the unconditioned stimulus, the putatively octopaminergic neuron VUM_{mx1}, most likely acting on octopamine receptor II receptors. In the antennal lobe, both cAMP/PKA and Ca^{2+}-dependent PKC are upregulated during STM, and the cAMP/PKA signaling cascade is indicative of the associative component (Müller, 2000). However, unlike in *Drosophila*, blocking the cAMP/PKA pathway does not interfere with learning and STM. The transition to MTM is a rather slow process and makes the memory trace unsusceptible to retrograde amnesic treatments. Single and multiple learning trials lead to different long-term forms of memory (LTM, see discussion below). An important molecular component in the transition to LTM formation is enhanced and prolonged PKA activity after multiple learning trials. Two lines of evidence support the conclusion that LTM formation requires enhanced PKA activity shortly after multiple trial learning, but is not involved in the learning process itself: (1) blocking NO synthase during lSTM reduces PKA activity and impedes LTM formation (Müller, 1996); (2) enhancing PKA activity by uncaging cAMP in the antennal lobe after a single learning trial facilitates the formation of LTM in the same way as multiple trials do (Müller, 2000). MTM is characterized by a first wave of PKC activity (Grünbaum and Müller, 1998). The constitutive activation of PKC is a proteolytic process of formation of PKM that lasts for several hours. Inhibition of proteases in the whole brain reduces the formation of PKM and blocks retention during the MTM phase. LTM formation is also blocked in this way, indicating that protein synthesis-dependent LTM and high levels of long-lasting PKC activity (until the third day after conditioning) are formed parallel to PKM-dependent MTM.

Two forms of LTM must be distinguished in honeybees: early LTM (1–2 days) characterized by translation-dependent retention and constitutively active PKC, and late LTM ($\geq$3 days) characterized by transcription-dependent retention and no more enhanced PKC activity. The two forms of LTM arise differently, after massed and spaced multiple learning trials (Menzel *et al.*, 2001). Memory resulting from spaced trials is blocked by protein synthesis inhibitors, whereas memory resulting from massed conditioning trials (intertrial interval 30 s) is independent of protein synthesis.

1.26.6.2 Working Memory: Capacity and Duration

The capacity and time span of working memory has been estimated in invertebrates only for the honeybee in the appetitive context of nectar foraging. As pointed out above, very short intervals ($<$1 min) between a learning and a test trial lead to high but rather unspecific responses, while long intervals lead to specific responses of the learned stimulus. Chittka *et al.* (1997) recorded the frequency of intervals between stay and shift flights made by bumblebees

foraging on more than two plant species. Stay flights appear at shorter intervals (~2 s) than shift flights, indicating that immediate choices are dominated by the most recent and the most effective STM, but reference to more remote memories needs more time. To interpret it from another perspective, one could say that longer intervals release working memory from the dominant memory of the last visit and allow for contributions from an earlier memory that has meanwhile been consolidated. Greggers and Menzel (1993) found for bees foraging in a patch of four feeders that delivered different flow rates of sucrose solution that they store the reward properties of these feeders in working memory. Similar results were found for eight feeders, indicating that the reward properties of eight feeders can also be stored in feeder-specific memories. The capacity of working memory is, therefore, at least eight items. The time range of these specific working memories could be estimated as lying around 6 min.

Recently, working memory in foraging honeybees has also been estimated using the DMTS procedure (see Section 1.26.4 and Giurfa *et al.*, 2001), in which a free-flying bee is exposed to a visual stimulus (the sample) through which it should fly to then subsequently choose between two options, one of which corresponds to the sample. If the bee matches its choice to the sample it is rewarded with sucrose solution (Giurfa *et al.*, 2001). Using this paradigm, Zhang *et al.* (2005) estimated the duration of the working memory for the sample, which allows a bee to choose between alternatives after passing though it. The duration of such a working memory was around 5 s. Longer delays between exposure to the sample and subsequent choice of stimuli result in random choices.

1.26.6.3 Reconsolidation

When memory is retrieved from a remote store by exposing the animal to the learned stimulus without reinforcement (extinction), two processes are initiated: extinction learning, due to the fact that the stimulus originally associated with reinforcement is now presented without it, and reminder learning, which may either recruit the original stable memory about the learned stimulus and bring it back into an unstable form (trace dominance hypothesis, see discussion below), or it initiates a new learning trial based on the fact that a learned stimulus also activates the reward system and thus initiates new learning (internal reinforcement hypothesis, see below). Both extinction and reminder learning are followed by their respective consolidation processes: consolidation of an extinction memory and reconsolidation of the reminder memory. Studies in the crab *Chasmaganathus* (Pedreira and Maldonado, 2003) and the honeybee (Stollhoff *et al.*, 2005) showed that the strength of these two consolidation processes depends on both the strength of the reminder memory and the strength or number of extinction trials. These observations resemble findings in vertebrates showing that the presentation of an extinction trial does not always result in extinction alone, rather it may lead to an opposing behavioral phenomenon, the stabilization of the response learned earlier. In this case, the extinction trial transfers the old memory from an inactive, stable protein synthesis-independent memory into an active and unstable protein synthesis-dependent reminder memory (Nader, 2003; Dudai and Eisenberg, 2004). In the honeybee, the balance between the extinction and reminder learning processes and their respective consolidation processes depends on the number of extinction trials. Extinction learning is dominant after two extinction trials, whereas reminder learning is expressed in a recovery from extinction and is induced by many (five) extinction trials. Consolidation of reminder learning (reconsolidation) depends on protein synthesis, which indicates that a new learning process is going on, as shown in the vertebrate studies. Nader (2003) and Dudai (2004) proposed the hypothesis of "trace dominance" and interpret the results as a competition between consolidation of extinction memory and reconsolidation of reminder memory "with the dominant one being the one most affected by protein synthesis inhibition." This hypothesis can explain the observations on aversive learning in the crab *Chasmaganathus* (Pedreira and Maldonado, 2003) but not those on appetitive learning in the honeybee (Stollhoff *et al.*, 2005). In *Chasmaganathus* extinction memory and its consolidation are dominant after either one strong or many extinction trials, whereas a weak or only one extinction trial leads to dominance of reminder learning and of its corresponding reconsolidation. Exactly the opposite was found in bees. One reason might be a difference between consolidation processes induced by aversive or appetitive learning. Furthermore, the trace dominance hypothesis proposes that either the reconsolidation of the reminder memory or the consolidation of the extinction memory occurs according to an 'all-or-none' rule. The bee data do not support such a conclusion, because inhibiting consolidation of extinction memory results in an opposite behavioral effect than the inhibition of reconsolidation of reminder memory. It was hypothesized that in bees these consolidation

processes take place in parallel, rather than following an 'all-or-none' rule (Stollhoff *et al.*, 2005).

The results on reconsolidation in the honeybee can be explained via properties of the reward system in the bee brain. Hammer (1993) found that the reward neuron VUM_{mx1} not only codes for appetitive reinforcement of odors, but also learns to respond to the conditioned odor stimulus, and an extinction trial does indeed activate the VUM neuron (Hammer, 1997). This means that an extinction trial will lead to new appetitive learning without an external reinforcing stimulus. This is exactly what was found: two forms of learning, one based on the lack of external reinforcement (extinction learning), and one based on the internal existence of reinforcement (reminder learning). These conditions are best captured by the 'internal reinforcement hypothesis', which states that the balance between extinction and reminder learning depends on the relative strength of the internal reinforcement. The balance will be shifted to the internal reinforcement with more unrewarded presentations of the learned stimulus.

1.26.6.4 Ecology of Memory Systems

From an evolutionary point of view one may expect that memory dynamics are adapted to choice behavior under natural conditions. Foraging in pollinating insects is a behavior with a highly regular sequential structure of events ranging from actions within seconds to those separated by months and thus may offer the opportunity to relate memory structure and ecological demands (Menzel, 1999). Different memories are consulted during the sequence of events during foraging. In the bee, the time courses of successive behaviors during foraging match the temporal dynamics of memory stages. Choices between flowers within the same patch quickly succeed each other and are performed during eSTM. Choices between flowers of different patches occur after the transition to lSTM. Successive bouts are interrupted by the return to the hive such that flower choices in a subsequent bout require retrieving information from MTM. The separation between the two forms of LTM may be related to the periods when flower patches are in bloom (Menzel, 2001).

Although these ecological considerations are highly speculative, they indicate, on the one hand, that sequences of natural behavior need to be examined with respect to the intrinsic properties of the neural machinery underlying memory formation. On the other hand, they emphasize the necessity of considering the results of laboratory studies on memory formation in the context of natural behavior. Only comparative studies will help us discern which properties reflect general mechanisms and which indicate species-specific adaptations, and invertebrates offer a huge range of ecological adaptations. This conclusion supports the fact that more studies on the natural behavior of animal models of memory are necessary. To which extent do the different memory phases of *Drosophila* or *Aplysia* correlate with specific sequences of their behavior? To which extent are aversive and appetitive memories coincident with respect to their dynamics, given the fact that they respond to different natural sequences and behavioral timing? These questions require comparative studies of memory that allow for the natural context in which memory is to be employed, a requirement that is seldom met by studies on invertebrate memory.

1.26.7 Representation and Planning, Observatory Learning; Navigation; Communication and Individual Recognition

One of the most important steps in conceptualizing cognition is the distinction between implicit and explicit knowledge. Explicit knowledge may – in a strict sense – exist only in humans. Animals (other than primates) might possess only implicit knowledge, but this does not rule out the possibility that certain forms of knowledge might reach an 'explicit-like' status specific for the animal species in question in the sense that internal operations on memories (or representations) are performed without motor expression of such operations. A telling example of this form of knowledge is the choice behavior of food-storing birds which makes their choices dependent on what kind of food they have stored and when and where they have stored it (Clayton *et al.*, 2003b). Thus, expectation, attention, planning, and decision making could be useful terms for animals, even if we assume that they possess only implicit knowledge. If such terms are used, we assume that the animal retrieves a memory whose structure allows two or more alternative outcomes to be evaluated before any motor action is performed. We shall address the question here whether it is reasonable to assume such forms of internal processing in invertebrates, in particular, in insects (e.g., the honeybee) and cephalopods (octopus) (for *Drosophila* see Greenspan and van Swinderen, 2004). Do these animals have a memory in the sense that its contents can be recollected outside of the immediate sensory–motor control, and used for internal operations?

There are good reasons for rejecting this kind of questioning when it comes to understanding invertebrate behavior. Too often, mentalistic reasoning has led to obscure arguments and untestable hypotheses. On the other hand, searching for experimental conditions that would allow us to address the internal processing of the brain devoid of sensory–motor control, its spontaneity and creativity, in even such a tiny brain as that of insects, may help to do better justice to the complexity of neural functions in bigger brains. In most behavioral studies, inference about internal processing can be made only indirectly by observing changes in behavior. In the honeybee, one can study a communicative process between foraging animals transcending the usual limitations of behavioral studies in invertebrates, and 'read' their reports on what they perceived, what they learned, and what they consider to be worth reporting. This unique situation was ingeniously exploited by von Frisch (1967), who discovered through it a whole range of sensory capacities and experience-dependent faculties. More recently, work on honeybees has benefited from cognitive perspectives (Menzel and Giurfa, 2001; Giurfa, 2003), and it is on this aspect that we focus in this article.

The topics of observatory learning, navigation and communication are addressed here because it is under these conditions that learning transcends elementary forms of association in particularly clear ways. The evaluating signal for storing experience must come from internal nervous system conditions at the time of learning, depends considerably on the motivational level, requires attention to a subset of stimuli, and is adjusted to the animal's own behavior in an intricate way. The signals learned are usually composed of multimodal inputs which cannot be isolated from each other, and the motor performances involve sophisticated sequences of motor programs. As will be seen, it is still very difficult to prove the cognitive nature of the processes, because more elementary interpretations need to be carefully considered. Close sensory–motor connections, simple partial matching strategies between experienced and remembered constellations, sequences of picture memories, and other forms of elementary solutions to complex conditions must be discarded before elaborating on an animal's cognitive sophistication.

1.26.7.1 Observatory Learning

Observatory learning differs from associative learning in the lack of an obvious external reinforcing stimulus. Thus, an animal capable of observatory learning should be able to internally evaluate environmental conditions as well as its own actions by activating a circuit that informs it about the value of signals and actions to which the animal is simply exposed.

The cephalopod mollusk *Octopus vulgaris* is able to learn a visual discrimination by observing the behavior of conspecifics (Fiorito and Scotto, 1992; Fiorito and Chichery, 1995; Fiorito *et al.*, 1998). In the experiment, one group of animals (demonstrators) was first trained to attack one of two simultaneously presented colored balls. When the animal attacked the correct ball, it was rewarded with food which was attached to the opposite side of the ball. If the animal chose the wrong ball, it was punished with an electric shock. In a second phase, untrained octopuses (observers) watched demonstrators attack that stimulus from an adjacent tank. No contingent reward or punishment was given to the demonstrator during this observation period. In the final phase, the observers were exposed to the two balls. In over 80% of all cases, they only attacked the ball of the same color as that attacked by the demonstrator. Untrained animals do not exhibit such a strong preference. This vicariously acquired discriminatory behavior is stable for at least 5 days after the observational phase.

The salticid jumping spider of the genus *Portia* was exposed to a three-dimensional maze which the animal could oversee in its entirety (Tarsitano and Jackson, 1997). One of the two wire paths led to a food lure, the other did not. After visually scanning the entire track, at the first trial the animal already made 75% correct choices at that vantage point. This remarkable display of problem solving requires planning and expectation, performed by a brain of only several hundred micrometers in diameter. Honeybees in a swarm searching for a new nest site inspect potential locations by running in various directions along the walls of the cavity and performing recruitment dances at the surface of the swarm according to the suitability of the cavity as a nest site (its size, humidity, proximity, and possibly other parameters (Seeley, 1977)). The kind of individual learning during these behaviors can only be addressed as observatory learning, because no reward is provided to the animal inspecting a cavity. The search is focused exclusively on potential nest sites: the animal has to integrate a large range of sensory inputs which are accessible only by its own exploratory behavior, and must evaluate them according to an innate template, which cannot be totally fixed, because otherwise a bee would never find a suitable new nest site. Many more such forms

of observatory learning exist in insects, crustaceans, and cephalopods, but only few have been studied carefully, because natural conditions are required for the animal to initiate its exploratory behavior, and it is often difficult to evaluate the learning during observation.

1.26.7.2 Navigation

Navigation is an orientation strategy that allows animals to travel between defined locations without having direct sensory access to these locations. In this sense navigation differs from general orientation and guidance, which include all forms of spatial relationships between the animals' body positions and trajectories of movement relative to sensory conditions. Navigation allows animals to travel over rather long distances relative to their body size and sensory range, according to their knowledge of the structure of their surroundings, which they acquire by sequential experience. Several classifications of navigation have been proposed, reflecting different conceptual frameworks, for example, route and local navigation (O'Keefe and Nadel, 1978), cognitive mapping, piloting and dead reckoning (Gallistel, 1990), egocentric and allocentric navigation (Wehner, 1992; Thinus-Blanc, 1987), random navigation, taxon navigation, praxis navigation, route navigation and local navigation, graph and map navigation (Gillner and Mallot, 1998). Irrespective of whether the classification focuses on sensory, neural, or mental processes, or whether the structure of the external signals was referred to, two basic navigation strategies emerge from these various viewpoints: route strategy (also called graph structure of navigation; Gillner and Mallot, 1998) and local navigation or map strategy (also called cognitive mapping; Tolman, 1948; Gallistel, 1990; Pastergue-Ruiz *et al.*, 1995). Besides these strict definitions, the term navigation is often used in loose terms, for example, when *C. elegans* explores its environment, and genes are characterized that control elements of this exploratory behavior in different ways (Gray *et al.*, 2005; Rodger *et al.*, 2004), or when *Drosophila* runs between two or more visual marks in a rather stereotypic way (Götz, 1975). It is an interesting but yet unresolved question whether genes identified by testing these very simple forms of movement may also be involved in controlling the ontogenetic setup and switching the circuits that underlie navigation in the strict sense. A hint in this direction comes from the observation that the foraging gene (Engel *et al.*, 2000) involved in exploratory behavior in *Drosophila* larvae appears to be more strongly expressed when honeybees switch to foraging behavior (Ben Shahar *et al.*, 2002).

Place learning in a small environment like the Morris water tank provides a useful paradigm for studying components of navigation in small mammals like rats, and their neuronal underpinnings (Morris, 1982). A similar attempt has been followed for the cockroach by providing a cool place on a hot platform (Mizunami *et al.*, 1998). In such a paradigm, called 'the Tennessee Williams paradigm' for obvious literary reasons, a cockroach learns to choose the cooler place using the spatial relationships between landmarks in the environment, though in a less robust way than rodents. In addition, it was found that bilateral lesions in the MB region reduce place learning. Coincidently, crickets may learn to use responses to olfactory stimuli at two different contexts (Matsumoto and Mizunami, 2004), or to combine visual and olfactory cues in choosing a particular exit hole among several identical holes in order to escape from a circular arena (Scotto-Lomassese *et al.*, 2003). MB neurogenesis seems to be crucial for the last task, since irradiating the dividing neuroblasts around this structure suppresses this ability.

In studies with rodents, an essential aspect relates to the distinction between navigation according to landmarks (true 'spatial-based' navigation), a hippocampus-dependent form of behavior, and 'cue-based' navigation, a behavior which in mammals is independent of the hippocampus (Morris, 1982). It is not yet known whether structures of the arthropod brain are differentially involved in these two paradigmatically different forms of navigation, and in particular whether the MB in the insect brain may be a structure necessary for relational, landmark-based navigation. However, a comparison between studies of the cockroach (Mizunami *et al.*, 1998), and the cricket (Scotto-Lomassese *et al.*, 2003) may provide an insight into these questions, because the cockroach study would reflect a case of spatial-based navigation, since the safe place in the arena had to be found on the basis of spatial relationships between external landmarks. The cricket study, on the other hand, could be considered as a case of cue-based navigation, because the correct and the wrong exit holes were marked by nonambiguous cues. Interestingly, the same structure, the MBs, was crucial for both kind of performances, although in the case of crickets it was the formation of new MB-constitutive neurons that was affected, and not the MB circuit itself, as in the cockroach study (Mizunami *et al.*, 1998).

Below we focus on navigation in social Hymenoptera, because the relationship between

route strategy and map strategy has been the subject of intensive and controversial debates in these insects. Traditional thinking about navigation in insects was based on the notion that a toolbox of rather simple sensory–motor routines is at the animal's disposal and their stepwise application may lead to the solution of isolated, rather independent navigational tasks. These robot-like concepts were developed by experiments based on the analysis of route learning, sometimes even at such a small scale that target-related orientation – rather than navigation – was tested (Collett and Collett, 2002). Bees and ants traveling between their nest and a food source learn the vector components of their movements (direction and distance) by a dead reckoning (path integration) process (Wehner, 1992). Landmarks experienced en route may serve to calibrate measured distances (Srinivasan *et al.*, 2000a), thus reducing the rotatory and translatory errors that may accumulate during path integration (Wehner *et al.*, 1996; Graham and Collett, 2002). Furthermore landmarks may provide procedural information about turns to make and distances to travel next (Collett, 1996, 1998; Collett and Collett, 2000; Kohler and Wehner, 2005) such that apparently complex performances could be based on simple rules of learning sensory–motor connections. Honeybees can, for instance, learn to negotiate complex mazes of adjacent boxes by associating colored disks with right or left turns (Zhang *et al.*, 2000; Srinivasan and Zhang, 2004). Since bees are able to refer to a compass direction even when the sun is not available (e.g., under an overcast sky and as measured by their dance performance; von Frisch, 1967; Dyer and Gould, 1981), landmarks also serve as compass-related directional cues that could be understood as a backup system, but it could also mean that landmarks are incorporated into a geostable map-like memory of the experienced environment (see discussion below). The redundancy of landmarks is thought to be reduced by reference to contextual information such as the visual panorama (Collett *et al.*, 2002; Kohler and Wehner, 2005). Consequently, 'isolated' landmarks may not be sufficient for successful navigation, or their information might be suppressed under competition conditions, as often occurs in experiments where bees are transported to an unexpected release site. The animal may then shift its reference to salient signals like farther-ranging landmarks. Furthermore, a dissociation of behavior may occur that seems to indicate the combined action of separate navigational cues. For example, bees flying in a narrow tunnel search at the correct distance if both local and contextual cues are available. If one of the two cues is shifted or removed, then the contextual cue appears to be the more important one (Collett *et al.*, 2002). Under more natural conditions, a dissociation of two forms of distance estimation, odometry by the visual flow field (Esch *et al.*, 2001; Srinivasan *et al.*, 2000b) and landmark sequences, can be found. Chittka and Geiger (1995) set up an experiment in which sequentially experienced landmarks guided free-flying bees over hundreds of meters to a feeding station. The bees searched both at the absolute distance as measured by odometry and at the location designated by the sequence of landmarks. The directional component of flight is also controlled by landmarks (Collett, 1996), and even novel directions can be traveled if a particular landmark constellation simultaneously triggers the retrieval of memories for two different flight directions (Menzel *et al.*, 1998).

Training bees along a route will establish a particular spatial memory structure, and very different forms of spatial memory may result from exploratory orientation flights that bees perform before beginning their foraging life (von Frisch, 1967; Capaldi *et al.*, 2000). Indeed, it was found that bees lacking route training were able to return to the nest from sites all around the hive, located several hundred meters away (Menzel *et al.*, 2000), a range over which orientation flights are performed (Capaldi *et al.*, 2000). Comparing such bees with those trained along a route showed that the working memory of the route dominated initial navigation, leading the animals in the wrong direction and first suppressing the memory that later quickly leads the animals back to their goal (the hive). Since only the initial flight path was monitored in these experiments, and vanishing bearings were taken as measures of navigation, inadequate concepts were derived because the multitude of spatial memories was not considered (Wehner and Menzel, 1990; Dyer, 1991; Wehner, 1992).

Most of the experiments on the role of landmarks on path integration, compass-driven sequential pictorial learning, and the relationship between 'isolated' landmarks and contextual landmarks were carried out in miniature environments which forced bees to fly through narrow entrances into small boxes or mazes (Collett and Collett, 2002). All these tests made forced route training necessary, avoided testing the sequential experience of natural landmarks in unhindered flight, and did not expose the bees to the temporal and spatial structures they would normally experience in free flight. Certainly, such experiments have the advantage of observing the bee over the full flight close to the goal, but the limitations for generalization to natural conditions

are obvious, since they reflect only the approaching components and orientation strategies that bees may adopt when close to the goal. Navigation in the real bee flight range (several kilometers) must be guided by compass-related learning of multiple sequences of landmarks that are visible under different perspectives and over different ranges of the flight path, some of which are only visible when the bees get close to them. The essence of the navigational problem – whether an animal is able to orient itself and infer a direction of movement along a novel path aiming toward another location that is not directly accessible – cannot be addressed by such reduced experimental setups. Questions that are not asked in an experiment cannot be answered by it. Working under natural conditions, however, limits the possibility of untangling the relevant parameters underlying navigation strategies. Therefore, such 'naturalistic' experiments have a different quality. They are necessarily more descriptive and less analytical, but they provide clues for behavioral capacities while allowing a rather limited mechanistic interpretation. Recently, a method based on harmonic radar detection of free-flying bees was applied that allows researchers to observe a bee when it travels over natural distances (see below).

By far most of the experiments on insect navigation were carried out with ants (the wood ant *Formica rufa*, the desert ant *Cataglyphis*, the Australian desert ant *Melophorus bagoti*) and the honeybee. The data were often used to transfer the concepts developed for ants to bees (and even to arthropods in general; Wehner, 1992), implying that navigation strategies are similar in running and in flying insects. Bees fly over distances of a few kilometers, cruising well above ground, with a bird's-eye view; ants run a few tens of meters. It would be rather strange if the navigation systems of running and flying insects, in particular their 'cognitive' (integrative) levels, were similar. Experiments addressing distance estimation in ants and bees clearly show, for instance, that these two insects differ dramatically in their manners of estimating distance. While bees seem to use the optic flow field (the relative displacement of the visual field on the insect retina) experienced en route to the goal, ants do not seem to rely on optic flow to the same extent (Ronacher *et al.*, 2000). Recently it was shown that ants can estimate the distance to travel within a tunnel in the dark without any kind of visual information (Thielin-Bescond and Beugnon, 2005), thus underlying the role of proprioceptive cues for distance estimation in ants.

1.26.7.2.1 The map concept and its experimental support Local navigation or map-based strategy allows goal-directed decisions at any place and toward any intended location in the experienced area, thus resulting in a transfer between routes and inference of novel routes. Such a strategy has until recently not been convincingly documented for insects, and is the subject of lively debate (Giurfa and Capaldi, 1999; Collett and Collett, 2002). Navigational memories that are more flexible than route memories are found in experiments that avoided route training in bees and proved that bees are able to return to the hive from any place around the hive within a rather short time (Menzel *et al.*, 2000). It was concluded that bees learn features of the landscape during their orientation flights (Capaldi *et al.*, 2000) and establish a special 'landscape memory' that relates landmarks to the bees' central place, the hive. It was only recently that the structure of this 'landscape memory' could be critically tested using harmonic radar technology to track individual bees (Menzel *et al.*, 2005). In this study, three test groups were studied and their flight paths recorded after they were released at many different release sites around the hive. The three test groups were: bees that were trained to a feeder placed at variable locations in close vicinity to the hive that was moved around the hive at a constant distance (VF bees) and that therefore did not develop a route memory; bees that were trained to a stationary feeder 200 m to the east of the hive (SF bees) and thus developed a route memory; and bees that were recruited by foragers that collected food at the stationary feeder (R bees). It was found that all bees returned to the hive along fast and straight flights from all regions around the hive. SF and R bees did so after they had performed the vector (distance and direction) components of their trained or instructed route flights; VF bees returned after searching for a while. Most importantly, SF bees performed either direct flights back to the hive or via the feeder to the hive.

Several operations must be at the animal's disposal: (1) recalling memories of these vectors (segments with defined headings and distances) pointing toward the hive with a large number of landmarks all around the hive that are recognized from different viewpoints, (2) a shift in motivation (fly toward the hive or toward the feeder), (3) reference to the outbound vector components of the route flight from hive to feeder, and (4) addition and subtraction of the flight vectors for at least two sets of vector memories; those which would lead directly back to the hive, and those that lead from the hive to the feeder. It is difficult to imagine that these

operations can be done without reference to vectors that relate locations to each other, and thus make up a map. The question now in bee navigation is not so much whether there is a map-like spatial memory, but rather 'What structure does this map-like memory have and how is it used?'. In any case, the map-like memory in bees is rich and can be used in a flexible way. Any model of bee navigation thus has to incorporate a strategy based on a map-like representation of the bees' large-scale home range and a freedom to choose between at least two goals. This further suggests that spatial relations between environmental features appear to be coherently represented in a map-like memory in insects as they are in other animals and humans (Gallistel, 1990; Shelton and McNamara, 1997; Klatzky, 1998).

Parsimony is a strong argument in the interpretation of experimental data, and has been applied rather strictly in studies of insect navigation (Wehner, 1992). However, it should not be overlooked that radical forms of parsimony as applied to behavioral science were (and may still, at least partially be), a historical burden. New approaches were required to correct for eliminating the brain in behaviorism and making too simple assumptions about the brain's functions in ethology. These cognitive approaches (cognitive ethology, psychology, neuroscience) provide us with novel avenues to brain function (Kandel and Squire, 1992). A frequently used argument in navigation studies, which states that reference to cognitive processing (a cognitive or mental map) must be avoided as long as 'simpler' explanations are at hand (Bennett, 1996), may warn us about potential traps, but should not be accepted as a ban. Furthermore, it is argued (Collett and Collett, 2002) that small brains, like that of the bee, need to solve their tasks with less 'cognition', meaning with a toolbox of loosely interrelated elementary functions rather than an integrated, allocentric level of spatial representation (see discussion above). It should be recognized that we simply do not know whether the integration of the multiple and complex sensory and procedural neural processes into a common spatial memory with geometric organization (a map) may not be a more economical and thus simpler way of representing sequential experiences during navigation (Griffin, 1984).

1.26.7.3 Communication

All sensory channels (besides magnetic sense) are used in invertebrates for communication, and elaborate sender–receiver systems have evolved for intersex communication, predator–prey relationships, and social interactions. Communication by pheromones has been addressed above (see Section 1.26.2). Optical signals include light emission by luminance organs in night-dwelling invertebrates ranging from unicellular organisms to crustaceans and insects (Lall, 1993; Buck and Case, 2002). Sex-specific coloration and movement patterns of body appendages or of the whole animal are often used to attract the other sex, and specific photoreceptors or visual interneurons have evolved (e.g., the flight maneuvers and the 'love spot' in diptera; Hornstein *et al.*, 2000; Egelhaaf and Kern, 2002). Airborne sound and substrate vibration are most important signals for all three behavioral conditions of communication (intersex, predator–prey, social interactions; Cocroft and Rodriguez, 2005). Although the sensory, ecological, and evolutionary aspects of these communication systems have been often studied in great detail in invertebrates (e.g., sound communication in insects: Henry (1994), Gerhardt and Huber (2002); substrate vibration in spiders: Barth (2002), and in insects: Hölldobler and Roces (2000), Cocroft (2003); visual signaling in butterflies: Eisner and Aneshansley (1973); chemical signaling: (Hölldobler and Wilson (1990), Eisner and Meinwald (1995); see also Section 1.26.2), very little is known about the cognitive dimensions of these communication systems, for example, how the innate mechanisms interact with experience-dependent developmental processes, how the innate mechanisms are related to internal and external context conditions, whether learning shapes the communication process, and if communication leads to individual recognition (see discussion below). More is known in these respects about the ritualized movements ('waggle dance') used by honeybees to communicate distance and direction from the hive or the swarm to important places (potential nest sites, feeding, water or resin places). We therefore consider this form of communication in more detail.

1.26.7.3.1 The cognitive dimensions of dance communication in honeybees In the waggle dance, a dancing bee (*Apis mellifera*) executes fast and short forward movements straight ahead on the comb surface, returns in a semicircle in the opposite direction, and starts the cycle again in regular alternation (each waggle dance involves several of these cycles; von Frisch, 1967). The straight portion of this course, called a waggle-run, consists of a single stride (Tautz *et al.*, 1996) emphasized by lateral waggling motions of the abdomen. The length of the single waggle-runs increases with the distance flown to reach the source, and their angles relative to gravity correlate with the direction of the

foraging flights relative to the sun's azimuth in the field and sun-linked patterns of polarized skylight. Thus, by encoding the visually measured distance (Esch and Burns, 1995; Srinivasan *et al.*, 2000a; Tautz *et al.*, 2004) and the direction toward the goal, the waggle dance allows colony members to share information about the distance and direction toward a desirable goal (von Frisch, 1967; Seeley, 1995; Dyer, 2002). Although Karl von Frisch used the term "dance language," Premack and Premack (1983) correctly stated that the honeybee dances should not be called a language, based on the argument that there is no evidence that the bees can judge whether their dances conform to anything in their surroundings. This question can be addressed by asking whether a bee receiving information from the dance responds differently to the information depending on its own experience. Such experiments have yet to be performed. There is also no evidence yet that honeybees employ chain communication whereby an animal picks up on the received information without experiencing itself the primary signals inducing the dance. In his studies of dance communication within a swarm, Lindauer (1955) did not observe a bee changing its dance pattern until it had actually visited the second cavity, and these observations were verified more recently by Visscher and Camazine (1999), who observed no higher attraction of bees to dances which indicated the same location as the one for which they had previously been dancing. The authors also found that it takes a swarm longer to get started with the flight to a new nest site if the decision must be made between alternative nest sites, and they present arguments for some form of collective "quorum sensing" (Seeley and Visscher, 2004; see also below). Furthermore, the term "language" is also misleading, because there is (as far as we know) no semantics or grammar in the ritualized movements of the dance. "Indexical" or "iconic" (Bermudez, 2003) would be better descriptive terms to characterize the informational status of the dance.

Since navigating bees benefit from path integration (Wehner and Menzel, 1990; Dyer, 1998; Collett and Collett, 2002; Wehner, 2003), vector memories derived from recent flight paths might be recalled in the dance context. Indeed, path integration (which requires working memory in order to continuously record the angular and linear components of the animal's movements) provides ants and most likely also bees with 'global' vectors at the ends of their outbound paths, which allow them to follow straight trajectories of the appropriate distance and direction during their inbound path. Although the global vector is emptied each time the animal returns to the nest, desert ants can store a short-lived 180°-reversed form of a recently experienced homing path, and use it to guide their outbound paths toward previously visited locations (Wehner, 1992). Moreover, when trained bees arriving at a foraging target are held captive for several hours, they subsequently fly farther outward away from the hive along the same hive-target direction (Dyer *et al.*, 2002). We may therefore assume that forager bees also store a form of global vector that they later recall in the context of the waggle dance. But does the waggle dance encode a global vector, an integrated form of the measures of distance and direction, and/or even code for a location?

Early detour experiments by von Frisch and colleagues (reviewed in von Frisch, 1967) indicated that the bees' visually driven odometer is primarily decoupled from the processing of directional information, indicating that no global flight vector is reported in the context of the waggle dance. When bees are compelled to fly a two-legged detour path to reach the goal, their dances indicate the direction of the straight line toward the goal (computed from the two legs of the detour), even when they followed the detour on the way back to the colony; but they signal the distances actually flown, and not the distance of the straight segment connecting the target and the hive's entrance. These early findings were recently confirmed by manipulating the navigational information provided to a dancing bee (De Marco and Menzel, 2005). Thus, one might ask whether the waggle dance encodes spatial information provided only by the actual flight path. The role of landmarks so far has been considered only in the context of resetting (Srinivasan *et al.*, 2000b) or calibrating the odometer (Tautz *et al.*, 2004) but not in the communicative process. The detour experiments by von Frisch suggest that the directional component reported in the waggle dance may also be derived from stored path integration coordinates of visually defined locations (landmarks). This idea is not without precursors. Early experiments showed that with increasing experience of the terrain, directional information available during the inbound flight may be computed for the purpose of directional indication in the waggle dance (Otto, 1959). If the waggle dance computes directional information which depends not only on the current state of the animal's path integrator, but also on information that the animal has associated with landmark views, that is, local vectors associated with landmarks (Etienne *et al.*, 2004), navigating bees would rely not only on an egocentric, but also on a geocentric system of reference.

It has been argued in the section on navigation (see Section 1.26.7.3) that the navigational strategies applied by foraging bees cannot be fully appreciated if one assumes a hive-centered egocentric form of spatial memory. Instead, it seems that the orientation flights of young or reorienting bees lead to a map-like spatial memory that appears to be derived from repetitive exposure to the same landmarks from different viewpoints. Given this capacity and the fact that bees are recruited by a dancing bee only after they performed their orientation flights, it is tempting to assume that bees attending a dance might recall from its memory of landmarks and homing vectors a corresponding outbound vector that is related to expected landmarks. Under these conditions neither the dance behavior nor the flight path of a recruited bee would be guided solely by two independent measures (direction and distance) but rather by an 'expectation' to arrive at a particular location. A component of this 'expectation' would be the route to be followed, as embedded in the map-like memory including sequences of landmarks. Indeed, already von Frisch (1968) stated that the effectiveness of waggle dances (in terms of successful recruitment) depends upon the foraging experience of the dance followers. When two groups of fellow bees have visited two different (and currently exhausted) unscented feeding places, contact with a dancer indicating the accustomed goal is much more effective than contact with a dancer indicating the unfamiliar one. In spite of these early findings, however, the role of stored navigational information on the decoding process involved in the waggle dance remains entirely unknown.

1.26.7.4 Individual Recognition

Cricket males perform rivalry songs, defend their territories, and fight against each other (Alexander, 1961; Adamo and Hoy, 1995); however, no clear evidence exists yet that winners and losers learn to recognize each other on an individual basis (Paul Stevenson, personal communication). The yellow–black patterns of the faces and the abdomen of the paper wasp *Polistes fuscatus* vary considerably, making it possible that individual animals in these small colonies might recognize each other (Tibbetts, 2002). More variable patterns with larger black components were found to be carried by individuals ranking higher in the nest hierarchy. Altering these facial and/or abdominal color patterns induces aggression against such animals, irrespective of whether their patterns were made to signal higher or lower ranking, and arguments – though not fully conclusive – have been provided stating that this altered aggressiveness may indicate individual recognition (Tibbetts and Dale, 2004). Although this study appears to indicate the first case of individual recognition in insects, it is rather likely (but not yet proven) that other invertebrates, in particular territorial cephalopods like octopus, should recognize each other on an individual basis.

An additional but in no way necessary component of individual recognition is 'self-recognition', the discrimination between signals from the animal's own body from those from the outside world. Do invertebrates experience 'pain', a form of self-recognition that includes an emotional and a warning component that points to the future? Locusts and crabs cast off body appendages when attacked. Do they experience different forms of sensory input when they perform these actions themselves or when the same appendages are removed? When honeybees lose their stinger the abdomen is damaged so much that the animal will die. It has been observed that alarm pheromone, which usually triggers an attack flight, induces stress analgesia via an opioid system in the honeybee (Nunez *et al.*, 1997), potentially indicating that a preparatory response of the nervous system leads to a reduction of the strong sensory input from the body distraction. Opioids, which are usually associated with stress-induced analgesia, have been found in other invertebrates such as crickets (Jaffe and Blanco, 1994) and the praying mantis (Zabala *et al.*, 1984), thus suggesting that their presence may serve to counteract the effect of nociceptive stimuli as in vertebrates.

E. O. Wilson states on the final page of *The Insect Societies*:

> The insect societies are, for the most part, impersonal. The small, relatively primitive colonies of bumblebees and Polistes wasps are based on dominance hierarchies, and individuals appear to recognize one another to a limited extent. In other kinds of social insects, however, personalized relationships play little or no role. The sheer size of the colonies and the short life of the members make it inefficient, if not impossible, to establish individual bonds (Wilson, 1971).

As pointed out above (Section 1.26.2), the sheer unlimited capacity of honeybees to discriminate odors provides the potential for discrimination of a very large number of group constellations, even to the level of individual recognition. Only recently has it become possible to separately mark all individuals in a bee colony for automatic detection, and it will now be possible to track life history, behavior, and social contacts on an individual basis continuously over long periods of time.

Sociobiological arguments have been put forward to argue that due to haplodiploid reproduction in

hymenopteran societies their members should be characterized by less individuality, more gene-related group effects, and some form of individuality of the society (Queller and Strassmann, 2002). From a cognitive point of view, individuals are defined by the operations within their nervous systems, and their experience that this nervous system belongs to a particular body. As Churchland (2002, p. 310) points out "Body-state signals have to be integrated, options evaluated, and choices made, since the organism needs to act as a coherent whole, not as a group of independent systems with competing interests." Body-state signals are continuously integrated in members of an insect society, options are implicitly evaluated as indicated in the communicative processes, and the individual organism acts within the society. As in the case of implicit operations on working memories (representations), individual recognition within the society does not require the assumption of any form of explicit (personal) recognition of oneself and another member of the society. In this sense, one may use the modern techniques to search for discrimination on the individual level in communication within insect societies.

1.26.7.5 Collective Cognition

So far, we have concentrated on individual cognitive capabilities, because learning and memory are properties which depend on individual experience and which have to be studied, therefore, at the individual level. However, individuals of many species live in societies or form groups, and therefore face problems that require coordination, task sharing, and collective decision making. From this perspective, it is legitimate to ask whether collective behaviors reflect or even surpass individual plasticity, due, for instance, to the possible additive effect of individual cognitive capacities.

This question has been the subject of debate in social insects in which colonies were considered 'superorganisms' (Seeley, 1989; Southwick, 1983; Wilson and Sober, 1989). From this point of view, it has been argued that the 'superorganism' protects and constitutes itself thanks to colony recognition systems based on cuticular hydrocarbons which are transferred between individuals within the colony, thus obscuring, in theory, individual identity (Queller and Strassmann, 2002). The metaphor of the 'superorganism' may be in a sense misleading, because an individual, behaving organism is made from cells and structures tightly interconnected by complex neuronal, circulatory, and regulatory networks, and has a central brain that commands and produces behavior; the 'superorganism', on the other hand, is made up of individuals which may be interconnected by complex chemical interactions but which are rather autonomous and can be hardly compared to constituent cells. The essential difference, however, is that although an insect colony produces collective behavior, it does not have a central brain to command and control such behavior. On the contrary, studies on collective decision making in social insects show that collective behavioral patterns can arise without any central control. How, then, can these patterns of collective behavior emerge? This question has been intensively tackled by studies focusing on self-organization models of collective behavior (Camazine *et al.*, 2003). Such studies deal with pattern formation processes in the physical and biological world, which determine the arising of global order and structure based on simple interactions between lower-level components, in this case, individuals (see above: decision making in a bee swarm).

Such studies have allowed researchers to understand that – despite their potential complexity – many collective insect behavior patterns emerge from simple interactions between individuals, which seem to act on the basis of extremely simple behavioral rules. For instance, cockroaches and other insects seeking refuge exhibit complex aggregation phenomena and group distribution between available shelters. Instead of resulting from individual decision making and evaluation and comparison of each refuge's characteristics, collective aggregation results from individual probabilistic rules determining when to stop walking or when to resume. Factors like the presence of borders or of a co-specific may amplify these probabilities like a snowball (i.e., the larger the cluster, the higher the probability of attracting even more individuals; see Theraulaz *et al.*, 2003) but the collective behavioral pattern emerges without central control or individual comparison strategies (Jeanson *et al.*, 2003, 2005). Similarly, complex architectural structures characterizing ant or termite nests arise without central control, simply based on a restricted set of individual behaviors performed in a rather automatic way, without 'knowledge' of the behavioral patterns exhibited by other individuals (Buhl *et al.*, 2004). Ants facing a diamond-shaped bridge with two branches choose randomly between branches if both are identical but collectively orient their choice and select one branch if it has a lateral wall along its edge. Pharaoh ants walking the wrong way along a trail are unable to reorient at a trail bifurcation if the angle is 120°, but can if the angle is smaller (Ratnieks, 2005). Such a collective systematic

choice does not result from a sum of individual evaluations and decisions but from amplification processes based on physical heterogeneities and chemical communication (Dussoutour *et al.*, 2005). Thus, a preference is set without a clear incidence of individual decision making and comparison. Differences in individual thresholds for reacting to environmental sensory stimuli seem to be a critical factor for the emergence of collective behaviors based on task partitioning. Not all individuals within a group will respond similarly to the same set of environmental stimuli such that differences in reaction thresholds may be the basis for behavioral specializations and thus for the emergence of sociality.

The conclusion emerging from these studies on insect collective behavior is that individuals, which may be viewed as extremely sophisticated at the cognitive level when performing some individual tasks, appear as automatons with limited cognitive capacities when performing collective tasks. This difference may seem puzzling, because it could be that cognitive richness is lost or at least temporally inhibited in a social context. What, for instance, drives a honeybee scout, which is able to learn space in the form of a cognitive map (Menzel *et al.*, 2005) and learns the localization of a potential nest site and its physical characteristics (Seeley, 1982), to follow dances once, at random, in the hive, instead of crossing over and comparing dances for selected sites in the process of nest selection (Visscher and Camazine, 1999)? In fact, it can be argued that the question does not actually make sense from the point of view of the individual insect: in an individual and in a social context, the animal will adopt the behavioral strategies leading to adaptive solutions either boosting or sacrificing what researchers would view as cognitive sophistication. The critical question in this context is therefore what determines the adoption of one or the other level of cognitive complexity? Which factors are responsible for the fact that an ant or a bee that can learn and memorize several cues while foraging solve complex discriminations and generate novel behaviors leading to adaptive solutions, behave like an automaton following a reduced set of repetitive patterns and simple rules in a social context? Which physiological changes, if any, determine the passage from one state to the other? Do social regulation pheromones intervene in the expression or inhibition of behavioral autonomy in a social context by acting on neurotransmitter levels in the insect nervous system? So far, we have no answers to these questions, but they can be approached on an experimental level. Studying whether or not individual learning and memory are modified by exposure to social pheromones or by chemosensory cues within a group and whether or not biogenic amine and neurotransmitter levels are changed in the presence of a group of co-specifics are just some of the paths that can be followed to provide some answers to these questions.

1.26.8 Conclusion

The environment poses the same basic demands on animals with small and with large brains. How do mates find each other, how much effort, risk, energy, and time must be invested to find food, what is the best way for the animal to protect itself and avoid predators or hazardous conditions, and how does the animal find its way around are questions that have to be answered both by vertebrates and invertebrates in order to survive. It is usually concluded that invertebrates, with their smaller brains, apply local solutions to these problems, that is, solutions that are specific and isolated, local in a verbal, a mechanistic, and a behavioral sense. Verbally, a localized solution may mean that it may suit only a problem at a particular location in space and time. Mechanistically, local solutions may mean that only specific sensory–motor connections in the nervous system may exist with no cross-talk between them and no common level of memory storage. Behaviorally, local solutions refer to independent behavior routines that are applied without gaining from each other in different environmental conditions. In other words, the concept of information transfer between sensory–motor routines, translated in the rise of novel behaviors that allow responding to novel environmental demands, seems to be neglected or minimized in the case of invertebrates.

Our review provides multiple indications as evidence against such an understanding, which ignores the enormous richness of invertebrate behavior, its high flexibility, and the cross-talk between different behavioral routines. Rather, it is appropriate to conceptualize invertebrate behavior from a cognitive perspective, meaning that small nervous systems also interconnect the sensory and motor systems, and install memories not only into specific sensory–motor circuits but into a common reference system as well. As a consequence, many invertebrate species that were studied in this respect were found to extract rules from particular sequences of experience and transfer these rules to other sensory domains. Furthermore, the structure of the memory established in this way represents the multiple sensory inputs and related behaviors in an integrated

way such that a representation of complex environmental conditions is formed. Such capacities may not be surprising when the underlying neural substrate subserving them is explored in detail. As in larger brains, two basic neural architectural principles of many invertebrate brains are: the existence of specialized neuropiles, which refer to specific sensory domains, and higher-order integration centers, in which information pertaining to these different domains converges and is integrated, thus allowing cross-talking and information transfer. In this sense, both modularity and central integration seem to be basic building principles adopted by different nervous systems to provide flexible solutions to a changing environment. Navigation and communication in social Hymenoptera are particularly telling examples in this respect, but it is fair to conclude that similar integrated forms of dealing with the environment will be found in other invertebrates when they are looked at more closely. In this sense, research addressing behavioral complexity and its underlying neural substrates is necessary to characterize the real potential of invertebrate learning and memory. Usually such an approach has been used to characterize behavioral simplicity rather than complexity. It therefore seems timely to focus on the latter by studying problem solving besides elemental forms of learning.

One of the major questions of behavioral biology in general is also unresolved for invertebrate behavior: the relationship between innate and acquired behavior. Innate behavior can often be considered highly integrated in the sense that rather complex motor performances are adequately expressed in particular stimulus combinations. The 'intelligence' of these integrated systems stems from the specific activation of such innate behavioral components in the animal's motivational conditions and the often less obvious experience-dependent adaptations. We have tried to capture these complex interactions between innate components, motivation, and acquired memory by coining the terms 'phylogenetic memory' and 'experience-dependent individual memory'. Indeed, both forms of stored information are based on the intimate connectivity of the nervous system, and from the point of view of how memory is retrieved it may not matter how the relevant memory has been stored. Rather, it seems crucial for the organization of memories and the expression of resulting behaviors how memory is acquired, that is, to which natural conditions do memories provide solutions. The intimacy between phylogenetic and experience-dependent memory is reflected in the fact that innate and acquired information can often not be separated in any given behavior. Although we have stressed the point that the richness and flexibility of acquiring information through experience is the key issue in a cognitive perspective of invertebrate behavior, it should not be overlooked that innate components cannot be considered less cognitive if they are closely connected with flexibility and adaptiveness. To which extent innate components constitute real limitations of invertebrate behavior must be analyzed in an ecological and evolutionary perspective which takes into account the evolutionary consequences of innate behaviors. Invertebrates provide us with an enormous range of solutions to these integrated forms of dealing with changing environmental conditions and the animal's needs. Ideally, more studies on invertebrate behavior will be inspired by this cognitive perspective.
