The focus on the chiasm midline began when tracing analyses revealed the course of fibers of retinal axons that diverged or turned away from the midline of the optic chiasm (Godement *et al.*, 1990). Only fibers from the VT retina, e.g., those with an ipsilateral projection, are tipped with highly complex growth cones, similar to those seen *in vitro* at a border of inhibitory substrate (Mason and Erskine, 2000, 2004). Time-lapse studies of retinal axon dynamics indicated that, in fact, growth cones arising from all parts of the retina pause at the midline and develop growth cone forms that are more complex than those seen in the optic nerve or tracts, where rapid, straight-ahead growth occurs (Godement *et al.*, 1994; Mason and Wang, 1997). The cellular composition of the midline region was then investigated to determine the cellular basis for inhibition of extension of the uncrossed fibers, and a slowing down of growth of the crossing fibers.

The midline region of the ventral diencephalon in which the optic chiasm develops contains two cellular specializations that have been implicated in regulating RGC axon guidance. One cell population is a group of radial glia with cell bodies positioned at the floor of the third ventricle, with their fibers straddling the midline and end-feet on the pia of the ventral diencephalon. During the establishment of the permanent ipsilateral projection (middle period, Figure 4b), all retinal growth cones enter this glial palisade before crossing or turning back from the midline. As seen by ultrastructural analysis, the lamellae of the growth cones interdigitate with the radial glia processes, suggesting that interactions between these cells play a critical role in directing RGC axon pathfinding (Marcus and Mason, 1995; Mason and Sretavan, 1997).

The second group of cells located at the ventral diencephalon during optic chiasm formation is an

early born population of diencephalic neurons (Mason and Sretavan, 1997; Mason and Wang, 1997; Sretavan *et al*., 1994). These neurons constitute a V-shaped template of cells around which retinal axons express specific carbohydrate epitopes such as stage-specific embryonic antigen-1 (SSEA-1)), CD44 (a hyaluronan-binding protein), and others (Kaprielian *et al*., 2001; Marcus *et al*., 1995; Sretavan *et al*., 1994; Figure 4). Experiments in which these cells have been perturbed provide evidence that they are essential for proper growth around the chiasm, even though the growth appears to be around the confines of the cell population (Sretavan *et al*., 1994). In lower vertebrates, with totally crossed pathways, there are equivalent ensembles of cells, e.g., early born neurons that constitute the tract of the postoptic commissure and midline glia, but less is known about their epitope expression and retinal growth cone relationships (Maggs and Scholes, 1986; Wilson *et al*., 1988).

In vitro experiments have shown that when cocultured with cells dissociated from the optic chiasm region, axons from the VT retina grow less well than axons from other areas of the retina (Wang *et al*., 1995, 1996). These *in vitro* experiments demonstrated that the midline glia and the early neuron population express signals that are repulsive for uncrossed RGC axons and less so for crossed RGC axons, as predicted by the different growth cone forms on retinal axons during divergence from the chiasm midline.

In summary, the growth pattern of divergence within the radial glial palisade and growth around the contours of the early born neurons, as well as the differential growth inhibition on dissociated chiasm cells, implicate midline radial glia and early born neurons as prime candidates for patterning the optic chiasm. In the following section, we review the molecular cues expressed on these cells of the chiasmatic region that serve as growth and inhibitory signals for proper channeling of axons and placement of the X of the optic chiasm and that produce the differential response of retinal axons to cross or avoid the midline – all critical for proper optic chiasm formation.

3.23.2 Molecular Mechanisms of Retinal Axon Guidance at the Optic Chiasm

3.23.2.1 Molecules That Shape the Placement and Integrity of the Chiasm

A number of guidance factors that play a role in axon guidance at the midline have been localized to the area in which the chiasm forms. However, rather than directing the crossing and/or avoidance of the midline to implement retinal axon divergence, several of these factors play a role in ensuring proper placement of the chiasm and general fasciculation of retinal fibers, without specifically being selectively repulsive or supportive of different subpopulations of retinal axons.

The secreted glycoproteins, the Slits, and their receptors, the Robos, lead to repulsive interactions that mediate midline crossing in *Drosophila* and in the ventral spinal cord of vertebrates (Kidd *et al*., 1999; Long *et al*., 2004). Slits and Robos are expressed in the early born neurons in the ventral diencephalon and radial glia in the preoptic area rostral to where the chiasm forms, as well as in the retina during the formation of the optic chiasm (Erskine *et al*., 2000), but the Robo receptors are not localized selectively in RGCs that give rise to crossed or uncrossed pathways. Mice in which both Slit1 and Slit2 are missing exhibit routing errors at the optic chiasm level, including multiple decussations and straying into the ventral diencephalon (Plump *et al*., 2002). However, an ipsilateral projection forms in the double knockouts, suggesting that Slits channel axons into a repulsion-free corridor, normally positioned at a precise point along the anteroposterior axis, rather than acting as midline gatekeepers for uncrossed versus crossed axons. Likewise, in zebra fish, Robo receptor nulls show extreme errors in fiber routing, with axons wandering and multiple chiasmata being formed (Fricke *et al*., 2001).

A second molecular family thought to play a role in the routing of retinal axons at the chiasm, based on localization and experimental perturbation, is the proteoglycans (PGs). Chondroitin sulfate proteoglycans (CSPGs) are expressed by the early born, CD44-SSEA-positive neurons in the ventral diencephalon (Chung *et al*., 2000) and have an age-dependent effect on RGC axon guidance. Enzymatic removal of CSPGs at E13.5 leads to axon stalling or misrouting and many axons fail to cross the midline. When CSPG removal is performed at later stages, only ipsilateral axons are affected. Heparan sulfate PGs, including neurocan and phosphacan, are localized to the chiasm region and optic tract and have been proposed to participate in fiber sorting rather than divergence *per se* (Leung *et al*., 2003, 2004). In the visual pathway of zebra fish, PGs have also been implicated in optic tract fiber sorting (Lee and Chien, 2004; Lee *et al*., 2004). This study and others based on genetic models (Kantor *et al*., 2004) have indicated that PGs can regulate the effect – either positive or negative – of known guidance receptors and cues, such as in the Robo/Slit and Semaphorin families (Lee and Chien,

2004). It remains to be tested whether or not these guidance cues interact with PGs in the chiasm, and if so, what their effect on divergence is.

Other guidance factors and morphogens that are prominent in other midline loci, such as the floor plate of the spinal cord, have been analyzed during optic chiasm formation. Sema5A functions to channel RGC axons within the optic nerve (Oster *et al.*, 2003), but the semaphorins have not been studied in detail at the optic chiasm.

Sonic hedgehog seems to restrict RGCs to the proper dorsoventral position around the chiasm midline in the earliest phase of axon growth, as studied in the chick (Trousse *et al.*, 2001).

Thus, many of the guidance molecules that function in other systems do not appear to directly mediate retinal axon divergence at the chiasm, even though they facilitate several aspects of retinal axon navigation in the ventral diencephalon.

3.23.2.2 Axon Guidance Factors That Mediate Divergence at the Chiasm

The guidance family whose function in retinal axon divergence is more defined is the B subclass of Ephs and their ephrin ligands (Klein, 2004). Ephs and ephrins are membrane proteins that mediate repulsion and regulate many processes during embryonic development and they are key in the formation of topographic projections of retinal axons in the optic tectum/superior colliculus. EphrinAs occupy a domain just ventral to the optic chiasm, where they may restrict retinal axons from growing into inappropriate regions of the hypothalamus (Marcus *et al.*, 2000). EphrinAs do not specifically instigate a differential response between contra- and ipsilateral axons. In contrast, there is ample evidence that ephrinBs direct retinal axon divergence at the optic chiasm. The retinal projection in *Xenopus* is completely crossed but at metamorphosis, an uncrossed retinal projection develops as a result of a new wave of RGC neurogenesis in the VT retina (Marsh-Armstrong *et al.*, 1999). An ephrinB is present at the chiasm coincident with the formation of this uncrossed component at metamorphosis, and premature misexpression of an ephrinB in the ventral diencephalon induces an ectopic ipsilateral projection (Nakagawa *et al.*, 2000).

In mouse, ephrinB2 is a prominent player in directing divergence at the chiasm. The uncrossed RGC axons from the VT retina are especially sensitive to ephrinB2, resulting in inhibition of their extension through the midline (Williams *et al.*, 2003). Importantly, these data support previous results describing direct interaction between retinal growth cones and midline glial cells because ephrinB2 is expressed in the radial glia population located in the chiasmatic region (Williams *et al.*, 2003; Figure 5).

3.23.2.3 Molecular Differences between Uncrossed and Crossed RGCs

The discovery of ephrinB2 as mediator of inhibition of uncrossed axons at the chiasm midline encouraged

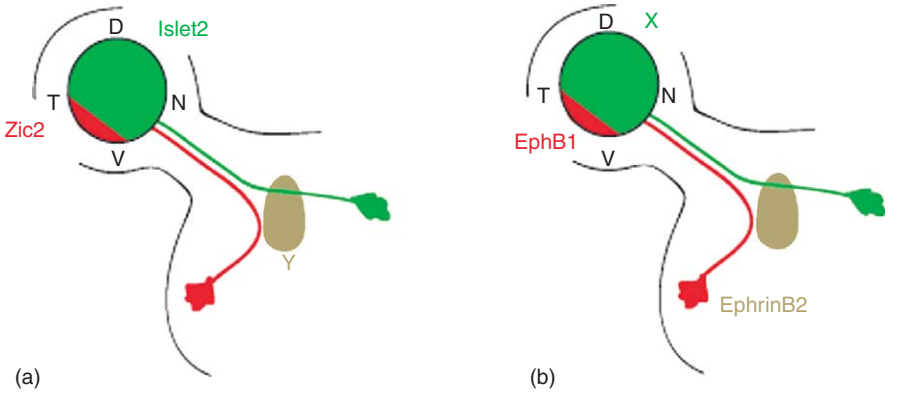

Figure 5 Molecular players mediating the retinal projections through the optic chiasm. a, Transcription factors: Zic2 is expressed by RGCs located specifically in the VT retina (red), which gives rise to the uncrossed retinal projection. Islet2 is expressed only in crossed RGCs (green) located in a pattern complementary to Zic2-positive cells. Islet2 does not specify contralateral cells, since mice deficient in Islet2 function still conserve most of the contralateral RGCs, but it could negatively regulate Zic2. A set of transcription factors localized at the ventral diencephalon (Y, brown) appear also to be important for specification of the cellular/molecular cues of the chiasm midline and to be crucial to retinal axon divergence. b, Axon guidance factors: Uncrossed RGC axons expressing EphB1 (red) turn away from ephrinB2-expressing midline glia near the midline (brown), whereas crossing RGCs (green) traverse the ephrinB2 zone. It is unknown whether the crossing axons express a complementary axon guidance molecule (X) functioning actively to overcome the inhibitory cues or whether they use an entirely different molecular mechanism to cross the midline.

the search for a specific receptor for ephrinB2 involved in this process. Of all the possible Eph receptors that could interact with ephrinB2, EphB1 is the only one that is highly expressed in the VT retina in RGCs with an ipsilateral trajectory during the period of their outgrowth. Furthermore, in mice lacking EphB1, the ipsilateral retinal projection is severely diminished, suggesting that this receptor is both specific and required for the formation of the uncrossed projection (Williams *et al*., 2003; Figure 5).

Thus, ephrinB2 at the chiasm and EphB1 at the retina appear to be the principal axon guidance molecules that direct retinal axon divergence at the chiasm midline. But what controls the finely tuned spatial and temporal specificity of the expression of these guidance molecules? The emerging view in other models used to study neural identity and axon trajectory is that each neuronal subtype possesses an intrinsic capacity to detect its own unique path soon after it becomes postmitotic (Shirasaki and Pfaff, 2002). This ability is conferred by the action of specific transcription factors that regulate programs of axon guidance, through the control of expression of receptors to guidance factors by binding to specific DNA domains.

Zic2, a zinc finger transcription factor involved in early neural patterning, has been identified as the first regulatory gene directly involved in axon divergence at the optic chiasm (Herrera *et al*., 2003). Zic2 is expressed postmitotically in RGCs that project ipsilaterally but not in contralaterally projecting RGCs, during axonal extension through the optic chiasm. Zic2 is crucial for directing the ipsilateral retinal projection, since genetically modified mice expressing low levels of this protein (Zic2 knockdown mice) show a severe reduction in the number of uncrossed axons. Interestingly, Zic2 expression in the VT retina is conserved in both mammals and amphibians, precisely mirroring the extent of binocularity. In ferret, the number of cells expressing Zic2 in the VT retina is greater than in mouse, according to the greater proportion of uncrossed axons. In *Xenopus*, Zic2 expression is upregulated at metamorphosis, coinciding with the late development of the uncrossed component, whereas chick lacks an ipsilateral projection and, accordingly, Zic2 is not expressed in any part of the retina. Of interest is that in albino mice, which have fewer uncrossed axons than pigmented mice, the number of Zic2-expressing RGCs is reduced, exactly matching the reduced size of the uncrossed component.

Zic2 expression in the VT retina matches the spatiotemporal expression of EphB1 (Pak *et al*., 2004). Despite the close spatiotemporal relationship between Zic2 and EphB1, whether Zic2 regulates EphB1 in the VT retina or is simply expressed in a parallel program remains to be tested. However, whereas Zic2 and EphB1 are co-expressed in the VT retina during the formation of the permanent uncrossed component, EphB1 – but not Zic2 – is present in the dorsocentral retina when the early transient ipsilateral projection forms (see Figure 4), suggesting that EphB1 expression at this time may be controlled by transcription factors other than Zic2.

EphB1 and ephrinB2 are axon guidance signals that mediate repulsion. Since retrograde labeling experiments in EphB1 null mice show that normally ipsilaterally projecting RGCs project contralaterally, it is reasonable to think that EphB1/ephrinB2 repulsive signaling is sufficient for guiding the turning of the ipsilateral projection at the midline. However, there are some ipsilaterally projecting cells remaining in the EphB1 mutant that appear not to respond to the absence of EphB1 when encountering the midline. Moreover, Zic2 knockdown mice exhibit a phenotype that does not perfectly match that of mice lacking EphB1. In both $Zic2^{kd/kd}$ and EphB1 mutants, there is a strong reduction in the number of fibers that project ipsilaterally (Williams *et al*., 2003), but in $Zic2^{kd/kd}$ mice, there is an additional defasciculation phenotype in which retinal axons wander from the distal optic nerve (Herrera *et al*., 2003), suggesting that Zic2 may mediate axon patterning by coordinating the regulation of multiple guidance genes. Further experiments will be required to clarify whether or not other forces apart from the inhibitory-EphB1/ephrinB2-mediated response of ipsilateral axons, for instance, an opposing program for crossing the midline, participate in divergence of uncrossed axons.

3.23.2.4 The Crossing Pathway

As described above, the proper expression of some axon guidance molecules, such as Slits/Robos and PGs, is required for contralateral axon crossing of the midline, in terms of fasciculation and placement of the cross-point. At the transcriptional level, one report identifies the LIM homeobox transcription factor Islet2 as being exclusively expressed by RGCs outside of the VT crescent. This pattern is complementary to that of Zic2 expression. Curiously, mice lacking Islet2 exhibit an increase in the number of ipsilateral axons arising from an expansion in the domain of ipsilateral RGCs in the VT retina, rather than a total loss of the contralateral projection (Pak *et al*., 2004). Concomitantly, the number of Zic2-positive cells increases. Based on these findings, Islet2 is thought to repress the Zic2-mediated

ipsilateral pathfinding program rather than acting as a specific determinant of contralateral RGCs. One interesting hypothesis arising from these results is that the Islet2/Zic2 border might determine the location of line of decussation, the boundary between crossed and uncrossed RGC populations, that changes with the degree of binocularity.

3.23.2.5 Other Regulatory Genes That Affect Optic Chiasm Formation

A number of other regulatory genes expressed in the developing retina have been suggested to play a role in retinal axon guidance at the optic chiasm.

The Pou4f2 (also called Brn3b) gene is expressed postmitotically in RGCs in which axonogenesis has commenced (Erkman *et al.*, 2000). The number of ipsilaterally projecting axons increases in Pou4f2$^{-/-}$ mice and this misrouting is partially prevented when Pou4f3 (also called Brn3c) is also removed (Wang *et al.*, 2002). Thus, Pou4f2/Pou4f3 could control the production of ipsilaterally projecting RGCs. However, the fact that these two genes are not expressed exclusively in the retinal regions giving rise to ipsi- or contralaterally projecting RGCs, along with the additional pathfinding defects observed at several decision points along the visual pathway in Pou4f2 KO mice (Wang *et al.*, 2002), argues for a more general function of these proteins in axon guidance, rather than the direct control of divergence at the optic chiasm.

Vax2-deficient mice show a reduction in the ipsilateral projection (Barbieri *et al.*, 2002; Mui *et al.*, 2002) and Pax2 null mice have a complete absence of contralateral projections (Torres *et al.*, 1996). Foxg1 or Foxd1 mutant mice also display alterations in the ratio of uncrossed versus crossed axons (Herrera *et al.*, 2004; Pratt *et al.*, 2004). All of these genes are expressed early in eye development, before RGCs differentiate, suggesting a role in morphogenesis and regional specification of the eye, and in turn, affecting events upstream of mechanisms directly controlling axon divergence, such as Zic2 and EphB1.

3.23.3 Patterning the Retina and Patterning the Chiasm: The Relationship between Them

Among the transcription factors expressed in the retina that regulate the ipsi/contralateral growth programs, the Fox genes are of interest. Foxd1 (also known as BF-2) is expressed in the VT retina but in a wider domain than Zic2. Foxd1 seems to act upstream of Zic2 and EphB1, since in mice null for Foxd1, these two proteins are not expressed in RGCs in the VT retina (Herrera *et al.*, 2004). In addition, Fox genes, and likely others, contribute to the formation of the optic chiasm itself. Foxg1 and Foxd1 are expressed in opposing rostrocaudal domains in the region of the ventral diencephalon, in which the optic chiasm forms (Marcus *et al.*, 1999). The Foxd1 domain includes the region that early retinal axons traverse to establish the optic chiasm, whereas Foxg1 is located more rostrally. Thus, both genes seem to play a role in the regionalization of the ventral brain during chiasm formation. In the Foxd1-deficient ventral diencephalon, Foxg1 expression invades the Foxd1 domain, Islet1 and Zic2 expression is diminished, and Slit2 prematurely expands (Herrera *et al.*, 2004). Thus, Foxd1 appears to play a dual role in the establishment of the binocular visual pathways: first, in the specification of the VT retina, acting upstream of proteins directing the ipsilateral pathway, and second, in the patterning of the developing ventral diencephalon where the optic chiasm forms.

Zic2, like Foxd1, is also expressed in the chiasm. The alteration of Zic2 expression in retinal explants *in vitro* is sufficient to change the behavior of RGC neurites in response to cues provided by chiasmatic cells, arguing that Zic2 acts primarily in the retina. However, as we have seen, both Fox and Zic genes are expressed in the presumptive chiasm and eyecup early in development before the uncrossed pathway forms, and mutations in Zic2 produce holoprosencephaly, a condition in which the halves of the forebrain are fused, occasionally associated with cyclopia in humans (Brown *et al.*, 1998). The relationship between the two loci of expression of these genes, both retina and ventral diencephalon, merits further analysis. It is intriguing that in the early development of *Xenopus*, a small group of cells migrates from one hemisphere to the other (Jacobson and Hirose, 1978). These cells contribute to the region where the chiasm will form as well as to the retinal region that will ultimately give rise to the uncrossed pathway. It is not known whether the migration of this cell group across the midline is related to the separation of the hemispheres, to the determination of the proportion of axons that remain in their own hemisphere, or even to the position of the eyes in the head. Whether the formation of the optic chiasm is an event unrelated to the specification of RGC subtypes is also unclear. Investigations on the derivation of subregions of the eye fields, the organization of the terrain on which the optic chiasm forms, and the designation of eye position in the head should reveal how binocularity is patterned.

In conclusion, progress has been made in understanding how the uncrossed pathway diverges

from the crossed pathway and in appreciating that the RGCs with a crossed and uncrossed trajectory may have different molecular profiles that encode for crossing or avoidance of the midline in the case of the uncrossed population. Zic2 and EphB1 are expressed concomitantly in the VT retina, the site of origin of the uncrossed RGCs. Gain- and loss-of-function experiments *in vitro* and *in vivo* strongly argue that this transcription factor and guidance receptor, respectively, constitute major determinants of the uncrossed pathway, with ephrinB2 acting as a key inhibitory ligand on the midline radial glia. Future experiments will reveal whether there is a link between Zic2 and EphB1. Furthermore, it appears that Islet2 plays a role in repressing the ipsilateral program. A crucial question is whether crossing axons actively overcome inhibitory cues or use a different type of mechanism, such as molecularly-mediated cell adhesion or other molecular receptor–ligand interactions, to specifically mediate extension to traverse the midline. Finally, some of the genes and molecular factors critical to patterning of the retina are also important for regionalization of the terrain on which the optic chiasm forms. Now that several molecular signatures have been ascribed to the crossed and uncrossed pathways, investigations of other genes involved in the process of patterning of the the binocular projection will be facilitated.

Additional Note

In a recent report (Williams *et al*., 2006), we show that the cell adhesion molecule Nr-CAM is expressed by RGCs that project contralaterally, but is critical only for the guidance of late-born RGCs within the VTC (Figure 4c). Blocking Nr-CAM function causes an increase in the size of the ipsilateral projection, and reduces neurite outgrowth on chiasm cells in an age- and region-specific manner. We also demonstrate that EphBl/ephrinB2-mediated repulsion and Nr-CAM-mediated attraction comprise distinct molecular programs that each contribute to the proper formation of binocular visual pathways.

3.24 Evolution and Development of Eye-Specific Layers in the Lateral Geniculate Nucleus

A D Huberman and B Chapman, University of California, Davis, CA, USA

Glossary

afferent Neural fiber projecting from one brain region and terminating in another.

axon guidance cue A molecule that acts on axons of developing neurons to alter the progression/stability/morphology of the growth cone as it migrates through the environment, thereby guiding the axon towards its target.

cDNA plasmid A circular double-stranded DNA molecule that contains a coding region for one or more mRNA molecules without introns.

center-surround receptive field The spatial visual receptive field characteristic of retinal ganglion cells and LGN cells, consisting of a central spot of one response type (ON or OFF) and a surrounding annulus of the opposite response type.

contralateral Located on or affecting the opposite side of the body.

cytoarchitecture The arrangement of cells in a tissue, especially the arrangement of nerve-cell bodies in the cerebral cortex.

Eph The largest subfamily of receptor tyrosine kinases (RTKs) important in mediating cell–cell communication and regulating cell attachment, shape, and mobility.

electroporation A significant increase in the electrical conductivity and permeability of the cell plasma membrane caused by an externally applied electrical field. It is usually used in molecular biology as a way of introducing some substance into a cell, such as loading it with a molecular probe, a drug that can change the cell's function, or a piece of coding DNA.

enucleation Removal of the eye.

ephrin An axon guidance cue; the ligand for the Eph receptors.

lateral geniculate nucleus (LGN) Thalamic nucleus that receives input from the retina and projects to the primary visual cortex.

line of projection A line of cells across the LGN that receives input from a given point in visual space.

immunotoxin Consisting of an antibody linked to a toxin, this chimeric protein targets a specific cell type, is bound and taken into the cell, and then kills the cell by the action of the toxin molecule.

ipsilateral Located on or affecting the same side of the body.

nasal Of, relating to, or near the nose.

nicotinic acetylcholine receptor Ionotropic receptor present in many brain areas, usually excitatory in nature.

ocular dominance columns Interdigitated bands of neurons in primary visual cortex that receive visual input from primarily one or the other eye.

optic chiasm The part of the brain where the optic nerves partially cross from one side of the body to the other.

retinal ganglion cell Retinal neuron that receives information from photoreceptors via bipolar neurons and projects to many targets in the central nervous system.

retinogeniculate Relating to the projections from the retina to the LGN.

retinorecipient nucleus	A brain region receiving input from ganglion cells of the retina.
retinotopy	Organization of a visual brain area in a way that adjacent points in the visual field (that fall on adjacent points on the retina) are processed by neurons in adjacent parts of that area.
starburst amacrine cell	A cholinergic type of retinal amacrine neuron thought to be important in regulating spontaneous patterns of activity in the developing retina.
superior colliculus	A structure of the midbrain receiving visual and other sensory information that is involved in the generation of eye and head movements.
temporal	Of, relating to, or near the temples of the skull.

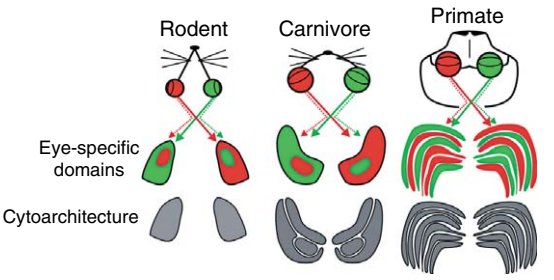

Figure 1 Differences in the degree and pattern of eye-specific connections to the LGN across orders. The top row shows the approximate position of the left eye (depicted in red) and right eye (in green) in the head of a prototypical rodent, carnivore, and primate. Note that the eyes are more lateralized in the rodent than in the carnivore, and eyes are more lateralized in the carnivore than in the primate, which has very frontally placed eyes. The middle row shows the pattern of eye-specific domains (axonal terminations from the retinas) in the LGN in red and green. The bottom row shows the degree and pattern of eye-specific cytoarchitecture (cellular lamination) in the LGN in gray. Rodents have no obvious cellular lamination in the LGN whereas carnivores and primates do.

3.24.1 Introduction

In mammals, the neural connections that transmit visual information from the left and right eyes are generally segregated from one another. A striking example of this is found in the lateral geniculate nucleus (LGN) of many species wherein ganglion cell axons arising from the right and left eyes are organized into a highly stereotyped arrangement of nonoverlapping domains (Jones, 1985). In some species, these eye-specific axonal domains are mirrored by eye-specific cellular layers: groups of postsynaptic neurons separated by cell-sparse, interlaminar zones. There are three basic types of LGN organization: poorly segregated inputs from the two eyes and no cellular lamination, well-segregated inputs but no cellular lamination, and well-segregated inputs with cellular lamination. In placental mammals, the degree of segregation of afferents and the number of eye-specific domains increases with the degree to which the two eyes reside in front of the skull, and thus the degree of binocular vision (see Visceral Afferents). Also, eye-specific cellular layers are generally found only in highly binocular animals. For instance, in insectivores with highly lateralized eyes, such as the hedgehog, there is poor segregation of inputs and no cellular lamination. In mice, which have lateralized eyes such that a small region of the visual field is viewed by both eyes, there is a single region of the LGN that receives axons from the contralateral eye, another region that receives axons from the ipsilateral eye, and no overt eye-specific cellular lamination (Figure 1). By contrast, the LGN of a carnivore such as the ferret has good segregation of inputs into two major eye-specific layers with clear corresponding cellular layers (Figure 1), while the LGN of the highly binocular macaque monkey contains three separate axonal domains per eye and six corresponding eye-specific cellular layers (Figure 1). In marsupials, the relationship between eye placement and LGN lamination pattern may not hold. Within marsupials, all three basic types of LGN organization are seen. There has not been a careful study of the placement of the eyes in the head among different species of marsupials, but in general all marsupials have relatively laterally placed eyes. Within one suborder of marsupials, polyprotodonts, there is a relationship between lifestyle and LGN organization similar to that seen in placental mammals, with carnivores having more complex LGNs than herbivores. However, within the other suborder, diprotodonts, this relationship breaks down. Most diprotodonts studied are herbivores, yet have very complex LGNs with as many as ten distinct retinal recipient layers. Thus, it is clear that other phylogenetic factors, in addition to eye placement and lifestyle, must also be involved in the evolution of LGN organization (reviewed by Kahn and Krubitzer, 2002).

It is noteworthy that eye-specific segregation is present in all of the 25+ retinorecipient nuclei (Muscat *et al.*, 2003), but in non-LGN retinorecipient nuclei, the shape and positioning of eye-specific domains is somewhat variable. In the LGN, however, eye-specific projections are highly stereotyped. Also, eye-specific cellular layers are only found in the LGN. To date, neither the segregation of axons from the two eyes nor the presence of eye-specific cellular layers has been directly linked to any particular aspect of visual

processing. It is tempting to speculate that the mere presence of these features indicates a role for them in visual processing, especially in the LGN of carnivores and primates where eye-specific patterning is so stereotyped within species (see The Role of Vision in the Origin and Evolution of Primates). However, it is equally possible that these features are epiphenomena – byproducts of developmental events that bear no purposeful impact on vision itself – as has been argued for ocular dominance columns in visual cortex (reviewed by Adams and Horton, 2005).

Regardless of their possible function (or lack thereof) in visual processing, eye-specific axonal domains and eye-specific cellular layers in the LGN are classic model systems for exploring how afferent targeting occurs during development, and how this targeting relates to anatomical and functional differentiation of cells within postsynaptic structures. Here we discuss what is currently known about the cellular and molecular mechanisms underlying development of eye-specific connections to the LGN in rodents, carnivores, and primates. In doing so, we address which of these mechanisms likely evolved to induce varying degrees of eye specificity in the LGN. Where relevant, we speculate about the possible role of eye-specific connections in visual processing.

3.24.2 Development of Eye Specificity in the LGN

Numerous studies have shown that the development of eye-specific retinogeniculate projections emerges from a state in which axons from the two eyes initially overlap (macaque: Rakic, 1976; ferret: Linden *et al.*, 1981; cat: Shatz, 1983; rat: Jeffery, 1984; mouse: Godement *et al.*, 1984). In addition, all of these experiments concluded that eye-specific segregation occurs before vision is possible. In some species, such as the monkey or cat, this is because eye-specific segregation occurs *in utero*, whereas in other species where segregation occurs postnatally (such as in the mouse or the ferret) photoreceptors do not become light responsive until after segregation is complete (Linden *et al.*, 1981; Godement *et al.*, 1984; Akerman *et al.*, 2002; Tian and Copenhagen, 2003). In all mammalian species where it has been examined, ocular segregation in the LGN appears competition-dependent; if one eye is removed at the stage of development when axons from the two eyes overlap, projections from the remaining eye become distributed throughout the LGN (rat: Lund *et al.*, 1973; macaque: Rakic, 1981; cat: Chalupa and Williams, 1984; ferret: Guillery *et al.*, 1985a). What mechanisms mediate binocular competition in the LGN? One popular hypothesis is that correlated activity of retinal ganglion cells within the same eye out-compete inputs from the other eye because there is increased synaptic efficacy from groups of ganglion cell axons arising from the same eye onto single LGN neurons, relative to axons arising from different eyes onto single LGN neurons. Because eye-specific LGN layers emerge before the onset of vision, such correlations must arise spontaneously. Maffei and colleagues reported the presence of correlated spontaneous ganglion cell activity in the embryonic rat retina (Galli and Maffei, 1988; Maffei and Galli-Resta, 1990). Others have shown that spontaneous retinal activity also occurs during the period of eye-segregation in ferrets. The activity recorded in the ferret retina during eye-segregation consists of waves of excitation that sweep across the retina, engaging neighboring retinal ganglion cells (RGCs) to fire in synchrony (Meister *et al.*, 1991; Wong *et al.*, 1993). These waves are driven by acetylcholine (ACh) acting through nicotinic receptors present on retinal ganglion cells (Feller *et al.*, 1996). The pharmacologic cholinergic agonist, Epibatidine (EPI), blocks this spontaneous retinal activity (by receptor desensitization) when acutely applied at high concentrations *in vitro* (Penn *et al.*, 1998), and binocular injections of EPI from postnatal day 1 (P1) to P10 completely prevent eye-specific segregation in the LGN, indicating that eye-specific segregation requires retinal activity. If EPI is injected into only one eye from P1 to P10, axons from the EPI-treated eye retract to occupy a smaller-than-normal region of the LGN, and the projection from the other eye expands. This indicates that ocular segregation in the LGN relies on activity-mediated binocular competition. Further reinforcing the binocular competition model, Stellwagen and Shatz (2002) showed that if activity is elevated in both eyes, there is no effect on patterning of eye-specific retinogeniculate projections. However, if wave activity is increased only in one eye, axons from the more active eye acquired more LGN territory than the projection from the normally active, untreated eye. These results indicate that the relative level of activity in the two eyes is a key parameter for patterning of eye-specific projections.

3.24.2.1 Which Aspects of Retinal Activity Drive Eye-Specific Segregation?

It is worth noting that although many experiments have shown activity blockades in the retina or the

LGN can prevent ocular segregation in the LGN (Sretavan *et al.*, 1988; Shatz and Stryker, 1988; Penn *et al.*, 1998; Cook *et al.*, 1999; Huberman *et al.*, 2002; Stellwagen and Shatz, 2002; Rossi *et al.*, 2001), when all spiking activity is abolished one cannot conclude that the pattern of activity is important in the segregation process. Unfortunately, in the experiment where retinal activity levels were elevated rather than eliminated (Stellwagen and Shatz, 2002), correlated ganglion cell activity was maintained. To test the hypothesis that correlated firing of retinal ganglion cells drives eye-specific segregation, we injected an immunotoxin that kills starburst amacrine cells, into the eye of P0 ferrets. Dual cell patch-clamp recordings showed that, in control ferrets, the spontaneous spiking activity and membrane potential changes of neighboring ganglion cells were significantly correlated, whereas the spiking and membrane potential activity of ganglion cell pairs from toxin-treated retinas were not. Importantly, despite the marked perturbation in ganglion cell activity patterns caused by starburst amacrine cell depletion, the mean firing rate of ganglion cells was not significantly elevated or reduced. What is the effect of eliminating correlated retinal activity on eye-specific segregation in the LGN? Surprisingly, axonal projections to the LGN of immunotoxin-treated ferrets were indistinguishable from those observed in control ferrets (Huberman *et al.*, 2003). Thus, the correlated firing of neighboring ganglion cells does not appear critical for eye-specific retinogeniculate segregation. This conclusion may differ across species. In macaques, modern axonal tracing techniques show that eye-specific segregation occurs before the stage when ganglion cell axons form synapses in the LGN (Huberman *et al.*, 2005a) and there is no correlated activity in the macaque retina during this stage of development (Warland *et al.*, 2006). Thus, as in the ferret, retinal waves are unlikely to drive eye-specific segregation in the macaque LGN. By contrast, in transgenic mice that lack the beta-2 subunit of the nicotinic acetylcholine receptor (β2nAChR), correlated waves of activity are disrupted only in the first postnatal week and eye-specific segregation fails to occur, indicating that waves may be important for eye-specific segregation in mice (Torborg *et al.*, 2005). Importantly, however, the β2nAChR knockout mice lack activity in approximately 50% of the ganglion cells, and it is unknown whether the LGN cells themselves are silenced. Therefore, it remains unclear if it is indeed lack of retinal waves or, alternatively, reduced activity levels in the retina and/or LGN that prevented eye-specific segregation in these knockouts. Experiments that employ retinal-specific knockouts of wave activity, and in which overall levels of retinal activity are unaltered, are necessary to resolve these issues. Another consideration is that the β2nAChR knockouts exhibit severely altered retinotopy of ganglion cell projections to both the superior colliculus and the LGN (McLaughlin *et al.*, 2003; Grubb *et al.*, 2003). Thus, it may not be surprising that eye-specific projections are disrupted in these mice. In speculating why different species would rely more or less on correlated activity in the retina for patterning of eye-specific projections to the LGN, it is worth noting that in carnivores and primates (such as ferrets and macaques) that have well-differentiated and stereotyped eye-specific LGN layers, ganglion cells projecting to each eye-specific domain arise from distinct regions of the retina. Therefore cues unique to different retinal regions, rather than activity, could drive eye-specific patterning in the LGN. In rodents, however, axons from throughout the entire contralateral eye project to the LGN. These eye-specific domains are less stereotyped and there is no cellular lamination, so retinotopic cues and activity may act in concert to influence eye-specific patterning without the need for additional bona fide eye-specific layer patterning cues. We consider these possibilities in more detail below.

3.24.2.2 What Cues Regulate Spatial Patterning of Eye-Specific Axonal Projections?

A striking feature of eye-specific inputs to the LGN (especially in carnivores and primates) is their remarkably stereotyped shape, size, and position. For example, in carnivores such as ferrets and cats, the axons from the contralateral eye always occupy the innermost LGN and axons from the ipsilateral eye always project to the more outer LGN. Although activity-dependent models can explain how inputs from the two eyes segregate from one another, they cannot explain how the ipsilateral eye axons always segregate into the same regions of the LGN. The same is true for the six-layered primate LGN; axons from the two eyes intermingle before segregating into their respective eye-specific territories, but the order of the layers is always the same (e.g., the ventral-most region is always innervated by ganglion cells from the contralateral eye) and there is remarkable symmetry of eye-specific projections in the two LGNs, even at very early stages of eye-specific differentiation (Rakic, 1976; Huberman *et al.*, 2005a). Simply put, there must be a bias for one or the other eye to win a given piece of LGN real estate.

3.24.2.3 What Mechanisms Could Dictate the Spatial Location that Axons from the Two Eyes Segregate into?

We carried out experiments in ferrets in which we prevented the segregation of retinogeniculate inputs (by silencing spontaneous retinal activity in both eyes with EPI) and then allowed these animals an extended period of recovery, during which spontaneous retinal activity returned to normal (Huberman *et al.*, 2002). We then assessed the effects of this manipulation on the pattern retinogeniculate inputs. As shown previously, in normal P1 ferrets, ganglion cell axons from the two eyes overlap extensively and by P10, they are segregated (Linden *et al.*, 1981). As seen by Penn *et al.* (1998) in ferrets that received binocular EPI injections from P1 to P10, inputs from the two eyes remain overlapped in the LGN. In ferrets that received binocular intravitreal injections of EPI from P1 to P10, but were then allowed to survive until P25 or older (hereafter called EPI-recovery ferrets) retinogeniculate afferents end up completely segregated. However, unlike control ferrets, the spatial pattern of eye-specific retinogeniculate projections is highly aberrant. There are multiple ipsilateral projections of various shapes, positions, and sizes, and these are distributed over a significantly greater than normal extent of the LGN. This indicates that there is something special about the developmental time window in which retinogeniculate segregation normally occurs for proper patterning of eye-specific inputs to the LGN. It is possible that the pattern of spontaneous retinal activity present from P1 to P10 provides an instructive cue for development of this feature. Indeed, the pattern of spontaneous retinal activity is different from P1 to P10, than it is during the recovery phase from P10 to P25 (Wong *et al.*, 1993). However, as noted in the introduction, ganglion cells send eye-specific projections to approximately 25 subcortical nuclei and yet, none of these nuclei contain the highly regular spatial patterning of eye-specific inputs witnessed in the LGN, despite the presence of normal P0–P10 retinal waves. For example, during the same developmental stage when retinogeniculate afferents segregate into eye-specific domains in the LGN, retinal activity induces ganglion cell axons to segregate into randomly positioned eye-specific clusters in the rostral superior colliculus (Thompson and Holt, 1989). Also, in studies where retinal inputs destined for the LGN were rewired into the medial geniculate nucleus (MGN), axons from the two eyes segregate into eye-specific patches that do not resemble the normal spatial organization of inputs to the LGN (Angelucci *et al.*, 1997). Spontaneous retinal activity is normal throughout development in these rewired animals and yet normal eye-specific domains fail to develop in novel targets, indicating that patterning of ganglion cell axons into stereotyped eye-specific regions in the LGN is controlled by cues that are intrinsic and unique to the LGN, rather than by patterns of retinal activity. Moreover, it is hard to imagine how activity could give rise to highly stereotyped eye-specific layers since activity is likely to differ across animals, and yet eye-specific domains in the LGN always form in the same location, size, shape, and orientation. Thus, patterning of eye-specific inputs to the LGN almost certainly relies on the presence of molecular signals that bias the location and boundaries of the regions into which afferents from one or the other eye segregate.

3.24.2.4 Ephrin-As Pattern Eye-Specific Axonal Domains in the LGN

The idea that molecular cues direct sorting of binocular inputs into their stereotyped pattern of eye-specific layers in the LGN has been proposed repeatedly (Williams *et al.*, 1994; Crowley and Katz, 1999, 2000; Chapman, 2000), but until recently the identity of those cues remained elusive. What sort of axon guidance cues might contribute to patterning of eye-specific inputs to the LGN? One clue is that, unlike in rodents where ganglion cells from the 'entire' retina project to the contralateral LGN, in carnivores and primates the contralateral retinal projection arises strictly from ganglion cells in the nasal retina and the ipsilateral projection from ganglion cells in the temporal retina. Thus, a candidate axon guidance cue that could mediate eye-specific patterning are the ephrin-As and their receptors (EphAs). Ephrin-As are known to regulate topographic mapping of the nasal-temporal retina in the SC and LGN of lower vertebrates and mice (Cheng *et al.*, 1995; Drescher *et al.*, 1995; Nakamoto *et al.*, 1996; Frisen *et al.*, 1998; Feldheim *et al.*, 1998, 2000; Feldheim, 2004; see The Evolution of Vertebrate Eyes). There are obvious differences between retinotopic maps (which are smooth and continuous) and eye-specific LGN layers (which have abrupt borders). However, the well-established role of ephrin-As in nasal-temporal mapping as well as on inter- and intra-areal pathfinding in other projection systems (Dufour *et al.*, 2003) leads us to hypothesize that in species where eye-specific layers obey the nasal- versus temporal-retina distinction, ephrin-As mediate patterning of eye-specific projections.

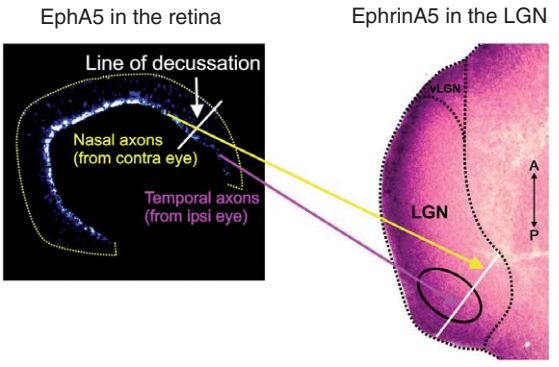

Figure 2 Model for ephrin-A induced targeting of eye-specific retinogeniculate projections. Ferret retina labeled for EphA5 mRNA shows a central → peripheral gradient of EphAs (high abundance of the transcript appears in white). The line of decussation is shown. Axons to the left of the line of decussation would project to the contralateral LGN (nasal axons), axon to the right of the line of decussation would project to the ipsilateral LGN (temporal axons). Here the inputs from two eyes into the same LGN are depicted as arising from the same retina. Ephrin-A5 mRNA appears in an outer → inner gradient in the LGN (high abundance transcript appears in purple). The axons from these two populations of ganglion cells send axons to the 'same' line of projection (white line in the LGN) but 'different' eye-specific layers. The relatively higher levels of EphA5 in the contralateral-projecting ganglion cells (yellow arrow) combined with the outer → inner gradient of ephrin-As in the LGN, causes these eye axons to project to the more inner LGN than the ipsilateral-projecting ganglion cells that view the same location in visual space (purple arrow). See Huberman *et al.* (2005b) for details.

Using *in situ* hybridization to detect mRNAs and affinity probe binding to detect proteins, we observed the presence of an outer → inner gradient of ephrin-A5 in the early postnatal ferret LGN (Figure 2). We also examined the pattern of EphAs in the developing ferret retina and observed a central greater than peripheral (central → peripheral) gradient of EphA5 (Figure 2). Therefore, there are relatively higher levels of EphAs expressed in the crossed (nasal) versus uncrossed (temporal) ganglion cell axons that converge on a single line of projection (Figure 2). Since ephrin-As have consistently been shown to be repellant toward ganglion cell axons expressing relatively higher levels of EphAs (Cheng *et al.*, 1995; Drescher *et al.*, 1995; Nakamoto *et al.*, 1996; Frisen *et al.*, 1998; Feldheim *et al.*, 1998, 2000, 2004; Brown *et al.*, 2000), the central → peripheral gradient of EphAs in the retina, combined with the outer → inner gradient of ephrin-As in the LGN therefore leads to a scenario whereby the contralateral-eye domain (expressing higher levels of EphA) always maps to the inner LGN (where there are lower levels of ephrin-A), whereas the ipsilateral-eye domain (expressing lower levels of EphA) maps to the outer LGN (where there are higher levels of ephrin-A) (Figure 2). To test directly whether ephrin-A:EphA interactions regulate eye-specific layer formation, we developed an *in vivo* retinal electroporation strategy to overexpress cDNA plasmids in ganglion cells of postnatal ferrets (Huberman *et al.*, 2005b). Axons of ganglion cells transfected with control plasmids were targeted normally in the P10 LGN. By contrast, ferrets that were electroporated with EphA5 on P1 showed markedly perturbed retinogeniculate projections. Axons from the ipsilateral eye were displaced to the inner LGN and into territory dominated by the contralateral eye. This resulted in ipsilateral-eye input to the LGN that was significantly expanded along the axis perpendicular to eye-specific layers (i.e., along lines of projection). In addition, axons from the contralateral eye were found in the region of the P10 LGN normally only occupied by axons from the ipsilateral eye. We also traced single retinogeniculate axons in control and EphA5 electroporated ferrets. In every control ferret examined, ganglion cell axons from temporal portion of the ipsilateral retina were restricted to the outer portion of the ipsilateral LGN, as expected for animals of this age (Hahm *et al.*, 1999). By contrast, ganglion cell axons labeled from the temporal retina of EphA5 electroporated ferrets at both ages extended much further along across the outer–inner axis of LGN than was observed in controls (Huberman *et al.*, 2005b).

By examining the time-course of ephrin-A and EphA expression in normal ferrets, we found that, whereas ephrin-A ligands are robustly expressed in the P0–P3 LGN, by P5 their levels are reduced conspicuously. Our previous work in EPI-recovery ferrets showed that normal development of stereotyped eye-specific inputs to the LGN is restricted to the early postnatal period when eye-specific segregation normally occurs, suggesting there may be a critical period for eye-specific layer formation (Huberman *et al.*, 2002). To test if expression of ephrin-As in the LGN contributes to this critical period, we electroporated ferrets with EphA5 at P5. Remarkably, despite the robust overexpression induced by retinal electroporation at this age, there was no detectable effect on patterning of eye-specific retinogeniculate projections. These results (Huberman *et al.*, 2005b) and those of an accompanying paper in mouse (Pfiffenberger *et al.*, 2005) represent the first evidence for axon guidance cue-based targeting of eye-specific projections. Also, Lambot *et al.* (2005), showed that EphA receptors are present in the fetal human retina, in patterns similar to that observed in ferrets (central → peripheral). Of course, ephrin-As likely represent only one

of several (and perhaps many) cues that nasal and temporal retinal axons rely on to pathfind to their stereotyped locations in the LGN. As mentioned above, in mice ephrins act as retinotopic cues, whereas in more binocular species ephrins may have additional, specialized roles in eye-specific patterning in the LGN. Regardless, it is clear that changing distribution patterns of mapping molecules such as ephrins could explain in part the varying number and patterns of eye-specific terminations seen across species. We now consider this hypothesis in more detail.

3.24.2.5 Eye-Specific Cellular Lamination

As mentioned in the introduction, primates and carnivores have eye-specific cellular layers in the LGN. Several studies have addressed the developmental relationship between axons from the two eyes and patterning of cellular layers in the LGN (Brunso-Bechtold and Casagrande, 1981; Casagrande and Condo, 1988). In the LGN of carnivores, cells form cytoarchitectural layers that lie in direct register with the layers formed by the terminals of retinal afferents (Linden *et al.*, 1981; Stryker and Zahs, 1983; Zahs and Stryker, 1985; Hutchins and Casagrande, 1990; Hahm *et al.*, 1999). Retinal axons appear to instruct development of cellular layers in the LGN: the development of cellular layers occurs after afferents from the two eyes segregate and if the pattern of retinogeniculate afferents is rendered abnormal, the cytoarchitecture of the LGN directly reflects these abnormal inputs. For example, in monocularly or binocularly enucleated animals, eye-specific cellular laminae do not develop (Brunso-Bechtold and Casagrande, 1981; Rakic, 1981; Guillery *et al.*, 1985a, 1985b; Sretavan and Shatz, 1986; Garraghty *et al.*, 1988; Morgan and Thompson, 1993) and in coat-color mutants, where the density of the ipsilateral-eye projection to the LGN is reduced, the cellular laminae mirror the reduced ipsilateral input and the associated abnormal topography of the retinal projections (Guillery, 1969, 1971; Guillery and Kaas, 1971). We observed that, despite the presence of well segregated eye-specific domains in the LGN of the EPI-recovery animals, the LGN completely lacked normal patterns of cellular lamination. Clusters of cells surrounded by cell-sparse regions are occasionally visible, but comparison of these clusters with the pattern of retinogeniculate afferents in the same tissue sections reveals that they do not correspond to eye-specific termination zones of ganglion cell axons. Because these animals lacked retinal activity from P0 to P10 but normal activity was present thereafter, this indicates that early postnatal retinal activity is required for patterning of eye-specific cellular layers. We also sought to determine whether disrupting the pattern of retinal afferent lamination alters the physiology of LGN neurons; we performed multiunit extracellular recordings in the LGN of EPI-recovery animals. All cells encountered were monocular, indicating that functional as well as anatomical segregation of eye-specific inputs to the LGN occurred following the termination of the EPI treatment. Cells in the LGN of the treated animals exhibited ON- or OFF-center responses typical of normal ferrets (Stryker and Zahs, 1983; Zahs and Stryker, 1985) and normal center-surround receptive field organization was present. Surprisingly, in the EPI-recovery animals, the topographic representation of the binocular visual field was mapped normally, even across the boundaries of eye-specific domains. Thus, dramatically disrupting the organization of eye-specific lamination does not affect the gross topographic representation of visual space in the LGN. This finding is unexpected given the widely varying pattern of eye-specific layers both between and within the LGNs of the EPI-recovery animals, and it indicates that neither stereotyped patterning of eye-specific axonal termination in the LGN nor eye-specific cellular layers are required for normal topographic mapping.

3.24.3 Which Developmental Mechanisms Might Explain the Variation in Eye-Specific Lamination Seen Across Species?

Given that the degree of eye-specific differentiation in the LGN of placental mammals scales directly with the degree of binocular vision, we now consider how the position of the eyes in the skull (the major determinant of the degree of binocular vision) could impact the number, shape, and location of eye-specific domains in the LGN. It is important to note that the percentage of ganglion cells that take an uncrossed route at the chiasm is in direct proportion to the degree of binocular vision. For instance, in rodents, which have minimal binocular vision, only approximately 5–8% of retinal ganglion cells in each eye project ipsilaterally, whereas in carnivores and primates 12–50% of retinal ganglion cells project ipsilaterally. So it follows that the developmental mechanisms that influence the number of ganglion cells that project ipsilaterally will directly impact the degree of eye-specific differentiation in LGN. Recent evidence indicates that ganglion cells expressing the ephrin-B receptor, EphB1, take an

uncrossed route at the chiasm because the repellant ligand, ephrin-B2, is expressed at the chiasm (Williams *et al.*, 2003). As described above, in ferrets (Huberman *et al.*, 2005b) and also in humans (Lambot *et al.*, 2005), the expression of EphAs in the retina is central → peripheral, whereas in the less binocular mouse, EphAs are expressed in a temporal → nasal gradient. Because repellant ephrin-A ligands are expressed in the LGN in a manner sufficient to induce stereotyped patterning of eye-specific layers (Huberman *et al.*, 2005b), the distribution of ephrin-As and ephrin-Bs, and their receptors, are important determinants of patterning of eye-specific differentiation in the LGN. Ephrin-Bs dictate how many cells from the two eyes project to the same LGN, and ephrin-As dictate where the axons from each eye will project to within the LGN. Retinal activity-mediated binocular competition might then act to sharpen the eye-specific boundaries induced by ephrin signaling. How could the position of the eyes in the skull dictate patterns of ephrin expression in the retina and/or LGN? Lambot *et al.* (2005) proposed an ingenious hypothesis that there is a (currently unidentified) molecule that is expressed in a fixed location within the skull and outside the eye and that this putative molecule influences the location of peak expression of both EphAs and EphBs in the retina. In their model, the rotation of the eye from the side to the front of the skull would change the location of this fixed signaling center relative to the neural retina, thereby changing the patterns of ephrins accordingly. The identification of this putative signaling molecule, examination of its expression patterns across species, and ultimately, its manipulation, will be required to determine the validity of this model. It is unknown what factors determine whether eye-specific cellular layers form in the LGN. Mice have well-segregated eye-specific axonal inputs to the LGN, but no corresponding cellular layers. Is this because the contralateral projection to the LGN of mice arises from ganglion cells throughout the retina and therefore cannot be molecularly distinguished from ipsilaterally projecting ganglion cells? At present, the answer to this question remains unknown. Experiments that focus on the possible function of eye-specific cellular layers may lend insight to this issue.

3.25 Evolution of Gustation

I E de Araujo, M A L Nicolelis, and S A Simon,
Duke University, Durham, NC, USA

Glossary

cyprinid	Pertaining to freshwater fish. All fish in this family are egg-layers.
papillae	A bump occurring in various animal tissues and organs. Taste buds are found in circumvallate, foliate, and fungiform papillae.
taste buds	Small sensory organs that contain gustatory receptor cells, basal cells, and supporting cells. Taste buds in humans are found in the epithelia of the tongue, palate, and pharynx. They are innervated by the chorda tympani nerve (a branch of the facial nerve), the glossopharyngeal nerve, and the vagus nerve.
taste cells	Neuroepithelial cells found in taste buds.
tetrapod	A vertebrate animal having four feet, legs, or leglike appendages.
TRP channels (transient receptor channels)	Calcium-permeable channels. They can be gated by a variety of chemical and physical stimuli. A subpopulation of taste cells contain TRPM5 channels and many pain fibers contain TRPV1 channels, which are activated by capsaicin, the component in chile pepper that produces a burning sensation.

3.25.1 Introduction

The sense of taste allows mammals to discriminate between nutrient-rich stimuli and aversive, potentially toxic compounds. In vertebrates with a developed central taste system, it is fundamental to appropriate feeding behavior and survival (see Evolution of Taste). We show that the development of the mammalian brain made possible the formation of complex associations in the gustatory–reward cortices between the perceptual features of taste stimuli and the internal, physiological state of the organism. Supported by an intricate circuitry containing several distributed interacting pathways, mammalian feeding behavior became adaptive and efficient.

3.25.2 Peripheral Taste System

In vertebrates, the sense of taste is mediated by specialized epithelial cells arrayed in specific sensory end organs, the taste buds. Taste buds first appear phylogenetically coincident with the vertebrate lineage. In contrast, in invertebrates, the sense of taste is mediated via bipolar sensory neurons that have a distal process reaching the surface of the epithelium and a central process extending directly into the central nervous system, indicating a nonhomology with respect to vertebrates (Finger and Simon, 2000).

Several morphological features of taste buds are shared throughout the vertebrate lineage. They consist of proliferative basal cells, centrally situated elongated cells, and flattened edge cells that form the lateral boundary of the taste bud and the transition to extragemmal epithelium (Murray and Fujimoto, 1969; Finger and Simon, 2000). Taste buds occur mainly within the oropharynx but can also be found in some species, in the epiglottis and lips. In some cases, they are found across the entire body surface (see below). Nevertheless, in all cases, at specific regions of the taste bud the epithelial (taste) receptor cells make synapses with primary sensory neurons from the facial (VII), glossopharyngeal (IX),

and vagal (X) cranial nerves (CNs) (Norgren, 1990; Finger and Simon, 2000). In most species, taste buds have the overall shape of an onion and can contain 20–100 cells, with widths ranging from 30 to 100 mm (Duncan, 1964; Finger and Simon, 2000).

In tetrapods (all of which have tongues), taste buds are located on the tongue as well as in the mouth and throat (Butler and Hodos, 1996). In some amphibians, such as the frog, the tongue is a soft organ covered by 400–500 scattered fungiform papillae, most of which contain disk-shaped taste buds with no pores (Rapuzzi and Casella, 1965), comprising distinct supporting cells that do not synapse onto sensory fibers (Osculati and Sbarbati, 1995). In birds, some avian taste buds are situated deep in the epithelium and have a long taste pore, called the taste canal (Ganchrow and Ganchrow, 1987). It is not clear whether this could be generalized to all birds, but in general they seem to have fewer taste buds than tetrapods (Butler and Hodos, 1996). Taste buds in bony and cartilaginous fishes contain three distinct cell types (elongated cells bearing small microvilli, elongated cells bearing a thick microvillus, and serotonergic basal cells) that synapse onto either other taste cells or sensory nerve fibers (Finger and Simon, 2000). In some fishes, taste buds are located in areas other than the mouth and throat. For example, in cyprinids (which include carps and goldfishes), taste cells are present across the entire body surface, allowing these animals to taste their environment while searching for nutrients (Butler and Hodos, 1996).

In mammals, taste buds normally comprise a collection of 50–100 elongated epithelial cells and a comparatively smaller number of proliferative basal cells (Kruger and Mantyh, 1996). Each taste bud contains several distinguishable types of elongated taste cells, based on morphological and biochemical features, first revealed by Murray (1973) in his studies on rabbit taste receptor cells. Among these features, one way to characterize these taste cell types is to study which proteins they express. Briefly, type I cells express GLAST, a glial glutamate transporter (Lawton *et al.*, 2000), suggesting glial function; type III cells can be characterized by the expression of SNAP25, a synaptic membrane protein, which indicates transmission of information to the central nervous system (Finger, 2005). Studies suggest that this is the only cell type that forms synapses and the transmitter is ATP (Finger *et al.*, 2005). Type II cells are especially interesting in that they express the entire transduction cascade for sweet, bitter, and umami chemoreception, including the downstream transduction-related molecules phospholipase Cβ2 (PLCβ2) and IP3R3 (Miyoshi *et al.*, 2001). The downstream product of these transduction pathways appears to be the TRPM5 channel (see Figure 1 and Perez *et al.*, 2002; Zhang *et al.*, 2003).

In any event, these different cell types express taste receptors on the apical surface corresponding to the considered five basic modalities of mammalian gustatory senses: sweet, sour, bitter, salty, and umami (often described as the taste of protein, as elicited by monosodium glutamate and 5′ nucleotide monophosphate) (Scott, 2005; see Figure 2).

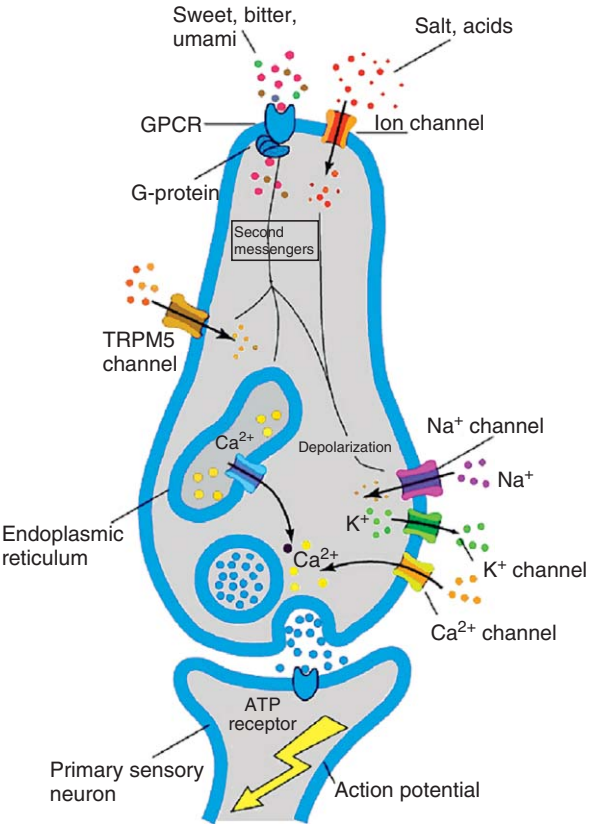

Figure 1 Schematic representation of sensory transduction in taste cells. Ion channels detect the presence of salty (NaCl) and sour (HCl) tasting compounds, whereas G-protein-coupled receptors respond to umami, sweet, and bitter tasting compounds (see Figure 2). All of these receptors are located in the apical domain of taste cells, which is separated from the basolateral domain by tight junctions. The components of the internal signaling cascade that is coupled to taste receptor molecules (including G-proteins and associated second-messenger molecules) are also preferentially expressed in the apical domain. Voltage-gated Na^+, K^+, and Ca^{2+} channels mediating the release of neurotransmitter from presynaptic specializations at the base of the cell onto sensory fibers are located in the basolateral domain, as well as the endoplasmic reticulum, which is also involved in regulating Ca^{2+} intracellular concentration. Communication between taste cells and primary sensory fibers is mediated by the neurotransmitter ATP and possibly serotonin. Another channel that is involved in G-protein-coupled receptor-mediated responses and taste cell depolarization is TRPM5.

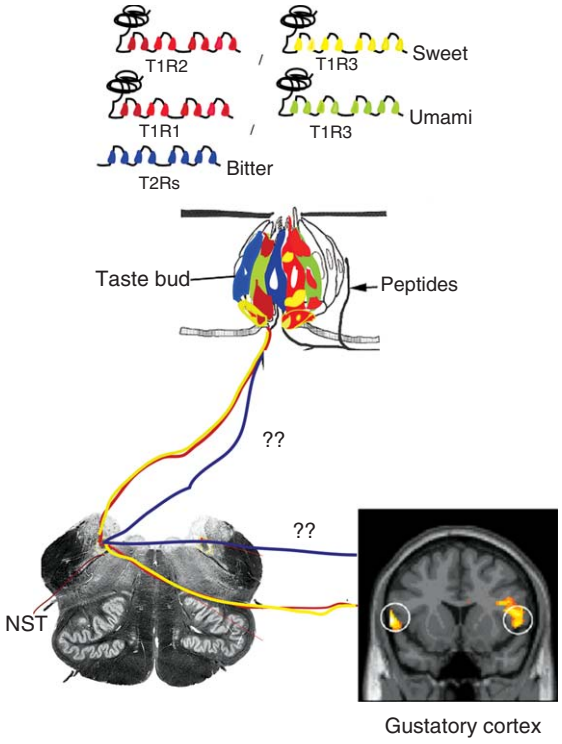

Figure 2 Diagram depicting families of taste receptors recognizing sweet, bitter, and umami substances. The heteromer T1R2/T1R3 responds to compounds that produce a sweet taste (e.g., sucrose, glucose), whereas T1R1/T1R3 responds to receptors that are activated by compounds that produce the umami taste (e.g., monosodium glutamate). The T2R family recognizes compounds that produce bitter taste sensations (e.g., caffeine, quinine). These signals seem to be transduced separately to the central nervous system through specialized gustatory neurons (labeled lines) that elicit different behaviors. Illustrated are these neurons' projections to the solitary nucleus and its tract (NST) and further projections to the primary gustatory cortex. This separation appears to persist at higher levels in the gustatory pathway although more definitive evidence is needed (question marks). The peptidergic general sensory perigemmal neurons are also shown. These neurons have receptors for molecules such as capsaicin (TRPV1) and provide information regarding the pungency of foods.

Salty (NaCl) taste uses the amiloride-sensitive sodium channel, ENaC (Lindemann, 2001). Other salts may permeate taste cells via a TRPV1 splice variant (Lyall *et al.*, 2004). Sour taste, which is represented by the hydronium concentration, uses a variety of pathways depending on whether it is a strong or weak acid (Lyall *et al.*, 2004; DeSimone *et al.*, 2001; Caicedo *et al.*, 2002). The other standard modalities are mediated by G-protein-coupled receptors. Sweet and umami detection are mediated by the T1R receptor family (see The Evolution of the Sweetness Receptor in Primates). Three genes, T1R1, T1R2, and T1R3, control their expression in taste cells. Evidence indicates that T1R receptors function as heterodimers, in that the T1R1/T1R3 combination in rodents is broadly tuned to amino acid detection (in humans it is narrowly tuned to glutamate) and T1R2/T1R3 to sweet detection (Li *et al.*, 2002). The T2R receptor family, comprising approximately 30 members, is known to be necessary and sufficient for the perception of bitter taste (Mueller *et al.*, 2005). T2Rs are of high behavioral relevance, since they mediate the detection and consequent rejection of potentially poisonous or toxic substances. Sequence polymorphisms between T2Rs of mice (Kim *et al.*, 2003) and nonhuman primates (Parry *et al.*, 2004) with respect to those expressed in humans were linked to different bitter sensitivities in these species. Species-specific sensitivities for sugars have also been shown (e.g., mice vs. human; Zhao *et al.*, 2003). This indicates ongoing evolutionary diversification of T1R and T2R receptors and a role in dietary adaptation and nutrient selection (Parry *et al.*, 2004).

3.25.3 The Mammal Central Taste System

3.25.3.1 Anatomy

Rodents and primates (including humans) constitute the most studied cases of central gustatory processing. The chemosensory information from CN VII primarily involves the sense of taste, whereas CNs IX and X convey chemosensory information that drives the swallowing and gaping reflexes (Markison *et al.*, 1996). Also, general sensory fibers from CNs V, IX, and X provide textural and thermal responses as well as information from irritating chemosensory stimuli. In all these species, CNs VII, IX, and X transmit electrical signals that convey the chemical properties and quantity of tastants to the rostral division of the nucleus of the solitary tract (NST) of the medulla, the principal visceral sensory nucleus of the brainstem. In the rat, second-order fibers (i.e., NST afferents) project ipsilaterally to the gustatory parabrachial nuclei (PBNs) in the pons, proceeding then to the parvicellular part of the ventroposterior medial nucleus of the thalamus (VPMpc). In primates, the NST projection fibers bypass the PBN only to join the central tegmental tract and synapse directly into the VPMpc (Pritchard *et al.*, 2000), whereas the PBN seems to be dedicated to convey general visceral information (e.g., from the vagus) to specialized thalamic nuclei including VPM (Pritchard *et al.*, 1989, 2000).

Thalamic afferents then project (reciprocally) to the gustatory cortex (Scott and Plata-Salaman, 1999). In the rat, it was found that parabrachial fibers reach some forebrain areas including the

lateral hypothalamus and the central nucleus of the amygdala, giving gustatory information direct access to motivational and reinforcement-related structures including the dopaminergic system (through direct projections from the central nucleus of the amygdala; Fudge and Haber, 2000).

The primary taste cortex in macaques can be defined in terms of VPMpc afferents (Scott and Plata-Salaman, 1999). Pritchard *et al*. (1986) have studied the efferent projections of the VPMpc of the monkey, *Macaca fascicularis*, with tritiated amino acid autoradiography. Two discrete cortical areas were characterized as a target of VPMpc projections. First, labeled cells were located in the ipsilateral insular–opercular cortex adjacent to the superior limiting sulcus and extending as rostrally as the caudolateral orbitofrontal cortex. Moreover, further projections were located within the primary somatosensory cortex (SI), in the precentral gyrus subjacent to the anterior subcentral nucleus (i.e., a precentral extension of SI). This area is anterior to the VPM projection sites representing somatosensory information and is adjacent to or overlaps with cortical somatotopic sites for the face and oral cavity (Jain *et al*., 2001). Thus, this area might be a target of VPM and VPMpc projection fibers and thus implement the convergence in the cortex of the somatosensory and gustatory aspects of stimuli delivered in the mouth (see below).

Scott and Plata-Salaman (1999) define the anterior limit of the primary taste cortex in the macaque as the junction of the orbitofrontal and opercular cortices, from which it extends 4.0 mm posteriorly. The mediolateral extension is defined ~16–19 mm lateral to the midline in an average adult macaque. The dorsal limit is defined as ~6 mm above the lateral fissure. The insular cortex, in the depth of the Sylvian fissure, has been divided into four rostrocaudal subdivisions (Cipolloni and Pandya, 1999): the most rostral portion has been designated the insular proisocortex; adjacent to it is the agranular subdivision of the insula, followed caudally by the dysgranular and the granular insular areas. In these terms, the VPMpc nucleus projects to the opercular and insular regions of the granular and dysgranular insula and extends to adjacent agranular portions of the insula.

One of the projections from this primary taste cortex is to the central nucleus of the amygdala where gustatory information reaches the basal forebrain, lateral hypothalamus (Scott and Plata-Salaman, 1999), and dopaminergic cells in the substantia nigra pars compacta and ventral tegmental area (Fudge and Haber, 2000). Fibers also project anterior to the dysgranular caudolateral orbitofrontal region (which is defined as a secondary taste cortical area by Baylis *et al*., 1995). This transition zone, including the more anterior parts of the primary taste cortex and the adjoining caudolateral orbitofrontal cortex, was also named area G by Carmichael and Price (1996). Taste neurons in the caudolateral orbitofrontal cortex form connections laterally with visual areas in the inferior temporal cortex and, importantly, converge with more medial cells receiving projections from primary olfactory cortex, which have implications for the perception of flavor. Taste-responsive cells in the caudal orbitofrontal cortex project to the caudate nucleus, where taste information is distributed throughout the striatum, and lateral hypothalamus (Öngur *et al*., 1998; Scott and Plata-Salaman 1999), which in turn communicates directly with the central nucleus of the amygdala. The central nucleus of the amygdala in turn projects back to the NST (Price and Amaral, 1981). The described circuit could then form a complex neural network integrating information about the identity of individual tastants with their hedonic and motivational properties.

3.25.3.2 Electrophysiology

In rodents and monkeys, taste cells have been sampled across the central gustatory pathway by electrophysiological techniques and this may reveal some species-specific features. For example, in rats, NST taste-responding cells seem to be modulated by physiological need and satiety signals (e.g., gastric distention; Glenn and Erickson, 1976). However, NST taste cells in primates are unaffected by satiety, as shown, for example, by reversing the incentive value of glucose in a sensory-specific satiety type of experiment (Yaxley *et al*., 1985). This apparent distinction between the rodent and primate cases might be partially accounted for by the fact that in primates NST projection fibers bypass the PBN, where visceral and physiological information could be preferentially processed.

Top-down regulation is an important feature of taste processing in that stimulation of the hypothalamus or the central nucleus of the amygdala can modulate responses to tastants in NST and parabrachial nuclei (Cho *et al*., 2002; Li *et al*., 2005). This is significant since both the amygdala and the hypothalamus receive projections from cortical taste areas and could thus work as an intermediate for cortical modulation of taste processing at the brainstem level. Notice that these top-down pathways also exist in primates (Price and Amaral, 1981).

In the primates, despite its name, only a small proportion of cells in the primary taste cortex do

actually respond exclusively and consistently to taste stimuli (Scott and Plata-Salaman, 1999; ~6.5%), whereas a higher proportion (~23%) responded during tongue or jaw movements, for example. This suggests that the primate primary taste cortex might be encoding simultaneously taste and oral somatosensory properties of (intraoral) stimuli. These recording studies then constitute an early indication that multisensory encoding might occur in the primary taste cortex.

In the primary gustatory cortex (in primates, including both frontal opercular and dysgranular insula), the responses of taste-related neurons are multisensory and are more broadly tuned than in NST and VPMpc (Sewards and Sewards, 2001). Interestingly, in the rodent case, Katz *et al.* (2001, 2002) have shown that when time is accounted for as a source of variability, the taste specificity of the responses increased from approximately 10%, when only the average activity is considered, to 41% of the recorded gustatory cells, suggesting that encoding of temporal information is a central feature of taste processing. In this regard, Katz *et al.* (2002) have also shown that neurons that exhibit synchronous activity may also contribute to the identification of tastants.

Single-cell recording studies of the secondary taste cortex (orbitofrontal cortex) were able to evidence more clearly the distributed and multimodal characteristics of taste processing in primates. The role of the primate orbitofrontal cortex in reward processing has been consistently established by a number of different lines of evidence. In nonhuman primates, there is strong evidence at the single-neuron level that the orbitofrontal cortex responds as a function of the reward value of taste (Rolls *et al.*, 1989), olfactory (Critchley and Rolls, 1996), and visual stimuli (Critchley and Rolls, 1996). This shows that vision, a sensory modality especially developed in primates, can also provide inputs for association with taste perceptual information (see Primate Brain Evolution in Phylogenetic Context).

In the specific case of neurons responding to the reward value of taste stimuli, neurons in the macaque monkey orbitofrontal cortex have been shown to respond in a sensory-specific satiety manner (Rolls *et al.*, 1989). In addition, reward-related learning and expectation appear to be represented at the single-neuron level in the primate orbitofrontal cortex (Schultz *et al.*, 2000), probably involving the midbrain dopaminergic system. Thus, the findings detailed above provide evidence that a part of the primate taste cortex could support the simultaneous encoding of several sensory features of taste stimuli, including stimulus identity, multisensory combinations (olfactory, somatosensory), and reward value (see The Loss of Olfactory Receptor Genes in Human Evolution, Evolution of the Somatosensory System – Clues from Specialized Species).

3.25.4 Functional Neuroimaging

Single-cell recording studies are limited to a relatively small number of samples from a single cortical area. To understand the dynamics between multiple brain areas representing taste–reward pathways, one may use bundles of electrodes implanted in each area (Nicolelis *et al.*, 2003). This field is in its infancy with respect to gustatory processing. However, advances in human functional neuroimaging techniques, such as functional magnetic resonance imaging (fMRI; for a description of its physiological basis, see Logothetis *et al.*, 2001), allowed for more general descriptions of taste processing in humans.

Human studies indeed confirmed that gustatory areas homologous to those of primates (as defined by anatomical studies) are responsive to unimodal taste stimuli in humans, including the anterior insula/frontal operculum, the orbitofrontal cortex, and the amygdala (Small *et al.*, 1999; O'Doherty *et al.*, 2001; de Araujo *et al.*, 2003a). This includes responses to glucose, NaCl (O'Doherty *et al.*, 2001), umami (de Araujo *et al.*, 2003a), caffeine, and citric acid (Schoenfeld *et al.*, 2004). In particular, the de Araujo *et al.* (2003c) study revealed activations for taste (sucrose) in all homologous areas in the ascending central taste pathway receiving first- or second-order projections from the VPMpc: the frontal operculum/insula complex, the orbitofrontal cortex, the amygdala, and the ventral forebrain, which most likely included anterior parts of the hypothalamus (see Figure 3).

Studies with human subjects provide evidence that gustatory cortices not only respond to the major perceptual categories of taste, but also support the encoding of the multisensory aspects of taste stimuli. In a study using taste and retronasal olfactory stimuli (and their combinations), de Araujo *et al.* (2003c) have shown that taste and olfactory inputs in the human brain converge in particular in the far anterior (putatively agranular) insular cortex. This region of the far anterior (agranular) insula is close to the part of the insular cortex where it adjoins the caudal orbitofrontal cortex.

A homology between the rodent and primate cases with respect to the central anatomy of taste and olfactory integration has been previously suggested and, thus, it is being proposed here that this homology would extend to humans to encompass at least three mammal species. In fact, Shi and Cassell (1998) reported that in rats both the granular and

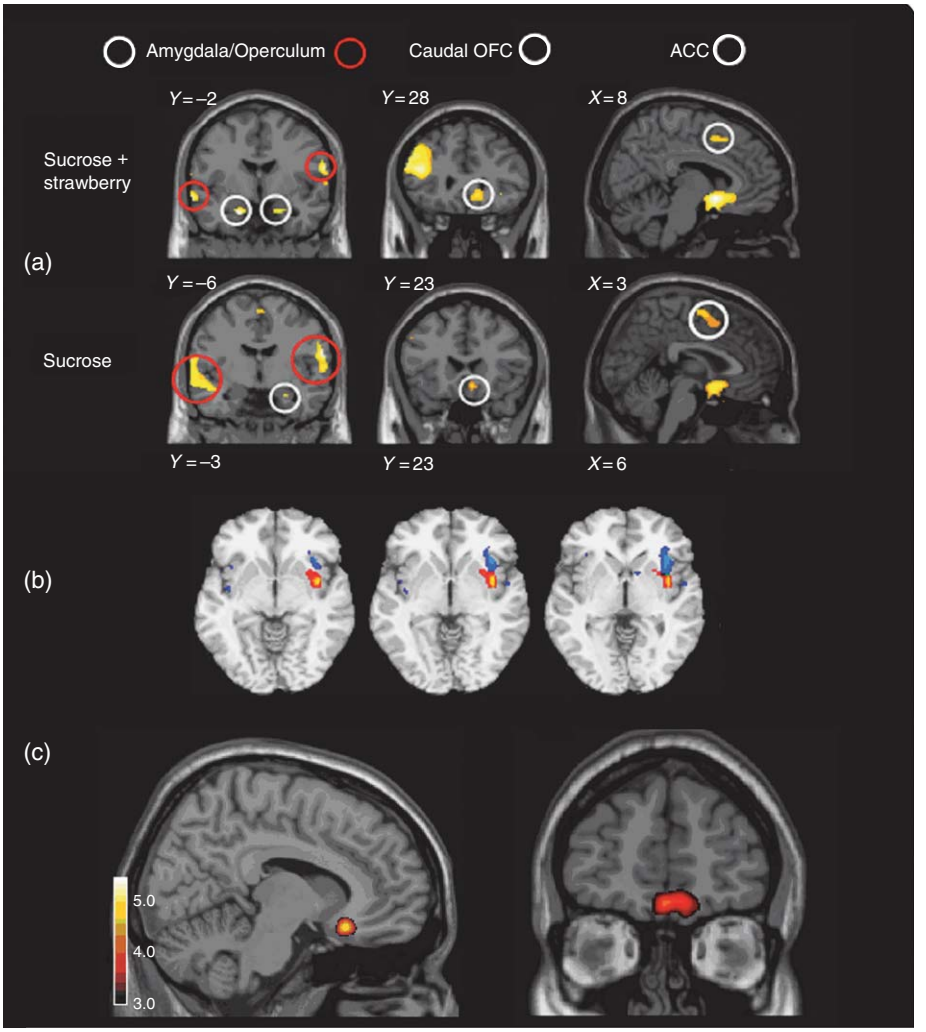

Figure 3 Increases in activity level in human gustatory brain areas as detected by functional magnetic resonance imaging. a, Activations produced by 0.5 M sucrose (bottom row) and sucrose combined with strawberry odor (top row) were observed in most of the central gustatory areas: insular/operculum, medial (rostral and caudal) orbitofrontal cortex, amygdala, and forebrain (which might include the hypothalamus and some parts of the thalamus). This shows that cortical gustatory areas support multisensory maps involving taste representations. b, Insular areas of the human brain responding to both pure tastants (sucrose) and water in the mouth (blue) and correlating with hydration states (red). c, Left, medial orbitofrontal cortex region, where it borders the subgenual cingulate cortex, that responds to water in the mouth only when thirst is present, thus indicating representations in the taste cortex of the internal state of the organism. Right, an anterior medial orbitofrontal cortex area in which activity correlates with the subjective pleasantness of a taste/olfactory mixture. Adapted from de Araujo, I. E., Kringelbach, M. L., Rolls, E. T., and McGlone, F. 2003b. Human cortical responses to water in the mouth, and the effects of thirst. *J. Neurophysiol.* 90, 1865–1876 and de Araujo, I. E., Rolls, E. T., Kringelbach, M. L., McGlone, F., and Phillips, N. 2003c. Taste–olfactory convergence, and the representation of the pleasantness of flavor, in the human brain. *Eur. J. Neurosci.* 18, 2059–2068.

the dysgranular zones in the posterior insula are part of the gustatory cortex (see also Cechetto and Saper, 1987). Moreover, based on the projection patterns among the granular, dysgranular, and agranular parts of the rat insula (as well as on the projection patterns from the VPMpc; Cechetto and Saper, 1987), Shi and Cassell (1998) claimed that the dysgranular insular cortex constitutes a secondary taste association cortex (in contrast to the lower-order granular zone). They further hypothesized that the agranular part of the insular cortex is a tertiary taste association cortex supporting flavor perception (given its afferent projections from the olfactory bulb and piriform/endopiriform cortices). Sewards and Sewards (2001) proposed thus that this homology between the rodent and primate cases holds also for the secondary (dysgranular) and tertiary (agranular) taste association area. In particular, the agranular insula and the adjoining caudal part of the orbitofrontal cortex would support flavor perception given the convergence of olfactory and taste inputs in these areas. Further regions of

taste/retronasal odor convergence found in this neuroimaging study (de Araujo *et al.*, 2003c) include the amygdala, the ventral forebrain, and the anterior cingulate cortex, which is targeted by regions of the anterior insula, possibly including taste cortex (Vogt and Pandya, 1987). The findings above thus indicate that several parts of the central taste system allow for combinations between taste and odor to form flavor percepts; moreover, its anatomical bases seem comparable across distinct mammal species.

As mentioned, it has been found in monkeys that a representative number of neurons in the primary taste cortex respond to oral somatosensory/motor stimulation (Scott *et al.*, 1986; Ogawa, 1994). In fact, it has been shown in humans (de Araujo and Rolls, 2004) that activation of the anterior insular (putative primary) taste cortex by oral viscosity stimuli occurs in such a way that brain activation in this region was proportional to the log of the viscosity of the oral tasteless stimuli (carboxymethyl cellulose), providing evidence of somatosensory/gustatory integration in the primary taste cortex. It is known that in more posterior regions of the insular cortex in owl monkeys (Jain *et al.*, 2001), the caudal part of the face representation in area 3b extends anterior beneath the central sulcus and above the upper bank of the lateral sulcus. The representation of the oral cavity is located rostral to this region extending to the orbitofrontal cortex (Manger *et al.*, 1996; Jain *et al.*, 2001). The de Araujo and Rolls (2004) study used quantitative variation of texture features of intraoral stimuli by manipulating viscosity and found activation of the midinsular and anterior insular cortices.

Another example of activations in the human primary taste cortex that are independent of the major perceptual categories of taste is activations to water in the mouth, when subtracted from activations produced by artificial saliva at the same viscosity (de Araujo *et al.*, 2003b). This corroborates previous electrophysiological studies in macaques showing that water in the mouth activates neurons in the primary taste cortex in the anterior insula and adjoining frontal operculum (Scott *et al.*, 1986; Yaxley *et al.*, 1990). Thus, not only the stimulation of taste receptors by prototypical tastants, but also substances generally relevant to behavior and survival, seem to elicit responses in the mammal gustatory cortices.

In fact, to guide feeding behavior and maintain energy homeostasis, mammal brains must not only represent the sensorial aspects of an intraoral stimulus, but also combine these with the internal state of the organism, in that they must ascribe the stimulus motivational value. Human studies also provide evidence that the reward value of taste is represented in the gustatory cortices, in particular in the orbitofrontal, insular, and anterior cingulate cortices. Small *et al.* (2001) found that the caudomedial part of the orbitofrontal cortex and a region of the midinsula represent the changing reward value of a food eaten to satiety. Interestingly, the same pattern of responses was found in responses to water in the mouth at different levels of hydration: activity in the mediocaudal orbitofrontal cortex and midinsula is modulated by the physiological state (thirst) of the body (de Araujo *et al.*, 2003b).

The finding that the midinsula and adjoining posterior insular areas respond to water in the mouth in a (thirst) state-dependent way is in agreement with the viscerotopic map of the rat insular cortex as proposed by Cechetto and Saper (1987). Their results suggest an anterior–posterior distribution of visceral representations in the rat insula, with special visceral (taste) projections situated preferentially in more anterior areas, whereas general visceral (including gastric mechanoreceptor-responsive and cardiopulmonary units) were distributed more posteriorly and dorsally. The human insula might thus reproduce such topography by combining special visceral (taste) and general visceral inputs in insular regions.

In addition to the current motivational value of a taste stimulus, the secondary taste cortex, the orbitofrontal cortex, and the adjacent anterior cingulate cortex area also represent the degree to which subjects ascribe reinforcing properties to gustatory-related stimuli. For example, correlations with consonance and pleasantness ratings for the smell and taste combinations were found in a medial anterior part of the orbitofrontal cortex (de Araujo *et al.*, 2003c), the pleasantness ratings for a food eaten to satiety were correlated with activity in the medial orbitofrontal cortex (Small *et al.*, 2001), and the (subjective) rewarding properties of water in the mouth under different hydration states were correlated with activity in the medial orbitofrontal cortex and in the far anterior cingulate cortex (de Araujo *et al.*, 2003b). Moreover, the orbitofrontal cortex is also involved in encoding the reward value of visual signals predicting taste stimulus receipt. In a classical conditioning paradigm, where a previously neutral cue was associated with receipt of glucose, expectation of the pleasant taste produced activation in particular in the amygdala and orbitofrontal cortex (equivalent results were found for a cue predicting receipt of an unpleasant taste, saline; O'Doherty *et al.*, 2002), also evidencing the ability of the human cortex to associate visual and taste representations.

The evidence described above indicates that the mammal taste cortex can serve a more general

purpose other than simply representing the end line for ascending taste information. It seems rather that this is a byproduct of a more general function, namely, to encode information about stimuli relevant for survival, be they taste stimuli (sugars), nutrient-rich stimuli with particular textures (fat), or clean water. Thus, it should be involved in generating behavior through back-projections to the noncortical regions of the taste system, such as the hypothalamus and the brainstem.

3.25.5 The Mammal Taste System in the Context of Vertebrate Evolution

Mammals first appeared approximately 210 Mya during the first interval of the Mesozoic era, approximately at the same time as crocodiles and dinosaurs (e.g., Rougier and Novacek, 1998). A characteristic feature of all living mammals is a 1–3 mm thick, multilayered sheet of neural tissue situated between more lateral olfactory areas and medial hippocampal areas, the isocortex (Northcutt and Kaas, 1995). Although there are different views on how the mammalian isocortex might have evolved from their nonmammalian ancestors (e.g., outgroup vs. recapitulation hypotheses; Northcutt and Kaas, 1995), it seems clear that it resulted in more complex cortical processing and much higher associative power. Aboitiz *et al.* (2003), for example, argued that the mammalian isocortex appeared by means of a dorsalizing effect during the early development of the pallium of the first mammals. This would have resulted in the formation of a hippocampal–dorsal cortex circuit supporting complex olfactory-based representations of space. The ability to form such complex representations and to use them to guide behavior would be then a hallmark of mammalian evolution.

In fact, when compared to other tetrapods, the multilayered cortex seems to account for most of the specificity in mammalian sensory processing. Comparative data on gustatory processing are very scarce. It nevertheless seems clear that in nonmammalian tetrapods, CN fibers provide taste-related information to the ascending gustatory pathway arising in the nucleus of the solitary tract that then projects to the parabrachial region, which in its turn projects extensively to the forebrain, as in the case of the lizard *Varanus exanthematicus* (Ten Donkelaar and De Boer-Van Huizen, 1981). The forebrains of reptiles and mammals are similar in that the dorsal surface of their cerebral hemisphere is formed by a pallium with three major segments: an olfactory (laterally situated) cortex, a limbic cortex (dorsomedial), and an intermediate cortical tissue that in the mammal case corresponds to the isocortex, but in reptiles and birds consists of part of the dorsal cortex and the dorsal ventricular ridge (Ten Donkelaar, 1999) (see Evolution of Vertebrate Olfactory Subsystems). In any case, in all tetrapods, gustatory information (as well as other modalities) reaches the telencephalon, and the intermediate pallial segment receives sensory projections from the thalamus and contains modality-specific sensory (presumably including gustatory) areas in reptiles, birds, and mammals (Ten Donkelaar, 1999).

If the ascending gustatory pathway is homologous from the CN fibers up to thalamic (forebrain) level in several classes of vertebrates (tetrapods), the possibility remains that mammal-specific gustatory cortices could be heterogeneously structured across different mammal species. There is, nonetheless, evidence to the contrary. That is, all mammals seem to have a primary somatosensory area and homologous adjoining fields (Kaas, 1980). In addition, homologous limbic, orbital, and lateral gustatory fields can also be found in different mammal species (Northcutt and Kaas, 1995; Preuss, 1995), unlike, for example, some prefrontal regions specific to primates such as the dorsolateral prefrontal cortex (Preuss, 1995). In particular, when comparing the connection patterns of the rat insular cortex with those on the insular cortex of cats and monkeys, Guldin and Markowitsch (1983) suggested that on the basis of thalamocortical connections, the insular cortex is a heterogeneous structure with homologous subdivisions in each of these species, including a separate gustatory (somatosensory) insular region. Likewise, basal mammals seem to possess structures supporting higher-order taste-related cortical areas homologous to higher mammals, such as the orbital fields of the hedgehog tenrec (*Echinops telfairi*; Radtke-Schuller and Künzle, 2000).

The strongest indication that the mammal central gustatory system is conserved across different species comes from molecular genetic studies performed on mice by Charles Zuker, Nicholas Ryba, and colleagues (Mueller *et al.*, 2005; Zhang *et al.*, 2003; Zhao *et al.*, 2003). As mentioned, mice and humans show different sensitivities for some sweet stimuli, such as aspartame, which cannot be recognized by mice. In this regard, mice engineered to express the human T2R homologous gene in place of the mice T2R gene develop a preference for aspartame, recognized as a sweet compound (Zhang *et al.*, 2003). This seems to indicate that when different mammal species are provided with receptors for the same class of ligands, then behavior (e.g., avoidance/approach) is controlled through an innate, homologous dedicated (Sugita and Shiba, 2005) neural circuitry.

In summary, based on the available neurophysiological data from mammals and especially humans, it seems that gustatory processing has also benefited from the mammal-specific development of cortical layers supporting higher-order, cross-modality associations. This would allow tastants and other biologically relevant intraoral stimuli to be represented in multisensory maps, whose processing is distributed across different regions of the cortex. Information about the physical properties of a given compound will be combined with information about the internal physiological state of the organism. Information about the physiological state of the organism is carried by visceral inputs to the taste cortices (as in the case of conditioned taste aversion; Garcia *et al*., 1955) and by indexes on the animal's current fluid and energy status (as provided by specific hypothalamic regions responsive to changes in levels of hormones – leptin, insulin, angiotensin; e.g., Niswender *et al*., 2004). These cortical sensory–visceral maps will then generate, through back-projections to the brainstem mediated by hypothalamic and amygdalar areas, a large repertoire of complex behaviors regulating food intake and body weight that is unique to mammals.

3.26 Vestibular System

W M Graf, Howard University College of Medicine, Washington, DC, USA

Glossary

1° Primary afferent (vestibular nerve).

2° Second-order vestibular neuron (vestibular nucleus).

AC Anterior semicircular canal.

AIN Abducens internuclear neuron.

ampulla A bulb-like hollow structure housing a sensory organ.

analogous Similar in function, but without phyletic continuity (e.g., human hands and the tongue of a chameleon used for prey catching: they both do the same thing at one time, but their origins are completely different).

ATD Ascending tract of Deiters.

C_2 Second cervical vertebra.

C_7 Seventh cervical vertebra.

cilia Sensory processes of hair cells.

common crus Common leg (Latin), a portion of the semicircular canal system shared by two canals.

cupula Receptor system of the labyrinth in the semicircular canal ampullae detecting angular accelerations (rotations).

ectoderm One of the three germ layers formed during the gastrula stage in embryogenesis and giving rise to, among other organs, the nervous system. The other two germ layers are the mesoderm and the entoderm.

FP Frankfurt plane.

hair cell Sensory cells of the inner ear and some other sense organs whose name derived from their mechanically sensitive cilia, the so-called kinocilia and the stereocilium. During a stimulus, e.g., mechanical or auditory, these cilia undergo a bending and via a specific ion conductance perform a mechanoelectrical transduction.

halteres Fast-moving (rotating) clublike righting organs of flies, working much like gyroscopes.

HC Horizontal semicircular canal.

hemilabyrinthectomy Global extirpation of the labyrinth of one side, resulting in distinctive lesion symptoms.

homologous Inherited from a common ancestor (with phyletic continuity), but not necessarily similar in function (e.g., the limbs of horses and sea lions, used for walking in one case, and swimming in the other case; another example are the wings of birds and bats which

	are both homologous and analogous, since they were both derived from forelimbs and are used for flying).
Hor	Plane of horizontal semicircular canals.
HorC	Horizontal canal.
III	Oculomotor nucleus.
IN	Internuclear neuron.
invertebrates	Animals without a back bone (spinal column), e.g., insects, worms, spiders, crabs.
IO	Inferior oblique.
IR	Inferior rectus.
IV	Trochlear nucleus.
kinematics	Muscle actions upon a movable body part, e.g., a limb, an eye.
lateral line	A sensory system present in many aquatic vertebrates of mechanoreceptive (water current) or electroreceptive nature (electric fields).
LR	Lateral rectus.
MN	Motoneuron.
MR	Medial rectus.
neural crest	Inductive tissue to form sensory and neuronal elements appearing between the neural tube and the surface ectoderm.
neuromast cell	Hair cell of the lateral line system.
optokinetic reflex	Eye (or head) movements elicited by large moving visual scenes, e.g., when observing the passing landscape in a moving train.
otic placode	Thickening of the ectoderm and precursor of the otocyst.
otoconia	Ear stones consisting of calcium carbonate crystals embedded in the otolith membrane.
otocyst	Invagination of the otic placode forming a cyst at first that later subdivides and gives rise to the complex adult three-dimensional structure of the labyrinth.
otolith	Receptor system of the labyrinth, so-called graviceptor, detecting linear accelerations (translations).
Otx	Member of a gene family (orthodenticle).
PC	Posterior semicircular canal.
rhombomere	Elements of segmentation of the rhombencephalon formed during embryology and thought of as an expression of developmental organization.
semicircular canal	Tubelike structure of the labyrinth filled with endolymph to detect angular accelerations.
SO	Superior oblique.
SR	Superior rectus.
statocyst	The balance organ of an invertebrate.
VAPC	Vertical anterior parasagittal canal.
vertebrates	Animals with a spinal column (back bone), i.e., fish, amphibians, reptiles, birds, mammals.
vestibulo-ocular reflex	Eye movements elicited by stimulation of the labyrinth.
VI	Abducens nucleus.
VPPC	Vertical posterior parasagittal canal.
VTC	Vertical transverse canal.

3.26.1 Introduction

The sense of balance, the vestibular system, is our unknown sense. We recognize its existence only under pathological conditions, such as seasickness, dizziness, vertigo, etc. Among the classical five senses, i.e., vision, taste, smell, touch, and hearing, our sense of balance is not mentioned. Quite often, the sense of balance is just considered as an appendix of the auditory sense due to the anatomical unity of cochlea and vestibular apparatus, the so-called inner ear (Figures 1a and 1b). The inner ear is really a fabulous example of the engineering capabilities of nature and evolution, as it is one of the most complex anatomical structures in the vertebrate history: in humans, we find two hypersensitive hyperprecise sensory organs housed within the space equivalent to that of an M&M ball – the auditory sense and the sense of balance. Moreover, under normal life conditions, we are not even aware of the latter's existence. The sense of balance could thus be considered our sixth sense, and its functions are manifold. At least four different and vital functions should be mentioned:

1. postural control and postural stabilization;
2. reflex movements;
3. perception of self-movement; and
4. autonomous control.

3.26.2 Spatial Coordinates

A large portion of our daily activity requires moving between different positions. To that end, we use different means of locomotion or transport, e.g., individual locomotion (walking, running, swimming), or with the aid of mechanical devices (bicycle, car, train, escalator, etc). During all these dynamic events, we have a sensation of self-motion, which we will largely attribute to visual inputs. The

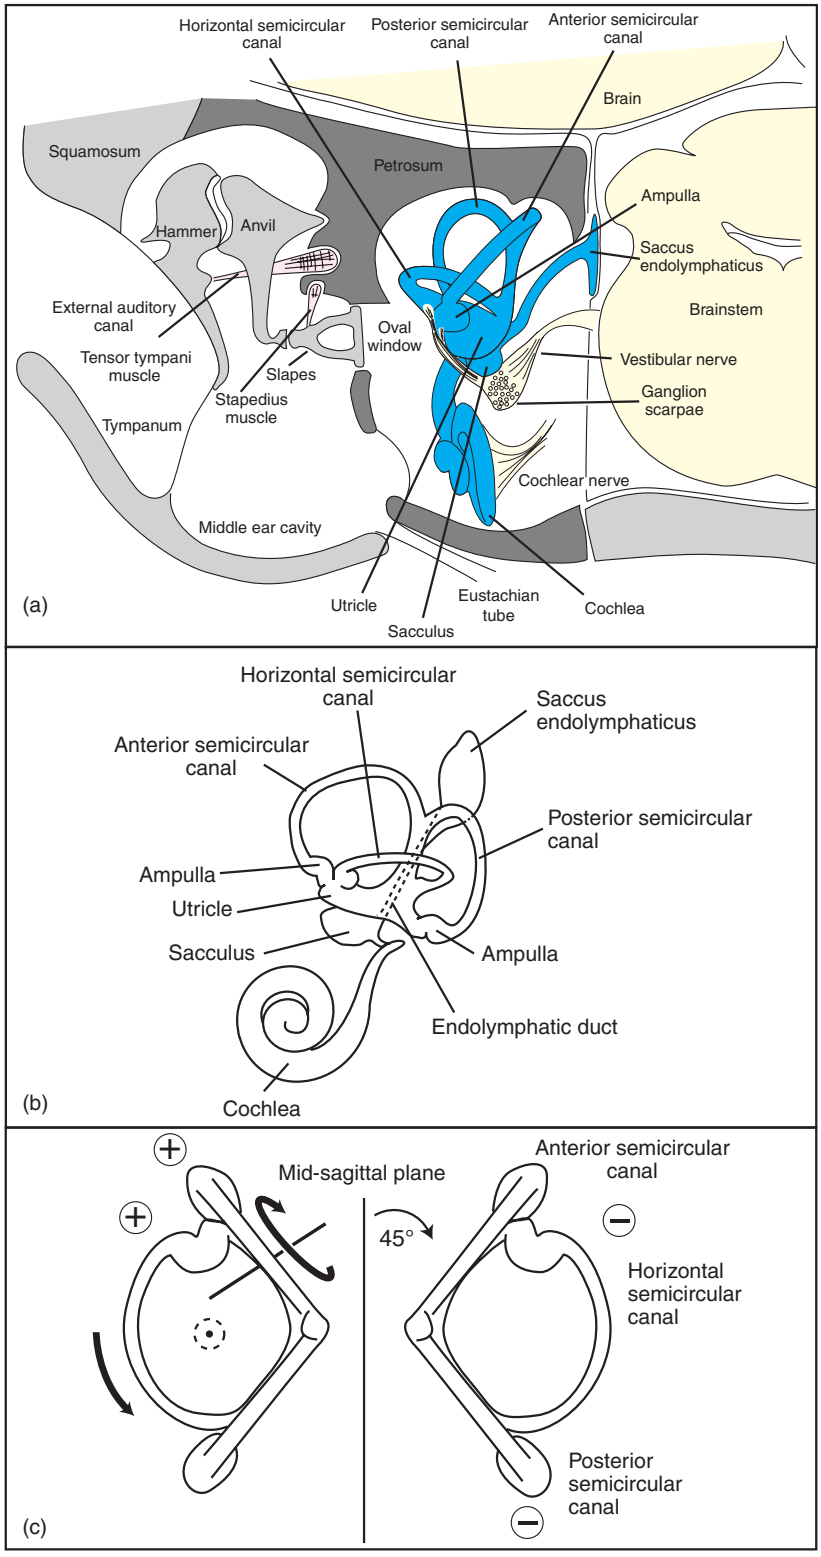

Figure 1 Anatomy of the organ of the sense of balance. a, Position of the labyrinth in the cranium. Cross section of the right Os petrosum with a frontal view of the right labyrinth and its topographical neighborhood. b, Lateral view of the left human labyrinth showing the portions of the sense of balance (semicircular canals and otoliths) and of the sense of hearing (cochlea). c, Spatial orientation of an idealized semicircular canal system (top view). Anterior and posterior canals are oriented vertically, horizontal canals are oriented horizontally. The vertical canals are oriented 45° off the midsagittal axis (diagonal orientation). Note bilateral symmetry, mutual orthogonality between canals, and the push–pull operational mode illustrated for the right posterior and the left anterior canals, and the right and left horizontal canals. When one canal becomes excited (+), its coplanar counterpart becomes inhibited (–). Canal on-directions are indicated by the directions of the arrows about the canal rotation axes. The combined excitatory and inhibitory responses of all canals during head movements produces a meaningful activity pattern in the afferent nerves and recipient brain nuclei to represent a movement vector in physical space (Werner, 1960).

role of the sense of balance in this function is often not realized, although fast reflex movements, such as certain eye movements or postural control adjustments are mediated by this sensory system. Triggering a fast eye movement via the sense of balance (the vestibulo-ocular reflex, VOR) requires only 16 ms, while eliciting the corresponding reflex via the visual system (optokinetic reflex) takes 80–150 ms.

Humans live in a three-dimensional environment; however, they rarely use the third dimension for every day transport in comparison to many bird and fish species, or even nonhuman primates. Nevertheless, our sense of balance uses a sensory organ to detect self-movements in three-dimensional space. Two fundamentally different movement categories have to be distinguished: rotations and translations. Each one of these has three degrees of freedom. Classically, these movements are described in a Cartesian coordinate system anchored to the head, which includes one vertical axis (along the gravity vector), and two earth horizontal axes, one naso-occipital (sagittal) axis, and one interaural (transverse) axis. All three axes intersect at one point in the middle of the head. It has to be mentioned, however, that the Cartesian coordinate system, as its name implies, is man-made (i.e., by the French philosopher and natural scientist René Descartes, 1596–1650) and bears no significance for the way biological systems developed movement detection systems during the course of evolution.

3.26.3 Receptors of Movement Input: The Labyrinth

3.26.3.1 Anatomy

The inner ear is a bilateral organ. It is located inside the petrosal part of the temporal bone of the cranium (Figure 1a). The balance organ is part of the inner ear and consists of the semicircular canals and the otoliths (Figure 1b). At first sight, the twisted and three-dimensional structure of the inner ear looks quite complicated and has earned the balance organ the name 'labyrinth'.

Semicircular canals and otoliths are sense organs, which detect accelerations. The semicircular canals detect angular accelerations (rotations), the otoliths linear accelerations. An example for a ubiquitous and permanent linear acceleration is earth gravity (gravity vector). Under normal living conditions, we rarely spend a thought about gravity, but when gravity becomes absent, the effects can be dramatic, as during space flight under microgravity conditions with resulting space motion sickness.

3.26.3.1.1 The semicircular canals The operational mode of the semicircular canals is independent of gravity. The canals are filled with a fluid, the so-called endolymph, which, during a given head movement, causes a so-called endolymph current, which displaces receptor cells inside a specialized area of the canal lumen, the so-called ampulla (Wilson and Melville Jones, 1979; Graf, 2003). An important characteristic of the macroscopic anatomy of the semicircular canals is their three-dimensional orientation. The ensemble of the six canals, three on each side, forms a physical coordinate system to detect angular accelerations in three-dimensional space. The semicircular canal system on each side of the head consists of a horizontal (lateral) canal, and two vertical canals (one anterior and one posterior canal) (Figure 1c). The horizontal canal is lightly tipped upward (about 30° in humans) at normal head resting posture (Figure 2a; see also Figure 2b). The vertical canals are oriented about 45° off the midsagittal plane of the head (Figure 1c).

The orientation of the semicircular canals in the head follows three interdependent functional principles:

1. Bilateral symmetry: both labyrinths are mirror symmetric.
2. Reciprocal operational mode: during head rotations receptors in a given canal will be excited, while the receptors in the contralateral coplanar canal will be inhibited; the so-called push-pull system.
3. Mutual orthogonality of canals: the functional planes of the canals enclose angles of 90°, or close to that value (Figure 1c).

The semicircular canal system thus constitutes an intrinsic sensory reference frame system, which provides a blueprint for the spatial coordination for a number of reflex functions and sensory interactions (Cohen *et al.*, 1965; Schaefer *et al.*, 1975; Simpson and Graf, 1981, 1985; Simpson *et al.*, 1981; Graf, 1988; Graf *et al.*, 1988; Leonard *et al.*, 1988).

3.26.3.1.2 The otoliths By contrast to the semicircular canals, the otoliths are receptors, which depend on the presence of gravity (graviceptors). They detect linear accelerations and do not function in microgravity. Most vertebrates, including humans, posses two otoliths on each side: the horizontal utriculus and the vertical sacculus. At normal resting posture of the head, the utriculus seems to be oriented earth horizontally (Figure 2b). The receptor cells of the otoliths are embedded in the so-called otolith membrane, which contains the

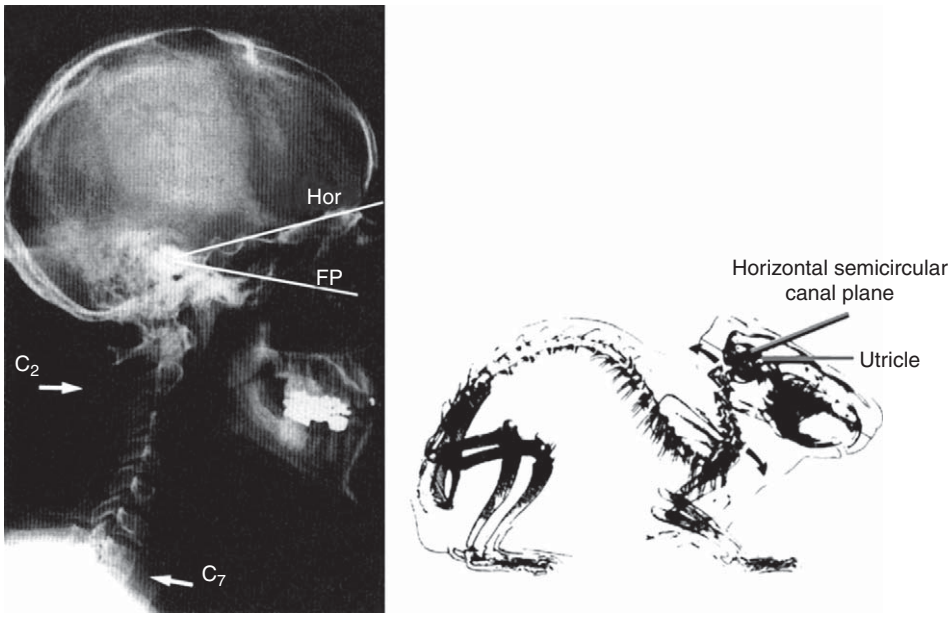

Figure 2 Lateral views of head and labyrinth orientation during normal head posture at rest in a biped and a quadruped. a, Radiograph of a human skull. C_2, C_7, second and seventh cervical vertebras; FP, Frankfurt plane; Hor, plane of horizontal semicircular canals. b, Artist's rendering of a lateral radiograph of an awake and unrestrained guinea pig. Note vertical orientation of the cervical vertebral column. Arrows indicate the direction of possible movement, i.e., at the upper cervical columns, only extension movements are possible, since the head is held in the extreme flexed position at the atlanto-occipital articulation, and at the cervicothoracic junction only flexion movements are possible, since here the vertebras are held at extreme extension. In both cases, the cervical vertebral columns are held vertically with the horizontal canals kept tipped upward by approximately 20°–30°. At this position, the utricles would be positioned about earth horizontally.

otoconia. During a displacement of the head from the normal upright position, the otoconia will slide across the otolith membrane and produce a shear force upon the receptor cells.

3.26.3.2 Evolutionary History of the Labyrinth

The phylogenetic origins of the vertebrate labyrinth are not known. The only living protochordate, *Amphioxus*, possesses sense organs, namely, a median eye, and bilateral balance organs (Lacalli, 2001; Lacalli *et al.*, 1994, 1999; Figure 3), but no functional–physiological data are available. Furthermore, only fragmentary fossil records exist that testify to the beginning of vertebrate life in Cambrian times, more than 500 Mya. However, there now seem to be indications from molecular biology data for a common ancestor regarding mechanoreceptor cell evolution between *Drosophila* and vertebrates, i.e., hair cells (Fritzsch *et al.*, 2000; see also Figure 6). Although for a long time, the balance organ had been thought to have evolved from the lateral line system, recent evidence based on multiple out-group comparison suggests that the inner ear of vertebrates evolved as a statolithic system before the lateral line system and before semicircular canals appeared.

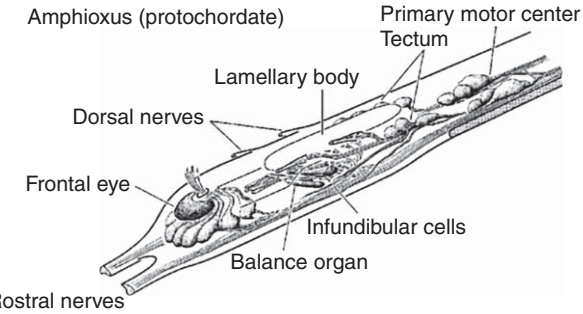

Figure 3 Amphioxus cerebral vesicle. Principal landmarks in the larval cerebral vesicle of amphioxus, showing the anterior pigment cup with the median eye, the ciliary bulb cells of the putative bilateral balance organ, and the lamellar body, which is assumed to be a pineal homologue (Th. Lacalli).

The fossil record becomes more complete only during the middle of the Paleozoic era, the Devonian period (350–400 Mya). The first record that demonstrates the existence of semicircular canals comes from jawless vertebrates, agnathan species of the Devonian and Silurian times, the ostracoderms. They possessed vertical, but not horizontal canals (Figure 4). Their vertical canals were oriented in the head as described before (Stensiö, 1927; Figure 1c). The ostracoderm labyrinth was

similar to the semicircular canal system of lampreys, the extant forms of their once-abundant ancestors. The Devonian period also marks the advent of jawed vertebrates (ganthostomes) and bony and cartilaginous fishes (osteichthyes and chondrichthyes, respectively; Figure 5). We know nothing about the labyrinth structure of the immediate ancestors of these newly appeared animals, but their modern successors display a new acquisition: horizontal semicircular canals. Thus, the vertebrate labyrinth now spans all three dimensions of physical space. The circumstances that led to the development of a horizontal semicircular canal system are unknown, but its presence most certainly introduced distinct advantages for the detection of three-dimensional space in comparison to the four canal system in the Agnatha. The acquisition of horizontal semicircular canals coincides with the expression of the vertebrate-specific gene *Otx1* (Fritzsch and Beisel, 2001, 2003; Figure 6). Knock-out mutants that do not express *Otx1* do not develop horizontal semicircular canals (Fekete, 1999). One could speculate that the appearance of horizontal semicircular canals, allowing an optimal solution, i.e., best and most economical (Gould, 1977), high signal-to-noise-ratio (Robinson, 1982; 1985; Graf, 1988) for movement detection in three-dimensional space constituted one prerequisite for the success of vertebrates later on in phylogeny. At any rate, it certainly provided one further advantage.

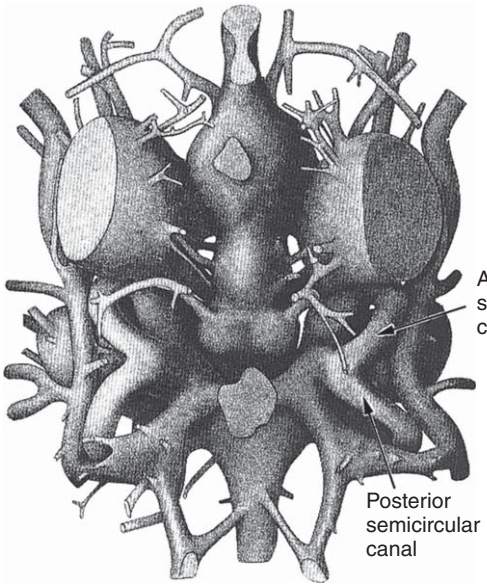

Figure 4 Photograph of a wax model of the cranial cavity of the fossil ostracoderm, *Kiaeraspis auchenaspidoides*, including labyrinths with anterior and posterior semicircular canals (Stensiö, 1927). Note diagonal orientation of the canals similar to the situation in extant vertebrates. Horizontal canals have not yet appeared.

Interestingly enough, there are two main lines of labyrinthine development in the surviving radiations, namely what we will refer to as the bony

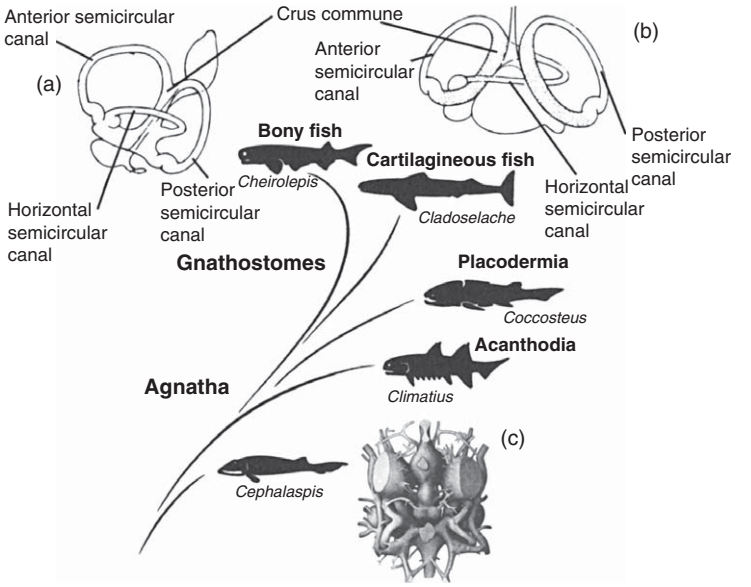

Figure 5 Phylogenetic relationship of early agnathans and gnathostomes (bony fishes, cartilaginous fishes, placoderms, and acanthodians) (Colbert, 1980), including prototypical vertebrate labyrinth characteristics. a, Human labyrinth (Werner, 1960). b, Shark labyrinth, *Chlamydoselachus* (Werner, 1930). c, Ostracoderm labyrinth without horizontal canals (Stensiö, 1927). Horizontal semicircular canals appear in bony fishes and cartilaginous fishes. In bony fishes through humans, the anterior and the posterior canal form a common crus. In cartilaginous fishes, there is no common crus between the anterior and the posterior canal. All labyrinths display a similar (diagonal) orientation of the vertical semicircular canals in the head.

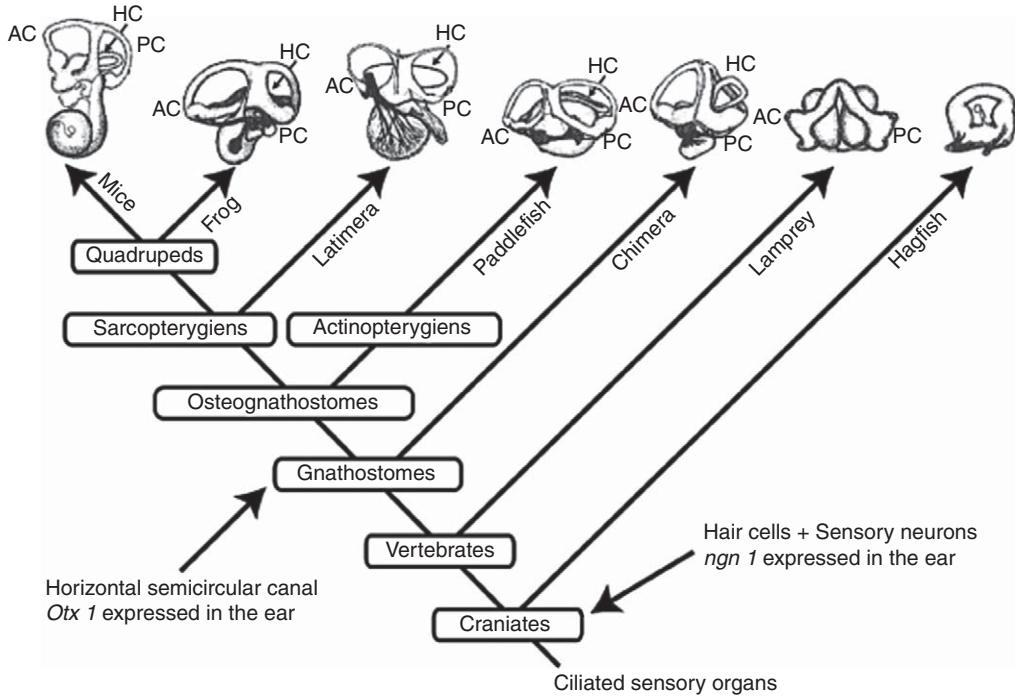

Figure 6 Morphogenic evolution of the vertebrate ear. Ciliated mechanosensory cells, so-called hair cells are now thought to be at the phylogenetic origin of the vertebrate inner ear. For the development of primary neurons, *ngn1* is necessary. One of the major morphogenetic events in vertebrate ear evolution was the appearance of horizontal semicircular canals in all gnathostomes. The development of horizontal semicircular canals coincides with the expression of the *Otx1* gene (Fritzsch and Beisel, 2001, 2003). Reproduced from Fritzsch, B. and Beisel, K. W. 2001. Evolution and development of the vertebrate ear. *Brain Res. Bull.* 55, 711–721, with permission from B. Fritzsch.

fish/tetrapod line and the cartilaginous fish line (Figure 5) (we are using the term 'bony fish/tetrapod' in the following to delineate vertebrate species between bony fish and mammals, quadrupedal and bipedal, i.e., including amphibians, reptiles, and birds). Unfortunately, no fossil record testifies to the labyrinth structures of earlier radiations that became extinct (e.g., acanthodians, placoderms).

In viewing a typical vertebrate labyrinth of the bony fish/tetrapod line, in this case a human labyrinth (Figure 5a), we observe that it consists of three canals, one anterior, one posterior, and one horizontal canal. Typically for this type of labyrinth, the anterior and the posterior canal form a so-called common crus; that is, they share a segment of their circular structure (Werner, 1960; Lewis *et al.* 1985). The typical cartilaginous fish labyrinth, in this case from a shark (Figure 5b) also possesses anterior, posterior, and horizontal canals that display the same orientation in the head as the bony fish/tetrapod labyrinth type. However, there is no common crus between the anterior and the posterior canals. The posterior canal is separate and has a communication with the sacculus, whereas a common crus-like structure is formed between the horizontal and the anterior canals (Daniel, 1928; Werner, 1930; Baird, 1974). This particular difference in labyrinth structure between bony fishes and cartilaginous fishes leads to the intriguing question of whether the phylogenesis of horizontal canals was monophyletic or polyphyletic in vertebrates.

3.26.3.3 Comparative Anatomy

A great variety of movement and position detectors, so-called statocysts, are found in invertebrates (Bullock and Horridge, 1965; Markl, 1974), and we will introduce only the most pertinent examples here (see Aggression in Invertebrates: The Emergence and Nature of Agonistic Behavioral Patterns, Evolution of Visceral Control in Invertebrates).

The statocysts of the fast-moving squid and cuttlefish (Figure 7a1) include grooves, which, similar to the vertebrate semicircular canals of vertebrates, direct endolymph flow toward a sensory crista with a cupula (Stephens and Young, 1978). These invertebrate canals, so-called tonoids, are oriented in space in a roughly orthogonal three-dimensional planar arrangement (Budelmann, 1977; Stephens and Young, 1978; Figure 7a2). Four canals on each side can be distinguished, which are oriented approximately in the main planes of the body, in contrast to the vertebrate

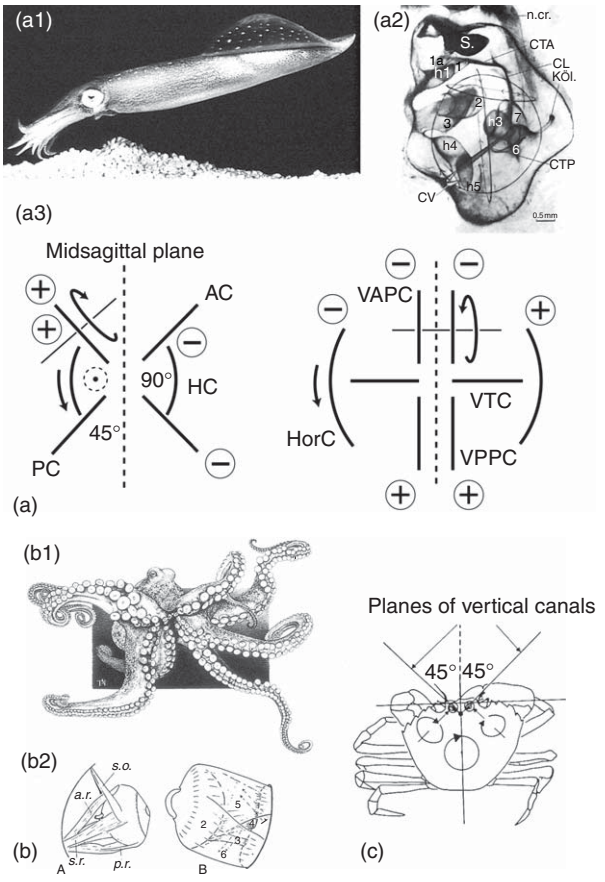

Figure 7 Convergent evolution of movement detection systems. a, Squid (a1), photo of a squid. The animal propulses itself rapidly backward by ejection of a jet of water. (a2), Retouched photograph of a squid statocyst indicating the orientations of the toroid planes (Stephens and Young, 1978). (a3), Comparison of the diagonal vertebrate semicircular canal system, and the principal axes system of squids. The squid system also fulfills the three criteria of orthogonality, bilateral symmetry, and push–pull operational mode. However, instead of six canals, it has eight toroid structures, and the on-directions of the sensory receptors are just about opposite that of vertebrates. Nevertheless, the squid movement detection system functions according to the same operational principles as the vertebrate semicircular canal system. b, Octopus (b1), drawing of an octopus. Despite its seemingly amorphous body structure, the octopus possesses a well-defined three-dimensional movement detection system similar to vertebrates. b2, Comparison of the extraocular muscles in a shark, left, and in the octopus, right. Note similar diagonal spatial arrangement in the two animals (Packard, 1972). c, Crab, spatial arrangement of the semicircular canal system in crabs. Although there are only four canals in crabs, the vertical canals are oriented just like the anterior canals of vertebrates, as are the horizontal canals (Fraser, 1981).

arrangement (Budelmann, 1977; Simpson and Graf, 1985; Figure 7a3). Sensory receptors detect movements in the transverse plane of the body, with excitation occurring during ipsilateral upward roll movements, in the longitudinal plane of the body, with receptors detecting pitch-up and pitch-down movements, and in the horizontal plane with receptors being excited during contraversive rotation (Figure 7a3, right). Some receptors also detect linear accelerations (Stephens and Young, 1978). The squid semicircular canal system can thus monitor three-dimensional angular accelerations just like the idealized vertebrate semicircular canal system with bilateral symmetry, orthogonality, and push–pull operational mode. Orthogonality of the semicircular canals would provide an optimal signal-to-noise ratio (Robinson, 1982, 1985), but in order to achieve paired orthogonality, the vertical semicircular canals need not necessarily be arranged in the familiar diagonal fashion. The one (and only) alternative arrangement is pairs in coronal, parasagittal, and horizontal planes as shown in Figure 7a3 (right). The squid/cuttlefish semicircular canal system could thus be termed a principal axes system, in contrast to the diagonal vertebrate arrangement.

In the octopus (Figure 7b1), the sensory receptor organ on each side consists of nine subsections, and is divided into three main planes, which are approximately orthogonal to each other (Young, 1960). The arrangement of the subsections suggests an angular acceleration detection system similar to that of vertebrates (Young, 1960; Budelmann, 1977). Interestingly, the extraocular muscle arrangement of the octopus resembles closely that of lateral-eyed vertebrates (Packard, 1972; Figure 7b2).

The third type of semicircular canal system introduced here in invertebrates of interest is found in crabs (Figure 7c), which possess one horizontal and one vertical toroid structure on each side. Depending on the species, these toroids can either be open or can form a closed canal system (Sanderman and Okajima, 1972; Sanderman, 1983; Fraser, 1981). In freely moving crabs, the horizontal canals are held earth horizontally, and since the horizontal and the vertical canals are close to orthogonal, the vertical canals are nearly vertical. Each vertical canal lies at an angle of 45° to the midsagittal plane in a configuration comparable to that of the anterior semicircular canals in vertebrates. Although there is only one vertical canal on each side, each one responds preferentially to movements about orthogonal axes and thus the canals of crabs are collectively capable of accurately transducing three-dimensional angular accelerations (Fraser, 1981).

Comparison of vertebrate and invertebrate solutions about how to build movement-detection systems shows a remarkable uniformity to an idealized three-dimensional geometry of optimal decomposition of all given rotation vectors. The semicircular canal systems of vertebrates and invertebrates are thus prime examples for convergent evolution.

3.26.3.4 Ontogeny and Phylogeny of the Labyrinth

The labyrinth develops from an enlargement of the ectoderm, the otic placode, which invaginates to form the so-called otocyst (for details see Rinkwitz *et al.*, 2001; Romand and Varela-Nieto, 2003). A number of genes and induction molecules play a role for the complicated morphogenesis of the labyrinth. There are genes that are necessary for the differentiation of various organ and system developments and some that are labyrinth-specific. Many genes work in parallel or are redundant. Gene duplication, or multiplication of genes during the progress of evolution has to be taken into consideration as well (Fritzsch *et al.*, 2000). The differentiation of the main structures of the labyrinth is guided by independent genes, which will be introduced in the following.

Although many vertebrate genes are homologous with *Drosophila* genes, the vertebrate labyrinth is a development of chordates and without precedent in other animal groups. Flies do not possess balance organs *per se*, but rely on relative movement of body parts (halteres) to orient in gravity. Homologies with other animal groups seem to be restricted to the development of receptor cells, which transform mechanical stimuli into electrical impulses (mechano electrical transduction). The receptors of the labyrinth are important examples for the general question of the origin of mechanoelectrical transduction at the level of receptor cells. For many years, evolutionary biologists believed that the labyrinth was derived from the neuromast cells of the lateral line organ of aquatic vertebrates. Meanwhile, however, functional interrelations between the pressure receptors of the nematode *C. elegans* and the sensory bristle receptors and proprioceptors of the fruit fly *Drosophila*, on one hand, and vertebrate hair cells, on the other hand, have been described (Fritzsch *et al.*, 2000; Fritzsch and Piatigorsky, 2005). The description of a mechanoelectrical transduction channel in *Drosophila* and *C. elegans* points to an early development of a mechanoelectrical receptor in evolution. The original receptors might have consisted of a cilia-like structure, including support cells. Thus, receptor cells seem to have been an important evolutionary component for the development of the sense of balance of vertebrates, but it was not the structure *per se* that led to the macroscopic expression of analogous sense organs. Interestingly, inner ear hair cells develop without involvement and influence of the neural crest, which normally guides the development of most of the sensory neurons of the peripheral nervous system of chordates.

The actual morphogenesis of the ear is governed by numerous genes, which also play a role in the development of lungs, kidneys, and extremities. Embryogenesis and morphogenesis occur during particular periods in ontogenesis, when certain genes are switched on or off, and when certain organs and characteristics are being developed. The development of sense organs is embedded into the general process of structurization and position specification. In this process, proneural genes will be activated, which are determining the precursors of the elements of sensory organs, such as support cells, glia, and portions of the actual sensory cells. Two mechanosensory basic helix-loop-helix (*bHLH*) genes are expressed in the ear, *Neurogenin 1* (*ngn1*) and *mammalian atonal homologue 1* (*Math1*). In insects, *atonal* (*ato*) is important, whose vertebrate homologue *Math1* is indispensable for the development of hair cells. Knock-out mutants without *Math1* develop support cells and primary neurons, but no hair cells. For the development of primary neurons, another *bHLH* homologue is required, i.e., *ngn1*, one of three so-called neurogenin genes.

For further labyrinth development, the so-called *FGF* and *FGFR* genes play an indispensable role (FGF, fibroblast growth factor; FGFR, tyrosine kinase receptor family). In particular, *FGF19* seems to be a fundamental element for the induction of ear development in chickens, which is activated together with *Wnt8c*. The interplay between FGFs and FGF receptors in vertebrates seems to induce the budding out of the growth zones of lungs, extremities, and the ear placode. With regard to inner ear development, the receptor FGFR-2(IIIb) is essential for the development of the semicircular canals, the endolymphatic duct, and the cochlea. Besides the *FGF* genes, *BMP*, *Pax*, *POU*, and zinc-finger genes were shown to be present in the ear. *POU4f3* knock-out mutants form a labyrinth with hair cells that are later lost. Missing the *Pax2* gene results in an ear without cochlea; however, with semicircular canals and otoliths (Fekete, 1999; Fekete and Wu, 2002).

While all genes described above have been shown to exist in insects, some vertebrate-specific genes are noteworthy, such as the above-mentioned *Otx1*, which regulates the development of the horizontal semicircular canals (Figure 6). Vertebrates without horizontal canals do not express this gene in the ear. Finally, the gene *mindbomb* should be mentioned, which plays a role during the development of the inner ear and the central nervous system. This gene is important in the context of the regeneration of inner ear hair cells, which has been demonstrated in

fishes and birds. The *mindbomb* gene seems to induce the transformation of the precursors of hair cells into support cells. Knock-out mutants produce an abundance of hair cells, but no support cells (Fekete, 1999).

Some homeotic genes also play a role for inner ear differentiation. Inactivation of *Hoxa1* produces various malformations of the inner ear and results in only the development of an epithelial cyst (Fekete, 1999).

3.26.4 Effectors of Sensory Input: Extraocular Muscles

3.26.4.1 The Extraocular Muscle Apparatus

The extraocular muscle apparatus can be considered as a prime example for the efficiency of biological systems. The spatial orientation of the extraocular muscles, in particular, illustrates in an almost ideal fashion how evolution solved a complicated problem of sensorimotor transformation.

The six extraocular muscles move the eye in a reference frame that corresponds to the spatial geometry of the vestibular semicircular canals, i.e., the typical diagonal, 45° off the midsagittal plane orientation of vertical canals, is reflected in the pulling direction of the vertical eye muscles (Helmholtz, 1910; Alpern, 1962; Figure 8). The vertical eye muscles are superior rectus (SR), inferior rectus (IR), superior oblique (SO), and inferior oblique (IO); the horizontal eye muscles are lateral rectus (LR) and medial rectus (MR). These anatomical designations give the impression of a distinct separation between straight and oblique eye muscles. In the true sense of the word, only LR and MR are straight eye muscles, whereas all vertical eye muscles, including SR and IR, are in reality oblique muscles. The illustrated example of Helmholtz's drawing demonstrates this fact very clearly (Figure 8). Unfortunately, an idealized, but erroneous figure by Bell (1823) has dominated the literature and clouded the understanding of spatial coordination of eye movements.

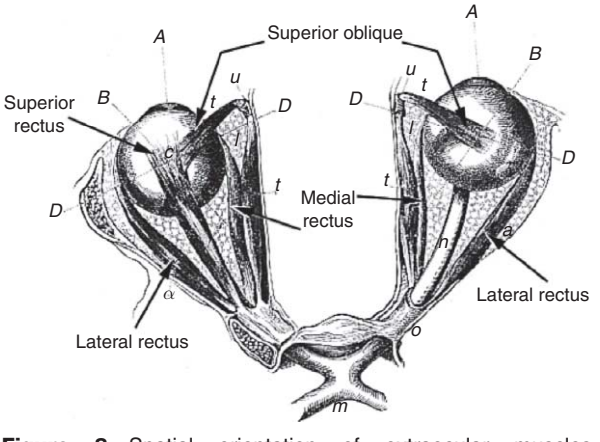

Figure 8 Spatial orientation of extraocular muscles (Helmholtz, 1910). Note diagonal orientation of vertical eye muscles, e.g., SR and SO.

3.26.4.2 Innervation of Extraocular Muscles

At the peripheral level of the six extraocular muscles, there are no gross differences between any of the vertebrate species, except that hagfishes do not possess eye muscles. However, at the central organization, distinct differences become evident. Across species, three patterns of eye muscle innervations can be distinguished:

1. The lamprey pattern where two eye muscles are innervated by ipsilateral (IO, IR), and one by contralateral (SR) oculomotor neurons, one by trochlear motoneurons (contralateral, SO), and one by the abducens nucleus (ipsilateral, LR).
2. The elasmobranch pattern with two ipsilaterally (IR, IO) and two contralaterally projecting (SR, MR) oculomotor motoneuron populations, one trochlear motoneuron population (contralateral, SO), and one abducens motoneuron population (ipsilateral, LR).
3. The bony fish/tetrapod pattern with three ipsilaterally (IR, IO, MR) and one contralaterally projecting (SR) oculomotor nucleus neuron population, one trochlear motoneuron population (contralateral, SO), and one abducens motoneuron population (ipsilateral, LR) (Figure 9; see also Fritzsch, 1998).

The lamprey pattern thus has only five extraocular eye movers, lacking the equivalent of a MR muscle (Fritzsch *et al.*, 1990). The main difference between the bony fish/tetrapod and the elasmobranch pattern is the positioning of the MR motoneurons, with MR motoneurons addressing a contralateral eye muscle in elasmobranchs, just as SR and SO motoneurons do (Figure 9b), and an ipsilateral placement with respect to the muscles it innervates in animals of the bony fish/tetrapod line (Figure 9a). This difference in motoneuron placement needs to be further investigated and reflected upon regarding vestibulo-oculomotor reflex connections (see below).

In evolutionary history, the MR muscle in elasmobranchs is thought to have evolved from a split of the dorsal rectus (SO) of ancestral agnathans, whereas it was derived from a split of the rostral rectus (IR) in the ancestors of the

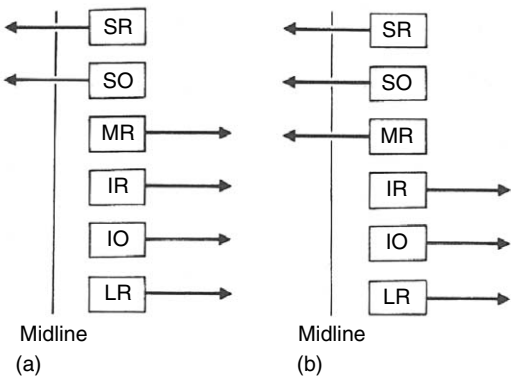

Figure 9 Oculomotor neuron projections in vertebrates of the bony fish/tetrapod line (a) and in elasmobranches (b). Note difference in MR motoneuron placement projecting ipsilaterally in bony fish/tetrapods and contralaterally in elasmobranchs. IO, inferior oblique; IR, inferior rectus; LR, lateral rectus; MR, medial rectus; SO, superior oblique; SR, superior rectus.

osteognathostomes (Nishi, 1938). Such a scenario would also explain the different motoneuron placements in the two vertebrate radiations.

There was also an idea that lungfishes actually possessed an elasmobranch innervation pattern, which would bring them taxonomically close to elasmobranchs (von Bartheld, 1992). This has now been shown not to be the case (Puzdrowski and Morshedi, 2003; Graf, unpublished observation). Clearly, lungfishes, at least the examined species, the African lungfish, *Protopterus dolloi*, shows a clear bony fish/tetrapod innervation pattern, with an ipsilaterally projecting MR subpopulation.

3.26.4.3 Ontogeny and Phylogeny of the Extraocular Muscles and Their Innervation

Although the geometric arrangement of the extraocular muscles is basically identical in all vertebrates that possess eyes, the horizontal eye muscles seem to have followed slightly different evolutionary paths in elasmobranchs and the bony fish/tetrapod line. Embryonically, the MR muscle seems to arise from the dorsal part of the premandibular head cavity in elasmobranchs; in other vertebrates it comes from its ventral part (see Graf *et al.*, 2002). This difference in embryonic origin may be a concomitant explanation for the contralateral versus ipsilateral placement of MR motoneurons in elasmobranchs when compared to bony fish/tetrapods. Other differences exist regarding abducens motoneurons. Abducens motoneurons originate in embryonic rhombomeres 5 and 6 in most vertebrates (lamprey, teleosts, birds, reptiles) (Gilland and Baker, 1993), exclusively from rhombomere 5 in frogs (Straka *et al.*, 1998) and mammals (Gilland and Baker, 1993), but only from rhombomere 6 in elasmobranchs (Gilland and Baker, 1992).

Abducens motoneurons are surmised to be somatic, originally being part of a series of homologous spinal-like nerves. Thus, the abducens nerve would have simply invaded a position once foreign to it (for a review of the pertinent literature, see Baker, 1992). According to this argument, the abducens would therefore not belong to the branchiomotor category. The special role of abducens motoneurons (and abducens internuclear neurons) is also underlined by the inhibitory transmitter employed by afferent vestibular and reticular neurons, i.e., glycin. In oculomotor and trochlear motoneurons, the inhibitory transmitter is GABA. Oculomotor myoblasts are thought to be derived from the premandibular region, trochlear myoblasts from the mandibular region.

The abducens nucleus is the only extraocular motor nucleus inside the *Hox* gene-expressing region, its expression being under the control of *Hoxb3*. The other extraocular motor nuclei are found around the brainstem–midbrain isthmus, with the trochlear nucleus originating in rhombomere 1. Development of the trochlear and the oculomotor nuclei seems to be primarily governed by two molecules, i.e., wingless (*wnt*) and engrailed (*en*).

3.26.4.4 Vestibulo-Ocular Connectivity

We described the three-dimensional geometry of the sensory periphery, the semicircular canals, and its related motor effectors earlier in this article. Clearly, there is a similarity between these geometries. The pulling directions of the horizontal eye muscles correspond with the orientation of the horizontal semicircular canals, that of the vertical recti with the orientation of the ipsilateral anterior semicircular canal, and the pulling directions of the oblique eye muscles are in line with the orientation of the ipsilateral posterior canal (Figures 10 and 12). We find this orientation principle from fish to humans.

The conservation of the coincidence of the spatial geometries of semicircular canals and eye muscles during vertebrate evolution is also accompanied by a conservation of the principal neuronal connections for the production of compensatory eye movements (VOR) from fish to humans. Within this framework, excitatory connections are formed between the anterior canal and the ipsilateral SR and the contralateral IO muscles, between the posterior canal and the ipsilateral SR and the contralateral IR muscles, and between the

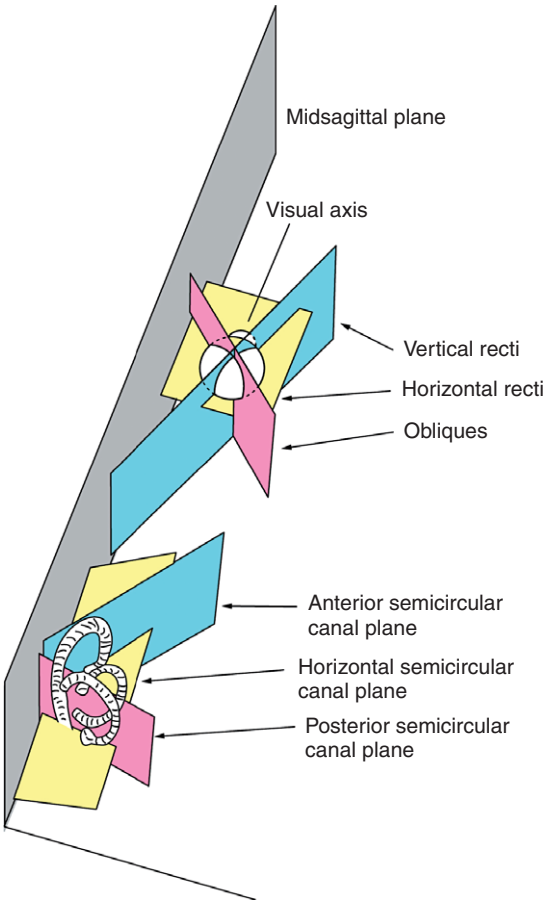

Figure 10 Three-dimensional orientation of semicircular canal planes and extraocular muscle pulling directions in humans. Note alignment of certain eye muscle pulling directions with particular canal planes, forming an intrinsic reference frame system.

horizontal canal and the ipsilateral MR and the contralateral LR muscles. Since the antagonists to these muscles will have to relax at the same time, we observe the existence of inhibitory connections to these antagonists arriving from the same semicircular canals (Figure 11). This innervation scheme has been termed the elementary VOR arc (Lorente de Nó, 1933) or the three-neuron arc (Szentágothai 1943, 1950) by the pioneers working in this field of research. The three neurons involved in this reflex arc are the primary vestibular neurons, the second-order vestibular neurons, and the respective extraocular motoneurons (Figure 11).

The development of the brainstem vestibular nuclei is under the control of a number of *Hox* genes, whose interactions are not yet completely understood (for details see Baker, 1998).

Compensatory eye movements following labyrinth stimulation in lampreys can be induced in any direction, although these animals do not possess horizontal semicircular canals or an equivalent of a MR muscle (Rovainen, 1976). The details of the neuronal connectivities underlying this behavior still need to be worked out.

While vestibulo-oculomotor connectivities have been elaborated in detail in the bony fish/tetrapod line (Figure 11), we are still lacking a definite answer as to the exact nature of the horizontal canal connections in elasmobranchs. Of particular interest are the special horizontal eye movement pathways in light of the contralaterally placed MR motoneurons in these animals.

Horizontal conjugate eye movements are produced by the simultaneous contraction of the LR muscle in one eye and the MR muscle in the other eye. In animals of the bony fish/tetrapod line, the decussating internuclear pathway from the abducens nucleus to the MR subdivision provides the necessary neuronal link between the two motoneuron populations (Figures 11c and 12a; Highstein and Baker, 1978; Carpenter and Baton, 1980; Highstein *et al.*, 1982). Since MR motoneurons in elasmobranchs are located contralateral to their respective muscles, they are found on the same side as the co-activated LR motoneurons. Therefore, we hypothesized that in these animals the organization of the horizontal VOR circuitry may be similar to that of the vertical systems, where one second-order vestibular neuron class links either the anterior or the posterior canal to two co-activated extraocular motoneuron populations (so-called yoke muscles) (Uchino *et al.*, 1980, 1982; Graf *et al.*, 1983; Graf and Ezure, 1986). In such a scenario, one horizontal second-order neuron would contact both LR and MR motoneurons to mediate conjugate eye movements in the horizontal plane (Graf and Brunken, 1984; Figure 12b). However, recent evidence suggests the existence of a contralaterally projecting internuclear pathway, besides other connectivities (Graf *et al.*, 2002; Figure 12b).

3.26.4.5 Lateral- and Frontal-Eyed Animals

Head movements in animals with different interocular angles, e.g., the extreme examples of rabbits and humans, seemingly require different compensatory eye movements. For instance, a head movement about the naso-occipital axis in a rabbit results in vertical eye movements, in a human, in torsional eye movements. In fact, if the reference frame is tied to the optic axis, such a difference is observed. However, if the reference frame is linked to the head, no difference occurs.

We had in fact elaborated the requirements necessary for compensatory eye movements in lateral, and frontal-eyed animals (Simpson and Graf,

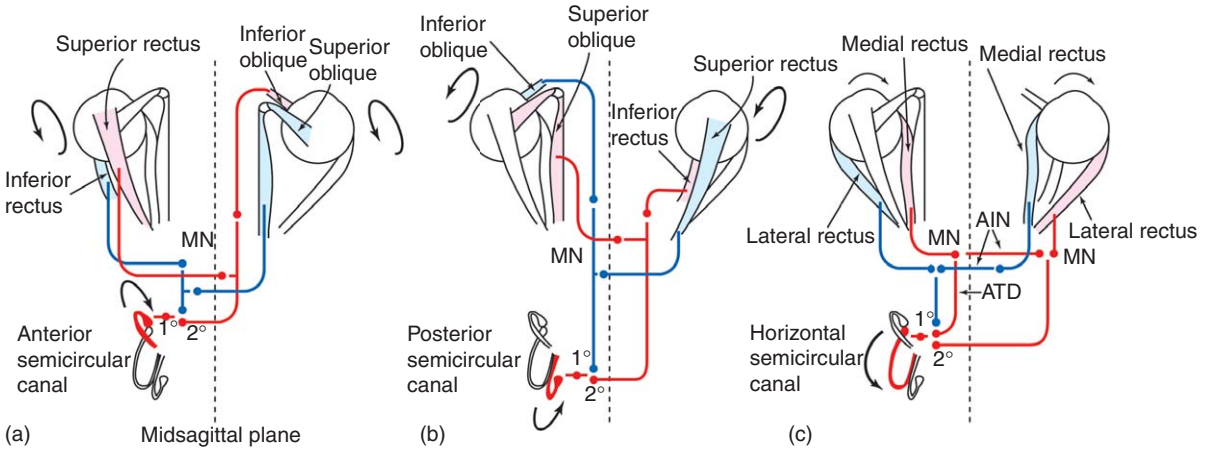

Figure 11 Spatial coordination of compensatory eye movements. Corresponding elements are illustrated in the same colors (red and blue). Semicircular canals and extraocular muscles form a three-dimensional intrinsic reference frame system for the production of VORs. The reflex arc consists of three neurons, the primary neuron (1°, vestibular nerve), the second-order vestibular neuron (2°, vestibular nucleus neurons), and the oculomotor neuron (MN, in oculomotor, trochlear, and abducens nuclei). Excitatory connections are shown in red, inhibitory connections are shown in blue. Contralaterally projecting vestibular neurons are in general excitatory, ipsilaterally projecting ones inhibitory. The respective semicircular canals (a, anterior canal; b, posterior canal; c, horizontal canal) and their efferent nerve pathways are marked in red. The on-directions of the semicircular canals are illustrated by thick black arrows. The connectivity of the horizontal system has a few peculiarities, such as an ipsilaterally projecting excitatory connection, the ascending tract of Deiters (ATD), and the abducens internuclear neuron pathway (AIN).

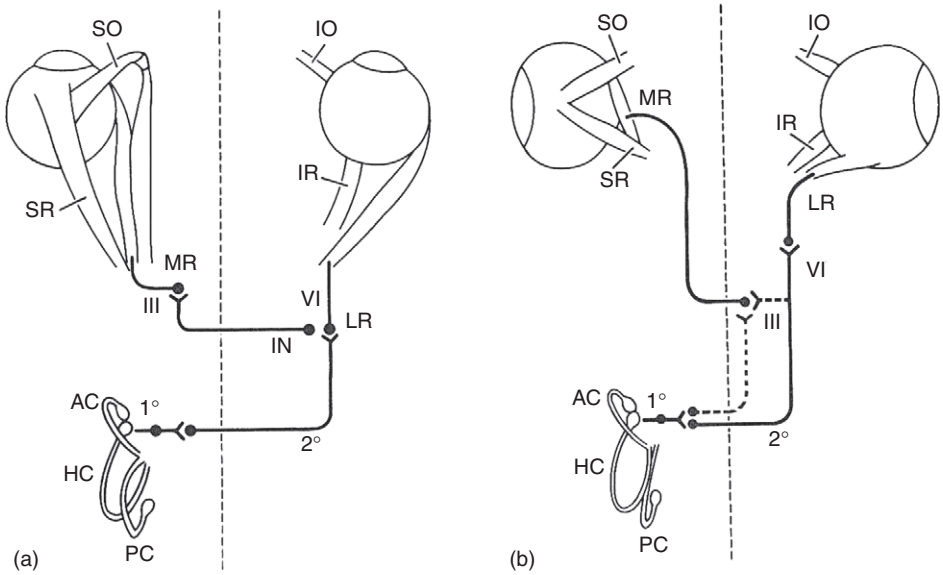

Figure 12 Schematic representation of vestibulo-ocular organization in vertebrates of the bony fish/tetrapod line (a) and elasmobranchs (b), including horizontal canal pathways. Note alignment of canals and related yoke muscles (left anterior canal, AC, with left SR, and right IO; left posterior canal, PC, with left SO, and right IR; left horizontal canal (HC) with left MR and right LR. The difference between the two prototypical vertebrate systems occurs in the horizontal reflex pathways. In vertebrates of the bony fish/tetrapod line (a), the connectivity to the lateral rectus muscle is of a three-neuron arc nature (vestibular afferent, 1°, second-order vestibular neuron, 2°, LR motoneurons in the abducens nucleus, VI), while an additional neuron, the abducens internuclear neuron (AIN) is inserted into the link to the co-activated MR muscle (MR motoneurons in the oculomotor nucleus, III). The three-neuron arc nature of the horizontal canal pathway in elasmobranchs (b), in particular the second-order vestibular neuron connectivity to LR motoneurons and MR motoneurons (2°) in the oculomotor nucleus, is hypothetical (Graf and Brunken, 1984). This fact is symbolized by the indication of the pathway in broken lines. Similarly, the nature of the contralaterally projecting internuclear pathway is not yet clear (Graf *et al.*, 2002).

1981, 1985; see also Ohm, 1919). There is no difference in the principal central nervous reflex connectivity, but subtle changes in eye muscle kinematics resulting from small changes in the insertion of vertical eye muscles during the course of evolution and the process of frontalization of the eyes.

3.26.5 Effectors of Sensory Input: Head–Neck Muscles

3.26.5.1 The Head–Neck Movement Reference Frame

Naturally, the system of the head–neck muscles used to perform head movements is more complex than that of the eye muscles, not only because of the far greater number of muscles involved (approximately 20 muscle pairs), but also because of the additional postural control functions these muscles have to fulfill. By contrast to the extraocular muscles, which do not have any postural function, one major task of head–neck muscles is to assure an upright head posture. Without the support function of the head–neck muscles, the head could not be balanced at labile equilibrium on top of the cervical vertebral column. Although the cervical vertebral column *per se* is relatively rigid, it has to be held upright, nevertheless, together with the head.

We were able to demonstrate the existence of a vestibular-based reference frame system also within the head–neck muscle system (Schaefer and Meyer, 1992; Graf *et al.*, 1997). However, the kinematic characteristics of the head–neck muscles are complex, and several muscle groups may cooperate and co-contract to perform a particular movement. Thus, the intrinsic geometry of the head–neck reference frame may not have become immediately obvious, although the very first systematic experiments by Flourens in the first half of the nineteenth century (Flourens, 1825, 1828) already pointed out its existence. These experiments involved selective transsections of semicircular canals in pigeons who subsequently performed movements in the plane of the lesioned canal. These could be eye–head, or even whole body movements (see also Suzuki and Cohen, 1964).

3.26.5.2 Vestibular Output and Postural Control

Some of the earliest motor control systems of vertebrates are the tectospinal and the vestibulospinal pathways. Tectospinal connections underlie visually based orienting and control mechanisms. Vestibulospinal pathways essentially provide tonic postural and balance control. This function can be impressively demonstrated following ablation of one entire labyrinth (hemilabyrinthectomy; see Schaefer and Meyer, 1974) or components thereof (de Waele *et al.*, 1989; Graf *et al.*, 1992). In essence, the horizontal semicircular canals provide the straight-ahead direction of the head, whereas the utricles assure the upright posture of the entire head–neck ensemble in the midsagittal plane, at least in birds and mammals. The sacculi seem to play a similar role regarding lateral tilt displacements of the head (Graf *et al.*, 1992). In this context, we have to mention that mammals in general possess a vertical cervical vertebral column, regardless of bipedal or quadrupedal locomotion (Vidal *et al.*, 1986; Graf *et al.*, 1995; Figure 2). The transition to bipedalism from quadrupedalism in mammals thus requires bringing the thoracic vertebral column into an upright position and modifications at the cervicothoracic junction and the lumbar level, but not within the cervical vertebral column or the atlanto-occipital articulation.

When considering the intrinsic geometry of the head–neck apparatus in the midsagittal plane, we observe that at resting position, mammals keep the articulations of the head–neck ensemble at the atlanto-occipital articulation and the upper cervical vertebral column in extreme flexion, and at the lower cervical and the upper thoracic vertebral column at extreme extension (Graf *et al.*, 1995; Figure 2b). At these endpoints, the head–neck ensemble takes on an intrinsic geometry that only has to be oriented into the correct direction by the vestibular system (Vidal *et al.*, 1993).

Since the cervical column is quite rigid, it also cannot be bent easily laterally. Lateral tilt of the entire head–neck ensemble in quadrupeds happens via rotation of vertebras at the cervicothoracic junction. Again, vestibular input provides the correct upright orientation (Graf *et al.*, 1992, 1995).

The intrinsic and semi-self-supporting architecture of the cervical column is a conserved feature in evolution, as some pertinent dinosaur findings have shown (dal Sasso and Signore, 1998). With regard to a general organization of postural mechanisms, vestibular circuits and their intrinsic three-dimensional coordinates are thought to provide a blueprint for a number of sensory and motor systems, and sensorimotor transformations (Cohen *et al.*, 1965; Schaefer *et al.*, 1975; Simpson *et al.*, 1981; Simpson and Graf, 1981, 1985; Graf, 1988; Graf *et al.*, 1988; Leonard *et al.*, 1988).

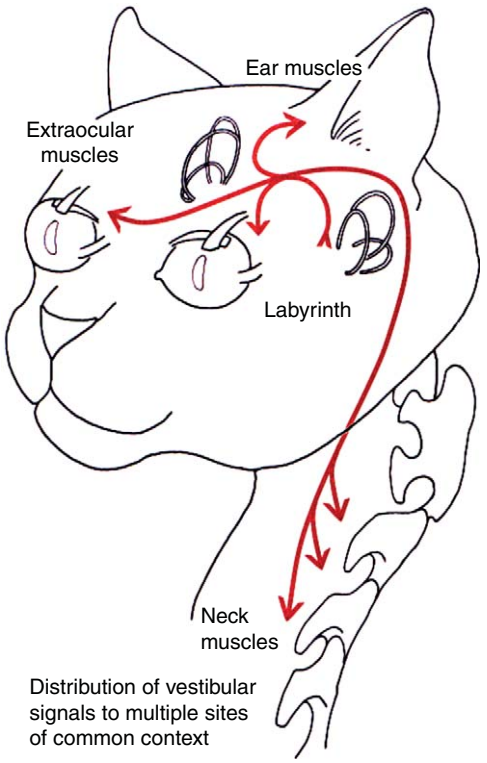

Figure 13 Schematic of vestibular neuron connectivity to motor centers of related architecture and common behavioral context. The shared neuronal pathway to eye, ear, and neck muscles would provide an economical distribution of an identical motor control signal to motoneuron pools involved in orienting behavior.

3.26.5.3 Vestibulocollic Connectivity

Within the vestibulocollic reflex connectivities, we find equally stereotypic innervation patterns as in the vestibulo-ocular circuitry (Wilson and Maeda, 1974; Shinoda *et al.*, 1994, 1996, 1997; Graf *et al.*, 1997). The only difference is that we are dealing with more muscles. Another indication for the similarity of reference frame systems for eye and head movements was indicated by the existence of vestibulo-ocular-spinal neurons (Graf and Ezure, 1986). These neurons would transmit their signals to oculomotor and spinal-motor centers at the same time (Figure 13). Thus, the same spatial information meaningful for the oculomotor system must carry a meaningful message for the spinal-motor system as well.

3.26.6 The New Wave of Vestibular Interest

The intriguing geometry and three-dimensionality of the vertebrate labyrinth has fascinated scientists since the beginning of modern science, i.e., Scarpa (1789), and numerous comparative studies have dealt with the expression of labyrinthine structures in basically almost all known vertebrates (Gray, 1907; Retzius, 1872, 1881, 1884; Werner, 1960; Lewis *et al.*, 1985). While all these studies used invasive methods to visualize ear structures, modern imaging methods have now opened a way to study them noninvasively in living tissue (Archer *et al.*, 1988; Spoor and Zonneveld, 1995); fossilized heads have also become accessible to large-scale investigations (Spoor *et al.*, 1994, 2002, 2003; Wittmer *et al.*, 2003; Clarke, 2005). These possibilities led to a number of interesting morphological discoveries that added to the vast data set already available.

In general, there were no surprises regarding the spatial orientation of the semicircular canals. These followed the familiar pattern (see Figure 1c), although some researchers seemed to be surprised by it (Spoor *et al.*, 1994). A number of authors also sought to make use of their new investigative tool to reinterpret the functional context of the vestibular system by putting it into the sole context of locomotion (Spoor *et al.*, 1994, 2002, 2003; Wittmer *et al.*, 2003). These authors argued that the dimensional morphology of the semicircular canals gave an indication about the locomotor capabilities of their owners. Thus, conclusions were drawn as to the point of effective bipedalism in certain hominids (Spoor *et al.*, 1994), or the agility of Neanderthal man (Spoor *et al.*, 2003). We have argued against such interpretations based on a number of known facts and characteristics of the vestibular system (Graf and Vidal, 1995). In essence, the former authors had based their arguments largely on the size differences in the circumference of semicircular canals within one species and across different species. However, canal fluid dynamics affecting sensitivity are also largely governed by the lumen of the canal, i.e., its cross section. Furthermore, to base locomotor activities solely on peripheral morphology means ignoring any well-known adaptive mechanisms at the receptor level, ion channel dynamics, and above all, the vast apparatus of the neuronal processing machinery that make use of vestibular signals from the brainstem and cerebellum to the cortex. Focusing on locomotion alone also ignores all the other important and vital functions subserved by the vestibular system, notably compensatory eye movements and perceptual mechanisms. Without compensatory eye movements, in particular, we would not be able to have unblurred vision during any movement. In addition, during active movements, a number of postural reflexes become suppressed, which is reflected in

elimination or attenuation of vestibular movement signals in the vestibular nuclei (McCrea *et al.*, 1999; Roy and Cullen, 2001). The arguments of Spoor *et al.* (2002) and Wittmer *et al.* (2003) have been forwarded to explain the behavior of cetaceans and pterosaurs, proposing a link between apparent extreme aquatic and aerial acrobatic capabilities of these animals, respectively. Although these findings received wide acclaim in the popularizing science literature (Stokstad, 2003; Unwin, 2003), the vestibular argument again did not take into consideration all aspects of vestibular function or the entirety of a biological system. Against the aerial capabilities of pterosaurs could be brought forward, for instance, the size and shape of their cerebellum, given that the cerebellum plays an eminent role in motor coordination. Pterosaur cerebella resemble closely that of certain bats (Baron *et al.*, 1996), and bats are not the very best flyers. As we have seen, postural control, locomotion, and eye movements are closely related to vestibular output, and there is a lot more to consider than meets the eye at first glance.

3.26.7 Conclusions

The evolution of the sense of balance of vertebrates and analogous systems in invertebrates suggests a number of important features of brain operations. We also observe conserved vestibulomotor organizations and circuitry in vertebrates after the development of one optimal solution, when arrangements have been preserved throughout subsequent vertebrate history. Compared to the many developments of eyes, for instance, the estimate is that eyes have been invented 40–65 times in evolution, only two basic types of three-dimensional movement detectors have been retained, the diagonal ones of vertebrates, octopus, and crabs, and the principal axes ones of squids. Each one of the two possibilities constitutes an ideal physical solution, with an optimal signal-to-noise ratio.

An additional important characteristic of central nervous operation seems to be that peripheral mechanisms are employed to simplify central operations. Such an operational principle has been ideally demonstrated in the common reference frames of the vestibulo-oculomotor system, including the central nervous connectivity. Thus, the workload of the brain is decreased in favor of animal economy and presumably higher-order operations (learning, perceptive functions, etc). When considering how the brain works, we have to look into similarities among apparent differences of expressions or behaviors. Disregarding obvious similarities of sensorimotor operations across species would mean disregarding one significant aspect of brain operation.

When viewing the particular example of the vestibulo-oculomotor systems across species, the conserved nature of the arrangement in its geometry, and to a large extent, its embryologic development is quite striking. Modern methods will hopefully enlighten us in the future, where traditional methods have failed and fossil records are absent. However, the early appearance of a viable and up-to-date conserved vertebrate vestibulo-oculomotor system, in tandem with systems of similar geometry in certain invertebrates may suggest that close to ideal physical solutions developed early in vertebrate history, onto which more advanced functions were added as a result of environmental pressure, or whatever circumstance, such as smooth pursuit or vergence eye movements. Finally, the initial function of the vestibulo-oculomotor system may well not have been to move the eyes, but to hold them still with respect to the environment in order to stabilize the visual world (Walls, 1962).

3.27 Neuropeptide Systems and Social Behavior: Noncoding Repeats as a Genetic Mechanism for Rapid Evolution of Social Behavior

E A D Hammock, Vanderbilt University, Nashville, TN, USA
L J Young, Emory University, Atlanta, GA, USA

Glossary

avpr1a	The gene encoding the vasopressin 1a receptor (V1aR).
compound microsatellite	A microsatellite locus that has more than one kind of repeat motif.
evolvability	The potential to mutate imparted by a flexible genome.
luciferase reporter assays	A genetic technique that allows visualization of the ability of a regulatory sequence to promote gene expression.
microsatellite	DNA comprised of repetitive sequences, usually with the smallest repeated unit in the 1–6 bp range; this kind of DNA is usually polymorphic and is often used in genetic fingerprinting; also known as SSR and VNTR.
monogamy	A social structure characterized by a suite of traits including high levels of selective affiliation, territorial aggression, separation distress, and biparental care; sexual monogamy is not implied in this definition.
nested deletions	A method of manipulating a sequence of DNA into a set of smaller and smaller fragments of the original sequence.
paralogous divergence	The evolutionary divergence of two genes within a species after a gene duplication event; oxytocin and vasopressin are paralogues.
psuedogene	A DNA sequence that has hallmarks of a protein coding region, but does not appear to produce a protein product.
slipped-strand mispairing	A DNA replication error where the two strands of DNA do not align properly.
SSR	Simple sequence repeat.
viral vector gene transfer	A genetic technique wherein artificial or foreign DNA sequences can be introduced into a population of cells and the foreign DNA will integrate into the genome of the host cell and stably express the protein encoded within it.
VNTR	Variable number of tandem repeats, a locus that is polymorphic for the number of repeats.

3.27.1 Social Behavior Evolves Rapidly

Diversity in social behavior is evident both between and within species. There are both species-typical behavioral tendencies as well as personality traits that distinguish among individuals within a

population. For example, humans are without question a highly social species, but there are clearly individuals who prefer to isolate themselves. This behavioral diversity within species could lead to the differences between species as extreme behavioral phenotypes diverge. The underlying genetics and molecular neurobiology producing individual and species differences in behavior are relatively unknown. The rich behavioral diversity of closely related species, domestic dog breeds, inbred strains of mice and rats, as well as the rapid domestication of foxes, indicates that behavior is a rapidly evolving phenotypic trait.

3.27.2 Genetic Mechanisms Generating Diversity

This idea of rapid evolution of social behavior presupposes (1) rich genetic polymorphism and/or (2) some genetic mechanism that can generate meaningful behavioral diversity *de novo*. From a gene-centric perspective, mechanisms of generating heritable behavioral diversity include gene variation that alters protein function, timing, and/or location of gene expression.

3.27.2.1 Single Nucleotide Polymorphisms

There are several well-established genetic mechanisms that could produce such changes. Single nucleotide polymorphisms (SNPs) can change a protein or its regulation depending on where the SNP occurs. For example, an SNP in the coding region of the neuropeptide Y receptor-like protein gene (*npr-1*) of the roundworm, *Caenorhabditis elegans*, results in an amino acid sequence change from a valine residue to a phenylalanine. This allelic variation in *npr-1* results in altered protein function and altered social feeding behavior (de Bono and Bargmann, 1998). In contrast, an SNP that occurs outside of a coding region might alter the level of expression by changing the quality of protein–DNA interactions of transcriptional regulators. Recently, individual variation in an SNP in the promoter of the vasopressin gene in rats has been implicated in individual differences in anxiety-like behavior that appear to be related to differences in levels of vasopressin gene expression in the paraventricular nucleus of the hypothalamus (Murgatroyd *et al.*, 2004; Wigger *et al.*, 2004).

3.27.2.2 Gene Duplication and Deletion

In addition to genetic changes in the sequence or regulation of genes, gene duplications as well as deletions must also play a role in the evolution of brain substrates for behavior. One infers from the complexity of the mammalian brain and genome that gene duplication with paralogous divergence creates new neural substrates, perhaps by adding layers of sensitive regulatory mechanisms as suggested in duplicated genes for circadian rhythmicity (reviewed in Looby and Loudon, 2005). Deletion of gene families also changes the capacity for behavior. In a recent example, demonstration of the pseudogenization of sweet taste receptors in feline lineages illustrates a mechanism whereby functional gene deletion can change an animal's perception of and behavior toward the outside world (Li *et al.*, 2005; see The Evolution of the Sweetness Receptor in Primates).

3.27.2.3 Microsatellites

In addition to SNPs and the duplication and deletion of genes, there is increasing interest in sequences in the genome that have higher rates of mutation as a consequence of their base pair content. Not all regions of the genome share equal probabilities of mutation. In particular, DNA comprised of repetitive sequences, such as microsatellites, has an estimated four orders of magnitude higher rate of mutation than the rate of SNP occurrence in nonrepetitive DNA (Radman *et al.*, 1995). The nature of mutation at repeat loci involves expansion or contraction of the number of repeats by slipped-strand mispairing during DNA replication. Therefore, a repeat locus not only has a higher rate of mutation than nonrepeat DNA, but it also has the possibility of generating more alleles than a single base pair mutation. Instead of being limited to one of four base pairs, the repeat DNA can expand and contract any number of times to any number of repeat units.

3.27.2.3.1 Microsatellites as trash or treasure Repeat DNA, or microsatellite DNA, can be found in both coding and noncoding regions of genes. Therefore, their expansion and contraction qualities can affect protein function as well as location, timing, or levels of expression. Repeat DNA has been appreciated in neuropathology since several neurological disorders appear to be a result of grossly expanded repeat number. Expanded repeats in coding regions as in Huntington's disease (The Huntington's Disease Collaborative Research Group, 1993) as well as in regulatory regions of genes like the repeat found in Fragile X (Yu *et al.*, 1991) have been determined to play a causal role in those disorders. Initially, these discoveries raised questions about the reason for the perpetuation of these repeats, or junk DNA, since they appeared to

carry such a potentially high cost, with no apparent benefits. In light of this puzzle, King (1994) proposed that perhaps this kind of DNA, when not grossly expanded, allowed for the generation of quantitative phenotypic traits. King and colleagues (Kashi *et al.*, 1997) have since suggested that, like a tuning knob, microsatellite expansion and contraction within some normal range may dial new heritable traits.

To date, there are several examples providing support for this very exciting hypothesis. There are both coding and noncoding repeat polymorphisms that appear to affect phenotypic changes within the normal range. For example, in the coding region of the period gene of the fruit fly *Drosophila*, there are differences in repeat number in threonine–glycine residues. The repeat number appears to influence the timing of the mating dance during courtship behavior of male flies (Yu *et al.*, 1987; Petersen *et al.*, 1988). Another more visually apparent example comes from Fondon and Garner's (2004) analysis of genetic correlates of dog snout morphology. In this analysis, coding region repeats in several developmental genes were very highly correlated with dog snout morphology (Fondon and Garner, 2004). This suggests a role for microsatellite expansion and contraction in the robust morphological variation of domestic dogs.

Microsatellite or repeat expansion and contraction in regulatory regions of genes have also been implicated in variation in behavioral traits as well as psychiatric disease risk in humans. For example, simple sequence repeats (SSRs) in the 5′ noncoding region of the serotonin transporter have been associated with risk for anxiety and depression (Lesch *et al.*, 1996; Pezawas *et al.*, 2005). The number of repeats in the 5′ noncoding region of the monoamine oxidase A gene has been associated with aggression (Manuck *et al.*, 2000), especially when paired with early adverse experience (Caspi *et al.*, 2002). In both examples, the numbers of repeats have been demonstrated to modify gene expression in *in vitro* cell culture assays (Lesch *et al.*, 1996; Sabol *et al.*, 1998).

3.27.3 Vole Species as a Model for the Evolution of Social Behavior

The following data derived from laboratory investigations of vole species provides support for the tuning knob hypothesis. In sum, the following data will implicate a microsatellite locus in the regulatory region of the gene encoding the vasopressin 1a receptor (*avpr1a*) in the evolvability of social behavior. By comparing this locus both between and within vole species, and even primates, the emerging picture is that this locus has an evolvability that allows its brain distribution pattern to be easily altered. This alteration in brain distribution changes the modulatory effects of the neuropeptide vasopressin, and therefore the behavioral response to external stimuli that cause the release of vasopressin within the brain. Furthermore, increasing evidence suggests that any genetic mechanism that alters the distribution patterns of neuromodulatory receptors may be an important general mechanism generating individual and species differences in complex behaviors.

3.27.3.1 Vole Social Behavior

Voles (*Microtus* spp.) comprise a large and diverse genus of rodent. Voles are quite behaviorally diverse and therefore comprise a tractable genus for questions regarding evolution of brain substrates underlying diverse behavior. Some species of voles, such as prairie (*M. ochrogaster*) and pine voles (*M. pinetorum*), are socially monogamous: males and females form long-term pair bonds, the males contribute to parental care, and the pair defends a shared nest site. In contrast, nonmonogamous montane and meadow voles (*M. montanus*, *M. pennsylvanicus*) do not pair bond, the males do not contribute to parental care, and none but the nursing mother and her offspring share a nest site (Thomas and Birney, 1979; Getz *et al.*, 1981; Jannett, 1982; Gruder-Adams and Getz, 1985; Shapiro and Dewsbury, 1990). Additionally, monogamous species show selective aggression toward strangers after becoming sexually experienced (Winslow *et al.*, 1993; Insel *et al.*, 1995) and the young of monogamous species show separation distress vocalizations and increased serum levels of the stress hormone, corticosterone (Shapiro and Insel, 1990).

3.27.3.2 Measuring Social Behavior in the Laboratory

Laboratory tests revealed that as in the wild, prairie and pine voles are socially monogamous and montane and meadow voles are not. The main laboratory assay used to investigate pair bonding is the partner preference test. In this test, a male and female are paired for a period of 6–24 h co-habitation with or without mating. After co-habitation, the animals are briefly separated as they are prepared for the 3 h behavioral assay. A three-chambered apparatus is used for this assay. The partner animal is tethered in one chamber, and a stranger

animal is tethered in another chamber. These two chambers are connected to each other with short Plexiglas tubes and a third neutral chamber that does not contain an animal. The dependent measure of this test is the amount of time the animal spends in side-by-side contact with the partner animal compared to the stranger, as well as the time spent alone in the neutral cage. Both the male and female of the pair can be tested in this apparatus. In this assay, prairie voles spend very little time in the neutral chamber and spend more time in side-by-side contact with their partner. In contrast, montane and meadow voles spend equal amounts of time with the partner and stranger but mostly spend their time in the neutral cage. The amount of time spent in side-by-side contact with the partner animal can be predictably altered in prairie voles by prolonging or truncating the duration of co-habitation and allowing or preventing mating during the co-habitation period. Mating and longer periods of co-habitation increase the amount of time that animals spend in side-by-side contact with their partner, indicating that these are important variables in the formation of a pair bond (Insel *et al.*, 1995; Williams *et al.*, 1992b).

3.27.4 Social Bonding and Oxytocin

This laboratory assay of social bonding has allowed for determination of molecular players involved in the formation of pair bonds. In female prairie voles, the neuropeptide oxytocin contributes to the formation of partner preferences (Williams *et al.*, 1992a, 1994). Oxytocin was originally identified as one of two neurohormones secreted by the posterior pituitary, or neurohypophysis, and was first appreciated as a critical player in parturition and lactation. Due to its flooding presence from the posterior pituitary during these early stages of the onset of maternal behavior, it was further hypothesized and confirmed to play a role in the transition to maternal behavioral states and in the formation of the mother–infant bond (Kendrick *et al.*, 1987; Pedersen and Prange, 1979). This action of oxytocin is a result of oxytocin released into the brain rather than by oxytocin released into blood circulation by the posterior pituitary. By extension, it was hypothesized that this neuropeptide acting in the brain might also play a role in the development of adult social bonds such as that found in monogamous social structures. Indeed, injections of oxytocin into the cerebral ventricles of the prairie vole brain prior to the co-habitation period facilitate the formation of partner preferences (Williams *et al.*, 1994). Additionally, delivery of oxytocin receptor antagonists to the brain blocks the formation of partner preferences (Williams *et al.*, 1994; Cho *et al.*, 1999). It appears that oxytocin and its receptor are necessary for the formation of social preferences in females, a prerequisite for the social bonds of monogamous species.

3.27.5 Social Bonding and Vasopressin

Vasopressin is the complementary neurohormone of the posterior pituitary and appears to contribute to partner preference formation in male prairie voles (Winslow *et al.*, 1993). This neurohormone was pursued as a candidate for partner preference formation because of its previously established role in male species-typical social behavior, such as aggression in hamsters (Ferris *et al.*, 1997). Studies in prairie voles indicated that vasopressin injected into the ventricles promotes partner preference formation (Winslow *et al.*, 1993). Furthermore, central infusion of vasopressin 1a receptor (V1aR) antagonists inhibit the formation of partner preferences (Cho *et al.*, 1999; Winslow *et al.*, 1993). Therefore, as with oxytocin, vasopressin and the V1aR appear to be necessary for the formation of social preferences.

All species studied to date have oxytocin and its receptor, as well as vasopressin and the V1aR. Selection pressures are very strong to keep these neuropeptides and their signaling mechanisms intact. Loss of oxytocin results in the inability for the female to lactate (Nishimori *et al.*, 1996). Loss of vasopressin results in diabetes insipidus (Bohus *et al.*, 1975). Only very artificial situations allow for survival or reproduction when these players are disrupted. If these players are so highly conserved and laboratory experiments in prairie voles indicate their role in partner preference formation, why are monogamous social structures rare among mammals?

3.27.5.1 Evolutionary Lability of Receptor Distribution Patterns

Behavioral pharmacology evidence from closely related bird species indicates that not all species respond in the same way to treatment with the same neuropeptide. Vasotocin, the avian orthologue of vasopressin, administered to the septum of zebra finches results in increased aggression (Goodson and Adkins-Regan, 1999), whereas the same treatment in closely related field sparrows or violet-eared waxbills inhibited aggression (Goodson, 1998a, 1998b). Similarly, in vole species, oxytocin and/or vasopressin injection into the brain increases

affiliative behavior in monogamous prairie voles, but not in nonmonogamous montane or meadow voles (Young *et al.*, 1999). The effect of any pharmacological agent depends, of course, on the presence of the pharmacological target, in this case the receptors for oxytocin and vasopressin. It turns out that while the brain distribution of the neuropeptides oxytocin and vasopressin are very highly conserved across species (Wang *et al.*, 1996), the location of their receptors is not conserved (Figure 1) (Young, 1999). This alteration in the location of receptors in the brain across species underlies some of the behavioral differences. The altered location of receptors must change behavior because it alters the neural circuits that can be modulated by oxytocin or vasopressin signaling. For example, in monogamous prairie voles, V1aR binding is very dense in the ventral forebrain, in particular the ventral pallidum, a brain region recognized for its role in reward and motivation (Lim *et al.*, 2004a; see Forebrain Size and Social Intelligence in Birds). Interestingly, montane and meadow voles have very low densities of receptors in this region (Insel *et al.*, 1994). This particularly dense receptor binding in monogamous prairie voles appears to be a key factor in the capacity for monogamous social structure in these species. Specifically, site-specific injections of a V1aR antagonist into the ventral pallidum blocks partner preference formation (Lim and Young, 2004). Additionally, experimentally increasing the levels of V1aR in the ventral pallidum using viral vector gene transfer increased partner preference in prairie voles (Pitkow *et al.*, 2001). In the definitive experiment, the nonmonogamous meadow vole was induced to form pair bonds by viral vector gene transfer of V1aR to the ventral pallidum (Lim *et al.*, 2004b). These series of experiments clearly demonstrate the importance of species-specific patterns of V1aR in the evolution of social behavior.

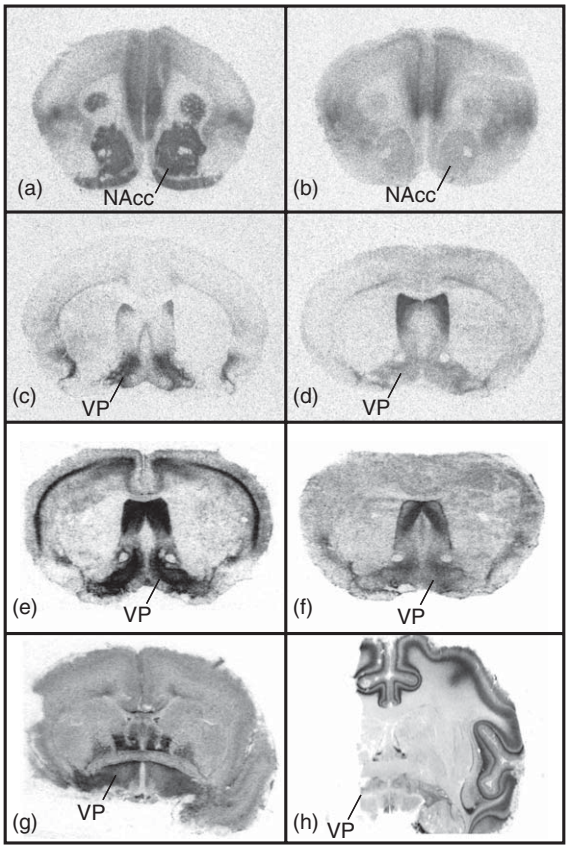

Figure 1 Neuropeptide receptor distribution patterns are associated with social structure. Monogamous prairie voles (a) and nonmonogamous montane voles (b) show dramatic differences in brain distribution of oxytocin receptor (Insel and Shapiro, 1992). V1aR distribution patterns are also associated with social structure. Monogamous prairie voles (c), California mice (e), and marmosets (g) all show high levels of V1aR in the ventral pallidum. In contrast, nonmonogamous montane voles (d), leucopus mice (f), and rhesus macaques (h) all have very little apparent V1aR in this brain region.

3.27.5.2 Genetic Mechanism of Diversity in V1aR Distribution Patterns

3.27.5.2.1 Comparative evidence for microsatellites as a genetic mechanism As one would expect, the pharmacokinetics of receptor–ligand interaction are identical among the vole species tested thus far (Insel *et al.*, 1994). Therefore, species differences in receptor patterns are not likely due to differences in the quality of ligand–receptor interaction. Additionally, analysis of mRNA distribution of the V1aR also reveals similar species differences in distribution (Young *et al.*, 1997). Theses results point to differences in gene regulation mechanisms. In support of this idea, a mouse transgenic for the prairie vole V1aR gene (*avpr1a*), including the coding region and flanking noncoding regulatory domains, displayed an altered receptor distribution pattern and an altered behavioral response to the central administration of vasopressin (Young *et al.*, 1999). Comparison of the *avpr1a* gene sequences from monogamous and nonmonogamous vole species revealed high homology across species in the coding regions. The noncoding elements were also very highly homologous, with the exception of an expansion of a compound microsatellite in the 5′ noncoding region in the monogamous prairie vole compared to the nonmonogamous montane vole (Figure 2). In the prairie vole, this expanded element consists of several dimer and tetramer repeat blocks interspersed with nonrepetitive sequences (Young *et al.*, 1999). Additionally, there appears to have

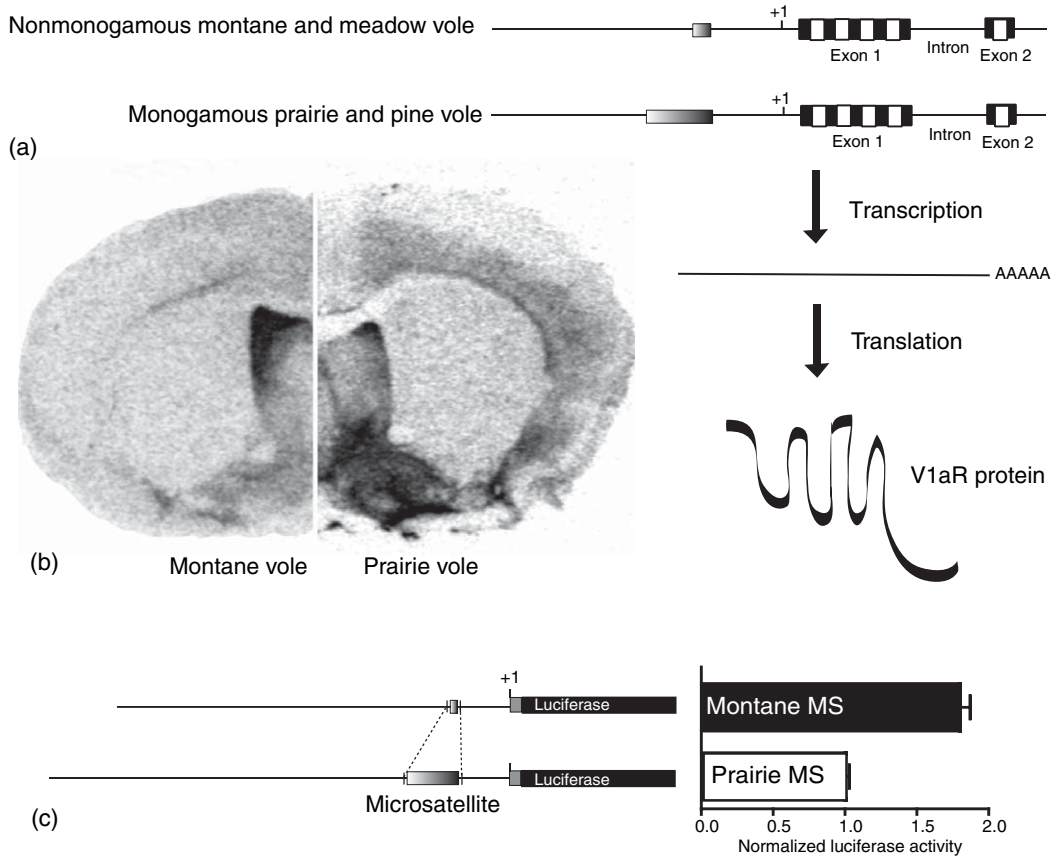

Figure 2 Species differences in receptor distribution pattern are associated with functional species differences in the length of a microsatellite in the 5′ regulatory region of the gene encoding V1aR (*avpr1a*). The microsatellite, indicated by shaded boxes, is highly expanded in *avpr1a* in prairie and pine voles compared to montane and meadow voles (a). This divergence in sequence length could lead to differences in cell-type-dependent gene transcription, which could explain the differences in protein distribution measured by autoradiography (b). The species differences in microsatellite length do modify gene expression. In cultured rat A7r5 cells, the montane microsatellite drives reporter gene expression more than the prairie microsatellite (c). Reproduced from Hammock, E. A. D. and Young, L. J. 2004. Functional microsatellite polymorphism associated with divergent social structure in vole species. *Mol. Biol. Evol.* 21, 1057–1063, by permission of Oxford University Press.

been a gene duplication event in the prairie vole species that if expressed would result in a truncated form of the receptor. The potential function of a truncated V1aR has not been addressed. Monogamous pine voles have the compound microsatellite similar in length to the prairie vole, whereas the nonmonogamous meadow vole has a short element similar to the montane vole. Because there were very few differences between species elsewhere in the *avpr1a* gene and because the differences appeared to be at the level of gene regulation, we investigated the role of 5′ noncoding elements, including the microsatellite, in the regulation of gene expression.

3.27.5.2.2 *In vitro* evidence for microsatellites as a genetic mechanism In a series of *in vitro* experiments, we determined that the species differences in microsatellite length were sufficient to change gene expression (Hammock and Young, 2004). First, we created a series of nested deletions of 3.5 kb of the prairie vole *avpr1a* 5′ region, which included the microsatellite locus. Using luciferase reporter assays in several rat cell lines, we observed that the effects of deleting sequences in the microsatellite altered reporter gene expression in a cell-type-dependent manner. In other words, deletions of microsatellite sequence altered the reporter gene activity in some but not all cell lines. We further probed the function of the microsatellite locus by deleting only the microsatellite locus out of the surrounding 3.5 kb of prairie vole *avpr1a* 5′ region. We tested this construct (no cassette) against the full-length prairie vole *avpr1a* in several rat cell lines and also observed a cell-type-dependent effect on reporter gene activity, in a manner similar to the results from the nested deletion series of experiments. Finally, to establish that species differences in microsatellite length at this locus could alter gene expression, we inserted either the prairie vole microsatellite or the montane vole microsatellite into the microsatellite position in

the no-cassette vector. The prairie and montane microsatellites were tested against each other in one of the rat cell lines that had previously demonstrated an effect of alterations at this locus. In this particular rat cell line, species differences in the microsatellite resulted in robust differences in reporter gene expression. Specifically, the montane vole microsatellite resulted in higher reporter activity than the prairie vole microsatellite. Because the previous reporter experiments demonstrated a cell-type-specific effect of changes at the microsatellite locus, it is possible that there would be no species differences in some other cell lines and there is likely to be a cell line wherein the prairie vole microsatellite drives gene expression to a greater extent. Regardless, these cell culture data have confirmed that the species differences in this locus can alter gene expression levels. Furthermore, the cell-type-specific effect of changes at the microsatellite locus indicate that the microsatellite would alter the expression of *avpr1a* in some but not all cells, and could therefore alter the pattern of expression rather than overall levels of expression.

Taken together, these data indicate that expansion or contraction mutation in a microsatellite locus in the regulatory region of the vole *avpr1a* gene likely resulted in altered distribution patterns of V1aR in the brains of voles. This altered distribution pattern modifies the behavioral response to external stimuli that cause the central release of vasopressin into the brain, such as mating or stress. Therefore, the instability of this microsatellite locus likely contributed to the evolution of divergent social behavior strategies.

3.27.5.2.3 *In vivo* evidence for microsatellites as a genetic mechanism If this hypothesis is correct, that microsatellite instability at this locus causes behavioral diversity across species, then a relationship should still exist between microsatellite length and behavior within a species. Like most repeat loci, there is ample intraspecific variation in this locus in the prairie vole species (Hammock and Young, 2002). The range of variation within the prairie vole species is much narrower than between prairie and montane voles. Likewise, there is intraspecific variation in V1aR distribution patterns (Phelps and Young, 2003) as well as behavior in wild-caught and captive populations of prairie voles. First, we established that like the species differences in microsatellite length, intraspecific variation in microsatellite length could modify gene expression in cell culture (Hammock and Young, 2005; Figure 3a). To investigate potential relationships between the microsatellite, V1aR distribution patterns and behavior, we first screened 20 males selected at random from our laboratory colony. Using a high throughput screening method, we determined that there were more significant relationships among the variables than could be due to chance alone (Hammock *et al.*, 2005), suggesting that there is likely a causal relationship between microsatellite length, V1aR distribution patterns, and behavior. To clearly address these relationships, we then set up a genetic selection breeding strategy (Hammock and Young, 2005). We genotyped our laboratory colony of prairie voles and created breeding pairs that were homozygous for either longer or shorter than the average length. Three litter cohorts were obtained from the 25 breeder pairs and two out of three cohorts were randomly cross-fostered on the day of birth to reduce potential nongenomic transmission of brain and behavioral traits. We measured the parental care of the breeding pairs and the social and anxiety-like behavior as well as the V1aR distribution patterns of the F1 male offspring. This analysis revealed that microsatellite length likely gives rise to altered V1aR binding patterns (Figure 3). Males with longer microsatellites displayed higher levels of V1aR in the olfactory bulb and lateral septum and lower levels in the hypothalamus, basolateral amygdala, and posterior cingulate cortex, for example. Additionally, breeder males with longer microsatellite alleles showed higher rates of pup licking and grooming, an important aspect of rodent parental care. F1 male offspring with longer microsatellites were quicker to approach a novel social odor and a novel juvenile animal and were also more likely to form pair bonds under unfavorable conditions (truncated co-habitation period). There was less of an effect on anxiety-like behavior, suggesting that the observed genotype differences in social behavior were not due to underlying differences in trait anxiety. This breeding strategy demonstrated a role for the microsatellite in generating diverse brain substrates that are associated with diverse behavioral traits. Furthermore, the identification of such relationships within the prairie vole species provides further support for the idea that instability in the microsatellite locus can produce sufficient change in brain and behavior upon which natural selection may act.

3.27.6 Comparative Evidence in Primates for Microsatellites as a General Mechanism

Microsatellite instability may have played a role in the evolution of human social behavior as well (Figure 4) (Hammock and Young, 2005). The human *avpr1a* locus has three polymorphic microsatellites in the 5′ flanking region (Thibonnier *et al.*,

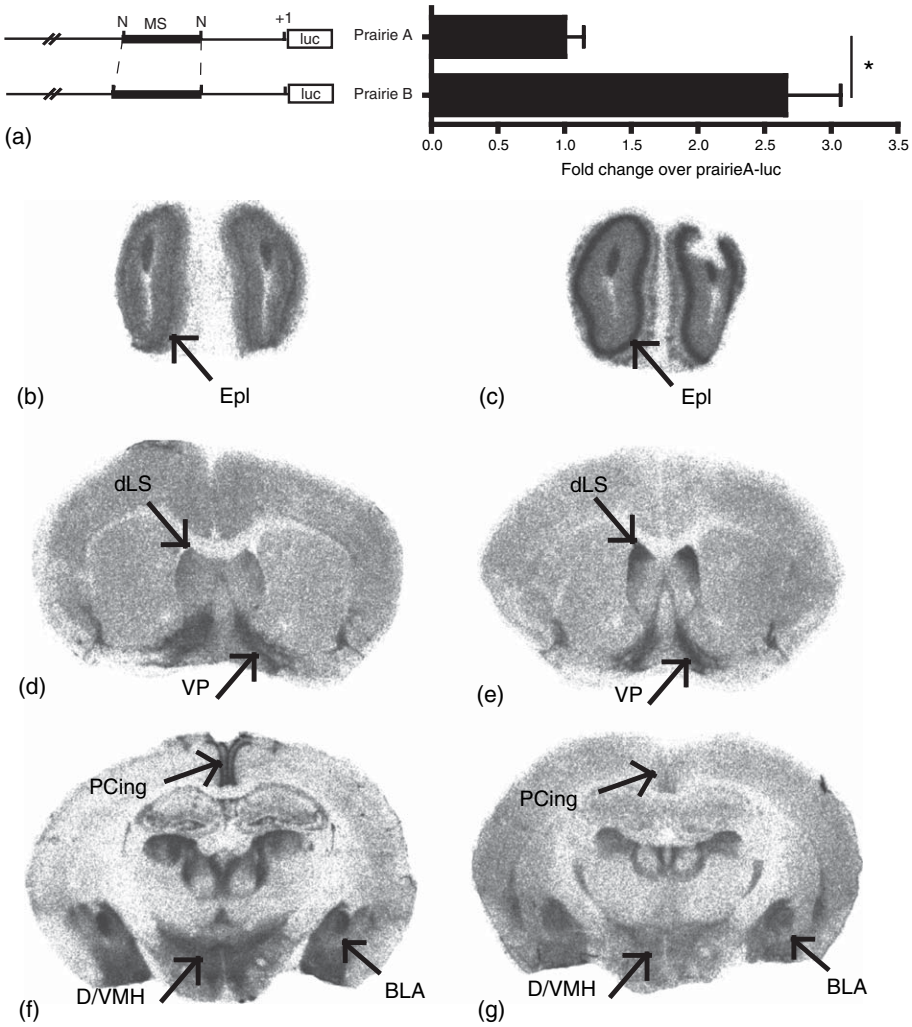

Figure 3 Intraspecific variation in V1aR distribution appears to be regulated in part by individual variation in the length of a compound microsatellite in the 5′ regulatory region of the prairie vole *avpr1a* gene. The gene encoding V1aR (*avpr1a*) contains a compound microsatellite in the 5′ noncoding region. The length of this microsatellite varies among individual prairie voles (a). Two representative microsatellites were tested against each other for their ability to regulate gene expression in luciferase reporter assays in rat A7r5 cells (a). In this cell line, the longer microsatellite allele drives luciferase expression to a greater extent than the shorter allele. Selectively breeding prairie voles for the microsatellite length reveals a genotype effect on the distribution of V1aR in the brain. In short-alleled males (b, d, f), compared to long-alleled males (c, e, g), there was reduced V1aR density in the external plexiform layer (Epl) of the olfactory bulb and dorsal lateral septum (dLS). In contrast, the short-alleled males had higher V1aR density in the posterior cingulate cortex (PCing), dorsal and ventral hypothalamus (D/VMH), as well as the basolateral amygdala (BLA). There was no apparent genotype effect in the ventral pallidum (VP). Reprinted with permission from Hammock, E. A. D. and Young, L. J. 2005. Microsatellite instability generates diversity in brain and sociobehavioral traits. *Science* 308, 1630–1634. Copyright 2005 AAAS.

2000). One of these, a compound microsatellite comprised of CT and GT dinucleotide repeats, located 3625 bp upstream of the transcription start site, has been reported in two independent studies to be associated with autism, suggesting that variations in this sequence may indeed result in variations in human social behavior (Kim *et al.*, 2002; Wassink *et al.*, 2004). Sixteen alleles of the microsatellite at –3625 kb have been found in the human population (Kim *et al.*, 2002). More recent studies have reported associations between alleles at this locus and normal social behavior, specifically levels of sibling conflict (Bachner-Melman *et al.*, 2005b). One recent study has even reported an association between *avpr1a* microsatellite polymorphisms, in combination with a serotonin transporter promoter polymorphism, and creative dance in humans, arguably a form of social communication (Bachner-Melman *et al.*, 2005a). Interestingly, the –3625 bp microsatellite is absent in the common chimpanzee *avpr1a* gene, a finding that parallels the species differences in the vole gene. In contrast, bonobos, known for high levels of social reciprocity, empathy, and sociosexual bonding (De Waal, 1988), have a microsatellite nearly

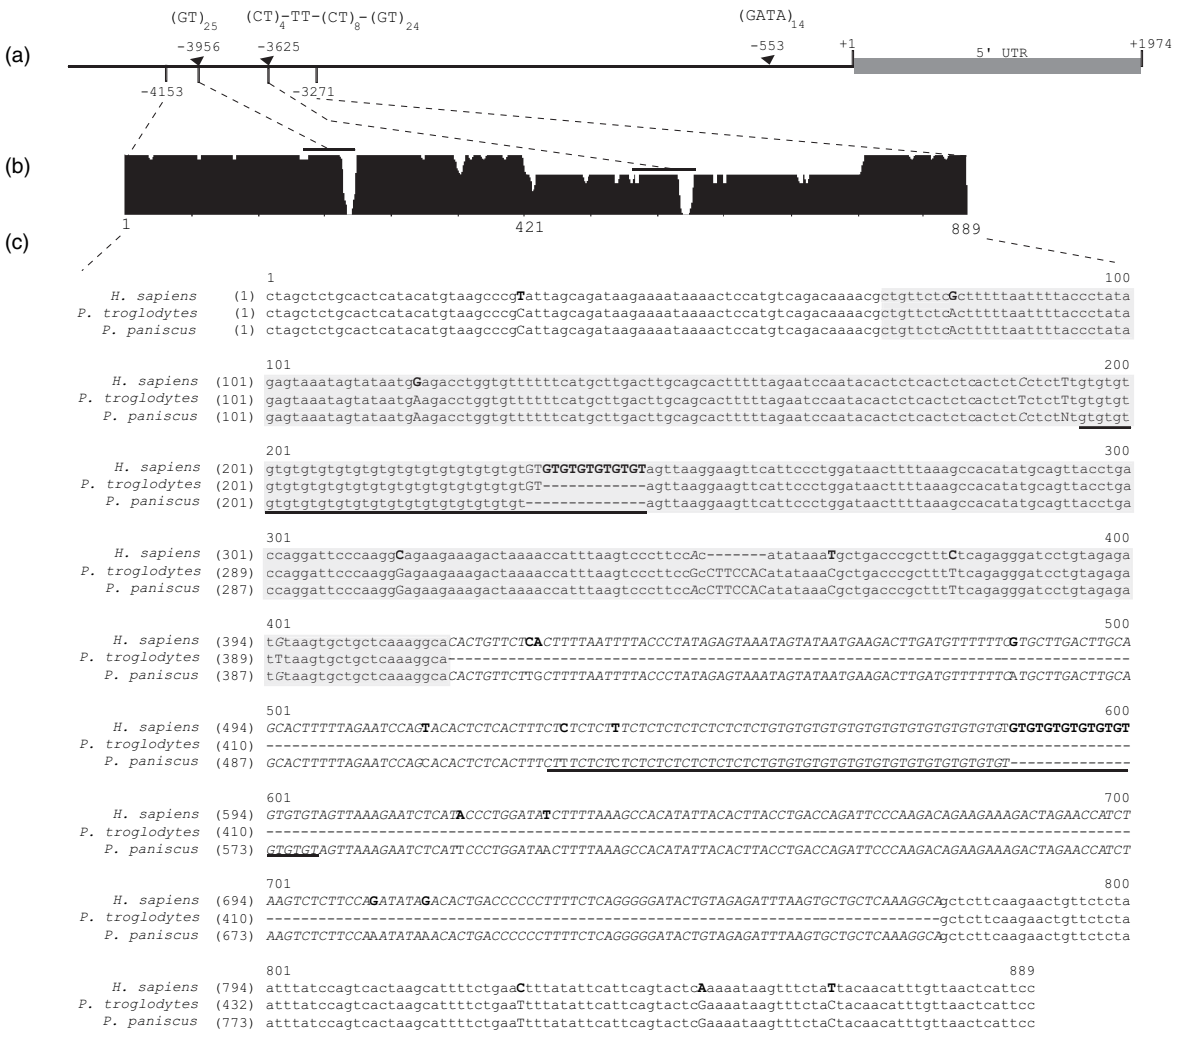

Figure 4 Humans (*H. sapiens*) and bonobos (*P. paniscus*) share a compound microsatellite element in the 5′ regulatory region of *avpr1a,* which is absent in the chimpanzee (*P. troglodytes*). The schematic (a) illustrates the position of 5′ microsatellite elements in relation to the annotated transcription start site (+1) of the human *avpr1a* gene (start codon at +1974). Human, chimpanzee, and bonobo similarity plot (b) at this region reveals high levels of homology around the –3956 bp microsatellite, whereas the microsatellite at –3625 bp is not as conserved. The reduction in similarity around the –3625 bp microsatellite is due to the complete absence of approximately 360 bp in chimpanzees (c). Underscores indicate the positions of the two repeat regions. Lower case letters indicate a sequence that is conserved across all three species. Upper case sequence represents conservation in two out of three species, while italicized upper case sequence represents sequence that is shared between human and bonobo, but not chimpanzee. Bolded upper case letters highlight sequence that is unique to humans. The sequence that is shared between bonobo and humans, but not chimpanzees, appears to be a duplication of the preceding sequence, indicated by the shaded grey box. identical to that of the human (Hammock and Young, 2005). Studies are currently underway to survey *avpr1a* microsatellite structure in a diverse group of apes and monkeys with varying social structure.

3.27.7 Caveat Regarding the Importance of Development

The simple V1aR model only highlights the differences in receptor expression and its behavioral effects in the adult animal, thereby completely ignoring the role of development and developmental plasticity in the life of the organism. It is highly probable that changes in gene expression patterns very early in development would affect the developmental trajectory of brain substrates for behavior by changing the fine-tuning effects of experience. For example, the presence of V1aR in the ventral pallidum of neonatal and juvenile prairie voles likely modifies their behavior during those important developmental windows and contributes to the creation of a social

environment that would drive further development and maturation of the social brain.

3.27.8 Conclusions

The evolutionary lability of expression patterns of neuromodulatory receptors such as V1aR and the oxytocin receptor may be a general mechanism producing diverse neural substrates. The presence of V1aR and oxytocin receptor in reward areas in the prairie vole gives vasopressin and oxytocin release a much different meaning than if these receptors were present in aggression-related areas. Furthermore, microsatellite instability in the regulatory region of *avpr1a* appears to contribute to the intra- and interspecies differences in V1aR distribution patterns. The high rates of expansion and contraction mutation in microsatellites might give genomes a useful tool for rapid generation of diverse phenotypic traits for "rapid exploration of the fitness landscape" (Radman *et al.*, 1999).

3.28 The Evolution of Motor Cortex and Motor Systems

R J Nudo and S B Frost, University of Kansas Medical Center, Kansas City, KS, USA

Glossary

autoradiograph (or autoradiogram) An image produced on photographic emulsion or film by the radiation emitted from a radioactive isotope that has been absorbed by tissue; e.g., radiolabeled amino acids can be used to visualize neuronal tracts via axoplasmic transport.

Betz cells The largest layer V pyramidal neurons. They are believed to comprise a large proportion of corticomotoneuronal cells.

cladogram A branching, treelike diagram in which the endpoints of the branches represent specific species of organisms. It is used to illustrate phylogenetic relationships and show points at which various species have diverged from common ancestral forms.

corticomotoneuronal Referring to corticospinal neurons that form monosynaptic contact with spinal cord motoneurons.

corticospinal tract Collective term for neurons with somata located in cerebral cortex that send axons to the spinal cord via the cerebral peduncles and medullary pyramids.

cytoarchitecture The cellular composition of a bodily structure; e.g., used to define a structurally distinctive cortical area.

eutherian Belonging to the infraclass Eutheria, a division of mammals to which all placental mammals belong.

funiculus One of the major white matter tracts in the spinal cord consisting of large bundles of ascending and descending fibers.

intracortical microstimulation A technique for stimulating a small neuronal cell population

	by introduction of a microelectrode and delivery of current pulses; used to stimulate corticospinal neurons to define functional motor representations in cerebral cortex.
lissencephalic	Characterized by a smooth cerebral cortex.
microelectrode	A very small insulated wire or fluid-filled micropipette used to study functional characteristics of living cells and tissues; commonly used for recording action potentials from one or more neurons, or for stimulating a small group of neurons.
prototherian	Neurologically primitive, egg-laying mammals found only in Australia, Tasmania, and New Guinea; the monotremes.
striatum	The phylogenetically more recent part of the corpus striatum (neostriatum) consisting of the caudate nucleus and the putamen.
supraspinal	Origin located above the spinal cord.
tetrapod	A vertebrate animal with four feet, legs, or leglike appendages.

3.28.1 Introduction

The varied and complex motor behaviors exhibited by vertebrates are the result of extraordinary alterations and enhancements over hundreds of millions of years of nervous system evolution. While this brief article cannot convey a complete picture of all of the selective pressures that likely gave rise to the differentiation of specialized motor structures, we will try to highlight some of the salient features that have marked the evolution of vertebrate motor systems and the uniquely mammalian motor cortex (see Evolution of the Somatosensory System – Clues from Specialized Species).

3.28.2 The Phylogenetic History of Descending Control of Spinal Cord Motoneurons

3.28.2.1 The Basic Vertebrate Plan

Based upon a large number of tract-tracing studies conducted over the past few decades, it is possible to survey extant mammals and surmise the probable evolution of descending control of spinal cord motoneurons in vertebrate species. This allows us to determine what features might be unique in specific lineages (e.g., the anthropoid lineage leading to humans), or specific ecological niches, and to appreciate the parallel contribution of common selective pressures regardless of lineage. To put the mammalian motor system in perspective, and to derive general principles for the evolution of motor systems, it is first necessary to review briefly descending control of spinal cord motoneurons prior to the divergence of mammals. With the addition of new evidence, this review represents an update of an earlier survey (Nudo and Masterton, 1988).

Even in the most primitive vertebrate forms still extant, neurons in the spinal cord are influenced by axons originating at supraspinal levels. Some of these descending pathways emerged in the most primitive vertebrate forms. The application of retrograde transport techniques has demonstrated supraspinal origins of spinal fibers in a wide variety of vertebrates (ten Donkelaar, 1976; Kokoros and Northcutt, 1977; ten Donkelaar *et al.*, 1980; Smeets and Timerick, 1981; Wolters *et al.*, 1982; Forehand and Farel, 1982; Kimmel *et al.*, 1982; Kunzle and Woodson, 1983; Oka *et al.*, 1986; Prasada Rao *et al.*, 1987; Ronan, 1989; Lee and Eaton, 1991; Cruce, *et al.*, 1999; Zhang *et al.*, 2002). Table 1 summarizes these results in various vertebrate classes for some of the major descending pathways that are found in mammals. Although these data do not provide a perfectly complete picture of all descending spinal afferents, and the species that have been studied cannot be considered to be either perfect representatives or random samples of their entire class, the many cases already available display several clear similarities that shed light on the very early, premammalian history of those descending pathways now found in mammals.

As shown in Table 1, at least three major supraspinal cell groups have projections to the spinal cord in every species of vertebrate studied to date: the reticular formation (a collective term for a diverse set of neurons that reside in the midbrain and hindbrain (Lee and Eaton, 1991) (reticulospinal tract), the vestibular nuclei (vestibulospinal tract), and the interstitial nucleus of the medial longitudinal fasciculus (interstitiospinal tract). Further, in all vertebrates yet studied, the spinal projections of each of these three cell groups travel down the cord in the ventral funiculus and each terminates in the ventromedial spinal gray (ten Donkelaar, 1976). Based upon their similar origins, trajectories, and terminations, it is probably safe to conclude that each of these three pathways is a true homologue of its respective counterpart throughout the vertebrate subphylum. If so, they can be considered to constitute a vertebrate common plan of descending spinal pathways.

In addition to these three pathways, tract-tracing studies in the most neurologically primitive

Table 1 Supraspinal cell groups with descending projections to the spinal cord in various vertebrate classes

	Agnatha	*Chondrichthyes*	*Osteichthyes*	*Amphibia*	*Reptilia*	*Mammalia*	*Aves*
Reticular formation	+	+	+	+	+	+	+
Vestibular nuclei	+	+	+	+	+	+	+
Interstitial nucleus	+	+	+	+	+	+	+
N. descending trigeminal tract	?	+	+	+	+	+	+
Raphe complex	?	+	+	+	+	+	+
N. solitary tract	?	+	+	+	+	+	+
Hypothalamus	+	+	+	+	+	+	+
Red nucleus	−	±	±	±	±	+	+
Cerebellar nuclei	−	−	−	+	+	+	+
Telencephalon	−	−	−	+	?	+	−

+, Pathway has been positively identified in all species examined in the class; −, pathway has been sought, but has not been found in any species examined in the class; ±, pathway has been identified in some, but not all species examined in the class; ?, differentiation of these structures is still unsettled in class Agnatha.

vertebrates (lampreys and hagfish; class Agnatha) have revealed spinal cord projections from brainstem neurons that may be homologous to those identified in gnathostomes, or jawed vertebrates. Despite their seemingly simple neurological organization, agnathans may possess spinal pathways originating in the nucleus of the descending trigeminal tract, the Raphe complex (many investigators include the cells identified here as the Raphe complex to be part of the reticular formation), the nucleus of the solitary tract, and the hypothalamus (Ronan, 1989). Thus, many of the cell groups that form spinal pathways in mammals were probably already in place early in vertebrate evolution. While these various cell groups became more specialized in different vertebrate classes, once established, this basic vertebrate plan was maintained throughout hundreds of millions of years of evolution, and still exists in all known living vertebrates.

3.28.2.2 Augmentation in Jawed Vertebrates (Gnathostomes): The Curious Case of the Rubrospinal Tract

Table 1 shows that in all vertebrate classes except Agnatha, descending spinal fibers have been identified that originate from the red nucleus and project to the contralateral spinal cord (rubrospinal tract). Although descending fibers originate from cells in the mesencephalic tegmentum in lampreys, the red nucleus is not differentiated (Ronan, 1989). It appears that all mammals and birds studied to date possess rubrospinal neurons. In contrast, in cartilaginous fish, bony fish, amphibians, and reptiles, rubrospinal neurons are present in some species and absent in others (see Somatosensory Adaptations of Flying Mammals, Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?).

Variability in the presence of the rubrospinal tract in vertebrate species has generated considerable discussion regarding its functional significance. At least in mammals, the rubrospinal tract is thought to play a major role in the control of limb movements (Massion, 1988). In this regard, it is interesting that the rubrospinal tract is absent in boid snakes, caecilians (wormlike amphibians), and sharks, but present in limbed amphibians, limbed reptiles, and in rays (ten Donkelaar, 1988). Curiously, a crossed rubrospinal tract has also been described in lungfishes (Ronan and Northcutt, 1985) and goldfish (Prasada Rao *et al.*, 1987). This raises the possibility that the rubrospinal tract functions to control fins in aquatic vertebrates as well as limbs in terrestrial vertebrates.

If the rubrospinal tract emerged early in the gnathostome radiation, then it apparently became vestigial in many limbless amphibians and reptiles. If so, the disappearance of the rubrospinal tract would represent a rare exception to the rule that, once established, descending spinal pathways are maintained throughout subsequent evolution.

3.28.2.3 The Tetrapod Augmentation

Table 1 shows that the cerebellum (i.e., the deep cerebellar nuclei) projects to the spinal cord in amphibians, reptiles, mammals, and birds. Again, since this cerebellospinal tract has a similar origin, trajectory, and termination pattern, this tract is probably homologous across the tetrapod classes. If so, the basic vertebrate plan appears to have undergone a second augmentation with the appearance of tetrapodal vertebrates, the true amphibians. Because the cerebellum provides a major input to the red nucleus via the crossed cerebellorubral pathway, it is likely that much of the evolution of the cerebellum and the emergence of cerebellospinal fibers occurred in concert with

the emergence of a differentiated red nucleus and rubrospinal tract.

3.28.2.4 The Mammalian Augmentation

Table 1 shows that telencephalic cell groups project to the spinal cord in amphibians, mammals, and possibly reptiles (Bruce *et al.*, 1980; ten Donkelaar *et al.*, 1981; Nudo and Masterton, 1988). However, the telencephalospinal neurons identified in amphibians and reptiles are located in the basal telencephalon, possibly homologues of amygdalospinal neurons of mammals (Nudo and Masterton, 1988). No spinal cord projections have been found in pallial (cortical gray matter) structures in any vertebrate species except for mammals. Therefore, in the lineage leading to mammals, it appears that the vertebrate common plan again was augmented with the addition of fibers originating in neocortex. Of course, this unique and possibly sole major addition to the mammalian lineage, a true corticospinal tract (CST), became more massive than any other descending pathway in some mammals.

In parallel with the enlargement of the CST, it has been suggested that the rubrospinal tract became reduced in size in the anthropoid lineage (Nathan and Smith, 1955, 1982). This would seem to contradict the consistent finding of rubrospinal neurons except in certain limbless jawed vertebrates. Though it has been rather widely accepted that the rubrospinal tract assumed a more modest role in the human lineage, comparative analysis suggests otherwise. When subjected to strict statistical tests for a variety of old and new hypotheses regarding the evolution of the rubrospinal tract and its adaptation to particular ecological niches, the number of rubrospinal neurons appears to be related to both body size and brain size of the host, with the relationship with brain size the dominant feature. Furthermore, the size of the tract was probably increased radically over the evolution of the carnivores (lineage leading to raccoons and cats) but not over the evolution of primates or rodents (lineage leading to tree squirrels), whether or not concomitant changes in brain size are held constant. Despite previous conclusions to the contrary, the number of rubrospinal neurons is positively, not negatively related to the number of corticospinal (CS) neurons (Masterton *et al.*, 1989).

3.28.2.5 Summary

Comparison of the major descending spinal pathways in vertebrate classes suggests that many of the pathways found in mammals can be traced to even more distant, premammalian ancestry, with several possibly as old as the entire vertebrate subphylum. The phylogenetic history of direct descending projections from brain to spinal cord along the ancestral lineage leading to mammals seems to have been marked by a series of widely spaced, steplike augmentations of the previous complement of descending tracts. The appearance of rubrospinal neurons coincides with the radiation of jawed vertebrates, but its presence is variable and is probably related to the presence of appendages. The appearance of cerebellospinal neurons coincides with the radiation of tetrapods, and seems to have been maintained in subsequent lineages. Finally, the appearance of CS neurons coincides with the radiation of mammals and the emergence of neocortex. The further differentiation of the CST in the mammalian lineage leading to humans is reviewed in a later section.

3.28.3 Emergence and Differentiation of Motor Cortex

3.28.3.1 Forebrain Motor Systems of Reptiles

Because a six-layered neocortex emerged in early mammals, there is no true homologue for mammalian motor cortex in nonmammalian species. Reptiles possess a telencephalic structure that is part of a neural circuit involved in the modulation of movement by sensory information. This structure, the anterior dorsal ventricular ridge (ADVR), receives information from the visual, auditory, and somatosensory systems and projects to the striatum, which sends efferents to descending pathways that modulate activity of motoneurons (Ulinski, 1983).

Early stimulation studies reported a motor area in dorsal cortex of turtles (*Chelydra serpentina*) in the rostrolateral subdivision or pallial thickening (Johnston, 1916). Due to its topographic position, the investigator concluded that this area represents a motor cortical area corresponding to motor cortex in the mammalian brain. Others reported a similar motor area in dorsal cortex of alligators (Bagley and Langworthy, 1926). Still others claimed to elicit motor responses in reptiles only when the striatum (most likely ADVR) was stimulated (Goldby, 1937; Koppanyi and Pearcy, 1925; Schapiro and Goodman, 1969). These early stimulation studies of the telencephalon in reptiles most likely evoked motor responses due to current spread to subcortical areas and the meninges (Peterson, 1980). Thus, to date, studies of the telencephalon in reptiles suggest

that there is no motor area in the dorsal cortex comparable to motor cortex in mammals.

3.28.3.2 Motor Cortex in Neurologically Primitive Mammals and the Concept of the Sensorimotor Amalgam

The somatosensory-motor cortex of most mammals (e.g., primates) is not an undifferentiated mass, but is comprised of at least two distinguishable somatotopically organized areas (Woolsey, 1958). According to Woolsey, although each of these areas displays both sensory and motor characteristics, one modality predominates. Woolsey introduced the term 'somatic sensory-motor area I', or SmI, to describe the postcentral, predominantly somatosensory area of primates (and its homologues in nonprimates), and the term 'somatic motor-sensory area I', or MsI, to describe the precentral, predominantly motor area of primates (and its homologues). During the evolutionary development of somatosensory-motor cortex, clear-cut changes seem to have taken place in the cytoarchitecture, input, and output of MsI, resulting in a separate motor area. But did this separation emerge by progressive differentiation of SmI, or did a true motor cortex emerge *de novo*, adding yet another augmentation to the previous complement of descending spinal cord pathways? Studies of neurologically primitive mammals still extant may hold clues to the emergence of early motor cortex.

Endocasts of skulls in the fossil record reveal that the brains of early mammals had a small volume of lissencephalic neocortex, similar to a number of small-brained species of extant Didelphid marsupials (Jerison, 1990). The family of Didelphid opossums has long been thought to have retained the basic brain structure approximating a form that can serve as a starting point for tracing the evolution of modern mammalian neural organization, whether marsupial or placental (Smith, 1910; Loo, 1930; Edinger, 1948; Simpson, 1949, 1959; Olsen, 1959; Frost and Masterton, 1992; Frost *et al.*, 2000).

The basic scheme of a progressively differentiating somatosensory and motor cortex in mammals was proposed at least by the 1940s. In 1945, von Bonin stated: "It is of the essence of cortical organization that sensory and motor areas become divorced more and more from each other – pulled further apart as it were – as evolution proceeds" (von Bonin, 1945).

Studies using cortical surface recording and stimulation in Didelphid opossums (*Didelphis virginiana*) conducted in the early 1960s by Richard Lende seemed to provide support for this notion. Lende referred to the undifferentiated cortical area as a sensorimotor amalgam (Lende, 1963a, 1963b, 1964) based on a complete motor map of the body superimposed on a complete somatosensory map. Similar results were found in *Didelphis azarae*. In both studies, the amalgam was quite large (perhaps due to the use of surface recording and stimulation techniques), encompassing the complete length of the parietal region.

Based strictly on electrophysiological grounds, however, it is now clear that the opossum's sensorimotor amalgam is not motor cortex in the same sense as it is in other mammals, such as primates. To begin with, the somatosensory cortex of primates is not without some motor properties. Evoked motor responses from electrical stimulation in primary somatosensory cortex (S1) of eutherian mammals resemble those evoked in primary motor cortex (M1), with the exception that stimulation thresholds are significantly higher (Welker *et al.*, 1957; Woolsey, 1958; Doetsch and Gardner, 1972; Sessle and Wiesendanger, 1982). In stimulation studies of cortex in opossums (Lende, 1963a; Beck *et al.*, 1996; Frost *et al.*, 2000), movements were most often evoked using relatively high stimulating currents compared to those typically observed using microelectrode stimulation in layer V of M1 in primates (Sessle and Wiesendanger, 1982; Nudo *et al.*, 1992; Stepniewska *et al.*, 1993; Nudo and Milliken, 1996; see figures 12 and 14 in Frost *et al.*, 2000, and figure 9 in Nudo *et al.*, 1996). This disparity in current thresholds for evoked movements suggests that the electrically evoked motor responses observed in opossums are representative of the motor component of somatosensory cortex found in eutherian mammals.

Further, even after M1 is extirpated in primates, electrical stimulation of somatosensory cortex produces movements in skeletal musculature. Therefore, a motor component in the opossum's somatosensory-motor area is not sufficient grounds to consider it motor cortex. Finally, the cytoarchitecture and myeloarchitecture of the motor response area in Sm1 of Didelphids also suggests that this is a sensory area rather than a true motor cortex. This area has a notable granular layer (layer IV) and does not have the agranular appearance characteristic of true motor cortex (Walsh and Ebner, 1970; Frost *et al.*, 2000). The sensorimotor amalgam of opossum cortex is probably no more motor than the somatosensory cortex of, say, monkey. It is probably safe to suggest that in opossum cortex specifically, and primitive cortex generally, there is no true motor cortex. If this is the case, and if opossum provides a reasonable representation of early neocortical organization, then motor cortex must have arisen anew sometime later in evolution.

3.28.3.3 Emergence of a True Motor Cortex

In eutherian species, M1 (i.e., MsI) is situated rostral to S1 (i.e., SmI) and has a parallel somatotopic organization, though modern microstimulation studies (e.g., Gould *et al.*, 1986) have revealed that the motor map is organized in a fractionated mosaic distribution with respect to evoked joint movements, in contrast to the relatively precise topography of receptive field organization in somatosensory cortex. The neocortex of two extant marsupials, the North American opossum (*D. virginiana*) and the South American gray short-tailed opossum (*Monodelphis domestica*) have been studied extensively in order to determine if any evidence of a primordial motor cortex could be found rostral to S1. These more recent studies employed microelectrode stimulation and recording techniques, allowing much greater spatial resolution of somatosensory and motor maps than afforded by the surface stimulation and recording techniques used in the early 1960s. Examination of *Didelphis* cortex using microelectrode techniques revealed that movements can be evoked from several sites within, and some sites just rostral to S1 (Beck *et al.*, 1996). Stimulation most often resulted in movements of the tongue, though evoked movements of body parts, including several forelimb movements, were also seen. Together with the evidence that most CS fibers originate from S1 in *Didelphis*, and very few originate from areas rostral to S1, the results so far seem to favor the idea that *Didelphis* cortex contains S1, but not a true motor cortex.

The gray, short-tailed opossum (*M. domestica)* may possibly represent an even earlier stage of somatosensory-motor differentiation. In this species, movements can be evoked from a large area coextensive with the somatosensory representation, as was found for *Didelphis* (Frost *et al.*, 2000). However, unlike *Didelphis*, in which orofacial as well as proximal and distal forelimb movements were evoked, electrical stimulation in *Monodelphis* evoked movements restricted almost exclusively to the vibrissae, and to a lesser extent, jaw (see Somatosensory Specializations in the Nervous Systems of Manatees). In this study, three modes of stimulation were used:

1. intracortical microstimulation (750 kΩ electrode impedance) in layer V;
2. low-impedance depth stimulation (100–200 kΩ electrode impedance) in layer V; and
3. bipolar surface stimulation.

Results were qualitatively similar using the different techniques, though the excitable area increased progressively with methods 2 and 3 (Frost *et al.*, 2000). No motor representation of body parts below the level of the head was found in S1 or in more rostral areas.

These results suggest that evolutionary pressures for development of motor components in cerebral cortex may have begun long before the emergence of a true, differentiated motor cortex, possibly due to a need for more refined movements of the face (Frost *et al.*, 2000). This putative selective pressure may have resulted in an early substrate for mediating movements of vibrissae, long before sufficient CS pathways were in place to mediate direct control of the forelimbs and hindlimbs, and long before a separate motor representation rostral to S1 was established (Figure 1). In this regard, it is important to note that *Monodelphis* contains almost 20 times fewer CS neurons than *Didelphis*, and nearly 40 times fewer than rat (Nudo *et al.*, 1995). Thus, S1 of *Monodelphis* may represent a primordial condition in which a complete somatosensory map has been achieved and retained, but the motor components of S1 have not yet fully developed. In this primitive condition, the anatomical substrate required for cortical control of movements below the level of the face is not yet present.

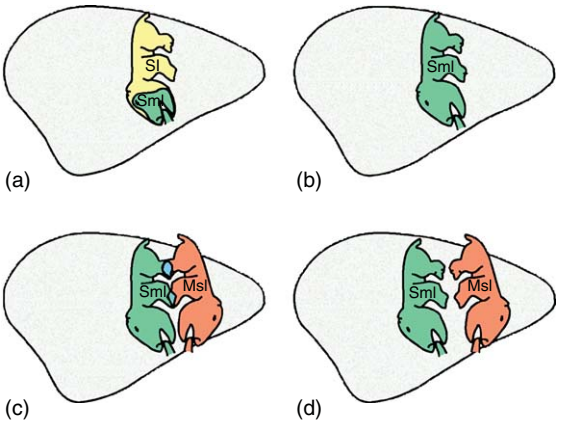

Figure 1 Hypothetical model of evolutionary divergence in sensorimotor cortex. a, Somatomotor representation in the earliest mammals, represented by *Monodelphis*. A complete somatosensory (SI) representation exists. An incomplete motor representation is congruent with the sensory representation of the face (SmI). b, A complete motor representation exists and overlaps the somatosensory representation (SmI). As noted by Lende, this sensorimotor amalgam is not unlike S1 of placental mammals. A reversed map characteristic of true motor cortex is absent. c, True motor cortex has emerged, as evident from a reversed motor representation (MsI) rostral to the somatosensory representation (SmI). MsI is largely segregated from SmI, though a partial overlap exists in the hindlimb and forelimb areas. d, In primates, MsI is completely segregated from SmI. Somatosensory cortex retains some motor properties, and motor cortex retains some somatosensory properties.

Based on these and other studies, it is thought that in opossums, motor functions at the level of the cerebral cortex, if they exist, are mediated by motor components of somatosensory cortex. Further, the motor map in S1 may have developed in stages, as it is restricted to the face, or to the face and upper extremity in *Monodelphis* and *Didelphis*, respectively. The cortical organization in monotremes, however, suggests that sensorimotor differentiation may not have followed a simple linear progression. For example, using surface stimulation techniques in the prototherian echidna (*Tachyglossus aculeatus*), Lende (1964) found a complete motor representation overlapping the somatosensory representation. Using surface stimulation techniques in the platypus (*Ornithorhynchus anatinus*), Bohringer and Rowe (1977) found a partial overlap of the motor and somatosensory representations. Electrical stimulation evoked movements of the bill and forelimb, but not the hindlimb. Thus, it is possible that the motor component of S1 is more complete in monotremes than in *Monodelphis* opossums.

Although motor components in S1 have been found in all mammals studied to date, the issue of whether a separate primordial motor cortex rostral to S1 exists in neurologically primitive mammals is not yet clear. In early surface stimulation studies in echidna (Abbie, 1938; Goldby, 1939) evoked movements were observed in an area rostral to S1. Surface stimulation studies in platypus also resulted in evoked movements rostral to S1, including representations of the forelimb. But the area immediately rostral to S1 in monotremes (rostral field or field R) contains neurons responsive to stimulation of deep receptors (Krubitzer *et al.*, 1995), similar to neurons in area 3a of eutherian mammals. Area 3a is considered to be a transition zone between area 3b of S1 and area 4 (M1). In eutherian mammals, movements can be evoked by microelectrode stimulation in area 3a using relatively low current levels. This raises the possibility that area 3a became differentiated from S1 prior to the emergence of a true motor cortex. Furthermore, based on electrophysiological and cytoarchitectonic criteria, a separate cortical area (the manipulation field, or field M) has been identified in both echidna and platypus (Krubitzer *et al.*, 1995). As field M shares some cytoarchitectonic similarities with M1, it is possible that this area is a homologue of M1 in eutherian mammals (Krubitzer *et al.*, 1995). However, at this point it is also possible that field M is a unique specialization in extant monotremes. Clearly, additional studies of its physiology and anatomy are needed to resolve this issue.

These findings of a possible M1 homologue rostral to S1 in monotremes suggest that the antecedents to a true motor cortex may have existed very early after the emergence of mammals. As evolutionary pressures for specialized motor functions (e.g., manual dexterity) grew, augmentations of the CST from a primitive to a more advanced pathway seem to have paralleled the origin of a true motor cortex.

It is not entirely clear when true motor cortex might have emerged. But it seems that somatosensory-motor differentiation occurred independently in several orders, and not just in primates. For example, a true motor cortex, as evidenced by a reversed motor representation rostral to the somatosensory representation and by movements evoked at relatively low microelectrode stimulating currents, is apparent in rats (Donoghue and Wise, 1982). Motor cortical fields have been localized to frontal cortex in other rodent species as well (Woolsey *et al.*, 1952; Hall and Lindholm, 1974). A separate and distinct topographic pattern comprising M1 in the rat forms a rough mirror image of the S1 representation, with the hindlimb caudomedial, the face rostrolateral, and the proximal and axial representations rostromedial (Neafsey *et al.*, 1986; Neafsey and Sievert, 1982). In rats, the separation of S1 and M1 is not complete, since some overlap has been demonstrated over most of the hindlimb representation and part of the forelimb representation (Hall and Lindholm, 1974; Donoghue and Wise, 1982; Sanderson *et al.*, 1983). This area of overlap has features similar to both S1 and M1 cortex. The overlapping hindlimb area receives a convergence of thalamic projections from the ventrolateral nucleus and the ventrobasal complex, whereas in nonoverlapping areas these projections are segregated (Donoghue *et al.*, 1979). Regardless of the partial overlap in rats, it appears that a true, separate motor area, distinct and separate from the S1 cortex exists in rodents, primates, and carnivores.

3.28.4 Evolution of the CST

The CST places the neocortex in direct neural contact with the spinal cord. The existence of direct synaptic connections between cortical neurons and spinal motoneurons in some eutherian mammals (including many primates) has been the structural basis for implicating the CST in a variety of motor functions, such as control of digital dexterity, conditioned movements, flexor activity, muscle tonus, and volitional movements (Lawrence and Kuypers, 1968; Beck and Chambers, 1970).

Since rather strong structure–function relationships for the CST can be advanced in primates, including humans, it has been tempting to presume that its function is the same in all mammals. However, it is now becoming apparent that because the morphology of the CST is so varied across mammals (in size, spinal course, manner of termination, etc.), the motor functions ascribed to the CST of primates probably cannot be extended *in toto* to other orders. Likewise, it cannot be assumed that the CST subserves only a motor function. It is also thought to be involved in descending control of afferent inputs, modulation of spinal reflexes, and trophic functions, to name a few (Lemon and Griffiths, 2005).

Furthermore, since its morphology is so varied, it often has been assumed that the CST arose more than once and possibly many times during the phylogeny of mammals (e.g., see Goldby, 1939; Noback and Shriver, 1969). More specifically, it has been suggested that the tract emerged independently within each mammalian order. In this view, any similarity in the tract across orders (such as its common origins in layer V of somatosensory-motor cortex) would be regarded as a consequence of parallel or convergent evolution and any similarity in function would be regarded as coincidental.

The present review attempts to reconstruct the morphological changes that have occurred in the CST during the course of mammalian evolution. Briefly, it is argued that the tract arose initially as collaterals of a phylogenetically older, corticobulbar tract (CBT), which itself includes part of the descending somatosensory system. Further, it is argued that these corticobulbar collaterals penetrated the cord after the major mammalian orders had diverged. Therefore, CSTs cannot, in principle, be traced to a single, common mammalian ancestor, but they can be traced to common corticofugal pathways that had their own origins early in mammalian evolution.

3.28.4.1 Variation in the Trajectory of CS Fibers in the Medullary Pyramids

Many pyramidal tract fibers terminate in the medulla before reaching the cord. However, many aspects of the pyramidal tract's morphology have been examined in a great number of species. Thus, to the extent that the CS fibers constitute a significant fraction of pyramidal fibers, a brief comparative analysis of the morphology of the pyramidal tract is not without interest.

It was first noted by Clarke in 1858 (Wiesendanger, 1981) and Spitzka in 1879 (Spitzka, 1879, 1886) that the pyramidal tract varies in size across mammals and that the anthropoid apes possess some of the largest pyramidal tracts. It is clear that absolute size of the tract, the number of fibers, the size of the largest fibers, and the average fiber size each increases in a phyletic series leading to humans. However, when body weight is held constant, all but one of these correlations collapses. The phyletic level remains significantly correlated only with the cross-sectional area of the pyramidal tract (Heffner and Masterton, 1983).

It is generally acknowledged that in most mammals, 90–95% of the CS fibers cross in the pyramidal decussation before entering the cord. But the exact location of the pyramidal decussation is not invariant. In the vast majority of mammals studied so far, the pyramidal decussation occurs just above the medulla–spinal junction. However, in at least one species of bat, and possibly in the anteater, the pyramidal fibers cross earlier, in the rostral medulla (Fuse, 1926; Broere, 1966); in at least two other species (pangolin, echidna), the pyramidal fibers seem to cross in the pons (Goldby, 1939; Chang, 1944); and in three other species (hyrax, mole, and hedgehog), no decussation has been observed at all (Linowiecki, 1914; Verhaart, 1967; Kunzle and Lotter, 1996). Finally, variation in the pyramidal decussation in humans has been frequently reported. Clearly, more information is needed on the consistencies and variation in this important aspect of pyramidal tract morphology.

3.28.4.2 Variation in the Trajectory of CS Fibers in the Spinal Cord

If the CST were homologous across mammalian orders, one might expect it to descend through the spinal cord in the same funicular pathway in each order. In contrast, CS fibers descend through the spinal cord in any of six different funiculi in mammalian species. These include the dorsolateral (sometimes called the lateral tract), dorsomedial (sometimes called the dorsal tract), and ventral funiculi (Armand, 1982). Further, CS fibers can travel in either side of the cord, i.e., contralateral or ipsilateral to the cells of origin in layer V of the cerebral cortex (Figure 2).

In an individual species, there is usually more than one CST. The principal tract (sometimes called the main tract) is usually defined as the one larger in area, containing more and larger fibers, and terminating in more caudal levels than the others. When the principal CSTs are arranged according to their funicular trajectories on a cladogram of mammalian

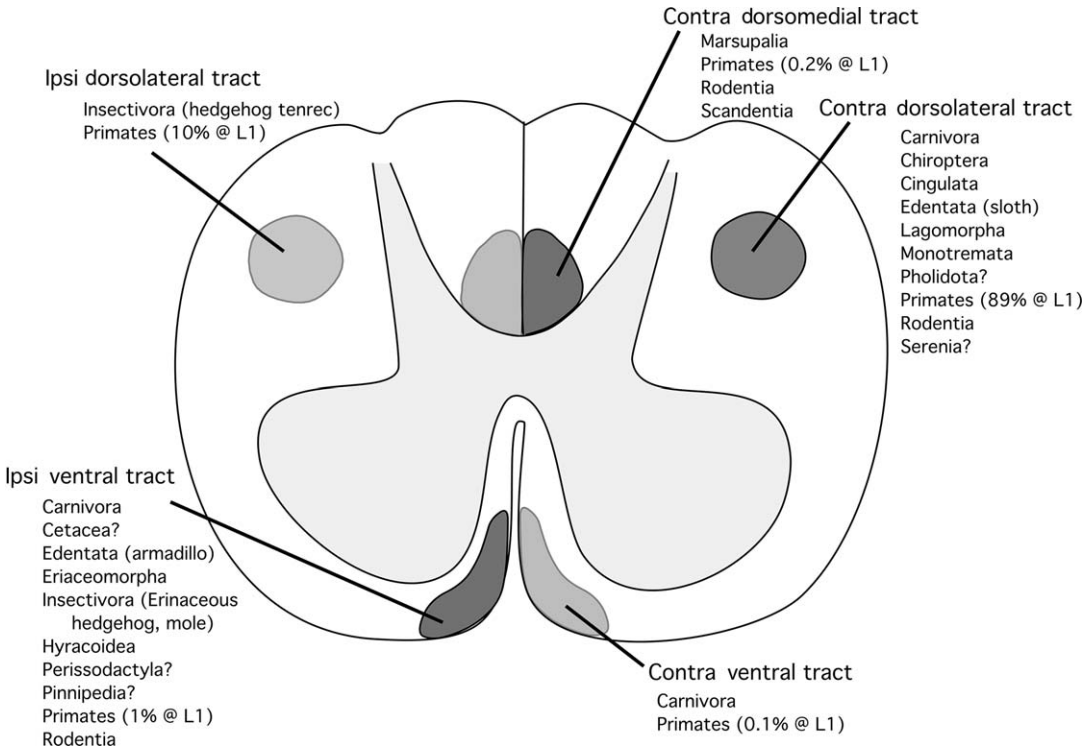

Figure 2 Location of CST in the spinal cord of mammals. All mammals studied to date possess CS neurons. The CST can travel in any one of six spinal cord funiculi: The dorsolateral, dorsomedial, or ventral funiculi, and either on the ipsilateral or contralateral side with respect to the cells of origin in layer V of cerebral cortex.

orders (based on other paleontological and comparative data), they do not appear to group into any other obvious subsets (Figure 3). This marked variation in the spinal location of the CST among orders of mammals has been the major point of reference for establishing the tract's early phylogeny. Based entirely on this variation in funicular trajectory among orders and the equally marked lack of variation within orders, it has been suggested that the CST may have penetrated the cord (and thus, arisen independently) within each mammalian order (Goldby, 1939; Noback and Shriver, 1966b).

Based upon the funicular trajectory of its principal tract then, the CST can be traced to a common ancestry within each mammalian order, but not to any higher-level taxa or more remote ancestry. Consequently, up to this point one may tentatively conclude that the majority of CS fibers entered the cord only after the various orders of mammals had diverged. This consistency within orders has not always been apparent because of changes in the taxonomy of the mammalian orders. For example, tree shrews, which possess a dorsomedial principal tract, were once classified as primates that possess a dorsolateral principal tract. Also, rabbits, now classified as lagomorphs, possess a dorsolateral principal tract, but were once classified as rodents, which possess a dorsomedial principal tract. It is of interest here that in the continuing debate concerning the taxonomy and evolutionary origin of tree shrews, the funicular location of the CST has been proposed as a criterion of classification. For more information, see review by Haines and Swindler (1972). This idea gains some further support by the observation that in some neurologically primitive mammals, relatively few CS fibers extend past upper cervical levels of the spinal cord. For example, in the short-tailed opossum, only 500 CS neurons have been identified (Nudo *et al.*, 1995); in the hedgehog tenrec, only 600 CS neurons have been identified (Kunzle and Rehkamper, 1992).

Until the late 1970s, the majority of studies examining the course and termination of the CST relied on either degeneration or autoradiographic techniques that have been superceded by more sensitive tract-tracing methods such as injection of wheat-germ agglutinin conjugated to horseradish peroxidase (WGA-HRP) or more recently, biotinylated dextran amine (BDA). The older techniques were quite adequate for identifying the principal CST, and thus, the early findings have largely been replicated numerous times. However,

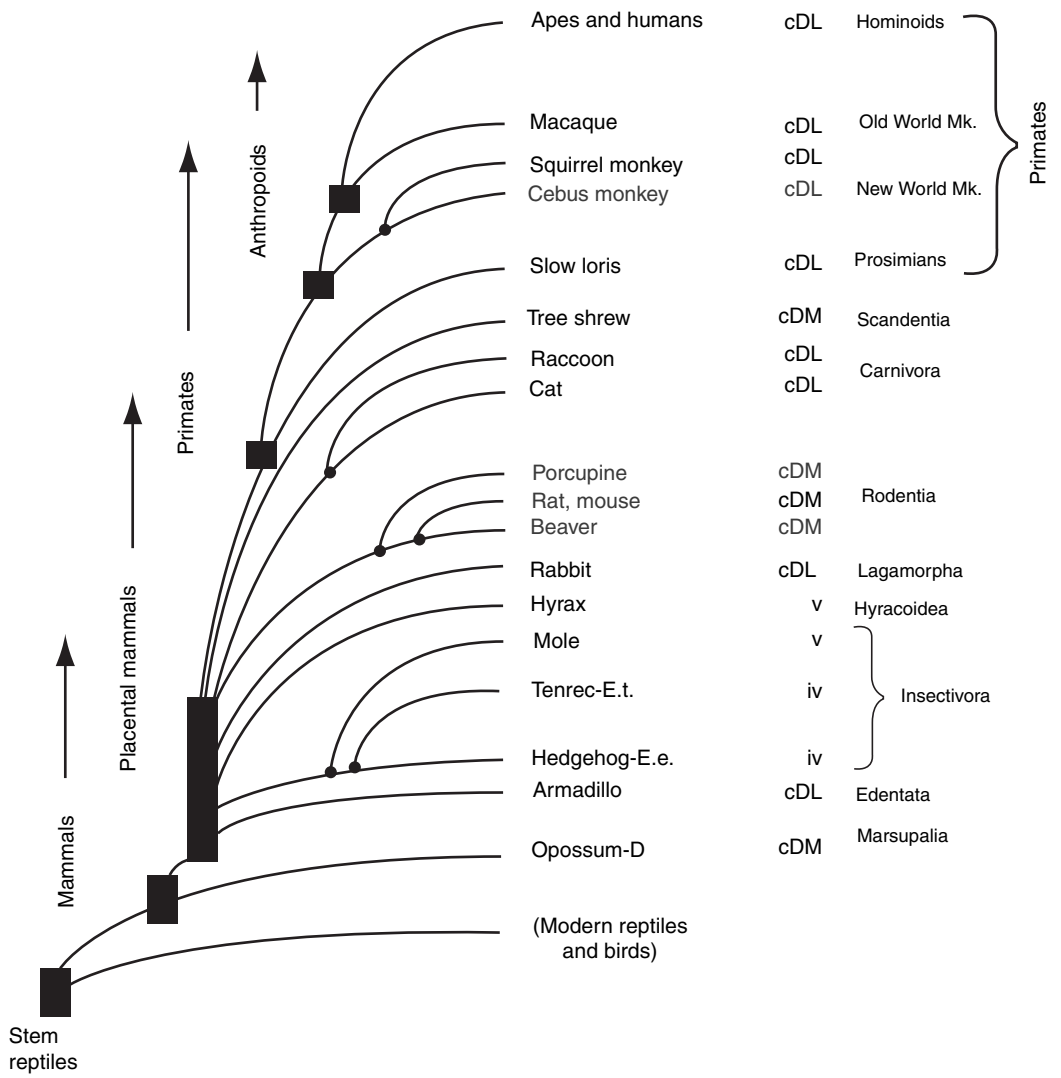

Figure 3 Principal CSTs in mammalian orders. Species are arranged according to progressively more recent common ancestry with apes and humans. Whereas the trajectory of the principal CSTs are the same within mammalian orders, they differ between orders. This has historically been the primary evidence to suggest that the CST emerged independently within each mammalian order. DL, dorsolateral funiculus; DM, dorsomedial funiculus; V, ventral funiculus; c, contralateral (to cell bodies of origin); I, ipsilateral (to cell bodies of origin).

as the more sensitive tracers have been employed, it has become evident that CS fibers travel in multiple funiculi in the same species. To date, while CS fibers have been examined using the modern, sensitive tract-tracers in only a few species (cat, macaque monkey, mouse, rat, hedgehog tenrec), at least some CS fibers travel in the dorsolateral funiculus (contralateral and ipsilateral), the ventral funiculus (ipsilateral), and the dorsomedial funiculus (contralateral) in each of these species (Table 2) (Satomi *et al.*, 1989; Kunzle and Lotter, 1996; Brosamle and Schwab, 1997; Lacroix *et al.*, 2004; Steward *et al.*, 2004). In cat, CS fibers have been described in all six spinal funiculi (Satomi *et al.*, 1989).

These recent results demonstrating common trajectories across orders of secondary CSTs suggest that at least some CS fibers in one or more spinal funiculi may be homologous. If so, the number of such fibers is likely to be very low indeed, based on results in *Monodelphis* opossum and the hedgehog tenrec. Thus, what we now call the principal CST very likely is a more recent specialization within each mammalian order that resulted from augmentation of the primordial CST. Because the bulk of the CST probably emerged after the radiation of mammalian orders, its funicular trajectory is probably of little value in determining its early origins in primordial mammals. However, the variation in the location of the principal CST in the various orders,

Table 2 Location of CS fibers in mammalian orders

		Funicular trajectory[a]		
Order	*Species (common name)*	*DM(c/i)*	*DL(c/i)*	*V(c/i)*
Artiodactyla	Goat		+	
Carnivora	Cat; raccoon	+/+	++/+	+/+
Chiroptera	Bat		++	
Edentata	Armadillo		++	
Hyracoidea	Hyrax			++
Insectivora	Mole, hedgehog	–/–	?/?	?/+
Lagamorpha	Rabbit		++	+
Marsupalia	Opossum, wallaby, potorou, kangaroo	++	+	
Monotremata	Echidna		++	
Pholidota	Pangolin		++	
Primates	Slow loris, bush baby, macaque, Cebus monkey, squirrel monkey	+/–	++/+	+/+
Rodentia	Porcupine, guinea pig, gopher, hamster, beaver, mouse, woodchuck, coypu rat, common rat	++/+	+/+	–/+
Scandentia	Tree shrew	++	+	+

[a]A fourth location of CS fibers, the intracommissural bundle, has been identified, though not with modern tract-tracing techniques. They will not be described further here.
++, Substantial number of fibers; +, relatively few fibers; ?, current data equivocal; DM, dorsomedial funiculus; DL, dorsolateral funiculus; V, ventral funiculus; c, contralateral; i, ipsilateral.

and the consistency within orders remains an intriguing clue that may yet provide a unique perspective with regard to the function of the CST.

3.28.4.3 Evolutionary Origins of CS Fibers: The Caudal Extension of the CBT

Although CS fibers appear to have entered the cord independently in each mammalian order, it is unlikely that they appeared, throughout their extent from cortex to cord, *de novo*. In seeking a more likely, more gradual origin, the most reasonable first guess is the CBT. This tract has a similar cortical origin and a similar trajectory within the brainstem as the CST. It is dissimilar only in its extent down the neuraxis. That is, regardless of order, both the CST and CBT descend in the internal capsule, cerebral peduncle, and pyramid before entering the cord (as the CST) or arborizing in the pons/medulla (as the CBT). Further, the CST and several of the CBTs originate in some of the same cortical areas (areas 4, 3, 1, and 2) (Wiesendanger and Wiesendanger, 1982).

Therefore, it is not unreasonable to suppose that CS fibers made their way into the spinal cord via the already established capsular, peduncular, and pyramidal tracts previously ending in the medulla, and it is not unlikely that they emerged first as collaterals of this phylogenetically older pathway to the medulla. This notion, shared by other investigators (Noback and Shriver, 1966a), has received support from the demonstration that many CS neurons send collaterals to dorsal column nuclei (Rustioni and Hayes, 1981). From an evolutionary viewpoint, however, the CS fibers are probably the collaterals of the older corticobulbar axons ending in the dorsal column nuclei, not vice versa.

3.28.4.4 Termination of CS Neurons

As would be expected from its multiple origins, the termination pattern of CS fibers (that is, where the CS fibers end within the spinal grey) varies greatly among mammalian orders. But perhaps unexpectedly, it also often varies within orders. This variation in termination pattern, along with the relationship to variations in function, have been discussed by Heffner and Masterton (1975) and will only be reviewed briefly here.

Two major points can be made concerning the termination of CS fibers. First, the caudal extent of the tract varies from cervical levels in goat and hedgehog to sacral (and even coccygeal) levels in primates, rodents, and some carnivores. Second, the fibers terminate in many spinal grey laminae. On one hand, regardless of order, all mammals are alike in that most CS fibers terminate at the base of the dorsal horn (lamina V–VI) at each spinal level. On the other hand, both among orders and among families within orders, the ventral (or anterior) limit of the CS terminations within the spinal cord grey varies widely. Although in many mammals, CS terminals reach no more ventral than lamina VI (e.g., goat, rabbit, marmoset, wallaby), in others (raccoon and most primates), they extend to both medial and lateral motoneurons in lamina IX.

Even though it appears that CS fibers penetrated the cord only after the orders diverged, certain trends in the termination patterns of the CST can be observed in a phyletic series across orders known to have successive (as opposed to sequential) origin (Heffner and Masterton, 1983). These trends are especially evident in a phyletic series of extant mammals having successive propinquity with humans. If CS termination parameters are plotted in such a series (with body weight constant), it is clear that with successive grades, first the CST reaches more caudal levels of the spinal cord, and second, at each cord level, the CST innervates more ventral laminae, eventually establishing direct contact with spinal motoneurons.

3.28.4.5 Cells of Origin of the CST

The search for the cortical cells originating the CST has a long history. Over the past century, as soon as a new neuroanatomical technique had been developed, it had been applied to this tract. Early in the history of its study, around 1830, Gall and Spatzheim recognized (by gross dissection) that the pyramidal fibers had their origins in cortex, but it was not until 1851 that Turck realized that many of these same fibers enter the spinal cord (Lassek, 1954; Clark and Dewhurst, 1974). When the Marchi technique for staining degenerating myelin was developed, electrical stimulation of the cortex guided investigators to the most probable sites for extirpation. For the next century, until the advent of modern neuronal tract-tracing techniques, this general procedure of electrical stimulation, extirpation, and the subsequent study of degenerated myelin, axons, or terminals (i.e., the Nauta–Gygax and Fink–Heimer techniques) yielded most of the knowledge concerning the origins of the CST.

However, the anterograde degeneration method can only reveal the general areas of cortex-originating pyramidal or CS axons. The exact cells of origin were still unknown by the turn of the century. At the time, it was suggested that large pyramidal cells (Betz cells) in the area gigantopyramidalis give rise to the CST. Although this idea has proved to be true, at the time it was erroneously thought that these were the only cells originating CS neurons. This incorrect notion was reinforced by retrograde degeneration after spinal hemisection (Holmes and May, 1909). Chromatolytic changes in Betz cells were observed but, once more, it was concluded erroneously that the CST originated exclusively from them.

Despite the powerful influence of Holmes and Page May's study over the next quarter century, some doubts were beginning to be cast on the notion that CS fibers arise strictly from Betz cells. By the 1930s, the anterograde degeneration method had revealed that the cortical origins of the CST were much more widespread than was previously thought (Kennard, 1935). The advent of precise electroanatomical techniques in the 1940s enabled investigators to locate pyramidal tract cells by electrically stimulating the tract on the ventral surface of the medulla and recording from antidromically stimulated cells in the cortex (Lance and Manning, 1954). Later, antidromically identified pyramidal tract neurons were injected with dye so that they could be visualized in cortical layer V of area 4 (Batuev and Lenkov, 1973).

However, the electroanatomical techniques hold one problem in common with the retrograde chromatolytic technique: large neurons are overrepresented. Nevertheless, it is clear that the CS area defined by either antidromic activation or by retrograde chromotolysis is coextensive with the area defined by anterograde degeneration techniques. But by the mid-1970s a detailed picture of the distribution of the cells originating CS axons had yet to be realized.

Precise information concerning the cells originating CS axons was obtained beginning in the mid-1970s based on the retrograde transport of horseradish peroxidase and other materials. This technique was first applied to the CST by Catsman-Berrevoets and Kuypers in 1975 (Catsman-Berrevoets and Kuypers, 1976). Based on retrograde tract-tracing studies over the past few decades, considerable anatomical information is now available regarding the morphology of neurons originating the CST in a wide variety of mammalian species (Nudo and Masterton, 1990a, 1990b; Nudo *et al.*, 1995). Several general features have emerged:

1. All CS neurons reside in cortical layer V. No exception to this sweeping generalization has yet been seen.
2. CS neurons are most concentrated in, but not confined to area 4.
3. Though less heavily concentrated, a very large number of CS neurons reside outside of area 4, especially in the somatosensory areas 3, 1, and 2 and in areas 5 and 6. This extent represents a far wider distribution than shown by earlier techniques, especially electrical stimulation, antidromic activation, or retrograde chromatolysis.
4. The giant Betz cells are neither the sole nor predominant originators of CS axons. In fact, Betz cells probably account for no more than about 3% of all pyramidal tract fibers. Pyramidal cells of many sizes contribute axons to the CST.

Aside from these sweeping generalizations, the morphology and distribution of CS neurons varies considerably. With regard to their distribution, there does appear to be some consistency across mammalian orders in that either two or three separate broad regions of neocortex originating CS fibers in all mammalian species studied. These regions are large but relatively well demarcated and are stable both in absolute and relative location on the cortical surface in all orders examined.

One broad region (region A in Nudo and Masterton, 1990a) contains nearly 90% of CS neurons. This region comprises primary somatosensory and motor cortex, as well as CS neurons in the dorsal premotor cortex, supplementary motor area, cingulate motor areas (at least in primates), and scattered cells in the parietal and frontal cortex. A second broad region (region B) comprises CS neurons in the second somatosensory area and related somatosensory areas of the parietal cortex. These two broad regions of CS neurons have been identified in every mammalian species studied to date, and thus can theoretically be traced to a common mammalian ancestor.

A third region of CS neurons is clustered in an area most likely corresponding to the primate ventral premotor cortex (region C). This group of cells appears to be uniquely present in all primate species studied to date, but in representatives of no other mammalian order. Another region (region C′) is present in all rodents studied as well as rabbit, but in no other mammalian species. This region, corresponding to the rostral forelimb area (RFA) of rats, will be discussed in a later section.

The total number of CS neurons varies considerably across mammalian species, with the lowest numbers in many insectivores and *Monodelphis* opossum, and the highest numbers in most primates and carnivores (Nudo *et al.*, 1995). As expected, body size and brain size are significant co-variates in the total number of CS neurons and in the amount of cortex devoted to the CST. However, even when body weight is held statistically constant, the number of CS neurons increases in the anthropoid ancestral lineage. Other characteristics of CS neurons also appear to have changed significantly in the anthropoid lineage, including an increase in average soma diameter and a decrease in volume density and concentration. Thus, with more recent common ancestry with humans, it appears that CS neurons became larger, more numerous, and less concentrated. This latter finding is interesting as it implies that the region of cortex-originating CS fibers added more non-CS neurons and more neuropil. Perhaps one of the unique attributes of primate motor cortex is the expansion of intracortical connectivity of regions originating CS neurons.

3.28.5 Specialization of Motor Areas in Primates

3.28.5.1 Criteria for Differentiation

It is generally accepted that no single feature is sufficient for characterizing an area as a distinct region. Features used to define cortical motor fields include its cytoarchitectonics, pattern of afferent and efferent connections, features of intrinsic connectivity, chemoarchitectonics, behavioral effects of ablation, and, particularly for motor cortical areas, the ability to elicit movements upon electrical stimulation.

A differentiated motor field has a unique cytoarchitecture, traditionally defined by stains for Nissl bodies and myelin. Additionally, areas have been examined and characterized based on cytochrome oxidase staining, acetylcholinesterase staining, neurofilament antibody staining, and receptor binding. Unique characteristics of cell types, laminar organization, cell density, fiber density, and various staining densities are all used for characterization. Extensive tract-tracing studies have been used to identify subareas of motor cortex based on differential afferent and efferent connections with the thalamus, basal ganglia, and other cortical areas, as well as their projections to the spinal cord. Intracortical microstimulation mapping procedures have been used to define somatotopic organization within each secondary motor area, with attention paid to minimal threshold requirements for initiation of movements, as well as the characterization of movements themselves. Finally, secondary motor areas have been characterized based on functional differences in ablation-behavior studies in nonhuman primates and functional imaging studies in humans.

3.28.5.2 Secondary Motor Areas in Primates

In addition to a primary motor area (M1 or area 4), there are several secondary motor areas recognized in the primate cortex (Kaas, 2004). These areas have been defined as having direct connections to both M1 and to the spinal cord. The premotor cortex, the supplementary motor area and the cingulate motor cortex have been identified in all primate species examined, including prosimian primates. Each of these secondary areas has been divided into subareas based on differences in cortical architecture that are related to hodological and functional differences. The lateral premotor area is divided into ventral and dorsal areas (PMv

and PMd, respectively), the supplementary motor area (SMA) into SMA-proper and pre-SMA, and the cingulate motor area has been subdivided into rostral (CMAr) and caudal (CMAc) divisions.

Neurologically more primitive primates represented by the prosimian bush baby (*Galago garnetti*) have a well-differentiated M1, with representation of the trunk, hindlimb, and face and a large forelimb representation, although there is little control of individual digit movements (Kanagasuntherum and Leong, 1966; see figures 1–5 in Wu *et al.*, 2000). In addition to M1, galagos possess most of the secondary motor areas that have been recognized in simian primates based on architectonic features, multiple somatotopic organization, and patterns of cortical and subcortical connections. These include the premotor areas, the supplementary motor areas, and the cingulate motor areas. These results suggest that as many as 10 motor fields emerged early in primate evolution (Wu *et al.*, 2000).

3.28.5.3 Is There a Primate Homologue to the Rodent RFA?

Intracortical microstimulation studies of sensorimotor cortex in the rat have shown a complete motor representation that is cytoarchitectonically defined as agranular cortex (Hall and Lindholm, 1974; Donoghue and Wise, 1982). The portion of this motor area in caudal portions of frontal cortex that is devoted to forelimb movements is referred to as the caudal forelimb area (CFA). In addition, a second motor representation of the forelimb has been identified in more rostral portions of the frontal cortex. This second forelimb representation, referred to as the RFA, is smaller than the CFA (Neafsey *et al.*, 1986). The RFA is separated from the CFA by a zone where intracortical microstimulation (ICMS) elicits vibrissa or neck muscle movements.

Because the presence of a secondary motor area in rats would appear to parallel the differentiation of motor areas in primates, suggestions have been made that the RFA is a homologue of one of the primate secondary motor areas. Based solely on the topographic location of CS neurons that originate in the RFA, Nudo and Masterton (1990a) concluded that secondary motor areas emerged independently in primates and rodents, and that there was no obvious homologue of RFA in primates.

However, it is important to consider additional details regarding the structure and function of the RFA in order to draw more firm conclusions. Tract-tracing studies of motor cortical connections in rat have shown differences in the thalamic, striatal, and cortical connections of CFA and RFA (Rouiller *et al.*, 1993). Comparison of these connections to the pattern of connections of primate motor areas suggests that RFA has some similarities to primate premotor areas. Roullier and colleagues found that the origins of thalamic inputs to the two areas are largely segregated, similar to the thalamic inputs to M1 and premotor areas in monkeys (Schell and Strick, 1984; Matelli *et al.*, 1989). Additionally, CFA has predominantly ipsilateral projections to the striatum, similar to M1 in primates (Leichnetz, 1986; Whitworth *et al.*, 1991). (The caudate and putamen are not differentiated in rodents. Thus, the collective term 'striatum' is used throughout this discussion for both rodents and primates.) RFA has diffuse bilateral corticostriatal projections equally dense to both hemispheres, similar to SMA and premotor cortex in primates (McGuire *et al.*, 1991).

In contrast, evidence suggests that lesions of RFA in rat result in more severe behavioral deficits than lesions of SMA in primates (Barth *et al.*, 1990; Passingham, 1993). Furthermore, the predominant layers of origin of intracortical connections between the RFA and CFA differ from those of M1 and PM/SMA in primates (Dum and Strick, 2005; Figure 4). In addition, the predominant thalamic connections of the RFA are with ventromedial thalamus, with few connections with the ventrolateral thalamus, rather than the predominantly ventrolateral and ventroanterior thalamic connections of primate PM and SMA (Figure 4).

Although corticofugal projections from CFA and RFA are similar, the RFA has interconnections with insular cortex similar to SMA and premotor cortex in primates. Additionally, the RFA does not appear to have cutaneous receptive fields, similar to supplementary motor cortex in primates (Neafsey *et al.*, 1986). Overall, based on its connections, CFA is more similar to the M1 forelimb area in primates and RFA in some ways appears to be more similar to nonprimary motor cortex in primates. It is not currently possible to decide whether RFA is a homologue of primate premotor cortex, supplementary motor areas, or a combination of secondary motor areas in primates (Rouiller *et al.*, 1993).

3.28.5.4 Further Differentiation of Primate Motor Areas

3.28.5.4.1 Nomenclature The nomenclature used for subdivisions of primate motor areas based on the study of macaques has varied across laboratories. The generalized current scheme includes M1 (or Brodmann's area 4); four subdivisions of the lateral

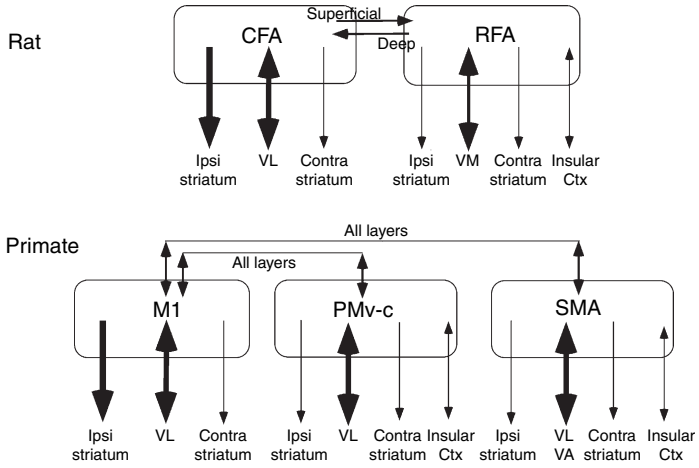

Figure 4 Comparison of secondary motor areas in rats and primates. Schematic diagram of the major (predominant) connections of the CFA and RFA in rat (top) compared to similar connections in M1, PMv-c, and SMA-proper in primates (bottom). CFA is similar to M1 based on its connections with ventrolateral thalamus (VL) and its strong projection to the ipsilateral lateral striatum (putamen in primates). RFA is similar to premotor areas of primates by its diffuse projections to ipsilateral and contralateral striatum (caudate and putamen in primates), and its interconnections with insular cortex. RFA differs from primate premotor cortex in its major connections with the thalamus (ventromedial thalamus in RFA vs. VL in PMd-c; VL and ventroanterior thalamus (VA) in primates) and its laminar differences in intracortial connectivity (deep layers of RFA project to CFA and superficial layers of CFA project to RFA, whereas all layers contribute projections between M1 and PMd or SMA).

premotor cortex (area 6) (PMd-c, PMd-r, PMv-c, PMv-r, or F2, F7, F4, and F5, respectively); two premotor subdivisions on the mesial surface of the hemisphere (SMA and pre-SMA, or F3 and F6), and three subdivisions of the cingulate motor area within regions lining the cingulate sulcus (CMAr, CMAd, CMAv, or area 24c, area 6c, and area 23c). SMA has also been referred to as M2 (Figure 5).

3.28.5.4.2 Differentiation of lateral premotor cortex Studies suggest that a premotor area first appeared with the divergence of prosimian primates, as evidenced by lateral premotor representations coincident with distinct cytoarchitectonics rostral to the M1 representation. Two major subdivisions, PMd and PMv, have been identified in the prosimian Galago (Wu *et al.*, 2000). PMd has been further subdivided in Galago into rostral and caudal components (PMd-r and PMd-c, respectively; see figures 4 and 5 in Wu *et al.*, 2000). To the extent that Galagos represent a primordial state of primate motor cortex, it is likely that PMd-r, PMd-c, and PMv are homologues in all extant primates. Intracortical microstimulation studies have also identified PMv and PMd in New World and Old World monkeys (Gould *et al.*, 1986; Stepniewska *et al.*, 1993; Preuss *et al.*, 1996; Frost *et al.*, 2003; Hoshi and Tanji, 2004; see Figure 5). The PMd has been shown to consist of representations of both hindlimb and forelimb (He *et al.*, 1993; Ghosh and Gattera, 1995; Preuss *et al.*, 1996; Raos *et al.*, 2003), while PMv contains representations of the forelimb and orofacial muscles (Stepniewska *et al.*, 1993; Preuss *et al.*, 1996).

In addition to the areas noted above that have been identified in prosimian primates and New World monkeys, the PMv is further differentiated in Old World monkeys. A total of four subareas of lateral premotor cortex are identifiable in macaques: PMd-c, PMd-r, PMv-c, and PMv-r (or F2, F7, F4, and F5, respectively) based on cytoarchitectonics, intracortical microstimulation results, and connections (Rizzolatti and Fadiga, 1998; Rouiller *et al.*, 1998; Morel *et al.*, 2005).

Studies implicate PMv in the initiation and control of limb movements based on visual cues and other sensory information (Kurata and Tanji, 1986; Gentilucci *et al.*, 1988; Rizzolatti *et al.*, 1988; Mushiake *et al.*, 1991; Mushiake *et al.*, 1997), whereas PMd is involved with movement parameters (Fu *et al.*, 1993; Kurata, 1993; Crammond and Kalaska, 2000). Thus, PMv is important for the integration of visual information derived from extrapersonal three-dimensional space and involved in the spatial guidance of limb movements (Kakei *et al.*, 2001), whereas PMd is involved in the integration of internal body representation and target information for the preparation of motor actions (Kurata, 1994; Hoshi and Tanji, 2004).

Unlike macaque monkeys, there have been no delineations of subareas F4 and F5 (PMv-c and PMv-r) in PMv of prosimian primates or New World monkeys.

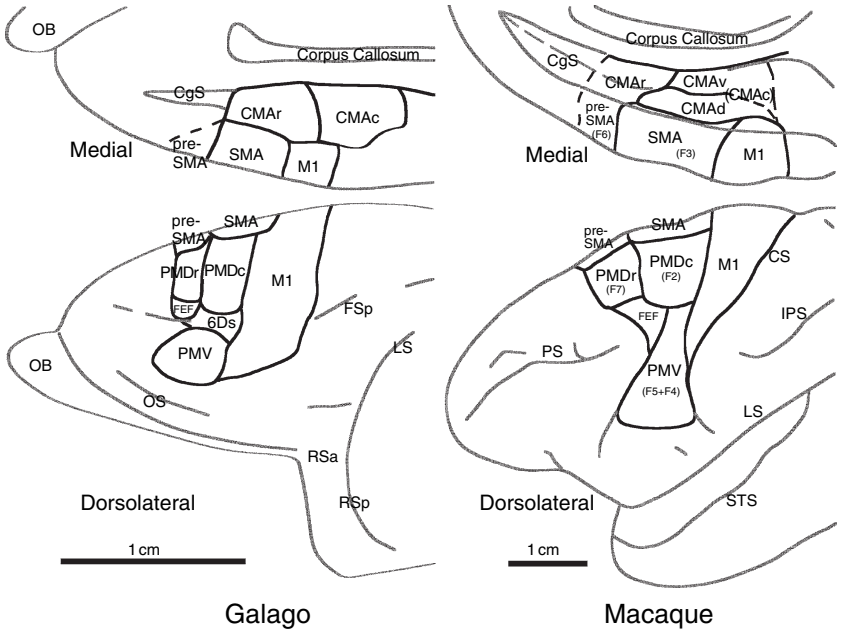

Figure 5 Multiple motor areas in galagos and macaques. Neurologically more primitive primates represented by the prosimian bush baby (*Galago garnetti*; left) have a well-differentiated M1, with representation of the trunk, hindlimb, face, and a large forelimb representation. Galagos possess most of the secondary motor areas that have been recognized in simian primates (macaque shown on right). These results suggest that as many as 10 motor fields emerged early in primate evolution.

In macaques, PMv is subdivided into caudal and rostral divisions based on cytoarchitectonic, connectional, histochemical, and physiological distinctions (Matelli *et al.*, 1985, 1991; Luppino *et al.*, 1999; Rizzolatti and Luppino, 2001; Rizzolatti *et al.*, 2002; Morel *et al.*, 2005).

In macaques, F4 appears to code goal-directed actions mediated by spatial locations (Rizzolatti *et al.*, 2002), and F5 has been shown to be involved in motor-action recognition (Umilta *et al.*, 2001) as well as in hand shaping in visuomotor transformations for grasping and manipulation (Fogassi *et al.*, 2001). Human area 44 has been shown to be involved in sensorimotor transformations for grasping and manipulation (Binkofski *et al.*, 1999) and is thought to be homologous to F5 in macaques (Rizzolatti *et al.*, 2002).

The special role of vision and visuomotor control in primates has led some to suggest that the remarkable increase in the size of the frontal lobes in this order, and perhaps the differentiation of frontal motor areas was driven by the increase in direct and indirect connections of the visual cortex with the frontal, especially motor cortex (Whishaw, 2003). The selective pressures for visually guided forelimb movements may have led to the specialized motor and sensorimotor areas in primates to integrate the somatosensory and visual frames of reference required for skilled movement.

3.28.5.4.3 Differentiation of the supplementary motor area Studies suggest that a supplementary motor area first appeared with prosimian primates, as evidenced by two distinct SMA motor representations corresponding to distinct cytoarchitecture located on the medial surface of the hemisphere in Galago. These two areas are referred to as SMA-proper and the pre-SMA, situated more rostrally (see figures 4 and 5 in Wu *et al.*, 2000). A supplementary motor area has also been identified in New World monkeys (Gould *et al.*, 1986).

Both SMA and pre-SMA (or areas F3 and F4) have been identified in macaques based on cytoarchitecture, intracortical microstimulation, and connections (Matelli *et al.*, 1991; Matsuzaka *et al.*, 1992; Luppino *et al.*, 1993; Rouiller *et al.*, 1999; Liu *et al.*, 2002; Morel *et al.*, 2005). Compared to SMA, pre-SMA has only sparse spinal projections, and high thresholds for evoking movement, and likely plays less of a direct role in the execution of movement (Luppino *et al.*, 1993; He *et al.*, 1995; Dum and Strick, 1996; Liu *et al.*, 2002). Pre-SMA is thought to have greater involvement in cognitive aspects of motor processing.

3.28.5.4.4 The cingulate motor areas Studies suggest that a cingulate motor area first appeared with prosimian primates, as evidenced by two cingulate motor representations and distinct cytoarchitecture in CMAr and CMAc in Galago (Wu *et al.*, 2000). A

third area that also has dense connections with M1 and the spinal cord in Galago was identified posteriorly in cingulate cortex and referred to as the cingulate somatomotor area (CSMA), although this may correspond to a supplementary sensory area (Wu *et al.*, 2000).

The primate cingulate cortex has traditionally been divided into rostral and caudal architectonic subdivisions (areas 24 and 23). More recently, in the macaque, the caudal CMA has been further differentiated into two distinct areas (CMAd and CMAv) based on distinct cytoarchitectonics and intracortical microstimulation studies identifying a third forelimb representation (Walsh and Ebner, 1970; Vogt *et al.*, 1987; Takada *et al.*, 2001; Hatanaka *et al.*, 2003).

Most medially, the rostral, dorsal, and ventral cingulate areas are buried in the cingulate sulcus (CMAr, CMAd, and CMAv, respectively). As with other secondary motor areas, the CMA areas send somatotopic projections directly to M1 and the spinal cord (Muakkassa and Strick, 1979; Dum and Strick, 1991, 1996; Luppino *et al.*, 1993; He *et al.*, 1995; Wang *et al.*, 2001). The somatotopy of CMA has been examined using intracortical microstimulation, demonstrating at least a forelimb representation in each of the subareas of CMA (Mitz and Wise, 1987; Luppino *et al.*, 1991, 1994; Takada *et al.*, 2001; Wang *et al.*, 2001; Hatanaka *et al.*, 2003). Tract-tracing studies in the macaque have shown that the CMAr and the caudal cingulate motor area (involving both CMAd and CMAv) are characterized by distinct patterns of intracortical and thalamocortical connections (Hatanaka, *et al.*, 2003). Functional studies examining cingulate motor areas suggest that CMAr plays a role in the cognitive control of voluntary movements, whereas the caudal CMA (CMAd and CMAv) is directly involved in the execution of voluntary movement (Devinsky *et al.*, 1995; Picard and Strick, 1996, 2001; Carter *et al.*, 1999; Tanji *et al.*, 2002).

3.28.6 Functional Significance of the Evolution of Motor Cortex

Because of the evolutionary changes that occurred in sensorimotor cortex and in the CST, especially in the human lineage, the functional contribution of the motor cortex and its descending outflow to the spinal cord is of natural interest. There is no question that evolutionary trends in motor control occurred in the human lineage resulting in increased dexterity of hand, especially of the digits. Investigators have long sought a morphological basis for the special motor skills of primates, including humans. It has been assumed that major changes must have taken place in the neural control of spinal cord motoneurons, since the peripheral anatomy of primates is remarkably similar (Napier, 1962).

In 1869, Spitzka suggested for the first time that the relative size of the pyramids might be related to the fine control of distal musculature. But even then, Spitzka realized that some species (e.g., seals and sea lions) possess large pyramidal tracts, but poor dexterity. In their review, Heffner and Masterton (1975) argue that among mammals, pyramidal tract morphology (size, number of fibers, fiber size) corresponds more closely to body size than to digital dexterity. However, the role of total number of fibers and fiber size should not be dismissed outright. Somewhat different results are obtained when correlations of pyramidal/CST parameters with digital dexterity are restricted to the human lineage (Heffner and Masterton, 1983). In this analysis, size of the pyramidal tract also becomes significant.

Also, CS morphology has for many years been suggested to be related to the specialized manual skills of primates. The giant Betz cells of M1 are likely to account for a significant proportion of corticomotoneuronal (CM) cells, and thus are likely to play a dominant role in skilled motor coordination. An important question though, is how closely CS soma size (as well as total number of CS neurons) is related to allometric scaling. When this issue was specifically examined, body weight accounts for over 30% of the variance in the number of CS neurons, and over 50% of the variance in their soma size (Nudo *et al.*, 1995). However, in primates, the number of CS neurons and their soma size deviate from the mammalian linear regression line. Primates have greater numbers and larger CS soma size than other mammals for their body weight. Strikingly, CS soma size and number of CS neurons track even more closely with neocortical surface area, which accounts for nearly 70% of the variance in number and over 80% of the variance in soma size in mammals. When this analysis is restricted to primates, neocortical surface area accounts for over 90% of the variance in CS soma size. (There was no significant difference between primates and nonprimates in the relationship between neocortical surface area and number of CS neurons.) Similar findings were found in a recent study of the allometric relationships of the size of Betz cells (Sherwood *et al.*, 2003). The authors suggests that Betz cells become larger in relation to body weight, brain weight, and encephalization quotient, but may not be related to digital dexterity, as others have suggested. Instead, the authors

propose that enlarged Betz cells may play a role in specialized locomotor behaviors in primates.

Before completely discounting the notion that CS soma size or Betz cell size is unrelated to specialized primate motor skills such as digital dexterity, one should consider that correlates of neocortical growth (brain weight, neocortical surface area, encephalization quotient) are not independent of the expansion and differentiation of motor and motor-related structures in primates. In fact, it is possible that morphologic alterations in motor structures (increased size of Betz cells and CS soma, differentiation of motor areas, increased intracortical circuitry, interconnected differentiated motor areas, increased corticofugal output, etc.) were major driving forces giving rise to a larger neocortex, at least in primates. Thus, number and size of CS neurons may still be important correlates of specialized motor skills such as digital dexterity, at least in the human lineage.

Mammals also differ widely in the pattern of CST terminations, and these differences appear to be related to digital dexterity. Heffner and Masterton (1975) showed that the mode of termination of CST fibers – both the extent of the fibers caudally in the cord and the ventral-most lamina in which they terminate – closely parallel the digital dexterity of a species. It is certainly reasonable to presume that animals with dexterous control of distal musculature might have direct cortical innervation of the (lateral) motoneurons that innervate this musculature. While this correlational study provides a rational hypothesis, the data were derived from older degeneration techniques that lack the sensitivity of more modern tract-tracing methods.

More recent neuroanatomical and electrophysiological data seem to corroborate this hypothesis. First, CST neurons that originate from a true motor cortex terminate in deeper laminae of the spinal cord (Ralston and Ralston, 1985). Most terminate in intermediate laminae in monkeys, somewhat more ventral to the termination of CS neurons originating in somatosensory cortex. However, a subset of CS neurons terminate in the ventral horn in the vicinity of motoneurons, and especially those motoneuron pools innervating muscles of the upper extremity. CS neurons originating in the primary motor cortex have the densest terminations to the deep spinal cord lamina where motoneurons innervating hand and finger muscles are located (Maier *et al.*, 2002).

There are also clear differences in the termination pattern of CS neurons among primate species. In some primates, a small subset of CS neurons terminates monosynaptically on motoneurons in the spinal cord. Such CM cells are present most notably in those primate species with the most highly developed digital skills. For example, squirrel monkeys accomplish grasping of objects with a prehensile, or power grip. A precision grip, in which the index finger is opposed to the thumb, is rarely if ever performed (Fragaszy, 1983). In this species, CM connections are relatively weak (Bortoff and Strick, 1993). Macaque monkeys display a precision grip and a number of other complex behaviors with the hand. This species possesses much more dense CM connections (Nakajima *et al.*, 2000). It has also been proposed that increased CM innervation is paralleled by decreased proprioceptive control of spinal cord motoneurons (Lemon and Griffiths, 2005).

Although rodents have surprisingly sophisticated motor control during grasping, and elaborate behavioral descriptions of complex movements of the digits have been reported (Walsh and Ebner, 1970; Iwaniuk and Whishaw, 2000), the termination of CS fibers differs from those in primates. CS neurons in rats tend to terminate in more dorsal laminae. Although there is a sparse termination in lamina IX, there is no evidence of monosynaptic connections between CS fibers and motoneurons (Yang and Lemon, 2003). Thus, control of the distal musculature may have evolved independently in various mammalian orders, and thus, neuroanatomical control mechanisms may differ among these species.

3.28.7 Summary and Conclusions

The evolutionary history of vertebrate motor systems is notable for its remarkable conservation of descending systems originating in upper levels of the neuraxis. All extant vertebrates apparently possess a similar subset of descending pathways that originated early in the evolution of the subphylum. Based on the available evidence from selected extant species, it would appear that the basic vertebrate plan was augmented by additional pathways, but antecedent pathways rarely became degenerate. The mammalian radiation was accompanied by the appearance of a new type of brain structure, a six-layered neocortex. In the earliest mammals, neocortex provided descending fibers to the medulla, and increasingly to the spinal cord. In multiple mammalian orders, a true motor cortex emerged, possibly through parallel or convergent evolution. Motor cortex became increasingly differentiated from the somatosensory cortex, and at least in primate species, terminated closer and closer to motoneuron pools, eventually providing fast, monosynaptic control of spinal cord motoneurons by the

cerebral cortex. At the same time, multiple motor areas became differentiated in the frontal cortex of primates, each with its own unique contribution to cortical motor control.

3.29 The Evolution of the Basal Ganglia in Mammals and Other Vertebrates

A Reiner, University of Tennessee Health Science Center, Memphis, TN, USA

Glossary

agnathans Jawless fish, including the extant lamprey and hagfish.

amniotes Collective term for vertebrate groups whose members develop inside an amniotic sac, and which is a synonym for birds, reptiles, and mammals.

anamniotes Collective term for vertebrate groups whose members do not develop inside an amniotic sac, and which is a synonym for fish and amphibians.

basal ganglia A subcortical telencephalic region that in mammals includes two cell groups, the caudate and putamen (together referred to as the striatum), and a third cell group known as the globus pallidus.

caudate-putamen The input subdivision of the basal ganglia (together referred to as the striatum).

cerebral cortex The part of the mammalian pallium that is organized into six layers and mediates higher-order learning, perception, and motor control.

chondroicthyans Cartilaginous fish, such as skates, rays, sharks, and chimeras.

direct pathway The striatal output pathway to the internal pallidal segment and the substantia nigra, which facilitates desired movement of enkephalin. Opiate neuropeptide characteristically present in the GABAergic spiny striatal neurons of the so-called indirect striatal output neurons that project to the external pallidal segment.

globus pallidus The output subdivision of the basal ganglia.

indirect pathway The striatal output pathway to the external pallidal segment, which inhibits unwanted movement.

neostriatum Outdated synonym for the caudate-putamen that reflects the repudiated notion that the caudate-putamen appeared after the globus pallidus in evolution.

paleostriatum Outdated synonym for the globus pallidus that reflects the repudiated notion that the globus pallidus appeared before the caudate-putamen in evolution.

pallidum Short-hand term referring to the globus pallidus.

pallium Term referring to the part of the telencephalon (cerebrum) that lies above and/or around the basal ganglia.

sauropsids Collective term for birds and reptiles.

striatum Short-hand term for the input part of the basal ganglia, also known as the caudate-putamen in mammals.

subpallium Term referring to the part of the telencephalon that lies below the pallium.

substance P Tachykinin neuropeptide characteristically present in the GABAergic spiny striatal neurons of the so-called direct striatal output neurons that project to the internal pallidal segment and the substantia nigra.

substantia nigra Cell group in the midbrain tegmentum, in mammals consisting of two parts, a pars compacta rich in dopaminergic neurons and a pars reticulata rich in GABAergic neurons.

subthalamic nucleus Cell group in the lower thalamus of mammals that receives input from the external pallidal segment and projects to the internal pallidal segment

tetrapods Collective term referring to the limbed vertebrate groups, and it includes amphibians, reptiles, birds, and mammals.

3.29.1 Introduction

The basal ganglia is a subcortical telencephalic region that includes two cell groups, the caudate and putamen (together referred to as the striatum), and a third cell group known as the globus pallidus. Whereas additional cell groups such as the nucleus accumbens, the olfactory tubercle, and the ventral pallidum are sometimes considered to be part of the basal ganglia (Heimer *et al*., 1985, 1997; Reiner *et al*., 1998), for present purposes these will be considered the limbic or ventral basal ganglia and regarded as a separate entity from the basal ganglia. Understanding of the organization and function of the basal ganglia of mammals has increased tremendously in the past 100 years. When the term basal ganglia first became commonplace in the late 1800s, it loosely referred to various subcortical telencephalic cell groups (i.e., the basal nuclei) that included the amygdala and claustrum (and in some cases the thalamus), as well as what are now regarded as the basal ganglia (Parent, 1986). Without reliable methods for tracing brain connectivity, knowledge of the basal ganglia largely consisted of efforts to identify the same cell groups in diverse species, with some inferences made about a role in motor function from clinical findings (Vogt, 1911; Wilson, 1912). This early view suggested that the basal ganglia and cerebral cortex exerted separate control on motor function: the motor cortex via projections to brainstem and spinal cord via the pyramidal tract, and the basal ganglia via nonpyramidal circuits. Thus, motor control was thought to be effected by pyramidal and extrapyramidal motor systems.

With the advent of silver staining of degenerating fibers in the 1950s, it was soon recognized that the caudate and putamen receive extensive cortical input and have extensive projections to the globus pallidus and substantia nigra (Carman *et al*., 1963; Nauta and Mehler, 1966; Parent, 1986). The globus pallidus, in turn, was found to project to thalamic cell groups projecting to motor cortices (Nauta and Mehler, 1966). These findings indicated that the role of the basal ganglia in motor control involved cortical input and was mediated by a return projection to motor cortex. Neurochemical methods developed in the 1960s revealed a major nigral input to striatum that used dopamine (DA) as a neurotransmitter and led to the discovery that loss of this input was the basis of Parkinson's disease (Carlsson, 1959; Carlsson *et al*., 1962; Dahlstrom and Fuxe, 1964). Understanding of the cellular makeup of the basal ganglia, the neurotransmitters used by its neurons, and delineation of its circuitry at a cellular level accelerated greatly with the application of immunohistochemistry in the 1970s, and of *in situ* hybridization histochemistry in the 1980s, to the study of the basal ganglia (Parent, 1986; Reiner and Anderson, 1990; Gerfen, 1992; Graybiel, 1990). Finally, over the past 10 years, great advances have been made in identifying the genes controlling the regional identity and development of the striatum, globus pallidus, and cerebral cortex. These genes include *Dlx1* and *Dlx2*, which specify the striatum and pallidum, and *Nkx2.1*, which specifies the globus pallidus (Rubenstein *et al*., 1994; Smith-Fernandez *et al*., 1998; Puelles *et al*., 2000). Other genes control pallial identity, such as *Emx1*, *Emx2*, and *Tbr1*, and are expressed at high levels in developing cerebral cortex (Rubenstein *et al*., 1994; Smith-Fernandez *et al*., 1998; Puelles *et al*., 2000). Projection neurons of the cerebral cortex and other pallial telencephalic areas characteristically use glutamate as their neurotransmitter, whereas those of the subpallium (to which the basal ganglia belongs) characteristically are GABAergic (Swanson and Petrovich, 1998).

This accumulation of data, together with insights from physiology, pharmacology, and molecular biology, led to circuit level models of basal ganglia function that relate the major aspects of basal ganglia cytology and circuitry to normal and pathological basal ganglia function (Albin *et al*., 1989; Crossman, 1990; DeLong, 1990). In these models, the striato-pallidal output circuitry is recognized as being organized into two channels. One arises from substance P (SP)-containing GABAergic striatal neurons that project to the large GABAergic neurons of the internal segment of globus pallidus (GPi) that promote movement. The second output arises from enkephalinergic (ENK^+) GABAergic striatal neurons that project to the large GABAergic neurons of the external segment of globus pallidus (GPe) that inhibit unwanted movement (Figure 1). The GPe neurons have indirect outputs to GPi neurons via the subthalamic nucleus (STN) and for this reason the SP^+ striatal projection to the GPi is called the direct pathway and the ENK^+ striatal projection to GPi via the GPe–STN connection is called the indirect pathway. Identification of the cell types of the basal ganglia by their neurotransmitter

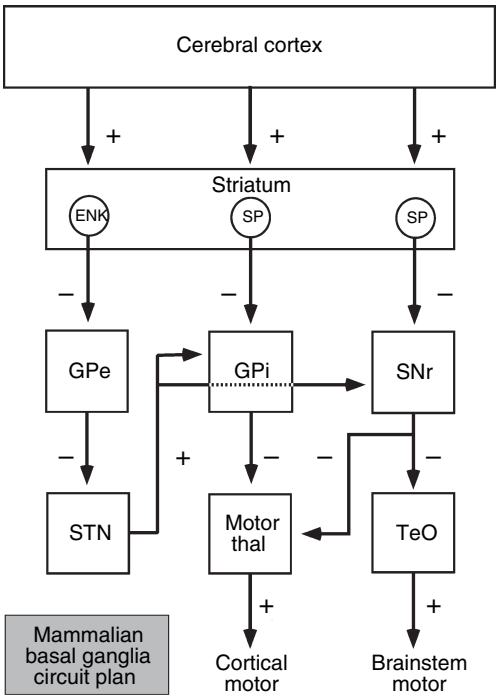

Figure 1 Circuit diagram illustrating the basic direct–indirect pathway organization of basal ganglia functional circuitry in mammals. The plus and minus signs indicate whether the specific projections of the basal ganglia circuitry are glutamatergic excitatory (+) or GABAergic inhibitory (–). ENK, enkephalinergic neurons; GPe, external globus pallidus segment; GPi, internal globus pallidus segment; SNr, substantia nigra pars reticulata; SP, substance P-containing neurons; STN, subthalamic nucleus; TeO, optic tectum; Motor thal, motor thalamus.

content and the genes controlling their identity led to the realization that the interneurons of both the striatum and the cerebral cortex, which tend to be GABAergic, migrate in from the Nkx2.1-expressing zone from which the globus pallidus also forms (Marin *et al*., 2000; Marin and Rubenstein, 2001). For striatum, these include three major neurochemically distinct types of interneurons: large cholinergic neurons, large GABAergic neurons co-containing parvalbumin (PARV), and small GABAergic neurons co-containing the neuropeptides somatostatin and neuropeptide Y and the nitric oxide (NO)-synthesizing enzyme NO synthetase (Kawaguchi *et al*., 1995).

Before the advent of modern neuroanatomical hodological methods, several investigators formulated a theory of basal ganglia and overall telencephalic evolution based strictly on the size, position, and cytological appearance of the major telencephalic regions (Edinger *et al*., 1903; Edinger, 1908; Ariëns-Kappers *et al*., 1936). This theory resulted in terminologies for both mammalian and nonmammalian telencephalons that have proven enduring, even in the face of their thorough repudiation by modern data. In this traditional terminology, the globus pallidus in mammals is alternatively referred to as the paleostriatum, whereas the caudate–putamen is called the neostriatum. These terms stem from the notion that the parts of the telencephalon had evolved in serial order during vertebrate evolution: the globus pallidus in jawed fish, the neostriatum in amphibians, and the primitive cerebral cortex in reptiles (Ariëns-Kappers *et al*., 1936). Mammals were thought to have elaborated cerebral cortex into neocortex, whereas birds were thought to have elaborated the basal ganglia by addition of a new territory known as the hyperstriatum. This view of telencephalic evolution has been refuted by modern neuroanatomical, molecular biological, and neurochemical studies, but vestiges of it have survived in the frequent use of the terms paleostriatum and neostriatum to refer to the globus pallidus and caudate–putamen in mammals and in the telencephalic terminology that was formerly used in birds (Reiner *et al*., 2004). Older views of telencephalic evolution also promoted the idea that a process of encephalization had occurred during vertebrate evolution, with more rostral structures taking over functions carried out by more caudal regions (Ariëns-Kappers *et al*., 1936; Herrick, 1948, 1956). In the case of telencephalic evolution, the cerebral cortex was thought to take over behaviors that had been carried out by the basal ganglia in a stereotyped fashion in the stem amniote common ancestors of mammals, birds, and reptiles, and still were carried out by the basal ganglia in modern birds and reptiles. The implication of this for mammals was the expectation that the cerebral cortex and basal ganglia size should be dissociated or inversely related.

The neuroanatomical tools that have been used to clarify the cellular neurochemistry and connectivity of the basal ganglia of mammals and determine the genetic control of regional identity in the developing mammalian telencephalon have been used to study telencephalic organization and development in members of other vertebrate groups as well (Parent, 1986; Reiner *et al*., 1998; Marin *et al*., 1998a, 1998b). These studies have dramatically revised our understanding of basal ganglia evolution and have profound implications for the traditional view of basal ganglia evolution that still is all too often promulgated in neuroanatomy textbooks. In the following paragraphs, I discuss evidence showing that both a striatum and a pallidum have been basal ganglia constituents since early in vertebrate evolution. I also examine data emphasizing the functional interrelatedness of cerebral cortex and basal ganglia, with both enlarging in parallel during brain expansion in the mammalian radiation.

3.29.2 Anamniote Basal Ganglia Evolution

3.29.2.1 Agnathans

There are two extant groups of jawless fish: hagfish and lamprey. Modern taxonomic studies suggest lamprey and hagfish to be only distantly related, with lamprey being a sister group of jawed vertebrates (Forey and Janvier, 1994). Telencephalic organization in these two agnathan groups reflects their taxonomic distance (see Evolution of the Deuterostome Central Nervous System: An Intercalation of Developmental Patterning Processes with Cellular Specification Processes). Neurochemical studies clearly identify a ventral telencephalic region rich in SP^+ perikarya in lamprey (Table 1; Figure 2; Nozaki and Gorbman, 1986; Auclair *et al*., 2004). This region receives a dopaminergic input from the midbrain and has a return projection to these dopaminergic neurons (Pierre *et al*., 1994; Pombal *et al*., 1997a). This region also expresses lamprey homologues of *Dlx1/2* (Murakami *et al*., 2001; Neidert *et al*., 2001) and contains some cholinergic interneurons (Pombal *et al*., 2001). For these reasons, this region appears to be homologous to the mammalian striatum. Although a globus pallidus in lamprey has not been demonstrated unequivocally (Nieuwenhuys and Nicholson, 1998; Murakami *et al*., 2001), SP^+ woolly fibers ventrolateral to the striatum in a field of GABAergic neurons within a region that has been called the ventral pallium delineate a field that may be pallidal (Pombal *et al*., 1997b). Alternatively, SP^+ woolly fibers ventromedial to the striatum define a field that may be pallidal (Figure 2; Nozaki and Gorbman, 1986). By contrast, SP and ENK immunolabeling fails to unequivocally identify a striatum or pallidum in hagfish (Wicht and Northcutt, 1994). Although lampreys clearly possess a striatum, the region is small and neuron sparse and the midbrain dopaminergic input is meager. Telencephalic inputs or descending projections of the lamprey striatum have not been investigated and not much is known of lamprey basal ganglia functional circuitry (Table 1).

3.29.2.2 Chondroicthyans

Cartilaginous fish possess simple tubular paired telencephalic hemispheres, as do lobe-finned fish and amphibians, and the ventrolateral sector of the telencephalon contains both a striatum and a globus pallidus, by neurochemical and hodological criteria (Table 1; Figure 2; Reiner and Carraway, 1985; Northcutt *et al*., 1988; Reiner *et al*., 1998). The striatal sector is located nearest the ventricle and is cell sparse, but contains SP^+ and ENK^+ neurons that give rise to projections to a cell plate lying external to the striatal field (Figure 2). This cell plate appears comparable to the globus pallidus, both because of this striatal input and because the neurons of the pallidal field contain the neurotensin-related hexapeptide LANT6 (Lys^8–Asn^9–neurotensin$^{8-13}$), which is present in mammalian pallidal neurons (Northcutt *et al*., 1988; Reiner and Carraway, 1985, 1987; Reiner, 1987a; Rodriguez-Moldes *et al*., 1993). In this pallidal field, the SP^+ and ENK^+ inputs overlap, indicating that GPi- and GPe-type neurons are intermingled. Moreover, the striatum receives a dopaminergic input from the midbrain and these dopaminergic neurons receive a return projection from SP^+ striatal neurons (Meredith and Smeets, 1987; Northcutt *et al*., 1988; Smeets and Reiner, 1994; Steusse *et al*., 1994). The pallium occupies the dorsolateral sector of the telencephalon in cartilaginous fish, its development is controlled by homologues of some of the same genes controlling pallial development in mammals (Derobert *et al*., 2002), and this region is larger and more complex in the more advanced cartilaginous fish (Northcutt, 1981a; Northcutt *et al*., 1988). Although not experimentally demonstrated, it seems likely that *Dlx* homologues control subpallium development in cartilaginous fish, given their expression in lamprey and bony fish subpallium (Murakami *et al*., 2001; Neidert *et al*., 2001; Stock *et al*., 1996) and their demonstrated existence in cartilaginous fish (Stock, 2005). Interneuron populations of the striatum in cartilaginous fish have not been extensively studied, but appear to be sparse at best (Reiner *et al*., 1998).

3.29.2.3 Osteicthyes – Ray-Finned versus Lobe-Finned Fish Divergence

Bony fish diverged into two very different groups early in their evolution (Nieuwenhuys, 1966; Northcutt, 1981a). One group, the lobe-finned fish, possesses the same paired tubular evaginated telencephalons as cartilaginous fish and includes the ancestors of amphibians. The other group, the ray-finned fish, evolved a very different telencephalic morphology, referred to as the everted telencephalon (see Evolution of the Nervous System in Fishes). In both groups, a basal ganglia has been demonstrated by modern hodological, neurochemical, and developmental criteria (Table 1; Figure 2; Reiner *et al*., 1998). For lobe-finned fish, the topography and cytology of the basal ganglia resemble those in cartilaginous fish (Reiner and Northcutt, 1987), whereas the peculiarities of the ray-finned fish telencephalon have rendered basal ganglia

Table 1 Summary of the major features of basal ganglia organization and whether those features are present in the major extant vertebrate groups possessing an evaginated telencephalon

Animal group	*Striatum*	*Pallidum*	*SP^+ striato-pallidal pathway*	*ENK^+ striato-pallidal pathway*	*SP^+ striato-nigral pathway*	*DA^+ nigro-striatal pathway*	*Glu^+ thalamo-striatal pathway*	*BG pretecto-tectal pathway*	*Glu^+ cortico-striatal pathway*	*GPe and GPi neuron location*	*GPe- STN-GPi pathway*	*GPi-thalamo-cortical pathway*
Lamprey	Present	Present	Present	Present	Present	Modest	Unknown	Unknown	Unlikely	Unknown	Unknown	Unlikely
Cartilaginous fish	Present	Present	Present	Present	Present	Modest	Unknown	Unknown	Unlikely	Intermixed	Unknown	Unlikely
Lobe-finned bony fish	Present	Present	Present	Present	Present	Modest	Unknown	Unknown	Unlikely	Intermixed	Unknown	Unlikely
Amphibians	Present	Present	Present	Present	Present	Modest	Present	Present	Negligible	Intermixed	Unknown	Absent
Reptiles	Present	Present	Present	Present	Present	Prominent	Present	Present	Present	Intermixed	Likely present	Likely present
Birds	Present	Present	Present	Present	Present	Prominent	Present	Present	Present	Intermixed	Present	Present
Mammals	Present	Present	Present	Present	Present	Prominent	Present	Indistinct	Present	Segregated	Present	Present

The table emphasizes that basal ganglia evolution was highly conservative among anamniotes, with the major changes occurring at the anamniote–amniote transition. A few additional changes have occurred in the evolutionary transition from stem amniotes to mammals. BG, basal ganglia; DA, dopaminergic; ENK^+, enkephalinergic; Glu^+, glutamatergic; GPe, external segment of globus pallidus; GPi, internal segment of globus pallidus; SP^+, substance P-containing; STN, subthalamic nucleus.

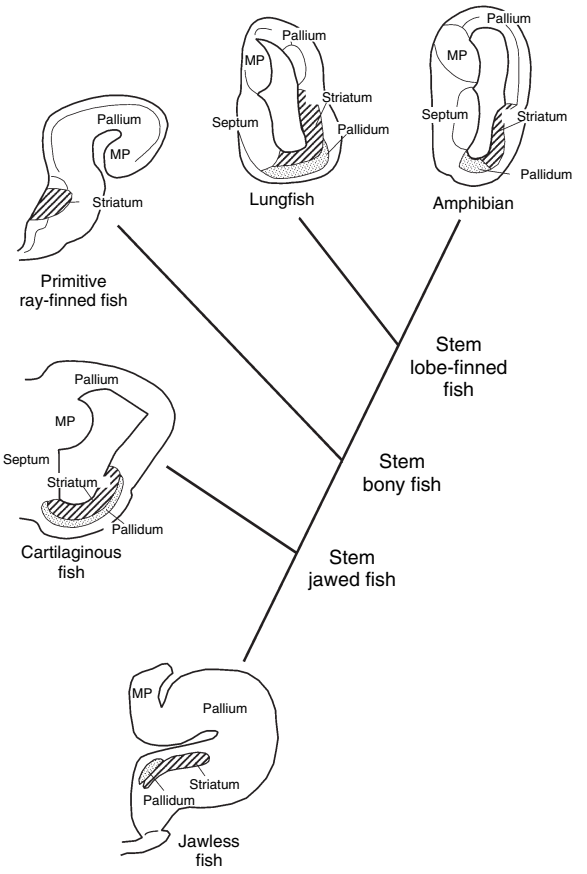

Figure 2 Schematics of frontal sections through the basal ganglia of the right telencephalic hemisphere in representative species from five anamniote groups: a lamprey (jawless fish), a shark (cartilaginous fish), a polypterid (ray-finned bony fish), a lungfish (lobe-finned bony fish), and a frog (amphibian), arranged according to their evolutionary divergences. The basal ganglia in all groups with an evaginated telencephalon (lamprey, shark, lungfish, and frog) consists of a striatum and a pallidum located in the basal telencephalon, beneath the pallial regions. Note that the pallium contains a medial (hippocampal) pallium (MP) in all amniote groups, with the medial pallium located laterally in ray-finned fish due to their telencephalic eversion. A striatum is evident in the ventral uneverted part of the telencephalon in ray-finned fish, but a pallidum is not well defined. Medial is to the left and dorsal to the top in all schematized sections.

topography and cytology less reminiscent of those in cartilaginous fish (Reiner and Northcutt, 1992). For example, in lungfish, the only lobe-finned fish whose basal ganglia has been studied (Reiner and Northcutt, 1987), the ventrolateral sector of the telencephalon contains both a striatum and a globus pallidus, by neurochemical and hodological criteria (Table 1). As in cartilaginous fish, the striatal sector contains SP^+ and ENK^+ neurons, but unlike in cartilaginous fish these are located in a cell-rich periventricular zone of neurons. The SP^+ and ENK^+ striatal neurons give rise to projections to a ventrocaudal neuronal cell group that appears comparable to globus pallidus (Figure 2), both because of this striatal input and because its neurons contain the neuropeptide LANT6. In this pallidal field, the SP^+ and ENK^+ inputs overlap, indicating that GPi- and GPe-type neurons are intermingled. Moreover, the striatum receives a dopaminergic input from the midbrain and these dopaminergic neurons receive a return projection from SP^+ striatal neurons (Reiner and Northcutt, 1987). The major populations of interneurons characterizing the striatum of amniotes may be scarce in lobe-finned fish basal ganglia (Reiner and Northcutt, 1987; Reiner *et al.*, 1998). The pallium occupies the dorsal sector of the telencephalon, but it is unknown whether it projects to the striatum.

In ray-finned fish, a striatum containing SP^+ and ENK^+ neurons (Reiner and Northcutt, 1992; Reiner *et al.*, 1998), likely to be GABAergic (Martinoli *et al.*, 1990; Medina *et al.*, 1994), having reciprocal connections with midbrain dopaminergic neurons (Reiner and Northcutt, 1992; Reiner *et al.*, 1998; Rink and Wullimann, 2001), and expressing a *Dlx1/2* homologue has been identified (Stock *et al.*, 1996; Wullimann and Mueller, 2004). Consistent with a dopaminergic input, the striatum in ray-finned fish is enriched in D1 and D2 dopamine receptors (Kapsimali *et al.*, 2000; Vacher *et al.*, 2003). A pallidal field may be present in the subpallium, since a ventral part of the subpallium expresses an *Nkx2.1* homologue (Wullimann and Mueller, 2004). The pallium in at least the more advanced ray-finned fish (i.e., teleosts with a large pallium) projects to the striatum and thalamic projections to the striatum appear to be present in all ray-finned fish (Northcutt, 1981b; Rink and Wullimann, 2004). The major populations of interneurons characterizing the striatum of amniotes are scarce in ray-finned fish basal ganglia (Reiner and Northcutt, 1992; Reiner *et al.*, 1998). The extent to which the divergent evolution of the ray-finned fish telencephalon has affected the circuitry or function of the basal ganglia is uncertain. Nonetheless, as in mammals, loss of DA^+ input to ray-finned fish striatum results in 'Parkinsonian' symptoms, i.e., slowed movements or bradykinesia (Pollard *et al.*, 1992). In any event, since ray-finned fish are not on the evolutionary line to mammals, further consideration of ray-finned fish basal ganglia anatomy is not entirely relevant here.

3.29.2.4 Amphibians

The telencephalon in amphibians is tubular in shape and its neurons largely occupy a periventricular position. This similarity to lobe-finned fish reflects the

evolutionary origin of amphibians from lobe-finned fish (Figure 3; see Evolution of the Amphibian Nervous System). The major features of basal ganglia organization demonstrated for lobe-finned fish and cartilaginous fish have also been demonstrated for amphibians (Table 1; Marin *et al*., 1998b; Reiner *et al*., 1998). Additionally, considerable hodological and developmental data are available for amphibians that definitively clarify many aspects of amphibian basal ganglia organization vis-à-vis that of amniotes (Table 1). For example, the ventrolateral sector of the telencephalon contains both a striatum and a globus pallidus, by neurochemical, hodological, and molecular developmental criteria. As in cartilaginous and lobe-finned fish, immunolabeling shows that the striatal sector contains SP^+ and ENK^+ neurons (Marin *et al*., 1997, 1998a, 1998b; Reiner *et al*., 1998), with the identity of the striatum further confirmed by the expression of glutamic acid decarboxylase (GAD) and an amphibian homologue of *Dlx1/2* (Papalopulu and Kintner, 1993; Bachy *et al*., 2002; Brox *et al*., 2003). Moreover, the SP^+ and ENK^+ striatal neurons give rise to projections to a ventrocaudal cell group that appears to be comparable to the globus pallidus (Figure 2), because of this striatal input, because it contains large GABAergic neurons, and because it expresses a homologue of *Nkx2.1* (Marin *et al*., 1998a, 1998b; Gonzalez *et al*., 2002; Brox *et al*., 2003). As is true in other anamniote groups, the SP^+ and ENK^+ inputs overlap in this pallidal field, indicating that GPi- and GPe-type neurons are intermingled. The amphibian striatum receives a dopaminergic input from the midbrain and these dopaminergic neurons receive a return projection from SP^+ striatal neurons (Table 1; Gonzalez and Smeets, 1994; Marin *et al*., 1998a, 1998b; Reiner *et al*., 1998). Both striatum and pallidum are, nonetheless, typically much more cell poor in amphibians, and the dopaminergic input more modest, than they are in amniotes. The types of interneurons characterizing the striatum of amniotes also seem to be scarce in amphibian basal ganglia (Reiner and Northcutt, 1992; Marin *et al*., 1997; Gonzalez *et al*., 2002; Reiner *et al*., 1998). The pallium occupies the dorsolateral sector of the telencephalon, but the major excitatory input to the striatum appears to arise from the thalamus rather than the pallium (Kicliter, 1979; Wilczynski and Northcutt, 1983; Marin *et al*., 1998b; Reiner *et al*., 1998). The basal ganglia in amphibians appears to have its major output to motor areas via a projection to the pretectum and a homologue of the substantia nigra pars reticulata, both of which affect head and eye movements by an input to tectal neurons with descending projections (Wilczynski and Northcutt, 1983; Marin *et al*., 1998b; Reiner *et al*., 1998). As in mammals, loss of dopaminergic input to amphibian striatum results in bradykinesia (Barbeau *et al*., 1986).

3.29.3 Amniote Basal Ganglia Evolution

3.29.3.1 Reptiles

Whereas the telencephalic hemispheres of reptiles also possess the same tubular evaginated structure as in amphibians during early development, the pallial and subpallial sectors of the telencephalon become much more cell rich than those in amphibians (Figures 3 and 4; Reiner *et al*., 1998). The

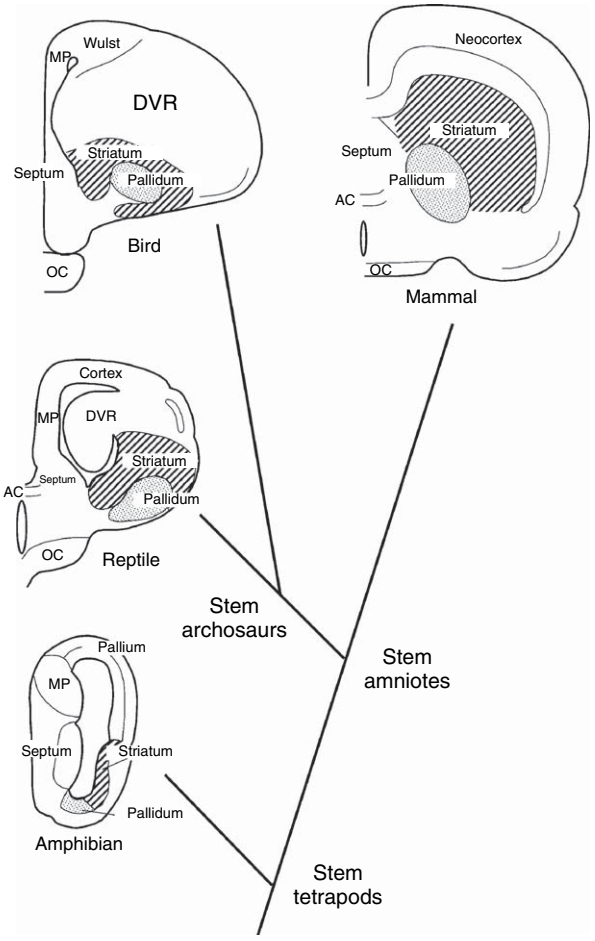

Figure 3 Schematics of frontal sections through the basal ganglia of the right telencephalic hemisphere in representative species from four tetrapod groups: amphibian (a frog), reptile (a turtle), bird (a pigeon), and mammal (a rat), arranged according to their evolutionary divergences. The basal ganglia in all four groups consists of a striatum and a pallidum located in the basal telencephalon, beneath the pallial regions. The pallidum, however, tends to be more laterally located in reptiles and birds than in amphibians and mammals. The phylogenetic distribution of pallidal laterality suggests that this trait arose in the reptilian lineage and was retained in birds. Medial is to the left and dorsal to the top in all schematized sections. AC, anterior commissure; MP, medial pallium; OC, optic chiasm.

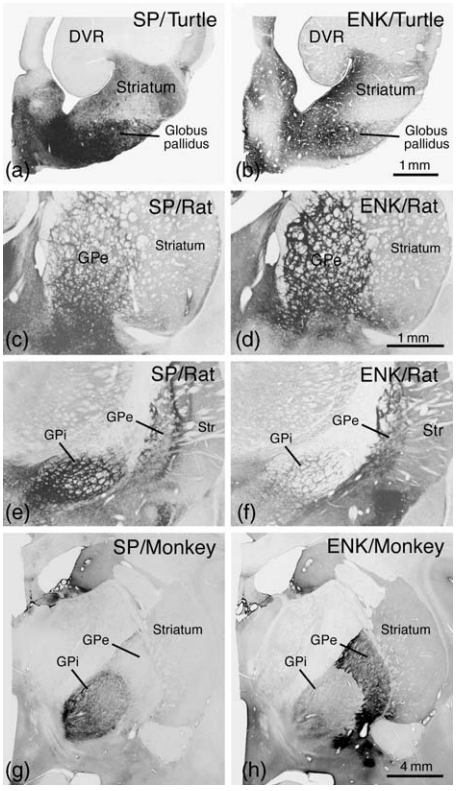

Figure 4 Images of frontal sections through the basal ganglia of one telencephalic hemisphere in a turtle (a), (b), rat (c–f), and rhesus monkey (g), (h). Sections were immunohistochemically stained for substance P (SP) (left-hand column) or enkephalin (ENK) (right-hand column). Note the intense SP^+ and ENK^+ immunoreactivity in the ventrolateral wall of the telencephalon that defines the region of the striatum and distinguishes it from the dorsal ventricular ridge (DVR) of the overlying pallium in the case of turtle. As in mammals, the striatum region is rich in SP^+ immunoreactivity due to the presence of numerous SP^+ and ENK^+ neurons and their processes. Note also that the globus pallidus in turtle is rich in both SP^+ and ENK^+ fibers, indicating that in turtles the ENK^+ fiber recipient GPe-type and SP^+ fiber recipient GPi-type pallidal neurons are intermingled. By contrast, in rats and monkeys GPe and GPi pallidal neurons are spatially segregated, more so in rat than in monkey. Medial is to the left and dorsal to the top in all images. GPe, external segment of globus pallidus; GPi, internal segment of globus pallidus; Str, striatum.

basal ganglia of reptiles reflects its inheritance from amphibians, but shows some differences that reflect the elaboration of the thalamus and pallium in reptiles (Table 1; see Evolution of the Nervous System in Reptiles). For example, as in amphibians, the ventrolateral sector of the reptile telencephalon contains both a striatum and a globus pallidus, by neurochemical, hodological, and developmental molecular criteria (Reiner *et al.*, 1998; Smith-Fernandez *et al.*, 1998). Also as in amphibians, immunolabeling shows that the striatal sector contains SP^+ and ENK^+ neurons (Reiner, 1987b; Russchen *et al.*, 1987; Reiner *et al.*, 1998), with the identity of the striatum further confirmed by the expression of GAD or GABA (Bennis *et al.*, 1991), and a homologue of *Dlx1/2* (Smith-Fernandez *et al.*, 1998). Moreover, the SP^+ and ENK^+ striatal neurons give rise to projections to a ventrocaudal cell group that is comparable to globus pallidus, because of this striatal input, because it contains large GABAergic neurons (Bennis *et al.*, 1991), and because its neurons contain LANT6 (Reiner and Carraway, 1987; Reiner *et al.*, 1998). The globus pallidus is, however, somewhat more laterally migrated than in amphibians (Figure 3). As is true in anamniotes, the SP^+ and ENK^+ inputs overlap in globus pallidus, indicating that GPi- and GPe-type neurons were intermingled in the stem amniotes (Figure 4). The reptile striatum receives a much more substantial dopaminergic input from the midbrain than in amphibians and these dopaminergic neurons in turn receive a substantial return projection from SP^+ striatal neurons (Smeets and Reiner, 1994; Reiner *et al.*, 1998). As in mammals, dopaminergic effects on striatum are mediated by D1 and D2 dopamine receptors, with DA agonists inducing hyperkinesia and DA antagonism yielding hypokinesia, indicating a similar role of the dopaminergic system in modulating striatal output as in mammals (Andersen *et al.*, 1975; Richfield *et al.*, 1987; Reiner *et al.*, 1998).

A distinguishing feature of the basal ganglia in reptiles is that it is much larger and more neuron rich than that in amphibians. Concomitant with the basal ganglia enlargement, the pallium in reptiles is also enlarged and is the source of a major excitatory input to the striatum, with the thalamus also providing excitatory input (Gonzalez *et al.*, 1990; Butler, 1994a, 1994b; Reiner *et al.*, 1998). Moreover, the glutamate receptors employed by specific types of striatal neurons to respond to this excitatory input in reptiles are very similar to those in mammals (Fowler *et al.*, 1999). These features of living reptiles indicate that a major telencephalic enlargement and elaboration of corticostriatal circuitry occurred by the evolutionary appearance of stem amniotes (Figure 5; Reiner, 2002). The three major types of striatal interneurons characteristic of the mammalian basal ganglia (cholinergic, $PARV^+$, and somatostatinergic) are also present in the striatum in living reptiles, although they are not as highly abundant as in mammals (Powers and Reiner, 1993; Reiner and Carraway, 1987; Reiner *et al.*, 1998). The basal ganglia in reptiles has its major output to motor areas via a projection to the pretectum and to the tegmentum (a substantia nigra pars reticulata (SNr) homologue), which affect head and eye movements

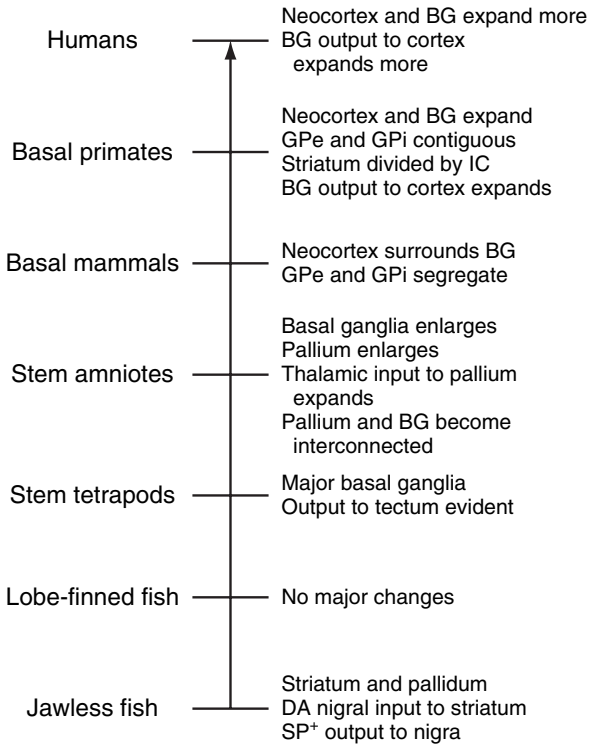

Figure 5 Time line indicating the points in the evolutionary line from jawless fish to humans at which major changes occurred in the basal ganglia.

by input to tectal neurons with descending projections to brainstem premotor cell groups (Reiner *et al*., 1980, 1998; Medina and Smeets, 1991).

3.29.3.2 Birds

Birds evolved from archosaurian reptiles, of which crocodilians are the only other living group (Chiappe, 1995). Unsurprisingly, therefore, the basal ganglia in birds highly resembles that in reptiles, with the main differences in the available data stemming from the overall telencephalic enlargement in birds and the deeper insights into basal ganglia anatomy and function stemming from the more extensively studied nature of birds (Table 1; Figure 4). For example, as in reptiles, the ventrolateral sector of the avian telencephalon contains both a striatum and a globus pallidus, as defined by neurochemical, hodological, and developmental molecular criteria (Reiner *et al*., 1998). Also as in reptiles, immunolabeling shows that the striatal sector contains SP^+ and ENK^+ neurons (Reiner *et al*., 1998), with the identity of the striatum further confirmed by the expression of GAD or GABA (Veenman and Reiner, 1994), and a homologue of *Dlx1/2* (Smith-Fernandez *et al*., 1998; Puelles *et al*., 2000). Moreover, the SP^+ and ENK^+ striatal neurons give rise to projections to a ventrocaudal cell group that is comparable to globus pallidus, because of this striatal input, because it contains large GABAergic neurons that also contain LANT6, and because its neurons express *Nkx2.1* (Karten and Dubbeldam, 1973; Reiner and Carraway, 1987; Veenman and Reiner, 1994; Reiner *et al*., 1998; Puelles *et al*., 2000). As in reptiles, this cell group is more laterally migrated than in lobe-finned fish, amphibians, or mammals, indicating that the pallidum was more medially located in stem amniotes and that the lateral migration of pallidal neurons evolved in the reptile–bird lineage (Figure 4). The three major types of striatal interneurons characteristic of the mammalian basal ganglia (cholinergic, $PARV^+$, and somatostatinergic) are present in striatum in living birds and as abundant as those in mammals (Medina and Reiner, 1994; Reiner and Carraway, 1987; Reiner *et al*., 1998). The reptilian striatum receives a dopaminergic input from the midbrain and these dopaminergic neurons receive a return projection from SP^+ striatal neurons (Reiner *et al*., 1994, 1998). As in reptiles and mammals, dopaminergic effects on striatum are mediated by D1 and D2 dopamine receptors, with DA agonists inducing hyperkinesia and DA antagonism yielding hypokinesia, indicating a similar role of the dopaminergic system in modulating striatal output as in mammals (Nistico *et al*., 1983; Richfield *et al*., 1987; Dietl and Palacios, 1988; Yanai *et al*., 1995; Reiner *et al*., 1998; Sun and Reiner, 2000; Reiner, 2002).

The pallium occupies the dorsolateral sector of the telencephalon, is much expanded in birds, and is the source of a massive excitatory input to the striatum (Veenman *et al*., 1995; Veenman and Reiner, 1996), with the thalamus also providing excitatory input (Wild, 1987; Reiner *et al*., 1998). The communication between pallium and striatum in birds appears to be mediated by the same two corticostriatal cell types as in mammals (Cowan and Wilson, 1994; Veenman *et al*., 1995; Reiner *et al*., 2001, 2003) and by the same cell type-specific glutamate receptors in striatum as in mammals (Reiner, 2002). The avian basal ganglia has its major output to motor areas via a projection to the pretectum and the tegmentum (an SNr homologue), which affect head and eye movements by input to tectal neurons with descending premotor and motor projections (Reiner *et al*., 1998). Additionally, birds possess a correspondent of the mammalian striato-pallido-thalamic circuit to motor cortex (Medina *et al*., 1997; Medina and Reiner, 2000), which suggests that one may be present in reptiles as well (see Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor

Cortices?). These various striatal output pathways to pretectum, tegmentum, and thalamus are all direct pathway type outputs that appear to facilitate behavior (Reiner *et al*., 1998). Birds have also been shown to possess a subthalamic nucleus and indirect pathway circuitry, as well (Jiao *et al*., 2000). The organization of the avian basal ganglia into direct and indirect striatal output circuits closely resembling those in mammals, and the presence of both SP^+ and ENK^+ striatal outputs in reptiles as well, suggests that the direct–indirect pathway plan of basal ganglia functional organization was already present in stem amniotes (Reiner, 2002).

3.29.3.3 Mammals

A few major changes in telencephalic morphology appear to have occurred in the evolution of the mammalian basal ganglia from the inferred stem amniote condition. First, from a simple, poorly laminated state, the pallium evolved into the multilayered neocortex that came to wrap around the basal ganglia (Karten, 1969; Puelles *et al*., 2000; Reiner, 2000, 2002). As a consequence, the basal ganglia occupies a more central position in the telencephalon than it does in nonmammals (Figures 2–4). The development of the basal ganglia versus the neocortex, however, reflects its ancestral basal position. The globus pallidus develops from an *Nkx2.1*- and *Dlx1/2*-expressing bulge (called the medial ganglionic eminence, or MGE) at the lower aspect of the lateral telencephalic wall and the striatum develops from *Dlx1/2*-expressing bulge that does not express *Nkx2.1* just above the MGE (called the lateral ganglionic eminence). By a process of extensive lateroventral migration from the pallium, where it meets the subpallium, the neocortex comes to surround the basal ganglia in mammals (Alvarez-Bolado and Swanson, 1996). Unlike in nonmammals, in which GPi and GPe neurons are intermingled, in mammals these pallidal populations occupy separate sectors, in either of two arrangements (Figure 5). In primates, the GPe and GPi are contiguous and distinguishable by their differential neurochemistry, namely, an enrichment in ENK^+ terminals from striatum in GPe and an enrichment in SP^+ terminals from striatum in GPi (Parent, 1986; Reiner *et al*., 1999; Hardman *et al*., 2002). All other mammal groups show a pallidal arrangement that must therefore be the primitive pattern for mammals. In this primitive pallidal pattern, the GPi and GPe are spatially separated, with the GPi enveloped by the internal capsule and seemingly dragged medially to a thalamic proximity. The gap between the two pallidal segments is so large that they have customarily been identified by different names than in primates: the globus pallidus instead of the GPe and the entopeduncular nucleus instead of the GPi. The globus pallidus is, however, clearly homologous to GPe and the entopeduncular nucleus to GPi. As a result, some neuroanatomical atlases for rodents embrace the primate names for the pallidal segments (Paxinos and Watson, 1998). Since it seems generally sound and parsimonious to call homologous structures by the same name (Reiner *et al*., 2004), this policy will be employed here as well.

The primate basal ganglia is also distinguished by being divided by the internal capsule into parts, called the caudate and putamen (Figure 4). Nonprimate mammals vary in the extent to which the striatum is divided by the internal capsule into a caudate and putamen, generally as a function of cortical development (Ariëns-Kappers *et al*., 1936; Parent, 1986). In many mammals with a lissencephalic cerebral cortex, such as some rodents, insectivores, bats, and monotremes, the caudate and putamen are not separated by the internal capsule and rather are pierced by myriad separate thalamocortical and corticothalamic fascicles that coalesce to form the internal capsule ventromedial to the striatum. In other mammalian groups, such as carnivores, ungulates, and some South American rodents, which independently evolved a gyrencephalic cortex, the striatum is divided by an internal capsule, but the point of division varies and differs from that in primates. This variation in internal capsule placement reinforces the notion that it, as well as cortex enlargement and convolution, evolved separately in different mammalian orders (Northcutt and Kaas, 1995). Since mammalian groups that are presumptively closer to the basal mammalian condition, such as monotremes and insectivores, do not show striatal division by the internal capsule, an undivided striatum is likely to be primitive for mammals.

There appear to be no noteworthy differences between mammals and sauropsids in the major types of neurons making up the striatum and pallidum (Table 1). In both amniote groups, the striatum consists of two main neurochemically distinct types of neurons, the SP^+ and the ENK^+ GABAergic neurons, and three types of interneurons, the cholinergic, the $PARV^+$, and the somatostatinergic (Graybiel, 1990; Gerfen, 1992; Reiner *et al*., 1998). In both groups, the projection neurons far outnumber the interneurons and pallidal neurons are large and GABAergic. Moreover, in mammals as in sauropsids, basal ganglia circuitry is organized into the direct–indirect pathway plan (Albin *et al*., 1989; DeLong, 1990; Gerfen, 1992; Reiner *et al*., 1998).

Massive glutamatergic inputs to striatum arise from cortex and thalamus, and a massive dopaminergic input to striatum arises from the substantia nigra pars compacta (Gerfen, 1992; Reiner *et al*., 1998), and the general role of the basal ganglia in motor learning and control seems similar in all amniotes. Mammals do differ from birds and reptiles in that they lack an obvious correspondent of the basal ganglia output to midbrain via pretectum (Table 1; Figure 5; Reiner *et al*., 1998), and their output to motor cortices via the thalamus seems instead more prominently developed, especially in primates (Albin *et al*., 1989; DeLong, 1990; Gerfen, 1992; Reiner *et al*., 1998). Additionally, mammalian striatum is compartmentalized into a network of interlaced zones called striosomes and a much larger sector in which the striosomes are embedded called the striatal matrix (Graybiel, 1990; Gerfen, 1992). These two striatal sectors, which differ in their connectivity with cortex and midbrain, consist of neuronal populations that are more uniformly interspersed in birds and reptiles (Reiner *et al*., 1998). Thus, striosomes are not evident in the striatum of birds or reptiles, but are in all mammals (Künzle, 2005).

Little is known about diversity in basal ganglia organization among mammals, largely because most hodological and neurochemical studies in mammals have focused on only a few groups: rats, mice, cats, and monkeys. Stephan (1979) compared the volume of the striatum in various insectivore, prosimian, and simian species. Although the raw data indicated that striatal volume as a percentage of the telencephalon decreased from approximately 8% to 3% from insectivores to humans, scaling according to body weight revealed an increase in striatal size (relative to body size) from insectivores to prosimians to simians. Along these lines, Stephan (1979) specifically noted that the human striatum would be 14 times larger than that of a basal insectivore of human size. The human cerebral cortex would be larger yet, approximately 30 times the size of that in a basal insectivore. Striatal enlargement, thus, in evolution from basal mammals through primates has contributed to overall telencephalic enlargement, but less so than has expansion and areal diversification of the neocortex (Stephan and Andy, 1969). Neocortical expansion and diversification, in particular, exceed striatal enlargement in the primate radiation from prosimians to simians. Another morphometric study using a slightly different approach also concluded that both neocortex and striatum had expanded progressively in the primate radiation, with the neocortical expansion outpacing the striatal expansion, especially in humans (Clark *et al*., 2001). These findings confirm, as suggested by the connectivity data, that cortex and striatum are functionally linked and that cortex does not take over the role of striatum, as had been presumed in early twentieth century ideas about telencephalic evolution (Ariëns-Kappers *et al*., 1936; Herrick, 1948, 1956).

Hardman *et al*. (2002) performed a quantitative morphological study on the size and neuronal abundance of several additional basal ganglia cell groups or targets in rats and several primate species. Immunolabeling for various cell type-specific markers was used to objectively define the extent of the different cell groups measured, which included the GPe, GPi, STN, substantia nigra pars compacta, and SNr. Corrected for overall brain size, the sizes of the GPe, GPi, and STN in relation to one another were relatively constant across the groups examined, with GPe being larger (and more neuron rich relative to brain neuronal abundance) than GPi and with GPi being larger than STN in each species. The substantia nigra was, however, relatively larger and more neuron rich (relative to brain neuronal abundance) in rodents than in the primates examined. This is likely to reflect a relatively greater importance of striato-SNr circuitry in motor control than striato-GPi circuitry in rat than in primate. Whether this is generally true of nonprimates is uncertain, but it suggests a possibly increased role of basal ganglia outflow to motor cortex in primates than nonprimates (Figure 5).

3.29.4 Mammalian Basal Ganglia Evolution – Outdated Concepts and Terminology

The preceding overview of basal ganglia evolution in vertebrates reveals that the striatum and pallidum are ancient structures, with both apparently being present in jawless fish ancestral to modern jawed vertebrates (Table 1; Figure 5). Thus, the notion that the pallidum (i.e., the so-called paleostriatum) evolved first and is older than the striatum (i.e., the so-called neostriatum) is incorrect. Because the terms paleostriatum and neostriatum reflect and perpetuate outdated ideas about basal ganglia evolution, we recommend their abandonment. Although the evidence was not reviewed here, the notion that the paleocortex (olfactory or pyriform cortex), archicortex (hippocampus), and neocortex evolved successively in evolution is also flawed, since paleocortex and archicortex seem to be equally ancient parts of the vertebrate telencephalon (Northcutt, 1981a; Northcutt and Kaas, 1995; Rodriguez *et al*., 2002). Because the term neocortex refers to a new, uniquely mammalian structure, this

term is, however, debatably suitable. Similarly, the notion that the basal ganglia are a part of the motor system separate from the descending cortical pyramidal tracts is belied by the extensive interconnections of the cortex and basal ganglia and by the output of the basal ganglia to motor cortices. Thus, the classification of the basal ganglia as part of a motor system called the extrapyramidal system is also suspect. The history of basal ganglia evolution seems to be characterized by an increase in neuron number as the telencephalon expanded during the anamniote–amniote transition, with the elaboration of prominent cortical glutamatergic inputs and midbrain dopaminergic inputs, and by an increased role for telencephalic circuitry in motor control all occurring in stem amniotes (Figure 5). In mammals, especially the primate lineage, this trend has been furthered. Nonetheless, the basic direct–indirect pathway circuit plan by which the basal ganglia regulates movement may have already been in place in early anamniotes.

3.30 Evolution of the Cerebellum

M Glickstein, University College London, London, UK
J Oberdick, The Ohio State University, Columbus, OH, USA
J Voogd, Erasmus Medical Center, Rotterdam, The Netherlands

Glossary

allometry The approach to relate the size of (subdivisions of) the brain relative to the size of the body (body parts).

cerebellum The small brain. Posterior division of the brain. Connected to the brainstem through the cerebellar peduncles. The mammalian cerebellum is characterized by many transverse fissures of different depths. Vertebrate cerebella share the lattice character of the cerebellar cortex: its main elements, the Purkinje cells and the granule cells are oriented at right angles. Cerebellar-like structures, such as the dorsal cochlear nuclei, contain these elements in a less geometric structure.

clone The cells produced by one progenitor cell.

endocast The cast of the interior of a skull, which may reveal some aspects of the size and shape of the brain, formerly contained therein.

folia The smallest, leaf-like units of the cerebellar surface. A folium is oriented at right angles to the long axis of a folial chain and delimited by two transverse fissures.

folial chain Two deep longitudinal fissures subdivide the mammalian cerebellum in a median region, the vermis and two lateral hemispheres (Bolk, 1906). Transverse fissures of different depth subdivide both vermis and hemispheres in folia, lobules, and lobes. The cortex between adjacent folia within vermis and hemisphere, always is continuous. The term 'folial chain' accentuates this continuity.

folial pattern The combination of longitudinal and transverse fissures divides the cerebellar surface into its units. Variations in size and internal composition of these units, determine their positioning and, thus, the gross appearance of the cerebellum. The resulting pattern of these units is named after the smallest units, the folia.

function The function of the cerebellum can be studied at different levels. The algorithm performed by the cerebellar cortex is the most basic function, but is still unknown. Recorded activity or connections of certain parts of the cerebellum may indicate whether this unknown algorithm is used within the context of a certain functional system. Lesions or diseases affecting the

	cerebellum or its parts cause symptoms and signs that can be interpreted as a consequence of an alleged function of the cerebellum.
lineage	The origin of a particular cell type from a particular progenitor cell.
lineage restriction	The spatial restriction by temporary boundaries of groups of progenitor cells and their offspring.
lobe, lobule	Collections of folia delimited by deep, transverse fissures. The subdivision of the cerebellum in lobes, and of the folial chains in lobules is an arbitrary decision, depending on the importance given to particular transverse fissures of varying depth and their continuity in vermis and hemispheres.
module	Repeating neural unit with a specific structure, composition, and connections.
nomenclature	Set of terms used to indicate a coherent set of structures. Classical nomenclatures use resemblance of structures to everyday objects. Comparative anatomical nomenclatures use criteria derived from the variability and the development of a structure. Use of a particular nomenclature supposes knowledge of these criteria.
zonal pattern	Purkinje cells are distributed in multiple parallel zones that extend perpendicular to the transverse cerebellar fissures. Criteria to distinguish these zones are (1) the projection of the Purkinje cells of a particular zone to a particular cerebellar or vestibular target nucleus, (2) the innervation of each Purkinje cell zone by climbing fibers from a particular subdivision of the inferior olive, (3) the chemoarchitecture of the Purkinje cells of a particular zone. The disposition and extent of the longitudinal zones determine the zonal pattern. Zonal patterns defined by different criteria generally are congruent.

3.30.1 Introduction

This article aims to deal with the structure and function of the mammalian cerebellum from an evolutionary point of view. This approach can be only tentative since there are few clues from endocasts of fossil skulls; consequently, the fossil record can give only limited evidence on the evolution of soft tissues. In some vertebrate endocasts, for example, there is a possible cerebellar component that is encased within the petrous bone. In those living mammals in which it is present, this cerebellar subdivision is part of the dorsal paraflocculus, although it is sometimes mislabeled as flocculus in the literature. Since there is little data on the relative size of the entire cerebellum or its parts that can be derived from fossil evidence, and there are no guaranteed living primitive forms, we emphasize insights from comparative anatomy and development. As Bolk (1906) pointed out, there is a common plan to the structure of all mammalian cerebella. Moreover, the histology and the microcircuitry of the cerebellar cortex are preserved features among vertebrates. Comparative anatomy reveals the relative size of the cerebellum and its subdivisions and the variations upon the common plan among mammals, and hence may provide clues as to its evolution. Studies on the connectivity of the cerebellum give indications on the use of the stereotyped cerebellar cortical circuit in different functional systems, and may provide clues on adaptations in cerebellar structure during evolution. Cerebellar morphogenesis and its genetic control provide information on the crucial stages where mutations make these adaptations possible. The link between structure and function, so evident for many other parts of the central nervous system, unfortunately is lacking for the cerebellum. This aspect, the missing link in cerebellar evolution, is discussed in the final section of this article.

3.30.2 Gross Anatomy of the Mammalian Cerebellum

Figure 1 shows drawings of the human cerebellum. The cerebellum is made up of an extensive cerebellar cortex and its associated deep nuclei, which are located within the white matter. Only a small percentage of the cortex is visible on the surface, since most of the cortex is buried on the banks and in the depths of the fissures. The cortex is divided into a medial vermis and lateral hemispheres. Vermis is thus labeled because of its alleged resemblance to a worm. In the human brain, the vermis is overshadowed by the massive cerebellar hemispheres.

The cerebellum is also divisible into three lobes: anterior, posterior, and flocculonodular.

Figure 2 illustrates a midsagittal section through the cerebellum showing the cortex folded into lobes and lobules by deep fissures. Two of these fissures are of particular importance, because they segregate the three functionally important anterior–posterior divisions. The deepest of these is the primary fissure. The cerebellum in front of the primary fissure is the anterior lobe. Behind the primary fissure is the posterior lobe. The smaller posterolateral fissure separates the posterior lobe from the flocculonodular lobe.

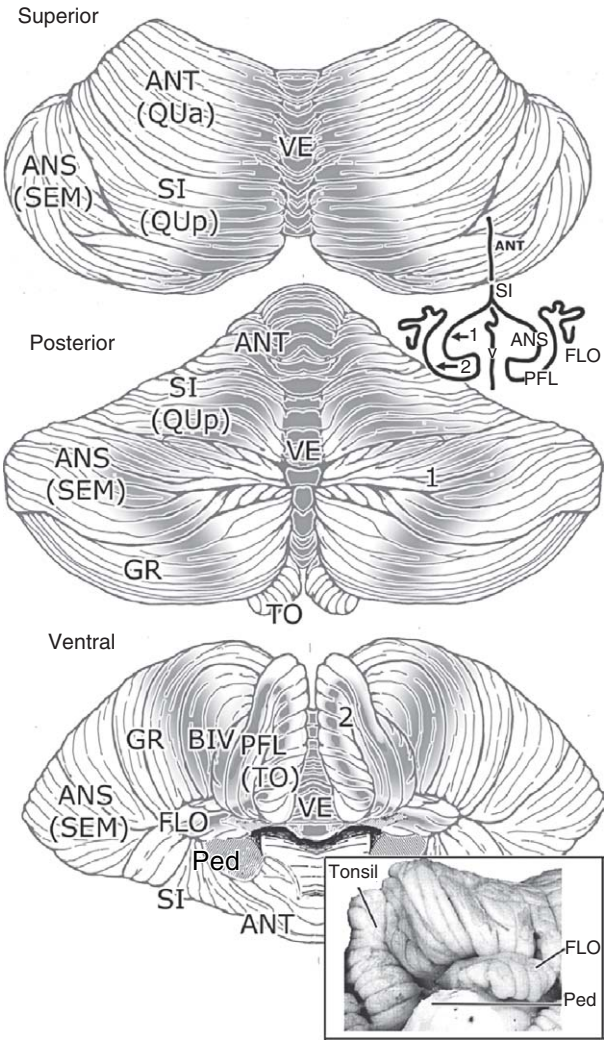

Figure 1 Three diagrams of the human cerebellum. Lobules are indicated with the nomenclature of Bolk (1906), classical names are given in parentheses. The grey band indicates the direction of the folial chains of vermis and hemispheres. The two loops in the folial chain of the hemisphere are indicated as 1 and 2. Insets show Bolk's (1906) wire diagram of the fundamental structure of the mammalian cerebellum and a photograph of the folial loop of the tonsilla. ANS, ansiform lobule; ANT, anterior lobe; BIV, biventral lobule; FLO, flocculus; GR, gracile lobule; Ped, cerebellar peduncles; PFL, paraflocculus; QUa, anterior quadrangular lobule; QUp, posterior quadrangular lobule; SEM, semilunar lobules; SI, lobulus simplex; TO, tonsilla; VE, vermis. Inset Reproduced from Rohen, J. W. and Yokochi, C. 1988. Human Anatomy. Photographic Atlas of Systematic and Regional Anatomy, 2nd edn. Schattauer. Voogd, J. 2003. The human cerebellum. *J. Chem. Neuroanat.* 26, 243–252.

Figure 3 shows a transverse section through the human cerebellum, demonstrating the deeply folded cerebellar cortex, with the cerebellar nuclei embedded within the white matter. The cortex is larger than the nuclei. The pattern of projection from the cortex to the nuclei is orderly. The most medial cortex projects to the middle (fastigial) nucleus and to the lateral vestibular nucleus. More laterally, the cortex projects to the interposed nuclei, called globose and emboliform in the human cerebellum. The cerebellar hemispheres project to the most lateral nucleus, the dentate nucleus. The functional units of the cerebellum are a series of long, parasagittal strips of cortex and their afferent and efferent connections. These will be discussed in detail in a later section.

Over several hundred years, anatomists have been identifying various finer subdivisions of the cerebellum, and there are many and varied systems of nomenclature for these subdivisions (Angevine *et al.*, 1961). Names were assigned long before there was any recognition of whether these subdivisions might be of functional importance. Thus, the most rostral region of the cerebellum was called lingula (originally linguetta) by Malacarne (1776) because it looked to him like a cat's tongue. Most of the traditional nomenclature is based on such superficial resemblance to a tonsil, a ball of wool, or

similarity to a particular geometric shape, such as a pyramid.

3.30.3 Comparative Anatomy of the Folial Pattern

The cell types and histological structure of the cerebellar cortex are similar among all vertebrates, and they are virtually identical among mammals and lower vertebrates. There is, however, great variability in the relative size and in the morphology of its lobes and lobules. The avian cerebellum, for instance, lacks a clear border between vermis and hemispheres. It consists of a series of simple folia, arranged like the pages of a book. The very small hemispheres are represented by the lateral, unfoliated cortex, and the auricle is the homologue of the mammalian flocculus.

Differences in shape and connections of the cerebellum among mammals are obvious (Voogd *et al.*, 1998). The comparative anatomy of the folial pattern of the mammalian cerebellum is based on gross inspection and dissection (Smith, 1903a, 1903b; Riley, 1928, 1929), and on its development (Kuithan, 1894; Stroud, 1898; Bradley, 1904; Bolk, 1906; Larsell, 1937, 1952, 1953, 1970). Larsell and Jansen (1972) combined both approaches. Bolk studied development in order to confirm his ideas on the basic folial pattern of the mammalian cerebellum. For Larsell, the basic pattern is revealed in its development. Inspection and dissection served to confirm this pattern in the adult.

Bolk (1906) emphasized the lack of a distinct border between vermis and hemispheres in the anterior lobe, and in the region immediately behind the primary fissure, known as lobulus simplex, which belongs to the posterior lobe. The transverse fissures in the anterior lobe and simplex run uninterruptedly over the entire width of the cerebellum. Caudal to the lobulus simplex, the cerebellum splits into the median folial chain of the vermis and the two folial chains of the hemispheres. By simple dissection, Bolk revealed the continuity of the folial chain in vermis and hemispheres in all of the 69 mammalian species that he studied (Figures 1, inset, and 4).

The vermis (lobule VII), immediately caudal to the lobulus simplex, is straight in many vertebrates, but it is bent in several carnivores, ungulates, and primates. The caudal lobules of the vermis (VIII, the pyramis; IX, the uvula; and X, the nodulus) show far less variation among species. The folial chain of the hemisphere forms two continuous loops, with a paramedian

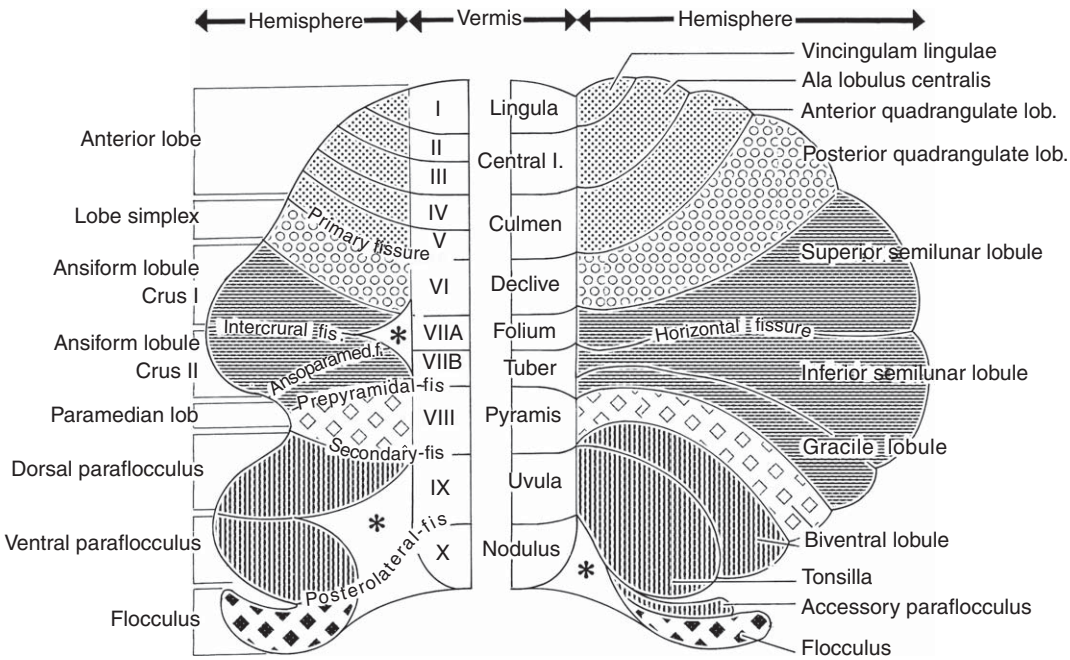

Figure 4 Diagram of the comparative anatomical nomenclature of the cerebellum (left panel) and of the classical nomenclature (right panel). The asterisks indicate superficial medullary areas not covered by cortex. From Voogd, J., Nieuwenhuys, R., van Dongen, P. A. M., ten Donkelaar, H. J. 1998. Mammals. In: The Central Nervous System of Vertebrates (*eds*. R. Nieuwenhuys, H. J. ten Donkelaar, and C. Nicholson), pp.1637–2097. Springer.

segment between the two loops. The rostral loop is known as the ansiform lobule, the caudal loop corresponds to the paraflocculus. The intermediate segment is the paramedian lobule. The caudal-most segment of the folial chain of the hemisphere is turned back upon the paraflocculus as the flocculus, Bolk's uncus terminalis. This basic mammalian folial pattern is present in all mammalian species (Figure 5). In Bolk's view, the anterior lobe and the lobulus simplex form a single growth center. Bolk considered the more caudal lobules of the folial chains of vermis and hemispheres to be mutually independent growth centers. Sultan and Braitenberg (1993) elaborated on Bolk's concept of the folial chains and illustrated this configuration in many mammalian species (Figure 6).

According to Larsell, the posterolateral and primary fissures are the earliest fissures to appear. Together with fissures that form later, they subdivide the cerebellum into 10 subdivisions, from the most rostral lobule I (lingula) to the most caudal lobule X (nodulus). Lobules I–V constitute the anterior lobe; lobules VI–IX are the vermian part of the posterior lobe; lobule X corresponds to the nodulus. Each of the vermian lobules is associated with a lobule in the hemisphere, indicated with the same Roman numeral, with the prefix H. Larsell emphasized the mediolateral continuity of the lobules of vermis and hemisphere. In his words, ". . . it is (also) clear in the adult and in the fetus that the lateral parts, namely lobulus ansiformis, paraflocculus and the lateral continuation of the pyramis are merely lateral extensions of the medial portion" (Larsell, 1937, p. 605).

Bolk attached more importance to the independence of the lobules of the folial chains of vermis and hemispheres. This independence was also emphasized in his studies on the development of the folial pattern of the human cerebellum (Bolk, 1906). He distinguished three rostrocaudal regions. In the rostral cerebellum, comprising the anterior lobe and the lobulus simplex, all of the fissures first appear in the midline and then grow out laterally. In an intermediate region, corresponding to lobule VII and rostral VIII (the pyramis) and the ansiform and paramedian lobules, the interlobular fissures arise medially, but the intralobular fissures arise independently in vermis and hemispheres. In the caudal region of the cerebellum, all of the fissures arise independently in vermis and hemispheres.

There are variations among mammals in the length and width of certain segments of the folial chains. The greatest amount of variability is seen in vermian lobule VII, in the ansiform lobule, and in the paraflocculus. Lobulus simplex, the vermian lobules VIII–X, the paramedian lobule, and the flocculus are less variable, although the width of the folia may vary. In some species, these variations

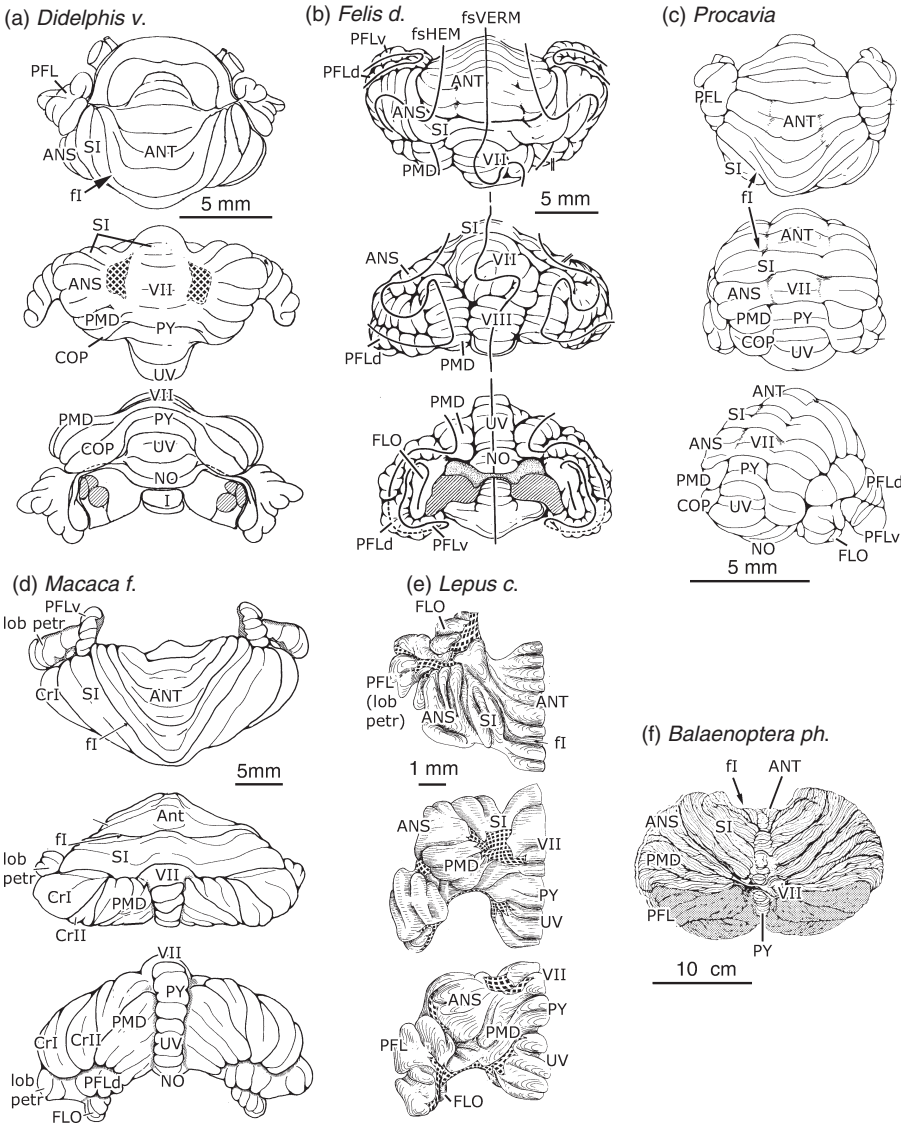

Figure 5 Anterior, dorsal, and caudal (ventral) views of different mammalian cerebella. In (b) the direction of the folial chains of vermis and hemispheres is indicated for the cerebellum of the cat. Medullary areas not covered by cortex are indicated by filled squares in (a) and (e). Note approximately equal width of the folial chains of vermis and hemispheres in opossum (a), cat (b), coney (c), and rabbit (e), and greater width of the hemiphere in monkey (d) and whale (f). A folial loop in the ansiform lobule is lacking in the coney (c). Size and shape of the visual vermis (lobule VII) differs in different mammals: it is large and convoluted in the cat (b), small and straight in the other species. Cetacea are characterized by the large, overall size of the cerebellar hemisphere, especially of the paraflocculus (shaded in f). can be related to the zonal organization of the individual lobules. The details of zonal organization will be discussed in a later section.

Bolk's fundamental plan of the cerebellum was confirmed in Riley's (1928, 1929) studies of the gross anatomy of the mammalian cerebellum and can be recognized in the plots of the number and the width of the folia of several mammalian species of Sultan and Braitenberg (1993), illustrated in Figure 6.

Parallel fibers are the axons of granule cells. They extend within the molecular layer, where they

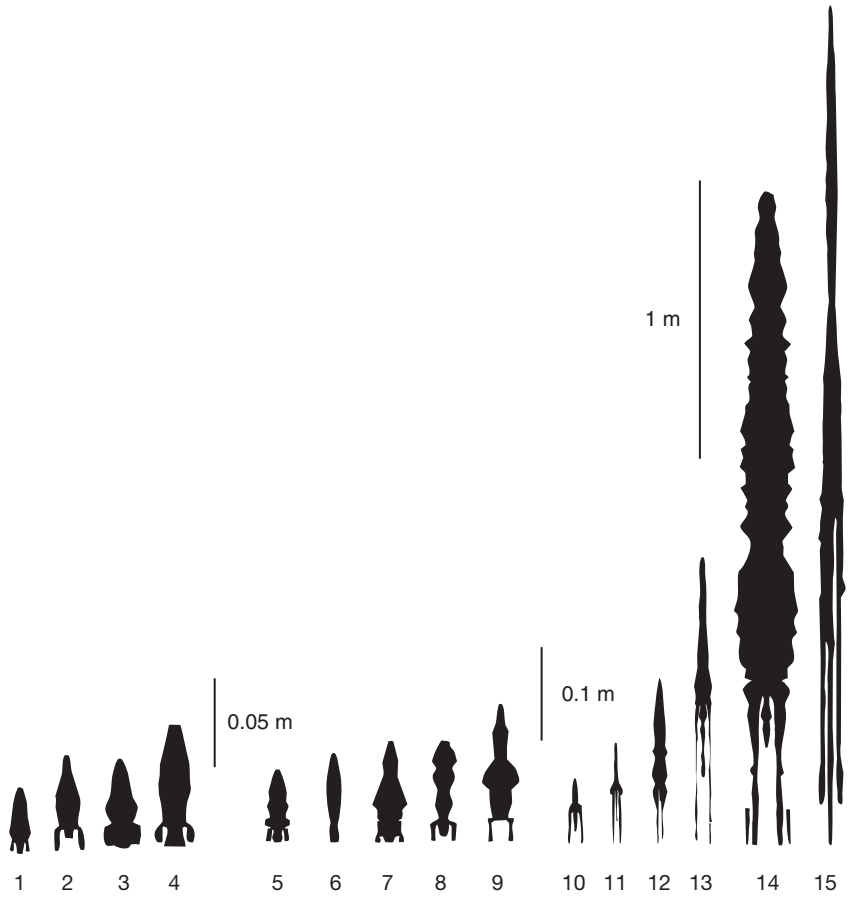

Figure 6 Outlines of the shapes of the cerebellar cortices, obtained by connecting the ends of the most prominent folia. The scale is the same in the laterolateral and anteroposterior direction. Note division of posterior cerebellum in the folial chains of vermis and hemispheres, and the relative width and length of these chains in different species. 1, Mouse; 2, bat; 3, flying fox; 4, guinea pig; 5, rabbit; 6, pigeon; 7, hare; 8, chinchilla; 9, squirrel; 10, dog; 11, cat; 12, macaque; 13, sheep; 14, human; 15, bovine. Magnifications differ for the diagrams 1–4, 5–9, and 10–15. Adapted from Sultan, F. and Braitenberg, V. 1993. Shapes and sizes of different mammalian cerebella. contact Purkinje cell dendrites. Mammals vary in the extent to which there is continuity of the parallel fibers between the vermis and hemispheres. This continuity is complete in the anterior lobe, the lobulus simplex, and between lobule VIII (the pyramis) and the paramedian lobule. The cortex is entirely or partially interrupted between lobule VII and the ansiform lobule, and between the caudal vermis (lobules IX, the uvula, and X, the nodulus) and the paraflocculus and the flocculus (Figures 5a and 5e) (Glickstein and Voogd, 1995).

3.30.4 Allometry and Cerebellar Size

Elephants and mice each have a four-chambered heart that works on the same general principles to pump blood around the body. The brain of an elephant, like its heart, is much larger than that of a mouse. To compare the weight of the brain or any body part between species, it is necessary to consider its relative, not its absolute size. Subdivisions of the brain will also vary with its total size. Allometry is an approach to dealing with such comparisons by plotting the size of each organ against total body size (see The Evolution of Human Brain and Body Growth Patterns). The same approach can be used to compare the relative size of one or another subdivision of the brain. The general form of the exponential equation that is used is typically in the form $\log Y = k \log X + \log b$, where X and Y are the two structures to be compared and k is the slope of a linear fit to the data. Thus, vast differences can be plotted in the same graph, and an exponential equation becomes linear. If brain weight is plotted against body weight in a log-log plot across a large number of mammalian species, there appears to be a satisfying linearity. But because a whale may weigh over 100 000 times more than a bat, important deviations from the linear fit may not be obvious. The same problem arises in studies in which the

volume of a brain subdivision is plotted against total brain weight (Finlay and Darlington, 1995).

Clark *et al.* (2001) compared the volume of brain subdivisions across several species of insectivores, tree shrews, and primates. They argue that although the telencephalon, and especially the cerebral cortex is relatively large in primates, the cerebellum remains a constant fraction of brain volume. On the basis of this analysis, they grouped mammalian species into several subtypes that they called cerebrotypes. Clark *et al.*'s conclusion about mammalian cerebrotypes was criticized on several fronts. De Winter and Oxnard (2001) used the same data set in a principal component analysis. Their results suggested that a grouping of species by locomotor types is more appropriate than the cerebrotypes postulated by Clark *et al.* Moreover, as Barton (2002) pointed out, Clark *et al.*'s data does, in fact, demonstrate an increase in the relative volume of the cerebellum among the species studied, but the increase proceeds at a slower rate than that of the cerebral cortex. Sultan (2002) has questioned the very basis of Clark *et al.*'s analysis. He argues convincingly that relative volume or weight is not an appropriate measure for the functional importance of a given brain subdivision. A crude volume estimate of subdivisions is inappropriate, since his own work clearly demonstrates that valid comparisons should be based not on volume but on surface extent of the cerebellum.

3.30.5 Cell Types and Cerebellar Circuitry

3.30.5.1 Histology of the Cerebellar Cortex

The histological structure of the cerebellar cortex was described and summarized by Ramon y Cajal (1911). Cajal paid attention to the histology of the cortex in lower vertebrates, but his 1911 description is mainly based on the situation in mammals. The following account also describes the cell types and the circuitry of the mammalian cerebellar cortex.

The cerebellum is made up of two fundamental subdivisions: a broad sheet of cells, the cerebellar cortex, and a group of deep cerebellar nuclei that are buried within the white matter (see The Evolution of the Cerebellum in Anthropoid Primates). The cerebellar cortex of all vertebrates shares several fundamental features (Nieuwenhuys *et al.*, 1998). Purkinje cells in all species constitute the main output element. The Purkinje cells receive two types of excitatory afferents: the climbing fibers, originating from the contralateral inferior olive, and the parallel fibers, which are the axons of granule cells. Granule cells receive their input from many sources outside of the cerebellum, all of which terminate as mossy fibers. The axons of Purkinje cells terminate in the cerebellar and vestibular nuclei.

Figures 7a and 7b are sketches showing the structure of the cerebellar cortex. Purkinje cell bodies form a single layer throughout the entire extent of the cortex. They have large flask-shaped cell bodies, and their axons constitute the only output from the cortex to the cerebellar nuclei. Purkinje cells are GABAergic and inhibitory. Their dendrites branch extensively in a plane perpendicular to the cerebellar folium. Their axon projects to the nuclei, giving off axonal collaterals within the cortex. By far the most numerous cells in the cerebellum, indeed in the entire mammalian brain, are granule cells. These are small cells, measuring about 7 μm in diameter, packed densely in the granular layer of the cortex. The axon of granule cells ascends to the outer molecular layer of the cortex, where it branches in a characteristic T fashion, and extends as a parallel fiber within the molecular layer. Parallel fibers are labeled as such because they are oriented parallel to the course of the cerebellar folia to which they project. The ascending axon of the granule cell and its parallel fiber branches contact Purkinje cell dendrites and dendrites of interneurons. In addition to Purkinje and granule cells, there are three other types of neurons, all three of which are inhibitory. Golgi cell bodies reside in the granular layer. Their dendrites extend into the molecular layer, where they are contacted by parallel fibers. Their axons ramify within the granular layer, where they terminate on dendrites of granule cells. Golgi cells use glycine as their inhibitory neurotransmitter. Basket and stellate cell bodies are in the molecular layer. Their dendrites and axons extend in a plane perpendicular to the long axis of the folia. Basket and stellate cells use GABA as their neurotransmitter. Basket cell axons give off several branches, each of which surrounds Purkinje cell bodies like a wicker basket. They have powerful inhibitory connections that are concentrated at the axon hillock of the Purkinje cell. Stellate cells inhibit the Purkinje cell dendrites.

Purkinje cells are activated by way of two totally independent systems of afferent fibers. Mossy fibers originate from the spinal cord, multiple centers in the lower brainstem, and the pontine nuclei. Mossy fibers branch extensively and terminate on the dendrites of the granule cells, which in turn connect to the Purkinje cells by way of parallel fibers. Some mossy fibers provide collaterals to the cerebellar nuclei. Each Purkinje cell also receives a completely different type of input, a single climbing fiber,

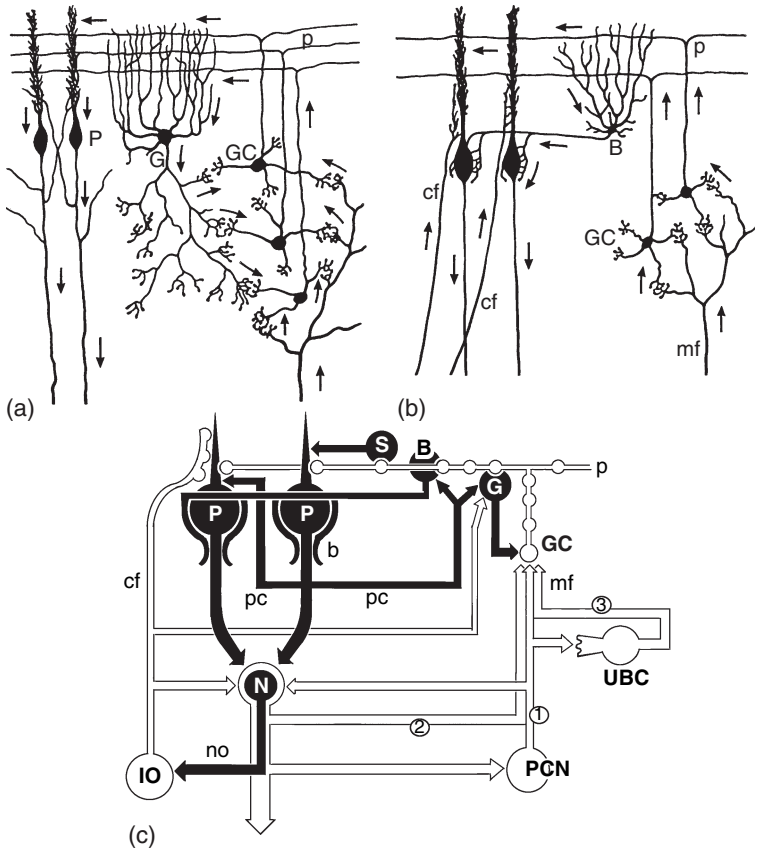

Figure 7 a, Diagram showing the main mossy fiber-granule-cell–Purkinje-cell circuit and the innervation of the granule cells by the axonal plexus of the Golgi cell. b, Diagram of the climbing fiber innervation of the Purkinje cells, and the basket cells with their axonal baskets surrounding the Purkinje cell perikarya. c, Diagram of the cerebellar circuitry. Inhibitory neurons are indicated in black. Histologie du système nerveux de l'homme et des vertebrés. Maloine.

because their terminations ascend along the dendrites of the Purkinje cells, making multiple and direct contacts. Climbing fibers all arise solely from the inferior olivary nucleus on the opposite side of the cerebellum, giving off collateral fibers to the cerebellar nuclei as they ascend to the cortex.

Both inputs to the Purkinje cells, the mossy fiber–parallel fiber system and the climbing fibers, are excitatory, but they terminate on different segments of the Purkinje cell dendritic tree. The climbing fiber terminates on short, stubby spines on the proximal, smooth portion of the dendrites. Parallel fibers contact long-necked spines of the distal spiny branchlets of the Purkinje cell dendritic tree.

The histology of the cerebellar cortex is very similar in mammals and in lower vertebrates. Purkinje cells, granule cells, and Golgi cells have been identified in all vertebrate genera. The main differences concern the lamination of the cortex, the spatial segregation of Purkinje cells and granule cells in certain forms, and the shape of the Purkinje cell dendritic tree. In fish, the proximal smooth dendrites with their climbing fiber afferents are located within the Purkinje cell layer and the spiny branchlets ascend into the molecular layer. In mammals, smooth and spiny branches are found throughout the molecular layer. In birds there is an intermediate arrangement in which the smooth branches are restricted to the lower half of the molecular layer (Nieuwenhuys *et al.*, 1998).

Cerebellar nuclei are not present in all lower vertebrates. In fish, the connections of the cerebellum with other parts of the central nervous system take their origin from cells that are located within the Purkinje cell layer (eurodendritic cells). Unlike the cerebellar nuclei, they are not buried in the white matter, but their axons, like those from nuclear cells in mammals, project to targets outside of the cerebellum. A similar type of cortical neuron with long, extracerebellar connections has been described only

in a fourth cerebellar layer of Pinnipedia (Ogawa, 1934).

The cerebellar nuclei are arranged from medial to lateral, with their major input from the overlying cerebellar cortex. The most medial cortex of the cerebellar vermis projects to the medial nucleus of the cerebellum, also called the fastigial nucleus (Figure 8). The lateral vestibular nucleus, which is in fact a fourth deep nucleus, receives its input from the lateral vermis. The most lateral fibers of the cerebellar hemisphere project to the lateral cerebellar nucleus, also called the dentate nucleus. Between the fastigial and dentate nucleus are the anterior and posterior interposed nuclei, also called globose and emboliform in the human cerebellum. The interposed nuclei receive Purkinje cell axons from the intermediate zone of the cerebellar cortex. Size and structure of the cerebellar nuclei are directly related to the size and the configuration of their Purkinje cell input and to the weight and the construction of the functional motor, sensory, and cognitive systems which serve as their targets.

3.30.5.2 Purkinje Cell Zones. Morphology, Connections, and Chemical Identity

The output of the cerebellum is organized as a series of independent modules. Each module consists of one or more longitudinal zones of Purkinje cells, oriented perpendicular to the transverse fissures, its cerebellar or vestibular target nucleus, and a climbing fiber system, innervating both the Purkinje cells

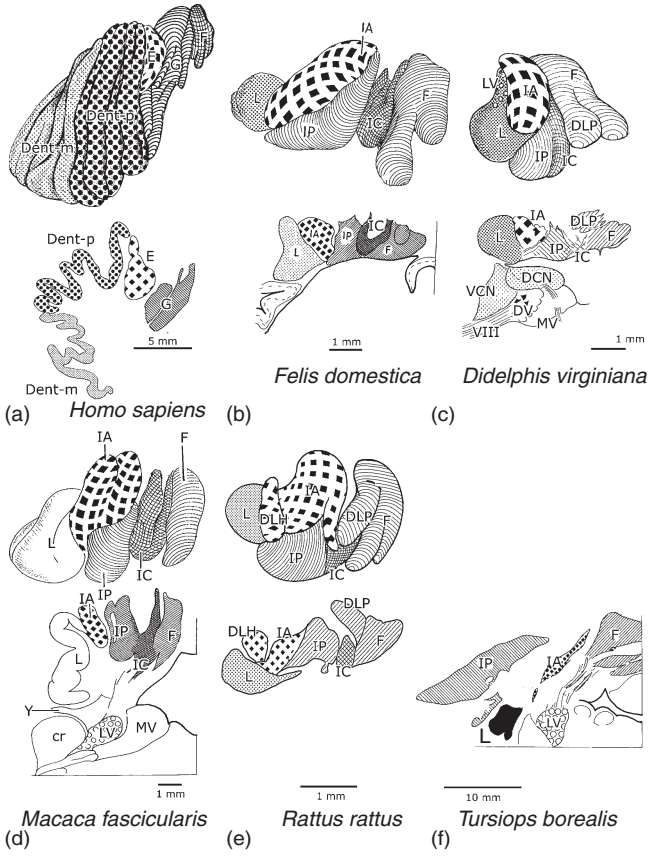

Figure 8 Diagrams of graphical reconstructions of the cerebellar nuclei (upper panels) and of a transverse section through the nuclei (lower panels) in different mammals. The interstitial cell groups (IC) are a nucleus located between the fastigial and interposed nuclei, which serves as the target nucleus of the X and CX zones. The dorsolateral hump (DLH) and the dorsolateral protuberance of the fastigial nucleus (DLP) have only been described in rodents and/or marsupials (c, e). Group Y is particularly well developed in primates (d). It serves as one of the target nuclei of the flocculus. For the dolphin (f; *Tursiops truncatus*), no graphical reconstruction was available. cr, restiform body; DCN, dorsal cochlear nucleus; Dent-m, macrogyric portion of human dentate nucleus; Dent-p, microgyric portion of human dentate nucleus; DLH, dorsolateral hump; DLP, dorsolateral protuberance of fastigial nucleus; DV, spinal vestibular nucleus; E, emboliform nucleus; F, fastigial nucleus; G, globose nucleus; IA, anterior interposed nucleus; IC, interstitial cell groups; IP, posterior interposed nucleus; L, lateral cerebellar nucleus; LV, lateral vestibular nucleus; MV, medial vestibular nucleus; VCN, ventral cochlear nucleus; Y, group Y. a, Reproduced from Voogd, J. 2004a. Cerebellum and precerebellar nuclei. In: The Human Nervous System (*eds*. G. Paxinos and J. K. Mai), pp. 321–392. Elsevier. b–f, Reproduced from Voogd, J., Nieuwenhuys, R., van Dongen, P. A. M., and ten Donkelaar, H. J. 1998. Mammals. In: The Central Nervous System of Vertebrates (*eds*. R. Nieuwenhuys, H. J. ten Donkelaar, and C. Nicholson), pp.1637–2097. Springer.

and the target nucleus of the module. Among all mammals studied, there is a similar pattern of longitudinal Purkinje cell zones in the mammalian cerebellum (Voogd, 1967; Buisseret-Delmas and Angaut, 1993; Voogd *et al.*, 1996, 2003; Voogd and Glickstein, 1998; Sugihara and Shinoda, 2004; Voogd and Ruigrok, 2004). Three of these zones occupy the vermis (Figure 9). The medial A zone is present along its entire length and projects to the medial (fastigial) nucleus and restricted portions of the vestibular nuclei. Its climbing fibers originate from the caudal medial accessory olive (MAO). The X zone is the next lateral zone. It projects to the junction of the fastigial and the posterior interposed nucleus (interstitial cell groups) and receives climbing fibers from an intermediate region of the MAO. The most lateral zone of the vermis is the B zone. It is only present in restricted anterior and posterior portions of the cerebellum, projects to the lateral vestibular nucleus of Deiters, and receives a climbing fiber projection from the caudal dorsal accessory olive (DAO). The cerebellar hemispheres are made up of seven or eight zones. The most medial of these, the A2 zone (not illustrated in Figure 9), projects to a dorsolateral protuberance of the fastigial nucleus (Figure 8) and is innervated by climbing fibers originating from the medial subnucleus C of the caudal MAO. Three successively more lateral zones, C1, C3, and Y, all project to the anterior interposed nucleus and all receive their climbing fiber afferents from the rostral DAO. The CX zone occupies a strip, immediately medial to C1. It shares its connections with the X zone. Like the B zone, the X, CX, C1, C3, and Y zones are only present in restricted anterior and posterior segments of the hemisphere (i.e., in the anterior lobe and the lobulus simplex and in the caudal ansiform lobule and the paramedian lobule, see below). The C2 zone, which is located between C1 and C3, is connected with the posterior interposed nucleus and receives climbing fibers from the rostral MAO. Two zones in the lateral hemisphere, D1 and D2, project to rostromedial and caudolateral portions of the lateral cerebellar (dentate) nucleus and are innervated by climbing fibers from the ventral and dorsal lamina of the principal olive, respectively. C2 and the D zones are present over the entire length of the cerebellar hemispheres.

This fundamental pattern, with very little variation, is present in all of the species studied. The main differences concern the relative width and the length of the zones in certain regions of the vermis and hemisphere. There are variations among mammals in the length of the A zone, which is located in the middle regions of the vermis, particularly in lobule

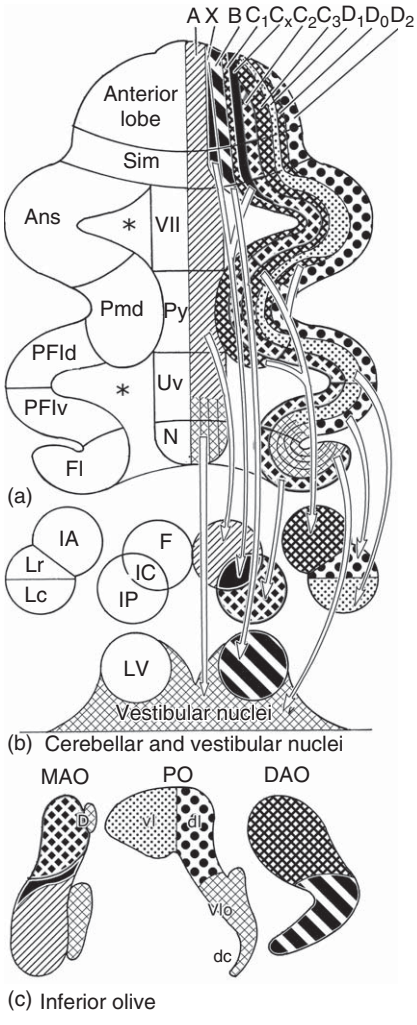

Figure 9 Diagram of the zonal organization in the corticonuclear and olivocerebellar projections. a, Diagram of the flattened cerebellar cortex. b, Diagram of the cerebellar and vestibular nuclei. c, Diagram of a projection of the monkey inferior olive in the horizontal plane. The longitudinal corticonuclear and olivocerebellar projection zones are indicated with capitals (A, X, B, C_X, $C_{1–3}$, Y, $D_{1,2}$). The zones, their target nuclei, and the subnuclei of the inferior olive that project to these zones are indicated with the same shadings. The diagram applies equally to the cerebella of rat, cat, rabbit, and monkey, with the exception of the floccular zones, the most medial one of which is lacking in the monkey. The A_2 zone, only present in the rat, is not indicated. Asterisks, areas without cortex. J. ten Donkelaar, and C. Nicholson), pp.1637–2097. Springer.

VII. This lobule is associated with the control of eye movements. In many carnivore, ungulate, and primate species, this increase in rostrocaudal length leads to the formation of an S-shaped curve in this portion of the vermis (Figure 5b; Voogd and Barmack, 2005). The B, C1, C2, and Y zones are represented only in the rather conserved anterior (anterior lobe and lobulus simplex) and posterior (pyramis, lobule VIII, and paramedian lobule) regions of the cerebellum (Voogd, 2003). They share similar corticonuclear and olivocerebellar connections, which are relatively constant.

Most variations in length and width concern the C2 and the D zones. The C2 zone and its connections with the posterior interposed nucleus and the rostral MAO and the associated brainstem circuitry are hypertrophied in cetaceans, where this zone is associated with the large size of the paraflocculus (Figures 5f, 8, 10, and 11) (Korneliussen, 1967, 1968a, 1968b). The C2 zone in whales was indicated by Korneliussen as the lateral intermediate zone (Figure 10). The D1 and D2 zones, along with the associated regions of the dentate nucleus and the principal olive are greatly enlarged in primates. They are responsible for the great size of the ansiform lobule in nonhuman primates, but also for the width of the folia of the anterior lobe, the lobulus simplex and the paramedian lobule in these animals (Figures 5d and 10). In the human cerebellum, this increase in width of the D zones also affects the homologue of the paraflocculus, the medial belly of the biventral lobule, and the tonsilla (Figure 1). The D1 zone, generally, is the more narrow of the two D zones (Voogd, 2003, 2004a, 2004b). Similarly, in the elephant, it is the dorsal lamina of the principal olive with its projection to the D2 zone that is specifically enlarged (Figure 11) (Verhaart, 1962). There is only one example of a zone, the A2 zone, that exists in some, but not other mammalian species. Judging from the presence of its target nucleus, the dorsolateral protuberance of the fastigial nucleus (Goodman *et al.*, 1993), the A2 zone is present in rodents, lagomorphs, and marsupials, but absent in carnivores and primates (Figures 8c and 8e) (Buisseret-Delmas, 1988a, 1988b).

Purkinje cells are not a homogeneous population; they differ in their biochemical properties. Two populations of Purkinje cells were distinguished by Hawkes and Leclerc (1987) on the basis of their immunoreactivity with an antibody against the zebrin I epitope. Zebrin-positive and Zebrin-negative Purkinje cells are distributed in alternating longitudinal zones (Figure 12). The zebrin pattern is correlated with the distribution of many different substances in Purkinje cells, such as enzymes (5′-nucleotidase and aldolase-C, or zebrin II), certain

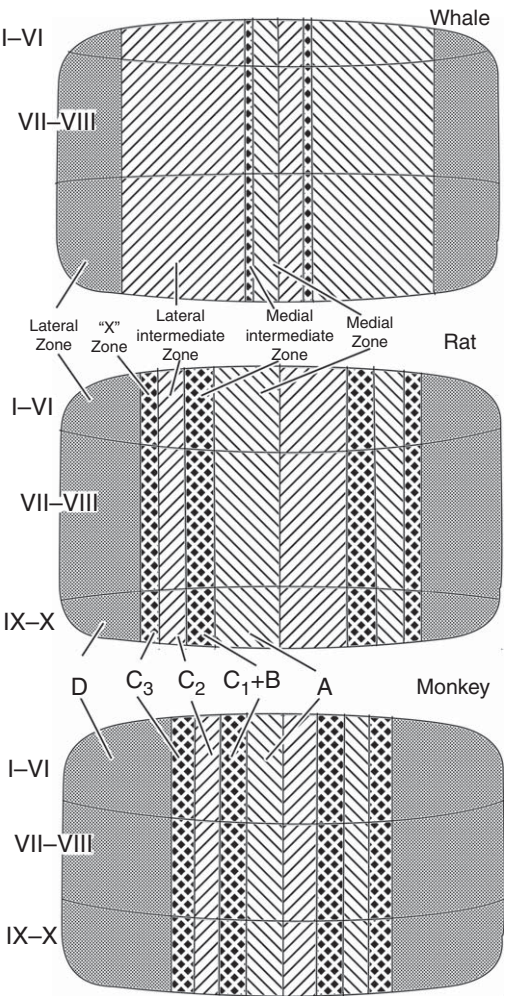

Figure 10 Diagram of the relative width of corticogenetic Purkinje cell zones in different mammals. During early development, the future Purkinje cell zones are present as Purkinje cell clusters at the still unfolded surface of the cerebellar anlage (see also Figure 16). The diagrams depict the relative width of these clusters. Corresponding zones are indicated with the same symbols. The nomenclature of Korneliussen for rat and whale differs from the traditional nomenclature, employed by Kappel. The diagrams of the whale and the rat are based on data from Korneliussen, H. K. 1967. Cerebellar corticogenesis in Cetaca, with special reference to regional variations. *J. Hirnforsch.* 9, 151–185. The data from the monkey are based on Kappel, R. 1981. The Development of the Cerebellum in *Macaca mulatta*. A Study of Regional Differentiation during Corticogenesis. PhD dissertation, University of Leiden.

glutamate transporters, growth factor receptors, etc. There are vast differences in expression of the zebrin II marker across the vertebrate subphylum. For example, basal vertebrates such as sharks and rays reveal uniform expression of the marker. In contrast, all mammalian species show a similar number of zebrin II zones, although the specific patterns are subtly different (Figure 13; Sillitoe *et al.*, 2003, 2005). Recent studies comparing the

connections and the zebrin-identity of Purkinje cells in the rat showed a close correspondence between the two patterns. Purkinje cells of the B, X, CX , C1, C3, and Y zones are zebrin-negative. Purkinje cells of the C2, D1, and D2 zones are zebrin-positive. The A zone is a composite of zebrin-positive and zebrin-negative areas. Crus I of the ansiform lobule and the paraflocculus and the flocculus, where only the C2 and the D zones are represented, are entirely zebrin-positive (Voogd *et al.*, 2003; Voogd and Ruigrok, 2004; Sugihara and Shinoda, 2004).

Purkinje cell zones are connected by way of the cerebellar and vestibular nuclei with the centers in the brainstem, the thalamus, and the spinal cord (Figure 14; see Voogd, 2003, 2004a, 2004b for reviews). The C1, C3, and Y zones project through the anterior interposed nucleus to the contralateral magnocellular red nucleus and, via the ventrolateral nucleus of the thalamus, to the primary motor cortex. They monitor activity in the rubrospinal and corticospinal tracts. The A, B, X, and CX zones maintain strong connections with the spinal cord, through the cerebellospinal, reticulospinal, and vestibulospinal tracts. Note that these Purkinje cell zones share somatotopically organized somatosensory climbing fiber projections. The connectivity of the C2 and D zones is different. Their target nuclei, the posterior interposed and dentate nuclei, project to centers at the junction of the mesencephalon and diencephalon which, in turn, give rise to strong descending systems to the inferior olive. For the dentate nucleus, the system relays in the parvocellular red nucleus, with the central tegmental tract as its descending system terminating in the principal olive; for the posterior interposed nucleus, the mesodiencephalic nucleus is the nucleus of Darkschewitsch, with the medial tegmental tract, terminating in the rostral MAO, as its descending system. In addition, the posterior interposed and dentate nuclei project to ventral thalamic nuclei with connections to motor, premotor, and prefrontal areas, including the frontal eye fields, and more limited projections to the parietal lobe. The closed cerebello-mesodiencephalic-olivary loops are under strong cortical influence of these same cortical areas (Voogd, 2003, 2004a).

Relative size and connectivity of the Purkinje cell zones and their target nuclei are indicative of adaptations of the cerebellum to changes in the organization of motor, sensory, and cognitive systems of the brain

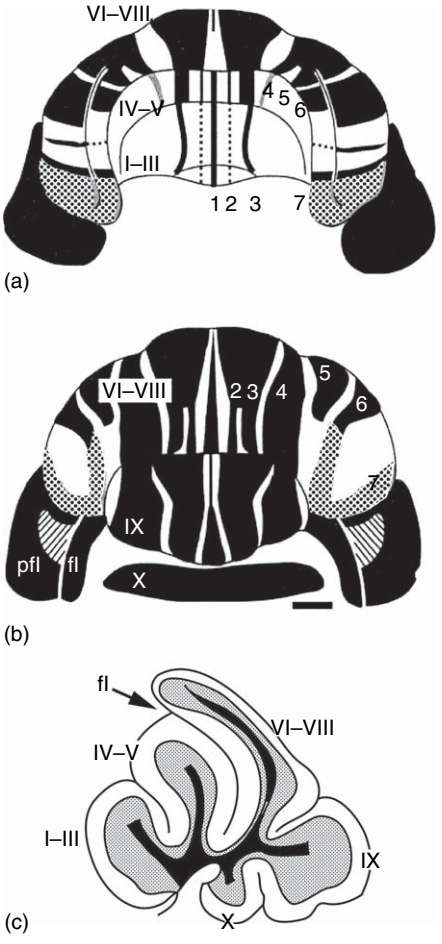

Figure 13 Reconstruction of the location of zebrin II immunoreactive Purkinje cell zones in anterior (a) and posterior (b) views of the cerebellum of the tenrec (*Echinops telfari*). The same zebrin-positive bands 1–7 can be recognized as in the rat (Figure 12). The cerebellum of this basal insectivore can be subdivided into the fused lobules I–II and IV–V of the anterior lobe, the combined lobules VI–VIII with the ansiform and paramedian lobules, the uvula (IX), the nodulus (X), the paraflocculus (pfl) and the flocculus (fl). a and b, Reproduced with permission from Sillitoe, R. V., Künzle, H., and Hawkes, R. 2003. Zebrin II compartmentation of the cerebellum in a basal insectivore, the Madagascar hedgehog, tenrec, *Echinops telfari*. *J. Anat.* 203, 283–296.

in different species. The prominence of the Purkinje cell zones of the vermis and the C1 and C3 zones in lower mammals, and the large hemispheres and the increase in length and width of the D1 and D2 zones in primates, parallels the shift from a local spinal and brainstem regulation of movement to a situation where movement is largely dependent on the cerebral cortex. Prominent vermal and C zones in lower mammals are associated with prominence of their target nuclei, such as Deiters' lateral vestibular nucleus and the magnocellular red nucleus and their spinal tracts. Prominent hemispheres, extensive D zones, and a large, convoluted and subdivided dentate nucleus are found in primates. Targets of the primate dentate nucleus include extensive and differentiated motor, premotor, and frontal association areas and the large parvocellular red nucleus, which links these cortical areas with the inferior olive and the cerebellum. It has been suggested that the functions of the primate dentate nucleus principally involve cognitive and emotional aspects of behavior (Schmahmann, 1997). However, the great development of the cerebellar hemisphere and the dentate nucleus can also be considered as an adaptation to visual and visuomotor exigencies in primates. Much remains unknown. The functional importance of the C2 zone, which overwhelms the cetacean cerebellum and the presence of additional Purkinje cell zones in rodents remain unexplained.

The caudal portions of the vermis and the hemisphere, i.e., the nodulus and the flocculus, are known as the vestibulocerebellum. The zonal organization of the nodulus and the flocculus represents a modification of the A and D zones, respectively (Figure 9). The afferent and efferent connections of the nodulus are mainly with the vestibular nuclei; the flocculus receives olivocerebellar systems mediating optokinetic information, and projects to vestibulo-ocular and vestibulospinal neurons mediating the optokinetic and the labyrinthine neck reflexes (Voogd and Barmack, 2005).

Both in the flocculus and the nodulus, the Purkinje cells are arranged in a complicated pattern of multiple longitudinal zones. For the flocculus, this is a highly conserved feature. It is present in the flocculus of mammals and birds (Voogd and Wylie, 2004). However, one distinguishing feature is present in the primate flocculus. The folial rosette, which links the flocculus with the paraflocculus (known as the ventral paraflocculus) has increased in size, while retaining its original floccular zonal pattern. This feature has been related to the development of foveal vision and smooth pursuit in primates. The flocculus still subserves the calibration of the vestibulo-ocular reflex, as it does in lower mammals; the ventral paraflocculus mediates smooth pursuit (Voogd *et al.*, 1987; Nagao, 1992; Rambold *et al.*, 2002). It exemplifies how a preserved, anatomical configuration can be used for another purpose.

There are limited data on variations in the zonal pattern between species, and our knowledge on the connectivity of sets of Purkinje cell zones and their target nuclei suggests that the combined A, B, C1, C3, and Y zones show little variation among species. The main differences concern the flocculus and the C2, D1, and D2 zones and their afferent and efferent connections. The functions of these zones and the kind of adaptations provided by their variations in width and length, however, remain largely unknown.

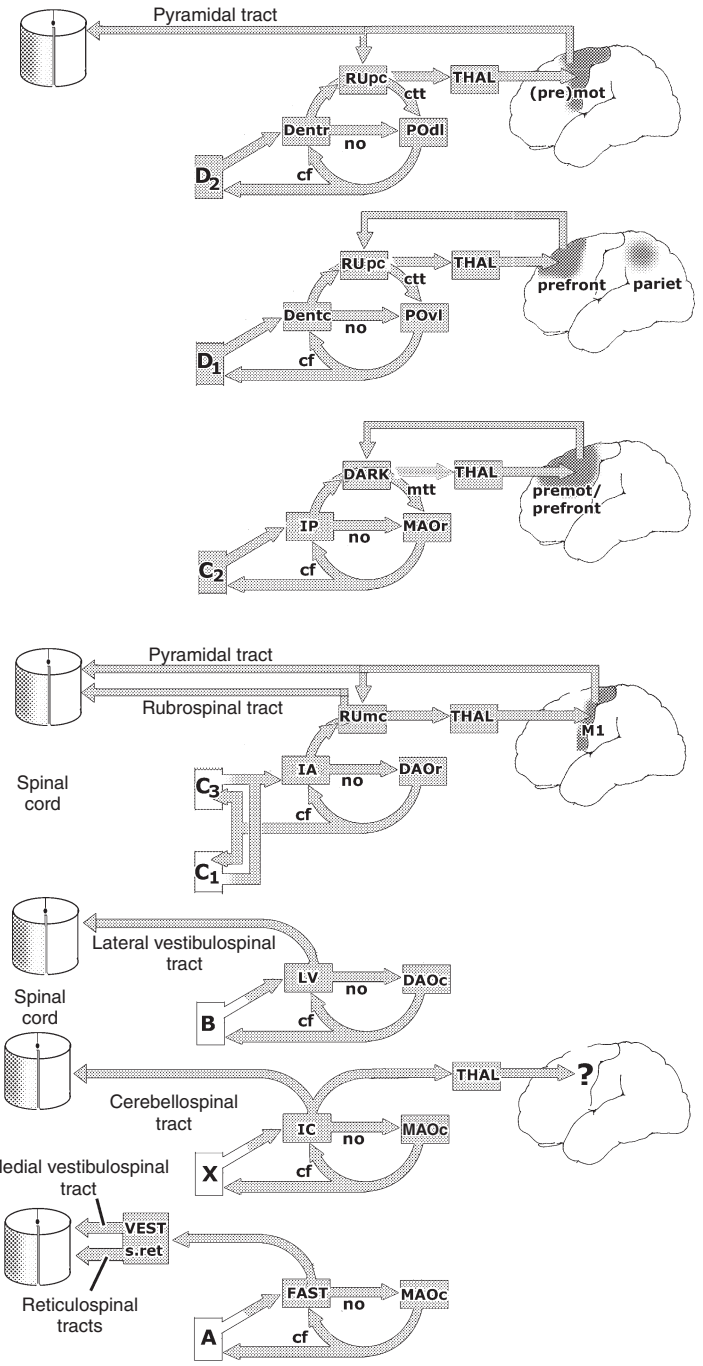

Figure 14 Diagrams of brainstem, thalamic, and cortical connections of the cerebellar Purkinje cell zones. The CX, A2, and Y zones are not included. All zones and their cerebellar and vestibular target nuclei are reciprocally connected with the inferior olive through a GABAergic nucleo-olivary pathway (no) and the climbing fiber projections with their collateral projections to the nuclei (cf). One set of zones (A, X, B, C1, C3, and D2) is connected with the spinal cord, through brainstem-spinal and/or corticospinal pathways. The D1, D2, and C2 zones and their target nuclei give rise to mesencephalo-olivary reciprocal circuits. These circuits are topically organized and include a relay in the parvocellular red nucleus (RUpc) or Darkschewitsch (DARK) nucleus at the mesodiencephalic junction. Similar reciprocal circuits do not exist for the other zones and their target nuclei. The D1, D2, and C2 zones, in addition, project to the cerebral cortex through the thalamus. For the D2 zone, these projections include the motor and premotor cortex; for the D1 zone they include the frontal eye field and prefrontal and parietal areas (see Voogd, 2004a, 2004b). (pre)mot, (pre)motor area; CA–X, zones A–X; cf, climbing fibers; ctt, central tegmental tract; DAOc/r, caudal/rostral part of the dorsal accessory olive; DARK, Darkschewitsch nucleus; Dentc, caudal dentate nucleus; Dentr, rostral dentate nucleus; FAST, fastigial nucleus; IA, anterior interposed nucleus; IP, posterior interposed nucleus; LV, lateral vestibular nuclues; M1, primary motor cortex; MAOc/r, caudal/rostral part of the medial accessory olive; mtt, medial tegmental tract; no, nucleo-olivary pathway; POdl, dorsal lamina of the principal olive; POvl, ventral lamina of the principal olive; prefront, prefrontal cortex; RUpc, parvocellular red nucleus; RUmc, magnocellular red nucleus; s.ret, reticular formation, THAL, thalamus; VEST, vestibular nuclei.

3.30.5.3 Mossy Fiber Afferents to the Cerebellar Cortex

The main afferent system of the cerebellum are the mossy fibers. The distribution of the mossy fibers differs from that of the climbing fibers. Mossy fibers generally distribute bilaterally, the mossy parent fibers collateralize into multiple longitudinal aggregates, and mossy fiber systems generally distribute to certain cerebellar lobules only (Wu *et al.*, 1999). Some mossy fiber systems contribute collaterals to the cerebellar nuclei on both sides. The multiple longitudinal aggregates of mossy fiber terminals are topographically related to the longitudinal pattern of Purkinje cell zones and their climbing fiber afferents, but our knowledge on this subject is still far from complete (Voogd, 2004a, 2004b).

Mossy fibers originate both from intrinsic and extrinsic sources. Collaterals of the axons of the cells of the cerebellar nuclei and the axons of a recently discovered cell type of the granular layer, the unipolar brush cell (Dino *et al.*, 2000), terminate as mossy fibers.

By far the largest single extrinsic source of mossy fiber afferents for humans, primates, and many other species is the pontine nuclei. Mossy fibers also originate from sensory relay nuclei, and as collateral systems from interneuronal pools of the spinal cord and the brainstem (the spino- and trigeminocerebellar tracts), certain reticular nuclei (the lateral, paramedian, and reticular tegmental nuclei), the vestibular nuclei, and the adjacent perihypoglossal nucleus (with its subsidiaries). Spino-, vestibulo-, and reticulocerebellar connections are constant among most mammalian species, although variations related to the prevalence of trigeminal over spinal connections in marsupials and rodents, as compared to carnivores, ungulates, and especially primates may also be expressed in the cerebellum (Voogd *et al.*, 1998). These mossy fiber systems terminate preferentially in anterior and posterior regions of the cerebellum, in relation to the A, B, C1, C3, and the Y zones, which, as pointed out above, constitute the stable backbone of the mammalian cerebellum.

On a higher resolution, a fine-grained microzonal topography is present in both the climbing and mossy fiber systems projecting to these zones, which subserve the local interaction of both afferent systems, believed to be at the core of cerebellar functioning (Ekerot and Larson, 1973 Garwicz *et al.*, 1998; Brown and Bower, 2001; Serapide *et al.*, 2001; Voogd *et al.*, 2003).

The pontocerebellar system is the final link in the main cerebrocerebellar pathway, although from a comparative anatomical point of view, it may have arisen as a tectocerebellar connection. In birds, two small medial and lateral pontine nuclei receive their afferents from the tectum and project to middle lobules (corresponding to lobule VII) and the caudal cerebellum (lobule IX, the uvula), regions that also receive an input from the pons in mammals (Freedman *et al.*, 1975). The tectopontine projection is preserved in mammals, but, in addition, the mammalian pontine nuclei now receive profuse projections from the cerebral cortex (Figure 15) (Münzer and Wiener, 1902; Mower *et al.*, 1979; Hartmann-von

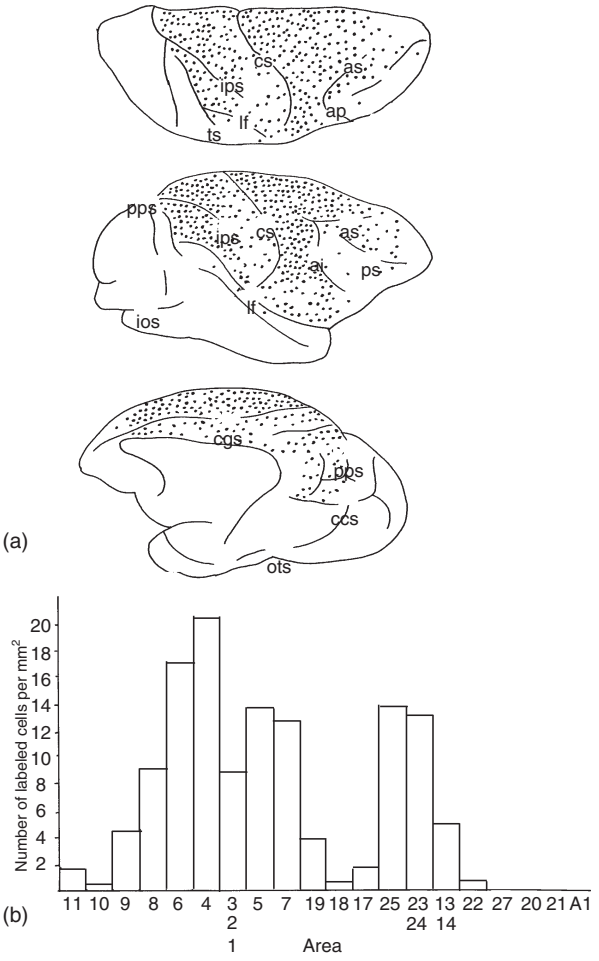

Figure 15 Distribution of corticopontine neurons in macaque monkeys. a, Distribution of retrogradely labeled neurons in the left cerebral hemisphere from a complete wheat germ agglutinin-coupled horseradish peroxidase filling of the pontine nuclei. b, Bar graphs illustrating the numbers of retrogradely labeled neurons in different cortical areas. ai, arcuate sulcus, inferior branch; as, arcuate sulcus, superior limb; ap, arcuate sulcus, inferior limb; ccs, calcarine fissure; cgs, cingulate sulcus cs, central sulcus; ios, inferior occipital sulcus; ips, intraparietal sulcus; lf, lateral (Sylvian) fissure; ots, occipitotemporal sulcus; pps, postparietal sulcus; ps, principal sulcus; ts, superior temporal sulcus. From Glickstein, M., May, J., and Mercier, B. 1985. Corticopontine projection in the macaque: The distribution of labelled cortical cells after large infection of horseradish peroxidase in the pontine nuclei. *J. Comp. Neurol.* 349, 51–72.

Monakow *et al.*, 1981; Glickstein *et al.*, 1980, 1985). These projections fall into two groups. One group, originating from the primary motor, the premotor, and the primary sensory cortices, contains collateral projection from the pyramidal tract (Ugolini and Kuypers, 1986). The second, originating from prestriate, posterior parietal, and prefrontal areas, may be considered in part as a collateral projection from the corticotectal system (Baker *et al.*, 1983; Keizer *et al.*, 1987). The largest evolutionary changes in mossy fiber connections occur in the second corticopontine cerebellar system. The pyramidal collateral system may subserve the coordination of skilled movements. The corticotectal collateral system probably is involved in the execution of sensory guided movements. The prominence of visual association and visuomotor areas of the cerebral cortex in the primate corticopontine projection indicates the importance of vision in the evolution of the primate cerebellum.

Pontocerebellar mossy fibers probably distribute to all cerebellar lobules, with the exception of the nodulus and the flocculus (Voogd, 1967; Kawamura and Hashikawa, 1981; Gerrits and Voogd, 1982, 1986; Glickstein *et al.*, 1994). A longitudinal zonal pattern in their termination was recently described by Serapide *et al.* (2001). In the anterior lobe and the lobulus simplex, they project to the apical and lateral portions of the folia, covering the spino-, reticulo-, and vestibulocerebellar mossy fibers, which terminate in more basal regions of the granular layer. A similar pattern may be present in the pyramis (lobule VIII) and the adjacent paramedian lobule. The apical coverage of pontocerebellar mossy fibers is much thicker in primates, where spino- and reticulocerebellar mossy fibers may never reach the cerebellar surface. Pontocerebellar mossy fibers terminate in lobule VII of the vermis and the uvula (lobule IX), in the ansiform lobule, and densely in the paraflocculus, the regions that display most variations in their folial pattern.

3.30.6 Embryological Origin of the Cerebellum

3.30.6.1 Determination and Origin of the Cerebellar Primordium

The past decade has seen rapid growth in our understanding of the molecular and cellular mechanisms underlying the embryological origins of the cerebellum. This has been fueled mainly by a great increase in knowledge on the mechanisms of action of key developmental control genes that sculpt the body plan in a large spectrum of animals ranging from insects to mammals.

In spite of the enormous species diversity with respect to size, foliation, and mediolateral patterning of the cerebellum, the following basic embryological scheme likely applies to all vertebrates. The cerebellum is derived from an embryonic territory at the junction of the developing midbrain and hindbrain, the so-called mid–hindbrain boundary, or MHB. Chick/quail transplantation experiments have revealed an organizing influence of a band of cells at the MHB called the isthmus (Marin and Puelles, 1994; Crossley *et al.*, 1996; Hidalgo-Sanchez *et al.*, 1999; reviewed in Joyner *et al.*, 2000). This region directs the formation of the midbrain, cerebellum, and anterior hindbrain and can induce midbrain and cerebellum tissue when placed ectopically. Genetic analysis in mice has shown that the position of the isthmic organizer is fixed at the boundary between the domains of expression of two homeodomain transcription factors, Otx2 and Gbx2 (Millet *et al.*, 1999; Broccoli *et al.*, 1999; reviewed in Joyner *et al.*, 2000). Otx2 is typically expressed throughout the embryonic forebrain and midbrain with a caudal border at the MHB; Gbx2 is expressed in the anterior hindbrain with a rostral limit at the MHB (Figure 16). Each of these factors mutually excludes the other from its territory. Using transgenic methods to artificially expand either expression territory results in malpositioning of the MHB and a variety of effects on development of the midbrain and cerebellum.

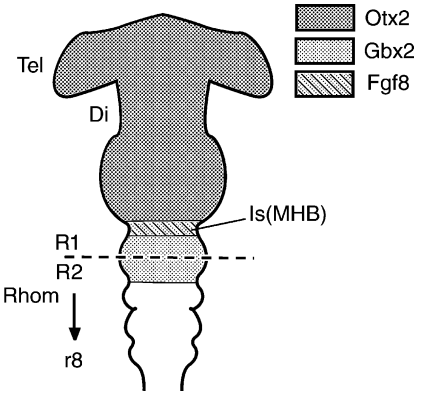

Figure 16 Position of the mid–hindbrain boundary (MHB) is genetically determined. Mutually exclusive domains of expression of Otx2 and Gbx2 define the position of the MHB and isthmus region of the developing vertebrate embryo. The organizer activity of the isthmus leads to the specification of cell fates in the midbrain, cerebellum, and rostral hindbrain. The major brain vesicles are indicated. Tel, telencephalon; Di, diencephalon; Mes, mesencephalon; Rhom, rhombencephalon; Is, isthmus. Shadings correspond to expression domains of developmental control genes. Redrawn and adapted from Joyner, A. L., Liu, A., and Millet, S. 2000. Otx2, Gbx2, and Fgf8 interact to position and maintain a mid–hindbrain organizer. *Curr. Opin. Cell Biol.* 12, 736–741.

All vertebrates, from fish to birds to mammals, have a similar embryonic pattern of brain vesicles that include the mesencephalon (midbrain) and rhombencephalon, the latter of which is made up of two secondary brain vesicles classically called metencephalon (cerebellum) and myelencephalon (hindbrain). The embryonic hindbrain is subdivided into eight transient swellings called rhombomeres, labeled R1 (the most rostral; really equivalent to the metencephalon) through R8 (Keynes and Lumsden, 1990; Lumsden and Krumlauf, 1996) (or R0–R7 in zebra fish; see Moens and Prince, 2002) (Figure 16). The cerebellum develops from the rostral rhombic lip, which corresponds with the part of the rhombic lip in R1. The rhombic lip is the dorsal rim of the alar plate, which gives attachment to the thin roof plate of the fourth ventricle. The border between the rostral and caudal rhombic lip is located at the greatest width of the fourth ventricle, between R1 and R2 (Figure 17). While expression boundaries of Hox and other control genes coincide with transient morphological constrictions between rhombomeres in many vertebrates, and genetic analysis indicates an intrinsic program controlling the segmental appearance of the hindbrain, there is no evidence of rhombomeric boundaries in the mature hindbrain. Thus, the major brain vesicles, the isthmic organizer, and rhombomeres are transient lineage restriction compartments for the generation of cellular diversity required for mature brain function (Fraser *et al.*, 1990; Keynes and Lumsden, 1990; Zervas *et al.*, 2004).

Several studies have examined the embryological origins of the cerebellum and its major afferent motor nuclei. For example, the inferior olive is generated from R8 and rostral spinal cord (Cambronero and Puelles, 2000), and the pontine nuclei are generated from R2–R8 (Marin and Puelles, 1994, 1995; Rodriguez and Dymecki, 2000). Although several studies using chick–quail chimera analysis indicate a contribution to the cerebellum from both the mesencephalon and metencephalon (or R1) (Martinez and Alvarado-Mallart, 1989; Hallonet and LeDouarin, 1993), this may be dependent upon the precise definition of the mes-/metencephalic boundaries. For example, another study in chick, using the marker Otx2 to define the caudal limit of the mesencephalon, indicated that the cerebellum is derived wholly from the metencephalon (or R1) (Millet *et al.*, 1996). A more recent study using an inducible fate-mapping technique in mice supports this view (Zervas *et al.*, 2004). This study suggests that lineage restriction boundaries restrict the intermingling of mes and met progenitor cells, and that the isthmus region (organizer), separating the mes and met, acts to further restrict any mixing of cells in these two neuromeres, in addition to influencing their distinct fates. Whether the cerebellum is derived wholly from R1 or not, the patterns of expression of key developmental control genes (En, Wnt, Otx, Gbx, Pax, Fgf8, etc.), which determine the positions of the isthmus and subsequent development of the midbrain and cerebellum, are highly conserved from fish to mammals. Thus, this highly conserved developmental program, activated in all vertebrates, guarantees the formation of the same basic brain substructures but allows for the expansion of features within these substructures required for species diversification.

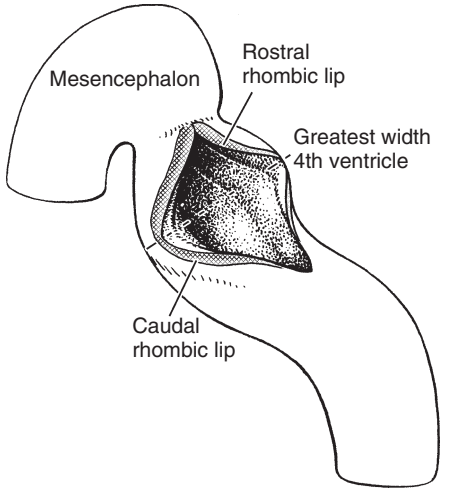

Figure 17 Diagram illustrating the position of the rostral and caudal rhombic lip.

Many of the genes that control specification of the cerebellar primordium are vertebrate orthologues of genes that control formation of the fruit fly body plan, such as Engrailed (En1, En2), Wingless (Wnt-1), Orthodenticle (Otx1, Otx2), etc. While no brain structure exists in the fruit fly that might remotely be considered a cerebellum, it is possible to trace the evolutionary origins of cerebellar development based on expression of these same genes in primitive chordates. In Amphioxus and Ascidians, for example, there is a single Otx gene expressed in the head region with a sharp posterior boundary of expression reminiscent of that in vertebrates (Williams and Holland, 1998). It is possible that the Otx territory in these primitive chordates is functionally homologous to the forebrain and midbrain in vertebrates. As in vertebrates, the rostral-most boundary of Hox gene expression in these species is posterior to the caudal boundary of Otx expression (Figure 18). While not yet identified in Amphioxus, Pax gene

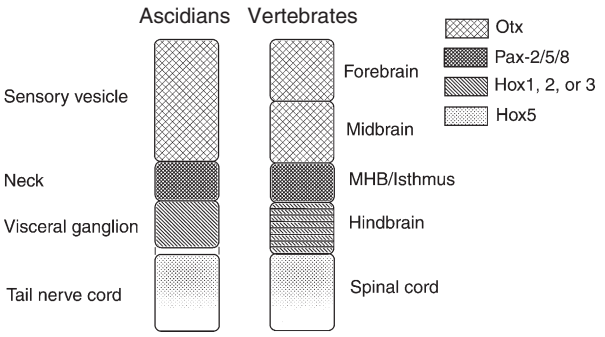

Figure 18 Comparison of the ancestral chordate neural tube structure to that of vertebrates. Homologous functional domains in the neural tubes of ascidians and vertebrates are hypothesized based on the observed expression domains of orthologous developmental control genes. The MHB of ascidians does not give rise to a cerebellum, and therefore new functions are acquired by this domain in vertebrates. Similarly, modification of these functions and the acquisition of new ones are likely to explain evolutionary changes within the vertebrate cerebellum. The subdivision of the rostral neural tube into forebrain and midbrain is hypothesized to be a novelty of vertebrates due to novel rostral expression domains of developmental control genes such as Dmbx 1 that emerge in the vertebrates (not shown). Di, diencephalon; Is, isthmus; Mes, mesencephalon; MHB, midbrain–hindbrain boundary; r1/8, rhombomere 1/8; Rhom, rhombencephalon; Tel, telencephalon. Redrawn and excerpted from Takahashi and Holland (2004).

expression in Ascidian embryos is wedged in between the Otx and Hox domains. Therefore, it is possible, but by no means proven, that this region could be homologous to the MHB of vertebrates, but without the capacity to generate a cerebellum.

This is analogous to the observation that these primitive chordates, which do not have a neural crest, nonetheless show expression of crest regulatory genes in the lateral plate (e.g., Snail; Langeland *et al.*, 1998; Erives *et al.*, 1998; for review, Shimeld and Holland, 2000). Thus, the Pax-positive MHB cells and the Snail-positive lateral plate cells of primitive chordates may be the evolutionary progenitors of cerebellum and neural crest, respectively.

Primitive basal vertebrates such as lampreys have a neural crest and a primordial cerebellum with primitive Purkinje cells (Larsell, 1967). So far, in the limited number of cases where it has been examined, expression of known Purkinje cell markers such as Zebrin II cannot be detected in these primitive cells (Lannoo and Hawkes, 1997). The failure to detect these cell markers is most likely due to species divergence of the specific biochemistry of Purkinje cells or of marker protein structure, rendering them undetected by antisera generated to vertebrate proteins. Nevertheless, all other vertebrate species that have been examined, from fish to humans, express most of the classic Purkinje cell markers, many of which deal with Ca^{2+} metabolism (calbindin, parvalbumin, IP3 receptor type 1, etc.).

3.30.6.2 The Genetics of Cerebellar Morphogenesis and Zone Formation

As described above, there is a great deal of evolutionary conservation of the cerebellar zonal pattern among vertebrate species. Studies from multiple avenues have converged to suggest that the division of the cerebellum into zones occurs by mechanisms that are intrinsic to that tissue and genetically encoded. If this is the case, then it is likely that functional differences among the species could be added by slight modifications of the genetic program underlying this pattern, resulting in expansions or contractions of zonal dimensions and/or cell numbers as the need arises. So far, however, the precise mechanisms defining zonal boundaries within the cerebellum remain elusive. Nevertheless, based on what is known, development of zones in the cerebellum can be viewed as a special case of the general process whereby developmental fields are parcelled into progressively narrower functional domains.

3.30.6.3 Fate Mapping and Clonal Analysis

Early in its development, the rostral rhombic lip changes in position from a mainly rostrocaudal orientation to a mediolateral one (Hochstetter, 1929). This change in position may be caused by mechanical factors and is related to the development of the pontine flexure and/or differential growth within the cerebellar primordium. More recently Mathis *et al.* (1997) and Sgaier *et al.* (2005) drew attention to this change in position in their interpretations of their fate maps of the cerebellar anlage and suggested that rostral rhombic lip ultimately corresponds to the medial cerebellum and posterior rhombic lip to the lateral cerebellum (Figure 19).

Fate maps of the matrix of the rhombic lip have a spatial and a temporal aspect. Studies of the development of the cerebellum have shown that its neurons are derived from the ventricular matrix of the rhombic lip in a definite sequence (Altmann and Bayer, 1978, 1985). The earliest are the nuclear cells, followed by the Purkinje cells and the Golgi cells. Interneurons of the molecular layer are generated by cells derived from the ventricular matrix, which divide in the white matter during late stages of cerebellar development (Zhang and Goldman, 1996). The cells of the external granular layer (EGL), the secondary matrix that produces the granule cells, are derived from the dorsal margin of the rhombic lip (from the URL, or upper rhombic lip or

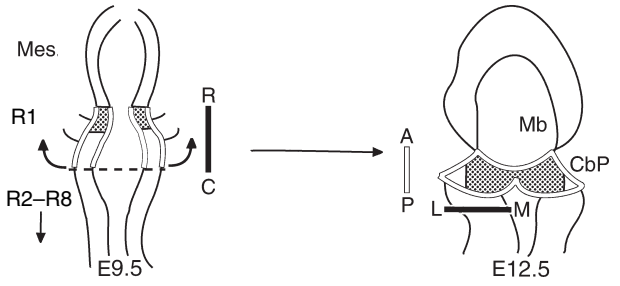

Figure 19 Orthogonal rotation of the A–P axis of R1 gives rise to the mediolateral orientation of cerebellar zones. Growth of the brain and cerebellar primordium in mouse between E9.5 and E12.5 results in a 90° rotation of the longitudinal axis of the rhombic lip. The darkly shaded region indicates a zone of cerebellar cell clones marked at E7.5 using an En2-promoter-based genetic fate mapping strategy. The open contour line indicates the rhombic lip and the cerebellar primordium. Note that the boundaries of the marked region change from a primarily anterior–posterior (AP) orientation to a mediolateral (ML) one. Mes, mesencephalon; Mb, midbrain; CbP, cerebellar primordium; R and C are rostral and caudal, respectively; A and P refer to anteroposterior axis; M and L refer to mediolateral axis. Adapted from Sgaier, S. K., Millet, S., Villanueva, M. P., Berenshteyn, F., Song, C., and Joyner, A. L. 2005. Morphogenetic and cellular movements that shape the mouse cerebellum; insights from genetic fate mapping. *Neuron* 45, 27–40, with minor modifications.

the germinal trigone) and subsequently migrate over the outer surface of the cerebellum.

Clonal analysis of cerebellar cells using a variety of techniques reveals a number of interesting relationships between cerebellar progenitors and both the determination of specific cerebellar cell types as well as their spatial organization. All of these studies have concluded that granule cells constitute a distinct lineage from all other cerebellar cell types, which is consistent with their initial origin from a spatially separate germinative neuroepithelium. In fact, mutation of the gene *Math1*, a molecular determinant of this unique lineage, results in a complete loss of this germinal region and thus granule cells, with no effect on the specification of Purkinje cells and deep nuclear neurons (Ben-Arie *et al.*, 1997). In contrast, in a study using replication defective retroviruses in chick, it was found that Purkinje cells and Bergman glia frequently occupied the same clone (Lin and Cepko, 1999). This study could find no strong evidence for a clonal relationship among the ventricular matrix-derived neurons. In another study designed only to detect relationships between neurons, however, Purkinje cells, deep nuclear neurons, Golgi neurons, and molecular layer interneurons in mice were often found to occupy the same clones (Mathis *et al.*, 1997). Thus, a picture emerges in which a common self-renewing progenitor in the ventricular matrix gives rise to most cerebellar cells except granule cells, and it does so asymmetrically and sequentially according to the known birth dates of these neurons. However, this view is now in need of some updating due to recent transgenic fate mapping studies. It is currently thought that large glutamatergic deep nuclear neurons, in addition to granule cells, are generated from the Math1-positive upper rhombic lip. Purkinje cells, inhibitory interneurons, and small inhibitory deep nuclear neurons are generated from a Ptf1a-positive ventricular zone immediately subjacent to the Math1 domain (Hoshino *et al.*, 2005; Machold and Fishell, 2005; Wang *et al.*, 2005).

One other feature of these clonal analyses is that clones were typically found to spread nearly the entire rostralcaudal dimension of the cerebellum, but were restricted in their spread along the mediolateral axis. No clones in any study were ever found to cross the midline, even in cases where clones spread rostrally into the midbrain or caudally into the hindbrain. In these cases, such large clones never occupied an entire hemicerebellum. Rather, these early labeled clones completely filled either a median territory (extending from the midline to roughly the edge of the vermis) or a lateral territory, but never both. Both territories extended the full rostralcaudal dimension of the cerebellum (Mathis *et al.*, 1997). The size of the median and lateral territories occupied by an intermediate-size clone varied with the actual clone size, and no fixed boundaries were observed that were respected by all or even several clones, except for the midline. Smaller clones cover less total space, but are similar in that they are oriented like zones, with distinct mediolateral boundaries but fanned out rostrally and caudally. When examined, no obvious relationship has been found to exist between these mediolateral clonal boundaries and boundaries defined by zonal markers, such as Engrailed, Eph's, and Gli, leading to the conclusion that individual cerebellar zones are not lineage restriction compartments (Lin and Cepko, 1999). Nevertheless, clones are always very limited in their spread along the mediolateral direction.

The finding of two precursor pools, a median one and a lateral one in each hemicerebellum, and the relative restriction of clone expansion in the mediolateral direction, may be consistent with what was observed using an inducible fate mapping technique in mouse (Sgaier *et al.*, 2005). This technique made use of the endogenous Engrailed promoters to inducibly and permanently label distinct territories of cerebellar precursors starting from embryonic day 7.5(E7.5) or later. Rather broad territories could be labeled (with lacZ) by this method, extending from the midline to variable lateral positions that depended upon the time of induction and the

promoter used. When the fate of cells that were labeled as early as E9.5 was determined by examination of lacZ expression in mature cerebellum, the mediolateral positions of cells at the time of their labeling were found to be unchanged in the adult. This is consistent with other studies that have observed gene expression in cerebellar cell clusters at E15 that are remarkably akin to the zonal pattern of expression of the same gene in adults (Oberdick *et al.*, 1993; Ozol *et al.*, 1999). From these studies, it seems likely that the rhombic lip is primarily divided by broad patterns of developmental gene expression rather than by lineage restriction, and the overlapping patterns of many such genes may result in embryonic zones with distinct cell fates whose positions are roughly maintained until adulthood. Time of birth of the cells may also play a role in the development of zonal patterns in the distribution of cortical neurons (see below).

It is formally possible that a transient lineage restriction boundary exists between the two clone pools within the rhombic lip, generating a medial and a lateral set of precursor cells, and that zone refinement occurs subsequent to this by overlapping patterns of expression of developmental control genes. At any rate, the rotation of a mostly rostrocaudally oriented pattern in the rhombic lip to one oriented mediolaterally during the period from E9.5 to E11.5 in mouse is consistent with many studies, as indicated above.

3.30.6.4 Late Embryonic Patterning and Cerebellar Morphogenesis

When Purkinje cells migrate toward the surface of the cerebellar anlage, they collect in a number of mediolaterally arranged clusters (Figures 10 and 20) (Korneliussen, 1967, 1968a, 1986b; Kappel, 1981; Feirabend *et al.*, 1985; Feirabend, 1990). Similar observations on the clustering of the Purkinje cells were made in studies using Purkinje cell-specific markers (Wassef and Sotelo, 1984; Smeyne *et al.*, 1991). Cell strands and/or fiber streams associate Purkinje cells of different clusters with different cerebellar nuclei. These connections of Purkinje cells are obvious even at these early stages, before synaptic connections have developed. The proliferation of enormous numbers of granule cells by the EGL leads to a great increase in the external surface area of the cerebellum and its folding into lobules and folia, most prominently in the rostrocaudal direction. This increase in the surface area causes the spreading out of the Purkinje cells of the clusters into a monolayer. The Purkinje cell clusters have been considered as the primordia of the adult Purkinje cell zones, and this is supported by studying their temporal morphogenesis through the use of zonal markers, as described above (Oberdick *et al.*, 1993; Ozol *et al.*, 1999).

Timing of Purkinje cell production by the ventricular matrix can be further subdivided into several successive stages, each of which gives rise to distinct clusters of Purkinje cells. Both in birds (Feirabend *et al.*, 1985; Feirabend, 1990; Karam *et al.*, 2000) and mice (Hashimoto and Mikoshiba, 2004), Purkinje cell clusters that are born at different dates typically form interdigitating patterns. In mice, early- and late-born clusters are located both in the vermis and in the hemisphere (Figure 21).

Purkinje cell clusters differ in their expression of different polarity genes such as En-2 (Millen *et al.*, 1995; Lin and Cepko, 1998). In the avian cerebellum, moreover, Purkinje cell clusters that are born

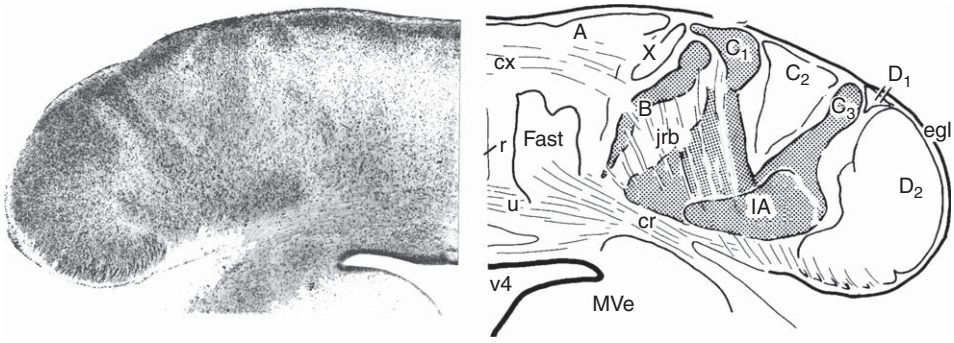

Figure 20 Coronal section through the cerebellum of a 55-day rhesus monkey fetus. Purkinje cell clusters are located at the surface of the cerebellum or are still located in a subcortical position. The cluster that will give rise to the future A zone is related to the fastigial nucleus. Cell strands connect the clusters C_1 and C_2 with their future target nucleus, the anterior interposed nucleus. The posterior interposed and dentate nuclei, the respective target nuclei of the C2 and the D zones are located at a different level. A–D, Purkinje cell clusters A–D; cr, restiform body; cx, cerebellar commissure; egl, external granular layer; Fast, fastigial nucleus; IA, anterior interposed nucleus; jrb, juxtarestiform body; r, midline recess; u, decussation of the uncinate tract; v4, fourth ventricle. From Kappel, R. 1981. The Development of the Cerebellum in *Macaca mulatta*. A Study of Regional Differentiation during Corticogenesis. PhD dissertation University of Leiden.

on different dates express different cell-adhesion molecules, such as the cadherins (Arndt *et al.*, 1998) and BEN (Chédotal, 1996, 1997), and repulsion molecules such as the ephrins and their receptors (Figure 22) (Karam *et al.*, 2000). The cadherins have been held responsible for the clustering of the Purkinje cells and the setting up of their corticonuclear projections (Arndt *et al.*, 1998; Luo *et al.*, 2004). The ephrins and BEN have been shown to be involved in the patterning of the olivocerebellar projection (Chédotal, 1996, 1997). The Engrailed gene products have been shown to be regulators of ephrin expression in other systems (Logan *et al.*, 1996). A sequence of events seems to emerge that determines the mediolateral zonal patterns in the distribution of the Purkinje cells and their connections. The fate maps of the rhombic lip, discussed in the previous section, and the temporal sequence in the production of the Purkinje cells of the different clusters form key features in their development. Further studies are needed to reconcile the spatial and temporal determinants of these zonal patterns.

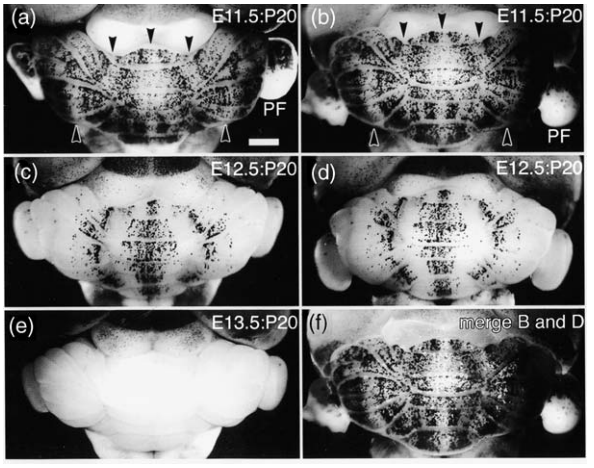

Figure 21 Comparison of the zonal localization of Purkinje cells with different birth dates. Purkinje cells are labeled with birth date-specific gene transfer of the adenoviral vector AdexCAG-Nl-lacZ injected into the midbrain ventricles of embryos at E11.5 (a, b), E12.5 (c, d), and E13.5 (e). At P20, each manipulated brain was stained by whole-mount for beta-gal. Purkinje cells born at E11.5 and at 12.5 are distributed in complementary zonal patterns. In (f) panels b and d are superimposed. The arrowheads in a and b indicate beta-gal-negative clusters. PF, paraflocculus. Scale bar: 1 mm. Reproduced with permission from Hashimoto, M. and Mikoshiba, K. 2004. Mediolateral compartmentalization of the cerebellum is determined on the 'birth date' of Purkinje cells. *J. Neurosci.* 23, 11342–11351.

It seems likely that some of the genes that control the very formation of the cerebellar primordium also play a role in the establishment and late embryonic refinement of cerebellar zones. En1, En2, Wnt1, Pax5, etc., are all known to be expressed in a zonal pattern during late embryogenesis of the mouse cerebellum (Millen *et al.*, 1995). That En and Wg (the fly orthologue of vertebrate Wnt genes) participate in establishing boundaries between fruit fly body segments and En/Wnt signaling is conserved in mice (Danielsen and McMahon, 1996) add fuel to the notion that these genes play a role in zone formation. So far, however, proof of a direct role has not been forthcoming. Null mutation of most of these genes results in deletion of the entire cerebellar primordium due to their very early action (McMahon and Bradley, 1990; Wurst *et al.*, 1994), and therefore effects on zones cannot be studied. However, ectopic overexpression of En-2 in mouse cerebellum starting from E15 has a mixed effect. It has no effect on the adult pattern of zones revealed by L7BG3 expression, a lacZ reporter gene driven by a truncated version of the Pcp-2(L7) promoter, but

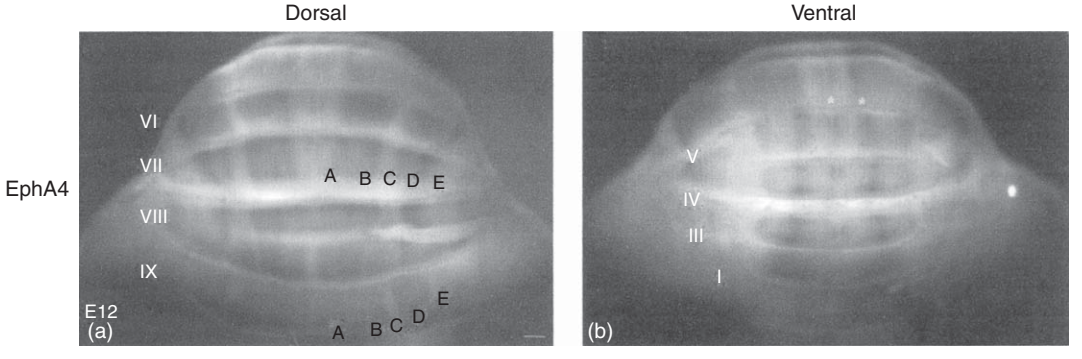

Figure 22 Dorsal and ventral views of EphA4 receptor localization (a, b) in whole-mount immunostaining on chick cerebella taken between stages 36 (E1O) and 38 (E12). Roman numerals refer to cerebellar lobules. EphA4-positive Purkinje cells in bands B and D are born early, EphA4-negative Purkinje cells in bands C and F are born late. The localization of Cadherin 6B (Arndt *et al.*, 1998) corresponds with the localization of EphA4. Reproduced with permission from Karam, S. D., Burrows, R. C., Logan, C., Koblar, S., Pasquale, E. B., and Bothwell, M. 2000. Eph receptors and ephrins in the developing chick cerebellum: Relationship to sagittal patterning and granule cell migration. *J. Neurosci.* 17, 6488–6500.

it has a severe effect on the pattern of stripes revealed by Zebrin II expression (Baader *et al.*, 1999). In addition, it results in an effect on the zonal organization of mossy fiber afferents, which could be explained by disruption of the expression of guidance molecules such as ephrin.

The development of the folial pattern of the cerebellum is closely related to the proliferation and migration of the granule cells in the EGL. An important aspect of transversely migrating EGL cells to the foliation of the cerebellum of the mouse was noticed by Sgaier *et al.* (2005). As previously revealed in chick, the transverse migration is mostly lateral to medial (Ryder and Cepko, 1994). However, one significant difference seems to be that in mouse there is a much greater flow of EGL cells from lateral regions in the posterior vermis (Sgaier *et al.*, 2005). This novel migratory trajectory was hypothesized to correlate with the expansion of the hemispheres in mammals.

The development and the patterning of the afferent climbing and mossy fiber connections were recently reviewed by Sotelo (2004). The inferior olive, the single source of the climbing fibers, and the lateral reticular, the external cuneate, the pontine tegmental reticular, and the pontine nuclei, all of which give rise to mossy fibers, are derived from the region of the caudal rhombic lip (R2–R8, as described above). Temporal and spatial sequences exist in their development from this region (Altman and Bayer, 1987a, 1987b, 1987c, 1987d). Neurons of the inferior olive and certain mossy fiber systems become specified as future mossy and climbing fibers at their birth. The molecular cues for pathfinding and translocation of the cell bodies to their definite positions have been extensively studied. Both mossy and climbing fibers enter the cerebellar anlage very early. Their transverse and longitudinal patterning occurs early, before synaptic connections are established, and, for the olivocerebellar climbing fiber projection at least, is related to the patterning of the Purkinje cells.

3.30.6.5 Conclusions on the Genetic Control of Cerebellar Development

1. Mutations in genes determining the production and differentiation of cells in the rostral and caudal rhombic lip, which are responsible for setting up the temporal and spatial gradients in the production of different cell types, expressing specific recognition and repulsion molecules, which would subserve the future patterning in their connections, are a possible substrate for natural selection.
2. The variations in the morphology of the mammalian cerebellum are mainly related to variations in length and the width of the C2, D1, and D3 Purkinje cell zones and their afferent climbing and efferent cerebellar nuclear connections in certain lobules of the cerebellum. Such variations are not observed in the zonal composition of the vestibulocerebellum, and the system of the A, C1, C3, and Y zones, which subserves the classical motor functions of the cerebellum. However, there are indications that these zones and their target nuclei can be integrated in newly developed systems, i.e., the development of the ventral paraflocculus in species with foveal vision. Generally, Purkinje cell zonation of the mammalian cerebellum is a highly conserved feature.
3. Mossy fiber systems, namely the corticopontocerebellar system, are subject to great variations among mammals. When the cerebellum is used for new or extended functions, adaptations in mossy fiber afferent systems may occur, which use the conserved, modular output system of the cortex for a new purpose.

3.30.7 The Functions of the Cerebellum

3.30.7.1 Historical Aspects

The earliest clues about functions of the cerebellum came from animal experiments. Rolando (1804) made lesions in the cerebellum of mammals and birds and found that the lesions impaired the animals' ability to move. Flourens (1824) agreed, but unlike damage to the spinal cord, the lesions do not abolish movement. Flourens agreed that the cerebellum is involved in the control of movement, but he argued that rather it is the 'coordination' of movement that is lost. Over the course of the nineteenth century, surgical technique improved, allowing more precise control of lesions and longer postoperative survival times. Luciani (1891) studied the long-term effects of cerebellar lesions in mammals. He believed that the observed lack of coordination caused by the lesion is best interpreted on the basis of more elemental deficits in muscle control. Luciani identified these deficits as asthenia, or muscular weakness, atonia, or loss of muscle tone, and astasia, the inability to fuse successive contractions, leading to a characteristic tremor.

Animal experiments strongly influenced the interpretation of the effects of cerebellar lesions in humans. Holmes (1917, 1939) studied the effects of cerebellar lesions on soldiers wounded in the First World War. Citing Luciani, Holmes interpreted most of the deficits in his patients as due to loss of the elementary functions of muscle tone, muscle strength, and loss of the continuity of movements. Babinski (1902) cited the experiments of

Flourens as the basis for his interpretations of the deficits caused by cerebellar lesions in humans. In addition to loss of coordination, Babinski added a characteristic symptom of cerebellar disease: the inability to execute rapid alternating movements, which he labeled adiadochokinesis.

All experimenters and clinicians agree that lesions of the cerebellum cause an impairment of movement. There is, however, no agreement on the underlying cause. Rodolfo Llinas and his colleagues (Llinas and Welsh, 1993; Welsh and Llinas, 1997) argue for a critical role for the inferior olivary nucleus and its efferent climbing fibers in the initiation and timing of voluntary movement. Bower (2002) and his colleagues (Parsons *et al.*, 1997) believe that the cerebellum is entirely a 'sensory' structure. According to this interpretation, the cerebellum receives sensory information that is used to predict the sensory consequences of a movement. Paulin (1993), who shares this view of the sensory role of the cerebellum, pointed out that the motor effects of lesions would be analogous to the effect on an automobile if its windshield were to be shattered. The car seems to perform poorly. Even though its motor, drive shaft, and wheels are intact, it is hard to steer. Thom Thach and his colleagues (Thach *et al.*, 1992) take a middle ground, arguing that the cerebellum serves as a sensory to motor coordinator. The parallel fibers are seen as allowing the coordination of movements among disparate body parts.

3.30.7.2 The Cerebellum and Plasticity

Humans and other mammals are capable of exquisitely precise control of movement. The nature of this control can best be studied in quantitative detail in eye movements. Saccades are rapid shifts of gaze that are characteristic of foveate animals. It has been estimated that humans execute as many saccades in a lifetime as they do heartbeats. In experiments with humans (McLaughlin, 1967) and monkeys (Straube *et al.*, 1997), it is clear that the saccades are highly accurate in finding a target. How is this accuracy maintained over a lifetime? If a human or monkey looks at a central fixation target and then makes a saccade to a target 15 degrees to the right or left, the saccade is typically made with great precision. If, when the eyes begin to move, the target is displaced by five degrees, the saccade is first made to the original position, and then a catch-up saccade brings the eyes to the new target position. Within a single session, the eyes now make a successively larger saccade. Saccadic adaptation requires the cerebellum (Barash *et al.*, 1999). After lesions restricted to lobule VII and caudal VI of the vermis, monkeys are completely unable to adapt to the altered target position. On average, saccades are made with some reduced accuracy to the presented target, but adaptation to the displaced target is no longer possible.

The failure of saccade adaptation reflects an important underlying function of the cerebellum. Each time a saccade is made, a measure of its accuracy is fed to lobule VII. Small errors due to perturbations such as fatigue are compensated and accuracy is restored.

Similar results show that the cerebellum is involved in other forms of motor calibration. The vestibulo-ocular reflex (VOR) is a mechanism whereby the stability of gaze can be maintained in the presence of head movements. As Melville-Jones and his colleagues have shown (Gonshor and Melvill-Jones, 1973; Melvill-Jones and Davies, 1976), as have Miles and his colleagues (Miles *et al.* 1980; Miles and Lisberger, 1981), the reflex can be modified by changing the direction or size of the image on the retina. The flocculus is an essential link in the long-term adaptation of the VOR. Paired Purkinje cell zones are able to adapt eye movements in the plane of the horizontal or the anterior semicircular canals, via the oculomotor neurons in the superior and medial vestibular nuclei (van der Steen *et al.*, 1994). The floccular zones also are a highly conserved system, present in mammals and birds alike (Voogd and Wylie, 2004). The circuit for smooth pursuit in monkeys includes the primary visual cortex, the middle temporal visual area (MT), and the frontal pursuit area in the arcuate cortex and converges upon the flocculus/ventral paraflocculus. Area MT extracts information about direction and speed of the target. The frontal pursuit area is concerned with the modulation of the visuomotor transmission for pursuit, but is dependent on feedback of the eye velocity command from the cerebellum or the brainstem for this task (Rambold *et al.*, 2002; Tanaka and Lisberger, 2002a, 2002b; Priebe *et al.*, 2003; Osborne *et al.*, 2004). The connections of the frontal pursuit area with the flocculus/ventral paraflocculus are not known, but may use the pontine nuclei (Leichnetz *et al.*, 1984; Glickstein *et al.*, 1985; Fries, 1990). The primate corticopontine system differs from mammals with nonfoveate vision in the presence of strong projections from parastriate and parietal areas belonging to the dorsal visual stream, including area MT. These visual corticopontine projections involve the rostral and lateral pontine nuclei, which project to the ventral and the adjacent dorsal paraflocculus. The primate ventral paraflocculus is an extension of the flocculus, using the same, conserved, zonally organized output system

(Voogd *et al.*, 1987). In lower mammals, it is represented by a single lobule (Gerrits and Voogd, 1982; Voogd and Barmack, 2005). The Purkinje cell zonation of the dorsal paraflocculus is quite different, and consists of the C2, D1, and D2 zones with an output through the posterior interposed and dentate nuclei. Visual corticopontine projections to the dorsal paraflocculus are already present in nonfoveate mammals (Burne *et al.*, 1981), and the output system of this lobule through the C2, D1, and D2 zones is the same in foveate and nonfoveate species. However, both the input and the output of the dorsal paraflocculus have differentiated and now include extensive areas of the parietotemporal and frontal association cortex, both as a source for the corticopontine mossy fiber input and as a target for the visual portions of the posterior interposed and dentate nuclei and, 'inter alia', as the origin of the corticomesodiencephalic principal olive climbing fiber paths to the C2, D1, and D2 zones (Voogd, 2003, 2004a). This differentiation in primates may provide the reciprocal pathways connecting the frontal pursuit area with the effective output through the flocculus/ventral paraflocculus.

3.30.7.3 Theories of Cerebellar Function

Some authors interpret the role of the cerebellum in the control of movement as being analogous to a problem of industrial control. Miall *et al.* (1993) propose that the cerebellum acts as a Smith predictor, taking their example from the field of industrial chemistry. In a typical arrangement, such as a petrochemical plant, there is a flow of material into a processor, which then acts on that material to produce an output. The output of the plant is monitored, but since online adjustments are too slow to correct for errors, the Smith predictor serves to compensate for the inherent delays. Rather than directly affecting the processor, there is a computer-based model of the processing system which controls production. The output of the plant is continuously monitored. Errors are fed into the model and corrections made. According to this view, the cerebellum is thought to contain an internal model of the motor system. Any deviations from an intended movement are fed into the cerebellum, which continuously compensates for errors in movement.

In addition to its obvious role in the control of movement, some have argued that the cerebellum, particularly the cerebellar hemispheres, plays a critical role in more complex functions, such as cognition, language, and emotion. Peter Strick and his colleagues (Dum and Strick, 2002; Strick, 2003) find the cerebellar hemispheres are preferentially connected by way of the lateral nuclei to the prefrontal cortex. This connection is interpreted as a closed loop; with the cerebral cortex accessing the cerebellar hemispheres and the cerebellar hemispheres projecting back to the same region of cerebral cortex by way of the lateral nuclei. They suggest that this loop plays a critical role in cognition and planning.

3.31 Do All Mammals Have a Prefrontal Cortex?

B Kolb, University of Lethbridge, Lethbridge, AB, Canada

Glossary

class-common behavior	Behaviors and behavioral capacities demonstrable in all mammals.
species-typical behavior	Behaviors and behavioral capacities that are specific to one or a number of related species.

3.31.1 What is the Prefrontal Cortex?

One of the most obvious characteristics of the mammalian cortex is the regional variation in cellular organization (cytoarchitecture). Beginning in the latter part of the nineteenth century, anatomists used the cytoarchitectonic differences to subdivide the cortex into a mosaic of regions that were presumed to be functionally different (see review by Kemper and Galaburda, 1984). Brodmann, and later many others, attempted to use naming systems that could be used across different species but such comparisons are not easy and are open to many criticisms (e.g., Lashley and Clark, 1946). A principal problem is that mammalian species differ profoundly in the total amount of cortex, in the relative differentiation of cortex, and in the fine details of cytoarchitectonics. For example, a region such as the visual cortex (Brodmann's area 17 or V1) can be presumed to have similar functions across species because it receives its input from the eyes via the lateral geniculate nucleus of the thalamus, yet the species differences in cytoarchitecture are so great that on cytoarchitectonic grounds it is not obvious that the regions are the same (Kaas, 1987). Nonetheless, it is clear that the cortex is divided into distinct anatomically defined areas and that the borders between these areas are relatively sharp. The difficulty is in determining which areas are equivalent in different species. There are clear differences in the size and number of areas across species and it seems likely that most cortical regions subserve more than one function.

The problem of identifying regions of the cortex that have sensory or motor functions is relatively easy insofar as they may receive unimodal input from sensory receptor systems (such as eye, ear, and tongue) or send connections to effector organs (such as muscles). But what about regions that have multiple sensory inputs and are not directly connected to effector organs? This is the problem we encounter in identifying the prefrontal cortex of mammals. What defines this region reliably across species? Although the term prefrontal suggests the tissue at the very front of the hemisphere, this is not a definition that is based either on anatomy of the tissue or on function. The answer to this question must include a consideration of multiple criteria that encompass not only structural comparisons but also functional ones.

The term prefrontal has an uncertain origin dating back to at least the early 1900s and over time has meant different things to different people. Today, however, prefrontal is generally regarded to be synonymous with orbitofrontal as used by Rose and Woolsey (1948). These authors first proposed that the cortical projection of the mediodorsal nucleus of the thalamus (MD) would define the orbitofrontal cortex of mammals. These authors saw their definition as a way of solving the problem that the frontal region of primates beyond the motor and premotor cortex has a prominent layer IV, and thus was called frontal granular cortex, whereas in nonprimates layer IV is indistinct or absent (see The Evolution of Motor Cortex and Motor Systems). Because the MD projection was constant across the mammals that they examined and the granular cortex was not, they believed that their definition of orbitofrontal cortex solved the apparent conflict. Although Rose and Woolsey's definition is useful and unambiguous, it has been criticized (see review by Reep, 1984). The major problem is that the MD is not a homogenous structure and shows large differences in organization and connectivity across mammalian species. The differences in connectivity are not just in the afferents to

the MD but also in the efferents from different regions of the MD. Just because the MD-projection cortex is present across mammalian phylogeny does not mean that the cortex has the same function. We thus must use other criteria in parallel with the Rose and Woolsey definition.

Reep (1984) proposed a different solution to the definitional problem. He proposed that the connections with the amygdala and certain brainstem regions, such as the dopaminergic input from the ventral tegmentum, as well as cytoarchitecture be used to make cross-species comparisons. Using these criteria, he identified five different subregions (see Figure 1) present in monkeys, cats, and rats including the following: (1) a medial infralimbic region receiving input from the amygdala but not the MD; (2) a medial prelimbic region (Brodmann's areas 25 and 32) receiving input from the MD, amygdala, and dopaminergic brainstem; (3) a region of agranular cortex overlying the claustrum receiving input from the MD, amygdala, and dopaminergic brainstem; (4) the anterior cingulate region receiving input from the MD and the anterior thalamus; and (5) a region of cortex lying between the prelimbic and insular areas that receives input from the MD but not the amygdala. He noted that other regions, such as area 9 of the monkey, do not appear to follow any obvious patterns across species and thus may be unique to one or a few orders of mammals. Although Reep preferred to avoid defining the term prefrontal by this set of connections to the subregions, it is an obvious conclusion that could be reached.

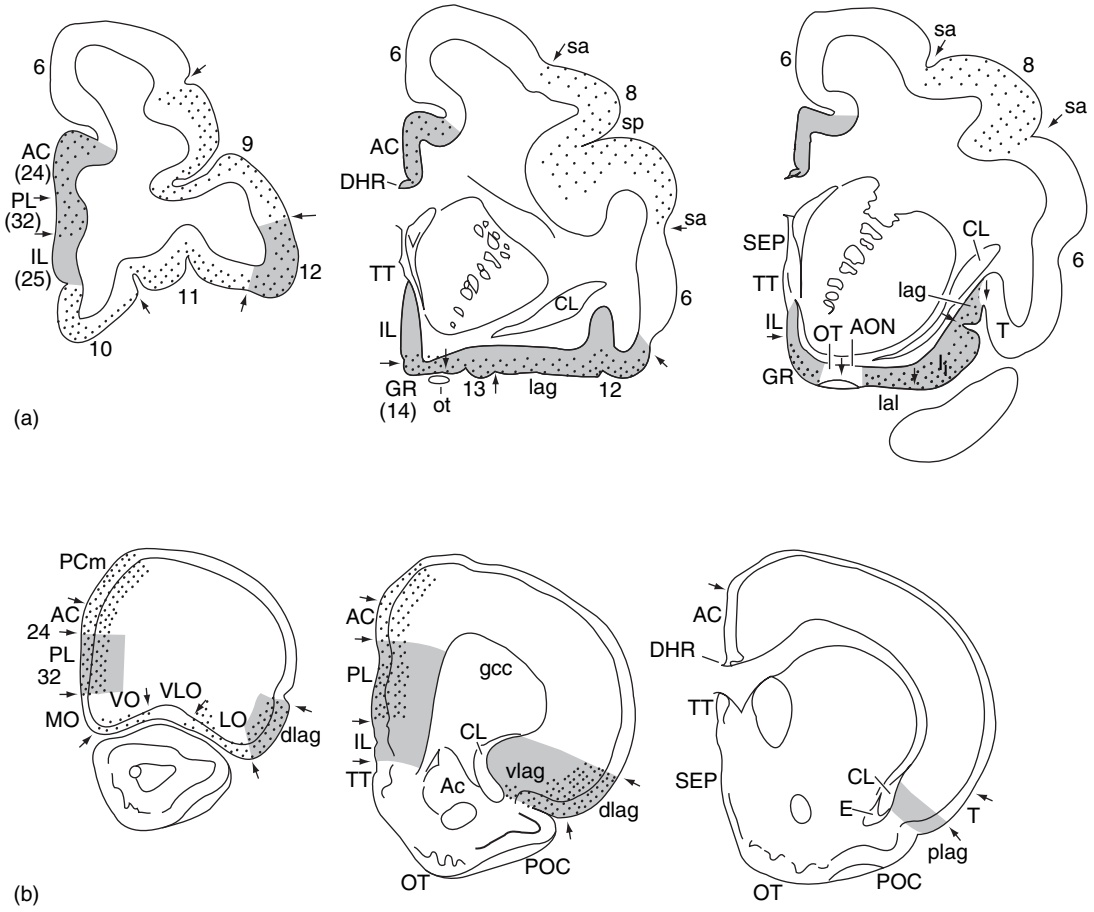

Figure 1 The prefrontal cortex. a, Serial sections through a rhesus monkey brain showing different cytoarchitectonic regions (Brodmann numbers are shown in parentheses). Dotted areas receive projections from MD; gray areas receive projections from the amygdala: b, Serial sections through a rat brain showing architectonic areas and MD and amygdala projection areas as in the monkey. Both species have similar regions of overlap in MD and amygdala projections as well as areas of no overlap. AC, anterior cingulate; Ac, anterior commissure; AON, accessory olfactory nucleus; CL, claustrum; DHR, dorsal hippocampal rudiment; dlag, dorsal agranular insular cortex; E, endo pyriform nucleus; gcc, genu of the corpus callosum; GR, gyrus rectus; lal, allocortical insular cortex; IL, infralimbic; lag, lateral agranular; LO, lateral orbital cortex; MO, medial orbital; OT, olfactory tubercle; PL, prelimbic; plag, posterior lateral agranular; POC, pyriform cortex; sa, arcuate sulcus; SEP, septum; sp, principal sulcus; T, taste cortical area; TT, tania tecta; vlag, ventral lateral agranular; VLO, ventral lateral orbital; VO, ventral orbital. Adapted from Reep, R. 1984. Relationship between prefrontal and limbic cortex: A comparative anatomical review. *Brain Behav. Evol.* 25, 1–80.

The Reep elaboration of the Rose and Woolsey definition of prefrontal is still problematic for two reasons. First, it does not include connections to other forebrain areas, especially the basal ganglia and sensory cortical areas, that are especially extensive with the MD- and amygdala-projection cortex. Unfortunately, these patterns of connection are well described only in primates and rodents but they are nonetheless instructive (for a review, see Uylings *et al*., 2003).

The frontal cortex as a whole has a special relationship with the basal ganglia because, although virtually all of the cerebral cortex projects to the basal ganglia, the frontal cortex receives most of the return projections via the thalamus (Middleton and Strick, 2000; see The Evolution of the Dorsal Thalamus in Mammals). These projections are present in species as diverse as monkeys and rats and, in addition, in both species there are a number of parallel, apparently functionally segregated circuits (Alexander *et al*., 1990; Middleton and Strick, 2000). For example, there are corticobasal ganglia circuits to the motor cortex, occulomotor cortex, anterior cingulate/medial orbitofrontal region, lateral orbitofrontal region, and dorsolateral region in both species.

In addition to the frontal–basal ganglia connections, in both primates and rats the prefrontal cortex is extensively connected with all cortical sensory regions (auditory, gustatory, olfactory, somatosensory, and visual), motor, and limbic cortical areas (e.g., Pandya and Yeterian, 1990; van Eden *et al*., 1992). Thus, in both species the prefrontal cortex receives multimodal corticocortical connections that make the prefrontal region appear to be a nodal station in several parallel networks (van Eden *et al*., 1992; Uylings *et al*., 2003).

In summary, the definition of prefrontal cortex remains inconclusive as no single criterion will suffice. The best definition is that the prefrontal cortex is the region in the cerebral cortex that includes the tissue that has projections from the MD and/or amygdala and that has extensive projections to the basal ganglia and the rest of the cerebral cortex. Given the extensive period of modification of cerebral regions in mammalian evolution, we should not be surprised that there is considerable variation in the details of prefrontal organization and function.

3.31.2 Unity and Diversity in the Prefrontal Cortex

Kaas (1987) proposed that a few basic areas of cortex are present in all mammals. These include primary and secondary visual and somatosensory areas (i.e., V1, V2, S1, and S2), at least one auditory and one taste area, a motor area, a transitional strip of cortex that relates the amygdala and hippocampus to other cortical areas, and a prefrontal cortex related to the mediodorsal nucleus of the thalamus. The assumption is that the common ancestor of modern mammals likely had all these areas and that they are maintained in extant species. Of course, evolution has had millions of years to modify these regions and as brains grew larger, especially in carnivores and primates, many more regions formed, probably by subdividing the prototypical regions. The prefrontal cortex expanded greatly in primate evolution and now has numerous subregions. Pandya and Yeterian (1985) proposed that the expansion of prefrontal subareas is related directly to the increase in sensory areas and the increase in posterior parietal cortex. The implication from this conclusion is that the prefrontal cortex must have some function in the integration of sensory information from different modalities and as more information is processed, the prefrontal cortex must enlarge.

Although the study of mammals in general suggests that all have a region that receives projections from the MD, that all have patterns of connections that have a general similarity, and that the prefrontal region expands as more sensory areas are added, studies of the brains of cetaceans (dolphins, whales, and porpoises) suggest otherwise (see Cetacean Brain Evolution). Cetaceans diverged from the line leading to primates approximately 90 Mya. Like the primate brain, the cetacean brain became large and highly encephalized over the course of evolution and when corrected for body size, many cetacean brains appear to be larger than the brains of chimpanzees or gorillas (e.g., Glezer *et al*., 1988; Marino, 2004). Marino and her colleagues have argued that a fundamental difference in brain development in cetaceans and primates is that, although there is a dramatic increase in the occipital, temporal, and parietal sensory regions, there is little elaboration of frontal lobe structures in cetaceans. Curiously, this lack of frontal lobe elaboration is correlated with a dramatic shrinkage of the olfactory system and in many cetacean species the olfactory structures are completely missing. In addition, limbic structures including the hippocampus and mammillary bodies are unusually small in the cetacean brain. What is not known is whether there is an MD-like structure in the cetacean brain and, if so, where it projects. Although there are studies on thalamic organization in cetaceans, they are all related to the sensory thalamus (e.g., Revishchin

and Garey, 1990) and there do not appear to be any studies of anterior thalamic nuclei.

The possible absence of, or at least the presence of, unusually small, prefrontal cortex and olfactory structures in cetaceans has obvious implications not only for cerebral evolution in general but for the question of why the prefrontal cortex evolved at all.

3.31.3 Why is there a Prefrontal Cortex?

A key concept in answering this question is to remember that evolution acts on the success of the organism, and a major component of the organism's fitness is related to its behavior. Although the brain produces behavior, the evolutionary pressure on brain evolution is indirect through selection of behavior. To understand why there is a prefrontal cortex, we must therefore ask what behaviors have been selected. Warren and Kolb (1978) proposed that although the details of behavior may differ somewhat, mammals share many similar behavioral traits and capacities that have a similar function. For example, all mammals detect and interpret sensory stimuli, relate this information to past experience, and act appropriately. Similarly, all mammals appear to be capable of learning complex tasks under various schedules of reinforcement (Warren, 1977) and all mammals are mobile and have developed mechanisms for navigating in space. Warren and Kolb (1978) proposed that behaviors and behavioral capacities demonstrable in all mammals could be designated as class-common behaviors. In contrast, behaviors that are unique to a species and that have likely been selected to promote survival in a particular niche are designated as species-typical behaviors.

The concept of class-common behaviors is useful in asking why there is a prefrontal cortex. There must be some set of environmental demands that are common across mammals and have encouraged the development of prefrontal cortex. At the same time, there must be differences in the details of prefrontal organization that are related to the differences in species-typical behaviors. For example, the prefrontal cortex has a role in social behavior (a class-common behavior) but mammals vary considerably the complexity of their social interactions (species-typical behavior). It seems likely that highly social mammals such as dogs will have different prefrontal organization than less social mammals such as domestic cats and, indeed, the volume of prefrontal cortex is considerably larger in dogs than in cats.

But what is the class-common function(s) of the prefrontal cortex? This is a difficult question but a review of theories of frontal lobe function have a common theme that the prefrontal cortex is involved in the temporal organization of behavior (e.g., Kolb, 1984; Goldman-Rakic, 1987; Fuster, 1989). The general idea is that the prefrontal cortex supports cognitive functions that are necessary to organize behavior in time. The temporal control of behavior requires at least six components (Kolb, 1990a). First, there must be an ongoing record of sensory experience that has occurred. This allows behavior to be disconnected from ongoing sensory stimulation and related to other stimulation that may have occurred previously. Second, there must be an ongoing record of what movements are being produced by the brain at any given moment, a record known as reafference. Reafference allows the prefrontal cortex to modify ongoing behavior in response to changes in the environment. Third, there must be selection of incoming experiential information, a process often referred to as attention. The importance of particular sensory information obviously varies depending on the environmental demands at any given moment. Fourth, there must be inhibition of some motor impulses and excitation of others to produce appropriate behavioral sequences. Fifth, behavior must be flexible with respect to both internal and external environments. It is one of the characteristics of mammals that we are able to adapt behavioral patterns to changing contexts. The importance of context-dependent behavior is clear in the complex social interactions of mammals. The makeup of the social group at any given time dictates the behavior of each animal. Species as diverse as apes and horses, for example, have a clear pecking order but the details of this social order vary with the precise grouping. Given the presence and position of certain animals, a given ape (or horse) may be bold and relaxed, whereas the presence of a single additional ape may lead to the same ape being quiet and nervous. An error in evaluating context can have grievous consequences. It is likely no accident that the prefrontal cortex has grown so large in primates, which are so highly social. Sixth, there must be an ongoing monitoring of the consequences of behavior. If reward is associated with a particular set of behaviors, but not with another, then the association between movements and consequences needs to be made.

In summary, whereas the principle of temporal organization of behavior provides a basis for the unity of prefrontal function, the necessary components for such a function provide the basis for diversity in the details of prefrontal function across mammals. The apparently unusually small (or absent) prefrontal region of cetaceans may provide

some insight into the class-common function of the prefrontal cortex although it is not immediately obvious what this might be. Another possibility is that the cetacean brain has evolved some other mechanism of integrating behavior over time that uses a fundamentally different set of cerebral processes, much as birds must be doing (see Divac and Mogensen, 1985).

3.31.4 How did the Prefrontal Cortex Arise in Evolution?

The existence of several discrete areas in the prefrontal cortex leads us to wonder whether there is some organizational principle that accounts for the different areas. Pandya and Yeterian (1990) have built on earlier ideas (e.g., Dart, 1934; Sanides, 1972) and conclude that in the mammalian brain the cerebral cortex has had a dual origin. They begin with the proposition that the cortex has evolved from two moieties – the hippocampus (archicortex) and the olfactory system (paleocortex). Each moiety is proposed to be tied to one of two basic functional issues common to all mammals, namely, the questions of 'what' and 'where'. During cortical evolution, the archicortex and paleocortex both give rise to tissue that Pandya and Yeterian describe as periallocortex (Figure 2). The next step is toward cortex that is nearly six-layered (proisocortex), which in turn leads to the most developed, six-layered isocortex. As these two parallel moieties develop, the olfactory-originated cortex develops the ventral and lateral prefrontal areas, whereas the hippocampus-originated cortex develops the anterior cingulate, ventral medial, and dorsolateral cortex. The two regions join on the dorsal surface in what are Brodmann's areas 8, 10, and 46.

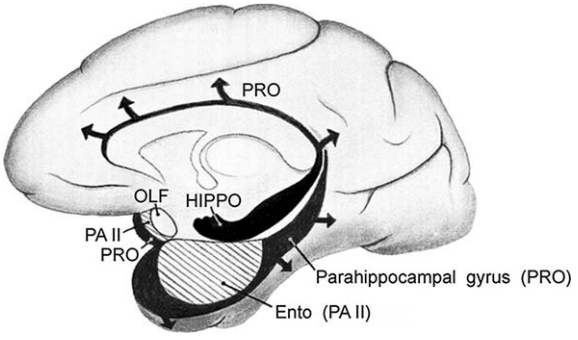

Figure 2 Schematic of a medial view of a rhesus monkey brain showing the hypothetical origin of the cortex from the olfactory system (OLF) and the hippocampal system (HIPPO). Adapted from Cerebral Cortex, vol. 4, 1985, pp. 3–61, 'Architecture and connections of cortical association areas.' Pandya D. N. and Yeterian E. H., with kind permission of Springer Science and Business Media.

In parallel to the prefrontal development is the development of the posterior sensory cortices. Although still poorly understood, the general idea is that the two frontal regions grow in conjunction with sensory regions that are related to the what and where questions. Thus, the paleocortical regions related to 'what' could be expected to develop gustatory, tactile, auditory, and visual connections, whereas the archicortical regions related to 'where' would be unlikely to develop connections with the olfactory and gustatory systems as their information would provide less reliable spatial information. This appears to be the case.

There are important implications of the Pandya and Yeterian ideas. First, the idea that there is an evolutionary development of dual cortical systems indicates that all mammals will have a functionally divided prefrontal cortex. Certainly all mammals that have been studied in detail do seem to have such a distinction (e.g., Kolb, 1984), although the relative size of the two subfields varies considerably (e.g., Benjamin and Golden, 1985). Second, there will be species differences in cortical (including prefrontal) organization and expansion depending on the relative importance of different sensory inputs to the species-typical 'what' questions. Obviously animals living in visually deprived conditions (such as underground) will have less prefrontal–visual interaction and likely more prefrontal–olfactory or tactile interaction. Third, animals that travel extensively in space or make discrete movements to points in space will likely have a more extensive archicortical system. The differences in species-typical behavioral selection of one or the other prefrontal subfields will likely have important implications for understanding much of the unity and diversity in prefrontal functioning. Finally, the fact that the cetacean brain has a marked reduction in both the olfactory system and the hippocampus is intriguing when seen in the light of the dual moieties and the apparently very small frontal lobe. If we assume that early mammals began with the two moieties that expanded into the modern terrestrial mammalian brain, then we can speculate that the two moieties may have regressed as the cetacean brain evolved. The puzzling thing is why did this occur? One intriguing aspect is that the two regions of the mammalian brain that continue to produce neurons in adulthood are the olfactory bulb and the hippocampus. How might these neurons be related to prefrontal functioning, if at all, and what are the implications for regression of these zones in cetaceans?

Jerison (1991) has proposed a complementary model of cortical evolution. His basic thesis is that the major change in mammalian brain evolution is the increase in the number of separate representations (maps) of the sensory world. Whereas relatively primitive mammalian brains (such as that of the hedgehog) may have only a couple of visual maps, the large brains of primates have 10 or more maps. The problem with developing so many maps is in making a single sensory–perceptual representation of the sensory world, a problem often called the binding problem. Jerison proposes that one solution is to bind events together in place and time so that events that are coincident in place and time, but represented in different places in the brain, are experienced as a single event. Recall that we noted earlier that an important class-common function of the prefrontal cortex is the temporal organization of behavior. We can speculate that the prefrontal cortex plays a role in binding sensory information from different sensory modalities together in time. Thus, as the sensory areas expanded to make more maps, the prefrontal cortex expanded to mediate the binding of the maps together. The Pandya and Yeterian model emphasizes the separate evolution of what and where systems in the prefrontal cortex and these represent a type of cognitive map of sensory information. They too must be bound together and the merging of the archicortical- and paleocortical-derived regions in the dorsolateral frontal regions (areas 9, 10, and 46) may contribute to the merging of these maps.

A final consideration in the question of whether the initial mammalian brain had a prefrontal cortex. The Pandya and Yeterian proposal would suggest that it does. Monotremes (egg-laying mammals) might be presumed to be most similar to the initial mammalian brain. Curiously, when Divac and his colleagues examined one monotreme, the Australia spiny anteater (echidna), they found not only that the echidna had an MD-projection cortex but that it had nonthalamic connections that are similar to those of the placental mammals, including Old World monkeys. In contrast, the other monotreme species, the platypus, has a small MD-projection cortex (Bohringer and Row, 1977). This may reflect the relatively smaller size of the MD in the platypus and the lesser importance of olfaction in the largely aquatic platypus (Rowe, 1990), a conclusion that would be concordant with the small frontal area in cetaceans. Studies of other relatively primitive mammals such as marsupials and insectivores have identified an MD-projection cortex (e.g., Broomhead, 1974; Joschko and Sanderson, 1987; Dinopoulos, 1994), suggesting that the initial mammal likely had a prefrontal-like cortex (but see Preuss, 1995; Krubitzer, 1998).

3.31.5 Brain Size and the Scaling of the Prefrontal Cortex

The relationship between brain size, cortical surface area, and behavior has fascinated comparative neuroanatomists for over 100 years. As a rule of thumb, as the brain becomes larger, the number of cortical subregions increases. Jerison (1991) has argued that the increase in cortical surface area is related to more cortical sensory subregions, each of which provides a different map of the sensory world. Pandya and Yeterian (1990) see the increase in sensory maps as being directly related to the increase in prefrontal regions. Kaas and Preuss (2003) propose that as brain size increases, there is a serious problem with connectivity as it is known that connections take up more space than cell bodies themselves (e.g., Klyachko and Stevens, 2003). Because most cortical connections are with functionally similar (and adjacent) regions, one solution to the volume of connections problem is to make connections as short as possible. It follows that if subregions of cortical areas are formed, then the number of connections can be reduced. Thus, as the brain increases in size, we can see for several reasons that there will be more subregions and that this will affect the organization of the prefrontal cortex. We can expect that mammals with large brains will have more prefrontal regions and that there may be species-typical differences in the functional organization of the prefrontal cortex.

But is there a linear relationship between the increase in brain size and the increase in the area of prefrontal cortex? Bush and Allman (2004) addressed this question by comparing the brains of 43 primate and 15 carnivore species. Their analysis shows that in primates the frontal cortex increases in size relative to the rest of the brain, whereas in carnivores it does not. There are no data for other mammalian orders but the Bush and Allman results indicate that not all mammalian orders have an equivalent relative volume of frontal cortex. Indeed, we have seen earlier that cetaceans have a very small frontal lobe given their brain size and the monotreme echidna has a surprisingly large area of MD-projection cortex. The difference in relative volume of prefrontal cortex is almost certainly related to function and the challenge for the future will be to determine whether there are significant functional differences in frontal functioning across

species. As noted above, it is likely that there is a unity in function related to class-common functions of the prefrontal cortex and the differences are related to species-typical specializations in prefrontal function. Identifying these functional differences has not proven easy and is a major challenge in behavioral neuroscience (e.g., Kolb, 1990a; 1990b; Uylings *et al*., 2003).

3.32 The Evolution of Neural Systems for Sleep and Dreaming

S Ribeiro and M A L Nicolelis, International Institute for Neuroscience of Natal (IINN), Natal, Brazil

Glossary

amniotes Vertebrates in which the developing embryo is protected from desiccation by a series of membranes, as an adaptation for terrestrial life. The group comprises reptiles, birds, and mammals.

arc Activity-regulated cytoskeletal-associated protein, a calcium-dependent immediate-early gene directly involved in synaptic remodeling and memory consolidation. Also known as Arg 3.1.

insight Sudden realization of the solution of a problem, achieved by way of a novel strategy not previously envisaged by conscious thought.

memory consolidation Maturation process by which recent memories are strengthened, amplified, propagated, and restructured so as to become long-lasting traces.

neuronal reverberation Poststimulus recurrence of spatiotemporal patterns of neuronal activity related to the stimulus. The phenomenon can be observed in multiple forebrain regions, such as the cerebral cortex, hippocampus, putamen, and thalamus.

plasticity-related genes Set of genes directly or indirectly involved in synaptic remodeling, and required for memory formation. Includes arc and zif268.

proteasomes Complex cellular structures that catabolize proteins. Proteasomes play an essential role in the regulation of the cell cycle, signal transduction, and gene expression.

wish fulfillment According to Sigmund Freud, dreams represent an unconscious attempt to resolve conflicts by way of the realization of repressed wishes.

zif268 Transcription factor required for memory consolidation, encoded by a calcium-dependent immediate-early gene. Homologues include egr1, Krox-24, NGFI-A, and zenk.

3.32.1 Introduction

> Macrobius and Artemidorus [sustained that] dreams were divided in two classes. The first was believed to be influenced only by the present (or the past), and was unimportant in respect to the future; it included the [...] insomnia, which directly reproduces a given idea or its opposite (e.g., hunger or its satiation), and the phantasmata, which elaborates the given idea fantastically (as e.g. the nightmare) [...]. The second class of dreams, on the other hand, was determinative of the future. To this belonged direct prophecies received in the dream (oraculum), (...) the foretelling of a future event (visio), (...) and the symbolic dream, which requires interpretation (somnium) (Freud, 1900).

To understand the evolution of sleep in mammals, one must first note that we lack the kind of direct evidence that lends plausibility to so many evolutionary narratives in biology. We completely lack neurophysiological and neuroanatomical records of ancestor species, and fossilized skulls tell little or nothing about the deep brain nuclei that generate and maintain sleep. At present, the most important data with regard to sleep and dream evolution come from the comparative neurobiological investigation of sleep in extant vertebrate species (Figure 1a). Reptiles, birds, and mammals experience at least two very distinct neural states. During waking (WK), amniotes interact with the environment, carving their ecological niches. During slow-wave sleep (SWS), a periodic state in which brainwaves and neurons slow down and synchronize, amniotes undergo behavioral quiescence and broad sensorymotor shutdown. Crocodilians, birds, and

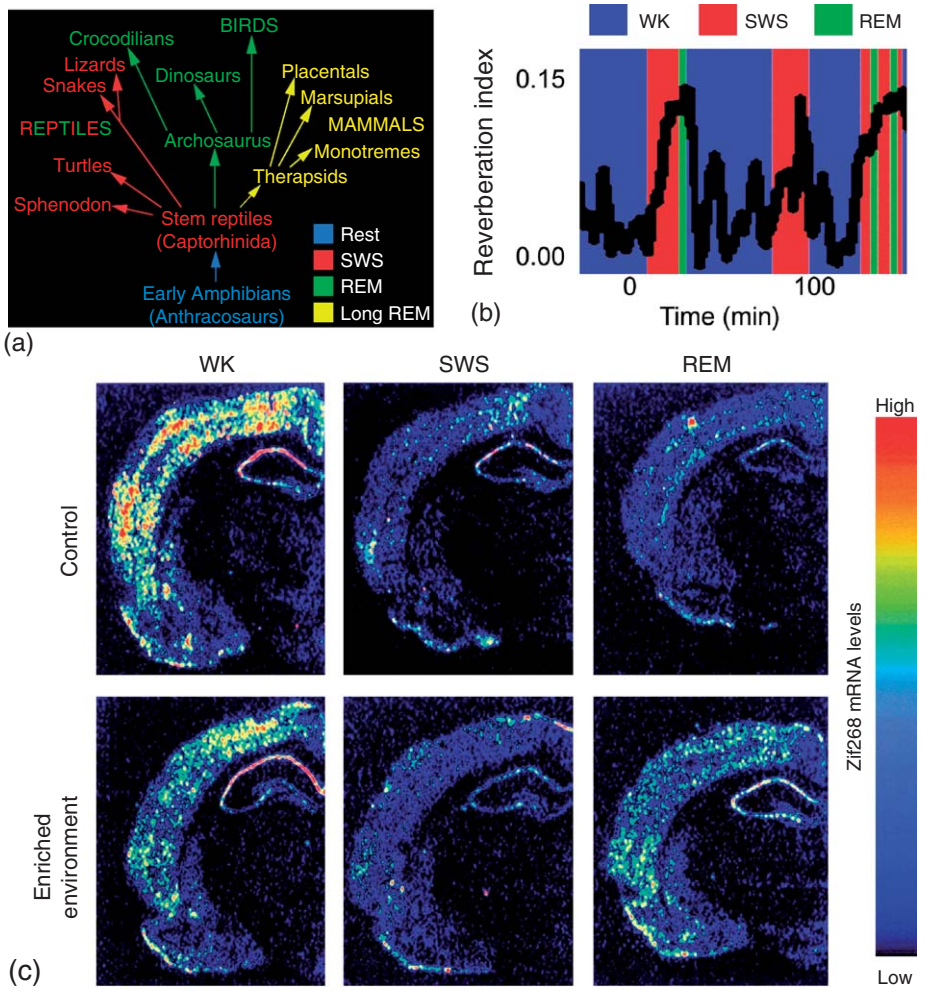

Figure 1 Functional evolution of sleep states. a, Sleep states in extant amniote species and presumed distribution in extinct ancestors; b, memory reverberation measured by neuronal ensemble correlation is strongest during SWS. Shown is a superimposition of successive neuronal ensemble correlations and concurrent behavioral states for neocortical neurons. Correlation peaks correspond to SWS or REM, while troughs match WK epochs. Adapted from Ribeiro, S., Gervasoni, D., Soares, E. S., *et al.* 2004a. Long-lasting novelty-induced neuronal reverberation during SWS in multiple forebrain areas. *PLoS Biol.* 2, 126–137. c, Experience-dependent upregulation of zif268 gene expression in the rat brain during REM sleep. Shown are autoradiograms of representative brain sections hybridized with a zif268 radioactive riboprobe. In controls kept in their familiar home cages before the experiment (top panels), zif268 expression decreased from WK to SWS and REM sleep. In animals exposed to an enriched environment for 3h before the experiment (bottom panels), zif268 levels decreased from WK to SWS, but increased from the latter to REM sleep. This effect was particularly noticeable in the cerebral cortex and the hippocampus. Adapted from Ribeiro, S., Goyal, V., Mello, C. V., and Pavlides, C. 1999. Brain gene expression during REM sleep depends on prior waking experience. *Learn. Mem.* 6, 500–508.

mammals also display another state called rapid-eye-movement sleep (REM), in which behavioral quiescence is concomitant with an increased activation of specific brain areas. Birds and crocodilians have very short REM episodes, lasting a few seconds each. In contrast, mammals have long REM episodes that may last more than 1h. In humans, REM is highly correlated with the occurrence of dreaming. What were the selection pressures that shaped SWS and REM? What are the extant functions of sleep and dreams, and how did they evolve?

After more than a century of anatomical and physiological investigation of the brain, the biological mechanisms underlying the generation and maintenance of sleep are reasonably understood (Aserinsky and Kleitman, 1953; Dement, 1958; Dement and Kleitman, 1957a, 1957b; Grastyan and Karmos, 1961; Jouvet, 1967; Jouvet *et al.*, 1959; Lee and Jones, 2004; Luppi *et al.*, 2004; Roffwarg *et al.*, 1962; Rechtschaffen and Kales, 1968; Siegel, 1990; Steriade, 1992; Steriade *et al.*, 1993; Sutcliffe and de Lecea, 2002; Timo-Iaria *et al.*, 1970), but the functions of sleep and dreams

remain controversial (Dave and Margoliash, 2000; Frank *et al.*, 2001; Gutwein *et al.*, 1980; Hennevin *et al.*, 1989; Hirase *et al.*, 2001; Hoffman and McNaughton, 2002; Lee and Wilson, 2002; Louie and Wilson, 2001; Maquet *et al.*, 2000; Nadasdy *et al.*, 1999; Pavlides and Winson, 1989; Peigneux *et al.*, 2003; Pompeiano *et al.*, 1994; Qin *et al.*, 1997; Ribeiro *et al.*, 1999, 2002, 2004a; Siegel, 2001; Skaggs and McNaughton, 1996; Winson, 1985; Wilson and Naughton, 1994). Deeper rifts exist within psychology. More than a century after the publication of *The Interpretation of Dreams* (Freud, 1900), a consensus about dreams and their relationship to human consciousness is yet to be achieved. While depth psychology focuses on dream meaning and wish fulfillment (Fosshage and Loew, 1978; Freud, 1900; Jung, 1953a, 1953b, 1974; Jung *et al.*, 1969; Solms, 2004), experimental psychology scrutinizes sleep-dependent learning in search of less subjective dream purposes (Bryson and Schacher, 1969; Fishbein, 1971; Jenkins and Dallenbach, 1924; Karni *et al.*, 1994; Lucero, 1970; Leconte and Bloch, 1970; Leconte and Hennevin, 1971; Maquet *et al.*, 2003; Mednick *et al.*, 2003; Pearlman, 1969; Smith and Butler, 1982; Smith and Lapp, 1986; Smith and Rose, 1996; Stickgold *et al.*, 2000; Walker *et al.*, 2002b; Wetzel *et al.*, 2003). Due to their different methods, each of these fields of investigation has, to a large extent, established a sleep and dream phenomenology of their own.

The persistent gap separating the neural processes underlying sleep from a comprehensive account of subjective dreaming has produced dream models that are outright incompatible with fundamental observations available to any introspective dreamer. One example of such dissociation is the notion that the bizarreness and hyperassociativeness of dreams can be trivially explained by random neuronal activation of the neocortex during REM (see Neuronal Migration, A Tale of Two CPGs: Phylogenetically Polymorphic Networks; Crick and Mitchison, 1983, 1995). According to this anti-Freudian theory, dreams arise from stochastic deep brain inputs to the neocortex, evoking a succession of neuronal firing patterns that correspond to randomly assembled memory fragments. The model proposes that such process has the function of erasing irrelevant memory traces, cleaning up storage space to allow the formation of new memories. A corollary of this theory is that dream content is intrinsically meaningless. This conclusion undermines the very significance of dream interpretation as a relevant window into human consciousness (Freud, 1900).

The 'random cortical activation' theory does not survive confrontation with the fact that dreams can be remarkably repetitive, especially when major trauma has occurred. Indeed, recursive nightmares are an important symptom of post-traumatic stress disorder, which is characterized by disturbed, hyperaroused REM (Ross *et al.*, 1994, 1999). For instance, war veterans dream about battle events for decades after the end of combat (Esposito *et al.*, 1999; Neylan *et al.*, 1998; Schreuder *et al.*, 1998). Given the colossal number of neurons and synapses in the human neocortex, it is clearly impossible to explain the activation of nearly identical neuronal firing patterns over several consecutive dreams by way of random neocortical activation.

If it is true that some neurobiological theories of dreaming lack introspection and conflict hopelessly with the basic dream phenomena, the humanities often err due to unwarranted anthropocentric or ethnocentric perspectives. The anti-Freudian philosopher Owen Flanagan, for instance, argues that dreams cannot possibly be a biological adaptation, based on his failure to recognize fitness-enhancing elements on his own dreams. Owen concludes that dreaming is meaningless and serves no function at all: "dreams are the spandrels of sleep" (Flanagan, 2000). On the other side of the road, the psychoanalytical tradition has been faulted and even ridiculed for insisting that dreams are always an attempt to fulfill a wish (Freud, 1900), and for considering censorship of scandalous thoughts a universal function of dreams (Freud, 1915, 1920) instead of a specific cultural mark of the conservative Viennese society in which Freud lived and produced his work (Gay, 1989).

It is time for a synthesis. A satisfactory theory of sleep and dreaming must first account for all the related phenomenology, and not selected parts of it. Second, it must distinguish the several functions of the different sleep and dream states. Third, it must produce a plausible evolutionary narrative of how these states enhanced fitness over phylogenetic time, evolving into a layered set of functions that can only be peeled apart in the appropriate chronological order.

3.32.2 The Evolution of SWS

When, why, and how did sleep evolve? With perhaps a few exceptions, all animals display intermittent rest in alternation with periods of activity, for energy conservation, metabolite replenishment, and predator avoidance (Berger, 1993; Berger and Phillips, 1990, 1995; Inoue *et al.*, 1995; Rattenborg *et al.*, 1999). While rest is unpredictable and mostly determined by external variables, sleep is an endogenous state of deep quiescence tightly regulated by mechanisms tuned to circadian

variations in ambient light. Flies and crabs possess a quiescent state similar to SWS in amniotes (Nitz *et al.*, 2002; Ramon *et al.*, 2004; Shaw *et al.*, 2000). It is not clear whether sleep is a conserved trait in vertebrates and invertebrates, or just a convergent adaptation driven by similar selection pressures such as circadian light changes. On one hand, the neurobiology of sleep in nonarthropod invertebrates is a vast unexplored frontier. On the other hand, it is still debatable whether fish (Shapiro and Hepburn, 1976; Tobler and Borbely, 1985) and amphibians (Hobson *et al.*, 1968; Lazarev, 1978; Monnier, 1980; Vataev, 1989) truly sleep, or rather display intermittent rest periods that occur whenever permitted by the lack of environmental opportunities or threats (Campbell and Tobler, 1984; Kavanau, 1998). The aquatic medium is only superficially affected by circadian light changes, being opaque most of the time due to depth or suspended particles. As a consequence, fish rely heavily on electroception, magnetoception, and olfaction to survive, but vision is usually of reduced importance (Butler and Hodos, 1996; Grier, 1984).

Amniotes are a monophyletic group derived from Anthracosaurs, a group of Paleozoic amphibians (Gauthier, 1994) (Figure 1a). Given the presence of SWS in all extant reptile, avian, and mammalian species investigated to date (Campbell and Tobler, 1984; De Vera *et al.*, 1994; Dewasmes *et al.*, 1985; Flanigan, 1973; Flanigan *et al.*, 1974; Hess *et al.*, 1953; Hobson, 1989; Huntley, 1987; Kavanau, 1997; Kleitman, 1963; Ookawa, 1972; Rojas-Ramirez and Tauber, 1970; Szymczak, 1987; Timo-Iaria *et al.*, 1970; Van Twyver and Allison, 1970; Wayne, 1950), one must conclude that SWS was favorably selected early on in the amniote lineage, during the ecological pilgrimage from water to dry lands of the Carboniferous period (354–290 Mya) (Futuyma, 1986). Conquest of the terrestrial environment involved a drastic change of the vertebrate sensory environment, as land dwellers in general depend heavily on visual and auditory information to survive. It is fair to assume that the absence of light during nighttime, by forcing protoreptiles to hide from predators in burrows, caves, or nests (Grier, 1984), was a strong constraint on the evolution of early SWS. The first sleepers were probably the ancestors of turtles (Broom, 1924; deBraga and Rieppel, 1997), large and morose Captorhinids (Figure 1a) that thrived in a vast Eden populated by relatively harmless protein-rich invertebrates and abundant edible vegetation, but eventually evolved heavy armor and discrete habits to avoid the predation of other evolving amniotes (Carroll, 1988). Sleep co-evolved with massive reciprocal connections between thalamus and cortex (Butler, 1994; Karten, 1991, 1997; Karten and Shimizu, 1989; Northcutt, 1981; Reiner, 1991). During SWS, thalamocortical interactions give rise to neuronal bursting and slow local field potential oscillations that maintain the sensory disconnection typical of SWS (Steriade, 1992; Steriade *et al.*, 1993).

How relevant was this step? SWS more than fulfills the primary rest functions related to energy conservation and metabolite turnover, but it also happens to enhance an additional biological function of immense behavioral impact – learning (Bryson and Schacher, 1969; Fishbein, 1971; Jenkins and Dallenbach, 1924; Karni *et al.*, 1994; Lucero, 1970; Leconte and Bloch, 1970; Leconte and Hennevin, 1971; Maquet *et al.*, 2003; Mednick *et al.*, 2003; Pearlman, 1969; Smith and Butler, 1982; Smith and Lapp, 1986; Smith and Rose, 1996; Stickgold *et al.*, 2000; Walker *et al.*, 2002b; Wetzel *et al.*, 2003). A 1991 random survey of 1000 Americans by the National Sleep Foundation and the Gallup Organization verified the devastating effects of insomnia on many aspects of the WK function, including impaired memory and decreased ability to accomplish daily tasks. During SWS, waking patterns of neuronal activity reverberate in several forebrain areas including the hippocampus and the neocortex (Dave and Margoliash, 2000; Hirase *et al.*, 2001; Hoffman and McNaughton, 2002; Lee and Wilson, 2002; Louie and Wilson, 2001; Maquet *et al.*, 2000; Nadasdy *et al.*, 1999; Pavlides and Winson, 1989; Peigneux *et al.*, 2003; Qin *et al.*, 1997; Ribeiro *et al.*, 2004a; Skaggs and McNaughton, 1996; Wilson and McNaughton, 1994), reflecting the absence of sensory interference (Pavlides and Ribeiro, 2003; Ribeiro *et al.*, 2004a). Such reverberation seems to promote the pretranscriptional amplification and consolidation of memories by way of calcium-dependent mechanisms (Buzsaki, 1998; Destexhe and Sejnowski, 2003; Massimini and Amzica, 2001; Sejnowski and Destexhe, 2000; Steriade *et al.*, 1993). By focusing endogenous brain activity on recently utilized neuronal networks, SWS increases the contrast between what will or will not be remembered so as to effectively amplify selected memories (Figure 1b). While the body saves energy, SWS promotes learning by repetition. It is conceivable that the cognitive function of SWS evolved as a mere epiphenomenon of the adaptation to a marked circadian regulation of rest behavior. Still, it is tempting to speculate that the evolution of an offline brain state able to enhance memory consolidation played a significant role in the reptile radiation that led to the long Mesozoic age of saurian supremacy (~250–65 Mya).

3.32.3 The Evolution of REM

REM is characterized by eye-closure, increased cerebral activation, and total absence of muscle movements, except for occasional localized muscle twitches (Aserinsky and Kleitman, 1953; Dement, 1958; Dement and Kleitman, 1957a, 1957b; Grastyan and Karmos, 1961; Jouvet, 1967; Jouvet *et al.*, 1959; Rechtschaffen and Kales, 1968; Roffwarg *et al.*, 1962; Timo-Iaria *et al.*, 1970). The mass extinction at the end of the Cretaceous (65 Mya) allowed for the ecological spawn of birds and mammals, warm-blooded vertebrates characterized by having REM (Siegel, 1995) and a superior capacity for learning (Balaban, 1988; Kaminski *et al.*, 2004; Kroodsma, 1974; Pepperberg and Brezinsky, 1991; Savage-Rumbaugh *et al.*, 1980; Thompson and Herman, 1977; Thorpe, 1958; Whiten *et al.*, 1999) (Figure 1a). Several pontine, mesencephalic, and forebrain nuclei co-evolved with REM for its generation and maintenance (Lu *et al.*, 2000; Luppi *et al.*, 2004; Nelson *et al.*, 1983). REM upregulates the cortical expression of the plasticity-related genes arc and zif268, (Ribeiro *et al.*, 1999, 2002, in preparation; Ulloor and Datta, 2005), which trigger the strengthening and remodeling of selected synaptic connections (Lemaire *et al.*, 1990; Richardson *et al.*, 1992; Sukhatme *et al.*, 1988; Wallace *et al.*, 1995). The same genes are downregulated during SWS, so that a single night of sleep witnesses several stop-and-go gene upregulation cycles (Ribeiro *et al.*, 1999) (Figure 1c). Both arc and zif268 are necessary for the formation of long-term memories (Bozon *et al.*, 2003; Jones *et al.*, 2001; Guzowski *et al.*, 2000). Arc interacts with the cytoskeleton and calcium-dependent enzymes at the presynaptic terminal (Donai *et al.*, 2003; Guzowski *et al.*, 2000; Lyford *et al.*, 1995), while zif268 promotes changes on the postsynaptic terminal in response to presynaptic excitation (Petersohn *et al.*, 1995; Takeuchi *et al.*, 2002; Thiel *et al.*, 1994). Furthermore, zif268 upregulation inhibits proteasome activity (James *et al.*, 2006), shifting the neuronal metabolism toward protein synthesis and synaptic plasticity (DiAntonio and Hicke, 2004). As a consequence, the SWS–REM cycle produces an anterograde propagation of memory traces across brain areas (Ribeiro *et al.*, 2002), increasing the reach and strength of memories over time (Ribeiro and Nicolelis, 2004). A single cycle involving both phases suffices to consolidate certain short-term memories (Mednick *et al.*, 2003), but it is the repetition of several cycles during a night that promotes deep transformations, gradually propagating memories through several brain areas (Pavlides and Ribeiro, 2003). This process likely anchors memories ever more solidly in the neuronal matrix (Cermak and Craik, 1979; Craik and Lockhart, 1972), causing a cumulative increment of learning at each night of sleep (Walker *et al.*, 2003). In mammals, anterograde propagation of gene expression during sleep seems to promote the continuous exodus of memories from the hippocampus to the cerebral cortex (Ribeiro *et al.*, 2002, in preparation), periodically freeing new coding space at the entry gate for episodic memories (Izquierdo and Medina, 1997; Bontempi *et al.*, 1999; Frankland and Bontempi, 2005; Frankland *et al.*, 2001; Scoville and Milner, 1957; Squire, 1992). It may be hard to determine today how important was the acquisition of REM for the ecological success of birds and mammals, but certainly its addition to SWS made for much faster, stronger, and durable learning.

Although ancestral reptiles were the first to evolve proper sleep, modern reptiles sleep less than most mammals, and (except for crocodiles) lack REM (Hobson, 1989). Why did turtles, lizards, and snakes fail to develop REM? Ectothermy is the most likely reason (Kavanau, 1997, 2002), because mammals and birds can only enter REM within a narrow range of relatively high temperatures (Amini-Sereshki and Morrison, 1982; Azzaroni and Parmeggiani, 1993; Glotzbach and Heller, 1994; Satinoff, 1988; Szymusiak *et al.*, 1999). Another possible key may be found in the temporal order of the two sleep states, and their different susceptibilities to fear. Under normal circumstances, in men and mice alike, REM can only follow SWS but the opposite never occurs (Aserinsky and Kleitman, 1953; Jouvet, 1967; Rechtschaffen and Kales, 1968; Timo-Iaria *et al.*, 1970). Furthermore, REM can only occur after a fair amount of SWS has taken place (Aserinsky and Kleitman, 1953; Jouvet, 1967; Rechtschaffen and Kales, 1968; Timo-Iaria *et al.*, 1970). Importantly, rats exposed to fear conditioning have a strong suppression of subsequent REM, but not SWS (Sanford *et al.*, 2001). The appearance of ever more implacable predator dinosaurs over the Mesozoic turned life on the dry land increasingly threatening. Could predation have prevented the ancestors of modern reptiles to sleep well? Maybe the myth of the dragon that sleeps with one open eye has its ethologic foundation in the fact that some reptiles display unihemispheric SWS, a strange split-brain state also present in birds and aquatic mammals (Ayala-Guerrero *et al.*, 1988; Ball *et al.*, 1986; Flanigan *et al.*, 1974; Lilly, 1964; Lyamin *et al.*, 2000; Mukhametov *et al.*, 1992; Rattenborg *et al.*, 2000; Szymczak *et al.*, 1996), shown to be positively correlated with predation risk (Rattenborg *et al.*, 1999). Or perhaps, quite to

the contrary, the cognitive advantage provided by reptilian SWS far exceeded the need for more animal intelligence in the rich and stable Mesozoic environment. Whether the most intelligent of the mighty Jurassic dinosaurs ever evolved REM is a mystery, but their closest relatives on the Earth, crocodiles (Flanigan *et al*., 1973) and birds (Dewasmes *et al*., 1985; Flanigan, 1973; Ookawa, 1972; Szymczak, 1987), do have REM (Figure 1a). Given the enormous evolutionary distance between the mammalian and saurian lineages, it is possible that REM is a convergent adaptation that evolved twice in vertebrates. Further neuroanatomical and neurophysiological investigation of the REM-related neural circuitry in birds and crocodilians is in order to resolve the issue.

3.32.4 The Evolution of Extended REM

When it comes to REM differences between mammals and birds, time is of essence. Whereas most mammals display a few long REM episodes per 24 h cycle, with episode duration of up to hundreds of minutes, birds exhibit hundreds of ultrashort REM episodes in a single night, with duration smaller than 20 s (Dewasmes *et al*., 1985; Flanigan, 1973; Ookawa, 1972; Szymczak, 1987) (Figure 1a). Why did birds fail to develop long REM? A clue may be found in the fact that, during REM, despite the lack of sensory inputs, great portions of the forebrain become as active as during waking. Such high levels of activity fail to become overt behavior (and therefore interrupt sleep) because inhibitory glycinergic neurons in the pons effectively block most of the muscle activity during REM (Jouvet, 1994). Thus, it is conceivable that the need to keep residual muscle tonus for perching was the ecological constraint for the small duration of avian REM episodes (Dewasmes *et al*., 1985; Flanigan, 1973; Ookawa, 1972; Szymczak, 1987). The current evidence indicates that plasticity-related gene expression, possibly the primary cognitive function of REM, is uncorrelated with time spent in REM (Ribeiro, 2000; Ribeiro *et al*., 1999, 2002), and reaches maximum levels even when REM episodes are cut very short (Shi *et al*., 2004). What sort of selection pressures drove the elongation of individual REM episodes in mammals? Do extended REM episodes contribute to learning in any special way?

The molecular and cellular sleep-dependent mechanisms described so far are involved in the stabilization and strengthening of already-acquired memories. There is however another form of learning, more dramatic and puzzling. The insight (Kohler, 1947), also known as abduction (Peirce, 1958), corresponds to the creation of new memories and ideas not trivially derived from pre-existing memories. Although insights may occur during waking (Jung-Beeman *et al*., 2004), they are greatly facilitated by sleep (Wagner *et al*., 2004). Several notorious examples of sleep-dependent insight can be drawn from both science and art (Barrett, 2001). Kekulé dreamt a snake eating its own tail and thus discovered the circular structure of benzene. Mendeleev, the discoverer of the periodic table, visualized his breakthrough concept in a dream. Intense dreams very much inspired artists like Dürer, Blake, Dalí, Frida Kahlo, and many others (Barrett, 2001). Although the biological mechanisms underlying sleep-dependent insight still remain unknown, the available subjective reports of the phenomenon point to an important role of dreams (Barrett, 2001).

In support of this hypothesis, mounting evidence indicates that extended REM harbors nonstationary neuronal reverberation, in contrast with highly stationary reverberation during SWS (Pavlides and Winson, 1989; Ribeiro *et al*., 2004a, 2004b; Winson and Abzug, 1977). Such 'noisy' reverberation during REM, long postulated by psychology (Hartmann, 1967, 1998) , should promote memory restructuring instead of memory strengthening, assembling 'new memories' from fragments of pre-existing ones. In other words, insights may derive from the shuffling or recombination of relevant memory traces during REM. Evidence in favor of this hypothesis comes from psychological experiments in which subjects were woken up from either SWS or REM and immediately asked to resolve anagrams. The results indicate that REM promotes more flexible cognitive processing than SWS, suggesting that memory restructuring is indeed facilitated by REM (Walker *et al*., 2002a). The evolution of extended REM may be related to the positive selection of insightful behavior, a feature of great importance in unstable changing environments such as the Earth after the Cretaceous–Tertiary cataclysm. All known species of monotremates, marsupials, and placentals possess relatively long REM episodes (Siegel, 2004), ranging from a few to several minutes. The echidna, long suspected to be the only exception among mammals (Allison *et al*., 1972), actually has a REM-like state (Nicol *et al*., 2000; Siegel *et al*., 1996).

3.32.5 The Evolution of Dreams as Emotional Simulations of Past and Future

In humans, REM is nearly always accompanied by dreaming (Dement and Kleitman, 1957a, 1957b;

Roffwarg *et al.*, 1962). Although the strengthening and restructuring of memories are at the roots of the cognitive functions of sleep and dreams, these concepts do not account entirely for the symbolic complexity that characterizes the oneiric narrative in adults. After all, it is not common to dream about the repetition of hard tasks, nor about static and isolated images, nor with the resolution of riddles. Dreams may have first evolved as a collateral effect of extended REM, and are likely present in all the mammals that possess such trait. Any pet owner knows that cats and dogs seem to act out dreams during sleep. More controlled evidence of dreaming in nonhuman mammals was obtained by lesions of the brainstem nuclei that promote muscle atonia during REM (Jouvet and Delorme, 1965). Cats with such lesions sleep quietly through SWS, but upon entering REM become suddenly agitated by vigorous species-specific behaviors, such as meowing and pouncing. What do cats dream about? What are the neural substrates of dreaming, what is the purpose of dreams as narratives, and which selection pressures shaped their evolution?

During human REM, a selected set of forebrain areas gets activated, including portions of the hypothalamus, amygdala, septum, and ventral striatum, as well as the anterior cingulate, orbitofrontal, entorhinal, and insular cortices (Braun *et al.*, 1997; Maquet *et al.*, 1996; Nofzinger *et al.*, 1997). Furthermore, it has been shown that dreaming ceases upon lesion of mesolimbic pathways connecting reward centers with the thalamus, striatum, and cortex (Solms, 1997, 2000). This suggests that dreams promote the "integration of neocortical function [...] with motivational and reward mechanisms" (Nofzinger *et al.*, 1997).

Human dreams are subjective narratives composed of familiar and unfamiliar beings, things, and places, interacting around a self-representation of the dreamer that mostly observes an unfolding plot. Dreams vary in intensity, ranging from confused and faint impressions to complex time-evolving narratives with vivid imagery and surprising turns. Although dreams tend to be dominated by visual images, they can also involve combinations of auditory, olfactory, tactile, gustatory, motor, vestibular, and linguistic modalities. Dreams can sometimes be extremely pleasant or just the opposite, but are usually characterized by a mix of emotions. Dreams are also hyperassociative, linking characters, places, and actions in bizarre ways. While normal dreams usually lack in logical coherence, remarkably meaningful dreams do occur to most people at least a few times in life. As noted by Freud, dreams often involve elements of the experience of the preceding day(s), the 'day residue' (Freud, 1900). Dreams can also anticipate events of the coming day(s), particularly when subjects undergo extreme anxiety and expectation. A good example is provided by the dreams of students before difficult exams, which often contain detailed anticipatory simulations of the expected challenges, either in content and/or context. Freud also observed that dream narratives fulfill wishes (or anti-wishes) of the awakened subject, simulating the realization (or frustration) of specific desires (Freud, 1920). Although the prevalence of overt wish fulfillment in the dreams of normal adults is low, it is common in young children (Foulkes, 1982).

Dreams are caused by intense and nonstationary memory reverberation during extended REM, with the neocortex lightened up at high neuronal firing rates and oscillatory frequencies predominantly above 30 Hz (Cantero *et al.*, 2004). The qualitative feeling of 'quasireality' in dreams derives from the fact that memory reverberation during REM occurs at an intensity and oscillatory spectrum comparable to those of WK (Steriade *et al.*, 1993). Such high levels of excitation cause the reverberating memories that comprise dreams to appear bright and vivid to the self-representation, and variations in neural activity levels explain the dynamic range of vividness that characterizes normal dreaming. Similarly, the simultaneous occurrence of neuronal reverberation in multiple forebrain sites during REM (Maquet *et al.*, 2000; Pennartz *et al.*, 2004; Ribeiro *et al.*, 2004a) explains the wide variation in dream modality. There is also a compelling relation between the high variability of neuronal reverberation during REM and the fragmentation, condensation, and bizarreness of dreams. Far from being random (Crick and Mitchison, 1983, 1995), dream narratives highlight waking events according to how recent, novel, and behaviorally significant they were, that is, dreams are directed by the anxieties and preoccupations of the dreamer (Winson, 1985). Dreams seldom occur during SWS (Kales *et al.*, 1967; Nielsen, 2000; Roffwarg *et al.*, 1962). Instead, the subjective experience of SWS consists of low-intensity but coherent thoughts resembling waking reasoning (Fosse *et al.*, 2004). The coherence of such 'mentation' likely reflects the high stability of neuronal reverberation during SWS (Pavlides and Winson, 1989; Ribeiro *et al.*, 2004a; Winson and Abzug, 1977). By the same token, the lack of intense imagery during SWS probably reflects the decreased cortical activity and slow oscillations below 4 Hz that characterize memory reverberation in this state (Steriade *et al.*, 1993; Timo-Iaria *et al.*, 1970).

If dreams first arose as a byproduct of neuronal reverberation during extended REM, what (if any) the functions of dreams are? So far, we discussed how sleep states co-evolved with learning-related neural mechanisms. Dreams, just like sleep states, were also selected for their adaptive value for learning. This may not be apparent in most people's dreams (Flanagan, 2000; Germain *et al.*, 2000), but normal human dreaming is arguably a good model of normal mammalian dreaming. Humans organized in complex societies face minimal behavioral challenges, in comparison with the constant game of life and death experienced by freely ranging animals. In nature, vital resources are scarce, competition is relentless, and populations of nearly all species suffer predation. Contrary to humans, most animals face the perspective of being eaten alive on a daily basis. Animal behavior in the wilderness is surely selected for fast and effective learning. The evolution of dreams in higher vertebrates was certainly shaped by a tough environment in which uncertainty was the rule, and REM-dependent insight was positively selected. Given this set of constraints, one should expect freely ranging mammals to possess a very limited dream repertoire, consisting of actions to avoid predation, spatial maps to orient foraging, mating, and a few other species-specific behaviors of high adaptive value.

To conceive the selection pressures that shaped dream evolution in nonhuman mammals, we must look toward the kind of dreams that humans have when confronted with primeval challenges. Two types of dream are of special interest, those following or preceding highly significant events (either good or bad). For instance, major psychological or physical trauma usually triggers vivid and repetitive nightmares (e.g., wartime dreams) (Kanzer, 1949; Ross *et al.*, 1994, 1999). The excessive reverberation of traumatic memories during sleep stems from the overwhelming emotional strength of those memories at the time of encoding. It is as if the brain was stuck with a problem that has no answer, which is often the case in seriously injured human patients. As to the second case, dreams that predict possible predation in the future are usually rare in humans, except during wartime. A more familiar example to most people can be found in the anticipatory dreams preceding school exams, which simulate potentially dangerous events from the point of view of the dreamer.

Dreaming co-evolved with a hypertrophy of emotion-related brain structures, such as the amygdala, the ventral striatum, and the hypothalamus (Adolphs *et al.*, 1995; Braun *et al.*, 1997; Cahill *et al.*, 1995; Davis, 1994; Maquet *et al.*, 1996, 1997; Nofzinger *et al.*, 1997). The data and concepts discussed so far suggest that mammalian dreams are probabilistic simulations of past events and future expectations. The main function of these simulations would be to test specific novel behaviors against a memory replica of the world, rather than the real world itself, leading to learning without risk. This hypothesis is a generalization of the threat simulation theory of dreaming (Revonsuo, 2000), that is, dreams may either simulate actions that lead to undesirable consequences and therefore should be avoided in the real world (e.g., being predated upon), or actions that lead to a desirable outcome and therefore should be performed in the real world (e.g., finding mates and food). An investigation of REM mentation found that over 70% of the reports included emotions, with a balanced proportion of positive and negative emotions (Fosse *et al.*, 2001). The notion that nightmares evolved as a way to negatively modulate particularly dangerous behavior simulations, while blissful dreams correspond to the association of pleasure (reward) with dream simulations of especially adaptive behaviors, is analogous to the concepts of eros and thanatos proposed by Freud as life and death drives (Freud, 1920).

In all species studied so far, REM is much more prominent in juveniles than in adults (Feinberg *et al.*, 1967; Hobson, 1989). Likewise, play is a behavior that evolved exclusively in birds and mammals and that is much more pronounced in youngsters than in adults (Grier, 1984; Hutt, 1966; Poole, 1966; Schenkel, 1966). These observations reflect the fact that naïve individuals rely heavily on simulation-based learning processes to survive in unpredictable and dangerous environments, online as well as offline (Chapman and Underwood, 2000; Cheyne, 2000; Humphrey, 2000). It is conceivable that daydreaming evolved as an invasion of dream-like mnemonic reverberation on top of waking sensory inputs. Playing, imagining, remembering, planning, scheming, practicing, and training skills are all examples of an extension of the self – an entity of the present – through past and future, a process that may be at the roots of our very kind of consciousness.

3.32.6 Human Dreams, Present and Future

According to the view presented here, the function of dreams is to trim and shape the memories acquired during waking, in a cyclic process of creation, selection, and generalization of conjectures about the world. Dreams are neither isolated pieces of a puzzle nor linear strings of memories, but rather a

concatenation of sensory and motor representations according to the dominant emotions of the dreamer. Dreams function as blind oracles, biological machines that create future scenarios based solely on the past experience, guiding the waking actions so as to maximize fitness. This aspect of future prediction, or more exactly future guessing, is probably the explanation for the widespread belief in dream premonition among ancient societies. Despite their stochasticity, dreams sometimes yield very accurate predictions of future events. This is a very rare phenomenon in modern human society, but dream soothsayers prospered during all of the antiquity (Jung *et al.*, 1969; Miller, 1997), and dream interpretation continues to play an important role in many so-called 'primitive' cultures (Kilton, 1951; Lincoln, 2003; Cawte, 1984; Shulman *et al.*, 1999).

As the challenges faced by humans became gradually easier and complex, dreams lost much of their predictive power but acquired a diversified symbolic repertoire. In comparison with other wild mammals in nature, modern middle-class humans experience much less serious anxieties. Nonhuman predators are very rare, law enforcement restricts conspecific predation, and, however stressful school and workplace examinations may be, they do not involve physical pain and possible mutilation. Nutritious food can be acquired in large quantities at grocery stores, health care is provided quickly after accidental injuries, and we inhabit permanent, safe, and solid shelters. In modern humans, dreams are no longer under the influence of life-or-death events, but are rather dominated by a myriad of minor frustrations, challenges, and expectations. In the absence of highly eventful recent experiences, it is not surprising that normal human dreams tend to mix recent though somewhat trivial elements of waking life with old, but strongly encoded, memories of childhood (Freud, 1900).

One remarkable feature of dreams is that they are almost never observed by dream characters other than the self-representation. Under normal circumstances, dreamers have limited control of their dream actions, and no control whatsoever of other dream characters and scenes, which display a large degree of autonomy. It seems obvious from these facts that the self-representation is just one among the many memories activated during REM, woven into dream narrative by the idiosyncratic probabilities of memory association in each individual. Dreams, conceived by Freud as "a conglomerate of psychic formations" (Freud, 1900), seem to reflect the fragmented activation of the very stuff the unconscious is made of, that is, latent memories (Freud, 1915). The limited volitional power of the self-representation during dreams likely reflects the deactivation during REM of the dorsolateral prefrontal cortex (Maquet *et al.*, 1996; Muzur *et al.*, 2002), a brain region essential for the planning, execution, and evaluation of goal-directed behaviors (Schultz, 2002; Tanji and Hoshi, 2001).

It is interesting to speculate on how human dreams will be in the future, as selection pressures continue to change. Although most people report no awareness of being dreaming while dreams takes place, it is possible for one to be aware of dreaming without waking up, a state called lucid dreaming (LaBerge and Dement, 1982; LaBerge *et al.*, 1981, 1986; Tart, 1965, 1972). Lucid dreams occur during REM episodes of greatly increased metabolism, characterized by increased eye movement density, heart rate, and respiration rate (Brylowski *et al.*, 1989). During lucid dreams it is possible for the dreamer to assume partial or total control of the unfolding dream narrative (LaBerge and Dement, 1982; LaBerge *et al.*, 1981), which indicates that the self-representation is more dominant in lucid dreams than in regular ones. This suggests that activity in the prefrontal cortex is enhanced during lucid dreams by mechanisms yet unknown but probably involving hyperdopaminergia and/or hypercholinergia. Despite the abundance of subjective reports on the use of lucid dreams to improve performance on a variety of real life skills (Brooks and Vogelsong, 2000; Green and McCreery, 1995; LaBerge, 1991; Wangyal *et al.*, 1998), the cognitive potential of such dreams also remains to be investigated by science. The use of lucid dreams for conscious simulation-based learning, if confirmed and made accessible to the general public, may represent a breakthrough for the future evolution of human consciousness.

3.33 Evolution of the Hippocampus

J R Manns and H Eichenbaum, Boston University, Boston, MA, USA

Glossary

amnesia	Memory impairment characterized by profound forgetfulness.
consolidation	Process by which memory becomes independent of hippocampal region over time.
declarative memory	Memory for facts and events.
episodic memory	Memory for events.
familiarity	Component of recognition memory characterized by a memory in the absence of recollected details.
hippocampal region	Cornu ammonis fields of the hippocampus proper, dentate gyrus, and subiculum.
macrosomatic	Describes an animal with a well-developed olfactory system
medial temporal lobe	Portion of brain, present in larger-brained mammals such as primates, that contains the hippocampal and parahippocampal regions.
microsomatic	Describes an animal with a poorly developed olfactory system
parahippocampal region	Entorhinal, perirhinal, and postrhinal (parahippocampal in primates) cortices.
place cell	Neuron whose firing rate correlates strongly with animal's location in an environment.
recognition memory	Capacity to judge an item as having been previously encountered.
recollection	Component of recognition memory characterized by retrieval of specific details relating to the incident in which the item to be remembered was encountered.
retrograde amnesia	Loss of information acquired prior to onset of brain damage.
semantic memory	Memory for facts.

3.33.1 Introduction

The hippocampus is a brain area that has received considerable attention because of its distinctive anatomy and its important role in memory. A particularly productive approach to studying the hippocampus has been to examine either its form or function across mammalian species (Brown and Aggleton, 2001; Burwell *et al*., 1995; Cohen and Eichenbaum, 1993; Insausti, 1993; Squire, 1992) or to consider whether homologous structures exist in other vertebrates (Aboitiz *et al*., 2002; Bingman *et al*., 2003; Day, 2003; Jacobs, 2003; Salas *et al*., 2003; Sherry and Schacter, 1987). The present article builds on these previous efforts and considers the evolution of the mammalian hippocampus from both anatomical and functional viewpoints. Based on this dual approach, we make two main points.

First, the anatomy of the hippocampal region is largely conserved across mammals. The connectivity and cytoarchitectural features of the hippocampus, dentate gyrus, and subiculum are

remarkably similar for all mammalian species for which information is available (see Sex and Species Differences in Hippocampal Volume). Further, the surrounding cortices in the parahippocampal region also show a substantial degree of conservation across the mammalian taxon. The anatomical details of the hippocampal and parahippocampal regions are not identical from species to species, but these differences are overshadowed by the substantial divergence in the organization of the neocortex. Moreover, structures homologous to the mammalian hippocampus appear in birds and reptiles, yet these structures do not directly parallel the distinct subdivisions of the hippocampal region. Accordingly, the first half of the article considers the anatomical homology of the mammalian hippocampus and details its features along with those of the adjacent parahippocampal region. This half ends by looking to birds and reptiles for evidence of how the hippocampus may have appeared in the earliest mammals.

Second, the hippocampus serves the same fundamental mnemonic function across mammals, and homologous structures in other vertebrates may support a similar capacity. Today, we know that the distinctive anatomy and physiology of the hippocampus anchors only one of several memory systems of the mammalian brain. Together with the parahippocampal region, the human hippocampal region enables a record of our experiences that can be subsequently brought back to mind as facts and events (Manns and Squire, 2002; Poldrack and Gabrieli, 1997; Schacter *et al*., 1998). This notion of memory as conscious recollection is difficult to extend to experimental animals, yet other operating characteristics of hippocampus-dependent memory apply equally well across mammals, including rapid learning, complex associative organization, and flexibility in retrieval (Eichenbaum and Cohen, 2001). The second half of the article tracks the progression of thought regarding the function of the mammalian hippocampus, starting with a point around 50 years ago at which the function of the hippocampus was uncertain and was presumed to be different for humans and experimental animals.

Current research focuses on identifying the fundamental principles that define hippocampus-dependent memory across species. We argue that this effort will be best served by taking an evolutionary approach. The divergence of mammals has provided a natural experiment in which a largely conserved hippocampal system can be explored among neocortical conditions that differ across species. The goal of this approach is to highlight the conserved function of the hippocampus and downplay most species-specific distinctions as a byproduct of differing neocortical inputs.

It is worth pointing out that the reader will find articles Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications, Sex and Species Differences in Hippocampal Volume, Evolution of the Nervous System in Reptiles, The Evolution of Vocal Learning Systems in Birds and Humans, The Hippocampal Formation in Food-Storing Birds, and Evolution of Vertebrate Olfactory Subsystems in the present work as very relevant and informative.

3.33.2 Anatomical Homology

3.33.2.1 Anatomy of the Mammalian Hippocampal and Parahippocampal Regions

3.33.2.1.1 Terminology The hippocampus is highly interconnected with several neighboring and closely interconnected structures, and its anatomy is best understood in combination with these structures (see Amaral and Witter (1995) for a more extensive anatomical review). Indeed, the term hippocampus is often used to refer to not only the cornu ammonis (CA; or hippocampus proper) but also to the dentate gyrus. The hippocampus proper is contiguous with the subiculum, and here these regions together with the dentate gyrus are called the hippocampal region. The adjacent parahippocampal region includes the entorhinal, perirhinal, and postrhinal (parahippocampal in primates) cortices and provides the majority of cortical input to the hippocampal region and is the recipient of its major cortical outputs (Burwell *et al*., 1995).

3.33.2.1.2 Gross morphology The hippocampus proper and dentate gyrus are both curled sheets of cortex that are rolled together to form a tube-like structure. In many small-brained mammals, the long axis of the tube begins at a medial, dorsal locus just posterior to the septum, and curves to a ventral and caudal apex before bending and heading rostrally and slightly laterally within the temporal region (see Figure 1a for the position of the hippocampal region in the rat brain). In mammals with larger brains, the general shape of the elongated tube has been conserved, but the structure has slid down along the same septotemporal axis described above so that in primates, the hippocampus is contained within the medial aspect of the temporal lobe (Figure 1). The parahippocampal region surrounds the hippocampal region and therefore takes on a different position

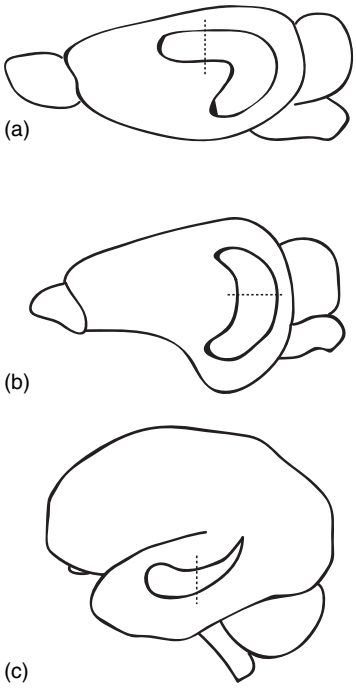

Figure 1 Position of the hippocampus in the brain of a rat (a), tree shrew (b), and human (c). The difference in position between small, medium, and big-brained mammals suggests that the hippocampus has slid through evolution along its long axis to the point that, in humans, the hippocampus is contained entirely within medial portion of the temporal lobe. The dashed lines in each drawing indicate cross sections perpendicular to the long axis of the hippocampus, similar to those depicted in Figure 2.

in the brain according to the position of the hippocampal region (Burwell, 2000).

3.33.2.1.3 Cytoarchitecture In all mammals, a cross section of the hippocampal region taken perpendicular to the long axis reveals the densely packed cell layers of the hippocampus proper and dentate gyrus, which at most septotemporal levels appear to fit together like interlocking arcs. Figure 2 shows examples from four species. The hippocampus proper consists of pyramidal cells bounded above and below by cell-sparse layers and can be divided into three subfields: CA1, CA2, and CA3. The pyramidal cells in CA1 were originally distinguished from those in CA3 on the basis of size; CA1 pyramidal cells are slightly smaller (Ramon y Cajal, 1911). The CA2 subregion is a small transitional area between CA1 and CA3. The dentate gyrus is also a curved sheet of three-layered cortex, although its principal cells are granule cells. Immediately adjacent to CA1 is the subiculum, another three-layered section of cortex whose principal cells are pyramidal neurons. Although the laminar organization of each subregion represents a 'simple' cortical organization with only one layer of principle cells, the principle cells in each subregion are wrapped in a plexus woven from interneurons.

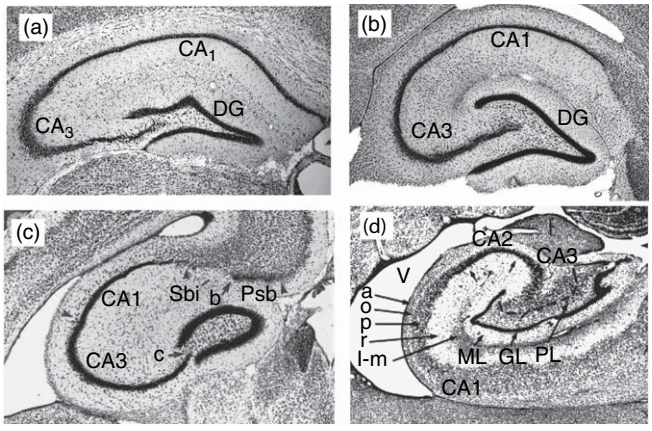

Figure 2 Cross sections taken perpendicular to the long axis of the hippocampal region in a mouse (a), tree shrew (b), tenrec (c), and human (d). The cell fields (CA1, CA3) of the hippocampus proper and the dentate gyrus (DG) appear similar in all four mammals. Note that CA1 appears below CA3 in the human hippocampus due to the evolutionary slide illustrated in Figure 1. See original sources for additional information. a, Reproduced from Van Groen, T., Kadish, I., and Wyss, J. M. 2002. Species differences in the projections from the entorhinal cortex to the hippocampus. *Brain Res. Bull.* 57(3–4), 553–556, with permission from Elsevier. b, Keuker, J. I., Rochford, C. D., Witter, M. P., and Fuchs, E. 2003. A cytoarchitectonic study of the hippocampal formation of the tree shrew (*Tupaia belangeri*). *J. Chem. Their architecture and major intrinsic connections. *Neurosci. Res.* 41(3), 267–291, with permission from Elsevier. d, Reprinted from Amaral, D. G. 1999. Introduction: What is where in the medial temporal lobe? *Hippocampus* 9(1), 1–6.

The adjacent entorhinal, perirhinal, and postrhinal/parahippocampal cortices have a more complicated laminar organization than the three-layered areas in the hippocampal region (for detailed descriptions, see Burwell, 2000; Suzuki and Amaral, 2003). Although the laminar profile of these regions does not directly correspond to the six-layered neocortex, each area of the parahippocampal region is typically partitioned into six layers. The cellular composition of these layers differs between the three regions and, in combination with differing patterns of connectivity, defines their borders. However, the cytoarchitectural details differ even within a region, and no single criterion can be used to define all the borders of any region. Further, the entorhinal, perirhinal, and postrhinal/parahippocampal cortices are typically divided into several subregions based on local differences in cytoarchitecture and connectivity. A full account of the cytoarchitecture in these regions is beyond the scope of the present article.

3.33.2.1.4 Intrinsic circuitry of the hippocampal region The major intrahippocampal connections are serial and unidirectional (Amaral and Witter, 1995). This intrinsic circuit traces a path from the dentate gyrus to CA3 before continuing to CA1 and finally to the subiculum. In addition, the pyramidal cells in CA3 send a substantial number of axons to other pyramidal cells in CA3. The connections between subregions are organized in different patterns, suggesting that information is being transformed in distinct ways at each step in the serial circuit. This organization is depicted in Figure 3 and is described next.

The projection from the dentate gyrus to CA3 involves a lamellar organization such that, at successive septotemporal levels, dentate cells project to the entire transverse extent of CA3 at about the same level (Gaarskjaer, 1986; Swanson *et al.*, 1978). In contrast to this transverse dispersion of connectivity, the projection from CA3 to CA1 involves an organization in which CA3 cells from a given septotemporal level project to about two-thirds of the septotemporal extent of CA1 (Ishizuka *et al.*, 1990; Li *et al.*, 1994). Moreover, the CA3 projections do extend in the transverse plane, although a gradient applies such that CA3 pyramidal cells close to the CA1 border project to the adjacent CA1 cells and CA3 pyramidal cells closest to the dentate gyrus project to CA1 cells closest to the subiculum. The projection from CA1 to subiculum is perhaps the most structured of the intrahippocampal projections and is organized in at least two dimensions: along the transverse axis and along the septotemporal axis (Amaral *et al.*, 1991). Three nearly discrete transverse columns project to the subiculum such that the third of CA1 cells closest to the subiculum project to the third of the subiculum that is immediately adjacent to CA1. The middle third of CA1 projects to the middle third of the subiculum, and the third of CA1 closest to CA2 (farthest from the subiculum) projects to the third of the subiculum farthest from CA1. Like the CA3 to CA1 projection, the CA1 to subiculum projection is also distributed along the septotemporal axis such that CA1 cells at any septotemporal level project to about one third of the septotemporal extent of the subiculum.

The anatomy of the hippocampal region offers insight into the potential role of its subregions. The

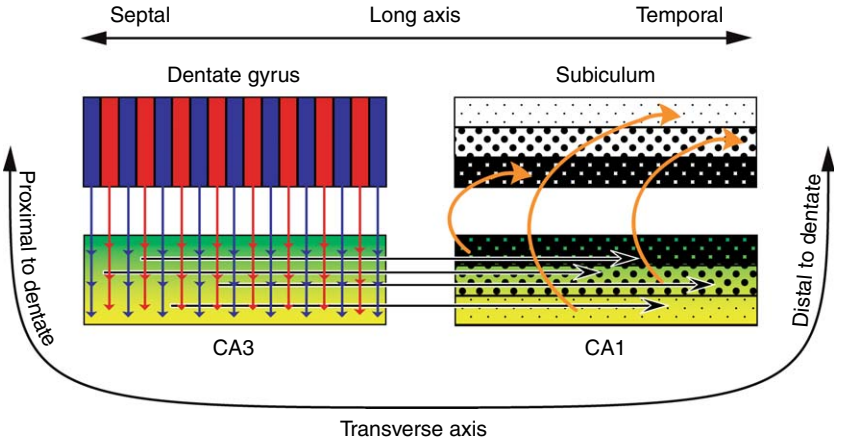

Figure 3 Connections between subregions of mammalian hippocampal region. The dentate gyrus projects to CA3 in a lamellar fashion (red and blue slices), whereas CA3 projections to CA1 are dispersed along the long axis. A gradient also applies to this projection (green to yellow) such that CA3 cells proximal to the dentate gyrus tend to project to CA1 cells distal to the dentate gyrus. The projections from CA1 to subiculum are partitioned into three transverse columns (indicated by dot patterns). Further, projections from CA1 reach about a third of the septotemporal extent of the subiculum. See text for more details.

orthogonal dispersion gradients of dentate gyrus to CA3 projections (transverse) and CA3 to CA1 projections (septotemporal) suggest that these connections might be involved in the final stage of reformatting sensory information in the service of enabling arbitrary associations within and across modalities. The recurrent CA3 to CA3 connections might also participate in this process. In comparison, the more organized CA1 to subiculum projection could represent the first step in repackaging new associations in a format compatible with the topography of the neocortex. In any case, it is clear that the serial circuit through the hippocampal region is not simply a passive relay of information.

3.33.2.1.5 Connections with the entorhinal cortex In addition to the prominent serial organization of intrahippocampal connectivity, there are parallel direct connections between each of the hippocampal subregions and the entorhinal cortex in all mammals (Figure 4). Thus, although some information traveling through the hippocampal region might proceed serially, there are also 'shortcuts' into and out of each subregion. The projections from the entorhinal cortex are collectively called the perforant path, but the trajectory of this path differs for CA1 and subiculum on one hand and dentate gyrus and CA3 on the other (Witter *et al.*, 2000b). The projections to CA3 and dentate gyrus originate mostly in layer II of the entorhinal cortex, whereas the projections to CA1 and subiculum originate mostly in layer III of the entorhinal cortex. The layer III projection is mirrored by direct return projections from the subiculum and CA1 to the entorhinal cortex.

The projections from entorhinal cortex to the hippocampal subregions can be distinguished further on the basis of the areas within entorhinal cortex from which the connections originate (Witter, 1993). Specifically, there are two parallel pathways, one arising from the lateral entorhinal area (LEA) and the other arising from the medial entorhinal area (MEA). The line bisecting LEA and MEA is not actually perpendicular to the lateral/

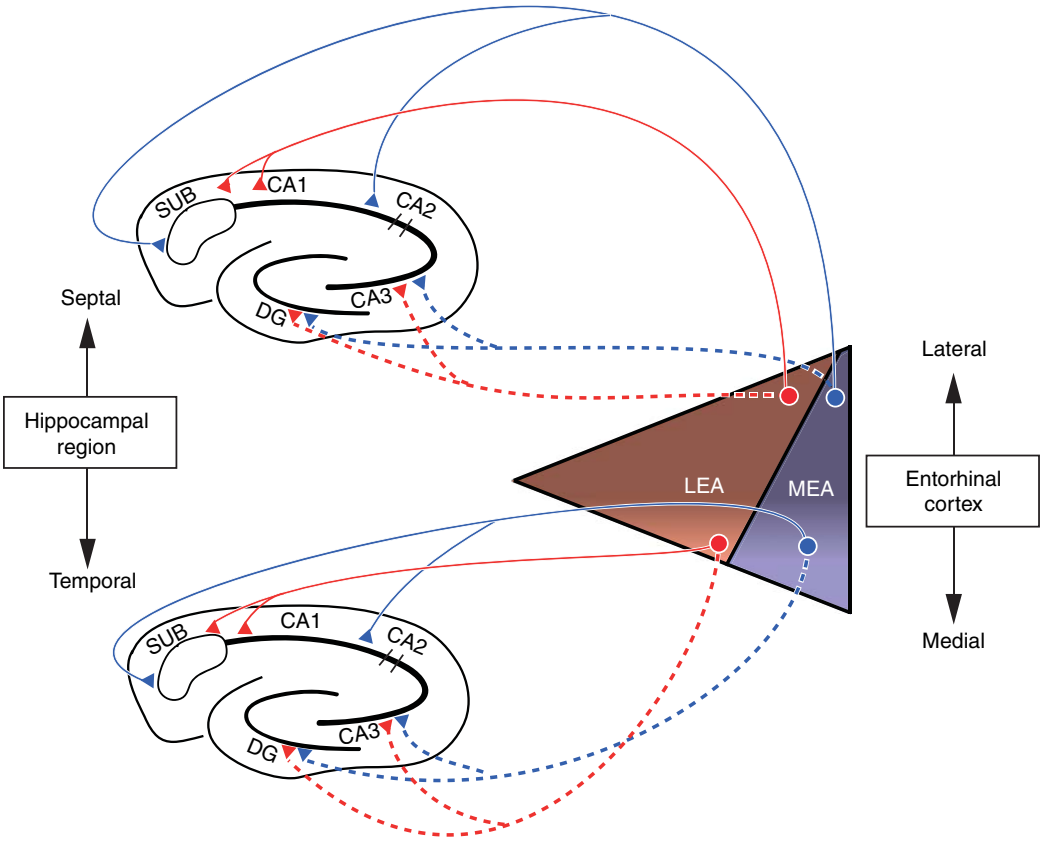

Figure 4 Organization of the mammalian perforant path. Three trends are apparent in the entorhinal projections to the hippocampal region. First, the lateral–medial axis of entorhinal cells corresponds to a septotemporal termination gradient in the hippocampal region. Second, separate branches of the perforant path originate in LEA and MEA. These projections are combined in the dentate gyrus and CA3 but are kept separate in the subiculum and CA1. Third, projections to the dentate gyrus and CA3 originate primarily in layer II of the entorhinal cortex (dashed lines), but projections to the subiculum and CA1 originate primarily in layer III (solid lines).

medial cardinal axis in any species, such that LEA and MEA are defined by the origins of the two pathways rather than by their cardinal positions. Both pathways contain projections from layers II and III and project to each of the four hippocampal subregions. However, the pattern in which the fibers from both pathways terminate in hippocampal targets differs between CA3 and dentate gyrus on one hand and CA1 and subiculum on the other (see Figure 4). The projections from LEA and MEA target the same subsets of dentate and CA3 cells. In contrast, the projections from LEA target portions of CA1 and subiculum that differ from the portions targeted by the projections arising in MEA. In particular, projections arising in LEA target CA1 and subiculum cells near the subiculum/CA1 border, whereas projections arising in MEA target CA1 and subiculum cells farthest from the subiculum/CA1 border. Thus, information passing through LEA and MEA appears to be combined in the dentate gyrus and CA3 but kept separate in the subiculum and CA1. Of course, both CA1 and the subiculum also receive intermixed LEA and MEA information via the serial input from dentate gyrus and CA3.

One additional feature characterizes the overall topography of the entorhinal inputs into the hippocampal region. Projections originating in the lateral aspect of the entorhinal cortex (including the lateral aspects of both the LEA and MEA) terminate largely in the septal end of the hippocampal subregions. Conversely, projections originating in the medial aspect of the entorhinal cortex (including the medial aspects of both the LEA and MEA) terminate largely in the temporal end of the hippocampal subregions.

3.33.2.1.6 Intrinsic circuitry of the parahippocampal region The LEA and MEA can be further distinguished on the basis of their inputs originating in the rest of the parahippocampal region. LEA receives more cortical projections from the perirhinal cortex, whereas MEA receives more cortical projections from the parahippocampal/postrhinal cortex (Witter *et al*., 2000a). This difference is distinguished even further by the fact that perirhinal cortex appears to receive a different subset of olfactory and neocortical inputs as compared to parahippocampal/postrhinal cortex (Burwell and Amaral, 1998a; Suzuki and Amaral, 1994). The postrhinal/parahippocampal cortex receives more inputs from cortical areas important for allocentric spatial information. The perirhinal cortex receives more inputs from olfactory areas and neocortical areas important for nonspatial information. Based on these observations, one view of the connectivity of the parahippocampal region is that information reaching the perirhinal cortex follows a path through the LEA to the hippocampal region that runs parallel to the path taken by information reaching the postrhinal cortex and continuing through the MEA (Witter *et al*., 2000a). These pathways appear to be largely combined in dentate gyrus and CA3 but kept at least somewhat separate in CA1 and the subiculum. However, the notion of parallel, functionally distinct input streams is tempered by the presence of a substantial projection from parahippocampal/postrhinal cortex to perirhinal cortex (and a smaller return projection) in addition to connections between LEA and MEA.

3.33.2.2 Summary of Anatomy of the Hippocampal and Parahippocampal Regions

The animals of the mammalian taxon represent a great diversity of habitats, means of locomotion, preferred diets, and social structure. They also represent a great diversity of neuroanatomy. For example, tenrecs and hedgehogs are both small-brained insectivores whose neocortex is predominately composed of primary sensory areas (Catania *et al*., 2000; Krubitzer *et al*., 1997). In contrast, the brains of primates contain numerous neocortical areas that are devoted to integrating information across modalities. Further, the amount of tissue devoted to a particular sensory modality also varies substantially between species (Krubitzer and Kaas, 2005). In macrosomatic animals such as rodents, large portions of the brain are involved in processing odors. In other animals, vision (e.g., primates), audition (e.g., bats), or somatosensation (e.g., star-nosed moles) have become disproportionately represented in the brain. Further, the anatomy of the hippocampal and parahippocampal regions includes many complex and highly organized patterns of interconnectivity. This complexity would seem to provide many opportunities for divergence throughout evolution, especially when considering that many other features differ substantially between species. Thus, it is surprising that the predominant trend with respect to the anatomy of the hippocampal and parahippocampal regions is one of conservation rather than divergence. Figure 5 shows an evolutionary tree of some of the animals discussed in this article and is meant illustrate how the diversity of these selected mammals contrast with the conservation of the anatomy of the hippocampal and parahippocampal regions. Nevertheless, there are differences between species with respect to the anatomy of the hippocampal region and to a somewhat greater extent the

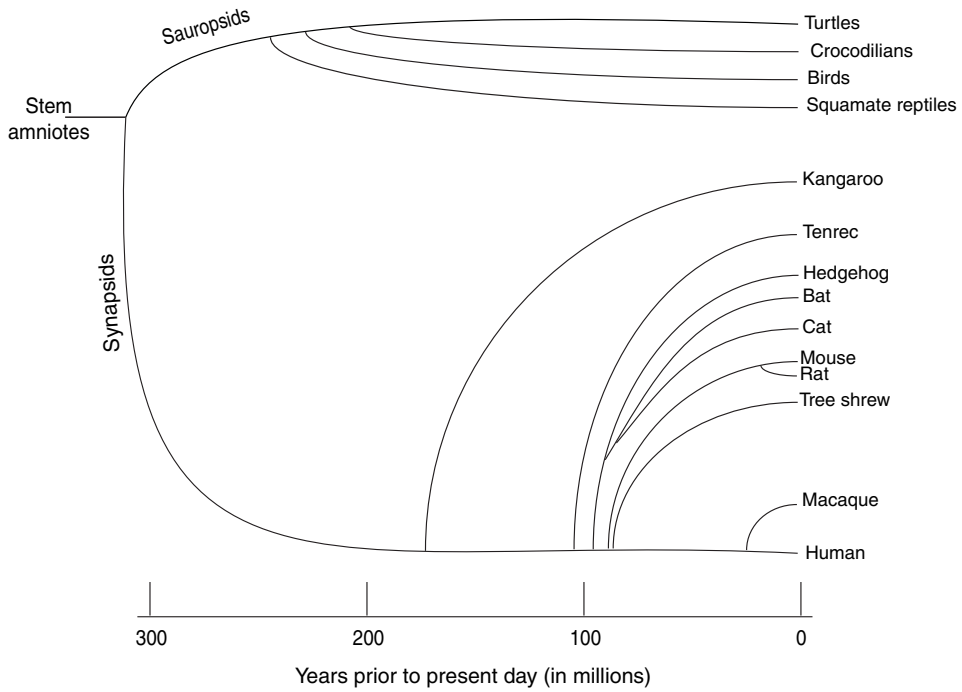

Figure 5 Phylogeny of birds, reptiles, and selected mammals. The dates are estimates based on recent molecular techniques (Arnason *et al.*, 2002; Springer *et al.*, 2003).

parahippocampal region. These differences are considered next.

3.33.2.3 Anatomical Differences between Species

3.33.2.3.1 Hippocampal region Species differences in the hippocampal region are best characterized as refinement rather than reorganization. The intermediate subregion CA2 can be clearly distinguished in primates (Bakst and Amaral, 1984; Green and Mesulam, 1988), but its identification is more difficult in smaller-brained mammals such as hedgehogs and tenrecs (Kunzle and Radtke-Schuller, 2001; West *et al.*, 1984). Also, the border that demarcates the transition from CA1 to subiculum is less clearly defined in small-brained mammals (Kunzle and Radtke-Schuller, 2001; West *et al.*, 1984). Furthermore, in hedgehogs, but not in tenrecs or in larger-brained mammals, the mossy fiber projection from dentate gyrus to CA3 invades CA1 to some degree (Kunzle and Radtke-Schuller, 2001; West *et al.*, 1984). Taken together, the overall similarities in cytoarchitectural plan and connectivity described above far outweigh these minor differences, especially when considering the complexity of the region's circuitry. Nevertheless, the trend for the hippocampal region appears to be one of increasing distinction between subregions as a refinement that often comes with evolution.

3.33.2.3.2 Entorhinal cortex The entorhinal cortex also follows an evolutionary trend of increasing diversification. In most mammals studied, including the hedgehog, LEA is clearly distinguished from MEA (Insausti, 1993; West *et al.*, 1984). One possible exception is the tenrec, in which the entorhinal cortex was poorly differentiated from the piriform cortex and LEA and MEA were not distinguished from one another (Kunzle and Radtke-Schuller, 2001). Nevertheless, in other mammals, the tendency is for entorhinal cortex to increase in diversity with brain size, such that six, seven, and eight subdivisions have been identified in the rat, monkey (macaque), and human, respectively (Insausti, 1993).

Despite the increasing complexity of the entorhinal cortex and refinement of the hippocampal region, the highly structured organization of connectivity between the areas is quite similar across mammals. In particular, the specific topography of entorhinal inputs to the hippocampal formation (Figure 4) is similar in all species for which detailed anatomical information is available, including bats (Buhl and Dann, 1991), mice (Van Groen *et al.*, 2002), rats (Witter, 1993), cats (Witter and Groenewegen, 1984), and monkeys (Witter and Amaral, 1991). However, there are several exceptions that are worth mentioning. In mice, the entorhinal projection to CA3 originates predominately in layer III rather than in layer II as

described in larger-brained mammals, including rats (Van Groen *et al*., 2002). Further, several species differences have been noted in the laterality of projections between regions. For example, projections from the subiculum to entorhinal cortex are solely ipsilateral in rats but are bilateral in cats and monkeys (Amaral and Witter, 1995). It is not always the case that bigger-brained mammals show more anatomical refinement than smaller-brained mammals. For example, LEA and MEA projections to dentate gyrus terminate at the same portions of the granule cell dendrites in monkeys (Witter and Amaral, 1991). In contrast, in the other mammals studied (bats, mice, cats, and rodents), projections from the LEA terminate in the superficial third of the granule cell dendrites, whereas projections from MEA terminate in the middle third of the granule cell dendrites (Buhl and Dann, 1991; Van Groen *et al*., 2002; Witter, 1993; Witter and Groenewegen, 1984). Thus, whereas there is a trend of increasing diversification and refinement over the course of evolution, there does not appear to be a clear shift in the organization of the connections between the hippocampal region and entorhinal cortex. Indeed, in comparison with the dramatic differences in neocortex between mammals (Krubitzer and Kaas, 2005), the hippocampal region and entorhinal cortex are surprisingly similar.

One potentially important distinction between macrosomatic and microsomatic mammals involves the prominence of olfactory input to the entorhinal cortex (Insausti *et al*, 2002). In particular, a direct projection exists in rats from the olfactory bulb to almost the entire extent of the entorhinal cortex (Price, 1973). In contrast, in the macaque, the olfactory bulb projects to only one of the seven subdivisions of the monkey entorhinal cortex, which was estimated to comprise 15% of the region's total area (Witter *et al*., 1989). The corresponding entorhinal subdivision in humans comprises less than 5% of the total human entorhinal cortex (Insausti *et al*., 1995). To the extent that the projection from the olfactory bulb to entorhinal cortex represents the prominence of olfactory processing in the hippocampal region, there is a clear trend toward the reduction of olfactory input to the hippocampus in microsomatic mammals.

3.33.2.3.3 Perirhinal and postrhinal/parahippocampal cortices The entorhinal cortex appears to have undergone more changes over the course of evolution than the hippocampal region, and the perirhinal and postrhinal/parahippocampal cortices may have undergone even more changes than the entorhinal cortex (Burwell, 2000). However, this observation is limited by the fact that detailed anatomy of the perirhinal and postrhinal/parahippocampal cortices regarding the neocortical afferents, interconnectivity, and projections to the entorhinal cortex and hippocampal region are available for only the rat (Burwell and Amaral, 1998a, 1998b) and the macaque (Lavenex *et al*., 2002, 2004; Suzuki and Amaral, 1994, 2003). Although these animals represent only one branch on the mammalian evolutionary tree (see Figure 5), they differ substantially in that the rat is a nocturnal, macrosomatic, and relatively small-brained mammal, whereas the macaque is a diurnal, microsomatic, and big-brained mammal. Thus, the commonalities in anatomy between the two mammals can highlight fundamental organizational principles of the perirhinal and postrhinal/parahippocampal cortices, and the differences can illustrate one path taken by the parahippocampal region in the evolution of big-brained mammals.

In both the rat and the macaque, the perirhinal and postrhinal/parahippocampal cortices represent major routes of entry into the entorhinal cortex and hippocampal region (Burwell and Amaral, 1998b; Suzuki and Amaral, 1994). Many unimodal and polymodal cortical regions project to the perirhinal cortex or to the postrhinal/parahippocampal cortex. The incoming information is presumably processed and passed on to the entorhinal cortex, where it is likely further processed before being relayed to the hippocampal region. In both the rat and the macaque, the perirhinal cortex tends to project more to the LEA of the entorhinal cortex, and the postrhinal/parahippocampal cortex tends to project more to the MEA (Witter *et al*., 2000a). Also, in both mammals, a strong projection from the postrhinal/parahippocampal cortex to the perirhinal cortex is met with a more modest return projection (Burwell and Amaral, 1998a; Lavenex *et al*., 2004). Thus, the hippocampal and parahippocampal regions can be described as a hierarchy of connectivity in which the perirhinal and postrhinal/parahippocampal cortices are positioned near the top and funnel information into the LEA and MEA, information which is then combined in the hippocampal region (Lavenex and Amaral, 2000; Witter *et al*., 2000a).

However, compared to the macaque, the patterns of connectivity in the rat less clearly conform to the idea of a hierarchy. In the macaque, more than two-thirds of the cortical input to the entorhinal cortex originates in the either the perirhinal or postrhinal/parahippocampal cortices (Suzuki and Amaral, 1994). In comparison, less than one-fourth of cortical afferents of the entorhinal cortex in rats

originate in these regions (Burwell and Amaral, 1998b). Some, but not all, of this difference can be accounted for by considering the prominent olfactory input in the rat that bypasses the perirhinal cortex and projects directly to the entorhinal cortex. Thus, the more rigidly serialized hierarchy in the monkey suggests that the primate entorhinal cortex (and therefore the hippocampal region) receives information that is on average even more highly processed than it is in the rodent. Further, the macaque entorhinal cortex reciprocates its strong perirhinal and postrhinal/parahippocampal input with equivalently strong return projections. In the rat, the projections into the entorhinal cortex are stronger than the return projections (Burwell and Amaral, 1998a).

3.33.2.3.4 Neocortical input to the parahippocampal region The most notable difference between the parahippocampal regions in rats and monkeys relates to the makeup of cortical information projecting into the perirhinal and postrhinal/parahippocampal cortices. Indeed, there are numerous dissimilarities that relate generally to the differences between a small-brained and a big-brained mammal (Krubitzer and Kaas, 2005). Compared to the rat neocortex, the macaque neocortex is substantially more invaginated and shows a more defined laminar organization. The macaque also has disproportionately enlarged frontal lobes and has more unimodal and polymodal association cortical areas. Further, the macaque displays a much more elaborate visual system. However, olfactory and somatosensory cortex is disproportionately larger in rats and thus may provide more detailed odor and tactile information to the parahippocampal region. Thus, even if the parahippocampal region was identical between rats and monkeys, differences between the species in terms of the kinds of information processed by the perirhinal and postrhinal/parahippocampal cortices would be virtually assured by the substantial neocortical differences. Furthermore, because the inputs to the parahippocampal region largely determine the input to the hippocampal region, one might also expect to observe differences in the content of information that is available to the rat and the monkey hippocampus. Thus, although the rat and macaque parahippocampal regions may share a separation of spatial and nonspatial inputs between postrhinal/parahippocampal cortex and perirhinal cortex, respectively, the details of the spatial and nonspatial information reaching these structures likely differs markedly between the species.

3.33.2.4 Summary of Anatomical Homology

The organization of the neocortex differs substantially between mammals, and because neocortical organization determines the organization of inputs to the parahippocampal region, the information fed into the parahippocampal and hippocampal regions might differ considerably across the taxon. Nevertheless, the internal anatomical details of the hippocampal and parahippocampal regions are quite similar across mammals. Indeed, the appearance of the hippocampus is so similar – even in mammals such as the tenrec whose brain is thought to resemble those of the earliest mammals – that one might expect to find brain structures resembling the hippocampus in animals who shared a common ancestor with mammals. Accordingly, we next envision the earliest mammals and consider whether birds and reptiles have a brain structure that is homologous to the mammalian hippocampus.

3.33.3 Ancestral Homologue of the Hippocampal Region

The earliest mammals appeared during the Triassic period, more than 200 Mya. They were likely small, nocturnal animals who relied on their well-developed olfactory abilities to capture their insect meals (Allman, 1999). The ongoing diversification of mammals increased around 65 Mya, coincident with the Cretaceous/Cenozoic boundary that marks the extinction of dinosaurs (Springer *et al.*, 2003). The increased diversification was likely due at least in part to the decrease in competition from dinosaurs, which opened many diurnal habitats, but was probably also due to the increasing separation of land masses (Hedges *et al.*, 1996). In any case, early mammals shared a recent ancestor with sauropsids, a group of animals that today includes birds and reptiles (Kumar and Hedges, 1998; see Figure 5). The brains of modern mammals appear quite different from those of birds and reptiles, but there are also many similarities between the taxa. These commonalities can suggest how the brains of the early mammals might have appeared. Indeed, both reptiles and birds have brain regions that are thought to be homologous to the mammalian hippocampus (Colombo and Broadbent, 2000; Aboitiz *et al.*, 2002).

3.33.3.1 A Hippocampal Homologue in Birds and Reptiles

3.33.3.1.1 Anatomical similarities Regions within the medial cortex in reptiles (possibly including

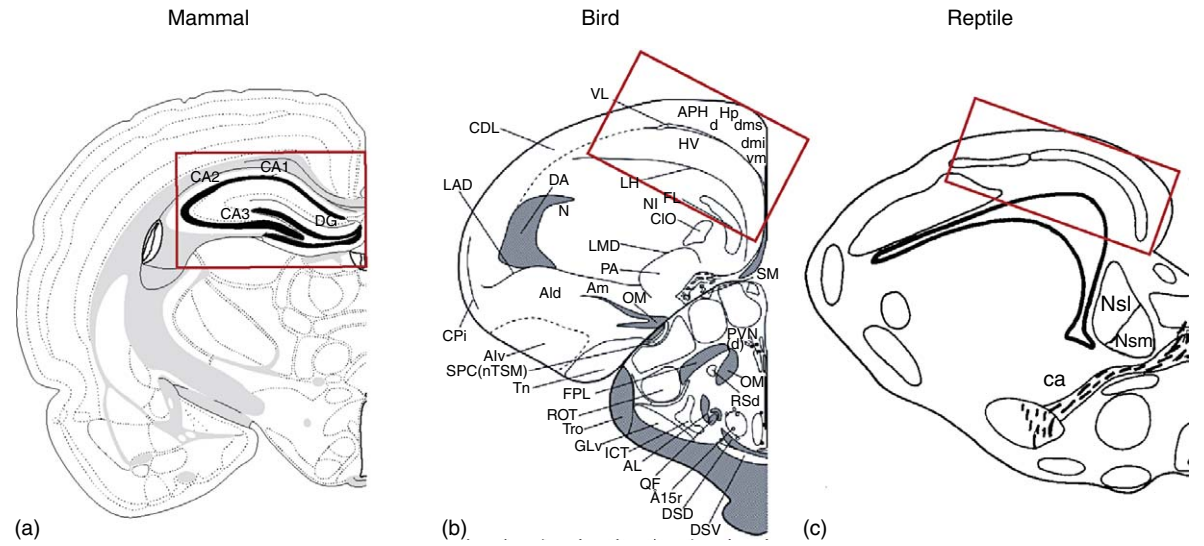

Figure 6 Brain regions thought to be homologous to the mammalian hippocampus in birds and reptiles (indicated by rectangles). One hemisphere from a rat, chicken, and lizard (gecko) is shown. A., and Vermeulen-VanderZee, E. 1998. Convergence of thalamic and cholinergic projections in the 'dentate area' of lizards. *Brain Behav. Evol.* 51(2), 113–122, with permission from S. Karger AG, Basel.

dorsomedial cortex) and medial pallium in birds (area hippocampus and area parahippocampalis) share several anatomical features with the mammalian hippocampus (see The Hippocampal Formation in Food-Storing Birds). For example, in all three cases the hippocampal homologue is a three-layered section of cortex that develops from the pallial telencephalon and is situated medially in the brain, adjacent to a main ventricle (Figure 6). In all three groups, the hippocampal homologue receives prominent projections from visual and olfactory cortices (Atoji *et al.*, 2002; Hoogland and Vermeulen-Vanderzee, 1993; Lavenex and Amaral, 2000). Also, the hippocampal homologue in all three groups shows physiological evidence of synaptic plasticity, suggesting an ability to associate incoming information (Bliss and Lomo, 1973; Muñoz *et al.*, 1998; Shapiro and Wieraszko, 1996). Thus, as in mammals, the hippocampal homologue in birds and reptiles may serve as a site of integration from already processed information.

3.33.3.1.2 Anatomical differences At the same time, there are notable dissimilarities between the mammalian hippocampus and the homologous regions in reptiles and birds. Superficially, neither the reptilian medial cortex nor the avian hippocampus have distinguishable subfields equivalent to those of the hippocampus proper, the dentate gyrus, and subiculum. Nor does the architecture of the reptilian or avian hippocampus resemble the characteristic shape of interlocking arcs formed by the densely packed cell layers of the hippocampus and dentate gyrus in mammals (Figure 6). Furthermore, dissimilarities in the distribution of sensory pathways between mammals and sauropsids suggest substantial differences in the kind of information processed by hippocampal homologues. In mammals, the hippocampus enjoys a confluence of highly processed unimodal and polymodal information (Lavenex and Amaral, 2000). Through its connections with the adjacent entorhinal, perirhinal, and parahippocampal/postrhinal cortices, the hippocampus receives input from widespread cortical areas. These connections suggest that the hippocampus serves as a central associative node in the cortical network that supports integrative processing in the mammalian brain. Likewise, in birds and reptiles, the hippocampal homologue also enjoys prominent connections with cortical/pallial regions. However, in comparison with the mammalian forebrain, the sauropsid cortex appears to play a disproportionately smaller role in cognitive functioning. Instead, higher-order functions that are mediated by the neocortex in mammals are supported by the dorsal ventricular region in reptiles and by the archistriatum/arcopallium in birds (Aboitiz *et al.*, 2002). Moreover, the hippocampal homologue in birds and reptiles enjoys few direct or indirect connections with these regions (Atoji *et al.*, 2002; Dubbeldam, 1998; Hoogland and Vermeulen-Vanderzee, 1993; Ten Donkelaar, 1998). Thus, the hippocampal homologue in sauropsids receives a

more limited range of connections and may support a more specific subset of associative abilities as compared to the mammalian hippocampus.

3.33.3.1.3 Functional similarities A growing number of studies suggest that the reptilian medial cortex and the avian hippocampus share some functional similarities with the mammalian hippocampus (Bingman, 1992; Day, 2003; Jacobs, 2003; Salas *et al*., 2003). Among the most commonly studied functions of the hippocampus in mammals is spatial memory (reviewed more comprehensively in the second part of this article). Ablation studies have indicated that the hippocampal homologue in reptiles and birds is important for spatial learning functions that are known to rely on hippocampal function in mammals. These experiments show that damage to the putative hippocampal homologue disrupts performance when the animal must learn relationships between distant environmental cues to identify important places in the external world but not when learning can be supported by approaching a specific landmark at the site of a reward (Bingman *et al*., 2003; Salas *et al*., 2003). For example, turtles with damage to the medial cortex were impaired at learning the location of an unmarked goal in an open field water maze surrounded by visual cues but were unimpaired when the target was marked by a consistent visual stimulus (Lopez *et al*., 2003). Similarly, homing pigeons with damage to the hippocampal homologue were able to orient themselves using the sun and familiar local landmarks at the release point but appeared deficient at navigating by using cues they saw along the route home (Gagliardo *et al*., 1999). Consistent with these findings on hippocampal damage, studies on the firing properties of hippocampal neurons also suggest a possible similarity in spatial representations by the hippocampus. Many studies in rodents and other mammals have identified hippocampal neurons that fire selectively when the animal is in a particular place within its environment (O'Keefe and Nadel, 1978). Recently, cells with the same property have also been identified in the avian hippocampus (Siegel *et al*., 2005). Thus, one commonality between mammals, reptiles, and birds is that the hippocampal homologue appears to be important for associating spatial relationships between environmental cues and learning places where important events occur.

3.33.3.1.4 Functional differences? The comparative anatomy of the hippocampus is consistent with the notion of a more limited scope of information processing in sauropsids than in mammals, and the results of several ablation studies are consistent with the idea as well. Mammals with damage to the hippocampal region have been found to be impaired on a variety of nonspatial as well as spatial memory tasks (Eichenbaum *et al*., 1999; also discussed in more detail below). For example, in one study (Bunsey and Eichenbaum, 1996), rats were trained on a transitive inference task in which they learned a series of overlapping paired odor associations. When presented with odor A, rats were rewarded for selecting odor B, and when presented with odor B, rats were rewarded for selecting odor C. Having learned the A–B and B–C pairs, normal rats also responded to C when presented with A, demonstrating they had linked the two paired associates and could infer the relationship between the indirectly related items A and C. Rats with damage to the hippocampus could gradually acquire the paired associates but did not show the transitive inference for A–C. In contrast to the findings on rats, a similar study found that birds with hippocampal lesions performed just as well as intact birds on the transitive inference task (Strasser, *et al*., 2004). Similarly, several studies have shown that mammals with damage to the hippocampal region are impaired in learning sensory discrimination reversals (e.g., Murray and Ridley, 1999), whereas turtles with lesions to the medial cortex are unimpaired at discrimination reversal learning (Grisham and Powers, 1990). These findings suggest that the hippocampal homologue in birds and reptiles might be more selectively involved in associations that involve a spatial component.

3.33.3.2 Summary of the Ancestral Homologue

The earliest hippocampus was likely a medial portion of a simple cortical mantle, and this medial portion was likely connected with dorsal and lateral portions of the mantle that processed visual and olfactory information, respectively. The visual and olfactory connections might have been brought together to form stimulus–stimulus associations to support spatial learning abilities in early mammals. However, it is unclear if this spatial learning ability was the sole ancestral function of the hippocampal homologue. It remains possible that further studies in birds and reptiles will uncover additional nonspatial associative abilities supported by the hippocampal homologue in these animals. Furthermore, even if the sauropsid hippocampal homologue is determined to be involved solely in forming associations that involve a spatial component, it cannot be assumed that this spatial specificity represents the ancestral condition. Indeed, several recent studies in goldfish have

indicated that the presumed hippocampal homologue in these vertebrates is important for nonspatial as well as spatial memory (Broglio *et al*., 2005). For example, goldfish with lesions to the hippocampal homologue were impaired in classical conditioning of the eye retraction response when a trace interval intervened between the conditioned and unconditioned stimuli but learned at the normal rate when those stimuli were contiguous (Álvarez *et al*., 2003), a pattern of results similar to those observed in several species of mammals (Clark *et al*., 2002). Thus, it is possible that the earliest hippocampal homologue supported a general (spatial and nonspatial) associative function and that this ability became specialized in birds and reptiles. Further studies using the classical conditioning paradigm, for example, might provide the critical evidence.

How might the ancestral hippocampus have supported the integration of information derived from its cortical inputs? Assuming that, as in extant mammals and sauropsids, the inputs to the ancestral hippocampus included prominent olfactory and visual afferents, one fascinating possibility concerns the mismatch in neural topography between olfaction and other sensory modalities. Visual stimuli are typically encoded in a retinotopic fashion that organizes information in terms of the spatial locations of external cues in the environment. By contrast, odors contain no inherent directionality, and accordingly there exists no topographic map for odor location in the olfactory cortex. Thus, associations between odors and other types of stimuli require reformatting in at least one modality to provide a common scheme of organization. For a comparison, consider how visual and auditory information is associated by birds. Both types of information are organized by a spatial topography, and an efficient overlapping map of the sight and sound from a noise-emitting object, such as a rustling mouse, has been identified in the barn owl tectum (Knudsen, 1987). It is difficult to imagine how this topographic organization could efficiently include the odor of the mouse. Further, it is important to consider that the olfactory bulb increased in size in early mammals (Aboitiz *et al*., 2002). Thus, the increasing adaptive value of olfactory abilities in catching prey may have driven the evolution of the hippocampus to support nontopographic associations between reformatted sensory information. Although olfaction may have made the greatest demand for nontopographic associations, the advantage of such a memory scheme would not have been limited to olfactory associations. Indeed, the hippocampus remains a crucial memory structure in microsomatic mammals including humans, so we might properly assume there is adaptive advantage for a nontopographic associative memory over a broad range of materials and modalities. The next half of the article considers whether this associative ability of the hippocampus is conserved across mammals.

3.33.4 Functional Homology of the Hippocampal and Parahippocampal Regions Across Mammals

3.33.4.1 Early Evidence on Hippocampal Function

The mammalian hippocampus appeared over 200 Mya, but the study of its function began in earnest only 50 years ago. The earliest and still compelling insights about hippocampal function in memory began with the dramatic characterization of the patient HM (Scoville and Milner, 1957). In an attempt to alleviate debilitating seizures, an experimental surgical procedure was performed in which large portions of both his right and left medial temporal lobes were resected. The ablation included large portions of the hippocampal region, the entorhinal cortex, and the perirhinal cortex (Corkin *et al*., 1997). The surgery reduced the intensity of the seizures but also had the unexpected and profound effect of leaving HM virtually incapable of acquiring new memories across a broad range of modalities of information. In striking contrast, his perceptual and motor capacities and other cognitive abilities, including language and attention, appeared normal. In addition, HM's capacity to acquire and retain information in mind for a brief period was also intact, although the new information was lost as soon as his attention was directed away from it. Although the majority of his childhood memories survived the surgery, there was a retrograde loss of memories acquired for several years prior to the surgery. The main interpretation of the findings was that the hippocampus was important for the consolidation of short-term memories into lasting long-term memories.

Immediately following the reports on HM, there were several attempts to determine whether the hippocampus was also involved in memory in monkeys and rats. Results from a large number of studies in rats of operant conditioning, sensory discrimination, maze learning, and avoidance learning were mixed and inconclusive (reviewed in Cohen and Eichenbaum, 1993; Eichenbaum and Cohen, 2001; O'Keefe and Nadel, 1978). The results from rats ranged from severe performance deficits to normal performance. Some studies even observed facilitation of learning following damage to the hippocampus. Thus, based on these early results, one possibility was that the hippocampus served

memory in humans but some other nonmemory cognitive function, such as response inhibition, in experimental animals.

The 1970s saw several important ideas emerge regarding the function of the hippocampus in experimental animals. Hirsh (1974) suggested the hippocampus was critical for context-dependent retrieval but not for modifications of behavior "along the performance line." Olton *et al.* (1979) suggested that the hippocampus was critical for what he called working memory (memory for single events) but not for reference memory (learning that can be applied across many events). O'Keefe and Nadel (1978) put forth the idea that the hippocampus is selectively involved in map-like spatial memory but not in learning guided by nonspatial cues. The ideas were far from consensual as to what specific function might be supported by the hippocampus in experimental animals, but all the views shared in common two features. First, all agreed that the hippocampus was involved in some aspect of memory. Second, all agreed that memory was not a single ability but was instead capable of being separated into multiple forms of memory, one that depended on the hippocampus and others that did not.

The spatial memory view of the hippocampus was the most successful of these early ideas. The idea of map-like spatial memory appeared well-suited to rats, for whom a memory of the area's geographical layout would be advantageous in supporting nighttime foraging. Further, the spatial map theory was supported by compelling results from studies in which action potentials of single hippocampal neurons were recorded while rats performed spatial tasks or merely explored an open field. The main finding of these studies was that many of the principal cells recorded from CA1 and CA3, which are noted for their very low baseline activity, increased their firing rate dramatically when the rat was in a particular location within the chamber (Muller *et al.*, 1987; O'Keefe, 1979; O'Keefe and Dostrovsky, 1971). O'Keefe and Nadel's (1978) interpretation of these findings was that the firing of hippocampal neurons signaled occupancy of a particular coordinate locus, a place field, within a cognitive map established in the hippocampus.

At the same time that these ideas emerged from work in experimental animals, the concept of multiple memory systems was being refined in parallel by work in human amnesic patients. Work with patient HM had already demonstrated that the hippocampus was not needed to acquire new motor skills (Milner, 1962). Yet these findings were typically set aside as motor-based exceptions to the general view that all memory depended on the hippocampus. A key finding came when Cohen and Squire (1980) observed intact learning outside the domain of motor skills in amnesic patients. Patients and age-matched volunteers were asked to read mirror-reversed words over the course of several days. Patients and control participants both improved their reading speed with practice, but only the control participants were able to describe subsequently the details of the testing situation. These results helped make the point that the human hippocampus was important for memory in the everyday sense of the word but was not important for other examples of procedural memory, such as the acquisition of cognitive skills, that are expressed through performance rather than recollection.

The observation of hippocampal cells with place fields in rats was compelling, yet for those who worked with amnesic patients, the idea of a special role for the hippocampus in spatial memory appeared to ignore a large body of data on HM and other amnesic patients indicating a critical role for the hippocampus in nonspatial memory, including verbal memory of recently encountered events that were not prominently spatial in nature. This disjuncture in the findings on rodents and humans exacerbated the already widely held view that the hippocampus supported distinct functions in humans and animals.

3.33.4.2 Convergence of Ideas on Hippocampal Function in Humans and Experimental Animals

A resolution of the contrasting findings from humans and experimental animals became available only through the systematic administration of similar tasks to humans and experimental animals. Points of contact between humans and experimental animals have now been made with numerous tasks, including the transitive inference task described in the first half of the article (Bunsey and Eichenbaum, 1996; Heckers *et al.*, 2004; Nagode and Pardo, 2002; Preston *et al.*, 2004). Here, we focus on three tasks that have been especially informative, either for the volume of data available or for the clarity of the results across species. The first is a task in which multiple pairwise discriminations are learned concurrently. The second is a recognition memory task called delayed nonmatch to sample (DNMS). The third is classical conditioning of the eyeblink response. A fourth point of contact exists, not in the form of a specific task, but as a pattern of results from several tasks related to premorbid memory in amnesic patients and experimental animals with damage to the hippocampus. That is, there is a similar pattern of temporally graded retrograde amnesia across mammals.

3.33.4.2.1 Concurrent discrimination One task that has been given to both amnesic patients and monkeys with medial temporal lobe damage is a task in which multiple sets of pairwise object discrimination problems must be learned concurrently. Both healthy humans and intact monkeys learn to identify the correct item for each of up to 20 pairs of randomly assigned junk objects over the course of multiple testing sessions. Monkeys with damage limited mostly to the medial temporal lobe perform as well as intact animals (Buffalo *et al.*, 1998; Malamut *et al.*, 1984; Teng *et al.*, 2000). In contrast, amnesic patients typically attain levels of performance much lower that that shown by healthy individuals (Hood *et al.*, 1999; Squire *et al.*, 1988). Based on these findings, one possibility was that the hippocampal and parahippocampal regions performed a different function in humans and monkeys, one that was important for the concurrent discrimination task and one that was not. Another possibility was that the hippocampal and parahippocampal regions served similar functions in humans and monkeys, both potentially contributing to the concurrent discrimination task. From this viewpoint, monkeys with medial temporal lobe damage performed normally because their memory impairment was masked by a capacity for habit learning that was underdeveloped in humans (Hood *et al.*, 1999).

A third possibility is that the line that divides declarative memory and nondeclarative memory is drawn similarly for monkeys, humans, and possibly all mammals (Squire *et al.*, 1988). From this viewpoint, the hippocampal and parahippocampal regions serve the same function in humans and experimental animals, and the capacity for hippocampus-independent procedural learning is also similar for all mammals. The difference is that humans enjoy cognitive skills such as verbal labeling and elaborations, which are presumably absent or less well developed in other mammals, leading them to adopt a memorization strategy. When this strategy is unavailable, as in the case of profoundly amnesic patients, humans appear to be able to fall back on habit learning and show a rate of learning on the concurrent discrimination task that is similar to that shown by monkeys (Bayley *et al.*, 2005a).

3.33.4.2.2 Delayed nonmatch-to-sample After HM's profound amnesia was described (Scoville and Milner, 1957), many studies in experimental animals were performed in attempting to duplicate his damage and memory impairment. One early line of studies focused on a test of recognition memory in which animals were first presented with one of two colored sample stimuli, then following a variable delay, were required to chose the sample stimulus over the other stimulus, that is, to match the sample. The same two color pattern stimuli were used on each trial, with either selected randomly to be the sample on that trial. The expectation was that damage to the medial temporal lobe would reproduce the observation of delay-dependent memory impairment in HM. However, monkeys with medial temporal lobe lesions performed surprisingly well on this and other delayed response tests, even at memory delay intervals of several seconds (Correll and Scoville, 1965, 1967; Drachman and Ommaya, 1964). These findings contributed to the early view that hippocampal function differs in animals and humans.

However, a breakthrough occurred when the task was modified to use different three-dimensional objects on each trial (Gaffan, 1974; Mishkin and Delacour, 1975). Also, because monkeys showed a natural preference for manipulating novel objects, experiments began using a nonmatch rule (i.e., the unstudied object was rewarded) for efficiency. Thus, the procedure was changed to become the now widely used trial-unique DNMS task. The results on the DNMS task were very different than those in the early studies. Monkeys with damage similar to that produced in HM could learn the nonmatching rule and performed normally at very brief delays, but rapidly declined in performance as the delay was increased, thus reproducing the pattern of delay-dependent memory impairment in human amnesia (Squire and Zola, 1996). The DNMS task was also soon adapted for use in rats (Mumby *et al.*, 1992). Similar to the results from humans and monkeys, damage that included both the hippocampal region and parahippocampal region resulted in a delay-dependent impairment in recognition memory performance (Mumby and Pinel, 1994). Although researchers have more recently debated whether the hippocampal region itself is important for recognition memory, the use of the DNMS task across species helped identify that the mammalian hippocampal and parahippocampal regions enable long-term memory for items encountered only once. Based on these and other observations, it is now appreciated that rapid, single-exposure learning is a hallmark of hippocampal-based learning.

3.33.4.2.3 Classical conditioning of the eyeblink response Another example of a success in demonstrating similarities in the profile of hippocampus-dependent learning across species shows an impressive distinction generated by a simple procedural parameter. In classical conditioning of the eyeblink response, a tone is repeatedly followed by

a mild puff of air to one's eye, causing a reflexive blink. After several tone–air puff pairings, subjects (across several mammalian species) begin to blink following tone onset and prior to the air puff, demonstrating the conditioned response. In the standard version (called delay eyeblink conditioning), the onset of the tone precedes the onset of the air puff and continues such that the stimuli then overlap and co-terminate. This simple form of associative learning is supported by a carefully described circuit that includes the brainstem and cerebellum (Christian and Thompson, 2003). In a slightly modified version (called trace eyeblink conditioning), the tone ends before the air puff and a brief ($\leq$1s) silent interval separates the two stimuli. This small gap in time necessitates the recruitment of additional brain structures, including the hippocampus, to support the association of the tone and the puff in the cerebellum. The distinction between trace and delay eyeblink classical conditioning is particularly compelling when one considers that the dependence of trace eyeblink conditioning on the integrity of the hippocampus has been established for mice, rats, rabbits, and humans (Clark and Squire, 2000). Thus, the difference between delay and trace eyeblink classical conditioning suggests something fundamental about the function of the hippocampus that has been conserved though evolution.

Classical conditioning was once viewed as a form of procedural learning, typically outside the domain of critical hippocampal involvement. However, the findings of additional experiments in humans have indicated that acquisition of trace, but not delay, eyeblink conditioning correlates with participants' ability to report information about the relationship between the tone and the air puff (Clark *et al.*, 2002). These results suggest two points. First, the close similarity of the experimental parameters for delay and trace eyeblink conditioning illustrate how subtle the change can be that disposes performance to rely on hippocampus-dependent memory available for verbal report. Second, the relationship in humans between trace eyeblink conditioning and awareness of the stimulus contingencies suggests that something similar might be occurring in experimental animals who successfully acquire trace eyeblink conditioning.

3.33.4.2.4 Retrograde amnesia In addition to cross-species similarities in the cognitive demands dependent on the hippocampus and in the nature of events represented by the hippocampus, there is also considerable evidence indicating conservation of a time-limited role of the hippocampus in memory consolidation. In numerous studies in experimental animals who were given lesions to the hippocampal region at various intervals after acquiring new information, the result emerged that the hippocampus is needed to retrieve information for a finite period of time (for a review, see Squire *et al.*, 2001). The typical finding is that animals in which the hippocampus was ablated immediately after a training session subsequently displayed impaired performance, whereas animals in which the hippocampus was removed one week to one month after a training session subsequently displayed normal performance. The interpretation of these studies was that the hippocampus was needed for acquisition and initial retrieval of the new memory, but that over time the memory eventually became independent of the hippocampus through a process of consolidation (Squire *et al.*, 2001). Although the critical training–lesion interval varied somewhat from study to study, the retrograde amnesia suggested that the process of consolidation lasts from a few days to a month.

These findings are qualitatively very similar to the pattern of temporally graded retrograde amnesia in HM and other amnesic patients. For example, one study assessed amnesic patients' memory for newsworthy incidents that occurred at various years prior to the patients sustaining damage thought to be limited to the hippocampal region (Manns *et al.*, 2003b). These results suggested that the impact of the hippocampal damage extended to memory from 5 to 10 years prior to onset of damage. Thus, although the results suggest that the process of consolidation is substantially longer in humans as compared to experimental animals, the findings indicate that the hippocampus plays a time-limited role in memory across species.

Taken together, the results of these three specific tasks and the common observation of temporally graded retrograde amnesia strongly suggest that the hippocampus serves a similar role in memory in both humans and in experimental animals. However, much debate surrounds the question of how to best characterize this role. For example, still under debate is whether the hippocampus itself is crucial for simple recognition memory or whether structures in the parahippocampal region support this ability (Manns *et al.*, 2003a; Mumby, 2001; Clark *et al.*, 2001). However, this uncertainty applies equally to the findings on humans, monkeys, and rats. In any case, it is clear that the extended hippocampal memory system, including the parahippocampal region, is important for examples of single-trial learning, including recognition memory judgments, for spatial memory, and for forming arbitrary relationships between stimuli, as in the transitive inference task. The example of trace eyeblink conditioning also illustrates that the

hippocampus is crucial for learning under circumstances in which the capabilities of extrahippocampal structures are unable to support the learning. In these instances, the hippocampal contribution becomes indispensable.

3.33.4.3 Remaining Points of Disconnect between Humans and Experimental Animals

With the greater understanding of multiple memory systems and the assurance of consistency of function between humans and experimental animals, researchers could explore hippocampal function in a variety of mammalian species and expect with some confidence that the results would be relevant to the entire taxon. This exploration has led to an understanding that the original features of memory that distinguished hippocampal function in humans and animals are more compatible with a cross-species approach than once was believed.

3.33.4.3.1 Understanding how place cells relate to the human hippocampus A remaining point of potential discontinuity between species is the difficulty in resolving the prominence of spatial correlates in the firing of rodent hippocampal cells with the observation that the human hippocampus is important for all examples of declarative memory, both spatial and nonspatial. The conclusion that hippocampal neurons fire primarily in association with an animal's location in its environment, whereas the human hippocampus is required for and engaged by a broad variety of nonspatial memories would seem to present a major exception to cross-species similarity of hippocampal function.

However, recent parallel studies in both rats and humans have demonstrated a much broader scope of information encoded by hippocampal neurons in both rats and humans. In rats, a direct comparison of spatial and nonspatial coding by hippocampal neurons was investigated by recording from hippocampal cells as rats sampled nonspatial cues at many locations in an environment (Wood *et al.*, 1999). The rats performed a task in which they had to recognize any of nine olfactory cues that were placed in any of nine locations. Because the locations of the odors were varied systematically, cellular activity related to the odors and to memory performance could be dissociated from activity related to the animal's location. The study found that similar proportions of hippocampal cells fired in association with a particular odor, a particular place, or whether the stimulus was recognized. In addition, a large subset of hippocampal neurons fired in association with only a particular combination of the odor, the place where it was sampled, and the match/nonmatch status of the odor. In a remarkably similar study on humans, Ekstrom *et al.* (2003) recorded the activity of hippocampal neurons in human subjects as they played a taxi driver game, searching for passengers to be picked up and dropped off at various locations in a virtual reality town. Similar to the findings with rats, equivalent proportions of the cells fired in association with particular landmarks, views of the environment, or places occupied in the virtual town. Also, many of these cells fired selectively in association with specific combinations of a place and the view of a particular scene or a particular goal.

Other studies have also reported a remarkable similarity of hippocampal neuron firing patterns in monkeys and humans associated with nonspatial stimulus analysis. Hampson *et al.* (2004) trained monkeys on matching-to-sample problems, then probed the nature of the representation of stimuli by recording from hippocampal cells when the animals were shown novel stimuli that shared features with the trained cues. They found many hippocampal neurons that encoded meaningful categories of stimulus features and appeared to employ these representations to recognize the same features across many situations. Kreiman *et al.* (2000a) characterized hippocampal firing patterns in humans during presentations of a variety of visual stimuli. They reported a substantial number of hippocampal neurons that fired when the subject viewed specific categories of material (e.g., faces, famous people, animals, scenes, houses) across many exemplars of each. A subsequent study showed that these neurons are activated when a subject simply imagines its optimal stimulus, supporting a role for hippocampal networks in recollection of specific memories (Kreiman *et al.*, 2000b). This combination of findings across species provides compelling evidence for the notion that some hippocampal cells represent abstract features of nonspatial stimuli that appear in different experiences.

Studies across species also emphasize the presentation of objects in relation to their location in the environment. Hippocampal cells that represent specific salient objects in the context of a particular environment have also been observed in studies of rats engaged in foraging (Gothard *et al.*, 1996; Rivard *et al.*, 2004) and escape behavior (Hollup *et al.*, 2001) in open fields. In addition, two recent studies highlight the associative coding of events and places by hippocampal neurons in rats and monkeys. In one study, rats were trained on an auditory fear conditioning task (Moita *et al.*, 2003). Prior to fear conditioning, few hippocampal

cells were activated by an auditory stimulus. Following pairings of tone presentations and shocks, many cells fired briskly to the tone when the animal was in a particular place where the cell fired above baseline. Another recent study examined the firing properties of hippocampal neurons in monkeys performing a task where they rapidly learned new scene–location associations (Wirth *et al*., 2003). Just as the monkeys acquired a new response to a location in the scene, neurons in the hippocampus changed their firing patterns to become selective to particular scenes. These scene–location associations persist even long after learning is completed (Yanike *et al*., 2004). These findings are entirely consistent with the findings of prevalent hippocampal neuronal activity associated with conjunctions of events and locations in Wood *et al*. (1999) study on rats and Ekstrom *et al*. (2003) study on humans. Collectively, these findings indicate that a prevalent property of hippocampal firing patterns in rats, monkey, and humans involves the representation of unique associations of stimuli, their significance, specific behaviors, and the places where these events occur.

3.33.4.3.2 Understanding how episodic memory relates to hippocampal function in experimental animals Another point of potential discontinuity involves a form of declarative memory called episodic memory. Episodic memory is characterized as the ability to replay in mind a particular episode in one's life, and this capacity has been closely identified with hippocampal function in humans (Tulving, 2002). Defined in these terms, episodic memory is considered by some to be a uniquely human ability (Tulving, 1983). If so, then the human capacity for episodic memory represents a break in the continuity of hippocampal research between humans and experimental animals. The difficulty in addressing this issue is that experimental animals are unable to report on their subjective experience.

A less mentalistic definition of episodic memory, and one that is experimentally tractable in experimental animals as well as in humans, characterizes episodic memory as including details about the time and place in which an episode occurred. That is, episodic memory includes information about the 'what', 'where', and 'when' of an event (Clayton and Dickenson, 1998). Experimental animals, including rodents and birds, have demonstrated evidence of the ability to remember where and when unique events occurred (Clayton *et al*., 2003; Dere *et al*., 2005; Eacott *et al*., 2005; Morris, 2001). Further, damage to the hippocampus impairs this capacity (Ergorul and Eichenbaum, 2004). By this definition then, it appears that animals other than humans are capable of episodic-like memory and that this ability depends on the hippocampus. However, the definition of episodic memory as the combination of 'what', 'where', and 'when' may be overly strict and may exclude examples of hippocampus-dependent memory. In particular, tasks that require memory for either temporal order (Fortin *et al*., 2002; Kesner *et al*., 2002) or spatial location (Day *et al*., 2003; O'Keefe, 1993) alone depend on the integrity of the hippocampus. Thus, although the hippocampus in humans and experimental animals appears to be crucial for combining temporal and spatial elements of a particular incident, this capacity does not represent the totality of its function.

Another approach to studying episodic memory in humans and experimental animals focuses on the notion that recognition memory can be supported by two processes: an episodic-like recollection of specific details and a feeling of familiarity with a previously experienced item (Atkinson and Juola, 1974; Mandler, 1980; Yonelinas, 1994). Although the status of familiarity-based judgments is currently under debate (Brown and Aggleton, 2001; Squire *et al*., 2004), it is generally accepted that the human hippocampus is important for recognition memory based on recollection. One approach to quantifying the relative contribution of recollection and familiarity to recognition memory judgments has adopted signal detection theory to characterize recognition memory in terms accuracy (proportion of hits to correct rejections) as either a function of confidence levels or tendency to endorse and item as having been repeated. These measures result in a receiver-operating characteristic (ROC) curve that, by one model, contains the signatures of distinct recollection and familiarity contributions to recognition (Yonelinas, 2001). From this viewpoint, a typical ROC curve can be thought of as composite of a familiarity curve that is symmetric to the diagonal and a recollection line that is asymmetric. Mathematical decomposition of these plots can thus provide numerical estimates of recollection and familiarity. One appeal of this technique is that the definition of episodic-like memory, the numerical estimate of recollection, can be used in both humans and experimental animals.

A recent study reported that the ROC curve in human amnesic patients with hippocampal damage is curvilinear and symmetric, indicating a loss of recollection (Yonelinas *et al*., 2002). Consistent with that finding, a recent study of rats found that the ROC curve of normal rats was both asymmetric and curvilinear, similar to the composite recollection and familiarity ROC curve observed in normal

human subjects (Fortin *et al.*, 2004). In contrast, performance of rats with damage to the hippocampus was best fit by a symmetric curve, suggesting a loss of episodic-like recollection. Although the measure of recollection in these studies is necessarily indirect, the closely parallel results suggest that the hippocampus contributes to episodic memory, or something closely resembling episodic memory, in both humans and experimental animals.

However, it should be noted that the view of the hippocampal function based on the distinction between recollection and familiarity is not consensual. Some argue that the shape of ROC curves can be better explained by factors such as differences in the variability in the perceived memory strength between studied and unstudied items (Donaldson, 1996). Others charge that the idea is based on a psychological dichotomy that is incompatible with the anatomical view of the hippocampal and parahippocampal regions as a hierarchical network of interconnectivity (Squire *et al.*, 2004). Further, the notions of recollection and familiarity are based on terminology and concepts tailored to psychological findings in humans. Although contact has been made between humans and rats with respect to the importance of the hippocampus for recollection, one could argue that the distinction is not one that is ideally suited to an evolutionary approach to the study of memory and the hippocampus.

3.33.4.4 Possible Divergence between Species

Although the bulk of the anatomical data from mammals regarding the hippocampal and parahippocampal regions indicates that the similarities outweigh the differences, several prominent anatomical differences were noted between rodents and primates. Perhaps the most striking difference is the prominence of olfactory input that reaches the entorhinal cortex in the rat. Based on this observation, one possibility is that the rat entorhinal cortex exhibits specialization in olfactory memory that is not exhibited by the primate entorhinal cortex. Indeed, in one study, rats with hippocampal lesions were nevertheless able to identify a novel odor from among 24 recently encountered odors (Dudchenko *et al.*, 2000). Their performance was presumably supported in part by the entorhinal cortex and was as good as that as shown by healthy rats. The basic procedure was adapted and given to humans with damage to the hippocampal region (Levy *et al.*, 2003). In contrast to the findings in rats, humans with damage to the hippocampal region performed poorly and performed worse than healthy individuals. Although it is difficult to rule out other variables such as the extent of the hippocampal damage, these studies hint that the rat entorhinal cortex might be able to support more odor-related memory abilities as compared to the human entorhinal cortex.

Another difference observed between humans and experimental animals concerns the apparent duration of memory consolidation. In experimental animals, the process apparently requires around a month when damage is restricted to the hippocampal region (Squire *et al.*, 2001). In humans, the process can last several years when damage is thought to be limited to the hippocampal region and can last even longer when damage also includes structures in the parahippocampal region (Bayley *et al.*, 2005b; Kapur and Brooks, 1999; Manns *et al.*, 2003b; Reed and Squire, 1998; Rempel-Clower *et al.*, 1996). Several factors likely contribute to the different timescales observed between humans and experimental animals. First, anatomical studies indicate that the organization of the hippocampal and parahippocampal regions in rats is less hierarchical than it is in the monkey. In the rat, the hippocampal region and the entorhinal cortex show more direct connections with olfactory and neocortical areas than are observed in the monkey (Burwell and Amaral, 1998b; Suzuki and Amaral, 1994). If the trend toward a more strict hierarchy was continued in humans, the decrease in direct cortical connections with the hippocampus and entorhinal cortex might suggest why the process of consolidation takes longer in humans. Second, the type of information being assessed in human studies of consolidation is often very different from the type of information being assessed in experimental animals. Studies in humans typically examine factual information about the world. In comparison, studies in experimental animals typically examine presumably simpler associations. For example, one study in rabbits identified that lesions one day after training, but not 30 days after training, impaired subsequent performance on a trace eyeblink conditioning experiment (Kim *et al.*, 1995). One possibility then is that some of the discrepancy between humans and experimental animals could be accounted for by differences in the complexity of the memories assessed.

A related topic concerns whether or not spatial memory holds a special status in terms of memory consolidation in the rat. In humans, it appears that spatial memory eventually becomes independent of the hippocampus, just as other examples of memory that are acquired by the hippocampus are thought to become. In one study, a profoundly amnesic patient who had virtually complete damage to the hippocampal region was nevertheless able to pretend he

was standing in his childhood neighborhood and point accurately to several town landmarks (Teng and Squire, 1999). In rats, the results are somewhat different. Indeed, most studies in rats have found that the hippocampus remains important for spatial memory for as long as the memory remains measurable (Moscovitch *et al*., 2005). In one study, healthy rats were able to demonstrate memory for a spatial location learned more than 14 weeks previously. However, rats with damage to the hippocampus performed at chance even when the training–surgery interval was 14 weeks (Clark *et al*., 2005). That is, there was no evidence for consolidation of spatial memory in these rats, despite the fact that the training–surgery interval was longer than that typically reveals consolidation of nonspatial memory in experimental animals. It is possible that the rat experienced environmental pressures that caused spatial memory to acquire a status in which its persistence became tied to the function of the hippocampus. However, it is also possible that further study will identify a process of consolidation for spatial memory in the rat. Indeed, one recent study in rats found that post-training lesions to the hippocampus spared memory for locations of different rewards, but only when the animals were exposed to the locations of the rewards very early in life (Winocur *et al*., 2005).

3.33.4.5 A Species-General Mechanistic Account of the Hippocampus

A challenge in memory research has been to provide a mechanistic account that could connect the anatomy of the hippocampal and parahippocampal regions to the examples of memory that depend on these structures. That is, it is now clear that the hippocampal and parahippocampal regions are important for the initial acquisition and temporary maintenance of declarative memory, but it is unclear exactly how these regions support this capacity.

One promising approach has been the development of anatomically plausible computational models of the hippocampal and parahippocampal regions. One particularly influential model built on the characterization for the hippocampal and parahippocampal regions as a hierarchical network and proposed that the hippocampus served as a central node of synaptic change (McClelland *et al*., 1995). The hierarchical network proposed by the model offered the brain several mnemonic advantages. First, incoming information that would be processed by widespread neocortical sites could be condensed through the process of funneling information through the parahippocampal region on its way to the hippocampal region. Accordingly, long-lasting associations between very different types of information could be made very quickly through a limited number of synaptic changes in the hippocampus. Thus, the model described how the anatomy of the hippocampus enabled rapid acquisition of arbitrary associations. Second, the binding of disparate neocortical sites by the hippocampus might allow the neocortical sites to develop more direct interconnectivity over time. That is, the model described how the process of consolidation might occur. This second point was based on the idea that several neocortical nodes would be joined by the hippocampus into a subnetwork whose co-activity could be propelled by repetition, rehearsal, or spontaneous reinstantiation during sleep. An important idea that emerged from the model was that the hippocampus allowed the brain to acquire new information rapidly and then to gradually interleave that information in existing neocortical networks. That is, according to the model, the hippocampus solves the problem of how to acquire new information quickly without disturbing the delicate network of existing knowledge.

The advantage to models like the one described above is that the concepts should apply equally well to any mammal, provided that the anatomical constraints included in the model are not violated by any species-specific anatomical idiosyncrasies. Indeed, additional computational models will be the most useful to an evolutionary approach when they are based on facets of the anatomy that are shared across mammals. In particular, accumulating evidence suggests that the information arriving at the hippocampal region through perirhinal cortex and LEA differs in content as compared to the information arriving at the hippocampal region through postrhinal/parahippocampal cortex and MEA. Further, the anatomy suggests that the dentate gyrus and CA3 may be important for combining this information and incorporating it with as yet uncombined information in CA1 and subiculum. Computational models that take advantage of this pattern of connectivity, which is shared by at least rats and monkeys, could contribute significantly to understanding principles of hippocampal function that apply across species.

3.33.5 Conclusions

The anatomy of the hippocampal and parahippocampal regions represents an elegant solution to a difficult memory problem. Natural selection shaped a network of structures that could quickly form stable associations between pieces of information

that bore no topographic similarity to one another. Evidently, a rough approximation of an answer had been sketched out early in the evolution of vertebrates, prior to the emergence of mammals. The modern blueprint appeared in the earliest mammalian hippocampus, and the solution was repeated again and again throughout the taxon. The occasional variations in anatomy between mammals with regard to the parahippocampal region might then represent flourishes added to what was already an anatomical masterpiece.

If the anatomy of the mammalian hippocampus is a finished product, then the study of its function might be best described as a work in progress. On one hand, much is already known about the function of the hippocampal and parahippocampal regions. These structures together support only one kind of memory, a type of memory referred to as declarative memory that is unambiguously important for recollecting episodic details, encoding spatial locations, and forming abstract or arbitrary associations. On the other hand, much is left to be discovered. A question at the forefront of memory research is how the individual components of the hippocampal and parahippocampal regions might each contribute to declarative memory. Accordingly, there is debate as to whether the hippocampus itself is important for aspects of declarative memory such as nonspatial memory and judgments of familiarity or if these abilities are supported by areas within the parahippocampal region. Thus, a clear set of principles that account for all examples of hippocampus-dependent memory has not been agreed upon. The hope is that the psychological, anatomical, physiological, and computational approaches will be combined to produce a view of hippocampal function that makes sense at all levels.

As researchers move toward a consensual view regarding the roles of the hippocampal and parahippocampal regions in memory, one challenge will be the struggle to identify ideas that attain a satisfactory level of psychological specificity for humans while maintaining enough contact with the anatomical and mechanistic details to generalize to all mammals. The goal is to identify the unifying principles that apply to all examples of hippocampus-dependent memory, both in humans and experimental animals. To date, many ideas that have been proposed that contain elements of species-specific psychology, such as spatial memory in rats and episodic memory in humans. The difficulty is that often the elements of psychology vary dramatically between species – despite the fact that the anatomical details of the hippocampal and parahippocampal regions are remarkably similar. For example, humans enjoy certain cognitive skills such as chunking and elaboration that may steer them toward memorization strategies. These abilities are presumably less advanced in experimental animals and therefore might lead animals to rely more on trial and error. In turn, rats may have evolved specialized skill sets that allow them in their nighttime foraging to be highly attuned to spatial layout and their position within it. For neither rats nor humans is it likely that these cognitive skills are fundamentally derived from the hippocampus. Instead, these skills are likely supported by areas outside the hippocampal and parahippocampal regions such as prefrontal cortex and posterior parietal cortex. That is, it is possible that any apparent differences in terms of the psychological properties of hippocampus-dependent memory might be more related to the differences in neocortical input to the hippocampal and parahippocampal regions rather than due to any differences between species for these areas themselves.

An evolutionary approach can help us understand the functional machinery of the mammalian hippocampus. At the same time, an enormous asterisk must follow any statement about our current understanding of the hippocampus, for the vast amount of data come from rodents and primates. Most of the mammalian taxon is unexplored, and every mammal presents an opportunity to probe the function of the hippocampal and parahippocampal regions with a unique neocortical instrument. For example, one might explore how auditory information in the bat echolocation system arrives in the hippocampal region. One might also take advantage of the simple cortex of the hedgehog to pare down the inputs to the parahippocampal and hippocampal regions. Thus, an evolutionary perspective can not only reveal the conservation of hippocampal form but can also offer many opportunities for exploring the function of this form.

3.34 Evolution of the Elephant Brain: A Paradox between Brain Size and Cognitive Behavior

B L Hart and L A Hart, University of California, Davis, CA, USA

Glossary

areas or modules	Large, functionally significant subdivisions of the cerebral cortex.
clan	A group of elephants made up of families which periodically come together and then separate but maintain communication with each other.
matriarch	The female leader of an elephant family that is generally related to other females in the family and who is the oldest and still capable of leading.
seismic signals	Vibrations transmitted across the top layers of the earth.

3.34.1 Introduction

Of all large-brained species, elephants have received the least attention from neurobiologists in terms of understanding neocortical cytoarchitecture and cerebral information processing. Other large-brained species, in particular chimpanzees and humans, have attracted considerable interest and much has been learned about the constraints that large brains impose on the nature and speed of information processing (Krubitzer, 1995; Kaas, 2000; Hofman, 2003; Changizi and Shimojo, 2005; see Mosaic Evolution of Brain Structure in Mammals, Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications, Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals, The Evolution of Crossed and Uncrossed Retinal Pathways in Mammals, Do All Mammals Have a Prefrontal Cortex?, The Evolution of the Basal Ganglia in Mammals and Other Vertebrates, The Evolution of the Dorsal Thalamus in Mammals). Elephants present a challenge in understanding the evolution of large brains because they have the largest brains of all terrestrial animals with the greatest volume of cerebral cortex, and even the greatest volume of nonsensorimotor cortex, which is that part of the cerebral cortex presumably involved in higher-order brain functions. The presence of such a massive cerebral cortex in the elephant poses a dilemma because several studies on elephant cognitive behavior, including tool use, mirror-based self-recognition, visual discrimination learning, and so-called insight behavior, reveal that their performance is unimpressive in comparison to chimpanzees, let alone humans. In this article we suggest that the paradigm of relating cognitive behavior to the amount of neocortex, as conventionally applied to large-brained primates, is not appropriate for elephants and point to some anatomical and cytoarchitectural features of the brains of elephants that would appear to explain why elephants fall short on their performance on primate-like cognitive behavior but excel in other areas of higher-order brain functions, namely long-term, extensive information storage.

There are currently three recognized species of elephants: (1) the African savannah elephant (*Loxodonta africana*), which is the largest species; (2) the small forest elephant, *Loxodonta cyclotis*; and (3) the Asian elephant (*Elephas maximus*). Because information on the behavior and brain structure of the forest elephant is virtually nonexistent, we discuss only the African and Asian species in the article.

3.34.2 Behavioral Considerations

Here we briefly review relevant behavioral studies on elephants to provide a background for discussion of elephant brain anatomy, cytoarchitecture, and information processing.

3.34.2.1 Comparative Aspects of Cognitive Behavior

For this topic it is appropriate to compare elephants with chimpanzees (*Pan troglodytes*), the great ape most commonly studied with regard to cognitive behavior. Using sticks to fish termites out of underground nests or to reach inside bones for marrow (van Schaik *et al.*, 1999; Matsuzawa, 2003) is a classic example of tool use in great apes. Perhaps the best example of complex tool use by chimpanzees is cracking nuts open by holding a nut against an anvil stone and hitting it with a smaller hammer stone (Humle and Matsuzawa, 2001).

Elephants engage in several types of tool use. Fly switching with branches, while not particularly complex, would appear, in fact, to be the first documented example of tool use among nonhuman animals, dating back to when a wildlife adventurer wrote in 1838 of seeing elephants emerging into an open glen, "bearing in their trunks the branches of trees with which they indolently protected themselves from flies" (Harris, 1838, p. 169). Elephant fly switching was even mentioned by Darwin (1871) in discussing the intelligence of beasts. We have documented the efficacy of fly switching in repelling flies (Hart and Hart, 1994) and the modification of branches to use as switches (Hart *et al.*, 2001). Asian and African elephants engage in other types of tool use, including scratching with a stick and throwing stones at rodents competing for fruit (Hart and Hart, 1994; Kurt and Hartl, 1995; Wickler and Seibt, 1997). Despite the historical significance, the complexity of tool use of elephants pales in comparison with the rich repertoire of fast-action, highly coordinated tool use described for chimpanzees such as the hammer–anvil style of cracking nuts.

Simultaneous visual discrimination learning is another area of cognitive behavior in which elephants have been compared to standards set by other mammals. Under seminatural conditions, Asian elephants may learn a black/white or large/small discrimination but the performance of even the fastest-learning elephants is unremarkable compared with other mammals (Nissani *et al.*, 2005). Tests of insight behavior, exemplified by pulling a cord to obtain a desirable object, also reveal disappointing behavior by elephants which do not perform in a manner consistent with that of chimpanzees, rhesus monkeys, and even several species of birds (Nissani, 2004).

Finally, in the way of classical tests of cognitive behavior, there is the test of self-recognition, as studied in the well-known mirror experiment in which the self-recognizing animal touches a mark on its head in front of a mirror. In contrast to chimpanzees that perform well (Povinelli *et al.*, 1997), Asian elephants fail in self-recognition (Povinelli, 1989; Nissani, 2004).

3.34.2.2 Elephants and Long-Term, Extensive Memory

Now we turn to an aspect of behavior for which elephants have legendary abilities ("memory like an elephant"; "an elephant never forgets"). Quantitative field studies actually support this popular perspective. One would expect long-term memory about details of the environment regarding food and water resources to be essential for survival of herbivores like elephants, whose digestive system is adapted to handle large volumes of low-quality forage. Among the studies where movements are documented by individual animal recognition and/or radio-tagged individuals are those of desert elephants that occupy a huge home range during the dry season and visit water holes spaced more than 60 km apart (Viljoen, 1989). One cannot help but be impressed by the ability of an elephant family, led by a matriarch of some 30-plus years, to head unerringly toward an isolated water hole after a stressful 4 days without water; especially when particular water holes may only be visited every 8 months or so. The same desert elephants travel annually from their home ranges to new forage grounds in response to localized rainfall almost 200 km away (Viljoen, 1989). The fact that elephants may arrive at such distant locations as soon as 3 days after the start of rainfall, and without prevailing winds to carry chemosensory cues (Viljoen, 1989), suggests they are responding to one or more sensory cues of distant rainfall. One possibility is that seismic waves, which are detectable by elephants (O'Connell-Rodwell *et al.*, 2005), and which are produced by lightning strikes and the accompanying thunder vibrations (O'Connell-Rodwell *et al.*, 2001), may be sufficient for elephants to detect over long distances. Thus, travel to distant foraging grounds could be triggered by seismic signals from distant storms with direction coordinated by long-term memory of where vegetation is likely to appear.

The fitness value of the long-term spatial–temporal information retained by long-living matriarchs was vividly illustrated in a study conducted during a prolonged drought in Tarangire National Park in Tanzania (Foley, 2002). Clans in which families

were led by older matriarchs left the park to forage in nonpark areas. However, a clan in which families were led by only young matriarchs (due to poaching) stayed in the park and sustained severe losses from insufficient water and forage: infant mortality and all-age mortality were more than double that of the clans with older matriarchs. To have experienced the most recent severe drought, where matriarchs could have remembered where to go, they would have had to be at least 35 years old and the matriarchs of the clan not leaving the park were apparently not this old.

Social memory is another area in which elephants show exceptional ability. An aspect of social behavior involves chemosensory communication and urine could theoretically allow an animal to identify particular conspecifics even decades after the last encounter. During sexual encounters, urine is typically orally investigated by adult male elephants, as in other ungulates, through the process of flehmen behavior that involves the transport of fluid materials from the mouth to the vomeronasal organ (Hart *et al.*, 1989). Because long-lived male elephants leave their natal group, an ability to identify the urine of mothers would be important in avoiding inbreeding. This appears to be the case, as revealed in a controlled laboratory study in which adult males identified maternal urine decades after being separated from their mothers (Rasmussen and Krishnamurthy, 2000).

Acoustic stimuli represent another area in which elephants may recognize individuals. Elephants can recognize individual calls of 100 or more elephants at 1 km or more. Because there is uneven attenuation of the various frequencies of the contact calls at 1 km away, this means that such extensive recognition can occur with just a fraction of the acoustic signature that is otherwise present at close range (McComb *et al.*, 2000, 2003). Discriminating between familiar and unfamiliar elephants is important in coordinating interactions at water holes and avoiding conflicts. One study revealed that families with older matriarchs are better at discriminating between familiar and unfamiliar individuals than families with younger matriarchs, and the age of the matriarch was a significant predictor of the number of calves successfully produced in the family per female (McComb *et al.*, 2001).

3.34.3 Information Processing in Large Brains

The foregoing discussion presents a sampling of the behavioral information available and suggests that the performance of elephants on fast-action, and/or fine-grained cognitive tasks is noticeably inferior to that of great apes (and humans) but that long-term or extensive memory ability would appear to exceed that of great apes and possibly even humans. We now turn to a discussion of some special anatomical features, as well as aspects of cerebral cortical cytoarchitecture and neuronal interactions that logically relate to these major behavioral differences.

3.34.3.1 The Elephant Hippocampus

As an initial consideration, an emphasis on long-term memory performance brings up the question of whether the hippocampal complex, long associated with memory consolidation, might be enhanced in elephants. Of relevance is that recent studies emphasize that the hippocampus is more crucial for the formation and retention of cognitive maps that code for unfamiliar spatial–temporal relationships that are viewpoint-independent representations of the environment than for memory consolidation involving familiar representations (Sweatt, 2004). Given that elephants appear to excel in the retention of infrequently used distant geographical areas, where their treks to the distant areas are independent of where they start out from (viewpoint-independent), the hippocampus would be particularly important to evaluate. Consistent with an expectation of a large hippocampus, recent magnetic resonance imaging of an African elephant brain reveals that the hippocampus is unusually large and convoluted, compared even with human brains (Hakeem *et al.*, 2005).

3.34.3.2 The Elephant Cerebral Cortex and Encephalization Quotient

As pointed out, the cerebral cortex of the elephant brain is the largest of all terrestrial animals and about three times larger than that of the human (Figure 1). The conventional approach to examining the relationship between brain size and higher-order brain functions is through calculation of the encephalization quotient (EQ), which is a representation of the ratio of brain volume to body mass (Jerison, 1973). Accordingly, the EQ of humans is 7.5, chimpanzees 2.5, Asian elephants 2.3, and the African elephant 1.3 (Jerison, 1973; Cutler, 1979). The markedly lower EQ of the African elephant reflects the fact that the brain is only slightly larger than that of the Asian but body mass is much greater.

3.34.3.3 Information Processing: Neurons of Elephants and Large-Brained Primates

Although going against the grain of conventionally profiling the relationship between EQ and cognitive ability, one could argue that more relevant for

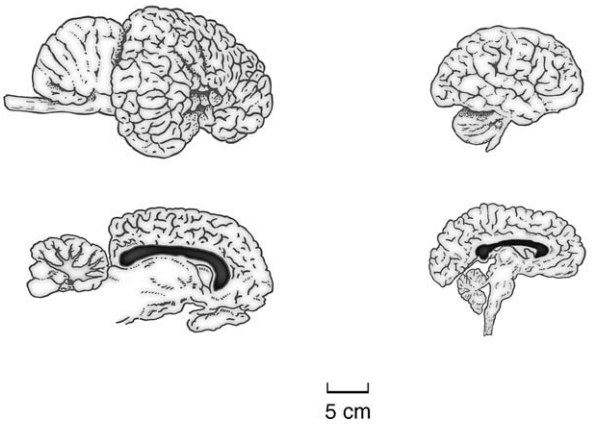

Figure 1 Lateral and midsagittal views of the elephant (left) and human (right) brain showing the relative sizes of cerebral hemispheres (top) and corpus callosum (solid black) in the midsagittal sections (bottom). The lateral views are drawn after images provided from the Comparative Mammalian Brain Collections with support from the National Science Foundation and the mid-sagittal views are drawn from magnetic resonance images from Hakeem *et al.* (2005). The scale is from Hakeem *et al.* (2005).

understanding behavioral capacities is the total amount of cerebral cortex which is available for higher-order brain functions. The cerebral cortex available for such functions is roughly represented by the volume of nonsensorimotor cortex, which may be calculated using a model of scaling cerebral cortical volume to body mass in primitive (marsupial) mammals, where almost all of the cerebral cortex is assumed to represent sensorimotor cortex (Hofman, 1982). One can then estimate the amount of sensorimotor cortex needed to support a given body mass in a large-brained species and subtract this from the total volume of cerebral cortex to arrive at the volume of nonsensorimotor cortex (Hofman, 1982). Accordingly, the chimpanzee is estimated to have 160 cm^3 of nonsensorimotor cortex, the human 660 cm^3, the Asian elephant 1800 cm^3, and the African elephant 1400 cm^3.

A greater volume of cerebral cortex does not necessarily translate into a greater number of information-processing neurons. The classical analyses by Tower (1954) introduced the concept of declining densities of neurons as cerebral cortex volume increases across species. Tower estimated neuron densities (rounded to nearest 1000 neurons per mm^3) of chimpanzees at 15000, humans at 9000, and Asian elephants at 7000. The more recent, and frequently cited, comparative study by Haug (1987), based on samples from multiple areas of the cerebral cortex, revealed much higher neuron densities for primates. Haug placed the approximate densities for chimpanzees at 41000, humans at 26000, and African elephants at 7000 per mm^3. What is noteworthy is that the very low density of neurons in the African elephant cortex in the Haug study was the same as that of the Asian elephant in the Tower study, perhaps reflecting the expectation that neuron density counts with various methodologies would be more similar with less dense neurons such as in the elephant.

Taking into account neuronal density based on data from Haug (1987), and cortical volumes based on data from Hofman (1982), we estimate the human brain to have about 17.4 billion neurons in the cerebral cortex compared with 12.6 billion for the elephant and 6.7 billion for the chimpanzee. A more updated technique of neuron counting reveals the human cortex to have about 20 billion neurons (range 19–23 billion; Pakkenberg and Gundersen, 1997). Because comparative data with the newer technique are not available for the elephant and chimpanzee, our comparisons use the Haug data, assuming the general picture would not change. One can roughly estimate the number of cortical neurons available for cognitive and long-term memory behavior by breaking down cortical volume into sensorimotor and nonsensorimotor volumes, so that the human brain is estimated to have about 17 billion neurons in the nonsensorimotor cortex, the elephant about 11 billion, and the chimpanzee about 6.5 billion.

With reduced neuron density, there is generally an increase in average neuron size. As reported by Haug (1987), human and chimpanzee cortical neurons were estimated to have a mean size of 1200 μm^3 with a high proportion of small neurons (granular cells), while the elephant has a mean neuron size of 4200 μm^3, and a size distribution toward large and very large neurons (pyramidal cells). Although not measured, one could assume that the cortical neurons of elephants have a greater number of synapses and interconnecting axonal ramifications than those of large-brained primates (Harrison *et al.*, 2002).

Cortical neurons interact with distant neurons of the cortex through the white matter which mostly comprises such transcortical axons (Zhang and Sejnowski, 2000). Several authorities have pointed out that across species cortical white matter increases disproportionately with cortical volume (Hofman, 1989, 2001; Allman, 1998; Zhang and Sejnowski, 2000; Bush and Allman, 2003). As the cerebral cortex increases in volume, a certain point is reached where interconnectivity is adversely impacted (Kaas, 2000; Hofman, 2001, 2003; Changizi and Shimojo, 2005). Also, because

transmission time along axons accounts for almost all of the time delay in information-processing time (Harrison *et al.*, 2002), another concern with large brains with extensive white matter is that information processing becomes prolonged.

3.34.3.4 Neuronal Interconnectivity and Information-Processing Efficiency: Primates versus Elephants

Ostensibly, to maintain an optimal level of interconnectivity, and a minimal information-processing time, cortical neurons of great apes and humans have evolved to become less global in transcortical connections and increasingly compartmentalized with more local circuit or modular connections (Kaas, 2000; Changizi and Shimojo, 2005). The manifestation of this is an increase in multiple cortical areas (Krubitzer, 1995), where the efficiency of interconnectivity and information processing within a subpopulation of neurons is maintained. One way of portraying this phenomenon across species is by calculating the proportion of neurons within a module that are local circuit neurons (LCNs), connecting only to other neurons in the same or adjacent modules (Hofman, 1985). Thus, in going from the chimpanzee to the human brain, where there is a threefold increase in cortical volume, LCNs increase from 93% to 98%.

In contrast to this continuum toward increasing compartmentalization and reduced global interconnections, which characterizes the evolution of large brains in primates, in elephants there appears to be a neural cytoarchitectural bias toward maintaining long-distance global connections and a reduced participation in local cortical areas or modules. Evidence for this comes from the above-mentioned study by Hofman (1985) on LCNs where, in going from the human to the elephant cerebral cortex, which is three times greater, LCNs actually decrease from 98% to 91% (Hofman, 1985).

With reduced axonal projections to local areas and a bias toward global connections in elephants, one would expect the disproportionate scaling of white- to gray-matter volume to be continued. Recent magnetic resonance imaging of an elephant brain reveals that the ratio of white to gray matter is in keeping with the disproportionate scaling principle (Hakeem *et al.*, 2005). In elephants, the corpus callosum, representing contralateral white-matter projections, is about twice the cross-sectional area of humans (Figure 1). Because the density of elephant cortical neurons is less than one-third that of humans, one interpretation of this finding is that a much larger proportion of cortical neurons in the elephant brain send axons through the white matter to distant cortical neurons than in the brains of comparison primates. Axons of large diameter conduct impulses much more rapidly than axons of small diameter, and would reduce information-processing time, but large axons occupy much more space (Swadlow, 2000) and this would reduce interconnectivity. If the axons were small, allowing for more interconnectivity, this would increase information-processing time. The size of axons comprising the elephant white matter is not yet known, but whether primarily large or small, there would appear to be a cost to information-processing efficiency.

3.34.4 Relating Brain Information Processing to Behavior

The large number of nonsensorimotor cortical neurons of elephants, second only to humans among terrestrial mammals, coupled with a bias toward maintaining global connections throughout the cerebral cortex, would appear to be related to their extraordinary capacity to acquire and retain long-term memory from a wide variety of social and spatial–temporal domains. The costs of maintaining transcortical global connections are prolonged information-processing time and less local circuit interconnectivity. These costs would appear to be related to the fact that elephants do not compare favorably even with great apes in the area of fast-action, fine-grained feats of cognitive behavior, even though great apes have about one-tenth the nonsensorimotor cortical volume of elephants.

While one may wonder if elephants have long-term social or spatial–temporal memory ability that exceeds that of humans, an interpretation along this line is difficult. Humans have at least 60% more cortical neurons available for higher-order brain functions. One could argue that humans have sufficient cortical white-matter projections for involvement of a large number of cortical neurons in transcortical communication, still leaving a high proportion for local circuit processing. Of course, humans cannot be compared with elephants in areas such as memory of acoustic or chemosensory ones where sensory capacities are vastly different. While examples of feats of long-term memory in humans comparable to that of elephants living in nature are generally not available, one cannot help but be intrigued by a rough parallel between the reports on the savant syndrome seen in a very small percentage of autistic patients who have extraordinary long-term and detailed memory abilities. Such exceptional skills are seen in the context of general, and sometimes severe, intellectual impairment (Miller, 1999).

Savants, previously referred to as *idiot savants*, have been of interest since the early 1700s (Heaton and Wallace, 2004). Savants are typically reported to have suffered some type of brain damage (Heaton and Wallace, 2004). One could conjecture that on occasion a certain type of brain damage may lead to neuronal regeneration and cortical reorganization of information-processing capacities along the lines typical of the normal patterns of elephants. Indeed, if one wanted to carry this conjecture further, one could say that, in comparison to great apes, large-brained elephants are intellectually impaired or 'idiots', but have skills in memory ability far exceeding that of 'normal' great apes.

Finally, the cytoarchitectural model of neural information-processing characteristic of large-brained primates should not be expected to apply to large brains that arise through a different evolutionary path. It is now clear that the evolution of elephants proceeded from aquatic rather than terrestrial mammalian lines (Glickman *et al.*, 2005). Conventional paleontological evidence, reinforced by mitochondrial DNA analyses (De Jong, 1998) and histological studies on the kidneys and testes, show that elephants and manatees (*Sirenia*) have a common aquatic ancestor unrelated to the ancestor of cetaceans. Thus, one can point to not only the influence of anatomy, physiology, and lifestyle to explain the evolution of differences in neural cytoarchitecture and information processing between elephants and primates, but a discontinuity in evolutionary development as well.

The perspective presented here is tentative and intended to bring together species differences in behavior of elephants and large-brained primates with recent information on the neural bases of the behavior. Clearly missing is more quantitative information on the three species of elephants, especially with regard to compartmentalization of the cerebral cortex and interconnectivity between adjacent areas versus distant cortical areas. For the time being, the available information offers a resolution to the paradox presented by the large, complex brain of elephants and the emerging picture of limitations in several aspects of cognitive behavior coupled with extraordinary ability in the area of long-term and extensive memory.

3.35 The Evolution of the Dorsal Thalamus in Mammals

J H Kaas, Vanderbilt University, Nashville, TN, USA

Glossary

layers and subnuclei	Parts of nuclei sometimes differ somewhat in histological characteristics, connections, and neuron response characteristics to the extent that they are recognized as subnuclei or layers, while having enough features in common to include them in a nucleus. Sometimes subnuclei are called nuclei.
nuclear complex	Adjoining nuclei of related functions are sometimes grouped into a complex such as the pulvinar complex. In some instances, the nuclei of the complex may have differentiated from a single ancestral nucleus.
nucleus	A collection of neurons and other cells in the thalamus that are united by a common function. Nuclei have been historically identified in brain sections as groups of neurons that differ from surrounding thalamus in the packing of neurons, cell types, and other histological characteristics. Nuclei should also differ in connections and, of course, the response properties of their neurons.
thalamus	A part of the forebrain between the cerebral cortex and midbrain. This review concerns the dorsal thalamus, the division that is largest in mammals, and projects to neocortex.

3.35.1 Introduction

While the region of the diencephalon called the thalamus includes the ventral thalamus, the hypothalamus, and the epithalamus, authors commonly use the term to refer to the dorsal thalamus only, the topic of this review. The dorsal thalamus of mammals is a collection of nuclei in the diencephalon with neurons that project to neocortex. If the neocortex is removed, the projection neurons die, leaving the nuclei of the dorsal thalamus severely degenerated, while the nuclei of the ventral thalamus, hypothalamus, and epithalamus remain intact or slowly respond to changes in the dorsal thalamus (Rose and Woolsey, 1943). In this way, the dorsal thalamus can be experimentally distinguished from other parts of thalamus. This is not to say that all of the neurons of the dorsal thalamus project to neocortex, as there are many intrinsic neurons as well, and a number of neurons project to the striatum (Jones, 1985), a major target of some of the nuclei of the dorsal thalamus of the reptilian ancestors of mammals. The major steps in the evolution of the thalamus in vertebrates, and the transition from the thalamus of reptiles to that of mammals, have been discussed in this series and elsewhere (Butler, 1994; Puelles, 2001; see The Dual Elaboration Hypothesis of the Evolution of the Dorsal Thalamus, Field Homologies, Evolution of the Nervous System in Reptiles). Therefore, this review focuses on the specializations of nuclei of the mammalian thalamus as the various branches of the mammalian radiation lead to the over 4500 extant species (Wilson and Reeder, 1993). Of course, there have been few or no observations on the thalamus of most of these species, so the concentration is necessarily on the thalamic nuclei of the few well-studied taxa.

Jones (1985) defined a thalamus nucleus as "a circumscribed region of cytoarchitecture receiving a particular set of afferent connections and projecting

within the borders of a particular field or fields." To elaborate on this definition, a nucleus is a collection of neurons and other cells that are unified by participating in a common function or set of functions. In order to do this, neurons within a nucleus require a unique set of inputs and outputs, and a great number of other specializations are possible as well, including neurons with distinctive morphological and histochemical properties. Nissl stains may reveal nuclei distinguished by neurons of distinctive sizes and staining properties, and this has been the traditional approach toward defining and identifying nuclei. In current investigations, nuclei are often identified with more assurance by differences in the expression of neurotransmitters and other components of neurons. Nevertheless, a major problem in comparative studies of thalamic organization is in reliably distinguishing nuclei. Identifying nuclei that are poorly or differently differentiated in various taxa can be difficult and result in errors. Regions of the thalamus can be misidentified as nuclei or misnamed, a problem confounded by the lack of a standard nomenclature. Homologous nuclei are not only given different names in the thalamus of birds, reptiles, and mammals, but different names in different mammals, or even in the same mammal by investigators that favor either one or another name. Another problem is distinguishing parts of nuclei from subnuclei. For example, the ventroposterior medial (VPM) nucleus is histologically distinguishable from the ventroposterior lateral (VPL) nucleus, but both are parts of the same functional unit, the ventral posterior nucleus, that contains a systematic representation of the cutaneous receptors of the contralateral half of the body. The ventroposterior (VP) nucleus also goes by several other names, including the ventrobasal nucleus. Finally, there is the problem of identifying nuclei that are present in some mammals and absent in others. There is generally a reluctance to identify any brain structure as new (Striedter, 2005), because it is difficult to determine if an easily identified structure in some taxa is not present in some cryptic form in other taxa. A similar dilemma exists with regard to the evolution of cortical fields, but it has gradually become clear that some areas of primate neocortex, for example, have no apparent homologues in other mammals (e.g., middle temporal (MT) visual area of primates; see Kaas and Preuss, 1993). It seems likely that some thalamic nuclei have evolved in some branches of the mammalian radiation but not in others. The evidence has become very strong that early mammals had few cortical areas, and the number of areas has increased independently in several lines of mammalian evolution by adding new areas. A comparable pattern of evolution must have occurred for the dorsal thalamus of mammals, with the thalamus adding new nuclei as the cortex added areas, although not necessarily in a matching matter. But less is certain about the thalamus, as the organization of the mammalian thalamus has been less intensively investigated. Thus, this review starts by considering the well-defined thalamic nuclei and how they vary across taxa, and then addresses the issue of increased complexity and new nuclei. We start with the visual relay nucleus, the dorsal lateral geniculate nucleus (LGN) (called dorsal to distinguish it from the ventral lateral (VL) geniculate nucleus of the ventral thalamus), often simply identified as the LGN. As the neuroanatomist Rose (1971) noted, "In the dorsal thalamus itself our anatomical and functional knowledge is at its best when it concerns the projection nuclei of the great afferent systems." The situation remains much the same today (see Mosaic Evolution of Brain Structure in Mammals, The Evolution of Neuron Classes in the Neocortex of Mammals, Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals, Do All Mammals Have a Prefrontal Cortex?, The Evolution of the Basal Ganglia in Mammals and Other Vertebrates, The Dual Elaboration Hypothesis of the Evolution of the Dorsal Thalamus).

3.35.2 The Lateral Geniculate Nucleus

The dorsal LGN is a thalamic structure common to all mammals. The LGN receives inputs from the ganglion cells of the retinas of both eyes, and has neurons that project to primary visual cortex (area 17 or striate cortex). This is a pattern that has been retained from the reptilian ancestors of mammals: extant reptiles such as turtles have a small but distinct dorsal LGN with retinal input and projections to dorsal cortex, the homologue of mammalian neocortex (Hall and Ebner, 1970b; Hall *et al.*, 1977; Ulinski, 1986; Zhu *et al.*, 2005). The LGN is located on the lateral margin of the thalamus, where it is innervated by axons coursing in the optic tract as other axons and collaterals of axons continue on to the superior colliculus of the midbrain. Across mammals, the LGN differs greatly in histological appearance, from a scattered group of neurons that is only marginally distinct from the adjoining thalamus, to a well-segregated and variously laminated structure.

A common form of the LGN, found in some members of most of the major branches of the mammalian radiation, is a rather undifferentiated nucleus with no obvious substructure, such as the LGN of a hedgehog (Figure 1). This nucleus is characterized by a nearly uniform distribution of

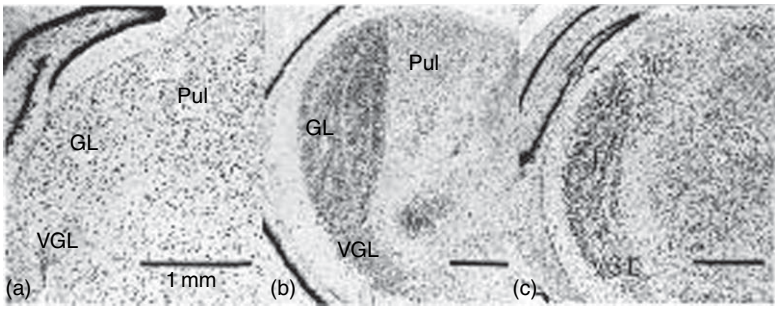

Figure 1 A coronal brain section stained for cells (Nissl preparation) through the dorsal lateral geniculate nucleus (GL), the ventral lateral geniculate nucleus (VGL), and the pulvinar (Pul) of, a, hedgehog, a small insectivore; b, a tree squirrel; and c, a tree shrew. Note that the nuclei are poorly differentiated from each other in the hedgehog, but well differentiated from each other in the squirrel and the tree shrew. Note also that the dorsal lateral geniculate nucleus has visible but different types of layers in the squirrel and tree shrew, and that no visible layers are seen in the nucleus in the hedgehog. The pulvinar is also more differentiated in squirrels and tree shrews. Scale bar: 1 mm.

neurons that are not very different in appearance and distribution from those in adjoining parts of the thalamus. Nevertheless, there is a concealed lamination, as retinal projections from the ipsilateral eye occupy a dorsocentral oval in the nucleus surrounded by terminations from the contralateral eye (Hall and Ebner, 1970a). Thus, the LGN of hedgehogs appears to have a middle layer with inputs from the ipsilateral eye, and adjoining layers with inputs from the contralateral eye. The layer for the ipsilateral eye does not extend into the most ventral third of the nucleus because that is where the monocular visual field of peripheral vision of the contralateral eye is represented (Kaas *et al.*, 1972). A similar LGN is found in Afrotherian tenrecs (Künzle, 1988), North American opossums of the marsupial radiation (Royce *et al.*, 1976), some rodents such as rats (Reese, 1988), rabbits (Holcombe and Guillery, 1984), pangolins (Lee *et al.*, 1991), and echidnas and platypuses of the monotreme radiation (Campbell and Hayhow, 1971, 1972). Such a distribution of a poorly differentiated LGN with perhaps three cryptic layers argues that this type of LGN was present in early mammals and was retained in many branches of the mammalian radiation. As most early mammals were small and likely nocturnal (Kielan-Jaworowska *et al.*, 2004; Rose and Archibald, 2005; however, see Martin, 2006), a large, highly differentiated visual thalamus would not be expected, and the present-day mammals with a poorly differentiated visual thalamus are those mammals that are not highly visual.

In contrast to the mammals noted above, the LGNs of the highly visual mammals that have been studied have an architectonic appearance that is distinct from the adjoining thalamus, and typically have several layers of two or more types. Thus, squirrels, a highly visual rodent, have a large LGN of darkly staining neurons that has three visible layers. These layers are separated from each other by cell-poor septa (Figure 1), with one of these layers subdivided by a segregation of retinal inputs into a middle layer of ipsilateral retinal inputs, and two adjoining layers of contralateral retinal inputs, making five layers in all (Kaas *et al.*, 1972). As another visually dominated mammal, tree shrews, are small, squirrel-like mammals that are closely related to primates (Kaas, 2002), tree shrews have a clearly laminated LGN, but in a different pattern of six layers that are separated by cell-poor septa (Figure 1). The layers are further distinguished by inputs from either the ipsilateral or the contralateral eye, histochemical characteristics, and innervation by different types of retinal ganglion cells, including the ON and OFF and W-cell pathways (Conway and Schiller, 1983; Conley *et al.*, 1984; Diamond *et al.*, 1993). ON ganglion cells are those that respond to an increase of light in the excitatory receptive field (light onset), while OFF ganglion cells respond to the dimming of light (light offset). The W-cell pathway includes ganglion cells with thin axons and slow conduction, possibly homologous with the K pathway of primates (see below).

Other visual mammals also have complexly differentiated LGNs but of various types. Sanderson *et al.* (1984, 1987) have described the LGN of some of the diprotodont marsupials, an advanced order including kangaroos, wombats, koalas, and varieties of possums. The LGN of these marsupials includes a visibly laminated segment with three cytoarchitectonic regions, some of which subdivide further, and a segment without visible lamination, which is subdivided by regions of inputs from either the ipsilateral or contralateral eye. Across species, the number of eye-specific layers varies from 8 to

11. The LGN of different ungulates has been described as consisting of three to five layers (see for review, Sanderson *et al.*, 1984; Clarke *et al.*, 1988). Carnivores are generally described as having two dorsal layers: layer A for the contralateral eye, layer A1 for the ipsilateral eye, and three ventral C (smaller cell) layers (Kaas *et al.*, 1972, 1973). In addition, mink and weasels of Mustelidae taxon of carnivores have duplicated their A and A1 layers with one A and one A1 layer for ON retinal ganglion cells (those responding to light onset) and one A and one A1 layer for OFF ganglion cells (those responding to light offset) (Sanderson, 1974; LeVay and McConnell, 1982). The projections from the ON and OFF ganglion cells are mixed in the A and A1 layers of other carnivores. The echolocating bats typically have poorly differentiated visual systems with a simple LGN, while the crepuscular fruit-eating megabats have large eyes and an LGN of five or six layers (see Kaas and Preuss, 1993, for review). The LGN of gliding lemurs, considered close relatives of primates, appears to have six layers (Kaas *et al.*, 1978; Kaas and Preuss, 1993).

Primates are highly visual mammals, and this is reflected in the LGN (Kaas *et al.*, 1978). The basic lamination pattern (Figure 2) consists of two parvocellular layers (one for each eye), with inputs from a class of retinal ganglion cells (P cells) that are specialized for detailed object vision and color, and two magnocellular layers (one for each eye), with inputs from the M-cell class of ganglion cells that are important for motion detection and vision in dim light. In addition, small koniocellular neurons are sometimes recognized as scattered within the septal zones between layers or as forming distinct layers. In prosimian primates, two thick koniocellular layers are generally recognized (Figure 3), while thinner distributions of K cells are only sometimes recognized as layers. In addition to the layers noted above, the parvocellular layers subdivide to form four or more parvocellular layers or sublayers in some taxa of anthropoid primates (Kaas *et al.*, 1978). In general, the magnocellular and koniocellular layers are well developed in nocturnal primates, while the parvocellular layers are well developed in diurnal primates. Thus, the laminar pattern is complex and variable across primate taxa.

Other features of the LGN also vary across mammals. In general, primary visual cortex is the main target of LGN projection neurons, with very few projections to other visual areas. But this too is one of the variable features. In cats and at least some other carnivores, a major projection of one class of LGN neurons is to the second visual area,

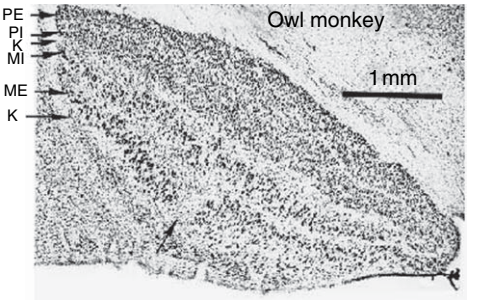

Figure 2 A parasagittal brain section through the dorsal LGN of an owl monkey. Owl monkeys are the only nocturnal monkeys, and this is reflected in the proportionately small parvocellular layers. Note that the external parvocellular layer (PE) is only marginally segregated by a cell-poor septum from the internal parvocellular layer (PI). Nevertheless, it is apparent that PE extends to the rostral pole of the nucleus (right) while PI does not, as PE represents the complete contralateral visual hemifield via the contralateral eye, while PI represents the slightly smaller binocular hemifield via the ipsilateral eye. The neurons of the magnocellular layers, MI (internal) and ME (external), are noticeably larger. ME, with input from the contralateral eye, also extends to the rostral pole of the nucleus, while MI, with input from the ipsilateral eye, does not. Koniocellular (K) layers of the smallest neurons are not commonly reorganized in anthropoid primates, although two K layers are widely recognized in nocturnal prosimian primates. In anthropoid primates, the two K layers noted here are well differentiated, and expanded in owl monkeys, suggesting that K layers are especially important for vision in dim light. The arrow pointing to the middle of ME indicates a small discontinuity in the layer that corresponds to the receptor-free oval of the optic disk (nerve head) of the contralateral eye (a discontinuity also occurs in PE of nearby brain sections). Such discontinuities are only apparent in mammals with good visual acuity. Modified from Kaas, J. H., Guillery, R. W., and Allman, J. M. 1973. The representation of the optic disc in the dorsal lateral geniculate nucleus: A comparative study. *J. Comp. Neurol.* 147, 163–180.

V2, and projections from another class of LGN cells extend across four visual areas (Stone, 1983). Some of the LGN neurons in primates also project to nonprimary visual areas in primates (Stepniewska *et al.*, 1999), including to visual areas such as the MT visual area that appear to be unique to primates. Thus, as new visual areas emerged in early primates or the immediate ancestors of primates, LGN projection patterns were altered to include these visual areas.

In summary, the poorly differentiated LGN with little substructure of early mammals appears to have differentiated in several ways in a number of branches of the mammalian radiation. There have been independent increases in numbers of cell layers. These layers appear to be segregating inputs from functionally different classes of retinal ganglion cells, inputs from the superior colliculus, and inputs from the ipsilateral and contralateral eyes. Some of the resulting segregations are similar,

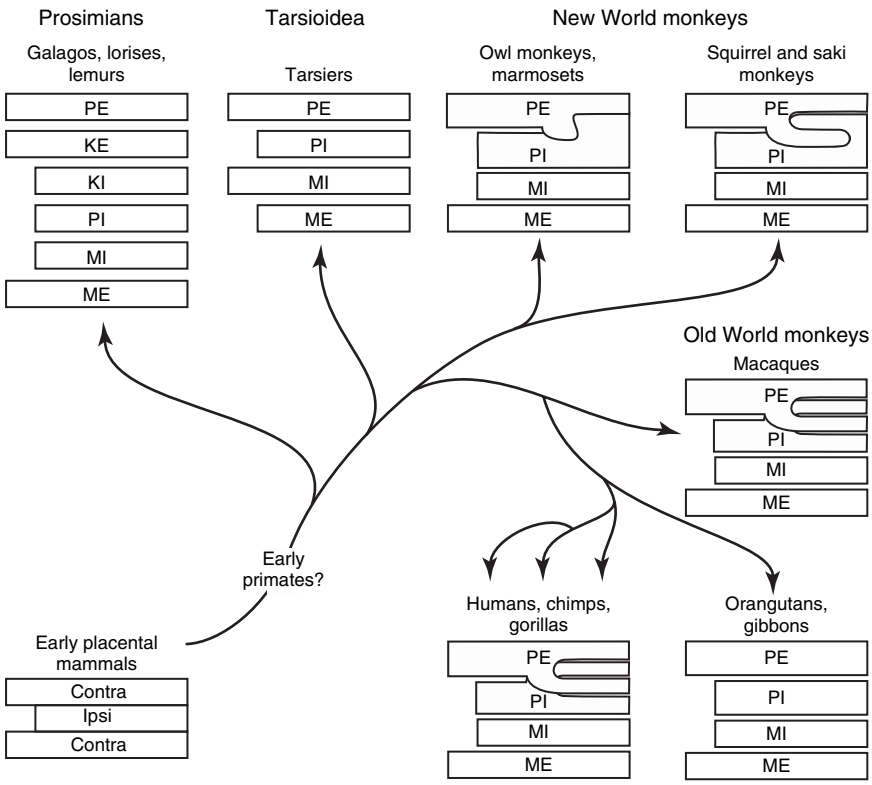

Figure 3 A schematic of the lamination pattern of the dorsal LGNs of primate taxa. Layers are labeled by the type of neurons that they contain (P, parvocellular layers; M, magnocellular layers; K, koniocellular layers) and their internal (I) or external (E) position in the nucleus. Short layers receive inputs from the ipsilateral eye and long layers from the contralateral eye. In some taxa, P layers subdivide and interdigitate, while in owl monkeys and marmosets, there is only a hint of this. Spaces between layers mean that the layers are well separated by septa. Note that the lamination pattern varies across primate taxa. Modified from Kaas, J. H., Huerta, M. F., Weber, J. T., and Harting, J. K. 1978. Patterns of retinal terminations and laminar organization of the lateral geniculate nucleus of primates. *J. Comp. Neurol.* 182, 517–554.

although independently derived, such as layers for ON and OFF ganglion cells in some carnivores and in tree shrews. Other types of segregations of neurons into layers may be unique, as there is much structural diversity. What this means in terms of acquired functions is not completely clear, but highly visual mammals have more distinct layers and more layers, and nocturnal mammals emphasize different types of layers than do diurnal mammals. It is also important to remember that changes were not always in the direction of increased differentiation. The LGNs of the microphthalmic blind mole rats, for example, have greatly regressed (Cooper *et al.*, 1993).

3.35.3 The Visual Pulvinar

The pulvinar in primates is a complex of nuclei that are largely, but not completely, visual in function. Because this part of the thalamus was so prominent in primates, most early comparative neuroscientists considered the pulvinar to be unique to primates, and a homologous region was not recognized in other mammals. Instead, this part of the visual thalamus was thought to be the homologue of another part of the primate thalamus, the lateral posterior nucleus, which in primates is generally associated with the somatosensory system. Le Gros Clark (1932) was one of the first to recognize that "the pars posterior of the lateral nucleus is the homologue of at least part of what, in higher primates, is termed the pulvinar." Although evidence accumulated in support of considering parts of the primate pulvinar complex homologous with parts of the lateral posterior complex in other mammals, the use of the term lateral posterior to refer to the pulvinar in nonprimate mammals has usually, but not always, continued. To add to the confusion, both terms have been used in the same mammal to refer to different parts of the pulvinar complex, as is currently done in cats. This confusion of terms has undoubtedly hindered comparative studies of the organization, and studies of the visual thalamus in mammals. Here the term visual

pulvinar is used in all mammals to designate those parts of the thalamus that receive inputs from the superior colliculus and/or are reciprocally connected with visual areas of cortex.

The reptilian homologue of the mammalian pulvinar complex, if any, is somewhat uncertain. In both reptiles and birds, the optic tectum (the homologue of the superior colliculus) projects to a well-defined nucleus rotundus of the dorsal thalamus (see Belekhova *et al.*, 2003; for review). For some time, a homology of the mammalian pulvinar complex with nucleus rotundus has been widely accepted, but recently nucleus rotundus has been compared to the intralaminar complex of mammals (see Belekhova *et al.*, 2003, for review). While the issue remains unresolved, the bulk of the evidence appears to favor the long-standing view of a rotundus–pulvinar homology. In support of this view, Major *et al.* (2000) have provided evidence that the tectorotundal and tectopulvinar pathways are homologous to the level of even involving the same cell subtypes.

In early mammals, the pulvinar complex appears to have consisted of a rather poorly differentiated group of cells in the posterior thalamus, just medial to the LGN, much as in present-day hedgehogs (Figure 1a). In such mammals, this poorly differentiated group of neurons receives inputs from the superior colliculus and projects to visual cortex, including primary visual cortex and the second area, V2. Quite possibly two or three regions or nuclei can be distinguished based on differences in cortical and superior colliculus connections (Crain and Hall, 1980). Overall, this caudal portion of the thalamus receives superior colliculus inputs and projects to visual cortex in all mammals studied, but the size and histological differentiation of the region differ considerably. Thus, a large pulvinar nucleus is easily identified histologically in both squirrels and tree shrews (Figure 1), and has expanded and become more differentiated than in most mammals. Moreover, in both tree shrews and squirrels, the pulvinar is not a single nucleus, but a complex of several nuclei differing histochemically and in connections. Thus, in tree shrews the pulvinar complex consists of four nuclei (Figure 4a) (Lyon *et al.*, 2003a, 2003b). A large central nucleus (Pc) receives a retinotopic pattern of projections from the superior colliculus and projects to primary visual cortex and adjoining visual areas. A smaller dorsal nucleus (Pd) receives diffuse projections from the superior colliculus, stains darkly for acetylcholinesterase, and projects to higher-order visual areas of the temporal lobe. A small ventral nucleus (Pv) expresses high levels of the antigen for the Cat-301 antibody that identify large neurons with rapidly conducting axons, is interconnected with primary visual cortex and adjoining visual areas, while having few or no inputs from the superior colliculus. A small posterior division of the pulvinar complex (Pp) appears to receive diffuse inputs from the superior colliculus while projecting to higher-order visual areas in temporal cortex. The large pulvinar of squirrels (Figure 1c) is subdivided into at least three nuclei (Figure 4b), two with superior colliculus inputs, but of different types, and one without. All three divisions differ in their connections with cortical visual areas (see Lyon *et al.*, 2003b, for review).

The pulvinar complex has been extensively studied in domestic cats, which have divisions of a lateral posterior complex as well as a pulvinar (Figure 4c). A large nucleus receives inputs from the superior colliculus while projecting to temporal visual areas. This nucleus expressed high levels of acetylcholinesterase and the neurotransmitter, substance P. Another large nucleus is interconnected with primary and secondary visual areas, and a third nucleus projects to visual areas of temporal cortex. Monkeys have even more subdivisions of the pulvinar complex, which is large and dominates the posterior thalamus (Figure 4d). The classical inferior pulvinar consists of four nuclei differing in histochemical characteristics and patterns of cortical connections. Two of these nuclei have dense inputs from the superior colliculus. The large lateral pulvinar has two divisions, differing in connections and patterns of retinotopic organization. The traditional medial pulvinar and anterior pulvinar have nonvisual connections, and are not subdivisions of the visual pulvinar.

The point of this brief and limited survey is that mammals in different lines of evolution have independently increased the differentiation and complexity of the pulvinar complex. The pulvinar of early mammals was probably a relatively undifferentiated mass of cells in the posterior thalamus that included one or two zones with superior colliculus inputs, and possibly a zone without such inputs, but with visual cortex connections. This ancestral condition is reflected in the posterior thalamus of many extant mammals with poorly developed visual systems. However, in some lines of descent, more nuclei appeared, but in different patterns and arrangements. As a result, some or most pulvinar nuclei will only be present in some taxa. However, it may be possible to homologize a few specific pulvinar nuclei across taxa. For example, a region of the pulvinar complex that receives the class of superior colliculus projections that

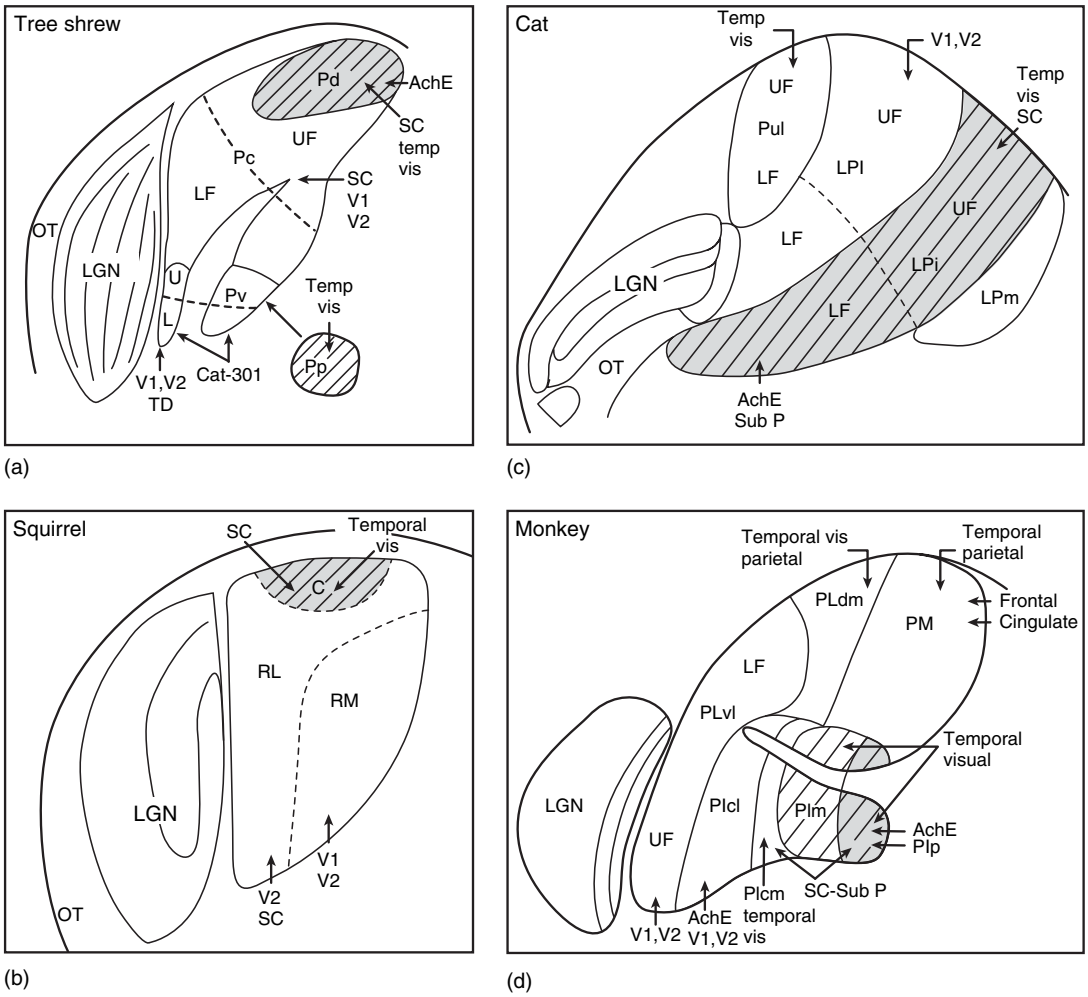

Figure 4 The organization of the pulvinar complex in four mammalian taxa. The drawings are of coronal brain sections through the caudal thalamus where the lateral border is defined by the optic tract (OT). a, In tree shrews, the four subdivisions or nuclei of the pulvinar complex include a large central pulvinar (Pc) with inputs from the superior colliculus (SC) and projections to visual areas V1 and V2, as well as a temporal dorsal (TD) visual area. Pc forms a systematic representation of the contralateral visual hemifield with the upper field (UF) represented dorsal to the lower field (LF). A dashed line approximates the zero horizontal meridian. The ventral pulvinar (Pv) also contains representations of the upper (U) and lower (L) hemifields, while expressing the antigen for the Cat-301 antibody and projecting to V1, V2, and TD. A posterior pulvinar (Pp) lies behind Pv and Pc, as indicated by an arrow, and projects to visual cortex of the temporal lobe. A dorsal pulvinar (Pd) expresses acetylcholinesterase (AchE), receives diffuse inputs from the SC, and projects to temporal visual cortex. b, In squirrels, only rostrolateral (RL), rostromedial (RM), and caudal (C) divisions of the pulvinar have been distinguished by differing connection patterns (abbreviations as in (a). c, In cats, one division of the pulvinar complex is called the pulvinar (Pul), while three others are called lateral (LPl), intermediate (LPi), or medial (LPm) nuclei of the lateral posterior complex. Note that three nuclei form separate representations of the visual hemifield, that nuclei differ in connections, and that LPi is distinguished by expressing AchE and the neurotransmitter, substance P (Sub P) that is expressed in one class of inputs from the SC but not others. d, Monkeys and other primates have a pulvinar complex that includes central lateral (PIcl), central medial (PIcm), medial (PIm), and posterior (PIp) nuclei of the inferior pulvinar, and ventrolateral (PLvl) and dorsomedial (PLdm) nuclei of the lateral pulvinar. The medial pulvinar (PM) is not completely visual and the anterior pulvinar (not shown) is somatosensory in function. Note that nuclei differ in connections and expression of AchE and Sub P. PLvl has the most precise representation of the contralateral visual hemifield, but other representations are in nuclei of the inferior pulvinar. Reproduced from Lyon, D. C., Jain, N., and Kaas, J. H. 2003b. The visual pulvinar in tree shrews. II: Projections of four nuclei to areas of visual cortex. *J. Comp. Neurol.* 467, 607–627, with permission.

express substance P may be revealed by further study to be homologous in a wide range of mammals (Hutsler and Chalupa, 1991; Stepniewska *et al.*, 2000). A broader survey of extant mammals with well-developed visual systems could usefully extend our appreciation of the variety of specializations that have emerged in pulvinar organization, and comparisons within and across taxa could provide an understanding of how specializations emerged.

3.35.4 The Somatosensory Thalamus: The Ventroposterior Complex and the Adjoining Posterior Complex

In all studied mammals, a VP nucleus can be identified by its characteristic position in the ventral thalamus, its inputs from the dorsal column and trigeminal somatosensory brainstem nuclei, and its projections to primary somatosensory cortex, S1 (area 3b) (Jones, 1985; Kaas and Pons, 1988). Commonly, investigators have divided VP into VPM and VPL. However, these represent only major divisions of VP, as VPM receives inputs from the trigeminal nuclei for the face, oral cavity, and head, while VPL receives inputs from the gracile nucleus for the lower body (hindlimb and tail) and the cuneate nucleus for the upper body (forelimb and trunk). Note, by the same logic, the trigeminal, cuneate, and gracile 'nuclei' are subnuclei. These inputs to VP via the medial lemniscus provide cutaneous receptor information about touch on the skin and hair movement. Other somatosensory afferents involving a larger range of modalities including touch, pain, and temperature course in the spinothalamic pathway (and the equivalent component of the trigeminal complex) to terminate in and around VP, sometimes including a segregated nucleus on the ventral margin of VP, the VP inferior (VPI) nucleus. Another collection of small brainstem subnuclei, including the external cuneate nucleus, relays proprioceptive information, mainly from muscle spindle receptors, to the region of VP in the thalamus. In some mammals (see below), the proprioceptive inputs are now recognized as terminating within a separate cell group on the dorsorostral margin of VP, termed in primates the VP superior (VPS) nucleus (Krubitzer and Kaas, 1992).

Adjoining VP along its dorsocaudal margin, a poorly differentiated region termed the posterior nucleus or posterior group contains neurons that respond to somatosensory, but also auditory and visual stimuli. In addition, in primates, an anterior pulvinar nucleus is recognized just dorsal to part of VP. This nucleus is interconnected with subdivisions of somatosensory cortex while receiving little or no other sources of sensory inputs (Kaas and Pons, 1988). Finally, a taste nucleus (with much broader functions), the parvocellular ventroposterior medial nucleus (VPMpc), receives gustatory, tactile, and visceral information from the brainstem, and projects to somatosensory and adjoining cortex (Kaas *et al.*, 2006b). At least some of these subdivisions of the mammalian somatosensory thalamus seem to be common to all mammals, and therefore they must have originated with or before the first mammals and diversified in various ways.

The stem reptilian amniotes that gave rise to modern reptiles, birds, and mammals likely had features of the dorsal thalamus that have been retained in all three groups. In present-day reptiles and birds, somatosensory inputs relayed from the dorsal column nuclei reach a nucleus and a perinuclear region in the dorsal thalamus. These inputs in turn project to the rostral part of the dorsal cortex of reptiles or Wulst of birds (Wild, 1997; Medina and Reiner, 2000), forming much of the evidence for the conclusion that a homologue of at least the mammalian VP nucleus was present in the common ancestor. Stem reptiles may also have had some segregation of proprioceptive and spinothalamic inputs in the thalamus, but this seems uncertain. Gustatory and related sensory inputs may have been segregated in the ventral thalamus, but the dorsal thalamus and the pallium were probably not the important processing centers for gustatory inputs (Finger, 1997; Pritchard and Norgren, 2004).

The mammalian VP nucleus can be identified by its ventral position and histological characteristics in all examined extant mammals. In some mammals, such as opossums (Pubols and Pubols, 1966; Donoghue and Ebner, 1981; Wild, 1997) and hedgehogs (Erickson *et al.*, 1967), the neurons stain somewhat darker in Nissl preparations, and they are grouped to form an identifiable nucleus, but the nucleus is only marginally different from the adjoining thalamus (see Ebbesson *et al.*, 1972 for review). The VPM subnucleus forms the largest component of the VP nucleus in most mammals. This observation suggests that, in many taxa of extant mammals, the important somatosensory information came from the whiskers of the face, the nose, and the tactile receptors of the mouth. A comparative analysis suggests that VP in early mammals was poorly differentiated, and was dominated by a large representation of the face and oral cavity within the medial division of the nucleus. As with most studied extant mammals, VP of early mammals projected not only to primary somatosensory cortex, S1, but also to a second somatosensory area, S2, and possibly to a more recently defined somatosensory area, the parietal ventral area, PV (Kaas, 2004). This basic VP has been modified in mammalian evolution in many ways to accommodate changes in somatosensory receptor distributions and functions.

One of the variables in the organization of VP is in the proportions of the nucleus that are devoted to representing different body parts. For example, rats, mice, and many other rodents devote much of VP to representing the inputs from receptors

associated with their facial vibrissae, as they use these vibrissae extensively as they explore their tactile world (Woolsey *et al.*, 1974). In a similar manner, the star-nosed mole, with its unique fleshy appendages of the nose as its major tactile organ, has much of VP devoted to the receptors of those nose appendages (Catania and Kaas, 1996). In the naked mole rat, a rodent that uses its enlarged front teeth, the incisors, to carry and manipulate food, young, and other objects, approximately one-third of VP represents the teeth (Catania and Remple, 2005). Primates (Kaas *et al.*, 1984) and raccoons (Welker and Johnson, 1965) have disproportionately large representations of their glabrous forepaws, as they use this skin surface to explore the environment. In addition, spider monkeys have a prehensile tail with a sensitive glabrous ventral surface near the tip, and this tail has a large representation in VP (Pubols, 1968). Bats have an enlarged representation of the tactile receptors of the wing that are used to guide flight (see Somatosensory Adaptations of Flying Mammals). Thus, the proportion of VP devoted to representing different body parts has been adjusted in both different and sometimes parallel ways in the various branches of mammalian evolution (Welker, 1973).

Another feature of VP that varies across species is the degree to which subnuclei are histologically obvious. In species where VP is histologically more distinct from the adjacent thalamus, cell-poor septa of fibers are typically present between highly innervated positions of the receptor sheet (skin) that are discontinuous but represented in VP next to each other. In primates, the glabrous foot, hand, and the face are separated from each other in VP by fiber bands into subnuclei for the head (VPM), hand, and foot (Kaas *et al.*, 1984). Often a subnucleus can be distinguished for the tail as well, and in some instances thin septa separating the representations of the digits in the hand representation can be detected. Fiber septa separating the representation of individual digits are even more obvious in VP of raccoons (Welker and Johnson, 1965; Wiener *et al.*, 1987a). The star-nosed mole has fiber bands that separate subnuclei in VP for each of the 11 long appendages on each side of the nose (Kaas and Catania, 2002). Rats and mice have visible subnuclei (barreloids) for each of the long sensory mystacial vibrissae on the side of the face (Akers and Killackey, 1979; Haidarliu and Ahissar, 2001). Other instances of visible subnuclei in VP have been reviewed by Welker (1973), and they appear to reflect a developmental mechanism that tends to segregate groups of neurons with different patterns of activation (Kaas, 1982; Kaas and Catania, 2002).

The connections of VP have also been altered in evolution. For example, the primitive mammalian pattern of cortical projections was to S1 and S2 (Kaas, 2004). The projections to S2 were lost in anthropoid primates, while a dense projection emerged in area 1 along the caudal border of area 3b (S1). A sparse but notable projection of VP to area 2, just caudal to area 1, developed in macaque monkeys and perhaps other catarrhine primates (Kaas, 2004). While VP independently activates S1 (area 3b) and S2 in most mammals, including prosimian primates, VP activates area 3b (S1 proper) and modulates areas 1 and 2 in catarrhine primates, reflecting the important roles of area 1 and 2 in these primates, and increased emphasis on higher-order processing in S2.

The VPI nucleus is a nucleus that has been described as only distinct in the primate brain (Jones, 1985), although it is also quite distinct in raccoons (Herron, 1983). In these mammals, VPI is composed of small, pale-staining neurons grouped just ventral to VP (Figure 5). VPI receives inputs from the spinothalamic somatosensory pathway and projects densely to the second somatosensory area, S2, as well as less densely to other somatosensory areas, including S1 (area 3b). Because similar connections exist for the cell-poor fiber septa that subdivide VP into subnuclei, and these septa have small pale-staining neurons, it seems likely that VPI is a nucleus that became largely segregated from VP in primates and raccoons, but much less so or not at all in other mammals (Krubitzer and Kaas, 1992). Thus, VPI may be an example of a new thalamic structure that arose independently via the process of differentiation and segregation in primates and raccoons from a mixed-cell population in ancestral VP. In both primates and raccoons, this birth of a new nucleus may be related to the increased use of the hand in skilled movements (Iwaniuk and Whishaw, 1999).

The VPS nucleus is another somatosensory nucleus with an uncertain history in mammalian evolution. In early studies of the primate thalamus, VPS was often included in VP. However, the recognition of VPS as a separate nucleus (Kaas *et al.*, 1984) was motivated by the evidence that it receives inputs from a brainstem relay of deep body (muscle spindle) receptors rather than cutaneous receptors. VPS forms a separate somatotopic representation of body receptors, but of deep rather than cutaneous receptors, as in VP. VPS is histologically distinct from VP in prosimians and New World monkeys, but not as distinct in Old World monkeys. VPS projects to area 3a and 2 in monkeys, rather than

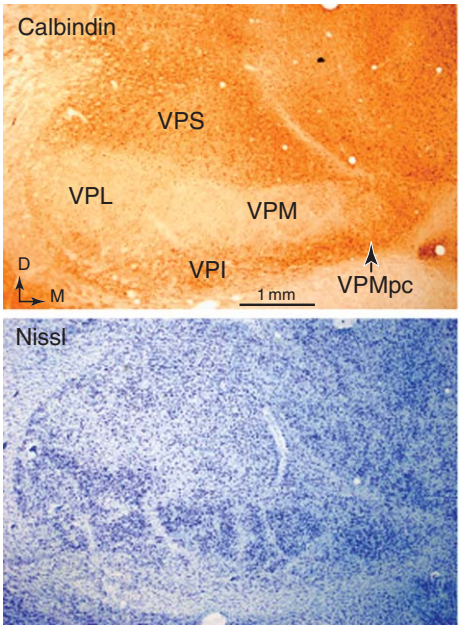

Figure 5 Above: Coronal brain section through the ventroposterior complex of a galago, a prosimian primate, which has been processed for the calcium-binding protein, calbindin. The ventroposterior, VP, nucleus, has two traditional subdivisions, the VPL and VPM, separated by a cell-poor septum. In this preparation, VP (VPL plus VPM) stands out as a light calbindin-poor region. Just ventral to VP, the ventroposterior inferior nucleus expresses a moderate amount of calbindin, while more is expressed in the taste nucleus of the thalamus, the VPMpc. Just above VP, the ventroposterior superior nucleus expresses moderate amounts of calbindin. Thus, calbindin levels usefully distinguish nuclei within the ventroposterior complex. Arrows indicate medial (M) and dorsal (D) in the photomicrograph. Below: An adjacent brain section processed for Nissl substance to reveal cell bodies. Note the cell-poor septa that divide VP into subnuclei.

area 3b and 1, as does VP (Kaas, 2004). While VPS has only been recognized in primates, the same nucleus likely exists in most mammals, and may have been present in the reptilian ancestors of mammals, given that they likely had distinct brainstem nuclei for the relay of muscle spindle information to the cerebellum and to the thalamus (Butler and Hodos, 2005). More significantly, a VPS-like nucleus or subnucleus has been identified in a range of mammalian taxa, including cats, raccoons, opossums, rats, and squirrels (Wiener *et al.*, 1987b; Gould *et al.*, 1989). The VPS-like nucleus is variously considered part of VP, part of the motor thalamus, or part of the posterior group of nuclei adjoining VP, but this kinesthetic or proprioceptive nucleus is always located on the dorsorostral border of VP, and is highly likely to be homologous across mammals, rather than independently derived.

The existence of VPS as a relay of deep receptor information raises the issue of what is included in the posterior nuclear group or complex. In rodents and cats, the part of the thalamus just dorsal to VP is commonly subdivided into a medial posterior nucleus (POM) and a lateral posterior nucleus (POL). The VPS relay nucleus in these mammals appears to occupy the ventral parts of these nuclei (Gould *et al.*, 1989), suggesting that some revision in nuclear boundaries and terminology is justified. Historically, the concept of a posterior group emerged from architectonic studies of the thalamus of sheep, cats, and rabbits by Rose (Rose and Woolsey, 1949). The complex includes parts of the thalamus dorsal and caudal to VP, and between VP and the medial geniculate complex. The region has poorly defined boundaries, and nuclear boundaries. Part of the region contains neurons that are responsive to more than one modality, often to both somatosensory and auditory, but sometimes visual stimuli, and the region has connections with nonprimary regions of sensory cortex (Jones, 1985). As nuclei of the posterior complex are difficult to identify and delimit, it seems likely that nuclei have been misidentified and misnamed across taxa. Thus, it is difficult to speculate on the evolution of the complex. As noted above, part of the complex probably includes the VPS of nonprimate mammals. Another part may well include the anterior (oral) pulvinar of primates. The anterior pulvinar is part of the somatosensory rather than the visual thalamus, and probably, it should not be grouped with the nuclei of the visual pulvinar. The anterior pulvinar receives inputs from somatosensory areas of cortex and projects back to somatosensory areas of cortex (Kaas and Pons, 1988). It has only been described in primates, and it has no known homologue in other mammals. The location of the anterior pulvinar on the mediodorsal (MD) border of VP, and the connections of the anterior pulvinar with somatosensory cortex, suggest that part of the posterior complex of other mammals is homologous with the anterior pulvinar of primates. The anterior pulvinar could also correspond to part of the lateral posterior region that is identified in most mammals, although most of the lateral posterior region corresponds to the pulvinar complex in mammals where the visual pulvinar is not recognized, or only part of the complex is recognized as the pulvinar.

3.35.5 The Auditory Thalamus: The Medial Geniculate Complex

The medial geniculate complex is another part of the mammalian thalamus that was retained from

reptilian ancestors. The reptilian homologue, nucleus medialis (also known as nucleus reuniens), has a core of more densely packed neurons, and a shell of more diffusely distributed neurons, already suggesting the existence of a nuclear complex rather than a single nucleus. The medial geniculate of reptiles resembles that of mammals in having its activating auditory input relayed from the auditory midbrain (the inferior colliculus in mammals), but differs from the mammalian medial geniculate by having a medial rather than a lateral location in the thalamus, and by projecting to the striatum and ventral pallium rather than to dorsal cortex, the homologue of neocortex. Puelles (2001) suggests that most of the auditory complex in the thalamus of reptiles migrated laterally in ancestral mammals, while keeping the auditory input from the midbrain developing a new collateral projection to the emerging neocortex, thereby forming several auditory fields. Parts of the auditory complex of the reptilian thalamus that did not migrate all the way may have led to the emergence of some of the intralaminar nuclei of mammals.

Three nuclei are widely recognized in the medial geniculate complex (Figure 6) of mammals: (1) the ventral medial geniculate (MGv); (2) the dorsal medial geniculate (MGd); and (3) the magnocellular medial geniculate (MGm), also termed the internal nucleus, as the neurons in the nucleus are not particularly large in mammals where the complex is not well differentiated (Jones, 1985). The ventral nucleus projects to one or more primary or primary-like areas

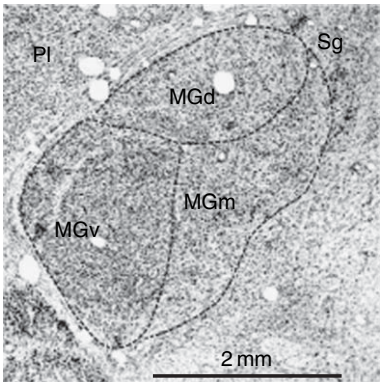

Figure 6 The medial geniculate complex of a macaque monkey. The coronal brain section has been stained for Nissl substance to reveal cell bodies. The ventral nucleus (MGv) is ventrolateral and composed of tightly packed small neurons. The dorsal nucleus (MGd) and the medial or magnocellular nucleus (MGm) have less densely packed neurons, and MGm has larger neurons. The suprageniculate nucleus (Sg) also has auditory functions, while the adjoining inferior pulvinar (Pl) is visual. Some investigators have defined further subdivisions of the medial geniculate complex in cats and monkeys (see text).

of a core region of auditory cortex in topographic patterns that preserve tonotopic organization in this cortex. As high-frequency hearing emerged with mammals, a major change from reptiles was the representation of high frequencies in MGv. The dorsal and magnocellular nuclei project more broadly to auditory cortex, to the secondary areas of the auditory belt and parabelt, with little input to the primary core (see Hackett *et al.*, 1998, for review). The divisions of the medial geniculate nucleus are distinct and well differentiated from each other and the adjoining thalamus in well-studied cats and monkeys, but much less so in hedgehogs and opossums (Winer *et al.*, 1988), supporting the contention that these nuclei became more differentiated independently in several lines of mammalian evolution. It is likely that in all mammals, the ventral nucleus is characterized by a dense distribution of the calcium-binding protein, parvalbumin, while the adjoining dorsal and magnocellular nuclei express the calcium-binding protein, calbindin (Cruikshank *et al.*, 2001). These two proteins distinguish other thalamic nuclei as well: parvalbumin distributions are high in the core nuclei that activate cortical areas, and calbindin distributions are high in the nuclei that largely modulate cortical activity.

As for other thalamic nuclei, those of the medial geniculate complex vary in differentiation and relative size in members of different taxa. As one would expect from the auditory needs of echolocating bats, the medial geniculate complex in these bats is the largest nuclear complex of the dorsal thalamus, occupying three-fifths of the rostrocaudal extent of the thalamus (Radtke-Schuller, 2004). The MGv occupies about 40% of the complex, somewhat less than 50% or more found in most mammals. The three divisions of the medial geniculate complex do vary in proportions relative to the total size of the complex in various mammals (reviewed by Radtke-Schuller, 2004). MGv occupies more of the complex in species where primary auditory cortex is prominent, while a relatively large MGd is found in species with expanded nonprimary cortical areas, as in macaque monkeys (Kaas and Hackett, 1998).

Of course, the medial geniculate complex in echolocating bats is also specialized in that the echo frequencies have a disproportionately large representation in MGv (Wenstrup, 1999). The ultrasonic communication calls of mice also appear to have an enlarged thalamic representation (Hofstetter and Ehret, 1992). Another distinctive feature of echolocating bats is that many neurons in both the MGv and MGd have complex sensitivities to sound frequencies, often having responses that are facilitated by combinations of frequencies

in the range of the biosonar signals (Wenstrup, 1999). However, the most remarkable specializations of the auditory thalamus of echolocating bats may be the existence of a direct auditory pathway from the suprageniculate nucleus to the unique frontal auditory area of cortex just rostral to motor cortex (Kobler *et al.*, 1987). While only three divisions of the medial geniculate complex have been considered here, the complex of cats and monkeys appears to have more subdivisions (Winer *et al.*, 2001; de la Mothe *et al.*, 2006), suggesting the independent evolution of new divisions.

3.35.6 The Motor Thalamus: The Ventral Lateral Complex and the Ventral Anterior Complex

The VL complex and the ventral anterior (VA) complex occupy the rostral pole of the thalamus just rostral to the somatosensory nuclei, VP, VPS, and VPI. The VL and VA nuclei are highly variable in size and differentiation, forming a small, poorly differentiated portion of the thalamus in many mammals such as hedgehogs, opossums, and even rats, while being large and architectonically subdivided into several nuclei in anthropoid primates. In addition to VL and VA, a ventromedial nucleus (VM) is often distinguished.

Much of the motor thalamus is defined by inputs from the deep nuclei of the cerebellum and from the substantia nigra and globus pallidus of the basal ganglia. The cerebellum and the basal ganglia, together with the motor cortex, are the main structures that regulate motor behavior. Thus, they provide important sources of information to the motor thalamus, which in turn projects to motor cortex. The cerebellothalamic afferents tend to project predominantly to VLp, a posterior division of the ventrolateral complex, while basal ganglia (pallidal) projections terminate more rostrally in the VLa, the anterior division of the ventrolateral complex, and in the caudal aspect of the VA complex (Ilinsky and Kultas-Ilinsky, 1984; Sakai *et al.*, 2000), although it is uncertain to what degree this segregation of inputs applies to all mammals. In tenrecs, a small insectivore from Madagascar with little thalamic differentiation, the region identified as VM receives a prominent input from the cerebellum (Künzle, 1998), but cerebellar input to VM is considerably less in rats (Herkenham, 1979).

In most mammals, VLp projects mainly to primary motor cortex, while VLa and VA project mainly to premotor cortical areas (Jones, 1985). The notable exception is in mammals that appear to have no motor cortex. Thus, in opossums and perhaps other marsupials (see Beck *et al.*, 1996, for review), there is no evidence for a primary motor area, M1, or any other motor area rostral to primary somatosensory cortex, S1. Instead, S1 is bordered rostrally by a narrow somatosensory area that resembles area 3a of cats and primates. All of the corticospinal projections in opossums originate from S1, the narrow 3a-like area, and S2 (Cabana and Martin, 1984). In other mammals, S1 and the narrow 3a-like strip of opossums have motor functions and electrical stimulation of these areas evokes motor movements. When this was noted by investigators, the S1 area was conceptualized as a sensorimotor amalgam in marsupials (Lende, 1963). Alternatively, this area in opossums can be considered to be simply S1, as it has the identifying features of S1, including sensory architecture, a characteristic somatotopic organization, bordering somatosensory areas, and input from the VP nucleus (Beck *et al.*, 1996).

However, S1 of opossums apparently receives inputs from both VP and VL (Killackey and Ebner, 1973), although these nuclei are poorly differentiated in opossums and difficult to separate. This apparent distinction between metatherian and placental mammals (where a primary motor area, M1, with inputs from VL has been consistently identified) suggests that a motor thalamus existed in early therian mammals, but separate motor cortex targets only evolved in eutherian (placental) mammals (note that projections from VL to parts of the rostral margin of parts of S1 have been reported for some eutherian mammals, but technical difficulties in obtaining relevant data make this uncertain). Arguing against the hypothesis that motor cortex emerged with placental mammals is the questionable evidence that protherian mammals (monotremes) do have a separate motor cortex (Ulinski, 1984; Krubitzer *et al.*, 1995). If so, it might be more parsimonious to argue that opossums and perhaps other marsupials have regressed from the ancestral plan, and have lost a separate primary motor area, M1. This uncertainty relates to the issue of whether reptilian ancestors of mammals had a motor thalamus. Although a region of the thalamus of birds and reptiles has been suggested as a homologue of the mammalian motor thalamus, the evidence has been described as inconclusive (Medina *et al.*, 1997; Medina and Reiner, 2000; see Field Homologies).

An unusual feature of hedgehogs is that the VL nucleus projects bilaterally to motor cortex (Dinopoulos, 1993). While crossed thalamocortical projections have been reported for midline nuclei in a range of mammals, they have not been described for VL of other mammals, including opossums

(Donoghue and Ebner, 1981) and echidnas (Ulinski, 1984). Given this apparently unique feature of the motor thalamus of hedgehogs, the most logical conclusion is that the immediate ancestors of hedgehogs developed a crossed projection that earlier ancestors did not have. However, Dinopoulos (1993) suggested instead that hedgehogs have retained a primitive trait, as their forebrain appears to be primitive in general and such connections exist in postnatal rats that are lost during development (Minciacchi and Granato, 1989). Thus, hedgehogs might have retained a primitive crossed thalamocortical projection from VL to motor cortex that is preserved in other mammals only as a transient projection early in development.

In anthropoid primates, VL and VA are large and architectonically divided into several nuclei or subnuclei (Stepniewska *et al.*, 1994). Thus, VL is commonly divided into four regions, with names varying across authors, and VA is divided into a parvocellular and a magnocellular division. This complexity likely relates to the changes that have taken place in the organization of motor cortex of primates, where dorsal and ventral premotor areas, a supplementary motor area, and a presupplementary motor area have been identified in dorsolateral frontal cortex. Such complexity has not been identified in nonprimate mammals (Kaas, 2004). Although prosimian galagos also have these additional premotor areas (Wu *et al.*, 2000), and the motor thalamus is large and subdivided, the subdivisions are architectonically much less distinct than in monkeys (Fang *et al.*, 2006).

In summary, the motor thalamus of mammals appears to be unusual in that it seems to have emerged as a subdivision or subdivisions of the thalamus before a separate motor area or motor areas existed. Alternatively, motor areas of cortex could have been lost in evolution while thalamic areas were preserved. In addition, the complexity in terms of subdivisions substantially increased at both cortical and thalamic levels in primates, but the architectonic distinctiveness of thalamic subdivisions especially increased with the advent of anthropoid primates.

3.35.7 The Anterior and Lateral Dorsal Nuclei

Three anterior nuclei and the associated lateral dorsal (LD) nucleus are well differentiated and histologically distinct in the anterior thalamus of most mammals. The anterodorsal (AD) nucleus is characterized by tightly packed, darkly stained cells in Nissl preparations, while the adjoining anteroventral (AV) nucleus is less darkly stained, but usually separated from AD by a cell-poor septum. The anteromedial (AM) nucleus resembles AV, but has a more VM position. The LD nucleus, lateral and dorsal to AD and AV, has pale-staining cells in Nissl preparations. The four nuclei are functionally related in that they project to different parts of limbic cortex on the medial wall of the cerebral hemisphere, and receive inputs from the hippocampal formation either directly from the subicular complex or indirectly via the mammillary nuclei of the hypothalamus (Price, 1995). The limbic connections of the anterior group suggest that these nuclei have roles in basic, ancient functions. Yet, this collection of nuclei has not been identified in reptiles. Butler and Hodos (2005) postulate that the elaboration of this complex involved a shift from a multisensory relay nucleus in the thalamus to a cortical–thalamic–cortical circuit resulting from an increased role of limbic cortex in learning and memory. In any case, the four nuclei vary in development across taxa in a way that suggests that their functions vary in importance. Monotremes appear to have only a single anterior nucleus (Butler and Hodos, 2005), possibly reflecting the state of early mammals, while opossums have all three anterior nuclei (Bodian, 1939). Other variations in the anterior nuclei across mammalian taxa have been reviewed by Jones (1985). In general, there seems to be an association between the architectonic representation of the nuclei and that of limbic cortex. The AM nucleus is sometimes indistinctly separated from the AV nucleus, and the AV nucleus is greatly enlarged in many primates. The AD nucleus is sometimes subdivided into regions of larger and smaller cells, and it is disproportionately large in some mammals such as echolocating bats.

3.35.8 The Mediodorsal and Intralaminar Thalamic Nuclei

A number of other nuclei of the mammalian thalamus deserve at least brief comment. The MD nucleus is a large group of cells in the AM thalamus that is often subdivided based on regional differences in cell size and packing. The nucleus or complex receives inputs from olfactory cortex, the amygdala, and entorhinal cortex while projecting to regions of frontal cortex (Price, 1995). An olfactory pathway through the thalamus to dorsal pallium appears to be widespread in reptiles and birds (Veenman *et al.*, 1997), suggesting that the reptilian ancestors of mammals had the homologue of an MD nucleus. An MD nucleus has been identified with

connections to frontal cortex in monotremes (Welker and Lende, 1980), marsupial opossums (Tobias and Ebner, 1973; Benjamin and Golden, 1985), and a wide range of placental mammals (see Benjamin and Golden, 1985, for review). One difference across mammals is that olfactory cortex projects to all of MD in opossums, but only to the medial part in placental mammals, which is further distinguished by the magnocellular division of MD in monkeys. These findings suggest that MD in early mammals functioned to relay olfactory information to frontal cortex. In some lines of evolution, especially in primates, the olfactory functions became less dominant, while MD differentiated into two or more subnuclei with olfactory and other functions.

The cell groups within the internal medullary lamina of the dorsal thalamus are called the intralaminar nuclei. The 'centre médian' is of special interest as it is a well-differentiated component of the primate thalamus, but not an obvious nucleus in most other mammals. The 'centre médian' has been suggested as one of the new components of the primate thalamus (Jones and Rubenstein, 2004). Historically, Le Gros Clark (1932) proposed that the 'centre médian' nucleus evolved from part of the intralaminar group, but the origin and primitive form of the nucleus are unclear. Veenman *et al.* (1997) propose, on the basis of immunohistochemical evidence and connection patterns, that the intralaminar, midline, and MD nuclei of the mammalian thalamus evolved from dorsal thalamic groups in reptilian ancestors that also gave rise to a dorsal thalamic zone in birds.

3.35.9 Conclusions

We have seen that there are both consistent and variable features of the mammalian dorsal thalamus. The most notable consistent feature is that a number of thalamic nuclei, such as the dorsal LGN, the medial geniculate complex, the pulvinar, and the VP nucleus, can be identified in most or all mammals studied, and likely were retained from the immediate reptilian ancestors of mammals. However, the architectonic differentiation of these nuclei was not marked, judging from the poor differentiation of thalamic nuclei in a range of extant mammals. Variable features, reflecting evolutionary changes in various lines of descent, include: increases (and, more rarely, decreases) in the absolute and relative sizes of some nuclei relative to others, changes in the proportion of nuclei devoted to some inputs over others (e.g., representation of inputs from face or hand in VP), the formation of layers and subnuclei in nuclei, alterations in the inputs and outputs of nuclei, and the emergence of new nuclei. Similar evolutionary changes have taken place in the more extensively studied neocortex (Krubitzer and Kaas, 2005).

It seems likely that few or no thalamic nuclei have been lost in mammalian evolution. Even the subterranean blind mole-rat has an identifiable, but small, dorsal LGN (Cooper *et al.*, 1993). In contrast, new nuclei appear to have emerged in many lines of mammalian evolution. A clear example is the pulvinar complex, where different nuclei have emerged in carnivore and primate lines. By using the expression of genes during development to help identify thalamic nuclei, Jones and Rubenstein (2004) listed six nuclei found in monkeys that are not found in mice, and this is certainly an underestimate. On the other hand, the patterns of gene expression suggested that some nuclei that are well differentiated in the thalamus of monkeys, such as the suprageniculate/limitans, do have a poorly differentiated homologue in the thalamus of mice. It seems likely that, as new expanses of neocortex subdivided into new areas in evolution, as is the case with much of posterior parietal cortex of anthropoid primates (Kaas *et al.*, 2006a), new thalamic nuclei with projections to the new cortical areas emerged. However, the increase in the number of cortical areas and thalamic nuclei was most likely not on a one-to-one basis, as the neocortex generally seems to have more subdivisions than does the dorsal thalamus. As an example of a new nucleus, the medial nucleus of the inferior pulvinar (IPm) of anthropoid primates projects densely to the MT visual area, but neither MT nor IPm appears to exist outside the primate order. However, in some instances, the complexity of the thalamus may exceed that of the cortex, as in opossums where the thalamic motor nucleus, VL, and the thalamic somatosensory nucleus, VP, both project to primary somatosensory cortex, S1. Also, there is no evidence of a separate primary motor area, M1, although a separate and distinct M1 with inputs from VL is characteristic of all placental mammals studied.

If new nuclei of the thalamus emerged, from where did they come? The prevailing notion is that poorly differentiated nuclei gradually differentiated to two or more nuclei in some lines of descent. This hypothesis has been stated repeatedly as an explanation for how new cortical areas emerged (Kaas, 1982; Krubitzer and Kahn, 2003; Krubitzer and Kaas, 2005). In some sense, one could argue that the new areas are not really new, and two or more nuclei in one taxon can be identified as a field homology with a single nucleus in other taxa. Alternatively, new nuclei could emerge as the result

of a change in gene expression, perhaps as a consequence of gene duplication (Allman and Kaas, 1971a, 1971b; Fukuchi-Shimogori and Grove, 2001, 2003). Finally, it is important to stress that the evolution of the thalamus is not well understood, as the great diversity of thalamic organization that must exist in mammalian radiation has been largely unexplored. For practical reasons, research efforts have focused on a few well-studied species. Clearly, there is much to learn, and many opportunities for the adventurous, comparative neuroscientist to make new discoveries of substance.

3.36 The Dual Elaboration Hypothesis of the Evolution of the Dorsal Thalamus

A B Butler, George Mason University, Fairfax, VA, USA

Glossary

amniote The major vertebrate taxon that comprises mammals, reptiles, and birds. Amniotes are characterized by having an amnion, which is a membrane that surrounds the embryo and contains amniotic fluid.

anamniote The major vertebrate taxon that includes fishes and amphibians. Anamniotes lack an amnion. See 'amniote'.

cladistic analysis Method in which the distribution of shared traits is used to infer phylogenetic relationships among taxa or to determine whether a particular trait was likely present in the common ancestor of a set of taxa.

collothalamus The set of dorsal thalamic nuclei that predominantly receive their inputs via a relay through the midbrain roof.

diapsid Major amniote taxon that includes modern reptiles and birds. Modern reptiles comprise lizards, snakes, turtles, the tuatara, and crocodiles. Diapsids are characterized by having two fenestrae (bony openings) bridged over by arches in the temporal region of the skull. These arches and fenestrae have become secondarily lost in modern turtles and substantially modified in modern lizards, snakes, and birds.

lemnothalamus The set of dorsal thalamic nuclei that predominantly receive their inputs directly, without relay through the midbrain roof.

sauropsid Major amniote taxon that includes modern reptiles and birds. The term 'diapsid' previously excluded turtles but can now be considered synonymous with the term 'sauropsid' for extant taxa.

synapsid Major amniote taxon that includes modern mammals. Synapsids are characterized by having one fenestra (bony opening) bridged over by an arch in the temporal region of the skull.

3.36.1 How Did the Dorsal Thalamus Evolve? The Problem and the Evidence

The dorsal thalamus consists of multiple nuclei and nuclear groups in the two major groups of amniote vertebrates (Jones, 1985; Butler and Hodos, 2005): sauropsids (reptiles and birds) and mammals. In contrast, in anamniotes (amphibians and fishes), the dorsal thalamus consists of only three nuclei: a rostrally lying nucleus anterior and two more caudally lying nuclei, the dorsal posterior and central posterior nuclei (Butler and Hodos, 2005). The latter two nuclei receive their predominant input from the midbrain roof and project predominantly to the striatum and/or to the neighboring part of the pallium, whereas the nucleus anterior receives its predominant input directly from the retina and/or from other sources and projects to the developmentally medial part of the pallium.

In sauropsids, several nuclei receive a major midbrain roof input, including nuclei rotundus, ovoidalis, and the caudal part of nucleus dorsolateralis posterior, or cDLP. (Avian nomenclature is used here for sauropsids, including the revised nomenclature of Reiner *et al.*, 2004.) Other nuclei, including several dorsomedial and dorsolateral nuclei, and the dorsal lateral geniculate nucleus (DLGN), predominantly receive more direct sensory inputs, which are not relayed from the midbrain roof. Likewise in mammals, nuclei that receive a major midbrain roof input include the posterior nuclear group (and the posterior intralaminar nuclei), the medial geniculate

body, and the lateral posterior–pulvinar complex, or LP–pulvinar. A large number of dorsal thalamic nuclei in mammals receive predominantly lemniscal, or direct, inputs, including those of the medial, midline, rostral intralaminar, anterior, and ventral groups, and the DLGN.

While multiple nuclei are present in the dorsal thalamus of all amniotes, and some nuclei, such as the DLGN (previously called OPT in birds), could be identified as homologous across sauropsids and mammals, the evolutionary origin of most nuclei had been enigmatic (Jones, 1985; see Evolution of the Visual Tectogeniculate and Pretectogeniculate Pathways in the Brain of Amniote Vertebrates). In 1942, Rose had identified five pronuclei in the developing rabbit thalamus (Figure 1) that subsequently differentiated into the adult dorsal thalamic nuclei, but their correspondence to sauropsid or anamniote dorsal thalamic nuclei was also unknown. The dorsal pronucleus differentiates into two entities, LP–pulvinar and the posterior group, whereas the medial geniculate pronucleus differentiates into the nucleus, or body, of the same name. These nuclei all receive substantial midbrain roof inputs and thus could be compared as a group to the dorsal posterior and central posterior nuclei of anamniotes and to the rotundus-ovoidalis-cDLP and related nuclei of sauropsids. The puzzle concerned the evolutionary source of all of the other dorsal thalamic groups in mammals, which are derived from the medial, central, and dorsal lateral geniculate pronuclei.

As the result of a cladistic analysis of the dorsal thalamus, Butler (1994a) recognized that the latter groups of nuclei and the DLGN were united by a number of common features of connections and position. She posited that these nuclei (and the three pronuclei that give rise to them) were all derived from a common embryological anlagen that is homologous to the nucleus anterior of anamniotes and that the similarly connected nuclei in sauropsids – the dorsomedial and dorsolateral nuclei, and the DLGN – were likewise derived. She thus identified two fundamental divisions of the dorsal thalamus across amniotes (Figure 2): the lemnothalamus, which receives most of its inputs directly rather than through midbrain roof relays, and the collothalamus, which receives its predominant inputs via the midbrain roof. Corresponding divisions of the pallium that are lemnothalamic-recipient (in mammals, the primary visual and somatosensory cortices and frontal lobe; in birds, the Wulst, or hyperpallium) and collothalamic-recipient (in mammals, including

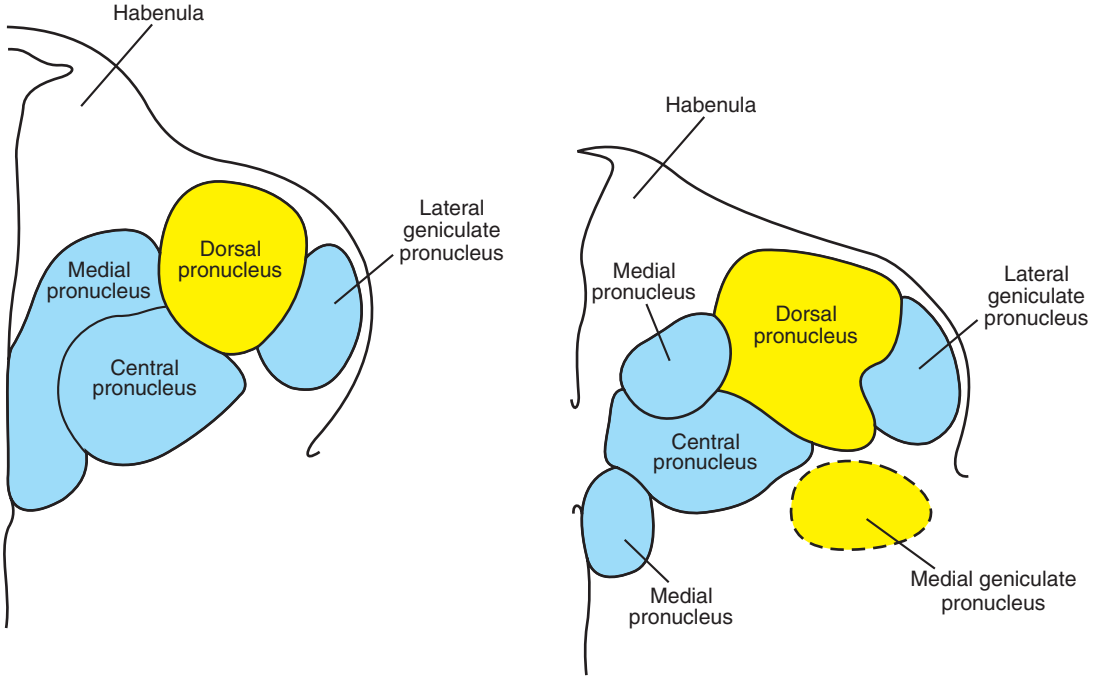

Figure 1 Drawings of pronuclei on the right side of the developing dorsal thalamus in the rabbit. The more rostral section is on the left. In the section on the right, the position of the medial geniculate pronucleus is outlined in dashes, since it actually occurs at a somewhat more caudal level than the one shown here. Blue indicates the lemnothalamus and yellow the collothalamus. Based on the findings of Rose, J. E. 1942. The ontogenic development of the rabbit's diencephalon. *J. Comp. Neurol.* 77, 61–129.

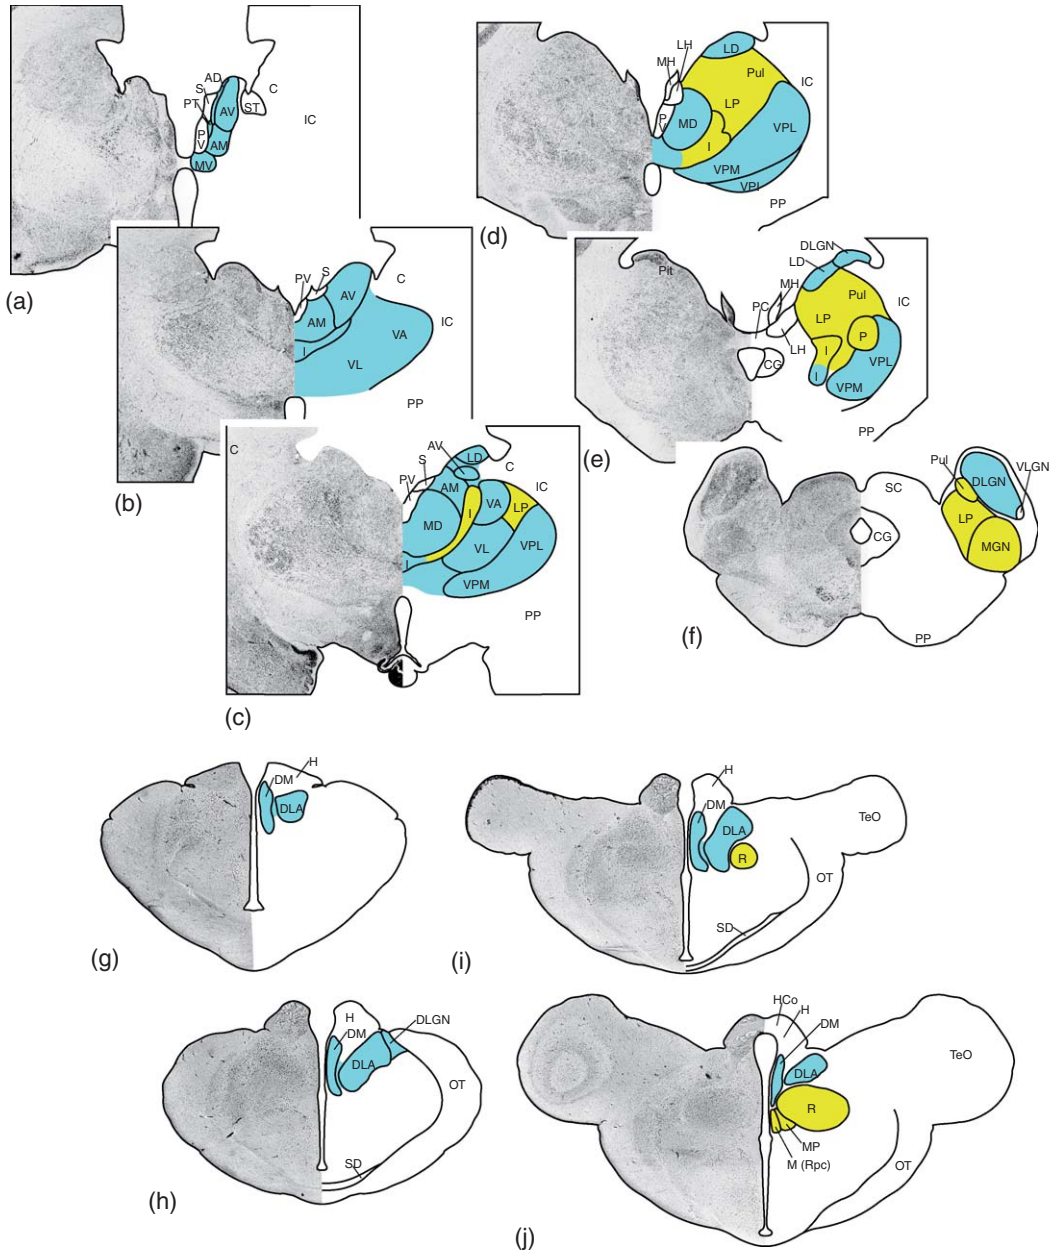

Figure 2 Series of transverse hemisections with mirror image drawings to show the distribution of lemnothalamic and collothalamic nuclei in the dorsal thalamus of an adult mammal, the raccoon *Procyon lotor* (a–f), and an adult sauropsid, the lizard *Iguana iguana* (g–j). For both species, the most rostral section is at the upper right. In mammals, the intralaminar nuclei are divided into rostral, lemnothalamic, and caudolateral, collothalamic groups, as indicated by their blue or yellow shading, respectively, with the former including the central medial, rhomboid, and central median nuclei and the latter the parafascicular, paracentral, and central lateral nuclei. Abbreviations for dorsal thalamic nuclei in a–f are: AD, anterodorsal nucleus; AM, anteromedial nucleus; AV, anteroventral nucleus; DLGN, dorsal lateral geniculate nucleus; I, intralaminar nuclear group; LD, lateral dorsal nucleus; LP, lateral posterior nucleus; MD, mediodorsal nucleus; MGN, medial geniculate body; MV, medioventral (reuniens) nucleus; P, posterior nuclear group; PT, parataenial nucleus; Pul, pulvinar; VA, ventral anterior nucleus; VL, ventral lateral complex; VPL, ventral posterolateral nucleus; VPM, ventral posteromedial nucleus; VPI, ventral posterior inferior nucleus. Abbreviations for dorsal thalamic nuclei in g–j are: DLA, nucleus dorsolateralis anterior; DLGN, dorsal lateral geniculate nucleus; DM, nucleus dorsomedialis; R, nucleus rotundus; MP, nucleus medialis posterior; M (Rpc), nucleus medialis (reuniens pars compacta). Abbreviations for additional structures labeled for orientation are: C, caudate nucleus; CG, central gray; IC, internal capsule; H, habenula; HCo, habenular commissure; LH, lateral habenula; MH, medial habenula; OT, optic tract; PC, posterior commissure; PP, pes pedunculi; PV, paraventricular nuclear group of the epithalamus; S, stria medullaris; SC, superior colliculus; SD, supraoptic decussation; ST, stria terminalis; TeO, optic tectum; VLGN, ventral lateral geniculate nucleus. Photomicrographs and guidance on nuclear boundaries for *Procyon lotor* were generously provided by Wally Welker. Identification of the DLGN in *Iguana iguana* is based on Kenigfest, N., Martínez-Marcos, A., Belekhova, M., *et al.* 1997. A lacertilian dorsal retinorecipient thalamus: A re-investigation in the Old-World lizard *Podarcis hispanica*. *Brain Behav. Evol.* 50, 313–334.

extrastriate, association somatosensory, and auditory cortices, as well as the lateral nucleus of the amygdala; in birds, the dorsal ventricular ridge – particularly its mesopallial and nidopallial components – likewise can be identified (Butler, 1994b; Bruce and Neary, 1995)).

Based on developmental, histochemical, and other criteria, divisions corresponding to Butler's lemnothalamus and collothalamus also had been recognized independently by Martínez-de-la-Torre (1985), Caballero-Bleda (1988), and Guillén (1991), working in the laboratory of Luis Puelles. Likewise, Reiner (1993) independently identified the two corresponding major divisions of the nonlimbic pallium to which the lemnothalamic and collothalamic divisions of the thalamus project (see The Evolution of the Dorsal Thalamus in Mammals).

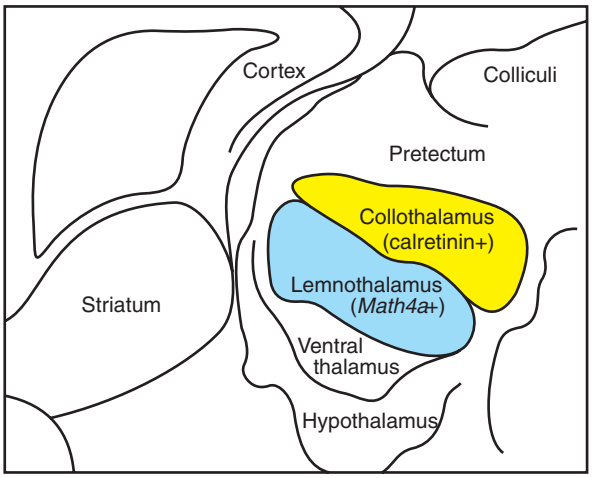

Figure 3 Drawing of part of a sagittal section through the diencephalon of the developing mouse brain, with rostral toward the left. The lemnothalamus (in blue) expresses the gene *Math4a*, while the collothalamus (in yellow) is calretinin-positive. Redrawn from photomicrograph from González, G., Puelles, L., and Medina, L. 2002. Organization of the mouse dorsal thalamus based on topology, calretinin immunostaining, and gene expression. *Brain Res. Bull.* 57, 439–442.

3.36.2 Recent Supporting Evidence for the Lemnothalamus and Collothalamus

Besides the defining issue of predominant input from either direct or midbrain-relayed sources, the basic pattern of connections of the lemnothalamic and collothalamic nuclei across amniotes (Butler, 1994a) includes: (1) projections from the lemnothalamus to dorsomedial pallial areas, some of which are bilateral, and (2) projections from the collothalamus that are solely ipsilateral and are to the striatum as well as to dorsolateral pallial areas. Additional findings of bilateral lemnothalamic projections to cortex in mammals (Dermon and Barbas, 1994; Dinopoulos, 1994; Carretta *et al.*, 1996) as well as similar previous findings by Preuss and Goldman-Rakic (1987) support this distinction. Additionally, the presence of ipsilateral striatal projections that arise from the extrageniculate visual nuclei in the cat (Harting *et al.*, 2001) is consistent with the collothalamic pattern.

Several studies in birds also have provided support for the unity of the lemnothalamus and its presence across amniotes. The afferent and efferent connections of a number of specific nuclei or nuclear regions within the lemnothalamus of birds support homology with various discrete components of the lemnothalamus in mammals, as predicted by Butler (1994a). These include somatosensory, basal ganglia- and cerebellum-related feedback, rostral intralaminar, and olfactory cell groups (Medina *et al.*, 1997; Veenman *et al.*, 1997; Wild, 1997; Montagnese *et al.*, 2003).

Recently, González *et al.* (2002) identified molecular markers that selectively label the lemnothalamus and collothalamus. In the developing mouse dorsal thalamus (Figure 3), the lemnothalamus is distinguished by expression of the gene *Math4a* and lack of calretinin immunostaining, whereas the collothalamus is negative for *Math4a* and positive for calretinin. Likewise in amphibians, acetylcholinesterase differentiates the two hypothesized divisions, with nucleus anterior (lemnothalamus) being strongly positive for it and the dorsal posterior and central posterior nuclei (collothalamus) being light to negative (Puelles *et al.*, 1996).

3.36.3 Independent Evolution of the Collothalamus and Lemnothalamus among Amniotes: Different Patterns of Evolution

Early stem amniotes gave rise to the synapsid lineage, which led to modern mammals, approximately 320 Mya, and to the diapsid lineage, which led to modern sauropsids (reptiles and birds), approximately 310 Mya (Evans, 2000). The lemnothalamus and collothalamus exhibit different relative patterns of evolution in these two lineages (Butler, 1994a, 1995). In sauropsids, the collothalamus was initially favored for elaboration, as is still evident, particularly with the relative size of nucleus rotundus in reptiles. Secondarily, in birds, the lemnothalamus also has undergone some degree of elaboration. These elaborations similarly are evident in the pallium (Butler, 1994b), with the enlargement in birds of the lemnothalamic-recipient

Wulst and the collothalamic-recipient nidopallium. Conversely, in mammals, the lemnothalamus was the first division to undergo elaboration, likely in correlation with elaboration of the medial-most part of the pallium, the hippocampal formation, and increased spatial mapping and sensory challenges. Extant monotremes have a large lemnothalamus and a large lemnopallium, particularly as evinced in the platypus with the expansive primary somatosensory cortex and echidnas with the expansive frontal lobe, combined with very small collothalamic-recipient regions (Krubitzer, 2000). Secondarily, within some orders of mammals, particularly as seen in carnivores and primates, the collothalamus elaborated markedly with expansion of the LP–pulvinar complex and corresponding extrastriate visual cortical areas (Kaas, 1995).

3.36.4 Homologies of Lemnothalamic and Collothalamic Components Across Amniotes

Homologous relationships of various lemnothalamic components and their pallial projection targets across amniotes are relatively well established and noncontroversial (Medina *et al.*, 1997; Veenman *et al.*, 1997; Wild, 1997; Medina and Reiner, 2000; Desfilis *et al.*, 2002; Montagnese *et al.*, 2003), as is that of the medial geniculate nucleus of mammals to the sauropsidian nucleus ovoidalis (Butler, 1994a; Puelles, 2001). Possible homologies of some other collothalamic components are the subject of current debate. In particular, whether LP–pulvinar, the posterior nuclear group, or both are homologous to the sauropsidian nucleus rotundus needs to be resolved. The possibility that at least part of LP–pulvinar is not a collothalamic but rather a lemnothalamic derivative has been broached (Puelles, 2001). However, cell migration patterns in the developing rat dorsal thalamus, as evinced by elongated cellular profiles between the region of the posterior nuclear group and LP (Figure 4), support the derivation of both LP and the posterior nuclear group from the unitary, collothalamic dorsal pronucleus, in agreement with Rose's (1942) observations in the rabbit. Recent molecular evidence indicating that some nuclei in the pulvinar of primates are unique to this order (Jones and Rubenstein, 2004) does not contradict the fundamental developmental relationship of LP and the posterior nuclear group.

3.36.5 Summary and Concluding Remarks

Delineation of the lemnothalamus and collothalamus allowed the evolutionary history of the dorsal thalamus to be understood in terms of differential elaboration of these two divisions within the two major amniote taxa: sauropsids and mammals. Initial elaboration of collothalamic nuclei in sauropsids was correlated with elaboration of their pallial targets within the dorsal ventricular ridge.

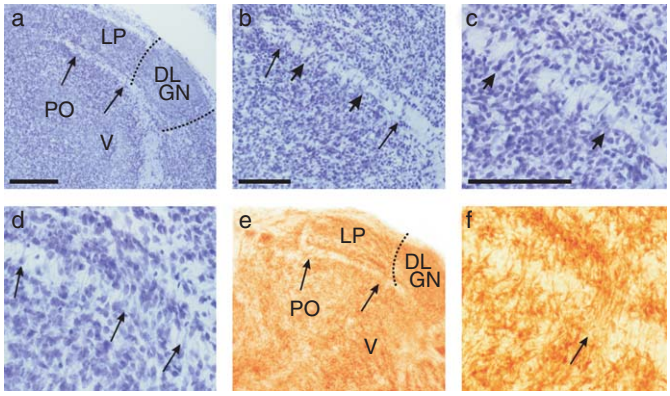

Figure 4 Photomicrographs of transverse sections through the diencephalon of the developing rat brain stained with cresyl violet (a–d) or reacted for cytochrome oxidase (e–f). The section shown in (a) is from embryonic day 21 and is enlarged in (b) and further in (c). Arrows in (a) indicate the same region between the posterior nuclear group (PO) and the lateral posterior nucleus (LP) as indicated in (b) by the longer, outside set of arrows. The shorter, arrows in (b) indicate the same region shown between the arrows in (c). Note the elongated profiles of cells, indicating migration of developing neurons from PO into the region of LP. A second example of PO to LP elongated cells, indicated by arrows, in this same region is shown in (d) from a case at postnatal day 1. A third example, also at postnatal day 1, is shown in (e), with a bridge-like cluster of elongated cells indicated by the arrow to the right also shown in (f), as indicated by the arrow, with a number of elongated cells also to the left of it. Elongated cell profiles also occur between the ventral nuclear group (V) and the DLGN, the borders of which are indicated in (a) by the dotted lines and likewise its dorsal border in (e). Scale bars: 0.25mm (a, e); 0.1mm (b); 0.1mm (c, d, f).

Initial elaboration of the lemnothalamus in mammals was correlated with elaboration of their pallial targets as well, in this case the primary visual and somatomotor areas and the frontal lobe. Subsequent elaboration of the complementary division of the dorsal thalamus occurred in each lineage. The previously cryptic but shared organization of the thalamus across mammals and sauropsids and their evolution from the relatively modest thalamic components in anamniotes can now be understood in terms of relative and sequential development of the two shared components.

4.01 Primate Brain Evolution in Phylogenetic Context

T M Preuss, Emory University, Atlanta, GA, USA

Glossary

anthropoids The primate group comprised of the New World monkeys (platyrrhines) and the Old World monkeys, apes, and humans (catarrhines).

Archonta The group of mammals consisting of primates and their closest relatives, currently thought to include tree shrews and flying lemurs.

catarrhines Members of the suborder Catarrhini, the primate group comprised of the Old World monkeys and the hominoids (apes and humans).

clade Any monophyletic group; that is, the set of species descended from a common ancestral species.

encephalization The disparity (usually expressed as a ratio) between the size of the brain in a particular species and the size that would be expected based on its body size.

haplorhines Members of the suborder Haplorhini, the primate group comprised of the tarsiers and anthropoids.

neomorphism An evolutionarily new feature, that is, a derived feature of a group of animals that has no homologue at the same level of organization in related mammals.

platyrrhines Members of the infraorder Platyrrhini, the New World monkeys.

prosimians Members of the primate group comprised of strepsirhines plus tarsiers; most workers think this is not a monophyletic group, so the term is not as widely used as a formal taxonomic term as it once was.

shared derived character Also known as synapomorphy. A character that evolved in the stem lineage of a group; typically, such a character is present in many descendents of the stem lineage and serves to distinguish that group from related groups.

stem lineage The segment of the evolutionary tree that connects the last common ancestor of a group of interest to the last ancestor it shares with its closest extant relatives. For example, stem primates are animals on the lineage, or on branches extending from the lineage, that connects the last ancestor of modern primates to the last ancestor primates share with other archontans (such as tree shrews).

strepsirhines Members of the suborder Strepsirhini, the branch of the primate tree consisting of the lemur group and the loris–bush baby group.

taxon (pl. taxa) Any formal grouping of related organisms, for example, any particular species, genus, family, etc.

4.01.1 Introduction

Almost anyone with some exposure to the neurosciences can tell you the story of primate brain evolution: through evolutionary time, brains became bigger and more complex, and their bearers increasingly intelligent, a process that culminated in the appearance of *Homo sapiens*, the brainiest and most intelligent animal of them all. This conception of primate brain evolution is so deeply embedded in

the foundations of neuroscience that it is easy to lose sight of the fact that the idea actually has a history, that it was the intellectual product of particular scientists at particular time points in the development of ideas about primatology and about neurobiology.

Times change. Neuroscience, as a discipline, has of course enjoyed tremendous growth over the past several decades, fueled in part by the development of a succession of new techniques that make it possible to explore brain organization and function in finer and finer detail. Less generally appreciated, perhaps, is that evolutionary biology has also undergone profound developments, with the introduction of new methods for determining how species are related to each other and for reconstructing the history of evolutionary change. The phylogenetic scale is gone, replaced by the branching tree of life. Evolutionary biologists now no longer read the history of life as the story of the Ascent of Man: humans are regarded as one of numerous specialized end-points of evolution. Unquestionably, we are justified in taking a particular interest in our own species, but we misunderstand ourselves, and other species, if we conceive of evolution as being mainly about how to get to *H. sapiens*.

As a consequence of the fundamental methodological and conceptual changes in evolutionary biology, we have a much better understanding of the evolutionary history of primates and the relationship of primates to other mammals, and textbooks on primate evolution that were current in, say, 1975, seem about as quaintly dated today as textbooks of neurobiology or physiological psychology from the same era. These new ideas and approaches to evolutionary biology have begun to make their mark on the neurosciences, as witnessed, for example, by the publication of Georg Striedter's landmark textbook on vertebrate brain evolution (Striedter, 2005) and of the volumes in the present series, but there is a long way to go, as so much of the neuroscientific enterprise takes place without any explicit reference to evolution. My main purpose in writing this article is to further the integration of primate evolutionary biology and primate neuroscience. I begin by setting the comparative context for understanding primate brain evolution with an overview of primate taxonomy, past and present ideas about primate origins and adaptations, and current thinking about how primates are related to other mammalian groups. I then review selected issues in primate brain evolution, attempting to localize specializations of primate brain organization within the context of primate evolutionary history.

4.01.2 Primate Origins and Evolution

4.01.2.1 The Primates

Primatologists currently recognize the existence of over 200 extant species of primates (Purvis, 1995; Fleagle, 1999). Traditionally, the order Primates was divided into two main groups, termed prosimians and anthropoids (the latter also known as 'simians'), or more formally, suborder Prosimii and suborder Anthropoidea. The familiar anthropoids consist of a group native to the Old World – the Old World monkeys, plus the hominoid (ape-human) group – and a group native to the New World, the New World monkeys. Formally, the Old World group is known as the Catarrhini and the New World group as the Platyrrhini. The Old World monkey group is the most successful primate group in terms of diversity, comprising no fewer than 87 extant species distributed from South Africa to Japan. These include the familiar macaque monkeys, widely used as research subjects by neuroscientists. By contrast, there are only 14 extant species in the ape-human group, and most of these are the so-called 'lesser' apes, that is, the gibbons. The prosimians consist of the lemurs, found today only on the island of Madagascar, the loris–bush baby group, with species distributed across sub-Saharan Africa and south Asia, and the tarsiers, native to the islands of the western Pacific.

Although this conventional taxonomy groups tarsiers with the lemurs and lorises, there has long been a body of opinion holding that tarsiers are actually more closely related to the anthropoids (Figure 1a). This relationship implies a different classification, in which the two major groups of primates become suborder Strepsirhini (the lemur and loris–bush baby group) and suborder Haplorhini (tarsiers plus the anthropoids). The strepsirhine–haplorhine taxonomy appears to be the preferred taxonomy among primatologists at the present time, because the majority of primatologists accept that tarsiers are the closest relatives of the anthropoids, although this matter is not entirely settled (Ross and Kay, 2004b).

Certain useful generalizations about the biology and behavior of the major primate groups can be stated (Martin, 1990; Fleagle, 1999). Compared to anthropoids, the strepsirhines tend to have small bodies and relatively small brains (when brain size is adjusted for body size). Many of the strepsirhines are nocturnally active. The smaller, nocturnal strepsirhines – such as bush babies (galagos), lorises, and mouse lemurs – tend to be solitary and subsist on a diet of insects, small vertebrates, fruit, and flowers. Some of the larger lemurs on Madagascar, however,

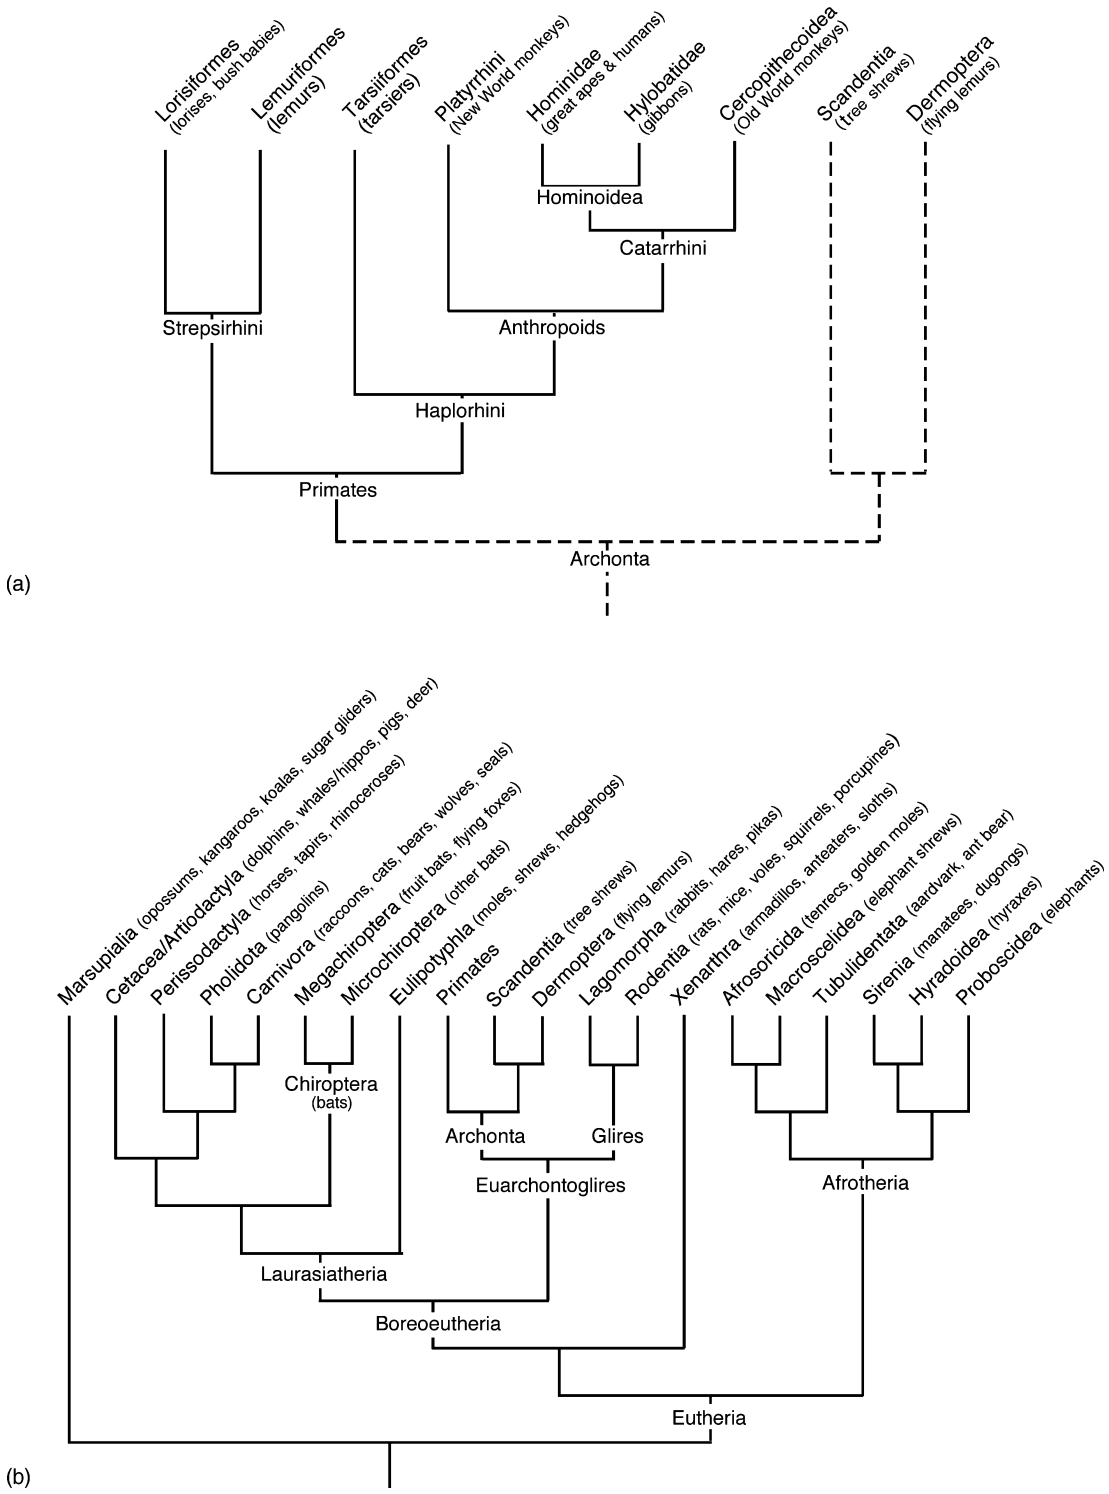

Figure 1 The evolutionary relationships of primates and mammals. a, The phyletic relationships of the major primate groups. Currently, tree shrews (order Scandentia) and flying lemurs (order Dermoptera) are the animals thought to be most closely related to primates. The Archonta is the higher-order group that includes Primates, Scandentia, and Dermoptera. b, A modern interpretation of the relationships of therian mammals, based on the comparative DNA studies of Murphy *et al.* (2001b). Murphy and colleagues recognized the close relationship between Primates, Scandentia, and Dermoptera (which they designated as 'Euarchonta' rather than Archonta). Note that the bats (order Chiroptera), in contrast to some other interpretations, are regarded here as monophyletic, but distantly related to primates.

are diurnal, live in social groups, and have a diet consisting primarily of plant material. By contrast to strepsirhines, the anthropoids are diurnally active (with the sole exception of the New World owl monkey, *Aotus*), and most live in sizable social groups, subsisting on fruit, flowers, gum, and leaves, and in some cases also insects and vertebrates. The tarsiers, although probably closely related to the anthropoids, resemble the smaller strepsirhines in being very small bodied, nocturnal, and solitary, and subsisting on a diet of invertebrates and small vertebrates. Tarsiers are readily identified by their enormous eyes.

4.01.2.2 Primate Evolution

4.01.2.2.1 Early views Not surprisingly, the history of ideas about primate and human evolution carries the very significant imprint of Charles Darwin (see especially Darwin, 1859, 1871). Darwin, of course, is a hero to modern evolutionary biologists, who tend to attribute to him a very modern view of evolution. In order to understand how Darwin influenced thinking about primate evolution, however, it is necessary to place him in proper historical context. Although Darwin is sometimes seen as a champion of the modern idea that phylogeny is like a branching tree rather than like an ascending scale – and there is indeed a prescient remark in one of his notebooks that suggests the primacy of the branching view of evolution – any fair reading of Darwin's large corpus of published writings makes it clear that he considered natural selection to be a process leading to progressive improvement, and that humans are, among animals, the most improved forms (Richards, 1992; Preuss, 1993, 1995b). Darwin, like most of the first generation of evolutionists, simply did not perceive a conflict between the branching-tree conception of evolution and the idea that evolution is a scale. As a result, early drawings of the tree of life generally have very stout vertical trunks, with humans at the top and little twigs branching off at lower levels of the trunk representing less-evolved (although nonetheless modern) forms. The archetype of this genre is the famous tree published by Haeckel (1874) and widely reproduced (see, e.g., figure 1 of Preuss, 2004b). Darwin, it should be said, was an unabashed fan of Haeckel (Richards, 1992).

For Darwin, then, an important part of the evolutionary story was about how to account for the ascendancy of humans among animals. In Darwin's view, the key to human success is not the human body, weak and feeble as it is, but rather the brain and the intellectual abilities it confers. It is important also to note, however, that Darwin – perhaps being concerned about drawing such a sharp line between humans and other animals as to create doubt about the theory of evolution – emphasized that the differences between the intellectual abilities of humans and other animals are matters of degree rather than kind. This is Darwin's 'Principle of Continuity', which has cast a very long shadow on the history of comparative psychology and neuroscience (Povinelli, 1993; Preuss, 1993, 1995b)

Theories of primate and human evolution developed during the early part of the twentieth century took their lead from Darwin, focusing on brain size and the conditions under which brain-size increases would be selected for (Cartmill, 1982). The British anatomists G. Elliot Smith and F. Wood Jones championed the idea that life in the trees selected for greater intelligence and enhanced vision (including the stereoscopic vision supposedly necessary for arboreal living). W. E. Le Gros Clark popularized these views in a series of books, including his widely read treatise, *The Antecedents of Man* (Le Gros Clark, 1959). Not only did Le Gros Clark promote the arboreal theory, he argued that the key to the success of primates was that they remained fundamentally unspecialized anatomically, the retention of a generalized, behaviorally adaptable skeleton serving as a better vehicle for the big brains of primates than the behaviorally limiting, specialized body forms evolved by terrestrial mammals. Thus, rather than being defined by a set of morphological specializations, primates were to be defined by a set of adaptive trends set in motion by an early commitment to arboreality: progressive enhancement of vision, reduction of olfaction, enlargement of the brain, and increasing intelligence. With respect to the brain, Le Gros Clark argued that as it became enlarged, the differences between regions became more sharply defined; however, the increased differentiation reflected the refinement of structural characteristics already present in more primitive forms rather the addition of new structural elements. This stance distinguishes Le Gros Clark from some other early neuroanatomists, notably Brodmann (1909), who believed that the greater histological differentiation of anthropoid and human cortex compared to other mammals represented the addition of new organs of mental function (Preuss, 1993).

Le Gros Clark also advanced a particular view of primate relationships and evolutionary history that proved extremely influential. He viewed primates as progressing through a series of ascending steps or grades reflecting the extent to which animals had

progressed along the adaptive trajectory initiated by arboreality, each grade being represented by some currently living forms. Arising from an ancestral insectivoran stock, the most primitive grade is represented by tree shrews, with lemurs, tarsiers, monkeys, apes, and humans representing successively higher evolutionary grades. Le Gros Clark did not think that humans are actually derived from modern lemurs, monkeys, or apes, of course, but rather that the modern forms have departed little from the ancient forms from which humans are descended. His inclusion of tree shrews among primates was controversial, although it enjoyed the support of the prominent paleontologist G. G. Simpson, and modern workers reject this view for reasons to be explained below.

The work of Le Gros Clark had a large impact on neuroscience. In part, this was because Le Gros Clark was himself an important neuroanatomist and had much to say about brain evolution. Perhaps more significant, however, was his treatment of the different groups of living primates as representatives of the stages of primate and human evolution. This led neuroscientists to bring insectivores (such as hedgehogs), tree shrews, and bush babies into the laboratory for study, particularly by Irving Diamond (Diamond and Hall, 1969; see also Hodos and Campbell, 1969). Diamond trained many students and had a strong hand in shaping modern comparative neuroscience. Le Gros Clark's impact is also apparent in the work of Heinz Stephan and his associates (Stephan and Andy, 1969) on evolutionary changes in the sizes of brain structures in primate evolution, who used hedgehogs and other supposedly 'basal' insectivores as stand-ins for the initial stage of primate evolution, tree shrews and other supposedly 'advanced' insectivores as stand-ins for the next higher stage, the living prosimians as representatives of the next stage, and so forth. Although the evolutionary concepts that inspired the work of Diamond, Stephan, and their colleagues are now considered to be flawed, the data generated remain invaluable.

4.01.2.2.2 Modern ideas about primate origins The 1960s and 1970s witnessed the emergence of a new movement in evolutionary biology, initiated by the writings of Willi Hennig (especially Hennig, 1966), and usually referred to as 'cladism'. Cladism comprises a set of methods for reconstructing the phyletic relationships of species based on comparative studies of their characteristics, and a set of rules for classifying organisms based on these relationships. (Not all who subscribe to cladistic ideas about reconstructing phylogeny adhere to these rules of classification.) The basic goal of a cladistic analysis is to identify groups of species that constitute the complete set of species descended from a common ancestral species; these groups are described as being 'monophyletic' and are called 'clades'. A clade is, simply, any complete branch of the evolutionary tree, complete with subsidiary branches. Cladistic analysis leads to the enumeration of sets of features of the last common ancestor (LCA) of a monophyletic group that distinguish that ancestor (and its descendants) from other taxa. These features are referred to as 'shared derived characters' or 'synapomorphies'. These are the features that define the group. Of course, the species making up the group will have many other features that arose much earlier in evolution and that are shared with a wide array of other species, but these features are not helpful for determining the relationships of the group with its close relatives. So, for example, the fact that primates and carnivores both have hair says nothing about whether or not carnivores are close relatives of primates, because hair is an ancestral feature of mammals and is present in most living mammalian forms. Cladism, then, inspires efforts to identify the set of shared, derived characters that define monophyletic groups (clades) and requires workers to grapple with the issue of whether characters shared by different groups of animals are shared by virtue of common descent, and thus should be considered synapomorphies, or as the result of independent, convergent evolution, and thus of no value in determining relationships (although convergence can be very helpful in understanding how organisms adapt to particular environmental circumstances).

With the rise of cladism, Le Gros Clark's approach to primate evolution became passé, his focus on grades giving way to an emphasis on identifying sets of characters that could serve as defining features of the primate clade and its subclades. This approach was explicitly adopted by Robert Martin and is now an accepted part of evolutionary primatology (see especially Martin, 1990, and the contributions in Ravosa and Dagosto, 2006). A survey of generally accepted primate synapomorphies would include: a divergent (grasping) big toe (hallux) and possibly also a grasping thumb; the presence of flat nails, rather than claws, on at least some digits; the presence of a complete ring of bone around the eye (i.e., a 'postorbital bar'); large, forward-facing eyes; brain enlargement; reduction of the olfactory apparatus; and enlargement of the visual apparatus.

One consequence of defining primates in this way was to remove tree shrews from the order

(see Martin, 1990, and the contributions in Luckett, 1980). Not only do tree shrews lack many of the defining anatomical characteristics of primates, but some of the ways in which tree shrews resemble primates, for example, the presence of an enlarged visual apparatus and of a complete orbital ring, came to be judged as convergences not relevant to common ancestry. Comparative studies of the nervous system have revealed many other ways in which tree shrews differ from undisputed primates (see especially the reviews of Campbell, 1980, and Kaas and Preuss, 1993).

Once one is focused on the character states that define a group, it is natural to try to reconstruct the anatomy and behavior of the LCA of the group and to ask why the defining features of the group evolved. The modern project of framing adaptive explanations of primate origins begins with the work of Cartmill (1972, 1974b) and Martin (1973) and continues today (for major reviews, see Martin, 1990; Cartmill, 1992; and the contributions in Ravosa and Dagosto, 2006). This led to a major re-evaluation of the arboreal hypothesis. By the 1970s, it was appreciated that the earliest primates were anatomically similar to some of the smaller-bodied living prosimians, such as the smaller bush babies (genus *Galago*), mouse and dwarf lemurs (*Microcebus*, *Cheirogaleus*), and tarsiers (*Tarsius*). Examination of their behavior suggests why primates have opposable first digits, and digits tipped with nails, rather than claws: animals such as *Galago* and *Microcebus* make their living in a particular kind of arboreal environment, specifically, in the fine, terminal branches of trees and shrubs (Charles-Dominique, 1977). Claws are of less utility for grasping fine branches than are opposable thumbs and big toes, and nails would provide support for the broad terminal segments for digital grasping. This, in brief, is the 'fine-branch niche' hypothesis (Martin, 1990).

Classically, the convergent, front-facing orbits of primates were explained as adaptations for binocular overlap and stereopsis, presumably required for safe arboreal locomotion. As Cartmill noted, however, there are many arboreal mammals (e.g., squirrels), that manage quite well in an arboreal environment despite having eyes on the sides of the head. Cartmill pointed out that living vertebrates such as raptors and cats that have convergent eyes tend to be predators. Recognizing that many of extant, small-bodied prosimians make their living at least in part by capturing insects and small vertebrates, often grabbing them with their hands, Cartmill proposed that the large, convergent eyes of primates are adaptations for predation, with stereoscopic vision enabling an accurate hand grab. Allman (1977) and Pettigrew (1978) helped flesh out this theory by suggesting that front-facing eyes might have less to do with stereoscopic vision than with establishing a direct light path between objects in the environment and the central retina, resulting in a sharper image. This advantage would be accentuated in a nocturnal environment.

Combining the arguments discussed above, we have a picture of the primate LCA as a small-bodied, nocturnal predator foraging in a fine-branched niche. This constitutes a sort of working hypothesis that frames modern research on primate origins. One matter of controversy is the relative importance of predation in shaping primate anatomy and behavior. Sussman, for example, has emphasized the importance of foraging for fruit and/or flowers – both available in terminal branches – in selecting for the grasping extremities of primates (Sussman and Raven, 1978; Sussman, 1991). Recent paleontological evidence suggests that the defining characteristics of primates did not emerge as a unitary adaptive package, but rather that grasping extremities evolved prior to orbital convergence (Bloch and Boyer, 2002).

4.01.2.2.3 Primates among mammals: Grandorder Archonta In order to understand primate specializations, it is necessary to reconstruct the ancestral condition from which the specializations evolved. In phylogenetics, one reconstructs ancestral organization by 'out group' analysis, that is, by studying the animals most closely related to the in-group. To understand primate specializations, then, we need to know who primates are related to. Recall that in the work of Le Gros Clark and G. G. Simpson, primates were regarded as emerging from an insectivoran stock. Indeed, for much of the twentieth century, insectivores such as hedgehogs and shrews were regarded as the wellspring from which all eutherian orders emerged, with the result that mammalian evolution was depicted as more like a bush than a tree. Not everyone took this view, however: early in the twentieth century, W. K. Gregory proposed that primates did not simply emerge from a generalized insectivore form, but instead were part of a small set of related mammalian taxa consisting of elephant shrews, tree shrews, bats, and the so-called 'flying lemurs', who are not lemurs at all but rather small animals adapted for gliding. He called this collection of primates and related mammals the grandorder Archonta (Gregory, 1910).

As cladism began to exert its influence, Gregory's ideas were resurrected by a number of workers, notably McKenna (1975). McKenna modified

Gregory's concept of a grandorder Archonta to consist of primates (order Primates), bats (order Chiroptera), flying lemurs (order Dermoptera), and tree shrews (order Scandentia). Subsequent research marshaled comparative data on many aspects of the biological organization of primates and their putative relatives, including skeletal anatomy, soft-tissue anatomy, and molecular biology, with the result that the Archonta concept is now widely endorsed (MacPhee, 1993; Ravosa and Dagosto, 2006). Despite this, there has been considerable wrangling over the pattern of interrelationships among the putative archontans as well as disagreements about which taxa should be included in Archonta. Some argued that bats were not a natural, monophyletic group and that only one group of bats, the megachiropterans, are closely related to primates, and are, indeed, the sister group of primates (Pettigrew, 1986; Pettigrew *et al.*, 1989). This is the 'flying primate hypothesis', which has spurred much debate (MacPhee, 1993).

Recently, comparative genomic studies were undertaken by O'Brien and colleagues with the goal of settling the question of how the different mammalian orders are interrelated (Murphy *et al.*, 2001a, 2001b). They examined 18 homologous DNA sequences from a wide array of mammals, drawn from genomic databases, and reconstructed the mammalian branching order using maximum-likelihood and Bayesian techniques (Figure 1b). It is perhaps too soon to conclude that these studies have settled all the really significant questions about mammalian relationships, but they have important implications for students of primate evolution. In particular, they support a modified version of the Archonta hypothesis. Interestingly, although their results support the monophyly of bats, they indicate that bats are distantly related to primates, and cannot be considered archontans, which in their system consist of primates, tree shrews, and flying lemurs. In addition, their results indicate that the rodents and lagomorphs form a monophyletic group (superorder Glires), which may be the sister group of the Archonta. Collectively, the clade consisting of Archonta (now also known as Euarchonta) plus Glires is referred to as Euarchontoglires.

4.01.2.2.4 Haplorhine/anthropoid origins and hominin origins In principle, any subsidiary branch of the evolutionary tree of primates can be subjected to the sort of analysis that has been applied to the tree as a whole, that is, to identify the shared, derived characters that define the group and to develop and test adaptive accounts to explain the evolution of those characters. Much effort has been devoted to exploring the origins of the haplorhine anthropoid primates (for reviews, see The Role of Vision in the Origin and Evolution of Primates and the contributions in Ross and Kay, 2004a). Among the derived features of haplorhines and anthropoids are several specializations of the eye: tarsiers and anthropoids possess a true avascular fovea and they lack the reflecting tapetum lucidum (presumably an adaptation for nocturnal vision) found in strepsirhines. In anthropoids, the eye is isolated in a bony cup that may help to stabilize the image on the retina and the concentration of cones in the central retina is much higher than in strepsirhines. These changes, plus the fact that all living anthropoids save *Aotus* are diurnal, suggest an early shift to diurnality in stem anthropoids and concomitant specializations for high-acuity vision under daylight conditions. The olfactory apparatus is reduced in haplorhines compared to strepsirhines. Anthropoids also tend to be larger bodied than strepsirhines and live in larger social groups, consisting of multiple adults. Early anthropoids known from the fossil record, however, were very small, suggesting that increased body size evolved after the emergence of stem anthropoids. The larger size of anthropoids implies dietary changes, as larger-bodied primates tend to meet their protein needs by consuming leaves more than insects. The masticatory apparatus of anthropoids is more robust than that of strepsirhines, which makes it possible for them to include harder food items (such as unripe fruit) in their diet.

An evolutionary scenario that has been proposed to account for these features of anthropoids holds that the earliest (stem) haplorhines were small, diurnal predators, which selected for high visual acuity, with later stem anthropoids evolving increased body size and increased amounts of plant material in the diet (Ross and Kay, 2004b). Increases in social group size may have evolved early: some early fossil species have sexually dimorphic canines, which suggests the existence of male–male intragroup competition. In this scenario, tarsiers are seen as an early offshoot of the lineage leading to anthropoids, in part because their visual systems share certain features of anthropoids, such as the presence of a fovea and the absence of a tapetum lucidum. The living tarsiers are also obligate small-animal predators. Although living tarsiers are nocturnal, they are thought to derive from diurnal ancestors. The scenario holds that although extant tarsier species are nocturnal, they evolved from a diurnal ancestor, resulting in loss of the tapetum lucidum, and have adapted to nocturnality by evolving enormous eyes, much as owl monkeys did.

Among anthropoids, the clade that has received the most attention with regard to its origins and adaptations is of course that consisting of humans and their close relatives. Humans (*Homo sapiens*) are a recent offshoot of the African apes, the branching date being 5–10 Mya (Fleagle, 1999). Our closest relatives are a clade consisting of the common chimpanzee (*Pan troglodytes*) and the bonobo (*Pan paniscus*), followed by gorillas (*Gorilla gorilla*). Traditionally, species connected to the branch leading to humans after its split from the African apes were classified as members of the family Hominidae, or colloquially, as 'hominids', and the domain of human origins was referred to under the rubric of 'hominid evolution'. The recent recognition of the propinquity of humans to the apes has led to the expansion of the category Hominidae to include the great apes and humans, and the expansion of the subfamily Homininae to African apes and humans. As a result, the branch leading uniquely to modern humans is usually classified today at the tribe level (a tribe being a sub-subfamily). Humans, therefore, belong to the tribe Hominini, and the study of human origins is referred to as 'hominin evolution' (see The Hominin Fossil Record and the Emergence of the Modern Human Central Nervous System).

We are fortunate to have an extensive physical record of human origins; this permits us to document evolutionary increases in hominin brain size from the study of fossils (see The Hominin Fossil Record and the Emergence of the Modern Human Central Nervous System) and behavioral changes from the archeological record. Hominins underwent a fantastic increase in brain size – modern human brains are approximately three times larger in volume than those of chimpanzees – and the fossil record indicates that most of the increase in brain volume took place during the last 2 million years. By contrast, bipedalism, that peculiar way humans have of getting around in the world, appeared much earlier in hominin evolution.

After many decades of focusing on the similarities between humans and apes, students of cognition have recently begun to appreciate the many respects in which humans are specialized relative to our ape cousins. Humans, of course, have a unique and highly developed system of symbolic representation and communication – language (see The Evolution of Language Systems in the Human Brain). The evolution of language may well be related to the extreme degree of hemispheric asymmetry exhibited by humans (see Nuclear Schizophrenic Symptoms as the Key to the Evolution of the Human Brain), although language is by no means the only function that is strongly lateralized in humans (see The Evolution of Hemispheric Specializations of the Human Brain). Recent research points to the existence of a variety of additional higher-order cognitive systems that mediate our understanding of the physical interactions of objects and the our inferences about the causes and mechanisms of the behavior of other organisms, and of ourselves (see Neurological Specializations for Manual Gesture and Tool Use in Humans, The Evolution of Human Emotion, Human Cognitive Specializations). The human propensity to concoct narrative accounts of events, and to maintain them even in face of contrary evidence (see The Interpreter in Human Psychology), would seem to reflect the interaction of the language system with systems for representing causation. Human cognitive specializations can in many instances be viewed as components of a broader human adaptation for culture, permitting individual humans to acquire the know-how, ideas, and values of their community, and making it possible for communities to adapt to an extraordinary variety of environmental conditions (Richerson and Boyd, 2005).

4.01.3 Topics and Issues in Primate Brain Evolution

4.01.3.1 Encephalization and Gross Morphology

We think of primates as being highly encephalized creatures. This is true of modern anthropoid primates, which are about twice as encephalized as 'average' modern mammals (Jerison, 1973). Modern strepsirhines, however, are not notably encephalized compared to other extant mammalian groups. Nevertheless, there is reason to think that brain size expansion was an early feature of primate evolution. As with other groups of mammals, notably carnivores, ungulates, and cetaceans, the order Primates underwent expansion of the brain relative to body size (encephalization) throughout its history (Jerison, 1973). At any given time period in the Cenozoic, however, primates appear to have been more encephalized than most of their contemporaries (Jerison, 1973). This was the case even early in the Cenozoic, prior to the diversification of the anthropoids. Moreover, Sacher (1982) argued that primates (including strepsirhines) commit a disproportionately large fraction of metabolic resources to brain growth in early development, so that at birth, primate brains are about 12% of total body size, compared to about 6% for most other mammalian orders.

Just as relative brain size increased independently in different mammalian orders, it is likely that there was some degree of independent encephalization among primate groups. Early primates from the Eocene (~55–34 Mya) that resemble modern strepsirhines in many features of anatomy were substantially less encephalized than modern strepsirhines. Early anthropoids may also have been less encephalized than modern anthropoids. For example, it has been argued that *Aegyptopithecus*, dated to about 33 Mya and generally accepted to be a catarrhine, had a brain about half the size of modern catarrhines of similar body size (Jerison, 1979). This suggests that although relative brain sizes are similar in New World and Old World anthropoids, some brain-size enlargement occurred independently in the two groups.

Primate brains are not simply uniformly enlarged versions of some common mammalian brain – particular regions, such as the neocortex, underwent disproportionate enlargement. The quantitative neuroanatomical studies of Stephan and colleagues, alluded to above, have documented differences in the sizes of brain components across a substantial range of primate and insectivoran species (Stephan and Andy, 1969; Stephan, 1972; Stephan *et al*., 1988), and their data set has been widely used to generate and test hypotheses about primate evolution. Unfortunately, however, most of the brain structures they measured are too large (e.g., neocortex, cerebellum) to correspond to meaningful functional units of the brains. Moreover, structures can undergo substantial modifications of internal organization without undergoing substantial size change. For example, the absolute size of the primary visual area is similar in humans and chimpanzees (Frahm *et al*., 1984), but the internal organization of the area is quite different in certain respects (Preuss and Coleman, 2002). Nevertheless, it is possible to say something about the relationship between the enlargement of particular brain regions in primate evolution and the evolution of the external form of primate brains.

The external morphology of primate brains reflects, to a considerable degree, the degree and pattern of enlargement of the visual cortex, which involved the expansion of the primary visual area, area V1 (an area common to most, if not all, other mammals), as well as the addition of new areas (see especially, Allman, 1977, 1982, 1999; Kass, 1977, 1982, 1987). In most strepsirhines and haplorhines, the cortex devoted largely or exclusively to the visual modality encompasses approximately half the cortical mantle (Allman, 1977, 1982). The expansion of area V1 was probably accompanied by the evolution of a distinctive sulcal configuration, the triradiate calcarine fissure, which consists of a retrocalcarine sulcus (the familiar 'calcarine fissure' of the neuroscientific literature) and ascending and descending branches expending from the anterior end of the retrocalcarine (Martin, 1990). This triradiate configuration is found in most living primates (Martin, 1990) and was probably present in early primates.

Expansion of the visual cortex is also reflected dramatically in the unusual morphologies of primate temporal lobes. In most extant strepsirhines and anthropoids, the temporal lobe forms a distinct ventral island of cortex, demarcated from the frontal and parietal lobes by a deep lateral (Sylvian) fissure. Much of the temporal lobe consists of visual cortex (the inferotemporal cortex) and multimodal cortex with major visual inputs (the superior temporal sulcal (STS) cortex). The inferotemporal and multimodal STS regions appear to be neomorphic in primates (Preuss and Kaas, 1999; Preuss, 2006). The ventral expansion of visual cortex influenced the morphology of adjacent regions. In most mammals, the hippocampus and associated tissues form an arc around the posterior end of the corpus callosum, whereas in strepsirhine and haplorhine primates, the hippocampus has a more inferior location, as though the temporal lobe in which it resides were rotated around the posterior pole of the callosum. The orientation of auditory cortex, located superiorly in the temporal lobe, appears to reflect the torque of the temporal lobe; in most mammals, the map of auditory frequencies in the primary auditory area (A1) is arranged with high frequencies anteriorly and low frequencies posteriorly, whereas in primates, high frequencies are represented in the superior and posterior part of A1 and low frequencies inferoanteriorly (Stiebler *et al*., 1997).

Although the visual cortex evidently underwent early expansion, it has been argued that the frontal lobe initially remained quite small, undergoing major expansion only later in primate evolution (Radinsky, 1970; Jerison, 1973; Gurche, 1982). Judgments of frontal lobe size depend, however, on how you determine the border between frontal lobe and its neighbors on the lateral surface, the parietal and temporal lobes, and this is not as simple a matter as one might suppose. In most anthropoid primates, there is a deep central sulcus that separates the frontal and parietal lobes. Tarsiers and most strepsirhines lack a central sulcus, however, and it is typically not apparent in the endocasts of early primates (Radinsky, 1970; Gurche, 1982), so the frontal–parietal boundary cannot be determined with any precision in the endocasts. We should therefore be cautious in drawing conclusions about

the size of the frontal lobe relative to other cortical regions in early primates.

Identifying the frontal–temporal boundary would seem to a more straightforward affair: in most modern strepsirhine and anthropoid primates, a deep Sylvian fissure divides the temporal lobe from the frontal and temporal lobes. Some of the endocasts of early primates, such as the specimen of the lemur-like *Adapis* illustrated by Radinsky (1970) and by Gurche (1982), also preserve an impression that is plausibly interpreted as a Sylvian fissure. Thus, it is tempting to conclude that the presence of a Sylvian fissure is an ancestral feature of primate organization.

Nevertheless, Sylvian fissure is evidently not, a feature of all primates, living and extinct. Tarsiers, for example, lack a Sylvian fissure (Le Gros Clark, 1959; Collins *et al*., 2005), so that the insular cortex, which is buried in the depths of the Sylvian fissure in most primates, is exposed on the surface of the tarsier brain (Woolard, 1925). The exposed insular cortex and adjacent portions of frontoparietal cortex appear to form a nearly vertical ridge where they join the remainder of frontal cortex. Le Gros Clark (1959) suggested that the peculiar morphology of tarsier brains results from the enormous enlargement of the orbits in these animals, effectively indenting the ventral portion of the frontal lobe and anterior portion of the temporal lobe. The morphology of tarsiers, however, may not be unique among primates: illustrations of endocasts of extinct primates from the Eocene show a diversity of sulcal patterns (Radinsky, 1970; Jerison, 1973; Gurche, 1982), some with typical Sylvian fissures and some that could have morphologies more like those of extant tarsiers. Moreover, the extant lemur *Daubentonia* (the aye-aye) also appears to lack a typical Sylvian fissure (Kaufman *et al*., 2005; Le Gros Clark, 1959), and the sulci that are present seem rather shallow for a brain of its size (Kaufman *et al*., 2005). Thus, we should probably be cautious in ascribing to the LCA of primates a Sylvian fissure morphology like that found in most extant primates.

A number of additional sulci have been described in primate brains. Primates, like other mammals, possess a rhinal fissure, which separates the hippocampal and entorhinal cortex from neocortex. Most primates possess a cingulate sulcus on the medial wall superior to the corpus callosum, although in smaller primates this may be just a shallow groove. Many extant strepsirhines possess on the lateral surface of the hemisphere an elongated, anteroposteriorly situated groove, termed the coronolateral sulcus (Radinsky, 1975), which in smaller-brained forms may be broken up into two or three segments, that have been termed from posterior to anterior, the intraparietal sulcus (IPS), sulcus e, and sulcus rectus (Connolly, 1950; Haines *et al*., 1974). The sulcus rectus, a term which has also been applied to the principal sulcus (PS) of Old World monkeys (Falk, 1978, 1982), has also been referred to as sulcus frontalis in lemurs (Brodmann, 1905, 1909). The use of the terms 'intraparietal sulcus' and 'sulcus rectus' (or 'principal sulcus') suggests that the cortical areas within which these grooves are found in strepsirhines are homologous to the areas within which the corresponding grooves are found in anthropoids, and specifically in Old World monkeys. Caution is in order, once again: Preuss and Goldman-Rakic (1991c), in their studies of frontal lobe organization in *Otolemur* (formally *Galago*) *crassicaduatus*, argued that the sulcus rectus marks the border between premotor and granular prefrontal cortex, and thus differs from the PS of macaques, which lies entirely within prefrontal cortex. Similarly, they noted that whereas the IPS of macaques separates area 7 and its subdivisions from area 5, the IPS of *Otolemur* lay entirely within the territory of area 7 (Preuss and Goldman-Rakic, 1991a). Thus, inferences about the areal organization of the cortex of different primates based on the configurations of sulci are problematic, especially when comparing relatively distantly related taxa such as *Macaca* and *Otolemur*.

4.01.3.2 Chemical Senses

Whereas primates are characterized by a well-developed visual system, evolution of the chemical senses mainly involved reductions or degradative changes (Figure 2). Evolutionary reductions are especially notable in the main and accessory olfactory systems, changes that were, however, probably concentrated in haplorhine or anthropoid phylogeny. By contrast to haplorhines, strepsirhines have comparatively well-developed olfactory systems, and it is likely that they retain many features shared with other mammalian groups. Unfortunately, we have very little modern information about the olfactory systems of the taxa most closely related to primates.

Evolutionary changes in the olfactory systems in primates were accompanied by changes in the anatomy of the primate face. Most mammals possess two distinct olfactory systems: a main system, with receptors in the epithelium of the nose, and an accessory system, with receptors located in a specialized zone of epithelium buried within the upper jaw known as the vomeronasal organ (VNO; also known as Jacobson's organ) (Martin, 1990). The

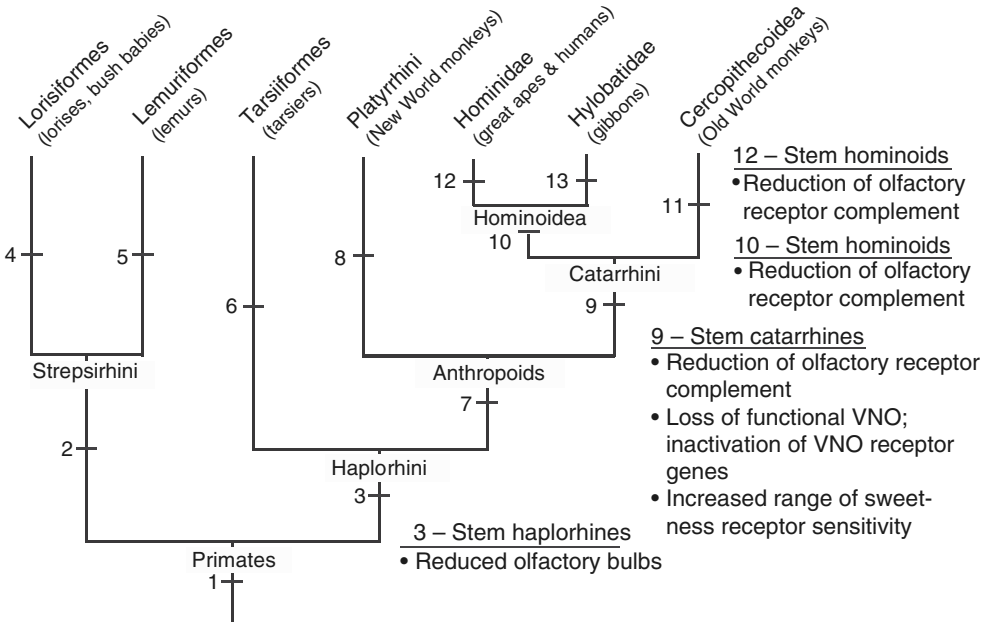

Figure 2 Evolutionary changes in the portions of the central nervous system devoted to the chemical senses. In this and following figures, characters interpreted as derived are mapped onto specific segments of the primate tree; the segments are numbered to facilitate comparisons across figures.

accessory olfactory system is usually thought to be involved principally in the detection of pheromones. In most mammals, there is a physical connection between the two olfactory systems. Most mammals have a naked, glandular external nasal membrane – a wet nose, in other words. This membrane extends down to the mouth where it is anchored to the soft tissue of the upper jaw. Some mammals (including strepsirhine primates) have a well-developed median cleft extending from the external nose to the space between the upper incisors. Ducts in the anterior palate allow passage of liquid from external nasal membrane to Jacobson's organ. Ducts also interconnect Jacobson's organ with the nasal cavity, superiorly.

Although the familiar haplorhine/anthropoid primates lack an exposed rhinarium of the type just described, the living strepsirhine primates exhibit this ancestral mammalian condition. The retention of ancestral nasal morphology in strepsirhines is accompanied by a generally well-developed central olfactory systems: compared to haplorhines, the main olfactory bulbs are quite large (Stephan *et al.*, 1988). The VNO and accessory olfactory bulbs are present, consistent with the apparent importance of pheromonal communication in extant strepsirhine primates (Charles-Dominique, 1977).

The VNO, however, underwent dramatic changes in anthropoid evolution. New World monkeys evidently possess functional VNOs, but they appear to be greatly reduced in Old World anthropoids, to the point of being vestigial (hominoids) or absent (in Old World monkeys) (see The Vomeronasal Organ and Its Evolutionary Loss in Catarrhine Primates). This doesn't necessarily imply that pheromonal communication is absent in Old World anthropoids, as it is possible that pheromones can be detected by receptors of the main olfactory system (Wysocki and Preti, 2004).

Information from olfactory receptors in the nasal epithelium reaches the brain through projections to the olfactory bulbs, which project in turn to the thalamus, amygdala, and ultimately to portions of the orbital and insular cortex. Taste inputs are relayed through the brainstem and thalamus, from which they also reach orbito-insular cortex. We know relatively little about evolutionary changes in the central pathways or structures representing the chemical senses in primates. One change that is well documented, however, is the evolutionary reduction in the size of the olfactory bulb in haplorhines: by comparison to haplorhines, the olfactory bulbs of strepsirhines are enormous (Stephan and Andy, 1969; Stephan, 1972; Stephan *et al.*, 1988). The olfactory systems of strepsirhines are clearly more conservative than those of haplorhines.

The sequencing of the genomes of a variety of mammalian species has spurred comparative studies of olfactory receptor (OR) and VNO receptor genes. These make ideal subjects for comparative

genomics, because mammals possess more than 1000 different OR genes, comprising multiple gene families, and on the order of about 250 VNO receptor genes. These investigations indicate that changes in olfactory and VNO receptor genes parallel the morphological changes described above. The morphological reduction of the olfactory system was accompanied by the accumulation of mutations that transformed functional OR genes into pseudogenes (see The Loss of Olfactory Receptor Genes in Human Evolution). The fraction of OR genes that is nonfunctional is higher in Old World monkeys than New World monkeys, higher still in hominoids, and highest in humans, among the hominoids that have been examined (Rouquier *et al*., 2000; Gilad *et al*., 2004). In humans, more than 50% of the OR genes have mutations that should render them nonfunctional (Gilad *et al*., 2005). This suggests a relaxation of selection pressures on OR genes in catarrhine primates, at least. Despite this, there is also evidence for positive selection in certain subsets of OR genes, even in humans (Gilad *et al*., 2005). Similar to the situation in the olfactory system, the morphological diminution or loss of the VNO in catarrhines was accompanied by the fixation of mutations that render inactive the *TRPC2* and *V1R* genes, which code for proteins essential for transducing signals from VNO receptors (see The Vomeronasal Organ and Its Evolutionary Loss in Catarrhine Primates; see also Liman and Innan, 2003; Zhang and Webb, 2003).

We know very little about the evolution of taste in primates, although comparative molecular and genetic studies are providing some new insights. In humans, five basic tastes are recognized: sweet, sour, bitter, salty, and umami (a savory flavor) (see The Evolution of the Sweetness Receptor in Primates). The number of taste-receptor genes is evidently much smaller than the number of OR genes. Three genes in the *TAS1R* family are believed to be involved in the perception of sweet and umami, with the protein products of the different gene family members combining to form heterodimers with different sensitivities. Bitter perception is mediated by a set of approximately 25 genes in the *TAS2R* family. The basis of salty and sour perception is poorly understood (Drayna, 2005).

Glaser has investigated the evolution of sweet perception in primates and found that humans and other catarrhines perceive more chemical compounds as being sweet than do other primates. The basis for this increased range of sensitivity reflects modifications of the structure of *TAS1R* receptors rather than the addition of new receptors (see The Evolution of the Sweetness Receptor in Primates).

4.01.3.3 The Visual System

4.01.3.3.1 Eye and retina Ancestral primates are thought to have been nocturnal animals, and the eyes of modern strepsirhine primates, most of which are nocturnal, retain the hallmarks of this heritage. For example, strepsirhines, in contrast to haplorhines, lack a retinal fovea and most strepsirhines have a reflective membrane, the tapetum lucidum, that is found in many nocturnal mammals and presumably enhances vision under low-light conditions (Figure 3). The tapetum is absent in some modern diurnal lemurs (Martin, 1990). The complement of photoreceptor cells in strepsirhine primates is also typical of nocturnal mammals: in addition to rods, which respond to light over a broad spectrum of wavelengths, strepsirhines have two varieties of cones, which respond to short-wavelength light (S cones) and medium- to long-wavelength light (M/L cones). Most nonprimate mammals that have been examined also have two-cone systems (Jacobs, 1993). Interestingly, mutations of the gene coding for the S-cone visual pigment have rendered this gene nonfunctional in the lorisiform (loris–bush baby) group of strepsirhines, which are nocturnal, and also in the nocturnal New World owl monkey, *Aotus* (Jacobs *et al*., 1996a; Kawamura and Kubotera, 2004). Although lacking a fovea, strepsirhines do possess a central specialization with a high density of photoreceptors, so that visual acuity is greatest in the central part of the visual field. The central specialization is populated by small rods and cones. In contrast to anthropoids, in which rods and cones are distinguishable by the morphology of their outer segments, strepsirhine rods and cones are similar in appearance and the existence of cones in strepsirhines was not definitively demonstrated until antibodies for cone-specific opsins were developed (Wikler and Rakic, 1990).

The eyes of tarsiers and of anthropoids differ markedly from those of strepsirhine primates. As both taxa lack a tapetum lucidum, this was probably lost prior to the tarsier–anthropoid divergence. A fovea is present in *Tarsius* and in anthropoids, and presumably evolved in stem haplorhines (Ross, 2004) although the density of retinal ganglion cells (the cells that transmit visual information to the brain) in the tarsier fovea is more typical of a nocturnal strepsirhine than a diurnal anthropoid (Collins *et al*., 2005). Tarsier foveae contain both rods and cones (Hendrickson *et al*., 2000), whereas the central retina (containing the fovea) of diurnal anthropoids is populated by small cones to the virtual exclusion of rods.

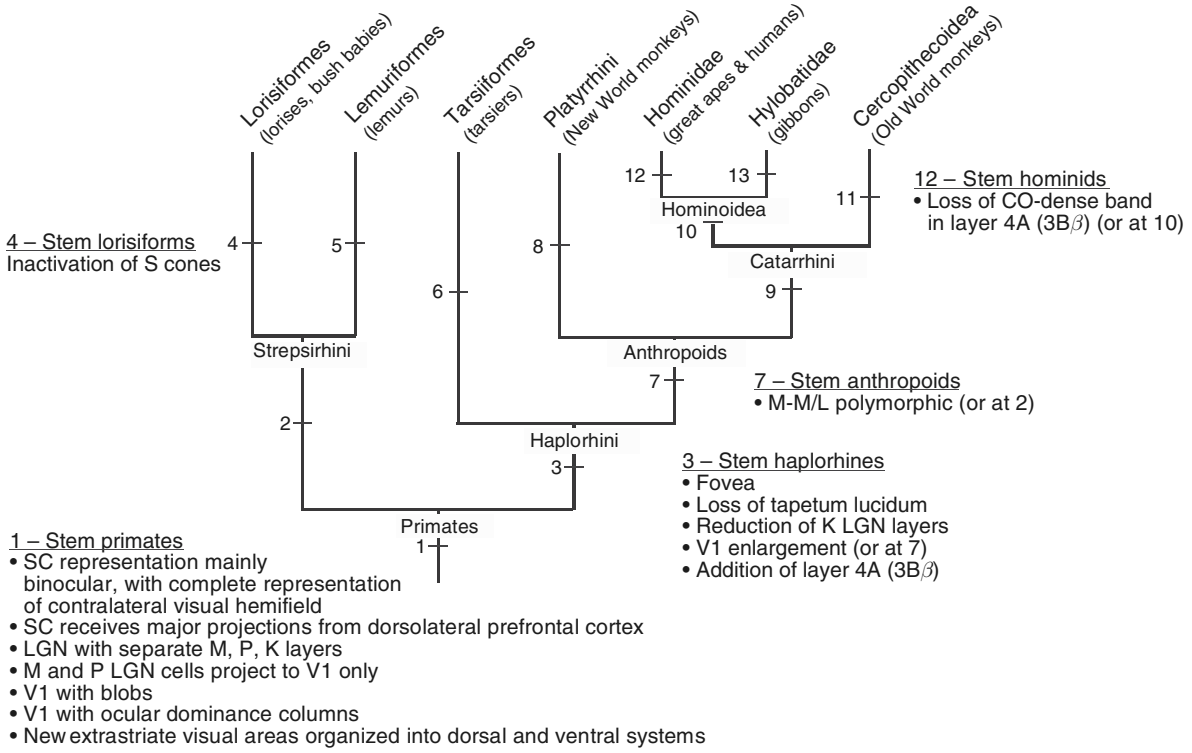

Figure 3 Interpretation of the shared derived features of the visual system in primates and major primate subgroups. For more details of the visual system specializations of hominoids, see Preuss and Coleman (2002) and Preuss (2004a).

The ancestral cone complement of haplorhines was most likely a two-cone system (Heesy and Ross, 2001), although it may have been a polymorphic system with some individuals having two cones and other individuals having three (Tan and Li, 1999). Most New World monkeys have only a single M/L gene, located on the X chromosome, but there are different alleles for this gene, each allele producing a protein with a different spectral sensitivity. Thus, most New World monkey populations are polymorphic for cone opsins, and because the M/L alleles are located on the X chromosome, many females have two different M/L alleles. These individuals are psychophysically trichromatic (see The Comparative Biology of Photopigments and Color Vision in Primates). Catarrhine primates have a three-cone system, the ancestral M/L opsin gene having duplicated to yield different M and L genes, both located on the X chromosome. (A similar event occurred independently in the New World howler monkeys, *Alouatta* spp.; Jacobs *et al.*, 1996b). Extant tarsier species have two-cone systems, but there is sufficient variation in the M/L genes of different tarsier species to prompt the suggestion that the ancestral condition for tarsiers (and thus for haplorhines, given the situation in New World monkeys), was polymorphic (Tan and Li, 1999).

The recent appreciation that many nocturnal primates have functional cones has had a substantial impact on thinking about color vision and its role in primate evolution. For one, it is now quite common to see primates referred to as 'trichromats', 'dichromats', or 'monochromats', based on their complement of cone pigments. For another, the likely existence of a two-cone system in ancestral primates is regarded by some as being incompatible with the claim that the primate LCA was nocturnal (Tan *et al.*, 2005). The latter conclusion would seem to assume that the function of cones is to permit color discrimination of the sort anthropoid primates are capable of. Anthropoid color discrimination certainly requires conditions of high illumination, so that color discrimination is essentially lost under nocturnal conditions. The relationship between cone types and color perception is by no means direct, however. So, for example, the ability to discriminate green and red in catarrhine primates is not simply a consequence of the fact that catarrhines have dedicated green and red photoreceptors. Although it is tempting to think of the M and L receptors as green and red receptors, in fact, the sensitivity peaks of the M and L pigments are about 530 and 560 nm, respectively, which correspond to the green and yellow-green parts of the visible

spectrum. The discrimination of red and green depends on the opponent (subtractive) interactions in the retina between M and L cones. These kinds of interactions evidently require high cone densities, such as those which occur in the anthropoid fovea (Dacey, 2000; Callaway, 2005). Yet anthropoids have cones in the retinal periphery, where they occur at much lower density than in the fovea, and many other mammals, both nocturnal and diurnal, have cones present at low density across the retina. The comparative psychophysical data suggest that nocturnal species have very poor color discriminative abilities, even those that have functioning S and M/L cones (see The Comparative Biology of Photopigments and Color Vision in Primates; Jacobs and Deegan, 2003). Indeed, even diurnal lemurs have very poor color discrimination (Blakeslee and Jacobs, 1985). It seems likely that the cones of most mammals are mainly doing something other than generating color-opponent signals such as those that form the basis for the fine color discrimination of anthropoids, for example, enhancing detection sensitivity in certain parts of the spectrum (e.g., Martin, 1990, p. 303; Winter *et al.*, 2003). It would be useful to have more experimental behavioral data about the vision of strepsirhine primates and nocturnal mammals; genetic, physiological, and anatomical studies of the visual systems of nonhuman species have advanced in recent years, but psychophysical and behavioral studies have not kept pace. We should be very cautious about making inferences about the color-vision capabilities of animals based on the presence or absence of cones expressing particular photopigments. To do so is, in effect, to adopt the anthropoid fovea – as specialized a bit of neural machinery as any we know of – as a general model of the mammalian retina.

4.01.3.3.2 Lateral geniculate nucleus and superior colliculus The retina sends visual information to numerous brainstem structures, of which we will consider only two here, the lateral geniculate nucleus (LGN) and the superior colliculus (SC), both of which underwent important changes in primate origins and evolution. The output from the retina is conveyed by the axons of retinal ganglion cells (RGCs). Currently, three main classes of RGCs are recognized, which in primates are usually termed M, P, and K cells, because they project to the magnocellular, parvocellular, and koniocellular layers of the LGN, respectively. These are probably homologous to the Y-, X-, and W-type cells described in other mammals (see The Evolution of Parallel Visual Pathways in the Brains of Primates). The different types of RGCs convey different types of visual information. At least some of the P-type cells carry color-opponent information, but it is likely that some P-type cells are not color selective and there is evidence that some K-type cells have a special relationship to S cones, so these may be involved in color processing as well (Callaway, 2005).

The LGN is important as a relay for visual information to the cerebral cortex. The structure typically appears to be composed of separate cell laminae, and in primates the lamination is very conspicuous. Moreover, primate LGNs are laminated in distinctive ways (see especially Kaas *et al.*, 1978; Kaas and Preuss, 1993; see The Evolution of Parallel Visual Pathways in the Brains of Primates and citations therein). In most mammals that have been studied in detail, M- and P-like cells are mixed in at least one layer of the LGN. In primates, however, M and P cells are strictly segregated, and there is a pair of M and P layers, one for each eye, yielding a fundamental four-layered pattern. In catarrhines, including humans, the P layers subdivide and interleave, yielding the 'six-layered' pattern described in neuroanatomy textbooks. Strepsirhine primates also have a pair of distinct K layers, sandwiched between the two P layers. In anthropoids, the K cells do not form distinct layers, but rather mainly occupy territories between the M and P layers. The nocturnal owl monkeys are unusual among anthropoids in having a well-developed single K zone located between the outermost M layer and the innermost P layer. Interestingly, tarsiers are reported to resemble anthropoids more than strepsirhines in their pattern of LGN lamination, and like owl monkeys, have a relatively well-developed K zone between the M and P layers (Collins *et al.*, 2005).

The SC occupies the most superior part of the midbrain. It is homologous to the structure referred to as the 'optic tectum' in most vertebrates, a name that reflects the fact that this structure plays an important role in visually guided behavior. The SC is a laminated structure; the upper layers receive visual inputs while the deeper layers receive auditory and somatosensory inputs (Huerta and Harting, 1984). Outputs from the SC descend to motor nuclei in the brainstem, especially those involved in eye movements, while ascending projections target the K layers of the LGN and the inferior pulvinar nucleus of the thalamus. Large regions of the neocortex project to the SC, although primates are distinctive among mammals in having a massive projection to the SC arising from the dorsolateral prefrontal cortex (Preuss, 2006).

Primates are also distinctive in the pattern of retinal projections to the SC. In most mammals, the SC receives its visual inputs mainly from the retina of the contralateral eye, with a small and variable contribution from the ipsilateral retina. In primates, by contrast, the SC receives strong inputs from both retinas, but only from the portion of each retina that represents the contralateral visual field. Thus, each SC in primates contains a 'map' of the contralateral half of visual space, whereas nonprimate SCs represent both contralateral and ipsilateral visual space, since the contralateral retina represents both parts of visual space (Lane *et al.*, 1973). This primate–nonprimate difference is well established (reviewed by Kaas and Preuss, 1993; Preuss, 2006). Pettigrew and colleagues have argued that megachiropteran bats have a primate-like SC, and cite this and other evidence that megachiropteran bats should be considered the sister group of primates (Pettigrew, 1986; Pettigrew *et al.*, 1989). The primate-like character of megachiropteran bats has been disputed (Thiele *et al.*, 1991), and defended (Rosa *et al.*, 1996), but in any event, there is now considerable evidence from comparative genomic studies indicating that megachiropteran bats are not closely related to primates (Murphy *et al.*, 2001b). To the extent that megachiropterans resemble primates, therefore, those similarities are probably the result of evolutionary convergence. Preuss (2006) suggests that the adaptive significance of the primate specialization of SC organization lies in the fact that individual SC neurons receive inputs from both eyes, and speculates that the primate SC uses binocular disparity to make precise adjustments of eye movements and visually guided reaching and grasping movements.

4.01.3.3.3 Primary visual area The principal target of projections from the visual system to the cortex is area V1, also known as area 17 (after Brodmann, 1909) and as the striate area, so-called because of the horizontal stripe of myelin characteristic of this area in primates. Area V1 is present in all mammalian groups that have been studied and is undoubtedly one of the 'heritage' areas that was present in the early mammals (Kaas, 1995). In primates, as in other mammals, visual information reaches area V1 via the LGN and from the pulvinar nucleus of the thalamus (in primates, from the inferior part of the pulvinar, specifically). Notwithstanding these commonalities, primates possess specializations of V1 that distinguish them from other mammals, and there are also prominent differences in V1 organization within the primate order (see The Evolution of Parallel Visual Pathways in the Brains of Primates; Kaas, 1993; Preuss, 2004a, 2006).

One distinctive feature of primate V1 is its pattern of inputs from the LGN (reviewed by Preuss, 2006). Virtually the entire cortical projection of the LGN reaches area V1 exclusively; only the K layers of the LGN project to other, 'extrastriate' cortical visual areas, and those projections are rather weak. In the nonprimates that have been examined, there are major LGN projections to extrastriate areas. The responsiveness of extrastriate cortex to visual stimulation depends more strongly on V1 in primates than in other mammals.

Another distinctive feature of primate V1 is its appearance when stained for cytochrome oxidase (CO), a metabolic enzyme. CO staining reveals a regular, repeating series of dark patches in the upper layers of area V1; these patches are technically known as 'blobs'. Blobs have been described in all strepsirhine and haplorhine primates that have been examined with appropriate histological material (Preuss and Kaas, 1996), including, most recently, tarsiers (Collins *et al.*, 2005). Tree shrews lack blobs, as do representatives of many other mammalian orders that have been examined for blobs (reviewed by Preuss, 2006). Some carnivores exhibit blob-like staining, but because carnivores are not closely related to primates, this is almost certainly a case of convergence (Preuss and Kaas, 1996; Preuss, 2000a). Although blobs are a common feature of primate organization, their connections and functions are matters of debate. Published descriptions of connectivity indicate that blobs receive direct projections from the LGN, including the K layers, but details of these connections differ between studies and there could be genuine species differences (see The Evolution of Parallel Visual Pathways in the Brains of Primates).

The strongest projections to V1 from the LGN in primates, as in most other mammals examined, terminate in the middle levels of cortex, specifically within a stratum of very densely packed small cells (granule cells) designated as cortical layer 4. Projections from the P layers target the deep part of layer 4, whereas projections from the M layers target its more superficial part. Interlaminar connections relay connections from layer 4 to more superficial and to deeper layers of cortex. This pattern of organization is common to the strepsirhine and anthropoid primates that have been examined. Anthropoid primates, however, have elaborated the organization of the upper layers of cortex. In particular, anthropoids possess an additional band of densely packed small cells above layer 4 that is separated from it by a narrow band of larger, more sparsely arranged cells. There are different ways of naming these layers: most workers follow

(Brodmann, 1909) in referring to the upper band of small cells as layer 4A, the sparse band of larger cells as layer 4B, and the deeper, thick band of small cells as layer 4C. Others believe that the bands called 4B and 4A by Brodmann should be considered as subdivisions of layer 3; in this terminology, Brodmann's layer 4A corresponds to layer 3Bβ (see The Evolution of Parallel Visual Pathways in the Brains of Primates). In most New World and Old World monkeys that have been examined, layer 4A/3Bβ receives a direct input from the parvocellular layers of the LGN, and there is a band of dense CO staining coincident with this input. Among New World and Old World monkeys, only *Aotus* is known to lack a direct LGN projection to layer 4A/3Bβ, and it lacks the corresponding CO-dense band, also (Horton, 1984). Although we do not have information about the connectivity of tarsier V1, histologically, the lamination of this area resembles that of anthropoids more than strepsirhines (Collins *et al.*, 2005). We also have virtually no information about the connectivity of area V1 in apes or humans, but its histology differs from that of monkeys: a band of small cells corresponding to layer 4A/3Bβ is present, but it lacks a CO-dense band (Preuss *et al.*, 1999), which suggests that its connectivity differs from that of monkeys. Additionally, layer 4A/3Bβ of humans exhibits histological features that differ markedly from those of apes (Preuss *et al.*, 1999; Preuss and Coleman, 2002). Since area V1 is a major source of visual information for extrastriate visual areas, these species differences in the processing of visual information in V1 could ramify through the cortical visual system.

In primates, the projections of the LGN to layer 4 of area V1 are segregated by eye, forming a set of alternating, elongated ocular dominance columns (Hubel and Wiesel, 1969). Although the degree of ocular segregation in adult individuals varies across species, some degree of ocular segregation has been found in every primate species examined, while ocular dominance is absent in the nonprimate species that have been examined with the exception, again, of carnivores (Horton and Hocking, 1996).

4.01.3.3.4 Extrastriate visual cortex Primates possess a large region of extrastriate visual cortex comprised of multiple, retinotopically organized visual areas (see, for example, Visual Cortex: Evolution of Maps and Mapping and the reviews of Kaas, 1995; Tootell *et al.*, 1996; Rosa, 1999; Orban *et al.*, 2004; Sereno and Tootell, 2005). These have been extensively studied in the New World and Old World monkeys, and to a lesser extent in strepsirhine primates, using microelectrode mapping techniques, tract-tracing experiments, and histochemical (architectonic) methods. Histochemical and functional imaging techniques have recently been applied to the study of extrastriate cortex in humans. From these studies, it is clear that there is a large number of extrastriate visual areas in anthropoids – at least 15 and perhaps many more. The diversity of opinion regarding the numbers of areas reflects in part the application of different criteria for assigning areas to the visual realm – does an area need to be exclusively visual to qualify, or need it only have a prominent visual input? – as well as differing interpretations of experimental data. Within the primate extrastriate cortex, investigators have determined that the extrastriate areas and their interconnections form two broad information processing pathways: a dorsal stream, which begins in V1, traverses the middle temporal (MT) visual area, and ends in the posterior parietal cortex, and a ventral stream, which begins in V1, traverses area V4 (also called the dorsolateral visual area, DL, in New World monkeys), and ends in the inferior temporal (IT) region. These pathways are functionally specialized: the ventral and dorsal pathways have been characterized as the 'what is it' and 'where is it' systems, respectively (Ungerleider and Mishkin, 1982). While recent work supports the idea that the ventral pathway is specialized for the visual identification of objects, it has been argued that the functional specialization of the dorsal pathway pertains to 'vision for action', that is, for organizing eye and hand movements to objects in nearby space (Goodale and Milner, 1992).

Present evidence does not provide a definite indication of differences in the complement of extrastriate areas between Old World and New World monkeys. Moreover, the evidence from humans suggests a pattern of extrastriate organization similar in many important respects to that of Old World and New World monkeys (Orban *et al.*, 2004; Sereno and Tootell, 2005). One might reasonably suppose, however, that anthropoid primates have more visual areas than strepsirhines. For one thing, the evolution of haplorhines and anthropoids was accompanied by the appearance of a fovea and modifications of retinal receptor distribution and circuitry supporting color vision. For another, the visual region makes up a large fraction of the cortical mantle in strepsirhines and haplorhines, but strepsirhines are about half as encephalized as anthropoids. Nevertheless, at present there is no clear evidence that strepsirhines have fewer visual areas than do New World or Old World monkeys. This may reflect the fact that much less effort has been devoted to the study of visual cortex in

strepsirhines than in anthropoids. This said, however, the studies that have been carried out in strepsirhines indicate that they possess many areas in common with anthropoids (e.g., Rosa *et al.*, 1997; Lyon and Kaas, 2002), and there is evidence from histological and connectional studies that the strepsirhine extrastriate region is divisible into dorsal and ventral streams, as in anthropoids (Preuss, 2006). (It would be very valuable to compare the organization of inferotemporal cortex in strepsirhines and in anthropoids, since this region would likely have been affected by the evolution of specializations of foveal vision that characterize anthropoids.) Moreover, cortical enlargement in anthropoids probably reflects in part the increased size of individual areas: area V1, in particular, is much larger in anthropoids than in strepsirhines of similar body size (Frahm *et al.*, 1984).

The organization of primate extrastriate cortex differs markedly from that of nonprimate mammals. Most of the nonprimates that have been studied – including even tree shrews of the genus *Tupaia*, which, as Le Gros Clark emphasized, are diurnal animals with well-developed visual systems – appear to have a small complement of visual areas, with homologues of the first and second visual areas (V1, V2), and perhaps four or five additional areas (Lyon *et al.*, 1998; Rosa, 1999). Certain groups of mammals, notably carnivores, independently evolved large complements of cortical visual areas. It follows, then, that many of the extrastriate areas of primates evolved after the separation of the primate lineage and therefore have no homologues in other mammals. Moreover, the visual areas of nonprimate mammals (even carnivores) do not appear to be comprised of functionally distinct dorsal and ventral streams, as they are in primates (Preuss, 2006).

Although the living primates share many common features of visual cortical organization, there are also differences. The best documented differences involve the intrinsic organization of particular visual areas. As noted above, the layering of area V1 varies markedly across primate taxa. V2 exhibits differences as well: when stained for CO, most anthropoids exhibit well-demarcated thick and thin stripes that extend from the caudal border to the rostral border of V2, while strepsirhines show much less distinct banding (Preuss *et al.*, 1993). The functional consequences of these variations in area V2 organization have not been investigated. Humans also are reported to have indistinct V2 bands (Tootell and Taylor, 1995). There are, in addition, differences in the functional properties of homologous areas between anthropoid primates. For example, area V3 of macaques is more motion sensitive than its homologue in humans, whereas area V3A of humans is more sensitive to motion and contrast than area V3A of macaques (see the reviews in Preuss, 2004a; Visual Cortex: Evolution of Maps and Mapping).

4.01.3.4 Somatosensory and Motor Systems

It is useful to consider the central somatosensory and somatic motor systems together (Figure 4), as they are intimately related structurally and functionally (see the reviews of Kaas and Pons, 1988; Kaas, 2004; see The Evolution of Sensory and Motor Systems in Primates). For example, the fine control of grasping forces is mediated by transcortical processing loops: sensory signals originating in the hands and feet are relayed through the spinal cord to the brainstem, thalamus, and somatosensory cortex, from there to motor cortex, and from motor cortex through the corticospinal tract (CST) to the motor neurons controlling digit flexion and extension (e.g., Evarts and Fromm, 1981). Similarly, the 'haptic' sense involves the assessment of somatosensory feedback about the shape, texture, compressibility, and other physical characteristics of objects resulting from grasping and manipulating them (e.g., Lederman and Klatzky, 2004).

4.01.3.4.1 Peripheral mechanisms Primates are characterized by specializations of the extremities related to grasping, including opposable first digits. Grasping abilities vary widely among primates, however (Bishop, 1964; Napier, 1993). Strepsirhines and most New World monkeys have little, if any, independent digit control. Catarrhine primates, as well as the New World *Cebus* monkeys, have a much greater degree of independent digit control. In apes and humans, the grasping ability of the thumb is greatly increased: the pad of the thumb can be opposed to the pads of other digits, yielding a precision grip. In humans, this capacity is extremely well developed and is accompanied by modifications of the hand bones and muscles (Susman, 1994). Primate grasping is facilitated by the presence on the ventral surfaces of the hands and feet of large regions of hairless (glabrous) skin with complex patterns of epidermal ridges. This 'dermatoglyph' skin, which is thought to reduce slippage, is also present in tree shrews and in arboreal marsupials (Cartmill, 1974a; Martin, 1990). Some New World monkeys have increased their grasping abilities by evolving prehensile tails, the pads of which also possess dermatoglyph skin. Primates also appear to differ from most other mammals in their fundamental pattern of gait: most primates have a

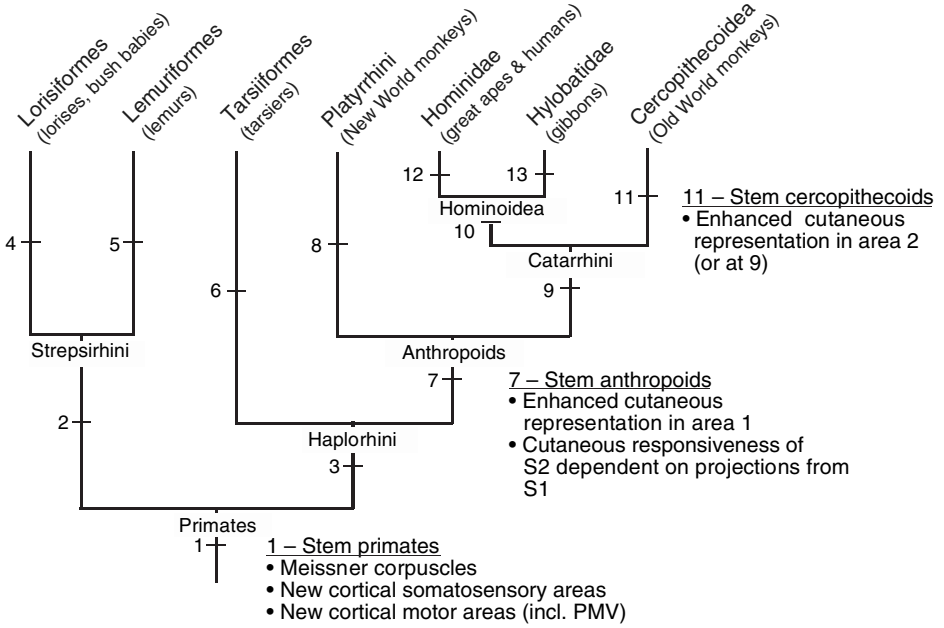

Figure 4 Interpretation of the shared derived features of the somatic sensory and motor systems in primates and major primate subgroups.

'diagonal-sequence' walk, in which a hind footfall is followed by the fall of the opposite forefoot, whereas most other mammals have a 'lateral-sequence' walk, in which a hind footfall is followed by the fall of the forefoot on the same side (Cartmill *et al.*, 2006; Lemelin and Schmitt, 2006).

We know rather little about the neurological bases of distinctively primate grasping and gait patterns at the level of spinal mechanisms. There is, however, evidence for a primate specialization on the sensory side. The sense of touch is mediated by several types of receptors, of which the Meissner corpuscles deserve special note. Meissner corpuscles consist of a nerve ending ensheathed in a capsule of non-neuronal cells, and linked to surrounding tissue in such a way as to make them exquisitely sensitive to deformation of the skin (Martin, 1990; Hoffmann *et al.*, 2004). They are concentrated in the epidermal ridges, especially of digits 1–3, which have been proposed to constitute a 'tactile fovea' (Hoffmann *et al.*, 2004). The placement of Meissner corpuscles suggests that they play an important role in the sensory control of grasping (e.g., by detecting slippage and initiating compensatory changes in grip force). Additionally, Meissner corpuscles could play an important role in the use of the hand as a haptic organ: some primates, especially catarrhines, appear to use active touch to investigate the mechanical properties of food items and other objects. Hoffmann *et al.* (2004) suggest specifically that Meissner corpuscles provide information for assessing the texture (and hence ripeness) of fruit. Meissner corpuscles are not, strictly speaking, unique to primates: morphologically similar organs are also present in the dermatoglyph skin of marsupials and on the finger-like tips of elephant trunks (Hoffmann *et al.*, 2004). They are, however, absent in tree shrews and most other mammals that have been examined (Martin, 1990; Hoffmann *et al.*, 2004). It seems likely that Meissner corpuscles evolved independently in several mammalian groups as the elaboration of a simpler type of mechanoreceptor.

4.01.3.4.2 Cortical somatosensory systems Mapping of the cortical somatosensory and motor fields has a long history, going back to the beginnings of experimental electrophysiology in the last half of the nineteenth century. It was clear from an early date that these fields are organized in an orderly, somatotopic fashion, with the tail and hindlimb represented medially in the cortex, near or within the interhemispheric fissure, and the forelimb and face represented laterally. In anthropoid primates, the principal somatic fields are located along the central sulcus, the somatosensory region posteriorly and the motor region anteriorly. In non-primates, which lack the large territory of dorsolateral prefrontal cortex present in primates, the somatic regions are located on the lateral surface near the frontal pole. Early comparative mapping

research culminated in the work of Woolsey (1958). Woolsey concluded that there were two somatosensory areas, the large primary area, SI, located along the central sulcus, and a smaller area, SII, located posterior and inferior to SI along the dorsal bank of the lateral sulcus. He also acknowledged two motor areas, the primary area, MI, located immediately anterior to SI, and a secondary area, MII (also called the supplementary motor area, SMA), located anterior and medial to MI along the mesial surface of the frontal lobe. Woolsey believed these four areas were present in most if not all eutherian mammals. The well-known neurosurgeon Wilder Penfield promulgated a similar understanding of human motor and somatosensory cortex (Penfield and Roberts, 1959). The elegance of Woolsey's schematic figures, with their artful drawings of somatosensory and motor homunculi, ensured that they would remain staples of neurobiology textbooks for many decades.

In the 1970s, the large surface electrodes that had been used for cortical mapping studies were replaced with fine-diameter electrodes that were inserted into the cortex to record from or stimulate neurons. The use of intracortical microelectrodes made it possible to map cortical areas in much greater detail, and with their application came the appreciation that Woolsey's interpretations of the somatosensory and motor regions were simplistic (Merzenich *et al*., 1978; Kaas *et al*., 1979). For example, the territory encompassed by Woolsey's 'SI' in anthropoid primates turned out to contain four separate representations of the body, two areas that receive inputs mainly from cutaneous receptors (including the Meissner corpuscles) and that correspond to cytoarchitectonic areas 3b and 1, and two areas that receive inputs mainly from muscle and joint receptors, corresponding to areas 3a and 2. Of these areas, the somatotopy of area 3b most closely resembled Woolsey's SI, so it was dubbed 'SI proper' (see the review of Kaas, 1983).

In contrast to SI, modern research has largely substantiated Woolsey's concept of an SII, an area of principally cutaneous representation located posteriorly and laterally to SI along the dorsal bank of the lateral sulcus (see the reviews of Kaas, 2004; see The Evolution of Sensory and Motor Systems in Primates). This research, however, has identified additional somatosensory representations in the lateral sulcus anterior and posterior to SII, as well as in the posterior part of the insular cortex, ventral to SII. These areas include the so-called parietal ventral (PV) and parietal rostral (PR) areas. There are also additional territories of somatosensory representation posterior to area 2, in the region termed area 5.

Comparative studies of strepsirhines (mainly *Galago* and *Otolemur*) and a variety of New World and Old World monkeys suggest that the areas discussed above are common to all major primate groups and were likely present in stem primates. It is also likely that at least some of these areas are neomorphic in primates, as most nonprimate mammals that have been studied, including tree shrews, have only a single main cutaneous representation in the region of SI, presumably homologous to area 3b/SI of primates (Kaas, 1983), and only a small region of somatosensory representation in the parietal cortex posterior to SI, which in primates contains areas 1, 2, and 5 (see The Evolution of Sensory and Motor Systems in Primates; Kaas, 1983; Beck *et al*., 1996).

There are some important variations in cortical somatosensory organization between primate groups. For one, New World monkeys that have prehensile tails, such as capuchins (*Cebus*) and spider monkeys (*Ateles*), possess prominent representations of the tail pads in SI (Pubols and Pubols, 1971; Felleman *et al*., 1983). In addition, cutaneous representation appears to be more extensive in anthropoids, and particularly in catarrhines, than in strepsirhines. Most strepsirhines that have been studied lack the second strip of cutaneous representation in area 1 caudal to area 3b/1 that is present in most anthropoids, although the slow loris, *Nycticebus coucang*, is reported to have a second representation of the glabrous skin of the hand (Carlson and Fitzpatrick, 1982). Although present in most New World and Old World monkeys, cutaneous representation in area 1 is reduced or lacking in tamarins (Carlson *et al*., 1986) and marmosets (Krubitzer and Kaas, 1990), both New World monkeys of the family Callithricidae that re-evolved claws in place of nails. Also, whereas areas 2 and 5 in strepsirhines and platyrrhines show little responsiveness to cutaneous stimulation, Old World macaque monkeys have a zone of cutaneous responsiveness extending across these areas (Pons *et al*., 1985). Finally, there is evidence for changes in the connectivity of the forebrain somatosensory network in primates. In galagos, there are parallel thalamic projections of cutaneous information to areas SI and SII, so that lesions of SI do not greatly impair the responsiveness of SII to cutaneous stimulation intact. This appears to be the primitive condition for eutherian mammals (Garraghty *et al*., 1991). In anthropoids, the cutaneous responsiveness of SII is the consequence of projections from area SI, lesions of which leave SII unresponsive (e.g., Pons *et al*., 1992).

There are interesting functional parallels in the organization of the cortical somatosensory and visual networks. The pathway from SI to SII is considered to be an important stage in a stream of somatosensory information processing that terminates in the hippocampus and provides the substrate for tactile recognition (Friedman *et al*., 1986). This constitutes an analogue of the ventral stream of visual processing – a somatosensory 'what' pathway. Information also flows from SI and neighboring areas in the central region posteriorly to area 5 and adjacent posterior parietal zones that control the movements of the limbs in space. This may be more than merely an analogue of the dorsal visual (vision-for-action) pathway, as the posterior parietal cortex is a locus of interaction of the somatic sensory and motor systems with the visual system.

4.01.3.4.3 Cortical motor systems Among the principal users of information processed through the somatosensory cortex are the areas of the motor cortex. Woolsey, as already noted, believed there were two cortical motor areas, MI and MII, and that these were present in many eutherian groups. Even in Woolsey's day, however, his conception of the MI as a single, large area, spanning the entire territory between the somatosensory and prefrontal region to include both areas 4 and 6 of Brodmann, was controversial. Other workers identified area 4 with the primary motor area, while area 6, which is less responsive to electrical stimulation and was thought to be involved in higher-order aspects of motor control, was termed 'premotor' cortex (reviewed by Wise, 1985; Preuss *et al*., 1996). Recent research has shown both these interpretations of the motor cortex to be overly simplistic, with modern researchers recognizing MI, which appears to consist of at least two major subdivisions, a dorsal and a ventral premotor subdivision (PMD and PMV, which, like MI, appear to include major internal divisions), an SMA (MII) located on the mesial wall of the hemisphere, a presupplementary motor area, located anteriorly to SMA, and several cingulate motor areas, buried within the cingulate sulcus (reviewed by Dum and Strick, 2002; Kaas, 2004; see The Evolution of Sensory and Motor Systems in Primates). Most of the evidence for these areas comes from New World and Old World monkeys, but recent work in the strepsirhine *Otolemur* suggests a similar set of areas, so it seems very likely that a similarly large complement of areas was present in stem primates. Among primates, there appears to be at least one notable difference in areal organization: in macaque monkeys, area PMV consists of two subdivisions, distinguishable on functional and anatomical grounds (Gentilucci *et al*., 1988; Rizzolatti *et al*., 1988), whereas in the strepsirhines and New World monkeys that have been examined, PMV appears to be a unitary field (Preuss *et al*., 1996; Wu and Kaas, 2003; Fang *et al*., 2005).

By contrast to primates, the motor region of the nonprimate mammals that have been investigated evidently consists of only a very few areas (see The Evolution of Sensory and Motor Systems in Primates). Of the areas present in primates, MI, at least, is probably a common feature of eutherian mammals. There is likely an additional, very small region of premotor cortex in nonprimate mammals, but there is very little indication of anything approaching the seven or more nonprimary motor areas present in primates, so presumably many of those areas are neomorphic in primates. The clearest case for a neomorphic motor area in primates can probably be made for area PMV. It includes an anatomically discrete field of corticospinal projections that is not seen in tree shrews or in other mammals (Nudo and Masterton, 1990). It also has a distinctive somatotopy, representing the face and forelimb virtually exclusively, and seems to play an important role in organizing grasping movements of the hands and mouth, which led Preuss (1993) to suggest that this area evolved to organize the visually guided reaching and grasping behaviors of stem primates in the fine-branch niche.

4.01.3.4.4 Corticospinal tract The cortex can affect motor activity via a number of routes, the most direct of which are the direct projections to cranial nerve nuclei in the brainstem (corticobulbar projections) and to the spinal cord (corticospinal projections). These projections arise from a broad territory of frontal and parietal cortex in primates and other mammals, spanning the motor and somatosensory regions.

The CST has attracted a great deal of attention from comparative neurobiologists. Early research noted that lesions of the cortex had profound and lasting effects on movement and motor control in primates, whereas in many other mammals the effects were minimal. Damage to the motor cortex in humans and other anthropoid primates results in paresis; with time, most aspects of motor control recover, but individuated movements of the digits are refractory to recovery (Kuypers, 1981).

Comparative anatomical studies of the CST reinforced the idea that the CST plays a special role in movement control in primates. The CST is reported to vary markedly across mammals in its location

within the brainstem and spinal cord, the number and diameter of fibers it contains, the levels of spinal cord to which it reaches, and the location of terminals with respect to the interneurons and motor neurons of the spinal cord.

In some mammals, the CST is reported to descend only to the level of the cervical or thoracic spinal cord (reviewed by Kuypers, 1981). In these animals, the CST can reach motor neuron populations controlling the forelimbs, but can have no direct effect on control of the hindlimb or tail, the motor neurons for which are located at lumbar and sacral levels of the cord. Tree shrews are said to have CST projections that reach no further than the mid-thoracic cord (Jane *et al*., 1965; Verhaart, 1966; Shriver and Noback, 1967). Other mammals, including primates, carnivores, bats, and rodents, are reported to have projections that extend into the lumbosacral cord (Kuypers, 1981). Primates, it has long been argued, are distinguished from most other mammals by having corticospinal fibers that terminate directly on the motor neurons that innervate the muscles of the hands and feet; among nonprimates, only raccoons were said to have comparable, monosynaptic innervation of hand muscle motor neurons (Kuypers, 1981). Moreover, it was argued that the extent to which the CST extends beyond cervical levels in the spinal cord, and the extent to which motor neurons receive direct, monosynaptic input from the cortex, determines the digital dexterity of animals, with primates and raccoons having these conditions and being the most dexterous animals (Heffner and Masterton, 1975, 1983; see also the review in Striedter, 2005).

One problem with the studies of corticospinal connectivity cited above is that for the most part they employed techniques for studying connections (lesion-degeneration methods) that are not considered very reliable today. It seems likely that the conclusions reached about the level of the spinal cord reached by the CST in a given species are trustworthy in most cases, but conclusions about whether or not CST projections reach the territory of spinal motor neurons in the ventral horn should be considered cautiously. A study by Bortoff and Strick (1993), using a modern tracer substance (WGA-HRP), reported a result quite in line with classical considerations. They compared the distribution of corticospinal terminations after injections of WGA-HRP into area M1 of two closely related New World monkeys: capuchins (*Cebus apella*), which are noted for their manipulative abilities, and squirrel monkeys (*Saimiri sciureus*), which are not. They reported that CST terminations are much more extensive in the ventral horn motor neuron territory of *Cebus* than *Saimiri*. Reliable conclusions about the evolution of the CST will require more investigation using modern tracing techniques. It is also necessary to apply better analytical techniques to multispecies data sets than have been used in the past. For example, the regression techniques used to relate CST anatomy to digital dexterity by Heffner and Masterton (1975, 1983) are no longer considered adequate; improved methods ('independent contrasts') make it possible to remove the confounding effects of phylogeny in correlations, such as the over-representation of primates in the sample. Using these techniques to re-analyze the Heffner–Masterton data set, Iwaniuk *et al*. (1999) concluded that the length of the CST was related to digital dexterity, but not the extent to which it invaded the territory of motor neurons controlling the distal extremities. This is certainly not the last word on the subject (as Iwaniuk *et al*., 1999, would likely acknowledge), but it does highlight the need for neuroscientists to apply the best methods of phylogenetic inference, as well as the best techniques for studying neural organization, to problems of nervous system evolution.

4.01.3.5 Auditory System

The auditory system has not been studied by comparative biologists with anything like the effort devoted to the visual system. There is presently little indication that the origins of primates were accompanied by marked modifications of the auditory sensory apparatus, although changes in central auditory systems are known and will be discussed below. Small, nocturnal strepsirhine primates, as well as tarsiers, use hearing along with vision to localize insect prey, and if stem primates were nocturnal predators this would likely have been true of them as well. It is noteworthy that some nocturnal primates (bush babies and tarsiers in particular) have large external ears (pinnae), that are ridged and can be moved and shaped to assist sound localization (Charles-Dominique, 1977). The orientation of the pinnae modulates sound frequency, and this may play an important role in sound localization, which in small mammals relies more on frequency differences than interaural timing differences (Heffner, 2004).

Glendenning and Masterton (1998) compared the volumes of auditory brainstem nuclei in a variety of mammals and reported that primates are fairly typical among mammals in terms of the sizes of the

different nuclei relative to each other. The dorsal cochlear nucleus, however, appears to have undergone a reduction of lamination in the origin of anthropoid primates, with further reduction in hominoids (Moore, 1980; Johnson *et al*., 1994).

As with other neocortical sensory systems, the cortical auditory system of primates is characterized by a large number of areas (see Organization and Correspondence of the Auditory Cortex of Humans and Nonhuman Primates). The areas are arrayed in a distinctive fashion: along the upper part of the temporal lobe (partly or completely buried within the lateral sulcus), there is a 'core' of areas that share similar histology, with a well-developed layer 4 densely packed with granular cells. The posterior-most core area is the primary auditory area (A1). A1 is bordered rostrally by the rostral (R) area, which can be difficult to distinguish from A1 cytoarchitectonically, and area R is replaced rostrally by the rostrotemporal (RT) area. The core is surrounded on all sides by a 'belt' of auditory areas; currently, there are thought to be eight belt areas. The lateral part of the belt is bordered by several 'parabelt' areas, which occupy the superior temporal gyrus. Posterior to the core and belt is an additional field involved in auditory processing known as area Tpt. Many of the core and belt areas are known to represent auditory frequencies in systematic fashion, that is, they are 'tonotopically' organized. As with other cortical sensory systems, the cortical auditory system exhibits a hierarchical organization, with areas in the core relaying auditory information to surrounding areas. The auditory system, however, exhibits a greater degree of parallel processing than the visual and somatosensory systems: the core and belt areas all receive inputs from the main auditory nucleus of the thalamus, the medial geniculate nucleus (MG), the three core areas receiving inputs from the ventral MG, and the belt areas from the dorsal MG (see Organization and Correspondence of the Auditory Cortex of Humans and Nonhuman Primates; see also Rauschecker *et al*., 1997). As the organization of primate auditory cortex has come to be better understood, it has been suggested that there are at least partly separate processing streams specialized for analysis of information about the identity of sound sources and about their spatial localization, that is, 'what' and 'where' systems (Romanski *et al*., 1999; see also Kaas and Hackett, 1999; Rauschecker and Tian, 2000).

The organization detailed above has now been documented in both Old World and New World monkeys (see Organization and Correspondence of the Auditory Cortex of Humans and Nonhuman Primates). Comparative architectonic studies indicate that an identifiable core is present in strepsirhine primates (Preuss and Goldman-Rakic, 1991a), and in chimpanzees and humans (Hackett *et al*., 2001). Also, Tpt has been identified architectonically in strepsirhines, Old World monkeys, and humans (Galaburda and Pandya, 1982; Preuss and Goldman-Rakic, 1991a). Area A1 is probably common to all mammals, and most nonprimate mammals have at least five or six additional auditory areas (see, e.g., Stiebler *et al*., 1997). It is not clear which of the primate auditory areas these are homologous to, nor is it clear that nonprimates exhibit the core-belt-parabelt system present in primates.

One of the major mysteries of human evolution is how auditory cortex was modified in relation to the evolution of language. One possibility is that humans evolved new areas to support language, but there is at present no evidence of this (Preuss, 2004b). Indeed, the cortical territory most strongly identified with Wernicke's area, the cortex of the planum temporale, posterior to area A1, contains architectonic area Tpt, which as discussed has also been identified in nonhuman primates (Galaburda and Pandya, 1982). Presumably, the cortex of Tpt must have undergone changes in its internal organization and/or its relationship to other cortical areas to support human language. Since humans tend to be left-hemisphere dominant for language, the fact that the planum temporale tends to be larger in the left hemisphere than the right might be seen as a language-related modification (Galaburda *et al*., 1978). This cannot be the entire story, however, as great apes exhibit a pattern of posterior temporal asymmetries at least qualitatively similar to those of humans (Gannon *et al*., 1998; Hopkins *et al*., 1998), although the possibility of quantitative species differences remain. To date, the only clear difference to have been documented between the posterior temporal region of humans and apes is an asymmetry of cortical minicolumns in area Tpt: humans have more widely spaced columns on the left than on the right, whereas no asymmetry is present in chimpanzees or macaques (Buxhoeveden *et al*., 2001).

4.01.3.6 Limbic System

The limbic system comprises a ring of cortex that makes up the lateral and medial margins of the cortex, including the hippocampus and parahippocampal cortex, retrosplenial and posterior cingulate cortex, the anterior cingulate and prelimbic areas (which are sometimes now considered portions of the medial prefrontal cortex), and orbital and

insular cortex (including regions of olfactory and taste representation), along with noncortical structures that are connected with these regions, such as the amygdala and portions of the hypothalamus. What unites these regions are their roles in motivation and emotion, mediated by connections with the autonomic system. One might think that the limbic system would be a hotbed of comparative neuroscientific investigation, if only because modern evidence indicates that the limbic system is critically involved in social cognition (see The Evolution of Human Emotion). There is also the very interesting question of how the specialized cortical systems of primates came to interact with the limbic region, which is composed of structures that for the most part have homologues not only in other mammals but in nonmammalian vertebrates (see, e.g., Rolls, 2004). Presumably, it is because these structures have been viewed as ancient (we apply terms like 'paleocortex' and 'archicortex' to the limbic cortex) that they have received so little attention from an evolutionary viewpoint, although of course old structures can undergo evolutionary changes just as new ones can.

In fact, there is good evidence that cortical components of the limbic system were modified in primate evolution (Figure 5). Primates possess divisions of posterior parahippocampal cortex (areas TH and TF) that have no obvious counterparts in other mammals (Preuss, 2006). These areas are important way stations between the neocortex and the memory systems of the hippocampus. In addition, the posterior cingulate region of primates contains a territory, area 23, that is not recognized in most other mammals (Preuss, 2006). Area 23 underwent further modification in anthropoid evolution, with the addition of a well-developed internal granular layer (Zilles *et al.*, 1986; Preuss and Goldman-Rakic, 1991a). Also, subdivisions of area 23 and retrosplenial area 29 identifiable in anthropoids are not distinguishable in strepsirhines, and strepsirhines possess divisions of retrosplenial area 30 that are not distinguishable in anthropoids (Zilles *et al.*, 1986). Tarsiers appear to share some features of anthropoid posterior cingulate cortex not present in strepsirhines (Zilles *et al.*, 1986). New World monkeys differ from other primates in the thickness and cell density of the outer layers of retrosplenial area 29 (Armstrong *et al.*, 1986). Evolutionary changes of the posterior cingulate and retrosplenial cortex are of special interest, as in humans these territories are believed to be part of the system for representing conscious self-reflection (Fink *et al.*, 1996; Vogt and Laureys, 2005).

There is also evidence of changes at finer levels of organization in the limbic system. Humans and great apes possess an unusual class of large, spindle-shaped neurons in layer 5 of anterior cingulate and orbitoinsular cortex (Nimchinsky *et al.*, 1999). These 'spindle cells' or 'Von Economo neurons' are especially large and prominent in humans, and they have been suggested to have a role in human social judgment (see Role of Spindle Cells in the Social Cognition of Apes and Humans). In addition to

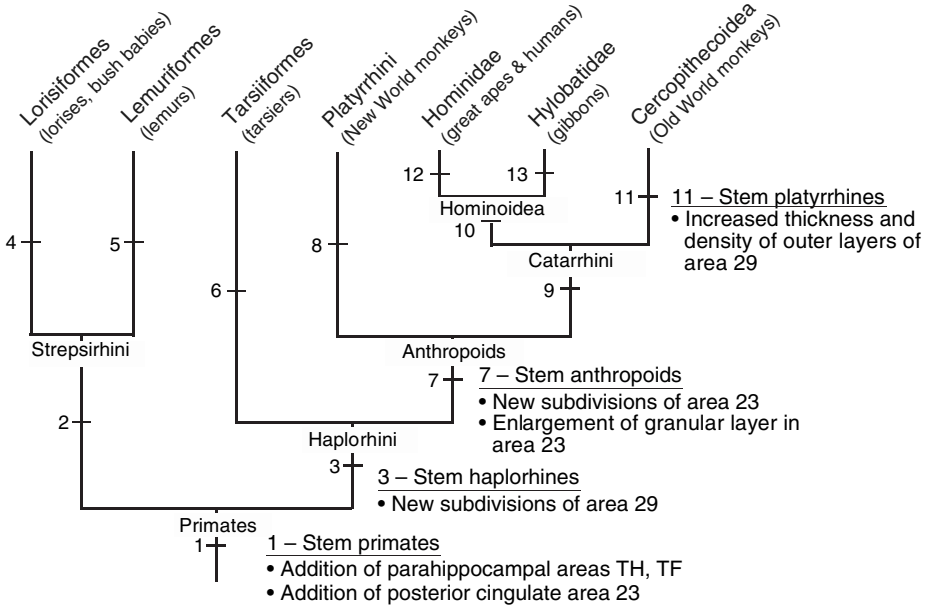

Figure 5 Interpretation of the shared derived features of the limbic system in primates and major primate subgroups.

spindle cells, great apes and humans have a specialized class of calretinin-containing pyramidal cells in anterior cingulate cortex (Hof *et al*., 2001).

4.01.3.7 Higher-Order Forebrain Systems

I include among the 'higher-order' regions of the forebrain the cortex of the STS, the posterior parietal cortex, and portions of the 'prefrontal' cortex (Figure 6). These are regions that receive information from the sensory cortical systems, integrating multiple inputs to perform specific, supramodal cognitive and behavioral functions. I also include in this discussion the dorsal pulvinar, a division of the thalamus that has extensive connections with higher-order cortical regions. These four anatomical regions are noteworthy, first, because they either have no homologues in nonprimate mammals or underwent major modifications in primate evolution (Preuss, 2006), and second, because they enlarged out of proportion to other brain regions in human evolution (Preuss, 2000b, 2004b).

4.01.3.7.1 Superior temporal sulcal cortex The STS of Old World macaque monkeys contains a series of anteroposteriorly elongated architectonically distinct zones that extend much of the length of the sulcus anterior to visual area MT. This region was dubbed the superior temporal polysensory (STP) area by Bruce *et al*. (1981), and it receives inputs from both the dorsal and ventral visual streams (Boussaoud *et al*. 1990; Cusick 1997). STP has attracted special attention since the discovery in macaques that its neurons are active in response to viewing biological motion (moving faces, eyes, limbs, and bodies) and that individual STP neurons can be very selective for particular actions (Perrett *et al*., 1985; see also the review of Puce and Perrett, 2003). Currently, STP is regarded as a key node in a network of cortical areas, also including posterior parietal and prefrontal cortex, involved in the analysis of conspecifics' social behavior (Frith and Frith, 1999; Puce and Perrett, 2003). Functional imaging studies strongly suggest that a homologue of STP exists in the posterior part of the STS of humans. Evidence from strepsirhine primates, however, suggests that the anatomy of the STS region differs markedly from monkeys: Preuss and Goldman-Rakic (1991a, 1991b) confirmed that the macaque STS was comprised of multiple architectonic zones, but could distinguish only a single zone in *Otolemur*. This implies that major changes in STS organization took place during anthropoid or catarrhine evolution. There is no evidence that a homologue of STP or its constituent areas exists in nonprimate mammals.

4.01.3.7.2 Posterior parietal cortex The posterior parietal cortex corresponds to areas 5 and 7 of Brodmann (1909) in monkeys and lemurs. In macaques, areas 5 and 7 occupy the superior and inferior parietal lobules (SPL, IPL), respectively. In humans,

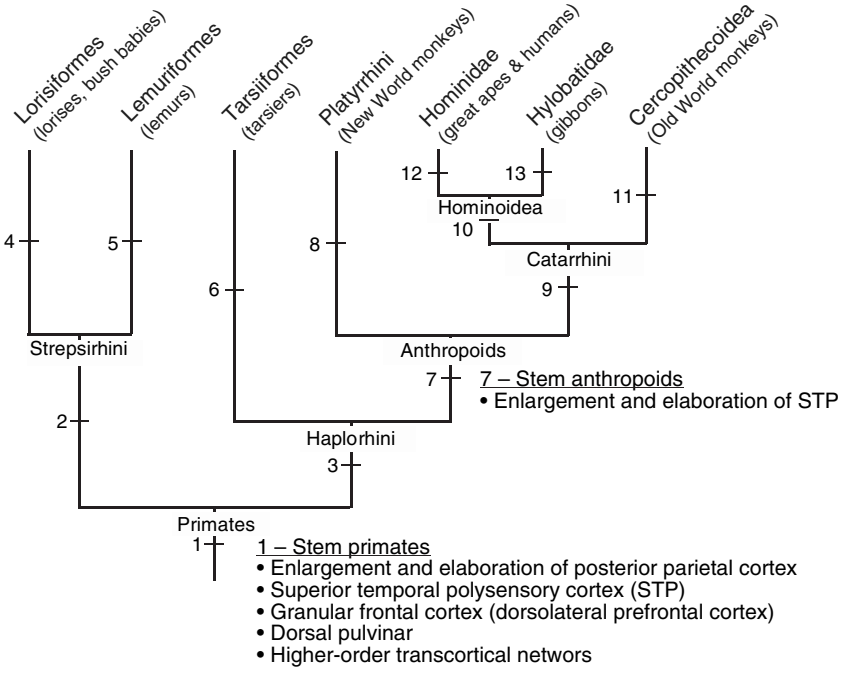

Figure 6 Interpretation of the shared derived features of higher-order forebrain systems in primates and major primate subgroups.

Brodmann maintained that the IPL was occupied by areas 40 and 39, for which he recognized no homologues in monkeys. Other authorities, however, have regarded areas 40 and 39 as homologous to the anterior and posterior parts of area 7, designated as areas 7b and 7a or as areas PF and PG, in nonhuman primates (see, e.g., Economo and Parker, 1929; Bonin and Bailey, 1947; Bailey and Bonin, 1951; Eidelberg and Galaburda, 1984). Neurologists have long appreciated that posterior parietal cortex plays an important role in spatial attention and in action control. In humans, these functions are strongly lateralized: lesions involving right parietal cortex result in hemispatial neglect (inattention to objects and events to the patient's left), while lesions involving left parietal cortex yield a bilateral manual apraxia, a deficit in the ability to produce skilled hand movements, such as those required to use tools or to gesture (see Neurological Specializations for Manual Gesture and Tool Use in Humans; Haaland *et al*., 2000; Muhlau *et al*., 2005). Modern studies of nonhuman primates indicate that posterior parietal cortex receives information from the dorsal stream of the visual system as well as information about eye movements and limb position, and furthermore, that the region is a patchwork of small, functionally specialized territories involved in controlling the direction of attention, eye movements, and reaching and grasping movements of the hands (Andersen *et al*., 1997; Colby and Goldberg, 1999; Grefkes and Fink, 2005). Results of functional imaging studies in humans are consistent with these studies, and reveal that posterior parietal subdivisions are involved in transcortical networks that mediate spatial attention (e.g., Corbetta *et al*., 1998; Kastner and Ungerleider, 2000) and attention to and control of action (e.g., Rushworth *et al*., 2001; Schluter *et al*., 2001; Johnson-Frey *et al*., 2005; see Neurological Specializations for Manual Gesture and Tool Use in Humans).

Although comparative studies indicate many commonalities among primates in the organization of posterior parietal cortex, it was by no means static in primate evolution. For one thing, there is no indication that any nonhuman primate exhibits the extreme degree of functional hemispheric specialization present in humans (see The Evolution of Hemispheric Specializations of the Human Brain; Corballis, 1991). Furthermore, functional imaging studies of human and macaque subjects viewing identical stimuli indicate that moving stimuli activate more discrete zones of parietal cortex in humans (Vanduffel *et al*., 2002; Orban *et al*., 2004; see also Orban *et al*., 2006). This might indicate that humans possess more parietal areas than macaques or, alternatively, that certain areas became more sensitive to certain classes of visual stimuli in humans than in macaques (Preuss, 2004a). At present, it is not clear whether these differences are true human specializations, or whether they evolved early in the history of the hominoid (ape-human) group, or (as could well be the case) specializations of macaques. It is noteworthy that the posterior parietal cortex of primates is very different than that of other mammals. In rats, for example, there is a small region of cortex between the visual and somatosensory regions that receives input from both and that been likened to posterior parietal cortex, but if this is the homologue of primate posterior parietal cortex, the region must have undergone extensive modification in primate evolution, with the addition of many new subdivisions specialized for primate-characteristic behaviors (Preuss, 2006).

4.01.3.7.3 Prefrontal cortex Prefrontal cortex in primates, as currently understood, includes several different territories: a large region with a well-developed granular layer 4 that occupies mainly the dorsolateral surface of the frontal lobe (i.e., granular frontal cortex, or more commonly, dorsolateral prefrontal cortex); an orbital region, the anterior parts of which are granular, but which grades off posteriorly into agranular cortex; and a medial region, which also is granular anteriorly but grades off posteriorly into agranular cortex. Classically, the medial agranular regions were classified as anterior cingulate cortex (Brodmann, 1909), rather than as prefrontal cortex, but for reasons to be discussed below, it has come to be thought of as 'prefrontal'.

Among mammals, only primates have a region of cortex with a well-developed granular layer on the dorsolateral surface of the frontal lobe (Brodmann, 1909). The region is present in all primates that have been examined, and is much larger in anthropoids than in strepsirhines (Brodmann, 1909; Preuss and Goldman-Rakic, 1991c). Owing in part to the influence of Brodmann, the granular dorsolateral prefrontal cortex initially came to be regarded as a hallmark of the primate brain. The fact that some neurologists in the early part of the twentieth century regarded this region as the seat of higher-order cognitive functions reinforced this view. Modern experimental studies in nonhuman primates (reviewed by Goldman-Rakic, 1988; Preuss and Goldman-Rakic, 1991b; Pandya and Yeterian, 1996; Barbas, 2000; Petrides, 2000) reveal it to have strong connections with the higher-order parietal and temporal areas discussed above, and functional studies in humans and nonhuman primates indicate

that different parts of the granular frontal cortex are involved in attention, working memory, and planning (Passingham, 1993; Goldman-Rakic, 1996; Fuster, 2000; Miller and Cohen, 2001; Tanji and Hoshi, 2001; Miller *et al*., 2002; Passingham and Sakai, 2004; Petrides, 2005).

The idea that dorsolateral prefrontal cortex is special to primates has, nevertheless, been challenged (see the reviews of Preuss, 1995a, 2006). With the introduction of the first generation of techniques for studying cortical connectivity (lesion-degeneration techniques), it became clear that the cortical regions differed in their patterns of connectivity as well as their histology. Early research on the forebrain connections of the cortex focused on connections with the thalamus because cortical lesions produce degeneration in thalamic nuclei that project to them; most other connections could not be reliably resolved until improved methods became available in the 1970s. Rose and Woolsey (1949) championed the idea that regions of cortex could be defined by the thalamic nuclei that projected to them. As the dorsolateral prefrontal cortex, the largest prefrontal region in primates, receives its major thalamic inputs from the mediodorsal thalamic (MD) nucleus, prefrontal cortex came to be defined as MD-projection cortex (Rose and Woolsey, 1948). As it happens, all mammals that have been examined have a MD nucleus and a cortical territory to which it projects, so by this reasoning, all mammals possess a homologue of dorsolateral prefrontal cortex, even though the MD-projection cortex of nonprimates lacks the well-developed granular layer that marks this region in primates (Rose and Woolsey, 1948; Akert, 1964). It was also reported that dopamine-containing nuclei of the brainstem project very strongly to MD-projection cortex in both primates and nonprimates, and this has also been used to identify homologues in different mammals (Divac *et al*., 1978). Attempts have also been made to refine this analysis by identifying homologues of specific subdivisions of primate dorsolateral prefrontal cortex in nonprimates (Akert, 1964). A region of special interest has been the cortex that lines the principal sulcus of macaques (principalis cortex), because lesions of this region impair performance on spatial working memory tasks, a set of cognitive tasks that have been adapted for use in a wide range of mammals. Using the criteria of MD projections, dopamine projections, and involvement in spatial working memory tasks, homologues of macaque principalis cortex have been proposed in nonprimate species, and most importantly in rats, which are the most widely used model animals in mammalian neuroscience. In rats, the principalis homologue has usually been localized to the medial surface of the frontal lobe, and some workers have identified it specifically with area 32 (the prelimbic area) (Brito *et al*., 1982; Passingham *et al*., 1988; Dalley *et al*., 2004; Vertes, 2004).

This might seem a satisfactory account of prefrontal homologies, but there are difficulties with both the evidence and the reasoning (Preuss, 1995a). For one thing, in primates, MD projects not only to the granular, dorsolateral prefrontal frontal cortex, but also to agranular regions, including orbital cortex, the classical anterior cingulate areas (areas 24 and 32 of Brodmann), and even to insular and premotor cortex. For another, while dorsolateral prefrontal cortex receives dopaminergic inputs, the strongest dopamine projections in primates are actually to the motor region and the orbital and medial cortex. Finally, in primates, lesions of the medial frontal cortex, involving the cingulate region and sparing the dorsolateral region, produce impairments on spatial working memory tasks. Thus, none of the features that have been used to identify homologues of granular prefrontal cortex in nonprimates are actually diagnostic of granular prefrontal cortex in primates. In fact, the medial frontal cortex of rodents very closely resembles the agranular parts of the medial frontal cortex of primates on a variety of structural and functional grounds – both are limbic regions, after all. It is true that the medial frontal cortex of rodents resembles primate granular frontal cortex in certain respects, but these are also the ways that the medial frontal cortex of primates resembles the dorsolateral prefrontal cortex of primates; the similarities are not diagnostic. Moreover, primate granular frontal cortex has additional features of areal organization and connectivity that do not match any known region of frontal cortex in any nonprimate mammal (Preuss, 1995a).

On present evidence, then, there are good grounds for concluding that dorsolateral prefrontal cortex is in fact one of the distinctive features of the primate brain. In addition, there is evidence that this region underwent extensive modification during primate history. A comparative study of the connectivity and histology of this region in galagos and macaques indicated that the latter have many more subdivisions of granular frontal cortex (Preuss and Goldman-Rakic, 1991b, 1991c). It was concluded that galagos share with macaques homologues of frontal eyefield and related areas, but that galagos lack homologues of the areas located within and surrounding the principal sulcus of macaques. This result suggests that the principalis areas are derived features of

anthropoid or catarrhine cortex, and reinforces the view that a principalis homologue is absent in nonprimates.

4.01.3.7.4 Tying it all together – the dorsal pulvinar As noted above, the higher-order temporal, parietal, and frontal regions of primates are strongly interconnected, making up a collection of distributed networks that subserve specific cognitive functions (Goldman-Rakic, 1988). In primates, these regions are all connected with a particular region of the thalamus known as the medial pulvinar, or more appropriately, the dorsal pulvinar (see Gutierrez *et al*., 2000, and the review of Preuss, 2006). Neuroanatomists have long noted the great size of the pulvinar in primates compared to other mammals (e.g., Le Gros Clark, 1959). The pulvinar consists of several different territories, however, and most attention has been paid to those regions of the pulvinar that are specifically related to the visual system, receiving input from the retina and SC and projecting to striate and extrastriate visual cortex. In primates, the visual pulvinar proper consists of the inferior pulvinar and part of the lateral pulvinar; the homologous territories in nonprimate mammals are referred to as the pulvinar or as the pulvinar-lateral posterior complex. The dorsal pulvinar is most likely neomorphic in primates, as there are no structures in a similar location or with similar connections in other mammals (Preuss, 2006). By virtue of its connections, the dorsal pulvinar is in a position to coordinate the activities of the distributed, higher-order cortical systems of primates, although the nucleus has received very little experimental investigation and its functions are presently unknown.

4.01.4 Conclusions and New Directions

This review documents numerous evolutionary changes in the nervous systems of primates, localizing them wherever possible to their period of origin in primate evolutionary history. It is clear that primate brain evolution cannot be understood simply as a matter of enlargement and general differentiation; rather, the record indicates that primate brains changed in very specific ways at particular time points in evolutionary history. Ultimately, one would like to see the evidence for evolutionary modifications of the nervous system woven into a broader account of primate evolution, an account that relates changes in the nervous system to changes in other aspects of anatomy and, of course, to behavior. We are a long way from realizing this goal. Without question, many of the nervous system specializations described here are, in a way, rather unremarkable in light of what we know about primate evolution generally. For example, given the emphasis placed in primate origins research on the importance of high-acuity nocturnal vision and visually guided grasping, it is not surprising that we find that stem primates underwent changes in central systems involved in vision, eye-movement control, and grasping. It is not possible at present, however, to make very strong claims about why primates evolved the particular nervous system features they possess, such as, why primate visual systems have such a strong hierarchical organization compared to other mammals, or why primates have CO-rich blobs in area V1. Current theories of structure–function relationships in the nervous system are not sufficiently well developed to provide us with much insight into issues at this level of detail.

How do we get better theories of structure–function relationships? In my view, we need more comparative research. Comparative studies have not been a high priority for the institutions that fund neuroscience, but there is some reason to think this will change. Driven by the need to make sense of data from dozens of different species coming from the various gene-sequencing projects, molecular biology has begun to incorporate the concepts and methods of evolutionary biology. Bioinformatics is, in a very real way, computerized evolutionary biology. We can expect the transformation of molecular genetics to affect the neurosciences. The demonstration of differences in the genomes and proteomes of different mammalian and primate species will naturally lead to the question: what are their phenotypic consequences? Already, we have seen how comparative genetic studies can inform our understanding of the evolution of primate sensory receptors (see The Vomeronasal Organ and Its Evolutionary Loss in Catarrhine Primates, The Comparative Biology of Photopigments and Color Vision in Primates, The Loss of Olfactory Receptor Genes in Human Evolution; Gilad *et al*., 2004). What's more, we can use the information provided by comparative molecular studies about changes in the sequences and tissue-specific expression patterns of specific macromolecules to drive 'phenotype discovery' (Preuss *et al*., 2004). For example, by knowing which molecules have undergone change, we can employ such routine methods as *in situ* hybridization and immunohistochemistry to localize those molecular changes in their anatomical context.

While we can expect comparative molecular biology to provide new insights into the primate brain evolution, the foregoing review draws attention to one really fundamental need: correlative comparative studies of the brain, behavior, and cognition. Consider this: many of the features that distinguish human brains from, say, those of rats, evolved very early in primate evolution. We possess them because our ancestors possessed them. To understand why our brains have these design features, we need to understand what they contributed to the behavior of early primates. To understand that, we need comparative studies of brain, behavior, and cognition in a variety of mammals, including especially anthropoid and strepsirhine primates, along with the animals to which primates are thought to be closely related, such as tree shrews, rodents, and rabbits. No such comparative science exists today.

In addition to sharing many design features with other primates and other mammals, humans presumably possess features that are uniquely human and that provide the basis for our distinctive cognitive and behavioral characteristics. We currently have very little reliable information about brain specializations of humans. One bright spot in this area is that imaging technologies have now developed to the point where we can examine humans and nonhuman primates on something like a level playing field (see, e.g., Orban *et al*., 2004). The problem is that most of these studies involve comparisons of humans and macaque monkeys. It is important to recognize that the demonstration of a human–macaque difference is not a demonstration of a human specialization. For example, a macaque–human difference could have arisen early in hominoid evolution, long before humans diverged from the African apes; this would be a hominoid specialization. Alternatively, an observed difference could be a macaque or a catarrhine specialization, with humans conserving the ancestral condition. Demonstrations of human specializations, therefore, require comparing humans to a wider range of primate species. Of central importance is the comparison of humans to chimpanzees: since chimpanzees are our closest relatives, any claim of human specialization requires the demonstration that humans differ from chimpanzees (Preuss, 2004b). Although there has recently been a renaissance of human–chimpanzee comparative psychological research (see Human Cognitive Specializations, The Evolution of Human Emotion) we know almost nothing of the differences in brain organization between humans and chimpanzees that would provide the basis for human cognitive and behavioral specializations. There is, therefore, a pressing need for comparative studies of the brain and cognition in humans and chimpanzees.

Acknowledgment

The author is grateful for the generous support of the James S. McDonnell Foundation (JSMF 21002093). This article is dedicated to the memory of Professor Patricia S. Goldman-Rakic.

4.02 The Evolution of Sensory and Motor Systems in Primates

J H Kaas, Vanderbilt University, Nashville, TN, USA

Glossary

area or nucleus — These are large, functionally significant subdivisions of neocortex and the brainstem. Each area (areas were the "organs of the brain" for Brodmann, 1909) or nucleus has a unique set of connections with other structures and uniquely contributes to the function of the system. Sensory and motor areas and nuclei, typically, topographically represent receptors of a sensory surface (skin or deep tissues) and/or body movements.

Eutheria — The mammalian clade stemming from the most recent common ancestor of placental mammals.

motor cortex — Subdivisions of cortex that are specialized to mediate and control body movements. Typically, movements can be evoked by electrically stimulating areas of motor cortex. Primary motor cortex (M1) is called agranular cortex because it has no obvious layer 4 of granule (sensory) neurons.

somatosensory cortex — Areas of cortex that are more specialized for processing sensory inputs than for motor control. While electrical stimulation of somatosensory areas may elicit movements, these areas have a well-developed layer 4 for receiving sensory inputs.

> And at last came the monkey, and anybody could see that man was not far off now. And in truth that was so. The monkey went on developing for close upon five million years, and then turned into a man – to all appearances (Mark Twain – *Letters from Earth*).

4.02.1 Introduction

Humans are known for their curiosity, and they are especially curious about themselves. Anyone that has viewed highly skilled athletes, musicians, or craftsmen must be impressed with their exceptional sensorimotor performances, which have been individualized and specialized by training and experience. These abilities depend on a massive sensorimotor network that has been gradually acquired during the course of human evolution. This network allowed our ancestors to make and use tools and weapons, craft garments, and process food. How did this system evolve and how does it work? Answers to these questions are incomplete, but we now have an outline of this system in humans and other mammals, information that allows the major steps in our evolution to be reconstructed, and a framework for understanding how the system works. This reconstruction of the course of brain evolution is informed by the fossil record, but it is largely based on comparative studies of extant primates and other mammals. Nevertheless, the fossil

record does indicate that early primates emerged as small, probably nocturnal (however, see Tan *et al.*, 2005), arboreal, small-brained mammals that likely fed on insects, fruit, small vertebrates, and buds (Ross, 1996). In some lines of primate evolution, the fossil record also indicates that brains got bigger in proportion to body size, and in the line leading to humans this transformation was remarkable, especially over the last 2 My. The extensive increase in the absolute and relative size of the brain suggests that major changes in brain organization occurred, but the fossil record provides little information about the nature of the changes.

In order to understand how sensorimotor systems evolved in primates, we need to compare the organizations of sensorimotor systems in primates and mammals most closely related to primates, and use distribution patterns across taxa to make inferences about when specific features of the human sensorimotor system emerged (see Eldredge and Cracraft, 1980; Wiley, 1981). While the focus is on the evolution of the human sensorimotor system, we also take note of a few interesting specializations that occurred in other lines of primate evolution.

4.02.2 The Somatosensory and Motor Systems of the Mammalian Ancestors of Primates: Inferences from the Systems of Rodents, Tree Shrews, and Other Mammals

It might seem strange to compare our nervous system with those of rats, rabbits, and tree shrews because rodents and lagomorphs seem so unlike us, and most of us know little about tree shrews. Yet these mammals turn out to be our closest living nonprimate relatives, and thereby these are the mammals to study if we want to know how the brains of our immediate nonprimate ancestors were organized.

Mammals emerged from mammal-like reptiles around 230 Mya and radiated into over 4500 surviving (extant) species of mammals. Because of recent advances in the use of molecular data to classify mammals (e.g., Murphy *et al.*, 2001, 2004), it has been possible to distinguish six major branches of mammalian evolution. Monotremes and marsupials constitute two early branches, while the placental mammals include Xenarthra (sloths, anteaters, and armadillos) and Afrotheria, Laurasiatheria, and Euarchontoglires as newly recognized clades (Figure 1). The Euarchontoglires clade emerged some 95 Mya and diverged into Glires, a line that gave rise to lagomorphs (rabbits, hares, and pikas) and rodents, and euarchontans, a line that gave rise to dermopteras (flying lemurs), scandentias (tree shrews), and primates. Of our closest living relatives – flying lemurs and tree shrews – we know very little about the brain of flying lemurs, but fortunately, tree shrew brains have been well studied, in part, because of early recognition by the great comparative anatomist Le Gros Clark that tree shrews resemble primates. Clark (1959) considered tree shrews to be primates, but this classification is no longer held tenable. In tree shrews, we look for traits that are shared by primates, rodents, and lagomorphs, as these traits may be those retained from a common ancestor of the Euarchontoglires clade. However, traits seen only in tree shrews need to be considered with caution, as they could be specializations of tree shrews rather than traits shared with the ancestors of primates (Kaas, 2002).

Euarchontoglires mammals also share a number of features of the sensorimotor system that were likely retained from early mammals. The basic features of the sensorimotor system of early mammals can be deduced by comparing components across members of the three major branches of mammalian evolution, monotremes, marsupials, and placental (eutherian) mammals (Kaas, 2004a). Some of the basic components of the somatosensory system of early mammals (Kaas, 2004b, 2004c) are illustrated in Figure 2. Starting with the inputs, low threshold cutaneous receptors project via peripheral nerves to the dorsal column–trigeminal complex in the lower brainstem, as well as to neurons in the dorsal horn of the spinal cord. Afferents terminate in the dorsal column–trigeminal complex in an orderly way so that ipsilateral tail, hindlimb, forelimb, and head are represented in a mediolateral sequence. Second-level neurons project to the ventroposterior nucleus (VP) of the opposite thalamus in a tail-to-tongue lateromedial somatotopic sequence. Third-level neurons in the VP in turn project to primary somatosensory cortex (S1) and to two smaller somatosensory areas just lateral (ventral) to S1, the second somatosensory area, S2, and the parietal ventral area, PV. Thus, VP neurons independently activate three somatosensory areas. Fourth-level neurons in S1 project to rostral (SR) and caudal (SC) somatosensory bands that border S1, and these areas and S1 all project to S2 and PV. Neurons in S2 and PV access neurons in perirhinal and parahippocampal areas that feed into the hippocampus for memory functions (Squire and Knowlton, 1994), and the amygdala for fear conditioning and other functions (LeDoux, 2000). Other

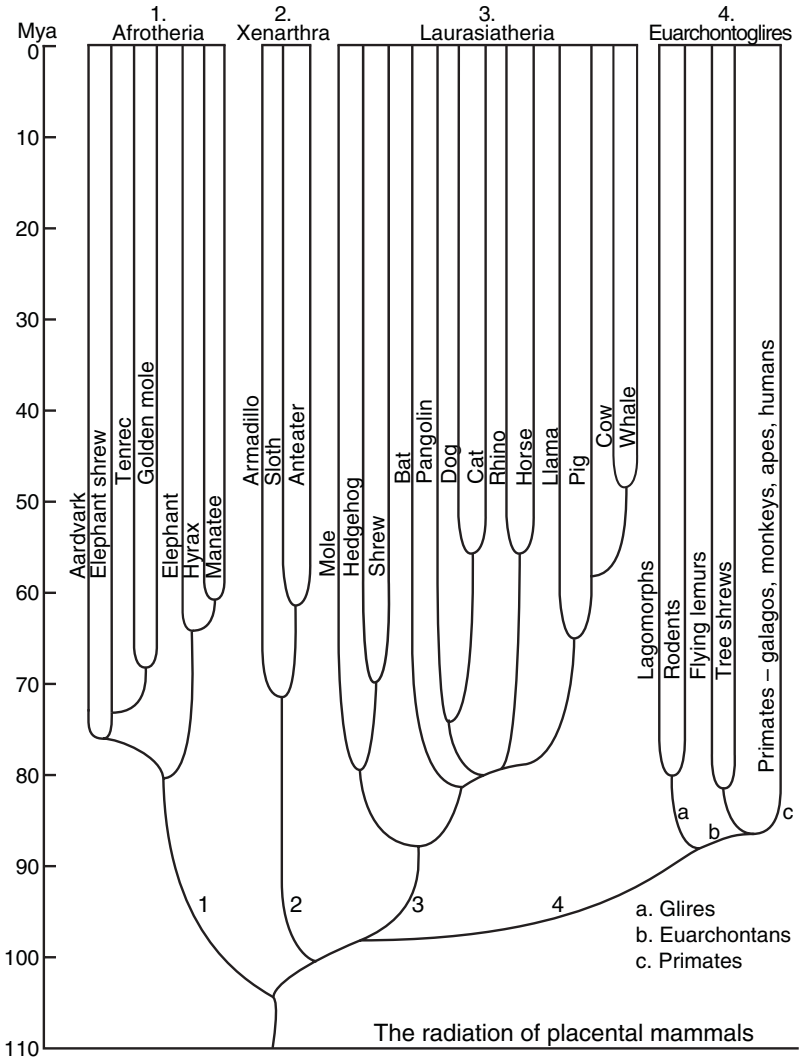

Figure 1 The emergence and radiation of the four major clades of placental (eutherian) mammals. In each clade, a few representative extant members are noted. (1) Afrotheria includes small insectivore-like mammals such as tenrecs and golden moles, as well as the very large elephants and manatees. (2) Xenartheria has the small-brained, specialized anteaters, sloths, and armadillos. (3) The diverse Laurasiatheria range from the widespread bats to carnivores, ungulates, and whales. (4) The Euarchontoglires include Glires – lagomorphs (rabbits) and rodents and euarchontans – primates, flying lemurs, and tree shrews. See Figure 6 for the primate radiation. Time in Mya is indicated on the left. Based on Murphy, W. J., Pevzner, P. A., and O'Brien, J. O. 2004. Mammalian phylogenomics comes of age. *Trends Genet.* 20, 631–639.

sensory inputs to the somatosensory thalamus include muscle spindle receptors for proprioception, which relay in parallel to the dorsal column pathway, first in the lower brainstem and then to the contralateral thalamus, where proprioceptive neurons in the posterior nucleus or a rostral subdivision of VP project to S1 and adjoining areas of somatosensory cortex. Muscle spindle and other somatosensory information are also sent to the cerebellum, and cerebellar deep nuclei project to the ventrolateral nucleus of the thalamus. Somatosensory information also reaches the thalamus via the spinothalamic path, which terminates in and around the VP. Early mammals apparently had no separate motor cortex, as somatosensory areas, especially SR, S1, and S2, had motor functions including those mediated by cortical projections to the brainstem and spinal cord. Other projections from the somatosensory cortex included those to the basal ganglia, and the somatosensory and motor thalamus. The zona incerta of the ventral thalamus is also an important part of this basic mammalian somatosensory system, with somatosensory inputs and inhibitory GABAergic projections to somatosensory cortex the brainstem, and the superior colliculus (Nicolelis *et al.*, 1992).

The most provocative component of the above summary of the sensorimotor system of early

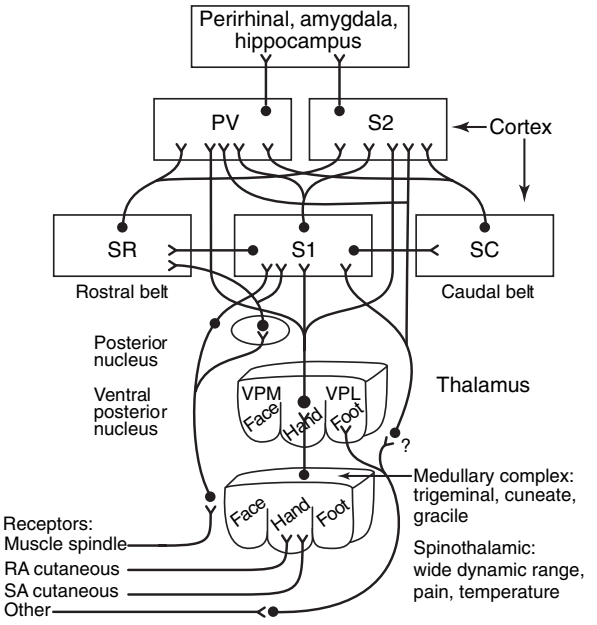

Figure 2 A block diagram of the proposed components of the somatosensory system of early mammals. Receptors and afferents in the skin, muscles, and joints projected to the brainstem and spinal cord, where branches contacted second-order neurons that projected to the contralateral thalamus, or formed fiber pathways to the medullary complex of the brainstem, where second-order neurons projected to the contralateral thalamus. Neurons in the ventral posterior nucleus (VP) received rapidly adapting (RA) and slowly adapting (SA) cutaneous receptor information and projected to primary somatosensory cortex (S1), the second somatosensory area (S2), and the parietal ventral (PV) somatosensory area. A posterior nucleus (a probable homologue of the primate ventral posterior superior nucleus) likely received a relay of muscle spindle receptor information while projecting to SR and S1. S1 projected to rostral (SR) and caudal (SC) somatosensory belt-like areas adjoining S1, and to PV and S2. All of these areas, but especially S1 and SR, were involved in motor control via subcortical projections (not shown) to the basal ganglia, the brainstem, and the spinal cord. PV and S2 interconnected with perirhinal cortex and thereby with the hippocampus and amygdala. The medullary complex, also known as the dorsal column–trigeminal complex, included the principal subnucleus of the trigeminal complex, and the cuneate and gracile subnuclei, to form a representation of the body from face (trigeminal) to forelimb (cuneate) to hindlimb (gracile). The medial subnucleus of VP (VPM) represents the face and mouth, while the lateral subnucleus (VPL) represents the lower body. Based on Kaas, J. H. 2004b. The evolution of the large, complex sensorimotor systems of anthropoid primates. In: Evolution of the Vertebrate Brain and Behavior (*eds.* S. Pellis and L. Marino), *Int. J. Comp. Psychol.* vol. 17, pp. 34–52.

mammals is the claim that there was no separate motor cortex. This is based on the evidence that at least some marsupials and monotremes lack motor areas of cortex. For example, the well-studied North American opossum has the four basic areas of somatosensory cortex (Figure 3) but no motor areas (Beck *et al.*, 1996). In opossums, there is no architectonic, electrophysiological, or connectional evidence for a separate primary motor area, M1, such as those found in all studied placental mammals. Instead, the projection of cerebellum to the motor thalamus, the ventral lateral nucleus, is relayed to somatosensory cortex (Killackey and Ebner, 1973). As a note of caution on this claim, some investigators have presented evidence for a motor region rostral to S1 in monotremes (e.g., Krubitzer *et al.*, 1995) and some marsupials (see Beck *et al.*, 1996), but the more compelling evidence suggests that M1 and other motor areas did not emerge until the advent of placental (eutherian) mammals.

Lagomorphs, rodents, and tree shrews represent the closest living relatives of primates that have been available for study (Figure 1). Together they share some features of sensorimotor system organization with most other mammals. All have S1 and S2 as subdivisions of somatosensory cortex. However, these areas are specialized in different ways. In rabbits, three-fourths of S1 and S2 are devoted to tactile receptors of the head, especially those of the lips and facial vibrissae (Gould, 1986). Little cortical tissue is devoted to the forepaw and less to the hindpaw. In rats (Figure 4), most of these areas represent the facial vibrissae, the buccal pad, and other parts of the face, but the representations of the forepaw is significantly larger than in rabbits (Remple *et al.*, 2003). This difference likely corresponds to the greater use of the forepaw in manipulating food objects by rats (Whishaw, 2003). In tree shrews, there is a large representation of the glabrous nose, as well as large representations of lips and mouth parts, but the forepaw has an even larger representation than in rats, and the arrangement of the forearm representation in S1 more closely resembles that of primates (Sur *et al.*, 1980, 1981). As representational features of S1 across species closely reflect their distributions of peripheral receptors and the specialized use of parts of the sensory surface (Johnson, 1990), these differences in representation, as well as the increased representation of the forepaw in rats and especially tree shrews, likely reflect independent evolutionary trends. Yet, it is safe to propose that the immediate ancestors of primates, as semi-arboreal grasping mammals, had emphasized the forepaw in their somatosensory representations, most likely to an even greater extent than in tree shrews, their close relatives. In rats (Remple *et al.*, 2003) and tree shrews (Remple *et al.*, 2006), there is evidence for a PV somatosensory area just ventral to S2. PV may exist in rabbits and other lagomorphs as well, as this area has been found in a wide range of mammals, but there has been no attempt to identify PV in

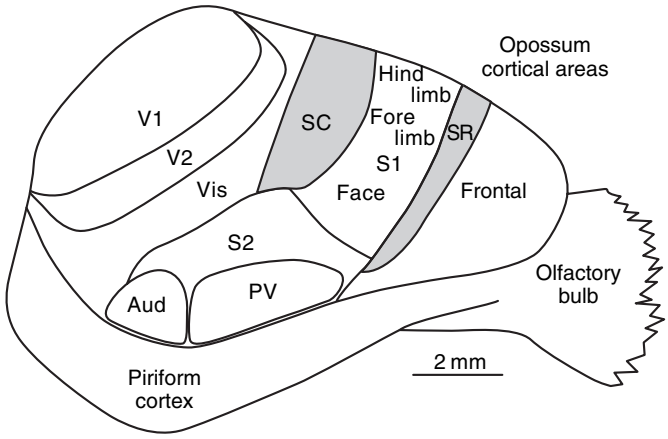

Figure 3 Subdivisions of somatosensory cortex in marsupial opossums shown on a dorsolateral view of the right cerebral hemisphere. Somatosensory areas include primary somatosensory cortex (S1), the adjoining rostral (SR) and caudal (SC) somatosensory belts, the second somatosensory area (S2) and the parietal ventral area (PV). Visual cortex (Vis) includes first (V1) and second (V2) visual areas, and auditory cortex (Aud) may include several areas. There is no evidence of a primary motor area or any premotor areas in frontal cortex. S1 represents the hindlimb to face in a mediolateral sequence, while S2, PV, and possibly SC and SR also contain topographic representations. Based on Beck, P. D., Pospichal, M. W., and Kaas, J. H. 1996. Topography, architecture, and connections of somatosensory cortex in opossums: Evidence for five somatosensory areas. *J. Comp. Neurol.* 366, 109–133.

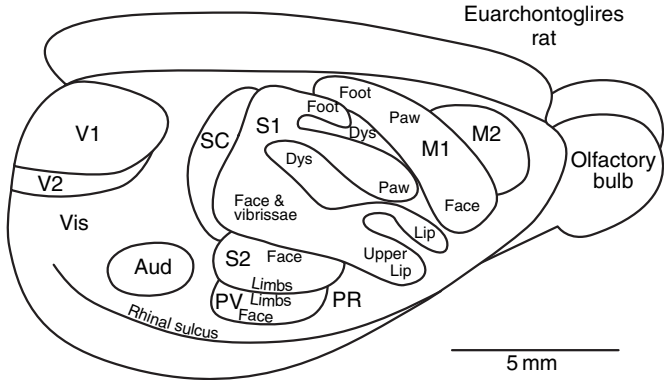

Figure 4 Subdivisions of sensorimotor cortex in rats on a dorsolateral view of the right cerebral hemisphere. The primary somatosensory area (S1), the second somatosensory area (S2), the parietal ventral somatosensory area (PV), and the caudal somatosensory (SC) belt are similar to those in other mammals. The rostral somatosensory area (SR) of other mammals (see Figure 3) forms a dysgranular (Dys) type of cortex that extends caudally to separate forepaw from face, and forepaw from foot representations of S1. A perirhinal (PR) region is indicated lateral to PV. Primary (M1) and secondary (M2) motor areas are found just rostral to S1 and Dys somatosensory cortex (SR). Auditory (Aud) cortex of the three areas, and the first and second visual areas (V1 and V2) are identified. Other visual areas (Vis) are lateral to V2. Based on Remple *et al.* (2003) and others.

lagomorphs. As in opossums (Figure 3), rats (Figure 4), and tree shrews (Figure 5) have caudal and rostral somatosensory bands with inputs from S1. Thus, they have at least five somatosensory areas. The rostral somatosensory belt has more connections with primary motor cortex, M1, and more motor functions, as judged by the thresholds for electrically evoked movements from their cortex. In addition, there is evidence for proprioceptive inputs from the posterior nucleus of the thalamus (Chapin and Lin, 1984; Hummelsheim and Wiesendanger, 1985; Gould *et al.*, 1989). The caudal somatosensory belt may be multisensory, with visual and perhaps auditory inputs (Wallace *et al.*, 2004; Remple *et al.*, 2006). Thus, the somatosensory cortex along the rostral border of S1 has motor and sensory features that resemble area 3a of primates, and the somatosensory belt caudal to S1 has features reminiscent of areas 1 and 2 of primates. A smaller adjoining posterior region resembles posterior parietal cortex of primates.

As in most other mammals, S1, S2, and possibly PV of tree shrews receive activating inputs from the VP of the thalamus (Garraghty *et al.*, 1991). Thus, VP projects in parallel to these areas. The cortical and VP activation is completely dependent on the

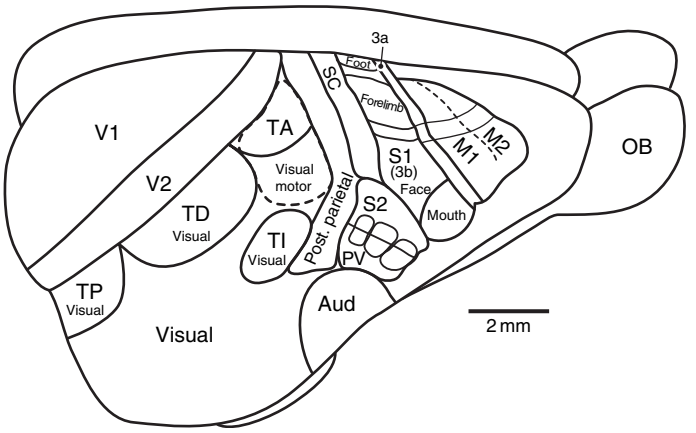

Figure 5 Subdivisions of sensorimotor cortex in tree shrews shown on a dorsolateral view of the right cerebral hemisphere. Somatosensory areas include primary somatosensory cortex (S1 or area 3b), a rostral somatosensory belt (SR in Figure 3) that is called area 3a here, a caudal somatosensory belt (SC) that has two divisions (SC1 and SC2), a second somatosensory area (S2), and a parietal ventral area (PV). In addition, a posterior parietal region has connections with somatosensory and motor areas, the anterior temporal area (TA) has visuomotor cortical connections, as does cortex just lateral to TA. The three ovals bridging the S2–PV border correspond to representations of the hindlimb, forelimb, and mouth in a caudorostral sequence. Motor cortex includes a primary motor area (M1) and a premotor area (M2). An auditory region (Aud) may contain several auditory areas, while most of the caudal half of the cerebral hemisphere is visual. The first and second visual areas (V1 and V2) are identified, as well as proposed temporal posterior (TP), temporal dorsal (TD), temporal anterior (TA), and temporal inferior (TI) visual areas. Scale bar: 2 mm. Based on Remple, M. S., Reed, J. L., Stepniewska, I., and Kaas, J. H. 2006. The organization of frontoparietal cortex in the tree shrew (*Tupaia blangeri*). I: Architecture, microelectrode maps and corticospinal connections. *J. Comp. Neurol.* 497, 133–154.

relay to VP of the dorsal column trigeminal brainstem complex via the medial lemniscus in rats (Jain *et al.*, 2003) and monkeys (Jain *et al.*, 1997), and it is not replaced after injury by the spinothalamic system.

As in other placental mammals, tree shrews (Remple *et al.*, 2006) and rats and other rodents (Wise and Donoghue, 1986) have a primary motor area, M1. In rodents, a popular proposal is that M1 partly overlaps S1, especially in the medial portion devoted to the hindlimb (Sanderson *et al.*, 1984). This premise largely stems from the observation that movements can be evoked from portions of S1 at current thresholds comparable to those for M1. This reflects the widespread role of S1 in motor functions. In rats (Li *et al.*, 1990), more of the corticospinal neurons originate in S1 than rostral somatosensory belt or M1, in marked contrast to primates (Wu *et al.*, 2000). In tree shrews (Remple *et al.*, 2006), S1 (3b), the rostral belt (3a), and M1 contribute nearly equally to corticospinal projections. M1 is an architectonically distinct area of agranular cortex in rats and tree shrews, with a complete or nearly complete representation of movements of the contralateral body. In rats, the emphasis is on facial whisker movements and in tree shrews, face and tongue movements; the evoked movements of the forelimb in these mammals are rather crude, with little evidence of individual digit control (Remple *et al.*, 2003; Sanderson *et al.*, 1984; Wise and Donoghue, 1986). As a reflection of the predominant origin of corticospinal axons from S1 rather than M1, the spinal cord terminations in most mammals are largely in the dorsal horn and intermediate zone of the spinal gray (e.g., Doetsch and Towe, 1981; Armand, 1982). The dense terminations of corticospinal axons of primates onto the motor neurons supplying distal limb muscles does not exist or is very limited in rodents and tree shrews. As an unusual feature, the spinal course of the corticospinal fibers in rodents and tree shrews is at the base of the contralateral dorsal columns rather than in the lateral spinal cord as in primates.

In addition to M1 (Neafsey *et al.*, 1986; Remple *et al.*, 2006), rodents and tree shrews have a second motor area, M2, along the rostrodorsal border of M1 (Figures 4 and 5). This second motor area has few corticospinal neurons, and higher currents are required to evoke movements than in M1. The overall pattern of somatotopy of evoked movements parallels that of M1. There are various possible interpretations of how this M2 compares to subdivisions of motor cortex in primates. As M1 in monkeys has rostral and caudal subdivisions (e.g., Stepniewska *et al.*, 1993), one possibility is that M2 is a subdivision of M1. A more likely possibility is that M2 is homologous to either the supplementary motor area (SMA) or the premotor cortex (PM) of

primates (Rouiller *et al.*, 1993). While premotor cortex has been divided into dorsal and ventral premotor areas in primates, and these areas have been further divided in monkeys (see below), the somatotopy of ventral premotor cortex, representing the head and forelimb, and the somatotopy of dorsal premotor cortex, devoted mainly to the hindlimb and forelimb, suggests that they may have differentiated out of a single premotor area bordering M1 (an area that might have resembled M2 of rats and tree shrews).

In conclusion, comparisons of the sensorimotor systems of the nearest available relatives of primates (lagomorphs, rodents, and tree shrews) suggest that the immediate ancestors of primates had a rather simple sensorimotor system. The basic subcortical components of the system were likely those found in many other mammals. In primary somatosensory cortex, a moderate enlargement and rearrangement of the forepaw representation was likely. Cortex caudal to S1 included a rostral somatosensory band (SC) bordering S1 and a more caudal zone of posterior parietal cortex with inputs from S1. The position of SC, the somatosensory region immediately caudal to S1, suggests that it subsequently differentiated into area 1 or perhaps areas 1 and 2 of primates. A band of dysgranular cortex on the rostral border of S1 had more pronounced motor functions and connections and possibly proprioceptive sensory inputs. This cortex appears to be the homologue of area 3a of primates. A separate and architectonically distinct agranular motor cortex, M1, was present as well as a premotor area, M2. However, the majority of the corticospinal projections emerged from S1, the rostral somatosensory area, RS, and M1 rather than M2. Furthermore, these corticospinal projections terminated in the dorsal and intermediate levels of the spinal grey and not in the motor neuron pools of the ventral spinal grey, thereby having a less direct effect on motor control. Finally, these cortical projections were focused in the brainstem and cervical spinal cord with little extension into the thoracic and lumbar spinal cord.

4.02.3 Somatosensory and Motor Systems of Early Primates: Inferences from Prosimians and Other Primates

Primates emerged as a branch of the Euarchontoglires superclade (Figure 1) over 7080 Mya (Block and Boyer, 2002; Murphy *et al.*, 2004). Subsequently, they separated into four main lines, including the plesiadapiforms, a semi-order of extinct archaic primates, and the euprimates. The stem euprimates led to the present-day lemurs, lorises, and galagos, the highly specialized tarsiers, and the greatly varied anthropoid monkeys, apes, and humans (Figure 6). Some of the lemurs and galagos closely resemble early primates in body type, brain size relative to body size, and brain shape. Most early primates were the size of cats or smaller, nocturnal, and fed in the fine branches of bushes and trees on insects, small vertebrates, fruits, and leaves (Ross, 1996; see The Role of Vision in the Origin and Evolution of Primates). This behavioral niche required exceptional sensorimotor abilities in that there was the need to stabilize the body in moving branches while reaching for food items (Block and Boyer, 2002). Whishaw (2003) suggests that visual control of hand movements is likely to be the distinguishing feature of primate behavior. To mediate improvements in visually guided reaching behaviors and other sensorimotor abilities, early primates were characterized by an increase in the complexity of visual cortex, the involvement of regions of posterior parietal cortex in visuomotor processing, and the emergence of premotor areas with visuomotor inputs.

Given that great effort is needed to reveal the organization of sensorimotor systems in any primate, and that there are over 200 species of primates (Purvis, 1995), with many of them protected or otherwise unavailable for study, research on primates has concentrated on a few useful and informative species (Kaas, 2002). Galagos are rat- to cat-sized, arboreal, nocturnal, African primates that feed on fruits, gums, and insects. They are easily bred and reared in the laboratory, and their nervous systems have been more extensively studied than those of other prosimian primates. Thus, much of what we know about the sensorimotor systems of prosimian primates is based on results of studies on galagos. In general, we assume that features of the sensorimotor system of galagos and other prosimians that are shared with other primates emerged early in primate or preprimate evolution. Traits present in prosimians and other Euarchontoglires mammals emerged early, with or before Euarchontoglires mammals.

As in other mammals, afferents from the skin and muscles of galagos and other primates enter the brainstem and spinal cord with one branch synapsing on cells in the dorsal horn or the brainstem and the other coursing to the dorsal column–trigeminal complex in the lower brainstem (Figure 2). A notable modification in primates is that the representation of the glabrous hand is expanded and differentiated in the cuneate nucleus of the complex. In galagos, this nucleus is larger than in rats

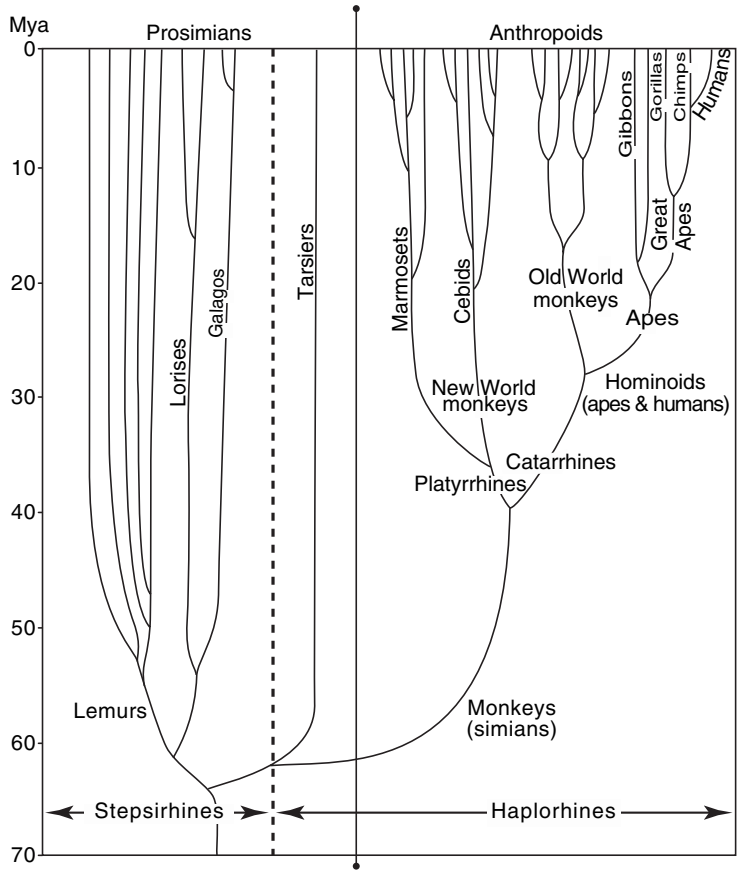

Figure 6 The evolution of extant primates. While archaic primates diverged from other Euarchontoglires over 80 Mya, the separation into prosimians, tarsiers, and anthropoids occurred between 70 and 60 Mya. Based on Purvis (1995) and others. Time in Mya is indicated on the left. Modified from Kaas, J. H. and Preuss, T. M. 2003. Human brain evolution. In: Fundamental Neuroscience (*ed.* L. R. Squire), 2nd edn., pp. 1147–1166, Academic Press.

and tree shrews, and the digits are represented from D1 (thumb) to D5 in a lateromedial sequence (Strata *et al.*, 2003). This nucleus receives the rapidly adapting and slowly adapting cutaneous afferents from the hand, while the muscle spindle (proprioceptive) receptors relay to a well-differentiated external cuneate nucleus. The dorsal column–trigeminal complex relays, as in other mammals, to the contralateral VP of the thalamus. VP is architectonically very distinct in Nissl (Figure 7), cytochrome oxidase, and other preparations (Kaas *et al.*, 2006), and the nucleus is subdivided by septa that separate subnuclei representing different body parts. Thus, a narrow lateral portion is devoted to the tail, an adjoining more medial portion represents the hindlimb, while a larger more medial sector is devoted to the forelimb, mainly the glabrous hand. An elongated medial portion has subdivisions representing various portions of the face and oral cavity (lips, tongue, teeth). VP of galagos and other primates differs from rats and tree shrews in that the nucleus is more elongated mediolaterally, with proportionally more of VP devoted to the limbs, especially the glabrous hand. Yet, the representations of the lips, tongue, and teeth are large. The VP projects to S1, S2, and PV, as in other mammals, thereby providing activating inputs in parallel to three areas of somatosensory cortex. Thus, lesions of S1 fail to deactivate S2 and PV (Garraghty *et al.*, 1991). In this way, galagos resemble their nonprimate ancestors and differ from anthropoid primates where VP no longer projects to S2 and PV, and lesions of S1 deactivate S2 (Garraghty *et al.*, 1990).

Three other nuclei of the primate somatosensory thalamus are apparent in galagos. Just ventral to VP, the ventroposterior inferior nucleus (VPI) contains small neurons that are pale-staining in Nissl preparations (Figure 7a). VPI receives inputs from the spinothalamic pathway and projects broadly to somatosensory areas of cortex, largely to the superficial layers. These VPI projections appear to modulate the activity of neurons in cortical areas, rather than provide an independent source of suprathreshold activation. VPI is not recognized as a

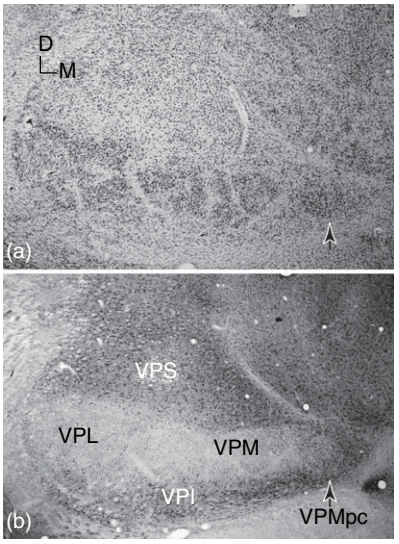

Figure 7 The somatosensory thalamus of a prosimian primate (galago). The thalamus has been cut into thin sections in the frontal (coronal) plane and processed with a Nissl stain for cell bodies (a) or for the expression of a calcium-binding protein, calbindin (b). In both sections, medial (toward the third ventricle) is right, and dorsal is up. In a Nissl preparation, the VP is apparent as a region of larger, darkly stained neurons (arrow), in contrast to the lightly stained, less densely packed neurons in the ventroposterior superior nucleus (VPS) just dorsal (superior) to VP and the ventroposterior inferior nucleus (VPI) just ventral (inferior) to VP. Medially, a 'taste' nucleus, the parvocellular ventroposterior medial nucleus (VPMpc), has more uniformly distributed, smaller cells. The VP is subdivided by a cell-poor septum into a large medial ventroposterior subnucleus (VPM) and a lateral ventroposterior subnucleus (VPL). Another septum separates VPL into a medial portion representing the hand and a lateral portion representing the foot. Other septa are apparent in VPM. In sections processed for calbindin, VP (VPL plus VPM) expresses little calbindin, while VPS, VPI, and VPMpc express more. Other histological preparations also demonstrate clear differences between these nuclei. These three somatosensory nuclei are well differentiated in primates compared to most other mammals. In many mammals (Figure 2), part or all of the region identified as the posterior nucleus may be a homologue of VPS, while a region comparable to VPI is seldom identified.

distinct nucleus in the nonprimate relatives of primates, but VPI is obvious in all primates. As spinothalamics also terminate in the septal zones of VP in primates, it is possible that VPI differentiated from a VP with both spinothalamic and medial lemniscus inputs. A VPI that closely resembles VPI of primates apparently differentiated independently in raccoons (Herron, 1983). The ventroposterior superior nucleus (VPS) is just dorsal to VP. This nucleus receives muscle spindle receptor inputs and projects to cortex termed 3a or SR (Figure 8) just rostral to S1 (area 3b). In Nissl preparations, VPS has less densely packed and less darkly stained neurons than VP, and these neurons express more calbindin and less cytochrome oxidase (Figure 7). VPS is apparent in all primates, but its homologue in nonprimates is uncertain. Possibly, the posterior nucleus of rodents or the proprioceptive rostral cap of VP is a homologue of VPS. Just medial to VPS, the anterior pulvinar (PA) projects widely to areas of somatosensory cortex, while receiving inputs from somatosensory cortex. This nucleus is more conspicuous in anthropoid primates, while having no obvious counterpart in rodents and tree shrews. Finally, a taste or gustatory relay nucleus, VPMpc, can be identified just ventromedial to VP in primates (Figure 7), as in other mammals.

In summary, the comparative evidence indicates that the somatosensory thalamus of early primates had been modified to reflect a primate pattern while retaining some primitive features. Most notably, the ventroposterior inferior and superior nuclei, together with the anterior pulvinar had differentiated to become identifiable structures. In addition, VP acquired more of a primate configuration, with a mediolaterally elongated shape and subdivisions separated by septa for the forelimb and hindlimb, as well as subdivisions of the face and oral cavity. The subdivision of VP for the forelimb, especially the glabrous hand, had become enlarged.

Somatosensory cortex of galagos has some, but not all of the features of somatosensory cortex in anthropoid primates. In some ways, anterior parietal cortex resembles that of tree shrews and rats. However, a primary somatosensory area, S1 (area 3b), is elongated mediolaterally and it contains an anthropoid-like somatosensory representation (Figure 8). The primary somatosensory area, S1, is bordered rostrally and caudally by parallel somatosensory representations. The rostral somatosensory field, SR, by position, architectonic features, responsiveness to stimuli, and inputs from VPS, seems to have most of the features of area 3a of anthropoid primates, and we use the term, area 3a, here. The caudal somatosensory area, SC, has the position, architecture, and the sparse inputs at least from the VP and the dense inputs from area 3b that characterize area 1 of anthropoid primates, but SC does not respond well to somatosensory stimuli in anesthetized galagos, and thus a detailed somatosensory representation has not been produced in microelectrode mapping studies. As such a map has been used to identify area 1 as a second systematic representation of the cutaneous receptors of the contralateral body surface in anthropoid primates (e.g., Kaas *et al.*, 1979), it remains uncertain if SC of

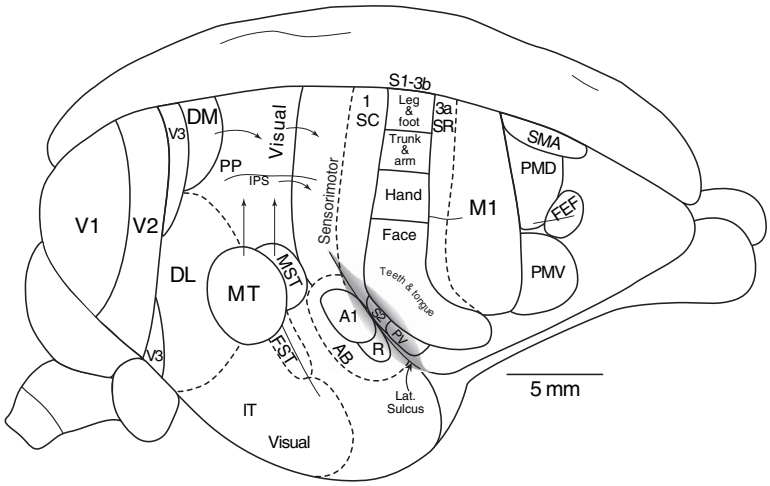

Figure 8 Sensorimotor cortex of a prosimian primate (galago) shown on a dorsolateral view of the right cerebral hemisphere. Somatosensory cortex includes S1 (area 3b), a rostral somatosensory strip (SR) that appears to be homologous to area 3a of other primates, and a caudal somatosensory strip (SC) that may be homologous to area 1 or areas 1 and 2 of other primates. On the upper bank of the lateral sulcus, adjoining S1, somatosensory areas S2 and PV are bordered deeper in the sulcus (not shown) by the parietal rostral somatosensory area (PR) and caudal and rostral divisions of the ventral somatosensory area (VSc and VSr), as well as a retroinsular somatosensory area (Ri). Posterior parietal cortex includes two major subdivisions: a rostral region with dense somatosensory inputs and projections to motor and premotor areas and a caudal region dominated by inputs from visual areas (arrows) and projections to the rostral somatosensory region of posterior parietal cortex (arrows). Both regions appear to contain several subdivisions or areas. Motor cortex includes primary motor cortex, M1, dorsal and ventral premotor areas (PMD and PMV), a frontal eye field (FEF), a supplementary motor area (SMA), a pre-SMA, and rostral and caudal cingulate motor areas (CMAr and CMAc) on the medial wall (not shown). The PMD has rostral (PMDr) and caudal (PMDc) subdivisions, differing in connections and architecture. For reference, first, second, and third (V1, V2, and V3), dorsomedial (DM), dorsolateral (DL), middle temporal (MT), medial superior temporal (MST), frontal superior temporal (FST) visual areas are shown. Auditory areas include the primary area (A1), rostral area (R), and the auditory belt (AB). IPS, intraparietal sulcus. Based on Wu *et al.* (2000), Wu and Kaas (2003), and Stepniewska *et al.* (2005).

galagos has all of the characteristics of area 1. Yet it seems reasonable to propose that SC in galagos, and perhaps other mammals, is the homologue of area 1 of anthropoid primates. Alternatively, SC could be the homologue of areas 1 and 2 combined (see below).

In cortex lateral to area 3b, galagos have the two areas, S2 and PV (Figure 8), with inputs from S1 (area 3b), SR (3a), and SC (area 1). S2 and PV in turn project to other areas located in the cortex of the lateral sulcus, including the insula (Wu and Kaas, 2003). Because these additional areas have been identified mainly by relative location, architecture, and connection patterns, their identities remain somewhat uncertain. Two of the locations appear to correspond to the recently defined caudal and rostral divisions of the ventral somatosensory complex, VSc and VSr of anthropoid primates (Coq *et al.*, 2004). Other locations with S2 and PV connections include the retroinsular cortex (Ri) and the parietal rostral area, PR, of monkeys (Krubitzer and Kaas, 1990). Thus, it appears that galagos have an array of somatosensory areas in cortex of the lateral sulcus that largely matches that described in monkeys, and includes at least two areas, PV and S2, also found in other mammals.

Posterior parietal cortex is more extensive and more complexly organized in galagos than in related nonprimates such as tree shrews and rats. The rostral half of posterior parietal cortex can clearly be identified as part of the somatosensory cortical network due to dense interconnections with somatosensory areas of anterior parietal cortex, especially area 1, and areas of the lateral sulcus, including S2, PV (Wu and Kaas, 2003), and adjoining areas (Fang *et al.*, 2005). The rostral half of posterior parietal cortex projects densely to subdivisions of motor cortex (see below). In addition, this cortex is clearly involved in motor functions. Electrical stimulation of sites throughout rostral posterior parietal cortex evokes movements of body parts, depending on the site stimulated (Stepniewska *et al.*, 2005). Overall, there is a tendency for the stimulation of medial locations in posterior parietal cortex to evoke hindlimb movements, middle locations to evoke forelimb movements, and lateral locations to evoke face and eye movements, but there is a more complex pattern imposed on this tendency. Subregions in this rostral half of posterior parietal cortex appear to relate to components of

ethologically relevant behaviors, so that there are regions where stimulation evokes defensive movements, reaching movements, and hand-to-mouth movements. All these evoked behaviors are mediated via other parts of the sensorimotor network, as movements are no longer evoked when the functions of primary motor cortex are blocked. Besides the direct somatosensory inputs to posterior parietal cortex, the rostral somatosensory half receives dense inputs from the caudal visual half, which is identified as predominantly visual in function by the presence of inputs from a number of previously defined primate visual areas (Fang *et al.*, 2005), including the middle temporal visual area (MT), the medial superior temporal area (MST), and the dorsomedial area (DM). Thus, visual and somatosensory inputs combine in posterior parietal cortex to provide guidance for the execution of reaching, retrieving, and defensive movements.

It is tempting to relate subdivisions of posterior parietal cortex in galagos to those proposed for anthropoid primates, especially the more fully studied areas of macaque monkey. Areas predominantly involved in reaching, retrieving, and eye movements have been described (Cohen and Andersen, 2002), and defensive movements have been evoked by electrical stimulation of one of these areas, the ventral intraparietal area, VIP (Cooke *et al.*, 2003). Unfortunately, not enough is known about these proposed areas in prosimians and simians to productively identify homologous areas and specify differences. Yet it is clear that galagos, as in anthropoid primates, have an extensive posterior parietal region with visual and somatosensory inputs, motor cortex outputs, and sensorimotor functions. This expanded region of cortex is larger and more complexly organized than in the extant relatives of primates.

Galagos also resemble anthropoid primates and differ from other mammals in the organization of motor cortex. In tree shrews and rats, there was evidence for only a primary motor area (M1), and a premotor field (M2). The primary motor area was not a major source of corticospinal projections, and representation of the forepaw was not proportionally larger. In galagos, M1 is not as architectonically differentiated as in simians, but a substantial sector of M1 represents forelimb movements, and this sector provides most of the corticospinal projections to the cervical spinal cord (Wu *et al.*, 2000), as in monkeys (e.g., Nudo and Masterton, 1990; Wu and Kaas, 1999). In both galagos and monkeys, additional corticospinal neurons are located in area 3a and in premotor cortex. However, M1 differs from monkeys (e.g., Stepniewska *et al.*, 1993) in that few locations in M1 of galagos evoke movements of digits. Thus, some aspects of galago M1 are intermediate between M1 of nonprimate relatives and M1 of simians.

Galagos have most of the premotor areas of anthropoid primates (Wu *et al.*, 2000). They have a dorsal premotor area, PMD, with a rostral division more densely connected to prefrontal cortex and a caudal division more densely connected to M1. They have a ventral premotor area, PMV, which is preferentially devoted to forelimb and face movements. Galagos also have a frontal eye field where electrical stimulation of sites evokes rapid, saccadic eye movements. On the medial lip of the dorsal cortex of the cerebral hemisphere, galagos have an SMA, and at least two cingulate motor areas, rostral (CMAr) and caudal (CMAc), exist in cortex of the medial wall, where there is evidence for a cingulate sensorimotor area. There is also evidence for a presupplementary motor area (pre-SMA). These motor fields are each characterized by a particular pattern of connections with other areas and thalamic nuclei in galagos and other primates (see Wu *et al.*, 2000; Fang *et al.*, 2005). Thus, PMD receives inputs from a broad band of mostly medial regions in posterior parietal cortex, PMV from more lateral and rostral parts of posterior cortex as well as from somatosensory areas, and SMA with the medial portion of posterior parietal cortex. Other connections are with frontal cortex, other motor areas including callosal connections between motor areas, basal ganglia, and the motor nuclei of the thalamus. All of these areas are also found in monkeys. As in macaques and other monkeys, these areas interconnect, and directly or indirectly influence the output of primary motor cortex, M1. In addition, most of these areas (PMV, PMDc, CSMA, CMAc, CMAr, SMA, and, of course, M1) contribute at least sparse corticospinal projections. Thus, both galagos and monkeys have highly similar systems of motor and premotor areas, as parts of a more extensive sensorimotor network.

In conclusion, it appears likely that the sensorimotor system of early primates resembled that found in present-day galagos. Many of the features of the system in galagos are shared with other primates, providing evidence that these features emerged early in primate evolution, perhaps in the immediate nonprimate ancestors of primates. To the extent that the sensorimotor system of galagos differs from that in anthropoid primates, galagos tend to resemble the nonprimate relatives of primates. Thus, M1 is less differentiated architectonically

and digit movements of the forepaw are poorly represented compared to M1 of monkeys. Posterior parietal cortex is less extensive and likely has fewer subdivisions in galagos. In addition, PMV appears to lack the rostral and caudal subdivisions that are apparent in macaque monkeys, and this would seem to be a more primitive condition. However, the important conclusion is that galagos share many features with other primates that are not found in the nonprimate relatives. The primate line emerged with an array of advances in the organization and connections of the somatosensory thalamus, anterior parietal cortex, lateral parietal cortex, posterior parietal cortex, and motor and premotor cortex.

4.02.4 New and Old World Monkeys: Similarities and Variations

While early primates were nocturnal visual predators in tropical rainforests, the line leading to haplorhine primates (tarsiers and anthropoids) were small, arboreal, insectivorous, but diurnal primates (Ross and Kay, 2004). The shift to diurnality led to a number of changes in the visual system (Kaas, 2003). The ancestors of tarsiers reverted back to a nocturnal niche, and specializations for nocturnal vision reemerged (Collins *et al.*, 2005). Tarsiers became the only primates who eat no vegetation. The early anthropoids modified their teeth and jaws to be able to add unripe fruits and leaves to their diet (Lockwood and Fleagle, 1999). Features of present-day platyrrhine (New World) monkeys and catarrhine (Old World) monkeys indicate that part of the anthropoid adaptation included modifications of the sensorimotor system. The radiation of New World monkeys was based on the chance immigration of early anthropoids from Africa to South America at least 30–40 Mya, probably by rafting (Flynn and Wyss, 1998). Several similar modifications of their sensorimotor systems probably occurred independently in both platyrrhine and catarrhine radiations.

In the somatosensory systems of monkeys, some modifications are apparent even at the levels of the brainstem and spinal cord. Because of an increase in the number of cutaneous receptors in the glabrous skin of the hand (forepaw) of monkeys, more of the dorsal horn of the cervical spinal cord is devoted to afferents from the digits and palm (Florence *et al.*, 1991) than in most other mammals. This selective enlargement is also apparent in the cuneate nucleus (representing the forelimb) of the dorsal column–trigeminal complex of the lower brainstem. In addition, there is at least one major variation in the somatotopy of the cuneate nucleus. In Old World macaque monkeys and humans, the distal phalanges of the digits are represented ventrally in the nucleus, and this appears to reflect the generalized mammalian pattern (Florence *et al.*, 1989). In New World squirrel monkeys, the pattern is reversed, with the representation of the digit tips dorsal in the nucleus (Florence *et al.*, 1991). This raises the possibility that different somatotopies in the cuneate nucleus characterize platyrrhine and catarrhine primates, with platyrrhines diverging from the ancestral pattern. However, more primates need to be studied to evaluate this hypothesis. While the somatotopic organizations are reversed in these two taxa, there is no obvious functional consequence of having either variation.

At the level of the thalamus, the ventroposterior (VP), ventroposterior superior (VPS), ventroposterior inferior (VPI), and anterior pulvinar (PA) nuclei are well differentiated in monkeys. However, in Old World monkeys, the marked histological differences between VP and VPS are reduced, with VPS becoming more similar to VP, suggesting an enhanced or altered role for VPS in the system. Cortical organization has also changed, as have patterns of thalamocortical connections. Most notably, in anterior parietal cortex, four strip-like, parallel somatosensory representations are found, corresponding closely to the classical architectonic fields 3a, 3b, 1, and 2 of Brodmann (1909). VP projects to layer 4 of area 3b and more superficially to area 1, and sparsely to parts of area 2 (e.g., Cusick *et al.*, 1985; Pons and Kaas, 1985; see Kaas, 2004c for review). A portion of neurons in VP, perhaps 20%, project to both area 3b and area 1. Nevertheless, evoked neural activity in area 1 depends on inputs from area 3b, as lesions of area 3b abolish the responsiveness of area 1 to cutaneous stimulation (Garraghty *et al.*, 1990). VPS projects to both area 3a and area 2, providing muscle spindle proprioceptive input, with perhaps 40% of the neurons projecting to both areas. Thus, some of the individual neurons in both VP and VPS project to areas 3a and 1, thereby providing the same information. Unlike other mammals, including prosimian galagos (Burton and Carlson, 1986), VP does not project to S2 and PV. Instead, VPI projects densely to these areas (Friedman and Murray, 1986; Krubitzer and Kaas, 1992). This VPI input apparently modulates the activity of S2 and PV neurons, as these areas depend on anterior parietal cortex for activation (Pons *et al.*, 1987). This is a modification from the ancestral condition seen in galagos and other mammals where VP activates S2 and PV independently. Thus, processing in anthropoid primates became more serial.

4.02.4.1 The Anterior Parietal Cortex of Simians

The representational features of the anterior parietal representations are somewhat variable across different New World and Old World monkeys. For example, the representations of the receptors of the glabrous digits are particularly large and distinct in the dexterous macaque and cebus monkeys, but the hand representation is not so pronounced in New World marmoset monkeys (Carlson *et al.*, 1986). Marmosets and other members of the family Callitrichidae are interesting as these very small monkeys have claws rather than nails on the digits of the hand. Although this has been considered a primitive feature, it appears to be a derived specialization (Sussman and Kinzey, 1984).

New World cebus monkeys and Old World macaque monkeys apparently evolved their greater hand representation and hand dexterity independently. Cebus monkeys are unusual in that they use their tail for active tactile exploration, and the ventral tip of the tail has a glabrous skin surface densely packed with cutaneous receptors. As one might expect from this arrangement, the somatosensory system devotes a large amount of tissue to these receptors in the prehensile tail, with over 10 mm^2 of area 3b activated by the tail (Felleman *et al.*, 1983). This is certainly a derived and remarkable feature of cebus and spider monkeys. Finally, certain aspects of the representation of the body in area 3b of monkeys are reversed in some taxa compared to others. In some monkeys such as cebus and squirrel monkeys, the dorsoventral dimension of the trunk is represented in a reverse order from that in other monkeys (Sur *et al.*, 1982; Felleman *et al.*, 1983). This reversal has no clear functional consequences or implications, but such features suggest that many details of brain organization will be found to vary in patterns that reflect phylogenetic relationships.

Area 1 is also variable in anthropoid primates. In most, area 1 stands out as an architectonically distinct strip of tissue along the caudal border of area 3b. In Nissl preparations, area 3b has a well-developed layer 4 of small cells (granular cells), area 1 has a notably less distinct layer 4, and area 2 has a more distinct layer 4. In addition, area 1 contains a systematic representation of cutaneous receptors, from tail to tongue in a mediolateral sequence, that forms a mirror reversal of the somatotopy of area 3b (see Merzenich *et al.*, 1978 for the first complete description). Neurons in area 1 have larger receptive fields and more complex response properties than those in area 3b. They constitute a second stage of cortical processing as they depend on area 3b projections for activation, although they also receive inputs from the VP of the thalamus. The strip of cortex caudal to area 3b in prosimian galagos also has most of these characteristics, as already discussed, but neurons in anesthetized galagos have not been responsive enough to demonstrate a second mirror image representation, as in monkeys. In addition, the cortex caudal to this strip in galagos is not architectonically very distinct from the strip. These differences suggest that some caution is needed in identifying the caudal somatosensory strip in galagos as area 1, although this does seem likely. This same need for caution applies to Callithricid monkeys, the small tamarins, and marmosets. Cortex just caudal to area 3b in the position of area 1 is not very responsive to tactile stimulation and a systematic representation in this cortex has not been demonstrated (Carlson *et al.*, 1986). Yet projection patterns from area 3b indicate that at least a crude parallel representation exists in this cortex (Krubitzer and Kaas, 1990). In this regard, the area 1 strip in marmosets resembles the SC strip in galagos. The reduced responsiveness of area 1 or SC in marmosets could reflect the retention of ancestral (prosimian) features, but more likely, a regression as the simian ancestors of marmosets evolved into the smallest of anthropoids.

Brodmann (1909) defined a strip of cortex just caudal to area 1 as area 2. In macaque monkeys, most of area 2 is highly responsive to tactile stimuli, and a representation of contralateral cutaneous receptors in area 2 roughly parallels the representation in area 1 (Pons *et al.*, 1985). Thus, the foot representation in area 2 is immediately caudal to the foot representation in area 1, and so on, to form a foot to face representation that parallels that in area 1. To some extent, this representation is a mirror reversal of the one in area 1, but the area 2 representation is not so simple, as it has further reversals of somatotopy within the field. In particular, glabrous digits and pads are represented twice. As area 2 has only been explored in detail in macaque monkeys, we do not know how or if it varies in organization across anthropoids, or even if it really exists in all anthropoids. The only microelectrode mapping study with evidence for an area 2 representation is New World monkeys provided only a brief description of a tail-to-hand representation of deep, possibly proprioceptive, receptors in a mediolateral sequence in parallel with the area 1 representation in owl monkeys (Merzenich *et al.*, 1978). More recently, Padberg *et al.* (2005) recorded from the lateral sector of the area 2 region of New World titi monkeys, and provided evidence for a forelimb representation in area 2 of New World monkeys. However, other interpretations are possible, especially in view of the lack of convincing architectonic evidence for an area 2 in New World monkeys.

Padberg *et al.* (2005) postulate that an area 2 does not exist in New World monkeys, but instead is a feature of the somatosensory system that emerged in catarrhine primates. A more conservative conclusion is that an area 2 representation of predominantly proprioceptive receptors (muscle spindle receptors) evolved in the early anthropoids and this representation became well differentiated in the early catarrhines, and perhaps independently in some of the platyrrhines such as cebus monkeys, although this is uncertain. In New World titi monkeys (Coq *et al.*, 2004), lateral area 1 has connections with the area 2 region, as expected for an area 2, and in New World squirrel monkeys (Cusick *et al.*, 1985), VPS projects to the area 2 region, as expected for area 2. Thus, there is some, but limited, evidence for the existence of an area 2 representation in New World monkeys.

4.02.4.2 The Posterior Parietal Cortex of Simians

The posterior parietal cortex of macaque monkeys has been subdivided in a number of ways into as many as 15–20 potential areas (Lewis and Van Essen, 2000b). The relative extent of posterior parietal cortex in some of the smaller New World monkeys is much less than in macaques, suggesting that more complexity evolved in catarrhine primates. Some of the proposed subdivisions of posterior parietal cortex of macaques are shown in Figure 9. These include the number of areas in the deep intraparietal sulcus of macaques, where the most studied region, the lateral intraparietal area (LIP), appears to be specialized for directing saccadic eye movements via connections with visual areas, the frontal eye field, and superior colliculus (Ben Hamed *et al.*, 2001). The adjacent medial intraparietal area (MIP) has been enlarged caudally by some investigators to become the parietal reach area (PRA), an area thought to be involved in the planning of visually guided reaching movements with the area via visual inputs and connections with dorsal premotor cortex (Marconi *et al.*, 2001; Cohen and Andersen, 2002). The ventral intraparietal area (VIP) receives visual and somatosensory inputs while projecting to premotor cortex (e.g., Lewis and Van Essen, 2000a). VIP appears to be important in guiding monkey locomotion, as well as defensive and avoidance movements to protect against collisions (Cooke *et al.*, 2003). The anterior intraparietal area (AIP) receives visual information from LIP, and projects to ventral premotor cortex, possibly to guide hand grasping and manipulation movements (Sakata and Taira, 1994; Nakamura *et al.*, 2001). The rostromedial bank of the intraparietal cortex, area 5ip or PEa, contains a systematic representation of cutaneous receptors of the hand and digits (Pons *et al.*, 1985) while receiving somatosensory inputs from areas 1, 2, and S2 and projecting to motor and dorsal premotor cortex (Pons and Kaas, 1986). A role in guiding reaching has been hypothesized for this region of cortex (Iwamura and Tanaka, 1996). Further subdivisions of posterior parietal cortex have been proposed for macaques, including subdivisions of large regions traditionally referred to as area 7a, 7b, 5a, and 5b. For example, the region of area 7 just lateral to the intraparietal sulcus has been recently divided into four areas with different patterns of connections to premotor cortex (Gregoriou *et al.*, 2006). At least some of these connection patterns and suggested functional roles are similar to those proposed for subdivisions of posterior parietal cortex in prosimian galagos (Stepniewska *et al.*, 2005), but too little is currently known to allow an area-by-area matching of homologous areas.

Another interpretation of the organization of the rostral half of posterior parietal cortex, including most of areas 5 and 7b, is possible. In monkeys, this broad band of cortex contains a crude somatotopic organization where medial parts relate to the shoulder, arm, trunk, and perhaps the forelimb, more lateral parts in the parietal sulcus relate to the glabrous hand, and the most lateral parts in area 7b relate to the face, lips, and oral structures (Krubitzer and Disbrow, 2006). Again, there is an overall similarity to the crude functional pattern in the rostral half of posterior parietal cortex of galagos. Thus, one could consider the complete band of cortex in both primates to be a single functional area. However, the bulk of the evidence suggests that this band of cortex contains several functionally distinct areas in both prosimians and simians.

In several parts of posterior parietal and parietal–temporal cortex of simians, both auditory and somatosensory inputs activate neurons. This includes VIP of posterior parietal cortex. More laterally, posterior parietal cortex adjoins the temporal lobe, where the caudodorsal portion of temporal cortex is subdivided into an array of three primary auditory areas, perhaps eight secondary areas, and at least two areas of a third level of cortical processing (Kaas and Hackett, 2000). At least one of the second-level areas, the caudomedial area (CM), has neurons that respond to auditory and somatosensory stimuli, with somatosensory inputs coming from somatosensory areas of the lateral sulcus and possibly the somatosensory thalamus (Schroeder *et al.*, 2003). Although cortical regions of somatosensory and auditory

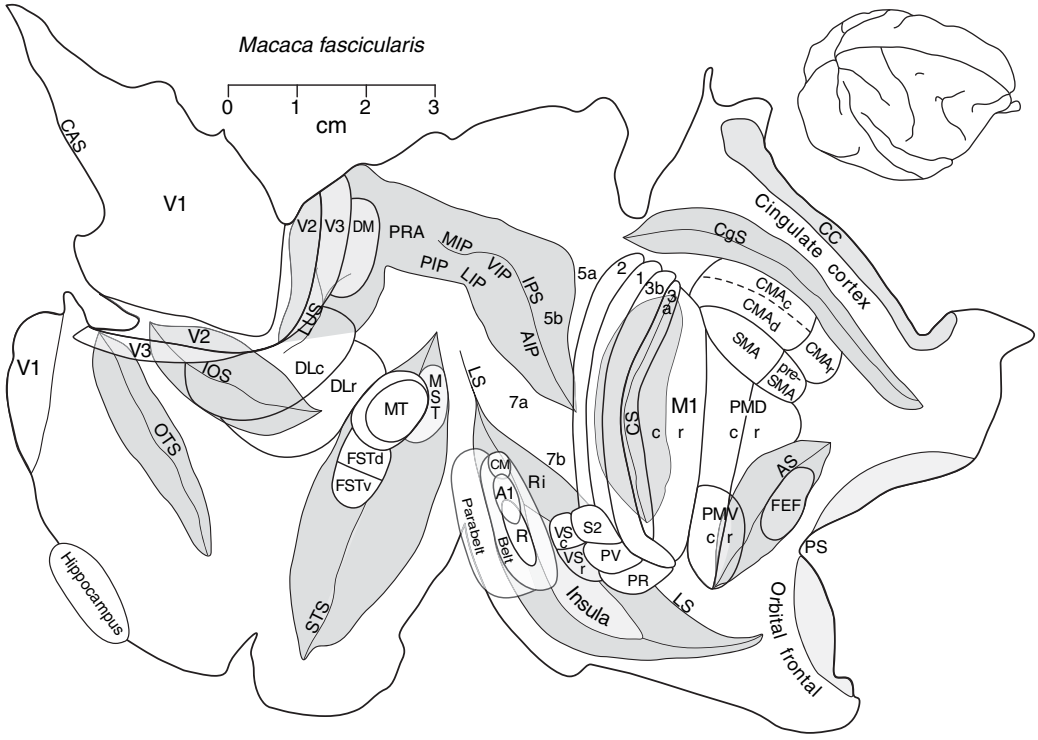

Figure 9 Some of the proposed subdivisions of neocortex of macaque monkeys. The neocortex of the macaque brain (upper right) has been separated from the rest of the brain and flattened (lower left) so that cortex buried in cortical fissures can be seen. To flatten the cortex as a single sheet, of course, requires some cuts and tears. In this view, the four large somatosensory areas of anterior parietal cortex, areas 3a, 3b, 1, and 2, are apparent as parallel, mediolateral strips. The parietal ventral (PV), second area (S2), rostral and caudal ventral somatosensory areas (VSr and VSc), the retroinsular area (Ri), and the parietal rostral area (PR) are in lateral parietal cortex, largely on the upper bank of the lateral fissure, but it is obvious that there is space for a number of other somatosensory areas. The lower bank of the lateral fissure contains auditory areas (primary, A1; rostral, R; auditory belt; and parabelt) with the caudomedial auditory area, CM, having both auditory and somatosensory functions. In posterior parietal cortex, several proposed areas are shown without boundaries, and many more areas have been proposed and may exist.

Areas of the intraparietal sulcus include anterior (AIP), lateral (LIP), medial (MIP), and posterior (PIP) intraparietal areas, along with the parietal reach area (PRA). The frontal motor areas include rostral and caudal divisions of primary motor cortex (M1r and M1c), rostral and caudal divisions of the ventral premotor areas (PMVr and PMVc), and the dorsal premotor areas (PMDr and PMDc), the frontal eye field (FEF), the supplementary motor area (SMA) with dorsal and ventral divisions, the presupplementary area (pre-SMA), and three cingulate motor areas (CMAr, CMAd, and CMAv). Several visual areas are denoted for reference: the first (V1), second (V2), third (V3), rostral and caudal dorsolateral (DLr and DLc), dorsomedial (DM), middle temporal (MT), medial superior temporal (MST), and dorsal and ventral divisions of the fundal superior temporal area (FSTd and FSTv). Cortex of the opened cingulate sulcus (CgS), the arcuate sulcus (AS), the lateral sulcus (LS), the principal sulcus (PS), the intraparietal sulcus (IPS), the lunate sulcus (LUS), the superior temporal sulcus (STS), the intraopercular sulcus (IOS), and the opercular temporal sulcus (OTS) are shaded, as is the corpus callosum (CC). See Kaas (1997) for a discussion of these visual areas.

1overlap in nonprimate mammals, there is no known homologue of CM in nonprimate mammals. Thus, CM appears to represent a primate elaboration of both auditory and somatosensory systems.

In summary, there is presently too little that is known about posterior parietal cortex in New World monkeys to allow detailed comparisons with Old World monkeys, but some overall features of shared organization are expected. Nevertheless, the large expanse of posterior parietal cortex in macaques, and the many proposed subdivisions, suggest that this region became much more complexly organized in catarrhine primates than in early anthropoids and most of their platyrrhine descendants.

4.02.4.3 The Motor and Premotor Cortex of Simians

Primary motor cortex varies in functional organization across taxa of simian primates in that representations of individual finger movements do not predominate in the forelimb portion of M1 in most New World monkeys (Gould *et al.*, 1986; Donoghue *et al.*, 1992; Stepniewska *et al.*, 1993), while larger parts of the forelimb region of M1 of

macaque monkeys is devoted to digit movements (e.g., Qi *et al.*, 2000). M1 of simian primates appears to have rostral and caudal subdivisions, differing in architecture and functions, with the caudal division more involved in digit movements (see Preuss *et al.*, 1996, 1997). M1 in humans may have similar subdivisions (Geyer *et al.*, 1996). Most New World monkeys, such as squirrel monkeys, differ from Old World macaques by having fewer direct projections from motor cortex to spinal motor neurons that control the movements of the hand, thereby allowing more independent movements of the digits (Nakajima *et al.*, 2000). The highly dexterous New World cebus monkeys have independently evolved similar direct cortical projections to spinal motor neurons (Bortoff and Strick, 1993).

The premotor region of cortex of macaque monkeys (Figure 9) also appears to have more functional subdivisions than premotor cortex of New World monkeys. Most notably, the ventral premotor region appears to be a single area in New World monkeys (Preuss *et al.*, 1996) and prosimian galagos (Wu *et al.*, 2000; Fang *et al.*, 2005), while ventral premotor cortex is subdivided into rostral and caudal areas (PMVr and PMVc) in Old World monkeys (Matelli *et al.*, 1985), termed PMVc or frontal motor area 4 (F4) and PMVr or frontal motor area 5 (F5) based on differences in histochemical (cytochrome oxidase) staining in the two fields. PMVc or F4 contains a motor representation of face and proximal arm movements, and neurons with tactile and visual receptive fields on (tactile) or near (visual) the face (Luppino *et al.*, 1999). PMVc (F4) appears to be involved in using information about nearby space to guide movements of the arm and face. Because PMVc resembles PMV of New World monkeys and prosimians, in that PMVc projects to primary motor cortex (M1) and to the spinal cord, PMVc of macaques likely corresponds to PMV of these other primates. PMVr (F5) has only been described in macaque monkeys, and it may be an area that is poorly differentiated or absent in New World monkeys. Stimulation of PMVr (F5) evokes movements of the hand and mouth. Neurons in PMVr (F5) respond when the monkey is performing hand and hand-to-mouth movements, and when the monkey is observing another performing such movements. Because the neurons respond both during an action or observing the same action performed by another monkey or human, they have been called mirror neurons (Gallese *et al.*, 1996). There is evidence that humans also have a mirror-neuron area, and human imitation may be based on a mirror-neuron system (Wohlschlager and Bekkering, 2002). Some have suggested that imitation is essential to language, and that PMVr (F5) is a monkey homologue of Broca's speech region. Petrides *et al.* (2005) postulate that part of dysgranular cortex just rostral to PMVr, is the monkey homologue of area 44 in humans. (Areas 44 and 45 are thought to correspond to Broca's speech region.) Electrical stimulation of this dysgranular cortex in monkeys evoked orofacial movements, and Petrides *et al.* (2005) suggested that Broca's area evolved from an area involved in controlling orofacial actions, such as area 44 of macaque monkeys (see also Preuss *et al.*, 1996). In addition, Nelissen *et al.* (2005) propose that F5 has a caudal region for the traditional mirror neurons, and an anterior region for neurons that are related to grasping, and these neurons for grasping respond to an isolated hand or a robot hand grasping, suggesting that the basics of grasping are coded in rostral F5. Thus, there is evidence for considerably more complexity in the PMV regions of macaques than in New World monkeys. Nevertheless, PMV of highly dexterous New World cebus monkeys has a well-developed representation of digits and dense connections with the hand portion of M1 (Dum and Strick, 2005), and further studies could reveal complexities of PMV organization in these New World monkeys.

In Old World monkeys, the region of the SMA has been divided into caudal SMA proper and rostral pre-SMA motor fields in macaques (reviewed by Tanji, 1994). A pre-SMA area may exist in New World monkeys, but the current evidence for such an area is limited (Sakai *et al.*, 2000). However, there is also some evidence for a pre-SMA in galagos (Wu *et al.*, 2000). Thus, pre-SMA may be an area common to primates.

4.02.5 Sensorimotor Systems in Apes and Humans

Compared to other primates, apes and humans are characterized by larger brains that take longer to mature and have higher energy requirements (Jablonski *et al.*, 2000). As a result, higher-quality foods are required, and reproductive rates are low. Success depends on a long life expectancy, and the ability to find and process high-quality foods. These requirements suggest that the larger brains of these primates function in many ways to allow food resources to be exploited and to extend the reproductive life span. However, only humans and some of their hominin ancestors with the largest of primate brains were able to expand their ranges from

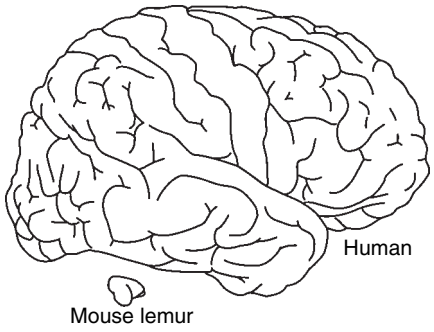

Figure 10 Primate brains vary greatly in size. The human brain is much larger than the brain of the mouse lemur, yet they share some sensorimotor areas. However, the large human brain has added a great number of additional sensorimotor and other areas, thereby becoming more modular and decreasing the problem of maintaining connections as the larger brain evolved. See text.

the favorable tropics where ripe fruit is regularly available to more challenging environments, where tool and weapon use allowed new food sources to be exploited, and resources to be defended. Changes in brain size were followed by changes in brain function, and brain organization, including alterations in the sensorimotor system (Figure 10).

As far as we know, the sensorimotor systems of apes and humans include the major components that have been proposed for their catarrhine relatives, the well-studied macaque monkeys. However, information is very limited, and there are many uncertainties. Yet early cortical stimulation (Hines, 1940; Leyton and Sherrington, 1917) and recording studies in chimpanzees (Woolsey *et al.*, 1943) indicate that at least one orderly somatotopic representation exists in anterior parietal cortex, and that an evoked movement map, M1, exists in architectonically defined area 4 (e.g., Bucy, 1935). Architectonic studies also indicate that anterior parietal cortex of apes and humans has the four fields of macaques, areas 3a, 3b, 1, and 2 (Grefkes *et al.*, 2001), and there is evidence for separate representations in areas 3a, 3b, 1, and 2 of humans (Young *et al.*, 2004). In humans, there is also evidence for areas PV and S2 of lateral parietal cortex (Disbrow *et al.*, 2000).

The organization of posterior parietal cortex in humans is generally modeled after proposals based on macaque monkeys, yet functional differences have been a focus of research. Clear evidence of the specialization of different functions in each cerebral hemisphere are evident in humans, where lesions of the right posterior parietal cortex typically produce a much more profound neglect of contralateral visual and tactile information than lesions of the left cerebral hemisphere (see Mountcastle, 2005). The general assumption, with some supporting evidence, is that the same frontal motor fields of macaques exist in humans, with, of course, specializations of ventral premotor fields of the left cerebral hemisphere to form Broca's speech region (e.g., Amunts *et al.*, 1999). Other specializations of motor fields of the left hemisphere are likely, given the greater role of the left hemisphere in motor planning and motor control (Kimura, 1993; Serrien *et al.*, 2006). Anatomical and functional asymmetries exist even in primary motor cortex. Further research is needed to determine what features of the sensorimotor cortex of humans are shared with apes and monkeys, and what features are new or perhaps lost.

For theoretical reasons, based on the major increase of brain size in humans, one would predict further evidence of differences in function between comparable regions of the two cerebral hemispheres, specialization of the larger somatosensory areas (3a, 3b, 1, and 2) and motor area (M1) for a fine-grain rather than global analysis of sensory information and motor control, and an increase in the number of cortical areas (Kaas, 2000).

Humans do have specializations of hand use that are reflected in the motor system. Humans are distinguished from other primates by their extremely dexterous use of the hands. In part, this was made possible by the evolution of upright posture, which freed the hand from a major role in locomotion, while allowing specialization that led to tool construction and use. Evidence of tool use pre-dates modern humans and extends back at least 2.5 My to our *Homo habilis* ancestors. The evidence suggests that the usual specialization of the right hand and the left sensorimotor cortex for dexterous functions began at least 2–3 Mya (Corballis, 1989, 1998; see The Evolution of Hemispheric Specializations of the Human Brain). Lethal intergroup violence, aided by the use of manufactured weapons, appears to have been an important selection factor in hominid evolution over the last 2–3 My (Kelly, 2005). Motor control for the making of tools and weapons would have likely depended on changes in the motor system. The neural basis for independent finger movements is thought to depend on the size and termination pattern of the pyramidal motor tract, which is exceptionally large in humans (Heffner and Masterton, 1983) and has the fullest monosynaptic linkage with spinal motor neurons in humans (see Wiesendanger, 1999; Lemon and Griffiths, 2005). These changes in the motor system were paralleled by changes in the hand, so a long, strong thumb could be apposed to fingertips in humans. The smaller thumb of early hominoids allowed a power grip, but possibly not a fully developed precision grip

(Napier, 1999), the hallmark of human hand use. These sorts of changes in the human motor system are well known, as they have been easy to measure, but they are likely to be only the tip of the iceberg. We expect that further research will reveal many additional hominoid and human specializations of the sensorimotor brain. Anatomical asymmetries of human cortex that are related to language functions are also expressed in the great apes (Gannon *et al.*, 2005), indicating that such hemispheric specializations initially evolved for functions other than language, and that hemispheric specializations have a long history.

4.02.6 Summary and Conclusions

The exceptional sensorimotor skills of humans reflect their massive and complexly organized sensorimotor system. While the details of the organization of this system are incompletely known for humans, and even more so for apes, we can deduce how the major features of the human system evolved by comparing features in extant mammals. Ideally, such an analysis would broadly survey extant mammals, consider features cladistically in a series of smaller clades leading to humans, and determine if conclusions are consistent with observations from the record of fossil brain endocasts on brain size and fissure patterns (e.g., Radinsky, 1975), as well as theoretical predictions based on brain size (Kaas, 2000). In practice, this approach is difficult to realize fully because understandings of the organizations of sensorimotor systems are fragmentary and incomplete. The sensorimotor systems of only a few taxa are well known. In addition, the fossil record is also fragmentary, and few cortical fissures, which often are apparent in endocasts, have an established significance in terms of marking functional boundaries in cortex. Finally, large brains would seem to need to be organized in specifically different ways than small brains, but comparative studies have only partially validated assumptions about how brains should change with increasing size. Nevertheless, enough is known to allow a broad outline of sensorimotor system evolution in primates, and this outline can be expanded and modified as further observations become available.

4.02.6.1 Early Mammals

Only a few subdivisions of the thalamus and cortex characterized the sensorimotor system of early mammals. The thalamus included a distinct VP for relaying slowly adapting and rapidly adapting cutaneous receptor information to primary (S1) and secondary (S2) somatosensory cortex, and possibly to the PV. Muscle spindle receptor information was segregated in a thalamic region dorsorostral to VP, either in the region generally referred to as the posterior nucleus, or in a cell group commonly included in rostral VP. This information relayed to the rostral belt of somatosensory cortex, SR, a region that is referred to as dysgranular cortex in rats. Spinothalamic inputs terminated in and around VP, and relayed broadly to somatosensory cortex. Just rostral to VP, the ventral lateral nucleus received input from the cerebellum and projected to somatosensory cortex. There were no separate motor and premotor areas in early mammals, and motor functions were mediated via projections from somatosensory cortex to the basal ganglia, brainstem, and spinal cord, as well as by subcortical sensorimotor circuits that functioned relatively independently of sensorimotor cortex.

4.02.6.2 Early Eutherian Mammals

In the line leading to eutherian mammals, a separate primary motor area of cortex, M1, emerged. M1 lacked a notable layer 4, while projecting to brainstem and spinal cord neuron pools, largely on neurons between those with sensory inputs and the motor neurons contacting muscles. Sensory inputs to M1 were from somatosensory areas S1, S2, PV, the caudal and rostral somatosensory belts (SC and SR), and an emerging but small posterior parietal cortex with somatosensory, visual, and perhaps auditory inputs. M1 also received inputs from a rostrally adjacent premotor area, M2, with posterior parietal and frontal lobe inputs, as well as from the motor thalamus (VL). M2 provided few corticospinal projections, while S1 and SR provided dense corticospinal projections. M2 may be the homologue of dorsal and ventral premotor areas, or of the SMA of primates.

4.02.6.3 Early Ancestors of Primates

The early members of the Euarchontoglires clade that emerged some 95 Mya did not differ significantly from other eutherian mammals, but the early archontan mammals, those that gave rise to flying lemurs, tree shrews, and primates, may have already developed some primate-like characteristics, judging from recent studies on tree shrews. Most notably, the posterior parietal region of cortex was expanded in size, and this cortex had considerable input from an array of visual areas, as well as from somatosensory areas of cortex. Posterior parietal cortex probably had several divisions projecting

differently to motor and premotor cortex. The SC belt may have had rostral and caudal subdivisions. More of S1 was devoted to sensory receptors of the forepaw, and motor cortex had more projections from a forelimb representation to the cervical spinal cord. The forepaw was used more for grasping and manipulating food items.

4.02.6.4 Early Primates

The most notable difference between primates and their nonprimate relatives is the presence of an array of premotor areas in the frontal lobe. Prosimian galagos and other primates have a dorsal premotor area, PMD, with a rostral division (PMDr) with connections with prefrontal cortex and sparse connections with primary motor cortex, M1, and a caudal division (PMDc) with dense connections with M1. Galagos also have a ventral premotor area, PMV, but without the distinct rostral and caudal divisions of anthropoid primates. Galagos have a frontal eye field (FEF), an SMA, a pre-SMA, and rostral and caudal cingulate motor areas (CMAr and CMAc). These are all likely features of the brains of early primates. Other changes occurred in posterior parietal cortex, which was more expansive in early primates and included a rostral zone, with subdivisions receiving different somatosensory inputs and projecting differently to motor and premotor areas, and a caudal zone with inputs from higher-order visual areas and with projections to the rostral divisions of posterior parietal cortex. The proportional representation of the glabrous hand (forepaw) was increased in somatosensory and motor fields, and the proportion of corticospinal projections from M1, compared to other fields, was increased, corresponding to an enhanced role of the forelimb in reaching and grasping small prey, fruit, and buds in the fine-branch niche of early primates.

4.02.6.5 Early Anthropoids

These primates gave rise to tarsiers and monkeys. As highly specialized primates, with little information about their sensorimotor system, not much can be said about tarsiers, except that VP, VPS, and VPI regions can be identified histologically in the somatosensory thalamus, and that a clear area 3b (S1) can be identified in cortex. Extant monkeys differ from prosimians by having four distinct subdivisions of anterior parietal cortex, areas 3a, 3b, 1, and 2, each with a separate representation of receptors of the contralateral body, a distinctive pattern of connections with other areas of cortex, and subcortical structures, and identifying histological features. Yet area 1 is poorly differentiated in one branch of New World monkeys, the small marmosets and other callitrichines, and the evidence for an area 2 has been questioned in these and other New World monkeys. As some features of somatosensory cortex may have regressed in the callitrichines, early anthropoids may have had a more differentiated area 1, and a poorly differentiated area 2. Area 2 became distinct in the line leading to present-day Old World monkeys, apes, and humans. In more recent anthropoids in the Old World line, posterior parietal cortex increased in size and complexity, ventral premotor cortex subdivided and motor and somatosensory areas increased their representations of the hand. Area 2 became a well-differentiated area, with inputs from VPS and interconnections with area 3a. At least some of these changes occurred independently in New World cebus monkeys, as well as their unique sensorimotor specialization for their tail.

4.02.6.6 Hominoids (Apes and Humans)

About 30 Mya or more, one line of Old World monkeys gave rise to apes, which are characterized by a longer gestation time, a longer time to first reproduction, and a generally larger size than monkeys. The longer gestation time, slower maturation, and larger size allowed ape brains to become bigger than monkeys', a trend that was accelerated in hominins, humans, and their bipedal ancestors. The brains of our early bipedal ancestors were about the size of those of modern-day chimpanzees (400–500 cm^3), but in the line leading to modern humans, the brain rapidly increased in size, especially over the last 1 My, to the range of 1200–1400 cm^3. This increase was accomplished by an increase in the surface area of each cerebral hemisphere from about 240 to 800 cm^2. Even the first hominids and their close ape relatives had brains much bigger than those of the well-studied Old World macaque monkeys with approximately 72 cm^2 of surface area for each cerebral hemisphere. Research and conclusions about brain organization in macaque monkeys has greatly influenced current concepts about how the human brain is organized, but because of scaling problems, it is extremely unlikely that human neocortex is simply a 10- to 15-fold enlarged version of macaque neocortex. Of course, there is clear evidence that this is not the case. Most notably, the easily identified primary sensory and motor areas are larger in the large human neocortex, but not as large as they would be if they maintained a monkey-like proportion of the total. The larger size implies that these areas

function differently than their homologue in smaller primate brains, allowing more emphasis on fine-grain discriminations and motor performances, but functioning less well on the global aspects of perception and movement control. However, if some areas of cortex did not enlarge proportionally, what happened to the rest of the neocortex? The obvious suggestion is that the number of cortical areas, the functionally distinct subdivisions of cortex, increased. The most compelling evidence for this is that humans have abilities not found in monkeys or apes, and that brain regions responsible for some of these abilities do not have symmetrical counterparts in each hemisphere. A large part of the temporal lobe and parts of the frontal lobe of the left cerebral hemisphere are specialized for language in humans, and a large part of posterior parietal cortex of the right hemisphere is specialized for spatial reasoning and functions that allow an appreciation of music and mathematics (Corballis, 1998). For purposes of reducing the connection problems of large brains alone, there should be a considerable increase in modularity, reflected in an increase in numbers of cortical areas, perhaps in the range of 150 distinct fields for human neocortex. How this impacts on the sensorimotor system is largely uncertain at this time, but the expectation is that posterior parietal cortex, lateral parietal cortex, and frontal lobe motor regions of humans have more functional divisions than Old World monkeys have or our early hominin ancestors had. The evidence for this, at least for monkey–human comparisons, is starting to emerge from ongoing fMRI studies that have great capacity and potential for revealing the functional subdivisions of human neocortex.

4.03 The Role of Vision in the Origin and Evolution of Primates

C F Ross, University of Chicago, Chicago, IL, USA
R D Martin, The Field Museum, Chicago, IL, USA

Glossary

Anthropoidea	Monophyletic group (clade) consisting of living monkeys, apes, and humans, their last common ancestor, and all fossil taxa more closely related to living anthropoids than other primates.
APA	Arcuate premotor area.
cathemeral	Active during the day and at night.
CMAd and CMAv	Dorsal and ventral cingulate motor areas, located in the cingulated sulcus on the medial aspect of the cerebral hemisphere.
corticospinal tracts	Fiber bundles consisting of axons from cell bodies in the cerebral cortex that connect to motor neurons and interneurons in the spinal cord.
crepuscular	Active in the evening and morning.
diurnal	Active principally or solely during the day.
euprimates or primates of modern aspect	Monophyletic group consisting of Haplorhini, Strepsirrhini, Omomyiformes and Adapiformes. The taxon was erected to distinguish primates of modern aspect from archaic primates, or plesiadapiforms.
frontation	Caudal angle between the nasion–inion chord and the intersection of the midsagittal plane with the orbital plane.
hallux	Big toe, first toe
Haplorhini	Monophyletic group (clade) consisting of Anthropoidea and tarsiers, their last common ancestor, and all fossil taxa more closely related to living haplorhines than to other primates.
MI	Primary motor cortex.
nocturnal	Active principally or solely at night.
orbital convergence	Degree to which orbits face in the same direction, or converge on each other. Convergence is the caudal dihedral angle between the plane of the orbit and the midsagittal plane.
PMv	Ventral premotor area
pollex	Thumb; first, or radial digit
SMA	Supplementary motor area, motor cortex located on the medial aspect of the cerebral hemisphere, dorsal to the cingulate sulcus.
stereopsis	Seeing objects as solid, or three-dimensional.

Strepsirrhini Monophyletic group (clade) consisting of living lemurs, lorises, and galagos, their last common ancestor, and all fossil taxa more closely related to living strepsirrhines than to other primates.

4.03.1 Introduction

The visual system features prominently in adaptive explanations for the divergence of primates from other mammals and the origin of anthropoid or simian primates from their prosimian ancestors. However, the origin and radiation of primates was associated with modification of a number of other sensory and motor complexes, including the auditory, feeding, and locomotion systems. The integrated nature of these modifications demands that considerations of the role of the visual system in primate evolution include changes in these other systems. Many current explanations for primate origins do not take this integration into account. Here, we consider the role of vision in association with other functional systems. After briefly reviewing the taxonomy of extant primates, we begin by enumerating the features distinguishing primates from other mammals, especially their close relatives. We then review the hypotheses advanced to explain the evolution of these features, evaluating those hypotheses with special reference to the neuroscience literature dealing with the visual system, motor control of hand movements, and eye–hand coordination.

4.03.2 What Is a Primate?

Living primates are classified into three universally accepted groups (Figure 1): Anthropoidea (monkeys, apes, and humans), Tarsiiformes (tarsiers), and Strepsirrhini (Malagasy lemurs together with lorises and galagos) (Martin, 1990; Fleagle, 1999; Hartwig, 2002). (Many publications spell this with one 'r', i.e., Strepsirhini. However, two 'r's are preferable because, although the Zoological Code of Nomenclature does not codify spelling of taxonomic names above the family level, the original spelling of the term was 'Strepsirrhini' (Geoffroy Saint-Hilaire, 1812a) and this is also the correct derivation from the Greek (Jenkins, 1987).) The phylogenetic position of *Tarsius* is controversial, with some researchers placing it as the sister taxon of anthropoids, making a clade Haplorhini (e.g., Cartmill, 1980; Martin, 1990; Kay *et al.*, 1997, 2004; Ross *et al.*, 1998) and others placing it as the sister taxon of strepsirrhines, making a clade Prosimii (e.g., Eizirik *et al.*, 2001). Many researchers accept Haplorhini as a valid clade, but use the term 'Prosimii' to refer to the paraphyletic group consisting of strepsirrhines and tarsiers. Here we follow the classification of Fleagle (1999).

Living strepsirrhines include the Malagasy primate families united in the Lemuriformes (or Lemuroidea) and the African and Asian strepsirrhines, grouped together in the Lorisiformes (or Lorisoidea). The Lemuriformes includes Cheirogaleidae, Daubentoniidae, Indriidae, Lemuridae, and Lepilemuridae (or Megaladapidae). Lorisiformes includes the African Galagidae, and the African and Asian Lorisidae.

Anthropoids (also known as simians) are divided into two major clades: the Platyrrhini, or New World monkeys; and the Catarrhini, including Old World monkeys, apes, and humans. There is general agreement on the family or subfamily groupings of most of the platyrrhines – Callithrichidae (marmosets and tamarins), Atelinae (spider, woolly, and woolly spider monkeys), Alouattinae (howler monkeys), Pitheciinae (sakis, bearded sakis, and uacaris), Cebinae (including *Cebus* and *Saimiri*), Aotinae (owl or night monkeys), and Callicebinae (titi monkeys) – but the relationships among these groups are debated. The Catarrhini are divided into two major clades, the Cercopithecoidea, including cercopithecines and colobines, and the Hominoidea, including the apes and humans (see The Comparative Biology of Photopigments and Color Vision in Primates, Visual Cortex: Evolution of Maps and Mapping).

It is generally believed that the closest living relatives of primates are scandentians (tree shrews) and dermopterans (flying lemurs), although the phylogenetic relationships of these animals to primates continue to stimulate debate. The hypothesis of a grouping of dermopterans, scandentians, primates, bats, and elephant shrews in a superorder Archonta (Gregory, 1920) is not supported by recent analyses. Bats instead are included with carnivores, ungulates, and whales in a clade Laurasiatheria, while primates group with tree shrews, dermopterans, and the rabbit–rodent clade, Glires, in a larger clade, Euarchontoglires (Springer *et al.*, 1997; O'Brien *et al.*, 1999). Recent molecular trees for mammals either place Scandentia and Dermoptera in a clade that is the sister taxon to primates (Springer *et al.*, 1997; Murphy *et al.*, 1999; Eizirik *et al.*, 2001, 2004) or group Scandentia and Primates in a clade with Dermoptera as the sister taxon (Liu *et al.*, 2001). The long-term robustness of these phylogenetic groupings remains to be seen.

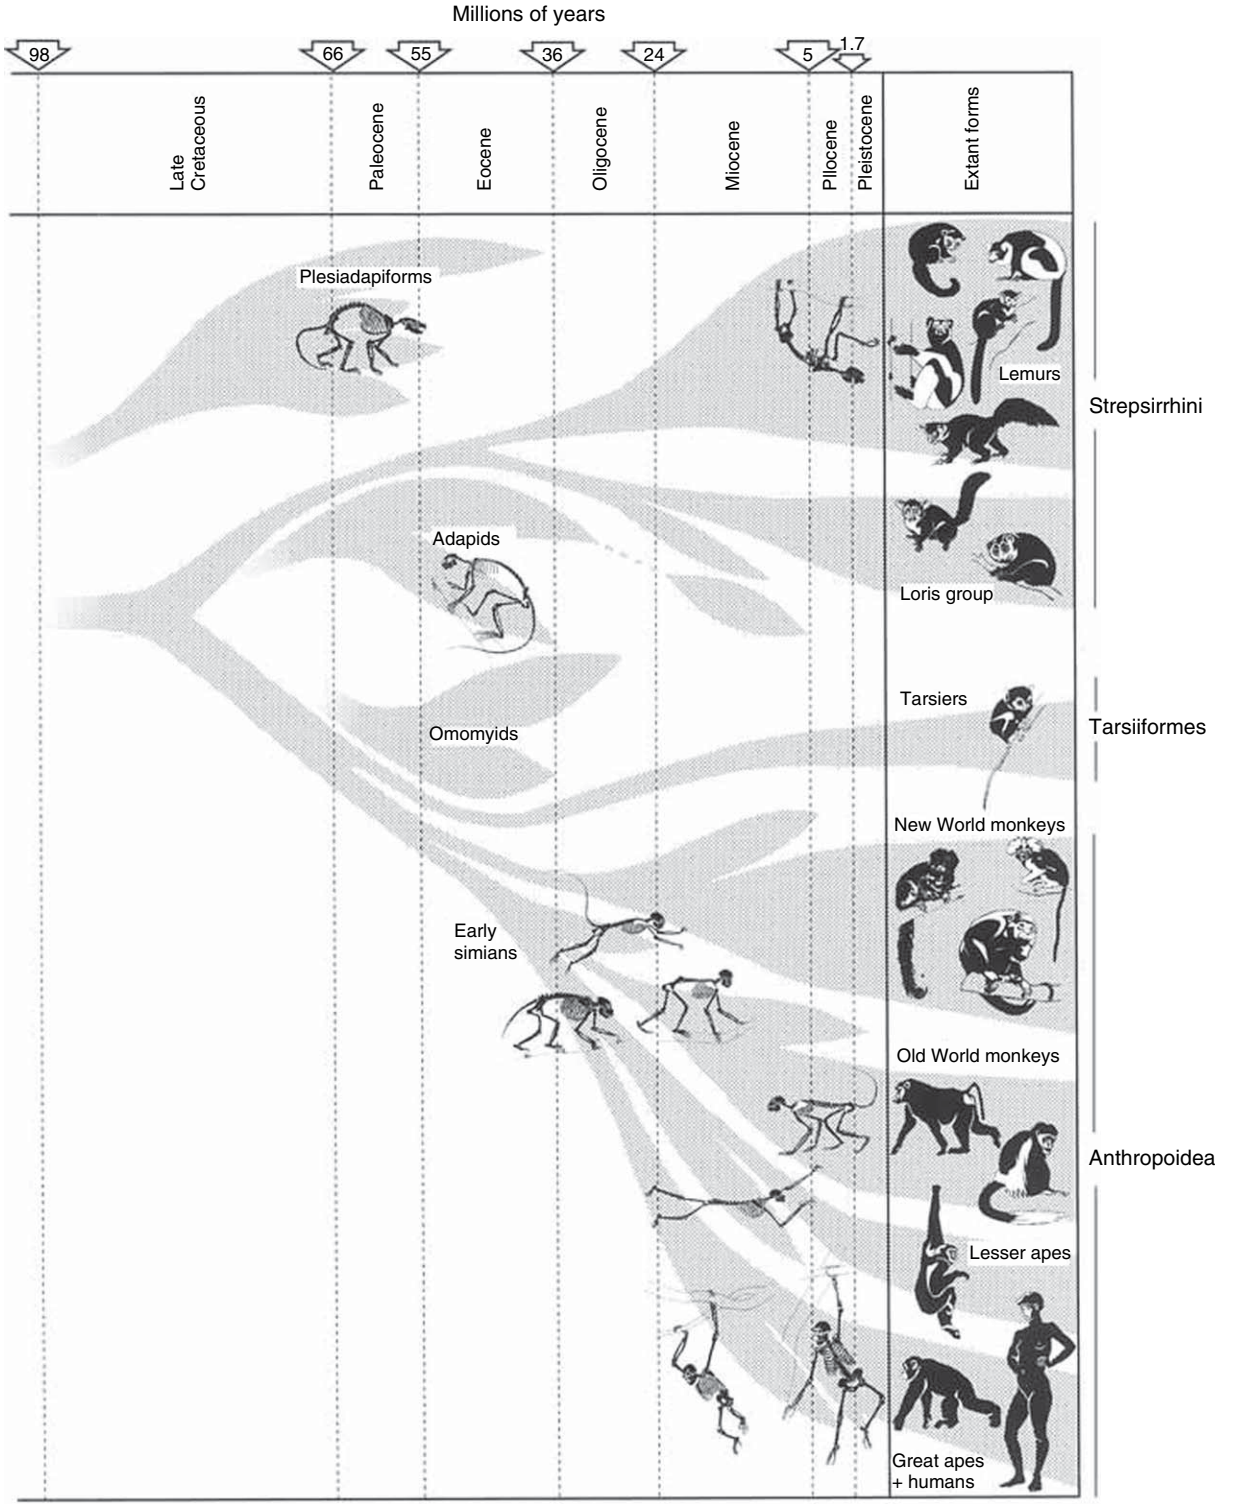

Figure 1 Outline phylogenetic tree of primates (modified from Martin, 1993). The generally accepted groups of living primates are shown on the right. Two groups of fossil primates that appear and radiate in the Eocene – adapids and omomyids – are of uncertain affinities to living primates (Martin, 1993). Plesiadapiforms and their relatives, including carpolestids (Bloch and Boyer, 2002), are also of uncertain affinities to primates. When plesiadapiforms are included in Primates, living primates, omomyids, and adapids are grouped together as Euprimates. Reproduced from Martin, R. D. 1993. Primate origins: Plugging the gaps. *Nature* 363, 223–234, with permission from Nature Publishing Group.

4.03.3 Early Explanations for Primate Origins

Primates have long been distinguished from other mammals by their grasping hands and feet, various enhancements of the visual system, and their relatively enlarged brains (Geoffroy Saint-Hilaire, 1812a, 1812b; Elliot Smith, 1924). Like many of the explanations to follow, Grafton Elliot Smith's early explanations for primate origins invoked functional benefits of these features in an arboreal habitat, but Elliot Smith also emphasized that changes in primate locomotion and grasping were integrated with changes in the somatic, auditory, and visual sensory systems. In an address to the Anthropological Section of the British Association for the Advancement of Science delivered in 1912 (Elliot Smith, 1924, chapter 1), Elliot Smith identified the neopallium (later termed neocortex) as the most salient feature distinguishing mammalian brains from those of nonmammals. The neopallium of mammals not only receives input from the visual, auditory, tactile, and kinesthetic senses, providing a substrate for merging and associating of the information streaming in from the periphery, but also contains the motor areas that put into effect the decisions made on the basis of these associations. Thus, Elliot Smith saw the neopallium as the organ that made it possible for mammals to learn and adapt to their surroundings.

The adaptability conferred on basal mammals by the neopallium was lost by many descendant lineages when they became specialized for cursorial, flying, aquatic, or burrowing environments. Primates, in contrast, retained their primitive adaptability, plasticity, and flexibility, primarily because they were arboreal. Arboreal mammals, Elliot Smith argued, require a balanced emphasis of the senses, with enhancement of vision, hearing, and touch. The agility of movement required in the trees "necessitates an efficient motor cortex to control and coordinate such actions as an arboreal mode of life demands . . . and also a well-developed muscular sensitivity to enable such acts to be carried out with precision and quickness" (Elliot Smith, 1924, p. 30). This general enhancement of the special senses, as well as the somatic sensory and motor systems used in locomotion, accounted for the general enlargement of the brain characteristic of primates.

Elliot Smith also emphasized the integrated nature of changes in the visual and tactile senses. The integrated nature of the neopallium meant that enhancement of the visual system in primates affected the whole neopallium, not just the visual areas.

> The sense of touch also shared in the effects, for tactile impressions and the related kinaesthetic sensibility, the importance of which to an agile tree-living animal is obvious, assist vision in the conscious appreciation of the nature and the various properties of the things seen, and in learning to perform agile actions which are guided by vision (Elliot Smith, 1924, p. 32).

This correlated development of visual and tactile senses led to integrated development of improved eye–hand coordination, linking up the tactile, kinesthetic, and visual cortical areas. Thus, for Elliot Smith, primate arboreality was not the only factor responsible for their adaptability, plasticity, and ability to learn, but it also resulted in enhanced development of their visual and grasping abilities, and in the integration and co-evolution of the two systems.

Wood Jones's theory of primate evolution included many of Elliot Smith's conclusions, but he also discussed specific features that are the focus of current explanations for primate origins. Wood Jones (1916) explained forward-facing eyes and postorbital bars as secondary consequences of a shift to arboreality, not specializations for it. He argued that, with progressive adoption of arboreal habits, the hindlimb became specialized for supporting the body weight during climbing, liberating "the fore-limb from any such servile function as supporting the weight of the body: it becomes a free organ full of possibilities," a process Wood Jones referred to as "emancipation of the fore-limb" (Wood Jones, 1916, p. 17). The emancipated forelimb could then take over from the jaws the role of food acquisition, allowing the snout to be reduced in size. As the snout recedes, the orbits are dragged around toward the front of the face, and postorbital ossifications (bar and septum) develop between the orbit and the temporal fossa (Wood Jones, 1916, p. 99). Echoing Elliot Smith, Wood Jones noted that one incidental benefit of the combination of a dextrous forelimb with forward-facing eyes is the ability to simultaneously manipulate and view an object in front of the face, making it advantageous to merge tactile and visual information in the newly expanding cortical association areas created by the expanding brain.

Wood Jones and Elliot Smith's arboreal theory of primate evolution (Howells, 1947) was adopted by Le Gros Clark (1934, 1959) as the explanation for general trends in primate evolution. The sensorimotor integration integral to Wood Jones' and Elliot Smith's theory was embodied in Le Gros Clark's total morphological pattern, "the integrated combination of unitary characters which together make up the complete functional design of a given anatomical structure" (Le Gros Clark, 1959, p. 13). The lack

of specialization and the retention of adaptability were attributed by Le Gros Clark to:

> . . . an arboreal habitat, a mode of life which among other things demands or encourages prehensile functions of the limbs, a high degree of visual acuity, and the accurate control and coordination of muscular activity by a well-developed brain (Le Gros Clark, 1959, p. 43).

Overlapping visual fields and high visual acuity were argued to confer the ability to judge distances necessary for leaping in an arboreal environment. Le Gros Clark also re-emphasized the importance of eye–hand coordination for primate evolution identified by Elliot Smith, arguing that the enhancement of the tactile senses that accompanied the changes to the visual system were related to improved ability for manual manipulation and appreciation of the environment.

4.03.4 Primates in the Fine-Branch Niche

Le Gros Clark's theory of primate evolution was promulgated to the next generation of primatologists and became the received view (Cartmill, 1982). In the 1960s and 1970s, field research on behavior and ecology of nocturnal strepsirrhine primates in Madagascar and West Africa by R. D. Martin and P. Charles-Dominique suggested to them some refinements of the arboreal theory. Their fieldwork revealed similarities between cheirogaleids and galagids in a number of features, including nocturnality, small body size, hindlimb-dominated locomotion utilizing grasping extremities in the fine-branch and creeper niche, and an omnivorous diet including fruit, insects caught with the hands, and gum obtained with the help of the toothcomb (Charles-Dominique and Martin, 1970; Martin, 1972, 1973). They interpreted these commonalities as retentions from the common ancestor of strepsirrhines at least, and possibly primates as a whole, suggesting that occupation of the fine-branch niche might be the adaptive shift that characterized primate origins.

The advantages of the distinctive features of the primate visual system to an occupant of the fine-branch niche were not precisely articulated, although Martin addressed them briefly in 1979:

> Occupation of the "fine branch niche" by a relatively small-bodied ancestral primate would hence explain the emphasis on the grasping foot characteristic throughout the order Primates and at the same time provide a reason for the emphasis on vision and replacement of the primitive prehensile function of the snout by mobile, grasping hands. (Leaping between adjacent fine branches and grasping of small animal prey on nearby supports with the hands would explain the relatively large eyes, the universal possession of a postorbital bar, and the reduction of the snout and anterior teeth among primates.) (Martin, 1979, p. 64).

Martin subsequently argued that forward rotation of the orbits enhances stereoscopic vision that would be advantageous for "[a]ctive locomotion in a network of fine arboreal supports" (Martin, 1990, p. 657). This fine-branch niche hypothesis for primate origins included only very general explanations for the origins of orbital convergence and a postorbital bar in stem primates, made no mention of eye–hand coordination, and emphasized the importance of locomotion in terminal branches over predation or food acquisition (Martin, 1979).

4.03.5 Orbital Convergence, Postorbital Bar, Manual Grasping, and Visual Predation

Cartmill (1970, 1972) took issue with the arboreal theory of primate evolution on the grounds that arboreality alone cannot explain the origins of grasping extremities, convergent orbits, and nails on the digits, because a variety of active, leaping arboreal animals, such as squirrels, lack these features altogether. He argued:

> If the primate evolutionary trends have not been characteristic of other lineages of arboreal mammals, we may conclude that there is something wrong with the arboreal theory in its received form and any explanation of the primate trends must involve a more detailed description of the habitus of the ancestral primate (Cartmill, 1972, pp. 102–103).

Cartmill (1974) noted that many nonprimate animals with forward-facing eyes, such as cats, owls, and hawks, are "visually directed predators," and many nonprimate animals with grasping extremities, such as chameleons and small marsupials, engage in "prolonged and stealthy locomotion on slender terminal branches in pursuit of insects." Cartmill's hypothesis was significant in that it demonstrated that arboreality alone could not explain the evolution of optic convergence and grasping extremities in primates; something more specific was needed. Cartmill invoked adaptation to visual predation in the fine branches of the shrub layer of tropical rainforests to explain both grasping hands and convergent orbits. An integral component of the hypothesis was the importance of eye–hand coordination originally identified by Elliot Smith:

> The prehensile forelimbs necessary for stalking insects along thin branches serve also, among living insectivorous prosimians, as prey-seizing organs analogous to the tongue of a chameleon. The importance to primates of hand–eye coordination, which [Elliot] Smith was the first to stress, can be plausibly traced to an ancestral habitus in which the hand was used for striking prey (Cartmill, 1972, p. 116).

Cartmill (1970) formally defined orbit orientation in terms of two variables (convergence and frontation) (Figure 2), which he measured in a wide sample of arboreal mammals. Subsequent morphometric work by Ross (1995), Noble *et al.* (2000), Heesy (2003, 2005), and Ravosa and Savokova (2004) has expanded the available data and the most extensive data set (Heesy, 2003, 2005) is shown in Figure 3. Primates certainly have more convergent orbits than do dermopterans and scandentians, but many other mammals overlap with primates in their degree of orbital convergence, including a number of carnivorans, bats, and marsupials. However, few mammals share the combination of high degrees of frontation and convergence seen in primates, and when allometric factors are taken into account, primates have more convergent orbits for their relative orbit size than other mammals (Noble *et al.*, 2000; Heesy, 2003).

Refinements to Cartmill's visual predation hypothesis were necessary. Pettigrew (cited by Allman, 1977, p. 29; Pettigrew, 1978) and Allman (1977) pointed out that orbital convergence has advantages for nocturnal animals that are not applicable to diurnal animals. The

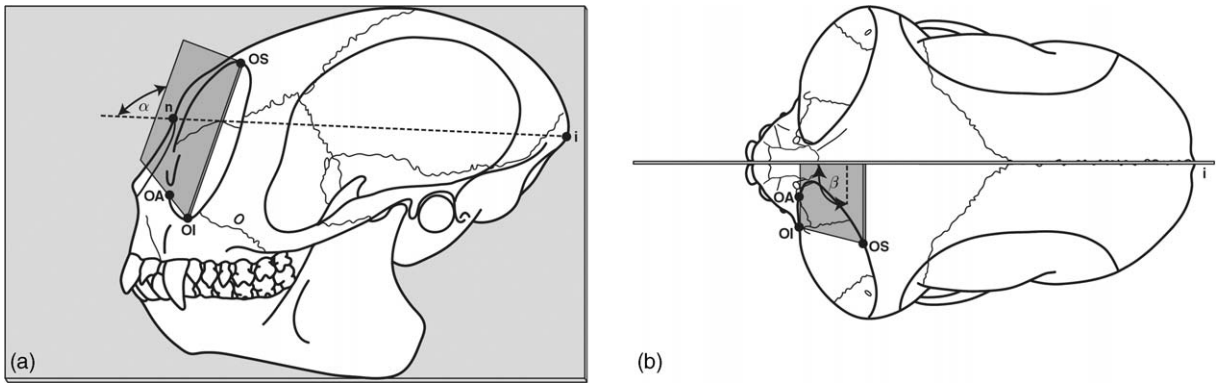

Figure 2 Diagram illustrating definitions of orbital convergence and frontation from Cartmill (1970, 1972) and subsequently used by Ross (1995), Noble *et al.* (2000), Heesy (2003, 2005), and Ravosa and Savakova (2004). The midsagittal plane is lightly shaded, the orbital plane heavily shaded. a, Frontation is the caudal angle between the nasion–inion chord and the intersection of the midsagittal plane with the orbital plane (i.e., $180^\circ - \alpha$). b, Convergence is the caudal dihedral angle between the plane of the orbit and the midsagittal plane (i.e., $180^\circ - \beta$).

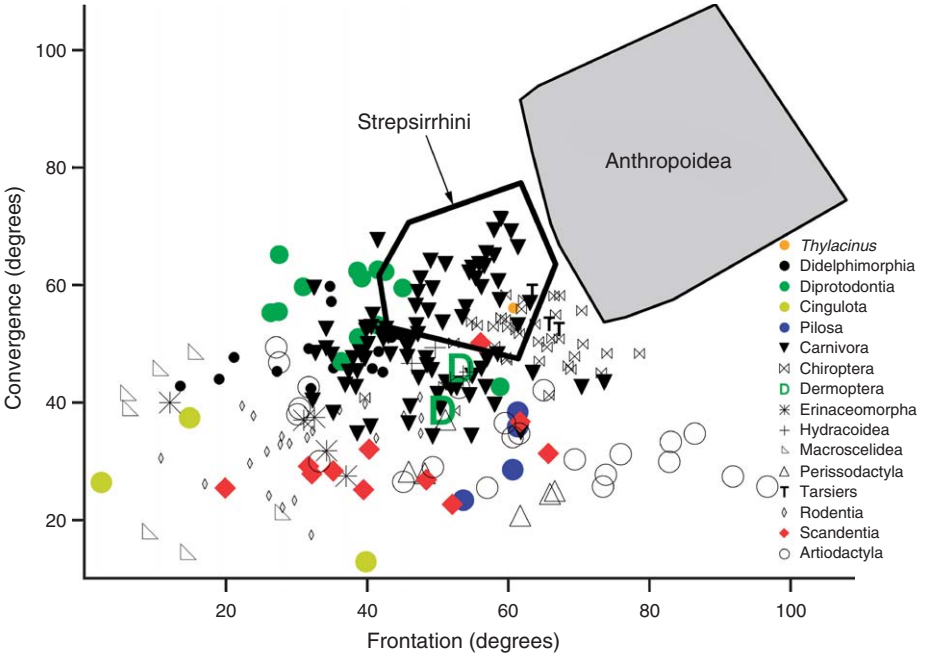

Figure 3 Bivariate plot of orbital convergence angle (degrees) against orbital frontation angle (degrees) in mammals. Individual data points for primates are excluded and replaced by minimum convex polygons (*sensu* Jerison, 1973). Data are from Heesy, C. P. 2005. Function of the mammalian postorbital bar. *J. Morphol.* 264, 363–380.

Allman–Pettigrew model notes that orbital convergence is associated with convergence of the optic axes on the visual axes, a means of improving retinal image quality that is necessary for nocturnal animals but not for diurnal ones. Whereas diurnal animals can ensure high retinal image quality by decreasing pupil diameter, thereby restricting incoming images to the paraxial region of the dioptric apparatus, nocturnal animals must maintain large pupil apertures in order to preserve image brightness. Consequently, nocturnal animals must improve image quality in the area of visual field overlap by optic and orbital convergence. This suggested to Allman (1977) that, if the first primates had high degrees of orbital convergence, they were probably nocturnal (Figure 4).

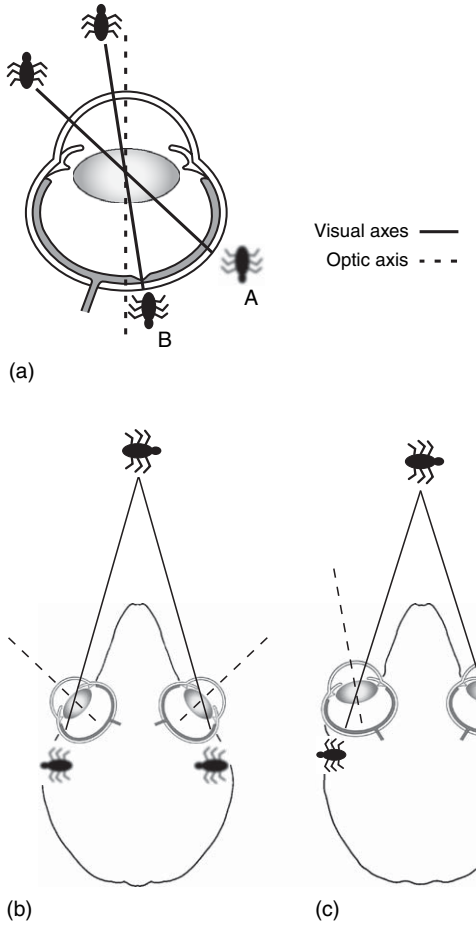

Figure 4 Diagrams illustrating functional significance of orbital convergence in nocturnal primates. a, Diagram of eye illustrating the effect of relative orientation of optic and visual axes on image quality. Image quality is best when the visual axis is more closely aligned with the optical axis. b, Diagram of visual and optic axis orientation in an animal with laterally facing orbits. c, Diagram of visual and optic axis orientation in an animal with convergent orbits. The quality of the image of the area in front of the animal is lower in (b) than in (c) because the optic and visual axes are less closely aligned.

4.03.6 The Primate Postorbital Bar

Primates all have postorbital bars which, while not unique to primates, do serve to separate them from their nearest putative fossil relatives, the plesiadapiforms. Cartmill (1970) and Heesy (2003) list a variety of other mammals with postorbital bars and processes. Dermopterans have postorbital processes (i.e., incomplete bars), while tree shrews have complete postorbital bars. Cartmill (1970, 1972) hypothesized that the primate postorbital bar functions to protect the orbital contents against movements originating from the chewing muscles in the temporal fossa. These movements might occur in all chewing animals, but Cartmill hypothesized that they were particularly problematic in animals with convergent orbits. Orbital convergence brings the plane of the orbit out of the plane of the temporal fossa, such that distortions of the postorbital ligament caused by contraction and bulging of the temporal muscles impinge upon the orbital contents (Figure 5).

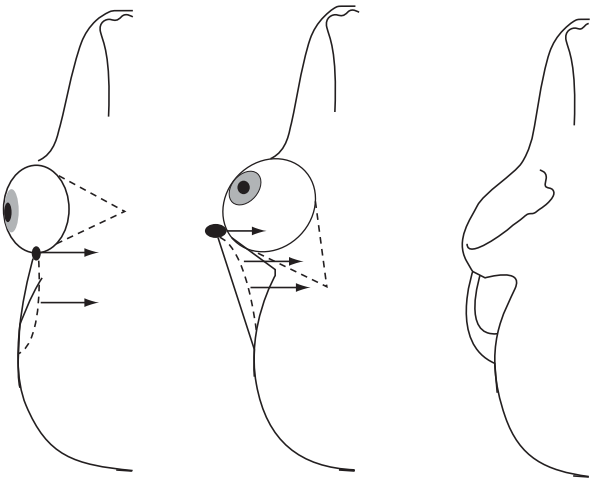

Figure 5 Diagram illustrating the function of the postorbital bar according to Cartmill (1972). In the left figure, the orbit is laterally directed and contractions of the temporalis muscle that pull the temporalis fascia and postorbital ligament medially do not impinge upon the eye (medially directed arrows). In the middle figure, the effects of moderate orbital convergence are illustrated. Convergence of the orbits is achieved by anterolateral displacement of the postorbital ligament. This brings the ligament lateral to the eye so that medial displacement of the ligament moves the eye around. As shown in the right figure, to prevent unwanted eye movements, the ligament is ossified into a postorbital bar to stiffen the lateral orbital wall. Adapted from Heesy, C. P. 2003. The Evolution of Orbit Orientation in Mammals and the Function of the Primate Postorbital Bar. PhD thesis, Stony Brook University, with permission of the author.

This hypothesis receives support from recent comparative morphometric analyses of orbit orientation in nonprimate mammals. Increased orbital frontation (roughly equivalent to verticality) in animals with moderate degrees of orbital convergence also causes the orbital and temporal planes to diverge, necessitating evolution of a postorbital bar (Noble *et al.*, 2000; Ravosa and Savokova, 2004). Heesy (2003, 2005) showed that the degree of postorbital ossification across a wide range of mammals is correlated with the degree to which the planes of the orbital aperture and of the temporal fossa diverge, regardless of whether that divergence is caused by increased orbital convergence, frontation, or displacement (Figure 6). This suggests that the evolution of the postorbital bar in primates represents an instantiation of a general principle identified by Cartmill that applies across all mammals: when the orbit and temporal fossa are not coplanar, movements in the temporal fossa are more likely to disturb the orbital contents and some kind of postorbital ossification is necessary to insulate the orbit.

The precise source, magnitude, and nature of the eye movements originating in the temporal fossa are unknown. Lemme *et al.* (2005) measured deformation in the postorbital ligament of pigs during stimulation of the temporalis and masseter muscles, and during mastication. They found that deformation of the ligament was primarily caused by contraction of the ipsilateral superficial masseter. In nonanthropoid primates, the chewing muscles, including the superficial masseter, are recruited much more vigorously on the working side than the balancing side, producing higher bone strain magnitudes on the postorbital bar of the working side than that of the balancing side (Ravosa *et al.*, 2000). Together, these results suggest that any disturbances suffered by the eyes during chewing would be asymmetrical. It might be difficult to offset or tolerate this asymmetry (Ravosa *et al.*, 2000), although this would depend on the nature of the movements. If the eyes were primarily protruded, the resulting diplopia would be less than if the eyes were abducted or adducted. Heesy *et al.* (2006) measured eye movements in anesthetized cats and galagos during stimulation of the masticatory muscles and found varying amounts of protrusion and abduction. Whether these movements occur in awake, chewing primates has not been established.

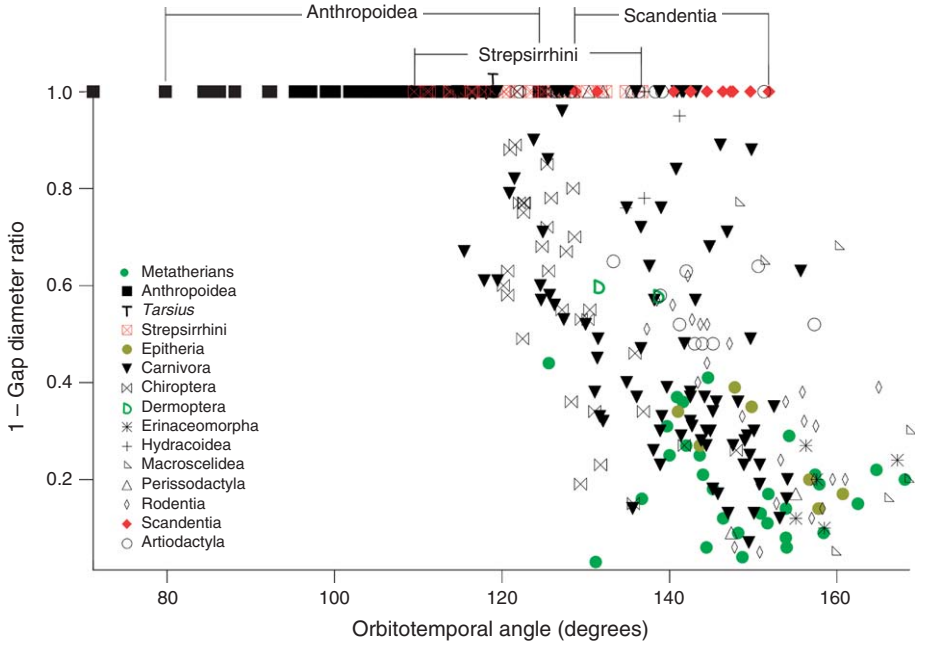

Figure 6 Bivariate plot of 1– postorbital gap:orbit diameter ratio against orbitotemporal angle. The gap:diameter ratio is the distance between the tips of the postorbital processes divided by orbit diameter. This value is subtracted from 1.0 so that animals with longer processes or bars are higher on the *y*-axis. Animals with values of 1.0 at least have complete postorbital bars. Orbitotemporal angle is the dihedral angle between the plane of the orbit and the plane of the temporal fossa. This angle quantifies the internal angle between the plane of the orbit and the plane of the temporal fossa. This plot shows that as the orbit becomes less coplanar with the temporal fossa (i.e., as the orbitotemporal angle decreases), the length of the gap between the postorbital processes decreases. Only animals with postorbital bars can have orbital planes that are strongly divergent from the plane of the temporal fossa. Note that only animals with postorbital septa (i.e., tarsiers and anthropoids) have extreme values of orbitotemporal angle. The data are from Heesy, C. P. 2005. Function of the mammalian postorbital bar. *J. Morphol.* 264, 363–380.

4.03.7 Criticisms of the Nocturnal Visual Predation Hypothesis

The visual predation hypothesis was the most widely accepted explanation of primate origins until counter-arguments began to appear in the 1990s. Critiques of the nocturnal visual predation (NVP) hypothesis can be grouped into three categories of argument: that the ancestral primates were not nocturnal; that the predatory adaptations of the ancestral primates were not visual; and that the visual adaptations of the ancestral primates were not predatory.

4.03.7.1 Ancestral Primates Were Not Nocturnal

Several researchers have argued against the NVP hypothesis on the grounds that basal primates were not nocturnal. Tan and Li's (1999; Li, 000) hypothesis that the ancestral primates were trichromatic and diurnal is unparsimonious in the context of a more comprehensive analysis of the data (Heesy and Ross, 2001). More recently, Ni *et al.* (2004) reported the discovery of a skull of the basal omomyiform primate *Teilhardina asiatica* from the earliest Eocene deposits of the Lingcha Formation, China (Figure 7). On the basis of the relative orbit size of this specimen, Ni *et al.* suggested that *T. asiatica* was diurnal. The use of relative orbit size as an indicator of activity pattern in fossil primates was pioneered by Walker (1967), but fully developed by Kay and Cartmill (1977; Kay and Kirk, 2000). This work showed that, in living primates with skull lengths below approximately 75 mm, nocturnal species generally have larger orbits than diurnal species. This separation of nocturnal and diurnal species in relative orbit size makes it possible to discriminate activity pattern in fossil species by plotting orbit size against body size to see whether the fossil resembles living nocturnal or diurnal primates. Applying this technique to interpret the activity pattern of the tiny *T. asiatica* necessitates extrapolation below the range of skull lengths exhibited by living primates. Ni and colleagues used a least-squares regression model to estimate the orbit dimensions of nocturnal and diurnal taxa at the skull length of *T. asiatica*, and argued that the relative orbit size of *T. asiatica* suggests that it was diurnal. Optimizing activity pattern onto a phylogenetic tree of primates and their relatives, Ni *et al.* reconstructed diurnality at the stem primate node, hence calling the NVP hypothesis into question.

Ni *et al.*'s analysis suffers from the difficulty of extrapolating the relationship between relative orbit size and activity pattern below the body size range of living primates (Martin and Ross, 2005). The

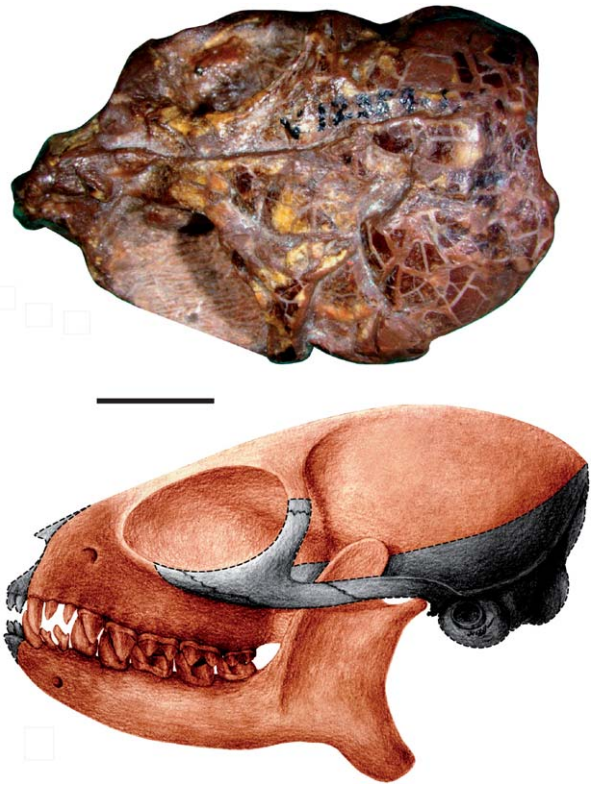

Figure 7 Skull of *T. asiatica* in dorsal and reconstructed lateral view; (IVVP V12357), earliest Eocene Lingcha Formation, Hengyang Basin, China (Ni *et al.*, 2004). Scale bar: 5 mm. relationship between eye size and body size in mammals has been claimed to be nonlinear, such that eye size declines rapidly at body sizes below the range of extant primates (Ross, 2000; Kiltie, 2000; Martin and Ross, 2005). In Figure 8, corneal diameter of the eye is plotted against head-and-body length in mammals. The line that best fits the data is a fourth-degree polynomial, and a quadratic explains the data better than a linear least-squares line, but none of these lines is significantly different from any others, making it difficult to determine what kind of regression line should be used at small body sizes. This calls into question the hypothesis that *T. asiatica* was diurnal and raises the thorny issue of how to reconstruct activity pattern in fossil primates at body sizes below those of extant forms.

Various lines of evidence point to a nocturnal origin for basal euprimates (reviewed by Ross *et al.*, 2006). Charles-Dominique and Martin (1970) argued that the ancestral primate was probably nocturnal because nocturnality characterizes galagids, cheirogaleids, and lorisids, and these animals are probably the most primitive members of their respective lineages. Later, Martin (1973)

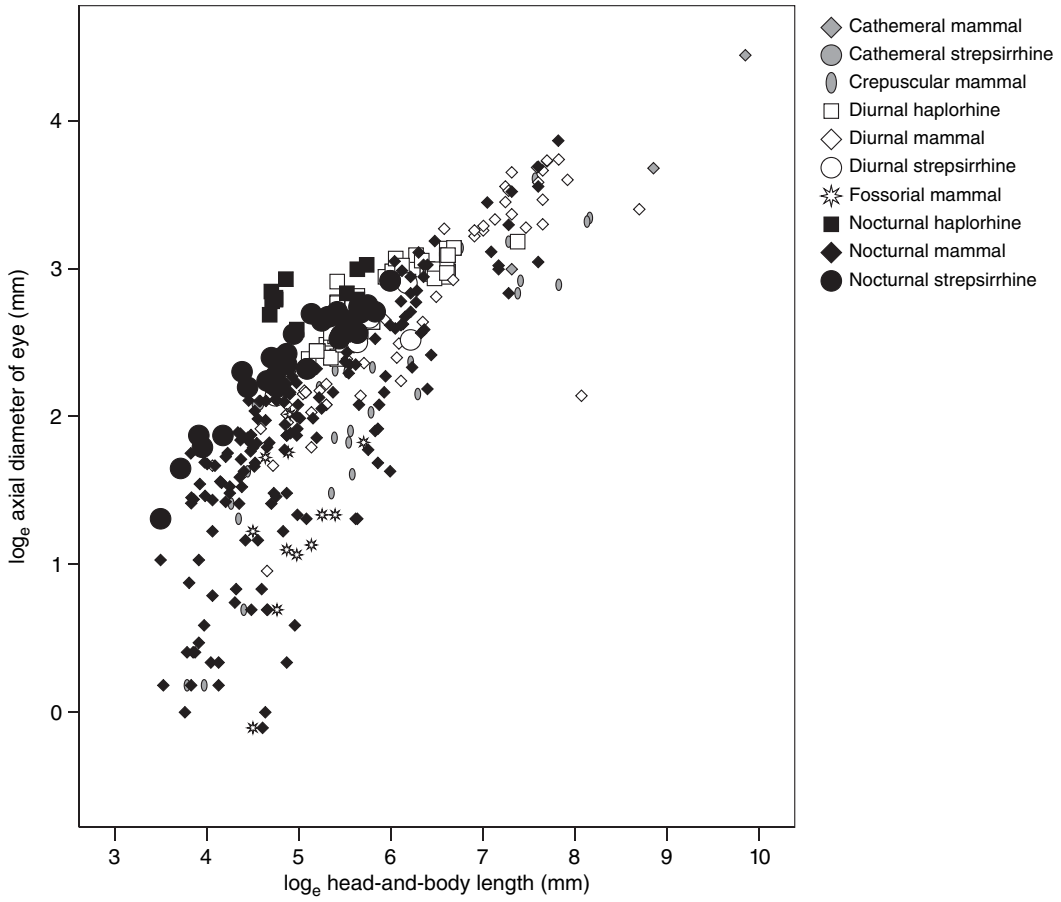

Figure 8 Plot of axial diameter of the eye against head-and-body length in mammals. Data from Ritland, S. 1982. The Allometry of the Vertebrate Eye. Unpublished PhD dissertation, Department of Biology, University of Chicago and Ross (unpublished data).

bolstered this argument by pointing out that the presence of the tapetum found in diurnal lemurids is best explained as a primitive retention from a last common ancestor of strepsirrhines that was nocturnal. Ross (2000) hypothesized that the earliest primates also probably possessed a tapetum. Explicitly cladistic reconstructions of the evolution of activity pattern in primates and their relatives corroborate the hypothesis that nocturnality characterized the first euprimates (Heesy and Ross, 2001). The possibility that certain early primates were extremely small, even around 10 g in size (Gebo *et al.*, 2000; Gebo, 2004), also suggests that these animals were nocturnal, as most living mammals in this size range are nocturnal. The possibility that basal primates were smaller than any living primates is not universally accepted, but some of them certainly were. It is therefore important to ask what the visual systems of such animals would have been like. Most extant mammals in this size range are olfactory-dominated animals. What kind of eye could a 10 g primate have carried and how would its brain organization have been affected (Kaas, 2000)? Theoretical investigations of such issues, combined with future fossil discoveries, promise to provide important clues as to the visual adaptations of early primates.

4.03.7.2 Predatory Adaptations of the Ancestral Primates Were Not Visual

The most common criticism of the NVP hypothesis is that primates use nonvisual senses to locate prey (Rasmussen, 1990; Sussman, 1991; Crompton, 1995). Sussman (1991) reviewed relevant data, pointing out that *Galagoides demidoff* and *Tarsius* can localize prey using hearing (Charles-Dominique, 1977; Niemitz, 1979), whereas lorises localize prey with olfaction. However, as has been noted previously, the fact that primates use nonvisual senses to localize prey does not necessarily mean that their visual sense is not important for prey localization (Dominy *et al.*, 2004; Ross *et al.*, 2005). Both galagos and lorises have been reported to use visual cues to localize moving prey (Charles-Dominique, 1977, p. 39; Schulze and Meier, 1995).

Moreover, it is also clear that, among extant mammals, increases in sound-localization acuity are associated both with increases in width of the binocular visual field and with narrowing of the field of highest visual acuity (Heffner and Heffner, 1985, 1992): animals with the highest auditory acuity also have large binocular visual fields and narrow fields of high-acuity vision. These data led Heffner and Heffner to suggest that the function of sound localizing is "directing the attention of other senses toward the sound-producing object" (Heffner and Heffner, 1992, p. 711). Primates notably have increased sound-localizing ability, increased binocular field width, and narrow fields of high visual acuity, and the work of Heffner and Heffner suggests that these features are interrelated. It cannot therefore be argued that use of auditory information for prey localization falsifies the hypothesis that visual cues are used as well (Sussman, 1991; Crompton, 1995). On the contrary, it suggests that if early primates were indeed nocturnal visual predators, they were probably auditory predators as well, and vice versa.

4.03.7.3 Visual Adaptations of Ancestral Primates Were Not Predatory

The most important criticism of the NVP hypothesis proposes alternate explanations for the origins of the high degrees of orbital convergence characteristic of primates. Two alternate reasons for orbital convergence have been suggested: localizing small fruits in terminal branches and locomotion in the fine-branch niche.

Sussman (1991) agreed with Cartmill that the divergent hallux and pollex and flattened nails are grasping organs, noting:

> It is generally agreed that these adaptations would have allowed Eocene prosimians far greater access to fruits and flowers, as well as plant-visiting insects, making them much more efficient at locomoting and foraging in the small terminal branches of bushes and trees than were the plesiadapoids (Sussman, 1991, p. 219).

But Sussman went on to suggest that the evolution of orbital and optic convergence is not explained either by locomotion or by predation on small insects, which he saw as being captured using hearing and olfaction. Instead, Sussman notes that fruit bats also appear to have convergent orbits, like primates, and implicitly suggests that in primates this might be related in some way to eye–hand coordination:

> these nocturnal animals [i.e., fruit bats and primates] were feeding on and manipulating items of very small size (e.g., fruits, flowers and insects), at very close range, and under low light conditions. This might require acute powers of discrimination and precise coordination (Sussman, 1991, p. 219).

Rasmussen's (1990) study of the feeding and locomotor behavior of *Caluromys* led him to suggest that there might be elements of truth to both Cartmill's and Sussman's models. He suggested that the stem primates were lured out onto the terminal branches by:

> . . . fruit and flowers with associated coevolving insect faunas . . . Once up into the swaying terminal branches, those individuals that could best meet their arthropod requirements by visual predation probably had a selective advantage over those whose visual, locomotor and manual coordination abilities were less suited for such a complex task (Rasmussen, 1990, p. 274).

Thus, Rasmussen argues that early primates were lured out into the terminal branches for the reasons advocated by Sussman, but the visual specializations were adaptations for the NVP suggested by Cartmill.

Crompton (1995) argued that stereopsis in the fine-branch niche "cannot readily be ascribed to the need to detect cryptic, immobile insects, since they are not the typical prey" (Crompton, 1995, p. 25). Instead, in a modified version of the fine-branch niche hypothesis, Crompton argued that foraging, leaping, and climbing among the dense supports of the fine-branch niche would benefit from stereopsis and grasping hands because this environment:

> . . . provides a visually complex, confusing background against which to distinguish a variety of mobile and immobile targets, both dietary items (fruit, as well as insects) and locomotor substrates (Crompton, 1995, p. 25).

In the end, Crompton invoked a multifactorial explanation for the origins of the orbital convergence.

> Orbital frontality is more likely to have first appeared as a consequence of the more general benefit that accrues, for a small-bodied primate similar to *Microcebus*, in the fine branch niche. This is provision of scotopic acuity and depth perception for the location of diverse targets, fruit and branches as well as insects in a complexly shaded environment (Crompton, 1995, p. 26).

The importance of the grasping hand for Crompton lies not only in climbing and manipulation of food, but also in securing a safe landing after short leaps. Once again, eye–hand coordination is implicit in Crompton's argument, although the relevance of this coordination for landing after a leap is not clear.

Thus, the adaptive significance of the distinctive features of the primate visual system is debated. Cartmill (1972, 1974) and Rasmussen (1990) agree that orbital convergence facilitates NVP on insects, captured with the hands in the fine-branch milieu; Sussman (1991) argues that orbital convergence is linked to manipulating small fruits, flowers, and insects under low light levels; Martin (1990) links orbital convergence to locomotion in a fine-branch niche, and Crompton (1995) invokes both

feeding on small food objects and locomotion to explain the evolution of orbital convergence.

These debates over the ecological significance of increased orbital convergence stimulated additional comparative morphometric research on orbit orientation in mammals. Heesy (2003) measured orbit orientation in a large sample of metatherian and eutherian mammals, and found strong effects of locomotor substrate, activity pattern, and diet on orbital orientation. Orbital convergence and frontation are higher in arboreal taxa than terrestrial or aerial taxa, and frontation and verticality are higher in faunivorous and omnivorous taxa than in opportunistic and nonpredatory animals. When these analyses were performed on eutherians exclusive of primates, nocturnal and cathemeral/crepuscular animals were found to have more convergent orbits than diurnal animals, and faunivorous taxa to have more convergent orbits than nonpredators. When all possible categories of locomotor substrate, activity pattern, and diet were considered, arboreal, nocturnal faunivores were ranked as having the highest degrees of orbital convergence. Heesy's analyses suggest that, across a wide range of mammals, nocturnal, arboreal faunivores tend to have more convergent orbits than other ecological categories. In a similar study, Ravosa and Savakova (2004) showed that, when allometric factors are taken into account, pteropodid bats do not have orbits that are as convergent as those of primates, negating one of Sussman's criticisms of the NVP hypothesis. Moreover, felid carnivorans (which are predominantly nocturnal) have primate-like degrees of orbital convergence, while nocturnal visual predatory tree shrews (*Ptilocercus*) and nocturnal procyonid carnivorans have more convergent orbits than diurnal predatory close relatives.

Both of these studies (Heesy, 2003; Ravosa and Savakova, 2004) corroborate the NVP hypothesis, but neither study explicitly evaluates the hypothesis relative to the fine-branch niche locomotion hypothesis. Ravosa and Savokova show that felids – NVPs not living in the fine-branch niche – have primate-like levels of orbital convergence, suggesting that NVP is sufficient to produce orbital convergence, but they do not exclude the possibility that fine-branch living also would produce this effect, even in the absence of NVP. Similar issues emerged from Lemelin's (1999) comparison of hand morphology in didelphid marsupials and primates. Although he confirmed that locomotion on fine terminal branches is associated with convergent similarities in hand and foot anatomy and proportions in marsupials and primates, the animals concerned also fed on small fruits and insects in the terminal branches. This makes it difficult to factor out the relative importance of feeding versus locomotion and of insectivory versus frugivory for hand and foot morphology.

To demonstrate that NVP is necessary and sufficient to explain orbital convergence and the unique hand morphology of primates, but fine branch locomotion or fruit feeding are not, NVPs living in the fine-branch niche need to be compared with non-NVPs living in the fine-branch niche. Variation in degrees of predation, hand morphology, and orbital convergence within primates provides one source of appropriate comparisons. Lemelin (1996, p. 173) reports preliminary results of analyses that demonstrated "significant and positive covariation between amount of insectivory, selection to catch styles, and relative lengths of the digits among closely related prosimians."

4.03.8 Comparative Neuroscience

In parallel with these developments in primatology, comparative neuroscience has revealed a series of distinctive features of the primate nervous system, which, judging by their common occurrence in most primates, can be hypothesized to have evolved along the primate stem lineage, after the divergence of any sister group, such as tree shrews and dermopterans.

4.03.8.1 Visual System

The high degree of orbital convergence characteristic of primates increases the size of the binocular field (Ross 2000; Heesy, 2004) and improves the potential and actual quality of the image falling on the central retina. These changes make it worthwhile increasing relative eye size to increase image size (Ross *et al.*, 2006), increase the density of photoreceptors and ganglion cells in the central retina to increase sampling frequency, and increase representation of the central retina in the visual structures of the brain (Allman, 1977). Barton (2004) has shown that, while controlling for body size, increases in relative orbital convergence are associated with increases in the relative volume of the lateral geniculate nucleus, relative area of the primary visual cortex, and relative neocortex size in general. Barton also shows that these increases are primarily attributable to increases in parvocellular rather than magnocellular pathways, suggesting that they reflect adaptations for improved fine-grained stereopsis, rather than increased sensitivity to movement. He suggests that:

> . . . the increase in visual brain size in primates with more convergent orbits might reflect enhancements of stereo-acuity and vergence-control mechanisms specifically related to the visually guided grasping and close-range manipulation of food items (Barton, 2004, p. 10115).

Barton's analysis treats variation in the visual system within primates, not across mammals, as a whole, so caution must be exercised when extending the results back into the primate stem lineage. To the extent that such extrapolation is valid, many of the changes to the visual system that occurred in the primate stem lineage can be hypothesized to have been not only integrated with each other, but also associated with improvements in fine-grained stereopsis and visual acuity in the center of the visual field. However, it is important to remember that the visual systems of stem primates were also characterized by an array of changes related to other functions, including improved sensitivity to movement, and improved ability to locate movements and sounds in space. Primates exhibit extensive projections from each retina to its ipsilateral lateral geniculate nucleus and superior colliculus, and both the visual cortex and superior colliculus contain representations of only the contralateral visual field. The superior colliculus provides the substrate for the visuomotor response, in which the eyes are directed to novel objects entering the visual field (Schiller and Stryker, 1972) and the unique arrangement of the projections to the superior colliculus in primates removes ambiguity regarding the position of those objects (Allman, 1999). As noted above, increased overlap of the visual fields across mammals is also associated with increased ability of the auditory system to localize sounds in space, suggesting that such abilities also characterized basal primates (Heffner and Heffner, 1982, 1992; Heffner, 2004). Primates are characterized by expansion and multiplication of their extrastriate visual areas, including not only areas that process information on fine-grained stereopsis and acuity (the ventral information stream in temporal cortex), but also areas such as the middle temporal (MT) area devoted to analysis of movement in the contralateral visual field (see reviews in Allman, 1977, 1999; Allman and McGuinness, 1988; Kaas, 2002). Thus, there is evidence that the basal primate visual system was modified not only to enhance fine-grained stereopsis (Barton, 2004), but also to improve the ability to detect and localize sources of movement and sound in the visual field. These latter attributes would be of particular benefit to NVPs, but of little obvious use for finding fruits and berries.

4.03.8.2 Hand Motor Control

In vertebrates, control of voluntary limb movements is mediated by descending pathways from the brain to the motor neurons in the spinal cord. All vertebrates possess reticulospinal, rubrospinal, tectospinal, and various other pathways from the brain to the spinal cord (Nudo and Masterson, 1988), but corticospinal tracts (CSTs) are found only in mammals. Simian primates and carnivores have larger CSTs than other mammals (Phillips and Porter, 1977; Figure 9), and the lateral CST of primates is unusual in both the degree to which it penetrates to caudal spinal cord segments and in the directness of its connections with motor neurons of the muscles of the distal extremities (Phillips and Porter, 1977; Heffner and Masterson, 1983). Across mammals and within primates, increased CST penetration down the spinal cord and increasingly ventral termination of CST connections within the cord are correlated with progressive increases in the degree of digital dexterity (Heffner and Masterson, 1975). This suggests that the emergence of these features in basal primates was associated with increased manual digital dexterity. Extant primates use their hands for many things, including grasping branches during locomotion, acquiring food, and social grooming (Bishop, 1964). Precisely which of these functions originally demanded enhanced dexterity is not immediately obvious from the anatomical data.

One question arising from these data is why there is a relationship between manual digital dexterity and CST penetration beyond those cervical spinal cord segments that supply the muscles of the forelimb (Heffner and Masterson, 1975). The answer to this conundrum may lie in a Wood Jonesian emancipation of the forelimb accompanying increased coordination of the hindlimbs and forelimbs. One benefit of this is illustrated in Figure 10, a photograph of a *Mirza coquereli* cantilevering from a

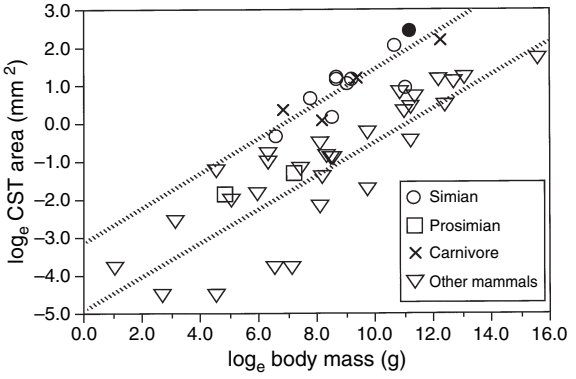

Figure 9 Bivariate plot of the natural log of CST area against the natural log of body mass in mammals. The least-squares regression lines for simian primates and for rodents are shown. Humans are shown by the solid circle. Simian primates have larger CSTs than other mammals, a feature in which they resemble carnivores. Data from Heffner, R. and Masterton, B. 1975. Variation in form of the pyramidal tract and its relationship to digital dexterity. *Brain Behav. Evol.* 12, 161–200.

Figure 10 *M. coquereli* adopting a cantilever posture. Image of Coquerel's dwarf Lemur, *M. coquereli*, Kirindy Forest, Madagascar, © Manfred Eberle, www.phocus.org.

vertical branch to grasp something out of the air. Various prosimians (cheirogaleids, galagos, and tarsiers) have been reported to manually acquire flying prey while holding onto branches with their feet (Crompton and Andau, 1986; Gebo, 1987; Martin, 1990). We hypothesize that extension of the CST down to lumbar and sacral spinal cord segments provides the anatomical connections necessary for arboreal mammals to coordinate a secure hold on the substrate with their hindlimbs or tail while they use their hands for catching insects, harvesting fruits, or other tasks requiring manual dexterity.

Another distinctive aspect of the primate corticomotor (CM), system is the degree of multiplication of premotor areas in frontal cortex. Macaques, for example, exhibit at least six separate premotor areas that project not only into primary motor cortex (MI), but also give origin to corticospinal neurons. In the three areas in which this has been studied, these corticospinal neurons include CM fibers that run directly from the cortex to the motor neurons in the ventral horn of the cervical and lumbar regions of the spinal cord (Dum and Strick, 2002). Five of the six premotor areas have distinct projections to both upper and lower cervical spinal cord segments. Three of these areas (supplementary motor area (SMA), dorsal cingulate motor areas (CMAd), ventral cingulate motor areas (CMAv)) project to lower cervical spinal cord segments, specifically to the intermediate zone and ventral horn, the latter of which contains the motor neuron cell bodies for the hand muscles. Each premotor area receives inputs from a different combination of posterior parietal and prefrontal cortical areas, "each participates in distinct loops with the basal ganglia and cerebellum" (Dum and Strick, 2002, p. 681), and each projects in parallel to the spinal cord. Just as the multiplicity of prestriate visual areas serves as the substrate for a multiplicity of diverse visual functions, so each of these multiple premotor areas is argued to be "a functionally distinct efferent system that differentially generates and/or controls specific aspects of motor behavior" (Dum and Strick, 2002, p. 677). The anatomical and physiological relationships between these areas and the control of hand movements suggests that the increased dexterity characteristic of primates is related to the multiplication and increased functional diversity of these cortical premotor areas.

Nudo and Masterson (1990b) showed that the size of CST cortex is highly correlated with body mass, brain mass, and the area of the neocortex, with the strongest relationship between CST cortex area and overall neocortex area. After they factored out the effect of increased cortex size, they found primates to show a constant proportion of CST cortex to overall cortex area, while raccoons show relative increases in CST cortex compared to other carnivorans. They attributed the enlargement of the CST cortex in primates to overall neocortical enlargement. Whatever the mechanism of enlargement, the size of the cortical areas giving rise to CSTs increases along the lineages leading to humans and raccoons from basal mammals in parallel with their dexterity (Nudo and Masterson, 1990b).

4.03.8.3 Eye–Hand Coordination

Elliot Smith noted that eye–hand coordination is an important component of the basal primate adaptations, but most explanations for primate origins in the literature have neglected to emphasize this basal attribute. Recent studies in comparative neuroscience have revealed distinctive anatomical features of the primate brain that are involved in mediating this coordination.

Although nonprimate mammals have premotor areas that give origin to CSTs, primates are unique in having CSTs arise from a distinct subregion of ventral premotor cortex not found in other mammals: region C of Nudo and Masterson (1990a) or the arcuate premotor area (APA) of Dum and Strick (2002). Allman (1999) synonymized region C with the ventral premotor region, PMv, but region C in macaques at least is only the rostral part of PMv lying within the posterior bank of the inferior limb of the arcuate sulcus. Regardless of terminology, primates are unique in possessing areas PMv and APA/region C, both of which appear to be important in the control of visually guided reaching and grasping movements (i.e., eye–hand coordination).

APA is unusual among the six premotor areas discussed above in that it exhibits very dense and numerous connections to the hand representation in MI, and to upper cervical segments supplying the muscles crossing the shoulder and elbow joints, but does not project to lower cervical spinal cord segments where hand motor neurons are located. Nevertheless, stimulation of this area commonly elicits movements of the fingers and thumb, but less commonly movements of more proximal joints, such as the wrist, elbow, and shoulder (Martino and Strick, 1987; Dum and Strick, 1991; He *et al.*, 1993). Dum and Strick (2002, p. 681) suggested that APA/region C "is primarily involved with control of distal forelimb movements" and the anatomical data presented above suggest that this control involves coordination of the movements in joints of the upper arm as well.

Preuss (1993) reviewed the evidence available at that time that PMv plays "a role in visually guided reaching and prehension." The work of Rizzolati *et al.* had revealed that neurons in PMv respond not only to tactile stimuli applied to the hands and face, but also to visual stimuli, especially to stimuli within reaching distance. Neurons in this region are active, "specifically during purposive, prehensive movements of the face and forelimbs" (Preuss, 1993). Preuss argued that integrated use of the mouth and the hand may have been important components of early primate feeding adaptations, whether for visually guided manual predation on insects as suggested by Cartmill (1970) or "visually guided grasping and manipulating fruits and flowers" as advocated by Rasmussen and Sussman (Preuss, 1993, p. 355). Preuss' hypothesis receives support from more recent observations that when PMv caudal to the inferior limb of the arcuate sulcus – close to the origin of the CST – is stimulated, coordinated movement of the hand to the mouth is elicited, accompanied by opening of the mouth (Graziano *et al.*, 2002a). This suggests an important role for PMv in visually guided movements of the arm and hand during feeding. However, PMv also functions in the integration of tactile, auditory, and visual information in the control of arm movements (Graziano and Gandhi, 2000; Graziano *et al.*, 1999, 2002a, 2002b). Graziano's work has revealed a polysensory zone that integrates visual, auditory, and tactile information into the planning of hand movements in space (Graziano *et al.*, 1999; Graziano and Gandhi, 2000). Integration of visual, auditory, and tactile information is plausibly related to capturing flying or moving prey, whereas auditory information is not obviously necessary for coordination of movements associated with locomotion or grasping fruits.

Improved sensorimotor coordination in control of primate hand movements is also indicated by expansion and elaboration of somatosensory areas (ventral somatosensory area (VS), the parietal rostral area (PR), and the retroinsular area (Ri)) and areas in the posterior parietal cortex that are important for visual and visuomotor processing (Wu *et al.*, 2000; Kaas, 2004). The latter areas connect forward into the array of new premotor areas in the frontal lobe, including the multiple premotor areas controlling hand and digit movements (e.g., PMv, SMA). Stimulation of the rostral half of posterior parietal cortex in *Otolemur* (Stepniewska *et al.*, 2005) and macaques (Their and Andersen, 1998; Cooke and Graziano, 2003) elicits complex movements that "seem to be components of ethologically meaningful behavioral patterns such as feeding and defense" (Stepniewska *et al.*, 2005, p. 4882). To the extent that these attributes and connections of PMv characterized stem primates, PMv was probably an important component of a neural system adapted not only for foraging for small fruits and berries, but also for NVP. Unfortunately, the available data do not allow definitive statements as to the original function of PMv. Graziano's research was carried out on macaques, and it is not clear to what extent nocturnal primates such as galagos and lorises possess a polysensory zone in PMv. Moreover, although the origin of PMv may have been more important for mediating eye–hand coordination used in feeding than in locomotion, the other premotor areas distinctive of primates (Kaas, 2004) may well have had locomotor-related functions originally, and the precise order in which they arose cannot currently be discerned. Indeed, it may be that the neurological adaptations associated with eye–hand coordination are either interchangeable with or so extremely similar for both NVP and fine-branch locomotion as to make it impossible to discriminate between these competing hypotheses regarding primate origins. However, both scenarios imply that improved eye–hand coordination was a fundamental adaptation in basal primates.

4.03.9 Locomotor System

As reviewed above, it was F. Wood Jones who suggested that specialization of the hindlimb for supporting body weight during climbing emancipated the forelimb from supportive functions, freeing it for specialization to perform other tasks. Several attributes of the primate locomotor system suggest that Wood Jones' hypothesis contains some nuggets of truth. The feet of primates are adapted for grasping as part of a distinctive grasp-leaping

pattern of locomotion (Szalay and Dagosto, 1988). Changes to the joint between the first metatarsal and the entocunieform allow the hallux (big toe) to be held in an abducted position, divergent from the rest of the digits, and to be stable under high forces during grasping. The proximal end of the first metatarsal manifests a robust process that not only buttresses the enotcunieform joint but also provides a hypertrophied area of attachment for the powerful peroneus longus muscle that plantarflexes and everts the foot at the ankle. The primate upper ankle joint is adapted for stability across an enhanced range of flexion and extension, as would be encountered during leaping, and the tarsal elements are elongated to enhance the length of the hindlimb, facilitating a more powerful leap (Martin, 1979). The lower ankle joint evinces adaptations for increased inversion and eversion of the foot necessary during climbing (Dagosto, 1988).

All digits of primates typically bear nails, rather than claws, although some species have re-evolved claw-like nails. Callitrichids and *Daubentonia* have claws on all digits except the hallux, and prosimians have a toilet claw on one pedal digit. The skin of the distal digits is expanded into pads sporting cutaneous ridges for increasing friction on arboreal supports. These ridges are also associated with Meissner's corpuscles for enhanced tactile sensitivity (Martin, 1986). The phalanges of the hands and feet are lengthened relative to the metapodials to improve grasping abilities on fine branches, an adaptation evolved convergently with didelphid marsupials (Lemellin, 1999).

Primate locomotor gaits are also distinctive (Martin, 1990; Schmitt, 2003). Primates typically employ diagonal sequence gaits in which the footfall of the forefoot always follows the contralateral hindfoot, ensuring a secure grasp of the substrate with the hindfeet before moving the forefoot (Cartmill *et al.*, 2002). Primates also walk with a compliant gait, characterized by more elbow flexion, less vertical displacement of the center of mass, and longer stride lengths than other mammals. These traits are hypothesized to have arisen as adaptations to locomotion on small compliant branches (Cartmill *et al.*, 2002; Schmitt and Lemelin, 2002). Convergent evolution of diagonal sequence gaits in the arboreal woolly possum, *Caluromys*, corroborates the hypothesized link between this trait and locomotion on fine supports (Lemelin *et al.*, 2003). Primates also have greater peak reaction forces at their hindlimbs than their forelimbs and they display a more protracted forelimb at touchdown than other mammals (Larson *et al.*, 2001). Convergent evolution of this complex of features in the arboreal kinkajou (*Potos flavus*), a carnivore that also possesses a prehensile tail, provides support for Wood Jones' suggestion that the forelimb function becomes more diverse when the hindlimbs bear the majority of the body weight. Kinkajous not only support more of their body weight with their hindlimbs than their forelimbs, and exhibit highly protracted forelimbs at touchdown, resembling primates (Larson *et al.*, 2001), but they also possess CM connections to the ventral horn of the spinal cord, and relatively dextrous forelimbs (Petras, 1969).

4.03.10 The Fossil Record of Primate Origins

Although it may not be possible to determine from studies of extant primates alone whether the visual and grasping adaptations of early primates originally functioned as adaptations for locomotion or for feeding on insects and small fruits in light-limited environments (Allman, 1977; Pettigrew, 1978; Martin, 1990; Cartmill, 1982; Crompton, 1995), more direct evidence from the fossil record can provide insight.

The lineage leading to extant primates is traditionally thought to have diverged from other mammals close to the Cretaceous/Tertiary boundary. The first members of this primate lineage were long thought to be the plesiadapiforms, a radiation of fossil mammals that thrived in the Paleocene and Early Eocene of the northern continents. The traditional interpretation is that plesiadapiforms, or archaic primates, gave rise to a single stem lineage for euprimates, which quickly divided into two lineages, the omomyiforms and adapiforms, which appear in northern continents at the beginning of the Eocene (*c.* 55 Mya). Compared with plesiadapiforms, these latter two clades manifest closer anatomical similarities and phyletic affinities with extant primates and are grouped with them as Euprimates. In the 1980s and 1990s, many researchers excluded plesidapiforms from Primates because they are not adaptively similar to euprimates, and because cladistic analyses identified at least some plesiadapiforms as basal dermopterans (Beard, 1990; Kay *et al.*, 1992). Recent fossil discoveries and reinterpretation of old fossils have called into question the possibility of dermopteran relationships for plesiadapiforms and have once again identified them as the fossil group most closely allied with euprimates, placing them even closer to extant primates than tree shrews (Silcox, 2001; Bloch and Boyer, 2002).

The best-preserved plesiadapiform skull, that of the paromomyid, *Ignacius graybullianus*, is illustrative of plesiadapiform skulls in general (Figure 11). The braincase is relatively small and the orbits are small, superiorly facing, and completely confluent with the temporal fossa. The infraorbital foramen, like that of *Palaechthon* (Kay and Cartmill, 1977), is relatively large, suggestive of the importance of the vibrissae in detecting prey (Kay *et al.*, 1992). Skulls of *Plesiadapis* are similar, suggesting that the pronounced visual adaptations of euprimates were not shared by plesadapiforms. In contrast, postcranial fossils of many plesiadapiforms display a range of adaptations for arboreality (Szalay and Dagosto, 1988). Recently, a grasping foot with a nail on the hallux was reported from the carpolestid plesiadapiform *Carpolestes*, a putative close relative of primates (Bloch and Boyer, 2002). If *Carpolestes* is indeed representative of the stem lineage of euprimates, it suggests that the manual and pedal grasping abilities of primates evolved prior to their visual specializations, potentially supporting Rasmussen's hypothesis that early primates originally ventured into the small terminal branches in search of small fruits and only subsequently developed the visual adaptations characteristic of living primates (Bloch and Boyer, 2002).

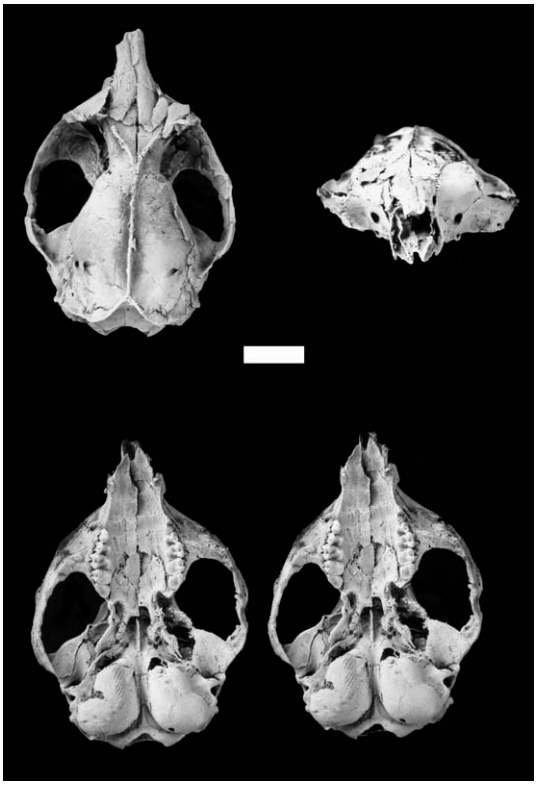

Figure 11 Skull of *I. graybullianus* in dorsal, rostral, and ventral (stereopair) view. Scale bar: 1 cm. Images courtesy of R. F. Kay.

Although *Carpolestes* may have resembled the antecedents of the ancestral primates in some respects, several problems dictate caution in basing interpretations on a direct reading of the fossil record. First, the fossil record is notoriously incomplete. Tavaré *et al.* (2002) have estimated that less than 7% of the species in the primate crown clade have been recovered such that major gaps are present. Hence, even when fossil evidence of extinct species of primates and their relatives is available, these species can be separated from events of interest by significant lengths of time, diminishing their relevance as direct indicators (Ross *et al.*, 2002). These issues are particularly relevant to *Carpolestes*. Statistical analysis of the primate fossil record suggests that the branching points for the origins of extant primates are significantly older than the earliest known fossil representatives currently available. Tavaré *et al.* (2002) estimated the age of primates to be approximately 82 Mya, whereas *Carpolestes* lived at the very end of the Paleocene (*c.* 56 Mya), 26 Mya later. This problem is compounded by the phylogenetic position of *Carpolestes*, which Bloch *et al.* (2001) have argued is nested deep within the carpolestids, removing the species morphologically as well as temporally from developments in the origin of primates. Indeed, from a temporal and phylogenetic perspective, the relevance of *Carpolestes* to questions surrounding primate origins is comparable (at best) to the relevance of living gibbons for hypotheses surrounding human origins. Future fossil discoveries will be needed to address these issues more directly.

4.03.11 Conclusions

The origin of primates of modern aspect was associated with the evolution of a suite of changes to the visual system in concert with changes in other functional systems. We contend that understanding the role of vision in primate origins and evolution requires an understanding of the integration between these systems. Changes to the visual system producing increased sensitivity to low light levels, improved fine-grained stereopsis, and increased visual acuity and motion sensitivity were accompanied by improved abilities to localize sounds or movements in space, increased dexterity, and changes to the somatosensory and somatic motor systems that provided for improved control of visually guided reaching and grasping movements. These changes were accompanied by modifications in gait and musculoskeletal anatomy of the hands and feet related to arboreal

locomotion, including leaping and grasping on fine-branch supports. These changes were manifest not only in the musculoskeletal periphery, but also throughout the central nervous system, including the origins and terminations of the CSTs, the premotor areas controlling limb movements, the visual cortex, and the primary and secondary sensorimotor areas.

4.04 The Comparative Biology of Photopigments and Color Vision in Primates

G H Jacobs, University of California, Santa Barbara, CA, USA

Glossary

dichromacy	A variant form of color vision. The defining character of dichromatic color vision is that a dichromat can match the appearance of a test light of any color by adjusting the relative intensities of two different colored lights.
LWS, SWS1	Abbreviations for two of the four families of vertebrate cone opsin genes.
monochromacy	An absence of color vision. Technically, a monochromat can match the appearance of test light of any color by adjusting the intensity of any other colored light.
opsins	Photopigment proteins.
S, M, L	The three types of cone photopigment found in primates. The letters are shorthand for short-, middle-, and long-wavelength sensitive, respectively.
spectrally opponent neurons	Cells in the visual system that transmit information used to support color vision.
trichromacy	A variant form of color vision that is the norm for catarrhine primates. The defining character of trichromatic color vision is that a trichromat can match the appearance of a test light of any color by adjusting the relative intensities of three different colored lights.

4.04.1 Evolution and Distribution of Primate Photopigments

Photopigments are sequestered in photoreceptors (in vertebrates, the familiar rods and cones) and serve to convert photon energies to neural signals, thus forming the indispensable first step on the path to seeing. Photopigment molecules consist of an apoprotein, an opsin, which is covalently bound to a chromophore. The genes specifying opsins have been the subject of intensive investigation and the opsin sequence information emerging from this work has in turn been used to produce photopigment phylogenies. Since many relationships between photopigments and vision have been elucidated in studies of contemporary species, it is possible to cautiously infer from these phylogenies something of the nature of vision in ancestral species.

Variations in opsin gene sequences serve to spectrally tune photopigments so that they preferentially absorb light most efficiently in a restricted portion of the spectrum (Nathans *et al*., 1986; Nathans, 1999). Although exceptions can exist, a basic feature of most visual systems that support color vision is the presence of two or more classes of photopigments, each having spectrally discrete absorption patterns. This requirement seems to have been achieved early on, perhaps by the date noted above (i.e., 800–1000 Mya), and by the time jawed vertebrates appeared (estimated as at least 540 Mya) there were already four separate classes of cone photopigments (rod photopigments were apparently added later) (Collin and Trezise, 2004). The implication drawn from the presence of multiple classes of cone photopigments is that rather elaborate color vision could also have been present by this time (see Evolution of Color Vision and Visual Pigments in Invertebrates).

A direct reflection of this early arrangement is that across contemporary vertebrates all cone photopigments are specified by genes drawn from four cone opsin gene families. Some groups of animals, for example, many birds, fishes, and reptiles, have retained representatives from each of these four families, and consequently have four types of cone photopigments

(Yokoyama and Radlwimmer, 1999). Other lineages have lost representation of one or more of these gene families and have correspondingly fewer types of cone photopigments. Among the latter are the mammals. It is now believed that sometime early in mammalian evolution, perhaps associated with the nocturnality of mammals during this time, two of these gene families were lost. The consequence of this loss is that contemporary mammals, at least all eutherian mammals, utilize opsins that are products of genes from only two families (Jacobs, 1993). Representatives from these two gene families, usually identified as short- and long-wavelength sensitive (respectively, SWS1 and LWS), produce pigments that, depending on the details of the gene sequence, can be spectrally tuned to have maximum sensitivity across the respective ranges running from the ultraviolet to the short wavelengths of visible light (SWS1 genes) and from the middle to long wavelengths (LWS genes) (see Figure 1a).

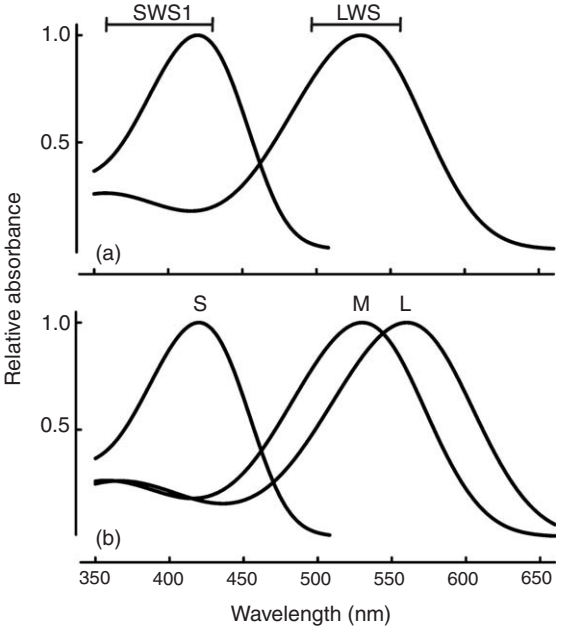

Figure 1 Spectral absorption curves for cone photopigments. a, The basic mammalian arrangement features two types of cone photopigment. These are respectively specified by representatives from two opsin gene families, SWS1 and LWS. In different species these genes spectrally tune the pigments across a range of wavelengths. That range is indicated for each of the two gene families by the horizontal bar shown above each pigment type. Thus, pigments specified by SWS1 opsin genes have λ_{max} from ~360 to 435nm while those produced by LWS opsin genes span the range from ~493 to 562nm. b, Spectral absorption curves for cone photopigments in catarrhine primates. These are typically designed as S, M, and L. The former is specified by a gene from the SWS1 family while the M and L pigments reflect LWS gene action. The separate M and L pigments arose as a result of an early gene duplication occurring at the base of the catarrhine radiation.

Primates are similar to other mammals in having a single rod opsin gene (located on chromosome 7) that encodes a rod photopigment with maximum sensitivity around 500nm. The SWS1 gene in primates is located on chromosome 3. This gene specifies a so-called S-cone pigment (S means short-wavelength sensitive, as before). There is some variation across primates in the absorption properties of the S-cone with peak sensitivities (λ_{max}) varying from ~415 to 435nm. In primates LWS genes are X-chromosome linked. From studies of human color vision, both its character and its inheritance, it has long been appreciated that humans with normal color vision must have two versions of these genes that specify spectrally discrete cone pigments. Although these were initially often called 'green' and 'red' cone pigments it is now conventional, and much less misleading, to refer to these pigments as M and L (respectively, middle- and long-wavelength sensitive).

In a landmark study 20 years ago, the human LWS opsin genes were cloned and sequenced (Nathans *et al.*, 1986). The genes specifying the L- and M-cone pigments are positioned in a head-to-tail tandem array on the X-chromosome and are very closely similar in structure having a 97% nucleotide identity. The implication drawn from this fact is that the two genes arose as a result of a duplication of an ancestral LWS gene. In humans, the resulting M and L pigments have λ_{max} ~530 and 562nm (as illustrated in Figure 1b). Subsequently, it has been learned that all catarrhines show evidence for the occurrence of the same gene duplication and thus the duplication event is believed to have occurred near the base of the catarrhine lineage, perhaps about 30Mya. This duplication was a hallmark in the evolution of primate vision as it set the stage for primates to acquire an additional dimension of color vision (Hunt *et al.*, 2005).

Although the cone pigment array in all catarrhines is similar to that illustrated in Figure 1b, there are some additional variations that can impact the character of catarrhine color vision. The chromosomal arrangement of the M and L opsin genes and their great sequence similarities allows mispairing and unequal crossing-over at meiosis. Depending on the detail of these two possibilities, this may result in either gain or loss of an opsin gene on one chromosome or the production of the so-called hybrid genes, that is, genes containing sequence from both M and L prototypes. One result of this process in humans is the widespread presence of multiple copies of the M opsin gene so that most individuals have, in total, more than two

X-chromosome opsin genes with, typically, a single L-cone opsin gene and multiple copies of the M-cone opsin gene. Another is that changes in the gene array can alter both the presence and the spectral absorption properties of the M and L pigments. These latter changes result in alterations in color vision, the most dramatic of which are the red–green color vision defects that are present in up to 10% of all males in some human populations. Whereas both these variations are commonplace in humans, they appear to be effectively absent in other catarrhines. This fact is puzzling and an explanation for it remains elusive. Differences in selective pressures against such variations in human and nonhuman primate lineages are often invoked as a possible explanation although there still seems to be no direct evidence on the matter one way or the other.

The photopigments and opsin gene arrays of platyrrhine primates differ dramatically from those of catarrhines. Like the catarrhines, platyrrhines have an S-cone opsin gene mapped to chromosome 7. However, unlike the catarrhines, most platyrrhine monkeys have only a single X-chromosome opsin gene. This gene is polymorphic with multiple allelic forms coding for photopigments with differing λ_{max} values (Jacobs, 1998). Most species have three such alleles. Since males have only a single X-chromosome, this means that all male monkeys have only two cone pigment types, but with variation in the λ_{max} of their single M/L cone pigment over the range from ~535 to 562nm. Females that are homozygous at the X-chromosome opsin gene site are like the males, but heterozygous females inherit genes that code for two spectrally discrete M/L pigment types. Through the agency of X-chromosome inactivation, the two pigments are expressed in different sets of photoreceptors and thus these females, like the catarrhine prototype, have a total of three cone types. The result is that these platyrrhine populations typically include three phenotypes characterized by two cone photopigments (all of the males plus the homozygous females) and three phenotypes having a total of three cone pigments (heterozygous females). These variations in turn underlie striking individual differences in color vision (Mollon *et al*., 1984).

There are some important variations on this opsin gene theme that have been detected in species from two genera of platyrrhine monkeys. One of these, the night monkeys (*Aotus*), show no evidence of polymorphism having only a single X-chromosome opsin gene that specifies an M-cone pigment (λ_{max}=543nm). Further, the *Aotus* S-cone opsin gene, although highly homologous in structure to other primate S-cone opsin genes, contains a number of insertions and deletions that introduce a premature stop codon in the gene sequence. As a consequence, these monkeys produce no viable S-cone pigment and thus have only a single cone pigment (Jacobs *et al*., 1996). The howler monkeys (*Alouatta*) provide a second interesting exception (Jacobs and Rowe, 2004). Like the catarrhines, these monkeys have two X-chromosome opsin genes that yield photopigments with peaks of ~535 and 562nm. Also similar to the catarrhines, the routine presence of two X-chromosome opsin genes in howler monkeys reflects the occurrence of an earlier opsin gene duplication. Although these X-chromosome opsin gene duplication events yield similar functional outcomes, they apparently occurred independently, once at the base of the catarrhine radiation and again in the line leading to modern howler monkeys. The howler monkeys have two sister taxa (*Ateles* and *Lagothrix*) that are similar to other platyrrhine monkeys in their X-chromosome opsin gene arrangements and that fact suggests that the gene duplication characteristic of *Alouatta* must have occurred subsequent to the divergence of these lineages, that is, <20Mya.

Our view of opsin genes and photopigments in animals from the third major group of primates, the more primitive strepsirrhines, remains incomplete. Originally, it was believed they were similar to the mammalian standard in routinely having two types of cone pigments as is illustrated in Figure 1a. That is apparently the case for some species. However, more recent work shows that other species have an opsin gene/photopigment arrangement similar to that described for *Aotus* with only one type of cone pigment (an M pigment) while still others have a polymorphism of the M/L opsin gene. These latter animals are thus similar to the polymorphic platyrrhines in that males and homozygous females routinely have only two cone pigments while heterozygous females have a total of three cone pigment types (Tan and Li, 1999). The distribution of these three patterns is not completely understood. Presently, it appears that: (1) the polymorphic strepsirrhines include lemurs and indrids from two families (*Varecia* and *Propithecus*), (2) those species with an opsin gene/pigment arrangement similar to *Aotus* include the Galagonidae (bush babies) and *Nycticebus* (slow loris), and (3) animals with two operational cone pigments and no evidence of polymorphism include both some common lemurs (*Eulemur* and *Lemur*) and at least one tarsier (*Tarsier bancanus*). There is some correlation between these opsin gene patterns and

the photic lifestyles of these species in that the polymorphic strepsirrhines are diurnal while those with only a single cone pigment are nocturnal. That relationship seems to break down for the third group that includes nocturnal and diurnal representatives as well as some species whose photic rhythms fall between these two patterns (usually termed 'cathemeral'). There is clearly more to be learned about opsin genes and cone pigments in the strepsirrhines.

4.04.2 Color Vision Variations in Primates

Multiple types of photopigment provide a necessary but not sufficient biological substrate for color vision. In addition, the nervous system must be so organized as to provide a means for contrasting signals that originate in cones containing different types of photopigment. A standard (perhaps universal) way to accomplish the latter requirement is to have the so-called spectrally opponent neurons in the visual system, cells in which signals originating in one or more of the cone types are effectively subtracted from signals originating in other cone types. Neural interconnections sufficient to produce spectral opponency between cones containing SWS1 specified pigments and cones containing LWS specified pigments seem common to all mammalian retinas (Wassle, 2004). In addition to this basic arrangement, primate retinas also contain spectrally opponent mechanisms that allow for signal contrasts between the LWS pigment subtypes (i.e., between the M and L cone types).

Extensive studies of human color vision, and particularly its variant forms, made clear that it is possible to infer much about the nature of color vision from knowledge of the cone pigment complement alone. Thus, any retina containing only a single type of cone pigment cannot support a color vision capacity (a condition termed monochromacy). Similarly, individuals with two types of cone pigment and associated spectral opponency derive a single dimension of color vision (dichromacy), whereas those with three classes of cone pigment get yet an additional dimension of color vision, becoming trichromatic. Within these broad classes the spectral positioning of the cone pigments can greatly influence the nature of color vision, so multiple forms of dichromacy and trichromacy are recognized. It is routine to assume the same sorts of linkages for nonhuman species, that is, the presence of two cone pigment types predicts dichromatic color vision, and so on.

Since it is generally easier to measure photopigments and examine opsin gene arrays than it is to do actual studies of animal color vision, much of what is assumed about nonhuman color vision reflects inferences drawn from studies of photopigments and their opsin gene precursors. Although such inferences are generally well supported, it should be kept in mind that extrapolations from cone pigment complement to color vision are just that, inferences. An important additional point, often ignored, is that knowledge about the cone complement *per se* cannot capture everything that is interesting about color vision. In particular, the acuteness of color vision, as opposed to its dimensionality, depends heavily on the numbers and spatial distributions of cones within the retina. Such information is typically not obtained from studies of photopigments and opsin genes. Thus, useful as they may be, inferences about color vision drawn strictly from studies of photopigments and opsin genes necessarily have some built-in limitations. With those caveats in mind the following summary statements about color vision among the primates can be offered.

4.04.2.1 Catarrhine Color Vision

The inference from comparisons of cone photopigments and their opsins is that all catarrhines would be expected to have very similar trichromatic color vision. Based particularly on a number of careful behavioral studies of various types of macaque monkeys, it seems clear that this assumption is correct. Although there may be some minor differences in color vision capacity among the catarrhines, including those suggested above, all these primates are predicted to share those basic color vision capacities that have been so exhaustively documented for normal human trichromats. Perhaps particularly important for primate success in the task of food harvesting, this includes the ability to make very discerning color discriminations across the red/green portion of the spectrum and thus, for example, allowing foraging primates to evaluate the ripeness of fruits or the potential palatability of foliage.

4.04.2.2 Platyrrhine Color Vision

The platyrrhine theme is polymorphism of the X-chromosome opsin genes and the M/L pigments. There are good studies of color vision in a number of these polymorphic species, particularly for squirrel monkeys (*Saimiri*), marmosets (*Callithrix*), and tamarins (*Saguinus*). The results indicate that the photopigment polymorphisms map directly into

corresponding color vision variations such that, in these species, all males and homozygous females have dichromatic color vision while heterozygous females gain an additional dimension of color vision, becoming trichromatic. Further, within each of these broad categories, subtypes can be detected reflecting the variations in the spectral positioning of the M/L cone photopigments. Although many species that have photopigment polymorphisms have not been subject to direct studies of color vision, the good predictability from photopigment to behavioral capacity in those that have been studied makes it quite likely that similar correspondences exist across all the polymorphic platyrrhines. It is a striking fact that within any group of such platyrrhine monkeys a variety of distinctive color vision phenotypes can be found. That observation has in recent years energized the search to understand the utility of color vision in natural settings (Surridge *et al*., 2003).

It was noted that monkeys of two platyrrhine genera do not have photopigment polymorphism. One of these, *Aotus*, has only a single type of cone photopigment. As predicted from this arrangement, these monkeys fail to show evidence of a color vision capability. Howler monkeys are alone among the platyrrhines in routinely having three types of cone photopigment. This predicts that they should be trichromatic. Although that seems likely to be the case, there are as yet no behavioral studies to verify that prediction. In view of the uniqueness of these monkeys, it would be very useful to make sure that prediction is in fact borne out.

4.04.2.3 Strepsirrhine Color Vision

Although there is at least an outline view of opsin gene and cone pigment variations among the various strepsirrhine species, there is at the same time very little in the way of compelling studies of how these arrangements map into color vision capacities. In accord with the linkages outlined above, one would predict some of the strepsirrhines to lack color vision, some would be expected to be routinely dichromatic, while still others may show color vision polymorphisms of the type known to characterize the platyrrhine monkeys. Whereas it seems reasonable to suppose these predictions are correct, there is at the same time some reason for caution. Unlike all catarrhine and platyrrhine species (save *Aotus*), the retinas of the strepsirrhines generally lack foveal specializations and the very high cone densities associated with these arrangements. The eyes of many strepsirrhines also retain a retinal tapetum, an anatomical adaptation classically associated with nocturnal vision. These facts would suggest, at the least, that color vision is apt to be a less acute capacity in strepsirrhines than in catarrhine and platyrrhine primates (Jacobs, 2004). It would be very useful to have new studies of strepsirrhine color vision conducted using modern techniques. For the present, one can do no better than to assume that the cone pigment arrangements at least predict the dimensionality of strepsirrhine color vision.

4.04.3 Conclusions and Continuing Issues

The comments above make clear that considerable headway has been toward an understanding of primate color vision and its biology and that, at least to a good first approximation, the distribution of color vision among the primates is known. Figure 2 is a phylogeny of primate color vision that summarizes

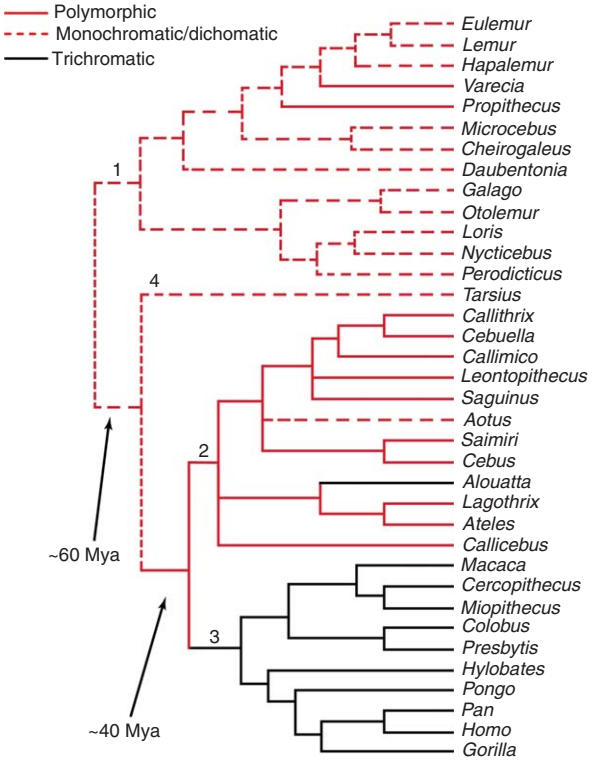

Figure 2 Distribution of primate color vision. Three categories of color vision capacity are indicated: routinely monochromatic or dichromatic, polymorphic, routinely trichromatic. The nature of these categories is further detailed in the text. The numbers on this primate phylogeny identify three taxonomic groups: 1, strepsirrhines; 2, platyrrhines; 3, catarrhines. *Tarsius* (#4) belongs to the same suborder as platyrrhine and catarrhine monkeys (Haplorhini). Reproduced from Jacobs, G. H. and Rowe, M. P. 2004. Evolution of vertebrate colour vision. *Clin. Exp. Optom.* 87, 206–216, with permission from Optometrists Association Australia.

the story. Identified there are three dimensional categories of color vision: routine monochromacy and routine dichromacy, polymorphic color vision that includes a rich mixture of dichromatic and trichromatic phenotoypes, and routine trichromacy. As noted, the picture is reasonably complete for the vast majority of catarrhines and platyrrhine species, but is much less well established for strepsirrhines.

There is some uncertainty about the staging of the changes that led to color vision in contemporary primates. Given the broad distribution of dichromacy across mammals, it seems likely that also represents the condition for ancestral primates. Accordingly, the loss of a functional S-cone pigment observed in a number of nocturnal primates would represent a secondary change. In addition to these primates, an analogous loss of function of S-cone opsin genes has been observed in a number of nonprimates, including both rodents and carnivores. In some of these lineages the loss is sporadic across species (e.g., nonhuman primates and rodents), suggesting that it probably occurred fairly recently. In others, however, S-cone loss appears universal (e.g., the pinnipeds and the cetaceans) and seems therefore to reflect an event that occurred near the base of the radiation. As yet the events triggering such loss are unknown, but since they reflect a variety of structural changes in the S-opsin gene that are different in different lineages they appear to have occurred independently a number of times. A traditional view has been that the ancestral primate was nocturnal (Martin and Ross, 2005). A counter view, recently offered, is that the ancestral primate was diurnal and that trichromacy originated early in primate history (Tan and Li, 1999). If that is so, there has been considerable subsequent loss of color vision dimensionality.

The appearance of three cone pigments in a handful of strepsirrhines might suggest that polymorphic trichromacy was present early on, well prior to the divergence of catarrhines and platyrrhines. If so, routine trichromacy in catarrhines could then have originated by unequal crossing-over between two chromosomes carrying different M/L alleles to produce different versions of the M/L opsin genes on a single X-chromosome. Alternatively, if polymorphism was not an ancestral condition, catarrhine trichromacy could have arisen from an X-chromosome gene duplication with subsequent structural divergence of the two genes to yield genes coding for spectrally discrete M and L pigments. In the latter view, then, opsin gene and photopigment polymorphism arose independently in the platyrrhines and in the small number of strepsirrhine lineages. Examination of the opsin genes of the howler monkeys supports the view that their routine trichromacy reflects events that also occurred independently from those that gave rise to catarrhine trichromacy. The origin and staging of photopigment polymorphism in the platyrrhines remains to be fully understood.

The remarkable variations in color vision across contemporary primates contrast sharply with what is seen in other mammalian orders where color vision is generally much less well developed and where there is greater uniformity of cone photopigments and color vision across species (Jacobs, 1993). Why has more elaborate color vision evolved in primates than it has is in other mammals? In recent years that question has been much debated. Typical answers point to the exploitation by primates of highly colored food sources such as fruits and leaves and to the evolution of a retinal organization in primates that supports high spatial resolution and thus provides a favorable substrate for the addition of new dimensions of color vision. The study of how particular primate color vision phenotypes map into natural behaviors is a topic of much current interest and the results of those studies may be expected to illuminate this issue in the coming years.

4.05 The Evolution of Parallel Visual Pathways in the Brains of Primates

V A Casagrande and I Khaytin, Vanderbilt University, Nashville, TN, USA
J Boyd, Medical University of South Carolina, Charleston, SC, USA

Glossary

analogy	Functional similarity between parts of different organisms due to parallel evolution, without common ancestral origin.
Brodmann	Brodmann (1909) developed a commonly accepted scheme for dividing V1 into six layers (I, II, IIIA, IIIB, IVA, IVB, IVCα, IVC*β*, V, and VI).
Hässler	We have used a modification of a nomenclature devised originally by Hässler (1967). The latter allows for more appropriate cross-species comparisons. This nomenclature subdivides cortex into the following layers, with Brodmann's nomenclature in parentheses: I (I), II (II), IIIA (IIIA), IIIBα (IIIB) and IIIB*β* (IVA), IIIC (IVB), IVα (IVCα), IV*β* (IVC*β*), V (V), and VI (VI).
homology	Similarity between parts of different organisms due to evolution from the same part of a common ancestor.
homoplasy	Correspondence between parts or organs as a result of evolutionary convergence.
K, M, P cells	Koniocellular (K), magnocellular (M), and parvocellular (P) cells found in different layers of the lateral geniculate nucleus of primates.
ON-/OFF-center cells	Retinal ganglion and lateral geniculate nucleus cells that respond with increases in response to either the onset or offset of light in the receptive field center.
ontogeny	Developmental progression of an organism from embryo to adult.

4.05.1 Introduction

The primate order to which we belong is quite heterogeneous in size, form, and lifestyle. Primate species range in size from some prosimians that can weigh as little as 100 g (e.g., the mouse lemur, *Microcebus murinus*) to species of great apes, whose males can weigh more than 300 kg (e.g., the gorilla; Figure 1). Such size differences can also be seen in the brain, which varies in weight from 1.73 g in the mouse lemur to 1400 g in humans (Bons *et al*., 1998; Williams, 2002).

These differences in body/brain size and lifestyle of existing primate species can make it difficult to trace the evolutionary history of brain parts and connections, particularly since big differences in brain size and lifestyle result in both addition and deletion of brain parts, and changes in connections due to scaling issues (Kaas, 2004). Moreover, the clues about brain evolution left by ancestors are limited. These clues rely on incomplete fossil records, and genes whose rate of change cannot be predicted precisely, or (in most cases) be linked to specific brain parts. Finally, relevant visual pathway data have been gathered for relatively small numbers of existing primate species. None of these clues alone, including current powerful genetic approaches, offer sufficient evidence to trace the evolutionary history of specific brain components and connections in primate evolution. The strongest evidence for evolutionary relationships between brain parts and connections of different primates is likely to be the common presence of a feature in several distantly related primates. The difficulty lies in trying to determine

(a)

Relative body and brain sizes

Mouse lemur (*Microcebus murinus*)	Body:	0.06 kg
	Brain:	1.73 g
Gorilla (*Gorilla gorilla*)	Body:	175 kg
	Brain:	535 g
Human (*Homo sapiens*)	Body:	65 kg
	Brain:	1400 g

(b)

The primate order includes mammals that range widely in body and brain size from mouse lemur to gorilla and human. a, Artistic depiction of the relative size differences between a mouse lemur and a gorilla; b, comparison of body and brain weights of mouse lemurs, gorillas, and humans (Bons *et al.*, 1998; Williams, 2002); c, schematic representation of relative brain sizes of these primates. a, Reproduced by permission of David Royal.

the history of these brain parts and connections since similarities may simply reflect a form of parallel evolution (homoplasy) and not necessarily homologous relationships. Also, the fact that connections can be added, deleted, or evolve at different rates in a mosaic fashion magnifies the problem. Nevertheless, some inferences can be made by careful comparisons across existing species and by combining this information with emerging genetic maps of relationships between species.

Our goal in this article is to review relevant evidence from a variety of sources in an effort to reconstruct a reasonable scenario as to how parallel visual pathways might have evolved in primates. Given that visual system studies of living primates are limited to only a few of the many existing primate species, we must rely on work on other mammals, and even nonmammals, to construct a reasonable scenario of the evolution of the visual pathways in primates. Historically, it has been argued that the main parallel visual pathways to cortex in mammals are the retinocolliculopulvinar and retinogeniculo-V1 pathways (see Casagrande and Royal, 2004; Casagrande and Xu, 2004).

For this article, we have chosen to focus on channels passing to and through the lateral geniculate nucleus (LGN), since these pathways may have become differentially specialized in primates and

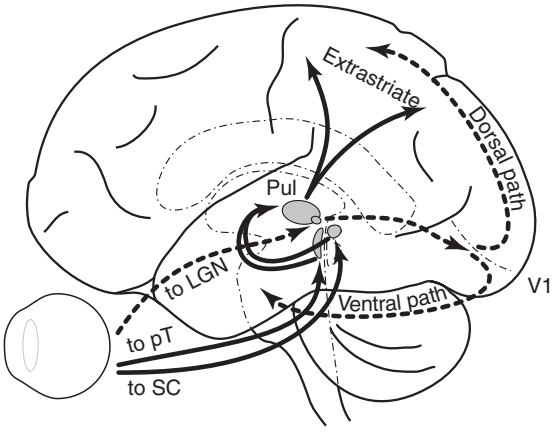

Figure 2 Parallel visual pathways from retina to cortex. In primates, visual information reaches cortex from retina via several pathways. The most studied, and important, is the pathway from the eye to the LGN to V1 (also called striate cortex or area 17), shown with dashed arrows. In V1, new pathways are constructed that enter two hierarchies of visual areas known as the dorsal and ventral paths or streams of processing, also referred to by some authors as the 'where stream' or vision for action stream and the 'what stream', respectively, in reference to their proposed function. Less studied is the pathway from retina (eye) via superior colliculus (SC) and pretectum (pT) to pulvinar (Pul). Pulvinar, in turn, sends widely distributed projections to most extrastriate visual areas to which the dorsal and ventral pathways also project.

are known to be the main pathways for conscious visual perception in primates (Figure 2). We have divided the article into eight sections, including this introduction. In Section 4.05.2, we define what we mean by parallel pathways and provide some other operational definitions that are used in the remaining sections. In Section 4.05.3, we consider whether magnocellular (M) and parvocellular (P) retinogeniculocortical pathways are homologous across primates and whether these pathways exist in nonprimates (e.g., Y and X streams in cats) as some have proposed (Casagrande and Xu, 2004). In Section 4.05.4, we address the controversies over whether the fine fiber system identified by Bishop (1933) in frog and rabbit optic nerve becomes the koniocellular (K) pathway in primates. Given that the K pathway is heterogeneous, we argue that the K pathway is actually made up of a number of pathways of which some are likely to have been present in the common ancestor of primates. A related issue, namely the evolution of chromatic channels and color vision in primates, is addressed separately in Section 4.05.5. Here we defend the position that one type of K pathway likely transmitted cone signals to the LGN even in the ancestors of primates, given that these cone signals have been found in K LGN cells in both New World and Old World primates and in some cat W cells (which share other features with primate K cells). In Section 4.05.6, we consider other properties that remain segregated in the LGN and cortex, such as input from the two eyes and whether it existed in the common ancestor of primates. We support the position that the laminar pattern of ocular segregation in the LGN and the columnar organization of ocular segregation in cortex show the same basic features across primates, suggesting that both were present in the common ancestor of primates. In Section 4.05.7, we examine the issue of whether parallel LGN pathways evolved as starting points for specific hierarchies of visual cortical areas that have been referred to as the dorsal and ventral streams of visual processing in the common ancestor of primates. In Section 4.05.7, we also consider the issue of whether such cortical streams are conserved across mammals or evolved separately in such species as cats. We take the position that the basic subdivisions into dorsal and ventral streams of visual processing at the cortical level can be identified in a diverse range of primates and so are likely to be homologous, but components may have been added, deleted, or modified in different primate lines. In Section 4.05.8, we provide a summary and also outline questions that need to be addressed in order to arrive at more definitive conclusions concerning the evolution of parallel visual pathways. We also outline some practical strategies for answering some of these questions.

4.05.2 Background and Some Definitions

In order to examine the issue of the evolution of parallel visual pathways we need to consider how to define the specifics of the problem. For example, how do we know if a visual pathway is homologous (derived from a common ancestor) or simply analogous (functionally similar but not inherited from a common ancestor)? Since parallel visual pathways are made up of cells at different levels of the neuraxis that differ in terms of neurochemistry, morphology, connections, and function, we need to clarify our level of analysis. For example, can we consider a pathway that carries chromatic signals from two cone types in the retina of a diurnal primate species as homologous to a pathway that appears similar in all other respects to one that carries signals from a single cone type in a monochromatic nocturnal species? We would argue that if this similarity extends to other defining features of the pathway and extends to several distantly related

species the answer should be yes. What would be useful is to understand which particular neural characters at any level in the pathway are conservative. It is likely that answers lie in the ontogeny of these pathways given that early embryological stages are quite conservative across mammals. Unfortunately, since there are almost no studies available comparing the neural development of the visual system of different primate species, we are unlikely to be able to identify such ontological characters, although some clues can be obtained by making comparisons between available primate and nonprimate developmental data. An additional related problem is that it is not clear how modifications at one level of the visual system (e.g., the retina) affect the development of more central target structures and vice versa. For example, Kaskan *et al.* (2005) have argued that major changes in retinal ganglion cell number or shifts in the proportions of rods and cones do not result in major differences in the size of the primary visual cortex (V1) which, instead, appears to scale with overall brain size (see Visual Cortex: Evolution of Maps and Mapping). This result implies that the developmental programs for visual areas in the telencephalon and diencephalon (forebrain) are relatively independent (at least at the early stages) from changes that occur in the original out-pocketing of the forebrain, the retina. If this is the case, then using the retina as the starting point for investigating the evolution of parallel visual pathways may be the wrong approach. Careful examination of V1, however, indicates that there may be differences in relative laminar development across primates that appear to correlate with changes in the eye. Examination of the thalamus, especially the LGN, also indicates that relative laminar development varies in predictable ways with phylogeny and visual niche in primates (Figure 3). Thus, examination of detailed structure (not just gross size) may offer more insights concerning the evolution of brain parts (see Elston *et al.*, 2001).

We argue that, although the programs of neural development that establish peripheral tissues and each level of the neuraxis can differ, they are never evolutionarily divorced from each other if they are connected in the adult. After all, the entire machine needs to run reasonably well for the adult organism to survive and reproduce and this requires that connections be made appropriately. Changes at one level can never be completely divorced from changes at the next level. The latter also raises the issue of epigenetic effects. Clearly, there are a number of epigenetic mechanisms, including neural activity/experience and competition for growth factors, that must be used to match neuronal populations at different levels in large brains since the number of synapses far exceeds the number of genes available for individual specification by a large margin. For example, in humans there are about 15×10^8 synapses per mm^3 of neuropil (DeFelipe *et al.*, 1999) compared with $26–38 \times 10^3$ genes (Venter *et al.*, 2001). Still, these epigenetic mechanisms must have a genetic base and must be selected in order to ensure that brain areas wire correctly (Easter *et al.*, 1985).

Another big question that must be answered before we can even begin thinking about evolution of parallel visual pathways is the question of why these pathways arose in the first place. Parallel pathways likely arise in evolution in response to incompatibilities. A cell cannot have a large dendritic field that integrates information across many receptors and have a small dendritic field capable of discrete fine grain sampling from just one or two receptors. Such incompatibilities could also provide an evolutionary drive for parallel pathway specialization. Parallel pathways presumably also arise from the constraints on the speed of transmission, particularly in relatively large mammalian brains. It seems likely then that true parallel visual pathways originate from ganglion cells that are clearly distinct in a number of ways. As argued eloquently by Rowe and Stone (1980), dividing ganglion cells into different classes needs to be based upon a parametric approach using a variety of criteria, given that it is difficult to prove that any single characteristic defines an entire class. A true class of ganglion cells should also tile the retina without visuotopic holes, otherwise differences may simply reflect natural variation within a cell class. Presumably once the number of ganglion cell types can be established then the number of parallel pathways to the brain/LGN will be limited to that number, assuming that each ganglion cell class projects to its own unique set of cells. In the case of the LGN, the number of different ganglion cells that provide input has still not been established, but, as explained more fully below, one can make comparisons between species based upon examination of some of the established pathways. Similarly, at the level of the LGN and V1, a true visual pathway should show anatomical segregation in terms of connections even if specific functional signatures cannot be traced from level to level. Beyond the first synapse in V1, however, it appears that a separate set of parallel pathways is established that links V1 to extrastriate areas (Casagrande and Kaas, 1994). The degree to which the geniculocortical pathways are actually linked directly to the pathways leading to extrastriate areas is a matter of debate given that most signatures of early pathways disappear at the level of V1

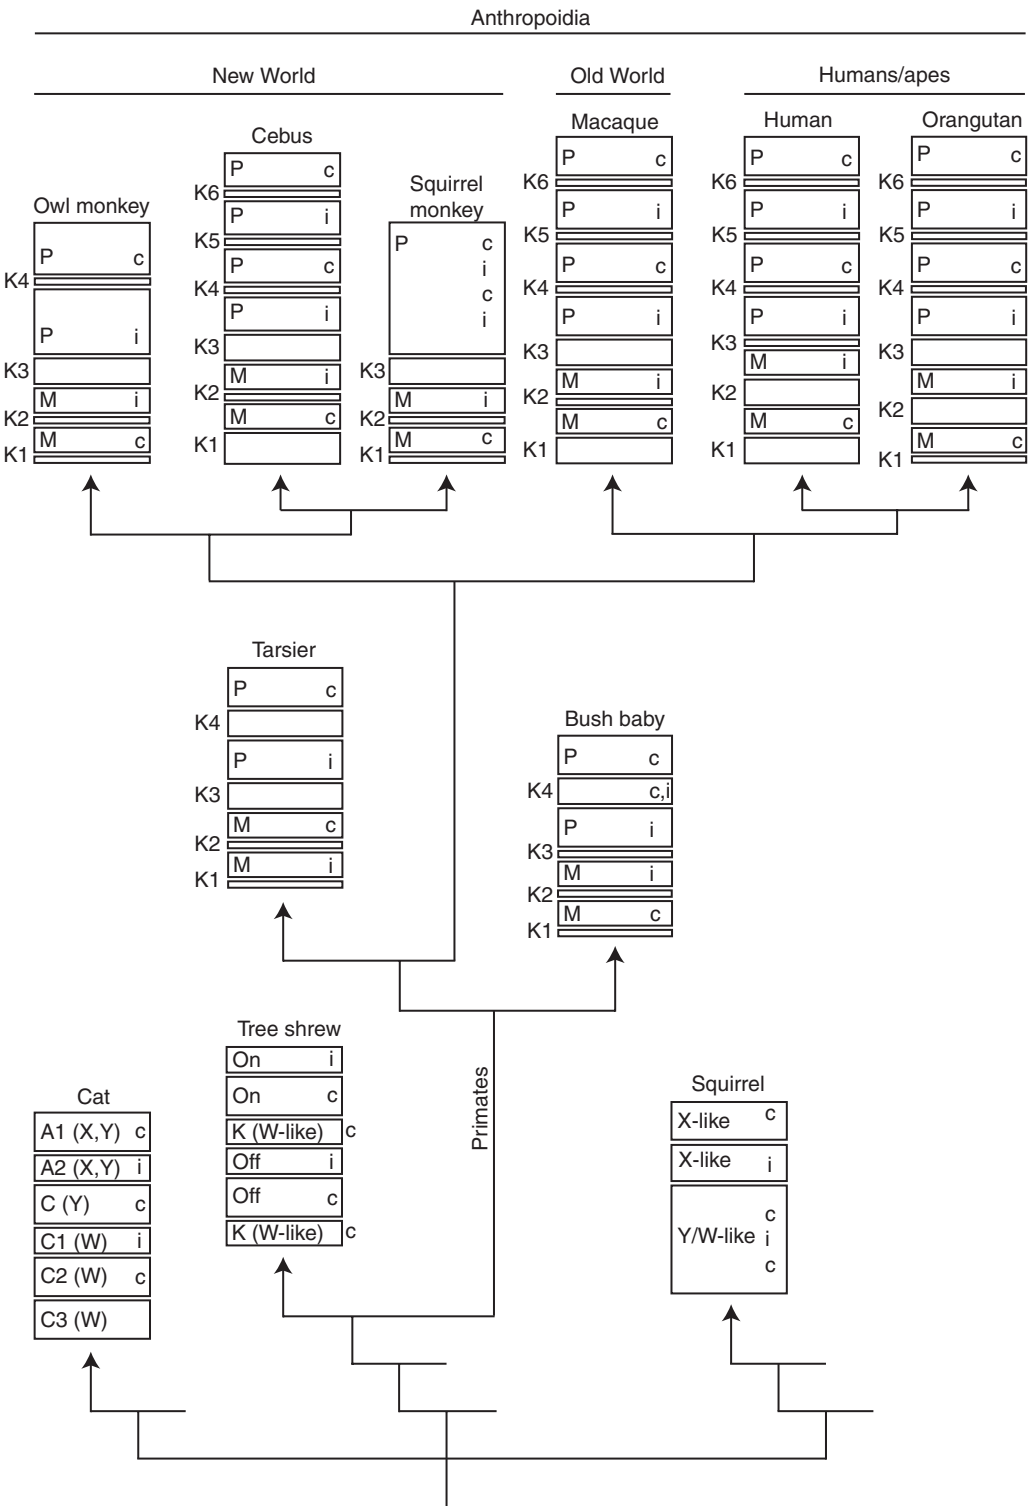

Figure 3 Laminar organization of the LGN in primates, tree shrews, squirrels, and cats. LGN cell layers for each species are indicated in boxes. The phylogenetic relationships between mammalian species are indicated by arrows, with the top branches indicating the relationships between primates. Only a few examples are shown. Note that in all primates the LGN is organized in a similar manner with two P layer and two M layers. In some primates (e.g., macaque monkeys), the P layers can split into four layers in a portion of the nucleus, and in others (squirrel monkeys) P cells exist as a cell mass where layers exist only based upon separate input from each eye. Tree shrews (Scandentia) are the closest living relatives of primates but have a very different LGN laminar organization as do squirrels (Rodentia) and cats (Carnivora). See text for details. c, contralateral retinal input; i, ipsilateral retinal input; K, koniocellular; M, magnocellular; P, parvocellular. Numerals refer to different K layers.

(Merigan and Maunsell, 1993; Casagrande and Xu, 2004). Nevertheless, similarities in the output of V1 to other cortical areas and their connections with each other allow us to ask whether similar hierarchies of visual areas are established across various primate species. As discussed in more detail below, it appears that V1 projects to the same areas in a range of primates (Casagrande and Kaas, 1994) but that, beyond V1, the evidence from connections, lesions, and behavior studies can support the idea that two major hierarchies of visual areas existed in a common ancestor of primates only in the broadest sense.

4.05.3 The Evolution of P and M Pathways

In almost all mammalian species so far examined, retinal and LGN cells can be physiologically classified into those that appear to convey information about higher spatial frequencies and respond in a more sustained manner, those that appear to respond better to higher temporal frequencies in a more transient manner, and those with slowly conducting axons and heterogeneous response properties (Stone, 1983; Lennie, 1993; Casagrande and Xu, 2004). In primate LGN, these classes correspond to P, M, and K neurons, respectively. In this section, we focus on the P and M pathways; the K pathway will be dealt with more fully in Section 4.05.4. Here, we consider the competing hypotheses that the P and M pathways (1) were present early in mammalian evolution and are thus homologous with similar pathways in nonprimates (e.g., X and Y cells in cats), (2) appeared early in primate evolution and their similarities with other mammalian species thus represent examples of parallel evolution, or (3) evolved independently in different primate lineages. Evidence for or against these hypotheses is sought from comparisons of response properties, anatomical organization, and neurochemistry in the retinogeniculocortical pathways of New World and Old World primates, cats, tree shrews, and rodents. Most of the nonprimate data come from cats, as their visual systems have been the most thoroughly studied of all nonprimate mammals.

In all primates, the M pathway originates from large retinal ganglion cells (parasol cells) which project to the M layers of the LGN, whereas the P pathway originates from smaller retinal ganglion cells (midget cells), which project to the P layers of the LGN (Figure 3). M cells in the retina and M LGN have larger receptive fields, lower preferred spatial frequencies, higher preferred temporal frequencies, and higher contrast sensitivities than their P counterparts. A similar dichotomy is found between Y and X cells in the cat retina and LGN (Table 1). Although X and Y cells in cats were first distinguished on the basis of a single criterion, linearity of spatial summation, the X versus Y classification was found to correspond to a host of other characteristics, and it is this extended sense of X and Y that is used here (Norton and Casagrande, 1982). Indeed, when W cells were described in cats, it was found that some were linear and some nonlinear, yet they were clearly a separate population based on the extended criteria that define X and Y cells (Table 1). Although it has been proposed that M and P cells are homologous to Y and X cells, respectively, an alternative hypothesis is that cat X and Y cells correspond to the linear and nonlinear subgroups of M cells, respectively, and that the P pathway is primate-specific (Kaplan and Benardete, 2001). X and Y cells, however, differ in many morphological and physiological characteristics in a similar way to M and P cells, while it is not clear that the linear and nonlinear M cells differ in characteristics other than linearity (see, however, Kaplan, 2004). It should be noted that linearity arises from a special mechanism that is added to the linear center surround mechanism present in all

Table 1 Comparison of primate M and P cells with cat X and Y cells

Attribute	*Primate M cells*	*Cat Y cells*	*Primate P cells*	*Cat X cells*
Cell size	Large	Large	Small	Small
Conduction velocity	Fast	Fast	Slow	Slow
Response dynamics	Transient	Transient	Sustained	Sustained
Spatial resolution	Lower	Lower	Higher	Higher
Temporal resolution	Higher	Higher	Lower	Lower
Contrast sensitivity	Higher	Higher	Lower	Lower
V1 projection	Upper tier of layer 4	Upper tier of layer 4	Lower tier of layer 4	Lower tier of layer 4
Linearity of spatial summation	Most linear, some nonlinear	Nonlinear	Linear	Linear
Chromatic opponency	No	No	Yes (in trichromatic primates)	No

retinal ganglion cells, so linearity of certain cell classes could be gained or lost in evolution without compromising other physiological properties.

Another physiological property that differs between primates and cats is color selectivity in that P cells have chromatic opponency, whereas X cells do not. However, this difference is affected by the fact that cats are dichromats, adapted for a nocturnal existence. As discussed more fully in the following sections, long-wavelength cones were gained (or, more likely, regained) independently in New World and Old World primates. The P cells of some dichromatic (or even monochromatic in the case of galagos and owl monkeys) primates also lack color opponency for similar reasons as cat X cells, yet they have all the other characteristics of P cells in trichromatic primates. Thus, P cells in all primate species should be considered homologous, regardless of color selectivity, because such differences can be explained by changes in single photopigment genes. By the same reasoning, lack of color opponency should not be used as evidence against homology of cat X cells and primate P cells (see Evolution of Color Vision and Visual Pigments in Invertebrates).

Although fewer data are available, distinct physiological classes, possibly corresponding to P and M pathways, have been found in other species. In gray squirrels, P-like cells with longer latencies, sustained firing, and linear spatial summation could be distinguished from M-like cells with short latencies, transient responses, and linear or nonlinear summation (Van Hooser *et al.*, 2003). In tree shrews, although linear and nonlinear cells have been found (Sherman *et al.*, 1975), it appears that the nonlinear cells are more like K or W cells than M cells, and that nonlinear M cells are lacking (Holdefer and Norton, 1995). A clear dichotomy between transient and sustained responses is found in the tree shrew, however (Sherman *et al.*, 1975; Lu and Petry, 2003).

Within the LGN, M and P cells are segregated into different layers. The standard primate laminar pattern consists of four layers: two M layers adjacent to the optic tract, followed internally by two P layers (Casagrande and Norton, 1991; Kaas, 2004). Each of these layers receives input from one hemiretina, with the first M layer receiving crossed (nasal hemiretina) input and the second M layer receiving uncrossed (temporal hemiretina) input. The P layer closest to the second M layer also receives an uncrossed retinal input, while the most internal P layer receives a crossed retinal input. The K layers, discussed in more detail below, lie mainly between or ventral to each of the P and M layers (Casagrande, 1994; Hendry and Reid, 2000; Casagrande and Xu, 2004). In some primates, the two P layers can split into four layers, but this occurs for only a topographically limited portion of the nucleus. For example, in macaque monkeys, four P layers can be identified only within the part of the nucleus representing about 2–3° to 17° of eccentricity (Malpeli *et al.*, 1996). In some humans, P layers split into as many as eight layers in some parts of the nucleus, but in other humans only two P layers exist across the whole extent of the LGN (Hickey and Guillery, 1979). In some primates, portions of the ipsilaterally innervated M layer can split off and form an extra layer next to the optic tract within a portion of the nucleus (Casagrande and Joseph, 1980). The latter is the standard condition for M layers in the tarsier, where it has been suggested that the ipsilaterally and contralaterally innervated M layers are reversed (Rosa *et al.*, 1996). Finally, in many New World primates (e.g., squirrel monkeys), P cells exist as an unlaminated cell mass where layers can only be defined based upon segregated input from the axons from the two eyes (Tigges and O'Steen, 1974; Fitzpatrick *et al.*, 1983). All of these differences, however, can easily be recognized as modifications of the basic primate laminar pattern (Figure 3).

In most nonprimate mammals with well-developed visual systems, three main subdivisions of the LGN can be recognized, progressing internally to externally (i.e., toward the optic tract): (1) a main contralateral layer receiving X- and Y-type input, (2) a main ipsilateral layer receiving X- and Y-type input, and (3) an outermost layer comprising sublayers receiving various combinations of contralateral Y-type input and ipsilateral and contralateral W-type input. The LGN of the cat, for example, consists of paired layers A and A1 receiving mixed X and Y inputs from the contralateral and ipsilateral eyes respectively, a magnocellular C layer receiving contralateral Y cell input, and several small-celled layers receiving either contralateral or ipsilateral W cell input. The LGN of sheep and other ungulates has a similar organization (Karamanlidis and Magras, 1972; Ebinger, 1975; Karamanlidis *et al.*, 1979; Clarke *et al.*, 1988). Additionally, carnivores and ungulates possess a medial interlaminar nucleus (MIN) which receives Y and W input. Layers A and A1 are subdivided into sublayers receiving input from either ON-center or OFF-center retinal ganglion cells in such mustelid carnivores as ferrets and mink (LeVay and McConnell, 1982; Stryker and Zahs, 1983). In squirrels, contralateral layer 1 and ipsilateral layer 2 receive X- and Y-like input (referred to by some as P-like and M-like; see above), while Y-like input is found in layers 1, 2, and especially 3, and W-like input is confined to layer 3 (Kaas *et al.*, 1972; Van Hooser *et al.*, 2003).

The primate LGN thus differs from the standard mammalian plan in having complete, not partial, segregation of different cell classes. As previously pointed out (Boyd and Matsubara, 1996; Matsubara and Boyd, 2002), a simple scenario for transitioning to the primate organization involves the coalescing of ipsilateral Y cells ventrally in layer A into a separate layer. The resulting lamination pattern would have the same contra-M, ipsi-M, ipsi-P, contra-P organization as seen in primates.

Interestingly, the tree shrew, which is considered phylogenetically closer to primates than the groups considered above, has a unique LGN organization which is unlike that in primates or other mammals. The tree shrew has a six-layered LGN with two layers containing W-like cells, and the remaining four layers segregated by both eye input and contrast sign (ON center vs. OFF center). Projections from sustained and transient retinal ganglion cells do not appear to segregate into different LGN layers in the tree shrew. The tree shrew visual system thus appears to have many derived characteristics that arose independently of those in primates (Rager, 1991; Kaas, 2002).

Another criterion that has been used to determine homology in the LGN is neurochemical content. M cells (but not P cells) in the LGN of primates and Y cells (but not X cells) in the LGN of cats are selectively labeled by antibodies against a cell surface antigen, Cat-301 (Hockfield and Mckay, 1983; Hockfield *et al.*, 1983; Hendry *et al.*, 1988), or against nonphosphorylated neurofilaments (Chaudhuri *et al.*, 1996; Bickford *et al.*, 1998). These molecular markers thus support the hypothesis of homologies between LGN cell classes in different mammalian lines.

Finally, the geniculocortical projections of the different classes of relay cells provide evidence for homology between different groups. In all primates, M cells project to the upper portion of layer IV, P cells project to the lower portion of layer IV, and K cells project above layer IV (Casagrande and Norton, 1991). In cats, the laminar segregation between X and Y cells is similar (though likely not as absolute) with X-cell terminations concentrated in lower layer IV and Y cell terminations concentrated in upper layer IV. W cells project outside of layer 4 (see Section 4.05.4 on K pathway for further discussion). In both cats and primates, the simple laminar dichotomy between X and Y cells is likely to be complicated by subclasses of X and Y cells and M and P cells. For example, the Y cells in layer C have larger receptive fields, higher contrast sensitivity, and more pronounced nonlinearities than A-layer Y cells (Frascella and Lehmkuhle, 1984; Yeh *et al.*, 2003). Their terminations are confined to the topmost third of layer IV and, moreover, selectively target cytochrome oxidase (CO) blob columns (Boyd and Matsubara, 1996). It has been argued that a similarly defined subclass of M cells exists in primates (Hawken *et al.*, 1988; Bauer *et al.*, 1999), although the evidence for this is not as conclusive.

The sublaminar organization of geniculocortical organization in other animals is not as well described as for cats and primates, but it can be noted that the layer 3 complex in squirrels, which contains Y-like and W-like cells, projects to the upper part of layer 4 and supragranularly, and these two projections likely come from Y-like and W-like cells, respectively (Weber *et al.*, 1977; Harting and Huerta, 1983). Tree shrews have a very different geniculocortical arrangement, whereby terminations from ON-center and OFF-center cells segregate within different sublamina of layer 4 (Fitzpatrick and Raczkowski, 1990). The W-like LGN layers, however, still terminate outside of layer 4.

The data reviewed here strongly support the hypothesis that the precursors to M and P cells were present in the earliest primates, so M and P cells in all primates are homologous. Moreover, the similarities in organization of the M and P pathways in primates and similar pathways in some other mammals provide some support for the hypothesis that the M versus P dichotomy arose prior to the divergence of primates from other mammals, with the unique differences found in tree shrews representing a derived condition, not primitive characteristics representative of early primates.

4.05.4 Is the K Pathway Evolutionarily Old?

In Section 4.05.3, we focused on the parallel M and P pathways connecting the retina with V1; in this section, we focus on a third parallel pathway, currently referred to as the koniocellular, or K, pathway (for reviews see Casagrande, 1994; Hendry and Reid, 2000; Casagrande and Xu, 2004). As for the M and P pathways, the K pathway consists of a distinct class (or classes, as K cells are heterogeneous) of retinal ganglion cells that project to distinct groups of cells in the LGN, which are in turn connected to distinct layers of V1. The K pathway has a constellation of features that distinguish it from the M and P pathways and that have led some to suggest that the K pathway is phylogenetically older than the M and P pathways. In this section, we review this hypothesis, while at the same time

reviewing the data for homologues of the K pathway in other mammalian species, particularly the W pathway in the cat, the nonprimate for which the greatest amount of data on the visual system is available.

The cat W pathway was relatively well studied years before the primate K pathway was closely examined (Stone, 1983), and indeed even before the extent and importance of the K pathway in primates was widely acknowledged. There are a large number of similarities between K and W pathways. At the level of the retina, both cat W and primate K retinal ganglion cells have small cell bodies, thin but extensive dendrites, and the thinnest most slowly conducting axons in the optic tract (Casagrande and Norton, 1991). There is evidence for a similar class of retinal ganglion cells in other mammals as well, including rats, rabbits, and tree shrews.

The geniculate projections of both K and W retinal ganglion cells are to small-celled layers that are either next to the optic tract or intercalated between the main layers. Neurochemically, these small-celled layers have been identified using antibodies to the calcium-binding protein calbindin. In prosimian bush babies, and both New World and Old World simians including owl monkeys, marmosets, and macaque monkeys, calbindin is found in K layers, but not in M or P layers of the LGN (Johnson and Casagrande, 1995; Hendry and Reid, 2000; White *et al.*, 2001; Xu *et al.*, 2001). Calbindin also labels cells in the tree shrew LGN exclusively in the layers that contain W-like cells, layers 3 and 6 (Diamond *et al.*, 1993). In the cat, although W-cell layers in the LGN contain calbindin, many GABAergic (γ-aminobutryric acid, GABA) interneurons in the LGN also contain calbindin (Demeulemeester *et al.*, 1991), obscuring a possible relationship between the W-cell pathway and calbindin content.

K cells in the LGN differ in their relative laminar development in different primate lines (Hendry and Casagrande, 1996). The K pathway also appears to be physiologically and anatomically more heterogeneous than either the P or M pathways (for review, see Casagrande and Xu, 2004). For example, K cells lying ventral to the M layers in K layer 1 project mainly to layers IIIA and I of primate V1, and can be distinguished physiologically from K cells that lie close to the P layers and send axons to the CO blobs located in layer IIIBα of V1. Some K cells carry S-cone input although most K cells do not, at least in marmosets (White *et al.*, 2001). Some K cells defined by calbindin antibody labeling appear to project exclusively to the middle temporal visual area (MT) in macaque monkeys (Stepniewska *et al.*, 1999; Sincich *et al.*, 2004). This means that subdivisions of the K pathway could have been lost or added in different primate lines (Ding and Casagrande, 1998; Shostak *et al.*, 2002). In cats, W cells have similar projections: to layer 1 and to the CO blobs in layer III of V1 (Boyd and Matsubara, 1996), and to extrastriate cortex (Kawano, 1998). It is not yet clear if these different structures are targeted by different classes of W cells, or by collaterals of the same cells.

The K-cell pathway and the W-cell pathway are also similar in that they have close interconnections with the superior colliculus. Some retinal ganglion cells of the K and W classes project to the colliculus, and the colliculus makes projections to the K- and W-cell layers of primate and cat LGN. In tree shrews as well, there is a projection from the colliculus to LGN layers 3 and 6. Because the colliculus is considered by some to be phylogenically older than the LGN, being homologous with the main target of retinal axons in nonmammalian vertebrates, the optic tectum, it has been suggested that the K/W pathway is phylogenetically older than the M/X and P/Y pathways (Bishop, 1959). Other features of the K/W pathway, such as finer axons with more diffuse projections, have also been suggested to be primitive conditions. Ultimately, the question of pathway evolutionary age is extremely difficult to answer since we have no good biological markers of relative age specific for visual pathways. If anything, the K pathway in primates shows more morphological and physiological variation than the P or M pathways, so could be considered biologically (perhaps evolutionarily) less stable.

In summary, there is strong evidence from anatomy to support the conclusion that K cells in all primates are homologous and that at least some K cells have homologues in other mammals: (1) both K and W cells receive midbrain input from the parabigeminal nucleus and superior colliculus; (2) some W-like and K cells always lie adjacent to the optic tract in a large variety of mammals (Harting *et al.*, 1991); (3) K and W LGN cells send axons that terminate above layer IV in V1; (4) K cells are more likely than other LGN cell classes to project to extrastriate areas outside of V1; (5) K and W cells tend to be slowly conducting and have smaller cell bodies on average; and (6) K LGN cells in all primates and tree shrews (and perhaps W cells in cats) contain calbindin. There is also a variety of physiologically defined similarities between these cell classes, although the overlap in response properties between all relay cell classes in the LGNs of mammals and the influence of lifestyle on spatial and temporal thresholds make it difficult to make useful comparisons.

4.05.5 Color Vision in Primates and the Evolution of P and K Pathways

The ability to see color derives from the ability to compare wavelengths. Such color opponency is constructed at the retina from cones sensitive to short (S; e.g., blue), medium (M; e.g., green), and long (L; e.g., red) wavelengths by creating receptive fields with ON responses to one wavelength and OFF responses to an opposing wavelength or wavelengths. Thus, S cones oppose the M plus L cones to create a blue/yellow color axis, M opposes L to create a green/red axis and all three cones oppose each other to create an achromatic OFF/ON black/white axis. This simple view is complicated by the facts that some primates have only a single cone type and are therefore presumably color blind, most primates are dichromatic possessing two cone types, and some primates (such as humans) are trichomatic (Jacobs, 1996, 1998). Trichromacy, however, appears to have evolved separately in different primate lines (Jacobs, 1996; see The Comparative Biology of Photopigments and Color Vision in Primates). A number of articles have been written about the evolution of color vision in primates as well as the genetics of color vision (Jacobs, 1996, 1998; Nathans, 1999; Tan and Li, 1999; Dacey and Packer, 2003). A commonly held belief is that primates evolved from a nocturnal ancestor. Support for this argument has been recently reviewed (Ross, 2000) and will not be considered in detail here except where relevant to parallel pathway evolution. Relevant to the current article are proposals concerning which parallel pathways carry chromatic signals and what this might tell us about the evolution of parallel pathways in primates. At least four types of ganglion cells carrying cone signals have been identified in macaque monkeys. Of these, three carry signals from S cones, small and large bistratified ganglion cells carrying blue ON signals and large monostratified ganglion cells carrying blue OFF signals. It has been proposed that these blue pathways project to LGN K cells given that some K cells have been identified at the level of the LGN to carry S cone signals in macaque monkeys and marmosets (White *et al.*, 1998). In marmosets, approximately 20% of K cells carry S cone signals based upon studies in which immunocytochemistry for calbindin was used to directly identify K cells at the level of the LGN after single unit recording (White *et al.*, 1998). In addition, it has been argued by many that midget ganglion cells in several primates carry L/M opponent signals to the P LGN layers (see Dacey and Packer, 2003; but see, however, Calkins and Sterling, 1996). At present, it is unclear if some P cells also carry S cone signals, as was originally proposed by Wiesel and Hubel (1966), given that K cells, defined by either calbindin or CamKII immunocytochemistry, can lie below each P and M layer, can be found scattered within these layers, or can even form bridges of cells that pass directly through the P layers (Johnson and Casagrande, 1995; Hendry and Casagrande, 1996; Hendry and Calkins, 1998). Definitive data linking particular ganglion cell classes whose chromatic signature is well defined to particular visual pathways that project through the LGN to cortex is still lacking.

Evidence that does exist suggests the following. In all primates examined it has been demonstrated that K cells in the LGN defined by immunocytochemistry or laminar location send axons above layer IV (IVC of Brodmann) of V1 (Lachica and Casagrande, 1992; Ding and Casagrande, 1998). These K axons terminate in the CO blobs of V1, in cortical layer I and probably also in cortical layer IIIBβ (IVA of Brodmann) (Yazar *et al.*, 2004). With the exception of projections to layer IIIBβ this pattern of axonal projections can be demonstrated in prosimians as well as in New World and Old World simians, apes, and humans. Since, as discussed earlier, some prosimians such as the bush baby and at least one simian, the owl monkey, have only a single cone type and lack S cones entirely (Jacobs, 2002), it could be argued that the K pathway evolved before the evolution of color vision in primates. This would have to be the case if the prosimian bush baby represents the ancestral original nocturnal condition of primates.

An alternative proposal is that ancestral primates were actually dichromatic (Tan and Li, 1999). The evidence to support this view is as follows. First, S cones are considered to be of ancient origin genetically and are present in many mammalian groups, including carnivores, ungulates, and primates (Calkins, 2001). More important is the fact that both prosimian bush babies and simian owl monkeys appear to have the gene for S cones but this gene is not expressed in either species due to defects in the gene (Jacobs, 2002). The presence of the gene strongly suggests that functional S cones existed in their ancestors. Support for this view comes from studies that have examined for the S opsin gene in a relative of the bush baby, the slow loris (*Nycticebus coucang*) (Kawamura and Kubotera, 2004) and found evidence to support the view that this gene was disrupted in the common ancestor of galagiods (e.g., bush babies) and lorisids. Second, S and M cones are both present in at least one nocturnal prosimian, the mouse lemur (*M. murinus*), as well as in several diurnal lemurs and in the tarsier (Dkhissi-Benyahya *et al.*, 2001). Third, S and M

cones have been identified in cat W cells (Wilson *et al.*, 1976). Cat W cells also project to the CO blobs in V1 (area 17) just as K cells do in primates. Cat W cells also share many other characteristics in common with primate K cells as reviewed above and earlier (Casagrande and Norton, 1991). Taken together, these data support the view that the common ancestor of primates may actually have been diurnal with S and M cone signals passing to a population of K cells. Since all LGN cells receive input from cones, this does not inform us about the evolution of color vision relative to the parallel pathways. If this hypothesis is correct, it does predict that, as in cats, S cone signals should be confined to K cells in those prosimians that have functional S cones, a hypothesis that could be tested directly by examining for S cone input to LGN K cells in the mouse lemur. It also predicts that in dichromatic lemurs (perhaps all dichromatic primates) wavelength discrimination would depend upon K cells since P and M cells would only receive from a single M cone.

The issue of whether some primate ancestors were trichromatic is more complicated given the different ways prosimians, Old World primates, and New World primates construct color vision. All Old World primates have two separate opsin genes (M and L) on the X chromosome in addition to the single S autosomal gene. New World simians, and prosimian lorises, and lemurs have only one opsin gene on the X chromosome, but polymorphism of this gene allows females with different versions of the opsin gene on each of their two X chromosomes to achieve trichromacy. Males, with only one X chromosome, can never be trichromats in species that rely on polymorphism. Tan and Li (1999) have argued that the phylogenetic distribution of the M and L opsins across strepsirhine primates (lemurs, lorisids, and tarsiers) supports the idea that the X-linked polymorphism and primate trichromacy arose early in primate evolution. It is interesting that, regardless of whether trichromacy is achieved via polymorphism of a single gene on the X chromosome as in New World simians or on two separate genes on the same chromosome as in Old World simians, it would appear that the M/L (green/red) opponency can be identified electrophysiologically in some P cells in both cases but not so far in K cells (White *et al.*, 1998). This would support the view that M cone input to P cells via midget ganglion cells was the default condition in dichromatic primates with L cone opponency added later. Whether the P pathway further specializes when trichromacy is the norm as in Old World simians, one branch of New World primates, as well as apes and humans, remains unclear (Jacobs, 2002).

One aspect of the chromatic pathway to V1 that appears to show species-specific differences concerns the S cone input to V1 layer IIIBβ (IVA of Brodmann). Callaway and colleagues (Chatterjee and Callaway, 2003) have shown that, in macaque monkeys, cells in layer IIIBβ respond to S cone input in the form of blue ON- and blue OFF-center cells. Since thalamic axons project to layer IIIBβ in many diurnal simians but not in the nocturnal owl monkey, the prosimian bush baby, or in some apes (chimpanzee), or in humans, this pathway appears to be a specialization of some primates and not others (Preuss and Coleman, 2002). These findings indicate that apes and humans may have diverged from a primate ancestor in which the K pathway carrying S cone input did not innervate layer IIIBβ. In macaque monkeys, there is no physiological evidence for a direct S cone input via the thalamus to the CO blobs based upon recording from LGN axons in V1 where cell responses were silenced with the $GABA_A$-receptor agonist muscimol (Chatterjee and Callaway, 2003). Presumably, S cone input reaches cortex via another pathway in apes and humans. Taken together, these observations support the hypothesis that components of the K pathway may either have been lost in the evolution of apes and humans or that their common ancestor showed a parallel pathway organization more like that of present-day prosimians where the thalamus does not project to layer IIIBβ.

4.05.6 Ocular Dominance and Other Properties

At the level of the LGN in primates, retinal ganglion cells within the left and right eyes send input to separate layers. Additionally, ganglion cells with either ON-center or OFF-center responses innervate separate sets of cells at the level of the LGN. These parallel pathway features from retina to LGN appear to generalize across placental mammals. At the level of V1, however, the degree to which these properties remain segregated at the first synapse varies widely among mammals (see Casagrande and Norton, 1991, for review). For example, although close relatives of primates (e.g., tree shrews) show both ocular segregation and segregation of ON- and OFF-center responses to separate cortical layers, primates do not. Instead ON- and OFF-center responses appear combined at the first synapse in all primates examined to date, even

Table 2 Ocular dominance columns in striate cortex

Columns present	*Columns present*	*Columns absent*
Macaque (Hubel and Wiesel, 1969)	Talapoin monkey (Florence and Kaas, 1992)	Rat (Hubel and Wiesel, 1977)
Human (Hitchcock and Hickey, 1980; Horton and Hedley-Whyte, 1984)	Capuchin monkey (Hess and Edwards, 1987; Rosa *et al.*, 1988)	Mouse (Drager, 1974)
Owl monkey (Rowe *et al.*, 1978; Diamond *et al.*, 1985)	White-faced saki (Florence and Kaas, 1992)	Tree shrew (Casagrande and Harting, 1975; Hubel, 1975)
Marmoset (DeBruyn and Casagrande, 1981; Spatz, 1989)	Chimpanzee (Tigges and Tigges, 1979)	Gray squirrel (Weber *et al.*, 1977)
Green vervet (Hendrickson *et al.*, 1978)	Cat (Shatz *et al.*, 1977)	Brushtailed possum (Sanderson *et al.*, 1980)
Red monkey (Hendrickson *et al.*, 1978)	Ferret (Law *et al.*, 1988)	Rabbit (Hollander and Halbig, 1980)
Baboon (Hendrickson *et al.*, 1978)	Mink (McConnell and LeVay, 1986)	Sheep (Pettigrew *et al.*, 1984)
Spider monkey (Florence *et al.*, 1986)	Bush baby (Glendenning *et al.*, 1976; Hubel and Wiesel, 1977; Diamond *et al.*, 1985)	Goat (Pettigrew *et al.*, 1984)

Reproduced from Horton J. C. and Hocking, D. R. 1996. Anatomical demonstration of ocular dominance columns in striate cortex of the squirrel monkey. *J. Neurosci.* 16, 5510–5522, with permission. Copyright 1996 by the Society for Neuroscience.

though ON- and OFF-center cells have been reported by some to be segregated to separate layers in the macaque LGN (Schiller and Colby, 1983). The finding that ferrets, but not cats, show segregation of ON and OFF pathways through the LGN to V1, suggests that parallel ON and OFF pathways that extend to cortex evolved several times in different mammalian lines of descent (Zahs and Stryker, 1988). The advantage of maintaining separability of ON and OFF pathways to cortex in diurnal tree shrews and nocturnal ferrets remains unclear given that these species have very different lifestyles and evolutionary histories.

Similarly, although eye input remains segregated at the first cortical synapse in cortex in tree shrews and many other mammals including some primates, the variability in both the pattern and degree of segregation of ocular inputs suggests that the organization of ocular dominance pathways from LGN to cortex evolved independently in primates and other mammalian species. In tree shrews, left and right eye input to cortex is segregated into sublayers within layer IV of V1 (Casagrande and Harting, 1975), whereas in all primates ocular input segregation (if present) occurs in the form of columns not layers. Among primates, examples of well-developed cortical ocular dominance columns can be found in some members of a number of distantly related groups including prosimian bush babies, New World simian spider monkeys, and all Old World simians and apes thus far examined, including humans (Florence *et al.*, 1986; Florence and Kaas, 1992; Preuss and Coleman, 2002; see Table 2). Even in primates in which ocular dominance columns show high interindividual variability, such as New World squirrel monkeys, or show very weak segregation, as in New World owl monkeys and marmosets, segregation occurs in the form of columns and not in the form of layers as in tree shrews (Florence *et al.*, 1986). These findings suggest that the tendency to segregate ocular information into columnar dominance columns in V1 was present already in the common ancestor of primates but not in the ancestor of tree shrews and primates.

Examination of the different patterns of ocular dominance columns in different primate species, however, indicates that well-developed ocular dominance columns either evolved several times in different lines of descent or regressed in different lines of descent from a well-developed pattern (Florence *et al.*, 1986; Florence and Kaas, 1992). Distinguishing between these different scenarios is difficult given that we do not understand the functional significance of ocular dominance columns since they appear to occur in both small nocturnal primates with no color vision and in large diurnal primates with good color vision, and appear variable across simians (Florence *et al.*, 1986). It may also be the case that such segregation is simply a byproduct of the degree of synchrony between active ganglion cells in the two eyes during a critical phase of development, especially since the expression pattern shows such a high degree of interindividual variation in squirrel monkeys (Horton and Hocking, 1996).

4.05.7 The Evolution of Dorsal and Ventral Cortical Streams

It has been proposed that there are basically two cortical streams for processing visual information

in primates – a ventral stream to the temporal lobe and a dorsal stream to the parietal lobe – the first being involved with object vision and the second with spatial vision or vision for action (Mishkin *et al.*, 1983). The dorsal and ventral streams both start with the intracortical circuitry in V1, which processes the three main classes of LGN inputs described earlier (M, P, and K) to create multiple distinct outputs originating from separate classes of projection neurons in cortical layer III and projecting to several different extrastriate areas. Two hierarchical chains of connections, one to the temporal lobe and one to the parietal lobe (albeit with some connections between areas and compartments belonging to the different streams), can be traced through the multiple (more than 30) extrastriate areas found in primates (DeYoe *et al.*, 1994).

The ventral stream, in order, consists of layer IIIBα blobs and layer IIIBα interblobs in V1, thin stripes and interstripes in the secondary visual cortex (V2), DL/V4, and various inferotemporal areas. The temporal areas at the top of this hierarchy are physically close to and interconnected with perirhinal cortex and hippocampus, structures involved with object recognition and encoding visual memories. The dorsal stream consists of layer IIIC and layer IIIBα interblobs, which give rise, respectively, to a direct and an indirect pathway via V2 to V5/MT, CO thick strips in V2, MT/V5, and surrounding superior temporal areas, and, finally, parietal cortex. These parietal areas are close to, and interconnected with, premotor cortical areas involved with programming eye movements and other visually guided behaviors. In this section, we examine the evolution of these processing streams. We will first consider the early stages of processing through V1 and V2, and then the later stages through specialized extrastriate areas.

To review, in primates, M LGN afferents terminate in upper layer IV, P afferents in lower layer IV, and K afferents in the blobs in layer IIIBα and in layer I. As mentioned in previous sections, these pathways likely have homologues in other mammals, so the building blocks for the two streams will at least be homologous structures. Immediately above the M input layer is found a population of projection neurons that are an important early part of the dorsal pathway, receiving M input and projecting directly to V5/MT. These cells are found in all primates, where they may be pyramidal (prosimians) or stellate (Old World monkeys) or both (New World monkeys). In cats, large pyramidal cells at the base of layer III receive Y-cell input and project to lateral suprasylvian cortex (Matsubara and Boyd, 2002), which is, like V5/MT, an area that processes motion (see below). These projections are probably homologous. In cats, prosimians, and New World primates, these projections are robust, and are concentrated directly below CO blobs. In macaque monkeys, there are far fewer MT-projecting cells in V1 and it has been debated as to whether or not these are concentrated beneath CO blobs (Boyd and Casagrande, 1999; Boyd and Matsubara, 1999; Sincich and Horton, 2003). This could represent a gradual evolutionary reduction of the fast direct pathway to V5/MT in primate evolution, and perhaps of the entire dorsal stream, as increased emphasis is placed on slower indirect pathways passing through upper layer III, which is proportionately thicker and more differentiated in primates (especially simians) then in other mammals. This scenerio suggests a change in visual processing, with more emphasis on analysis of visual form and less emphasis on reaction to movement.

The indirect dorsal stream through V2 originates from neurons in layer IIIBα interblobs that probably receive both M and P input via intralaminar projections from layer IV. The neurons of the ventral stream to V2 are in layer IIIBα blobs and interblobs, and so receive K input in addition to M and P. In species with color vision, the K input may carry color information (see previous sections), an important cue for object recognition but not for visuomotor tasks. Within V2, recent evidence points to the existence of four stripe compartments, two which stain darkly for CO (the CO thick and thin stripes) and receive input from dorsal and ventral stream neurons in V1, and two interstripe compartments that may also receive from both streams but definitely get input from ventral stream neurons in V1 (Xu *et al.*, 2004). In some prosimians, CO stripes are faint or absent in V2, but there still is evidence that projections from blobs and interblobs are segregated into different compartments within V2, so the striped architecture likely is homologous across all primates. There is no clear example yet of a similar striped architecture (with or without accompanying CO staining) in nonprimates. There is some evidence for segregation of blob and interblob projections to extrastriate areas in the cat, but this occurs not in V2, but in area 19. The cortical hierarchy in primates continues through V2 into V5/MT for the dorsal stream, and into V4/DL for the ventral stream. Again, although the prosimian galago does not have distinct CO stripes or functional compartments with low orientation selectivity as in simians (Xu *et al.*, 2005), neurons projecting from V2 to V5/MT and to V4/DL form interdigitated stripes (Krubitzer and Kaas, 1986), showing that the underlying architecture (albeit perhaps less complex) is the same in prosimian V2 as for other primates.

Thus, the earliest levels of the dorsal and ventral streams can be recognized in all primates. Can the same be said of the higher levels? This is an important question because an increase in neocortex size and an increase in the number of sulci and gyri have occurred independently in the evolution of different mammalian lines, and even in the evolution of different primate lines. Both Old World primates and sheep, for example, have large, gyrencephalic brains, but examination of fossil endocasts suggests that their last common ancestor had a small lissencephalic brain (Radinsky, 1967, 1975, 1981). Not surprisingly, sheep and primate neocortex, while superficially similar, show important differences, as, for example, the relative development of the temporal lobe, which is proportionately less prominent in sheep brains than in primate brains, and the olfactory cortex, which in sheep is proportionately enormous by primate standards. Also, the obvious occipital development and landmarks that characterize the primate visual cortex such as the calcarine fissue are not obvious in sheep (nor in other nonprimate mammals) in spite of the fact that other fissures are well developed and the sheep brain is larger and more fissured than many primate brains. In summary, primitive mammals had small brains and likely possessed only a few cortical areas for each sensory modality, perhaps only V1 and V2 for vision (Northcutt and Kaas, 1995). The number of extrastriate visual areas has increased independently in different mammalian lines, so it might be impossible to define homologies across mammalian groups for many extrastriate areas.

Even within the primate lineage, the patterns of sulci and gyri vary between New World and Old World monkeys, apes, and prosimians, and brain size has increased independently in these lines. It is therefore important to determine which of the multitude of visual areas can be unambiguously identified in all primates and are thus likely to be homologous. Homologies among visual areas in different primate lines are recognized on the criteria of size, shape, and position in the cortex with respect to other cortical areas, layout of the visual field map, physiological response properties, patterns of connections with other cortical areas and subcortical structures, and cortical architecture. For example, the V1 can be recognized, not just in primates but also in all mammals, by its position in the occipital lobe, by receiving strong projections from the LGN, by the complete map of the visual field it contains, and by its distinctive histological architecture.

In all primates (and likely all mammals), V2 forms a narrow strip immediately lateral to V1. In addition to its position, it can be recognized by its visual field organization, sharing a representation of the vertical meridian with V1, and by its distinctive mosaic pattern of connections with V1, which are related to the CO architecture (Casagrande and Kaas, 1994). In all primates, an important dorsal stream area, called MT (sometimes referred to as V5) in Old World primates, New World primates and prosimians, occupies a densely myelinated oval-shaped area in the dorsal temporal lobe. This area contains many motion-sensitive neurons, most selective for the direction of stimulus motion. MT/V5 is also identified by its distinctive patterns of projections from V1 and V2, and by its projections to parietal cortex. In all primates, an important ventral stream area, called V4 in Old World primates and DL in New World primates and prosimians, occupies cortex caudal to V5/MT and receives inputs from compartments in V2 not projecting to V5/MT. The homology, however, of this region is less well established, perhaps due to uncertainties in the extent and possible subdivisions of this region of cortex, as it does not have a distinctive architecture, and its visual field map is not as regular as that of MT. Proposed homologies of primate cortical areas higher in the hierarchy are even more tenuous, for similar reasons. It is possible that more homologies will become apparent when the cortical organization of different primates becomes better understood. (This presupposes that regions of cortex outside of primary areas and certain easily identifiable areas such as V5/MT are, in fact, best described as collections of discrete areas with sharply defined borders, and not as larger fields of loosely graded response properties and connections.) With presently available information, then, only areas on the lower levels of the visual-processing hierarchy can be homologized across different primate species, suggesting that areas higher in the hierarchy were added independently in different primate lines. Even so, the dorsal and ventral streams in different primate lineages can be identified without concomitantly identifying homologues for all of the visual areas involved.

Is it possible to identify dorsal and ventral streams in other mammals, given that so few extrastriate areas are likely to be homologous between primates and other mammals? As suggested above, processing in the dorsal and ventral streams prepares visual information for the ultimate use by motor cortex and limbic cortex, respectively, structures that are likely homologous in all mammals. Even if the primitive mammalian visual system consisted of a single area, V1 (although V2 at least was likely also present in the earliest mammals), separate

dorsal and ventral streams could still exist, consisting of separate populations of V1 neurons projecting directly to motor and limbic cortex, respectively. As was suggested to be the case for different primate groups, extra areas could be inserted to form processing hierarchies independently in different mammalian lineages. Inserting areas between V1 and limbic cortex will route the ventral stream through the temporal lobe based on simple proximity to the hippocampus. Similarly, inserting areas between V1 and motor cortex will result in a dorsal stream through parietal cortex.

There is evidence for dorsal and ventral streams in mammalian lineages as different as carnivores and rodents, both of which have multiple extrastriate visual areas that are unlikely to be homologous with any primate areas. The cat has about 15 different extrastriate areas and, as a model species, has the rare advantage that many of these areas have been extensively investigated (Payne, 1993). Evidence for dorsal and ventral streams in cats comes from studies of connections, physiological response properties, and behavioral deficits. Similar to V5/MT in primates, an area in the lateral suprasylvian (LS) sulcus of the cat receives a direct input from V1, projects to parietal and visuomotor areas, and displays motion selectivity. Inactivating this area leads to visual orienting and motion processing deficits (Lomber, 2001), as would be expected from a dorsal stream area. The cat also possesses a temporal visual stream consisting of multiple areas progressing through the temporal lobe to the hippocampus. As would be expected for the ventral stream, inactivation of the temporal lobe areas does not impair visual orienting behavior (Lomber, 2001).

The similarities between V5/MT and LS cortex are strong enough that it has been proposed that these areas are homologous (Payne, 1993). If V5/MT was present in the last common ancestor of cats and primates (more than 65 Mya), one would expect it to also be present in all mammalian lines that share a common ancestor with either cats or primates that is more recent than their last common ancestor (Northcutt and Kaas, 1995). Current mammalian classifications place primates in the superorder Euarchontoglires along with Glires (rodents and rabbits), flying lemurs, and tree shrews. As carnivores, cats are members of the superorder Laurasiatheria, which also includes insectivores, bats, ungulates, and whales (Madsen *et al.*, 2001; Murphy *et al.*, 2001; Waddell *et al.*, 2001; Amrine-Madsen *et al.*, 2003). Thus, if V5/MT and LS are homologous, a similar area should be identifiable in other members of these two superorders; such identifications are currently hampered by lack of data from relevant species.

For Euarchontoglires, at least partial data on extrastriate cortical organization are available from tree shrews and some rodents. Tree shrews have a series of visual areas adjoining V2, one of which, the temporal dorsal area (TD), has been proposed as a possible homologue for MT. Like MT, TD contains a complete representation of the visual field (Sesma *et al.*, 1984), stains more strongly than surrounding cortex for myelin and the Cat-301 antibody (Jain *et al.*, 1994), and receives inputs from V1 (Lyon *et al.*, 1998). However, TD in tree shrews is adjacent to V2, unlike MT, which is separated from V2 by DL/V4, and TD appears to lack connections with visuomotor areas of frontal cortex (Lyon *et al.*, 1998), which is part of the connectional signature of MT in at least some primates (Krubitzer and Kaas, 1990). No data on the detailed response properties in TD are currently available, so it is not yet known if this area contains direction-selective neurons.

The organization of extrastriate visual cortex in rodents is not completely clear, and appears to show substantial species variability (Rosa and Krubitzer, 1999). Germane to the present discussion is that rodents are thought to be monophyletic, and that mice and rats share a more recent common ancestor than either do with squirrels (Reyes *et al.*, 2004). In squirrels, V2 forms the lateral border of V1, with at least two tiers of multiple extrastriate areas lateral to it (Kaas *et al.*, 1972, 1989). In the rat, microelectrode mapping studies suggest that V1 is bordered laterally, not by a single area V2, but by multiple small retinotopically defined extrastriate visual areas named topographically (rostromedial, anterolateral, lateromedial, posterolateral, etc.) and corresponding to regions free of callosal connections (Espinoza *et al.*, 1992; Montero, 1993). Injections of tracers in different retinotopic locations in V1 lead to changes in the location of patches of label within these extrastriate areas that is consistent with the electrophysiological maps (Coogan and Burkhalter, 1993; Montero, 1993), mitigating against the argument that these projections correspond to multiple modules within a traditional retinotopically mapped V2 which, similar to other mammalian groups, extends along the entire lateral border of V1 (Malach, 1989). In mouse, microelectrode mapping shows a single V2 bordering V1 laterally, with at least one other area lateral to that. However, corticocortical projections from mouse V1 had a similar pattern as in the rat (Olavarria and Montero, 1989), suggesting that multiple visual areas adjacent to V1 were common at least to mice and rats. In order to resolve the

differences in cortical organization between different rodent species, it has been assumed that the largest of the areas bordering V1 laterally in rats (the lateromedial area, LM) is homologous to V2 in other species (Rosa and Krubitzer, 1999). According to this hypothesis, either new areas adjoining V1 were added in the mouse/rat lineage, or regressive events caused more lateral visual areas (perhaps homologous to the lateral visual areas in squirrels) to be shifted toward V1, at the expense of V2. A recent optical imaging study of mouse visual cortex (Kalatsky and Stryker, 2003), however, not only found evidence for multiple retinotopically defined extrastriate areas, but also suggested a narrow V2 with only a central visual field representation; detailed optical imaging maps of rat extrastriate cortex have not yet been published. The many patches following a V1 injection, and the tendency of visual fields to be congruent across borders, means that V1 projections to a narrow V2 could be continuous with a patch of labeling in an adjacent area, and thus overlooked in the anatomical mapping studies. The coarse sampling of microelectrode mapping, combined with the large receptive fields, may also have made it possible to have missed a narrow V2. Projections from V1 need to be combined with functional mapping and histological verification of the extent of V1 to determine if there really is a narrow V2 interposed between V1 and the lateral extrastriate areas in rats and mice.

Returning to the original question of functional streams, areas responding preferentially to moving stimuli can be found in both squirrels and mice/rats. In rats, the anterolateral area (AL) appears to have cells selective for movement (Montero and Jian, 1995), while, in mice, AL and another area (LM) bordering V1 laterally give rise to different connectional streams, AL preferentially connecting with dorsal and medial regions of cortex, LM with ventral regions of cortex (Wang and Burkhalter, 2004). In ground squirrels, an area (ML) with large receptive fields and direction-selective cells was found lateral to V2 (Paolini and Sereno, 1998), and thus in the right position to be homologous with MT. Both AL in rats and mice and LM in squirrels receive direct projections from V1, which is another similarity with V5/MT, although neither area appears to have the extensive myelination, an anatomical signature of V5/MT.

On the cat (Laurasiatheria) side, there is even less evidence from which to draw conclusions. It does appear that LS cortex, at least, has homologues in fellow carnivores, the mustelid ferrets (Manger *et al.*, 2002). Another laurasiatherian animal whose extrastriate cortex has been mapped is the megachirpopteran flying fox (*Pteropus*). Although once thought to be more closely related to primates than to michrochipoteran bats, all bats are now thought to comprise a single group within the Laurasiatheria (Van Den Bussche *et al.*, 2002). The occipitotemporal visual area (OT) was proposed as a possible megachiropteran homologue to LS/V5/MT based on its location lateral from V2, and its receptive field organization (Rosa, 1999). Microbats, relying on echolocation for navigation, have an enlarged auditory cortex, and very little extrastriate visual cortex. If this is a primitive condition for bats, it would mitigate against any proposed homologies of megachiropteran visual areas, given that bats are likely monophyletic. It is also possible that extrastriate cortex may have been reduced during microbat evolution.

In conclusion, specialized extrastriate areas belonging to dorsal and ventral cortical streams can be recognized in a wide range of mammals. Only the earliest stages of these streams and the last stages in motor and limbic cortex are likely to be homologous across mammalian lines, however. Even within primates, only a few areas can be unequivocally identified as homologues. Different lineages have added areas to the middle levels of these cortical streams independently. The constraint of proximity of the inserted areas to limbic cortex or motor cortex keeps the temporal stream temporal and the dorsal stream dorsal.

4.05.8 Conclusions, Questions, and Future Strategies

What can we usefully conclude about the evolution of parallel pathways in primates? We need to constantly remind ourselves that without specific definitions of what we are comparing and at what level (genes, molecules, cells, or pathways), we cannot develop definite or testable hypotheses. In this article we have focused on pathways originating with distinct classes of retinal ganglion cells and asked whether homologues of these visual pathways can be found across different primate species or between primates and nonprimates. We hypothesized that examining for similarities across distantly related species is the most important initial step in arguing for homology given the lack of genetic and fossil signatures of visual pathways. Nevertheless, we remain cognizant of the fact that different regions of the nervous system (e.g., retina, thalamus, and cortex) have different patterns of gene expression controlling their cellular composition and distribution. Therefore, we cannot simultaneously address the issue of homology at different levels of comparison (i.e., proteins, cells,

pathways, or brain regions). It is even more difficult to determine if similarities result from homology or homoplasy given that the developmental programs that establish visual cells and pathways are conservative and presumably have a restricted set of viable functional solutions for species to survive using the visible portion of the energy spectrum here on earth. Therefore, a useful future approach would be to compare the ontogeny (both early and late) of distantly related primates (e.g., a prosimian with a New World simian and an Old World simian) and primates and nonprimates (e.g., macaque monkey with rodent) examining for similarities at both the genetic and systems levels. A fuller understanding of commonalities in the ontogeny of different species would aid enormously in examining for homology in visual pathways.

Our examination of P, M, and K pathways leads to the hypothesis that these pathways are homologous across primates in spite of vast differences in the lifestyles and retinal organization in different primate species. It is also likely that what we call the P, M, and K pathways have general counterparts in other mammals since cats certainly appear to have pathways that specialize in spatial versus temporal resolution (i.e., X vs. Y cells) in a similar way to P and M cells in primates; W cells also resemble K cells anatomically and physiologically. Nevertheless, details of these pathways in nonprimates (even close relatives like the tree shrew) differ significantly; so significant changes have occurred independently in the P, M, and K pathways of different lineages.

We have also argued that the K pathway may be made up of more than one pathway so its evolutionary history is more difficult to try to define. Nevertheless, it does appear that cells in this pathway across a range of species can be recognized by the presence of calbindin. Other similarities to W cells in cats and other mammals suggest that a K-like pathway may have originated early in mammalian evolution. This does not necessarily make the primate K-cell pathway phylogenically older or newer than the P and M pathways since the K pathway shows enormous variability in the relative numbers of cells present in different LGN layers (identified neurochemically) across different primate species. What would be useful to know is which ganglion cells actually project to K layers in different primates and in close primate relatives such as tree shrews. For example, do bistratified ganglion cells project uniquely to K layers in tree shrews as would be predicted from work in macaque monkeys? This easily tested question would reinforce the view that some K cells evolved prior to the split between tree shrews and primates. Examining the same issue in cat W cells would extend the evolution of this component of the K pathway to other mammals.

A closely related issue concerns the evolution of chromatic pathways in different primates. Since some K cells receive input from S cones in some New World (marmosets) and Old World (macaque monkeys) primates, and K cells carrying S cone signals project to cortical layer IIIBβ in macaque monkeys, it will be important to understand how S cone signals are transmitted to V1 in primates such as apes and humans that lack an LGN projection to cortical layer IIIBβ. Such information could potentially inform us about the evolutionary split between monkeys and apes. Similarly, it would be informative to know if tarsiers or any diurnal lemurs that have functional S cones send these signals via K cells to cortical layer IIIBβ.

We have argued that, since nocturnal prosimians, such as bush babies, have the S cone gene (even though it is not functional) in addition to functional M cones, and that other prosimians (and tarsiers) also have both M and S cones, it is likely that earliest ancestors of primates were dichromatic like present-day tree shrews. If all nocturnal prosimians, however, show the same defect in the S cone gene, this would argue in favor of a nocturnal bottleneck. Alternatively, if distantly related nocturnal primates, such as galagos and owl monkeys, show that S cone genes were disabled in different ways, this would argue that the lack of functional S cones evolved secondarily when species moved from a diurnal to a nocturnal niche.

We reviewed also the evidence that segregation of ON and OFF pathways and segregation of left and right eye inputs (ocular dominance columns) evolved independently in different lines. ON and OFF pathways are combined at the first level in all primates examined, and the tendency to segregate ocular inputs into columns, although variable across primate species, exists in distantly related primates. These observations support the presence of at least weak ocular dominance segregation into columns in the common ancestor of primates and support the view that the ON and OFF pathways were not segregated to columns or layers in a primate ancestor. Why ocular dominance columns exist in primates remains a mystery. Given the high inter-animal variability of ocular dominance columns in squirrel monkeys, it might be useful to examine both the genetics and visual experience of animals that do with those that do not appear to show clear columns. It would also be useful to examine for ocular segregation in a wider range of primates.

Finally, we examined the most difficult issue, namely the evolution of dorsal and ventral cortical pathways originating in V1. Given that there is

disagreement even about the definitions of cortical areas that receive input from V1, we cannot provide solid conclusions about the homologies of dorsal and ventral streams beyond the statement that there is evidence for sets of projections to similar hierarchies of areas in all primates thus far examined. There is also evidence that the general cortical design for such streams may exist in nonprimate mammals even if specific cortical areas within each hierarchy are not homologous. Clearly, much more evidence concerning the number of visual areas in a range of primates and other mammals will need to be examined before more definitive statements can be made. Perhaps with the advent of high-resolution functional magnetic resonance imaging we will be in a position to more rapidly map visual areas in a variety of species.

Acknowledgments

4.06 Organization and Correspondence of the Auditory Cortex of Humans and Nonhuman Primates

T A Hackett, Vanderbilt University, Nashville, TN, USA

Glossary

architectonic features	Refer to the anatomical features that comprise brain tissue. These features typically vary among distinct areas of the cerebral cortex. Specific architectonic features include the number, arrangement, and types of neurons in a particular area of cortex. Other features include the differential expression of proteins or density of myelinated axons within an area. Comparison of architectonic profiles derived from multiple architectonic features facilitates identification of individual areas, as well as the grouping of areas with similar architectonic profiles into regions.
auditory cortex	Refers specifically to those areas of the cerebral cortex for which the primary sources of thalamic input are the principal nuclei of the medial geniculate complex.
auditory-related cortex	Refers specifically to those areas of the cerebral cortex for which the primary source of auditory input is the auditory cortex, with relatively little, if any, input from the principal nuclei of the medial geniculate complex.
cortical area	A subdivision of cerebral cortex defined by a unique set of anatomical and physiological features. An area may be considered a functional module with unique patterns of connections with other cortical areas.
cortical region	A group of cortical areas that share a defined set of features. In auditory cortex, for example, the core region includes three areas that occupy the first stage of auditory cortical processing, as defined by their patterns of connections with the medial geniculate complex and other areas of cortex.

4.06.1 Introduction

The identification and characterization of areas that contribute to auditory processing in the mammalian cerebral cortex has been the subject of sporadic investigation for over 130 years. The first insights were derived from lesion studies and detailed descriptions of anatomical features during the late 1800s and early 1900s (Beck, 1928, 1929; Broca, 1865; Brodmann, 1905, 1909; Clark,1936; Ferrier, 1875; Poljak, 1932; von Bonin, 1938; von Economo and Horn, 1930; von Economo and Koskinas, 1925; Walker, 1937; Wernicke, 1874). These studies, which often provided detailed parcellations of the superior temporal region, comprise the classical descriptions of human and nonhuman primate auditory cortex and remain influential to this day. In the mid-1900s, electrophysiological studies confirmed the location of auditory-responsive cortex on the superior temporal plane of monkeys and chimpanzees, and produced evidence that a representation of the basilar membrane was preserved in the organization of the primary auditory region (Ades and Felder, 1942; Bailey *et al.*, 1943; Celesia and Puletti, 1969; Gross *et al.*, 1967; Hind *et al.*, 1958; Katsuki *et al.*, 1962; Licklider and Kryter, 1942; Pribram *et al.*, 1954). These landmark studies were accompanied by others in which the connections of the superior temporal region were explored (Nauta, 1957; Pandya *et al.*, 1969; van Buren and Yakovlev, 1959). Interest in the organization of primate auditory cortex increased during the 1970s, marked by studies that related patterns of thalamic and cortical connections to architectonic subdivisions and tonotopic maps (Imig *et al.*, 1977; Merzenich and Brugge, 1973; Mesulam and Pandya, 1973; Pandya and Sanides, 1973; Sanides, 1975). Studies of the auditory cortex of nonhuman

primates and humans since that time have been characterized by stepwise refinements of earlier findings, culminating in a working model of the primate auditory cortex that is the subject of ongoing testing and modification (Kaas and Hackett, 1998, 2000; Kaas *et al.*, 1999). The development of the primate model has paralleled that of other mammalian models, yet the extent to which findings from one species can be generalized to another remains uncertain. The number of auditory areas identified varies between species, and presently only the primary auditory area, A1, is considered to be homologous. Additional homologies are likely, and may eventually be established on the bases of relative location, receptive field organization, and other anatomical and physiological features. The extension of findings from research animals to humans is especially problematic because experimental constraints greatly limit direct comparisons. Nevertheless, the model of auditory cortex established in nonhuman primates shares a number of key features with humans, and therefore provides a useful foundation for comparative study that will improve our understanding of audition in primates (Hackett, 2002).

4.06.2 Gross Anatomical Features of the Superior Temporal Lobe

Allometric measurements of surface area and volume indicate that the superior temporal gyrus (STG) increases in size successively by a factor of nearly three times each between squirrel monkeys, macaque monkeys, chimpanzees, and humans (Rilling and Seligman, 2002). The threefold expansion of the STG is proportional to overall temporal lobe expansion for all of these primates, except humans, where temporal lobe volume is about four times that of the chimpanzee (Figure 1). This appears to reflect greater expansion of temporal fields beyond the STG in humans.

In all primates, the auditory cortex is located on the dorsal surface of the temporal lobe where it occupies a large portion of the STG and lower bank of the lateral sulcus (LS). The relative size, location, and orientation of the auditory fields varies between species, reflecting differences in the morphology of the temporal lobe (Sanides, 1975). The length and depth of the LS increases with brain size, as does the prominence of the circular sulcus and insular region (Figure 1). In prosimians (e.g., lemur, galago), there are no major sulci on the lateral surface of the brain other than the LS; therefore, there is no obvious division between the superior and inferior temporal regions. In some New World monkeys (e.g., marmoset), a shallow superior temporal sulcus (STS) extends for a short distance, partly dividing the temporal lobe into superior and inferior gyri. STS depth in the marmoset ranges from 2.5 mm to little more than a shallow depression (de la Mothe *et al.*, 2006). In other New World monkeys (e.g., squirrel monkey), the STS is deeper and longer, clearly demarcating the superior and inferior gyri. In Old World macaque monkeys and great apes, the STS completely divides the temporal lobe into superior and inferior gyri, except at its rostral pole. Caudally, the LS and STS merge in the temporoparietal junction of these primates. In humans, gyrification of the ventral temporal lobe is more elaborate, but the STG remains bounded by the LS and STS.

4.06.3 Location of the Auditory Cortex in the Superior Temporal Lobe

'Auditory cortex' is defined as the array of cortical areas that receives its principal thalamic input from either the ventral (MGv) or dorsal (MGd) divisions of the medial geniculate complex (MGC) (see Shared Features of the Auditory System of Birds and Mammals, Specialization of the Neocortical Pyramidal Cell during Primate Evolution, Cerebral Cortical Folding Patterns in Primates: Why They Vary and What They Signify). Accordingly, the auditory cortex occupies a large portion of the ventral (lower) bank of the LS and STG in nonhuman primates (Figures 1 and 2). Cortical areas that receive inputs from auditory cortex, but not the MGv or MGd, are referred to as 'auditory related'. These areas are located in the temporal pole, and portions of the STS, intraparietal sulcus, and prefrontal cortex. The precise boundaries of the auditory cortex are not entirely known for any primate species, but are most certain in marmoset, owl, and macaque monkeys. In these primates, the medial boundary lies within the LS, where auditory areas adjoin the insula (rostrally) and parietal operculum (caudally). The caudal boundary is located near the junction of the LS and STS, bordering the temporal parietotemporal (Tpt) area, an auditory-related multisensory area that occupies the caudal terminus of the STG (de la Mothe *et al.*, 2006; Galaburda and Pandya, 1983; Hackett *et al.*, 1998; Leinonen *et al.*, 1980; Pandya and Sanides, 1973). The rostral boundary has not been defined with certainty, but thalamic and cortical connections indicate that auditory cortex does not extend all the way to the temporal pole (Galaburda and

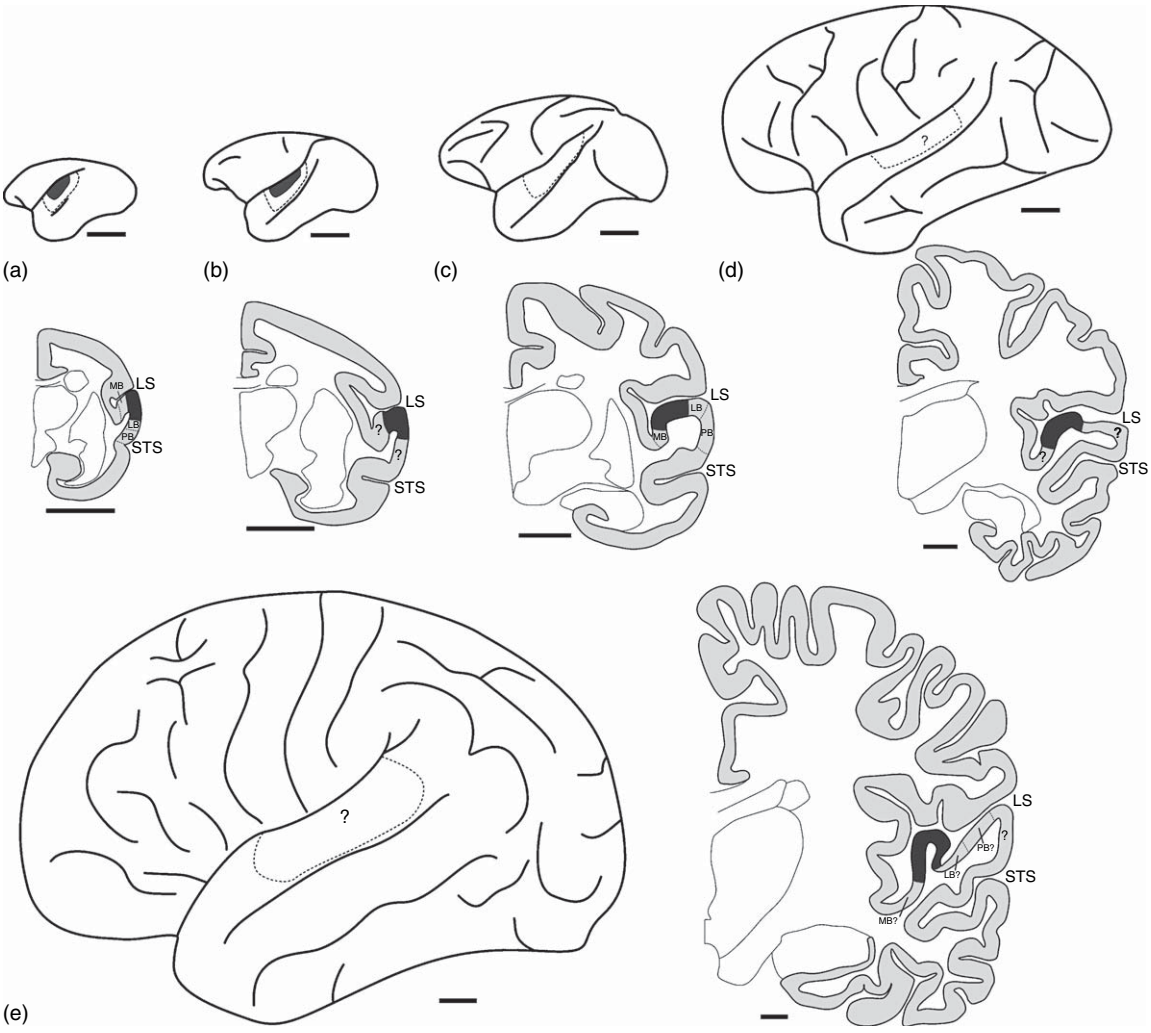

Figure 1 Schematic drawings of the cerebral cortex and location of auditory cortex in several primates. A lateral view of the left hemisphere and a coronal section through auditory cortex is illustrated in each panel. a, Marmoset monkey (*Callithrix jacchus jacchus*); b, squirrel monkey (*Saimiri sciureus*); c, macaque monkey (*Macaca mulatta*); d, chimpanzee (*Pan troglodytes*); e, Human (*Homo sapiens*). Dark shading, core region; MB, medial belt region; LB, lateral belt region; PB, parabelt region; ?, region not defined. Scale bars: coronal sections, 5mm; lateral views, 10mm.

Pandya, 1983; Hackett *et al.*, 1998; Kosmal *et al.*, 1997; Pandya and Sanides, 1973). The ventral (lateral) boundary has not been defined, but the connections of the STG and STS suggest that auditory cortex covers most of the STG, but does not extend far onto the dorsal (upper) bank of the STS (de la Mothe *et al.*, 2006; Hackett *et al.*, 1998).

Classic and modern studies of the human temporal lobe have localized the auditory cortex to a region encompassing the posterior STG, transverse temporal gyri (TTG) of Heschl (HG), and the planum temporale (Hackett, 2002). This corresponds generally to areas 41, 42, 52, and 22 of Brodmann (1909). Compared to monkeys, however, the precise location and extent of auditory cortex in great apes and humans is much less certain, because the thalamic or cortical connections of individual areas cannot be determined experimentally. Therefore, areas must be identified from other anatomical or functional characteristics. This is problematic for several reasons. First, auditory areas cannot be distinguished from auditory-related or nonauditory fields purely on the basis of architectonic features (e.g., cytoarchitecture, myeloarchitecture, chemoarchitecture), as there is no distinctive set of traits that defines a cortical area as auditory. Second, functional imaging and noninvasive electrophysiological techniques currently lack either the spatial resolution or functional specificity to distinguish one area of auditory cortex from another. In general, auditory stimulation activates numerous auditory and auditory-related cortical areas within and beyond the superior temporal cortex (Hall *et al.*, 2003; Scott and Johnsrude, 2003). The sources of this

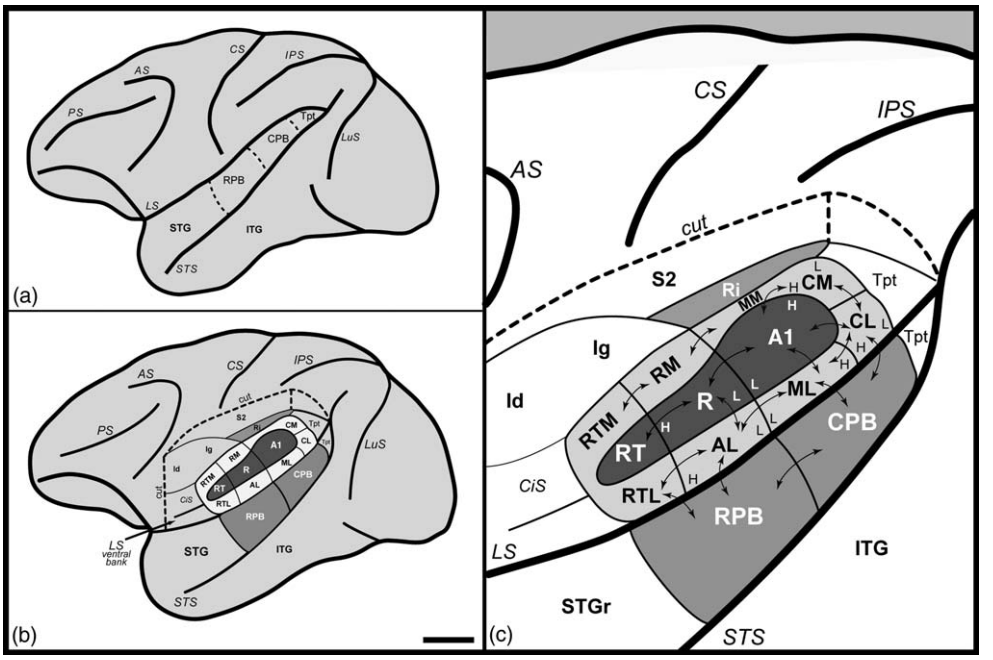

Figure 2 Schematic diagram of primate auditory cortex model illustrated for the macaque monkey. a, Lateral view of the left hemisphere showing locations of the rostral (RPB) and caudal (CPB) parabelt areas on the surface of the superior temporal gyrus (STG); b, the lateral sulcus of the left hemisphere was graphically opened (cut) to reveal the locations of auditory cortical areas on the lower bank of the lateral sulcus (LS); c, expanded view of auditory cortex, showing major connections between areas (arrows). The circular sulcus (CiS) has been flattened to show the rostromedial (RM) and rostrotemporal medial (RTM) areas that occupy its lateral wall. The upper bank of the LS was partly opened to show the locations of areas adjoining auditory cortex: the retroinsular area (Ri) in the fundus, second somatosensory area (S2) on the upper bank, granular insula (Ig), and dysgranular insula (Id). The three areas that comprise the core region of auditory cortex (dark shading) are located on the lower bank (A1, auditory area 1; R, rostral; RT, rostrotemporal). The core is surrounded by eight areas that belong to the belt region (light shading) (CM, caudomedial; CL, caudolateral; MM, middle medial; ML, middle lateral; RM, rostromedial; AL, anterolateral; RTM, rostrotemporal medial; RTL, rostrotemporal lateral). The core and belt regions are mostly contained within the LS. On the surface of the STG are the two areas that make up the parabelt region (medium shading) (RPB and CPB). The rostral part of the STG (STGr) extends to the temporal pole. The temporal parietotemporal (Tpt) area occupies the caudal end of the STG and extends onto the supratemporal plane within the LS. Tonotopic gradients within areas are indicated by H (high frequency) and L (low frequency). Other sulci and gyri shown include the arcuate sulcus (AS), central sulcus (CS), intraparietal sulcus (IPS), superior temporal sulcus (STS), lunate sulcus (LuS), and inferior temporal gyrus (ITG). Scale bar: 10 mm.

activity are largely indistinguishable, because the 'physiological signatures' of the auditory areas involved are not known. These uncertainties highlight the need for studies directed at the identification and characterization of auditory areas in the human brain. To some extent, this can be achieved through comparative studies involving nonhuman primates, for which the organization of the auditory cortex is more certain. As reviewed below, there is both direct and indirect evidence that major features of monkey auditory cortex organization are conserved in humans.

4.06.4 Organization of the Auditory Cortex of Monkeys

Models of auditory cortex organization in mammalian species other than humans are the subject of ongoing testing and refinement. Currently, most of this work is being accomplished in bats, cats, ferrets, mice, rats, New World monkeys, and Old World monkeys and apes. A common theme across models is that a central primary, or 'core region', containing one or more areas, is adjoined by a variable number of secondary areas comprising a 'belt region' (Figure 2). The core and belt regions are strongly interconnected, but the main source of thalamic inputs to the core areas is the MGv, whereas the MGd is the principal source of inputs to the belt areas. Species differ with respect to the number of areas present, their relative position and arrangement, connections (input/output), and tonotopic organization. For example, the number of areas identified ranges from 5 to 6 in rodents, 6 to 9 for cats and ferrets, 10 to 12 in monkeys, and over 30 in humans. Thus, there is a tendency to identify more auditory areas in larger brains. In nonhuman primates, the core–belt scheme has been extended to

include a third region, known as the 'parabelt region' (de la Mothe *et al.*, 2006; Hackett *et al.*, 1998; Morel *et al.*, 1993; Morel and Kaas, 1992). The parabelt region receives thalamic inputs from the MGd, but is distinguished from the belt region in that it does not receive direct inputs from the core (Figure 2c) (Hackett *et al.*, 1998). Information reaching the parabelt region from the core is mediated by connections with the belt region. Accordingly, a processing hierarchy (core–belt–parabelt) is formed across these three regions (Kaas and Hackett, 1998).

Each of the three major regions of the monkey auditory cortex contains two or more areas, or subdivisions (Figure 2). In our working model, there are three subdivisions of the core (Al, R, and RT), seven areas within the belt (CM, RM, RTM, CL, ML, AL, and RTL), and two divisions of the parabelt (RPB and CPB). Each subdivision receives inputs from lower and higher stages of processing, and subdivisions within a region appear to process inputs from multiple sources in parallel. Within the core, for example, each subdivision receives parallel inputs from the MGv (not illustrated), and has reciprocal connections with more than one belt area. In the belt region, all subdivisions receive inputs from the MGd and have reciprocal connections with one or more subdivisions of the core and parabelt. Thus, the connections between regions and areas within regions indicate that both serial and parallel processing is accomplished within the auditory cortical network (Kaas and Hackett, 1998; Kaas *et al.*, 1999; Rauschecker, 1998; Rauschecker *et al.*, 1997).

The establishment of individual subdivisions depends on the identification of unique subsets of anatomical and physiological features. Confidence in the delineation of an area is increased when its profile is based on multiple anatomical and physiological criteria; thus, some areas are defined better than others. The greatest differences are found between areas located in different regions (e.g., core vs. belt). By contrast, areas within a region share several key features, and since adjacent areas tend to share more features than nonadjacent areas, they are the most difficult to delineate. Within the core, for example, areas AI and R have similar architecture and connections. At present, the most reliable distinction between them is receptive field topography. The frequency organization of the cochlea is represented in both A1 and R, but the tonotopic gradients run in opposite directions from a common low-frequency border (see Figure 2) (Aitkin *et al.*, 1986; Brugge, 1982; Cheung *et al.*, 2001; Imig *et al.*, 1977; Kosaki *et al.*, 1997; Luethke *et al.*, 1989; Merzenich and Brugge, 1973; Morel *et al.*, 1993; Morel and Kaas, 1992; Rauschecker *et al.*, 1995, 1997; Recanzone *et al.*, 2000; Tian *et al.*, 2001). A reversal in the tonotopic gradient also distinguishes areas R and RT within the core (Bendor and Wang, 2005; Morel *et al.*, 1993; Morel and Kaas, 1992). Microelectrode recordings have also revealed tonotopic gradients in the belt region, supporting the existence of subdivisions that were previously distinguished on the basis of anatomical features alone. In these experiments, pure tones and narrowband noise stimuli were used to demonstrate complementary tonotopic gradients among the lateral belt areas (AL, ML, CL) (Kosaki *et al.*, 1997; Rauschecker *et al.*, 1995). In areas AL and ML, the gradients match the adjacent core areas (A1, R), while the tonotopic gradients in CM and CL mirror that of AI (Kajikawa *et al.*, 2005; Recanzone, 2000). Thus, an independent representation of the cochlea, or absence thereof, is an important criterion in the establishment of auditory cortical areas, especially when anatomical features are similar.

4.06.5 Organization of the Auditory Cortex of Great Apes and Humans

Compared to monkeys, much less is known about the organization of the auditory cortex in the great apes and humans. Due to the absence of information about connections and near-field electrophysiology, extending findings from monkeys to these primates is primarily limited to descriptions of architectonic features and noninvasive neurophysiology. Detailed parcelations have been produced by multiple investigators spanning about 100 years (Hackett, 2002). Most of these were derived from the analyses of cytoarchitecture and/or myeloarchitecture (Beck, 1928, 1929; Brodmann, 1909; Campbell, 1905; Flechsig, 1920; Galaburda and Sanides, 1980; Hopf, 1954; Morosan *et al.*, 2001; Pandya and Sanides, 1973; Poljak, 1932; Rademacher *et al.*, 1993; Seldon, 1981a, 1981b, 1982; Vogt and Vogt, 1919; von Economo and Horn, 1930; von Economo and Koskinas, 1925). The most recent studies also used the distribution of various markers (e.g., acetylcholinesterase, cytochrome oxidase, parvalbumin, receptor autoradiography) to identify or characterize auditory-related cortical fields (Clarke and Rivier, 1998; Hackett *et al.*, 2001; Hutsler and Gazzaniga, 1996; Morosan *et al.*, 2005; Nakahara *et al.*, 2000; Ong and Garey, 1991; Rivier and Clarke, 1997; Sweet *et al.*, 2005; Wallace *et al.*, 2002). Despite substantial variations in conclusions

and nomenclature across studies, a common finding has been the identification of a central core region with primary, or primary-like, architectonic features surrounded by belts of several nonprimary fields (Figure 3). The correspondence between the core region of monkeys, apes, and humans is rather certain, whereas the homology of areas located beyond the core is not.

In monkeys, the core region is elongated along the anterior–posterior axis of the temporal lobe. In apes and humans, the core is mainly confined to the posteromedial two-thirds of the TTG, which is oriented from posteromedial to anterolateral across the superior temporal plane (Figure 3; Hackett, 2002; Hackett *et al.*, 2001). This region most closely corresponds to area 41 of Brodmann (1908, 1909), as well as to comparable territory identified by other investigators (Table 1). The distinctive cytoarchitecture of the core is commonly referred to as 'granulous' or 'koniocellular', named for the dense concentration of small cells in layers II and IV. Other cytoarchitectonic features include a conspicuous absence of large pyramidal cells in layer III, and a relatively sparse population of pyramidal cells in layer V. Myelin density is higher in the core, compared to most of the surrounding fields. The myelination pattern of the core is characterized by a matrix of small to large caliber fibers of such high density that the inner and outer striae of Baillarger in layers IV and Vb are difficult to resolve (Hackett *et al.*, 2001; Hopf, 1954; Pandya and Sanides, 1973; Sanides, 1972). Other studies have added that the expression of the acetylcholinesterase, cytochrome oxidase, and parvalbumin is greater in layers IIIc and IV of the core than in the belt or parabelt regions (Hackett *et al.*, 1998, 2001; Jones *et al.*, 1995; Kosaki *et al.*, 1997; Morel *et al.*, 1993; Morel and Kaas, 1992; Nakahara *et al.*, 2000; Rivier and Clarke, 1997; Sweet *et al.*, 2005; Wallace *et al.*, 2002). The consistency of this architectonic profile is such that the core can be easily identified in monkeys, apes, and humans. Thus, there is significant conservation of these features among these primates.

Despite the architectonic similarities, there is greater variability in the gross morphological features of the superior temporal cortex of apes and humans, compared to monkeys. In chimpanzees and humans, the number of TTG varies between individuals and sometimes between hemispheres (Hackett *et al.*, 2001; Leonard *et al.*, 1998; Rademacher *et al.*, 1993). The position of the core region varies relative to sulcal and gyral landmarks; therefore, precise localization depends on the detailed architectonic analyses of individual specimens. In humans, the most common configurations are a single or paired TTG, also referred to as a posterior duplication or bifid HG. In humans with a single HG, the core occupies most of the gyrus and usually does not extend beyond its anterior and posterior sulcal boundaries. When the HG is divided by an intermediate transverse sulcus (i.e., bifid HG), the core occupies portions of both gyri and spans the intermediate sulcus. Most chimpanzees have a single HG, but some lack a definitive HG. In these cases, the core is situated deep in the LS and elongated along the medial edge of the superior temporal

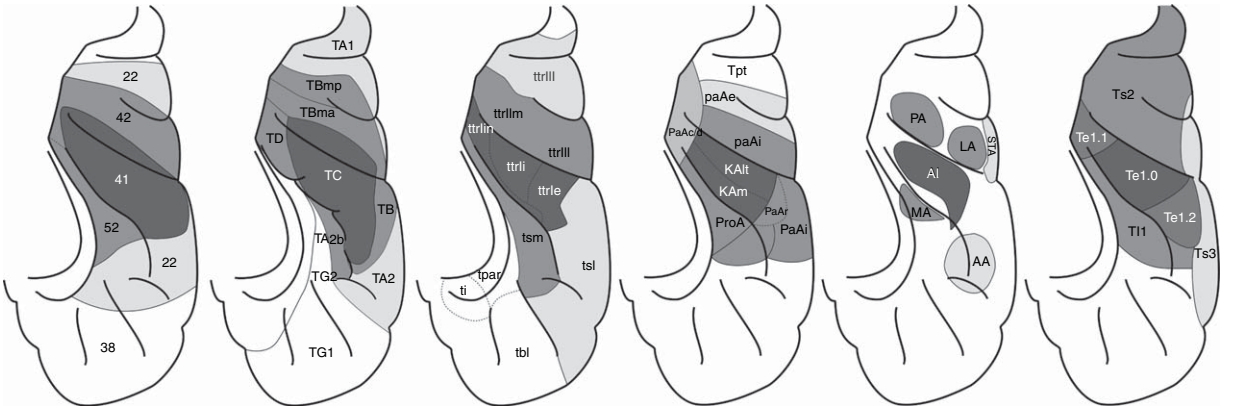

Figure 3 Parcelations of the human superior temporal cortex by different investigators. For each panel, the locations of major auditory cortical regions are drawn on a standardized schematic of the superior temporal plane. The STG is not visible. Dark shading, core region; medium shading, belt region; light shading, parabelt and possibly other regions. Posterior is up, lateral is right. Modified from Hackett, T. 2002. The comparative anatomy of the primate auditory cortex. In: Primate Audition: Behavior and Neurobiology (*ed.* A. Ghazanfar). CRC Press with permission from Taylor & Francis Group LLC.

Table 1 Proposed homologous auditory cortical regions in great apes and humans, with reference to the model of auditory cortex established in monkeys. For each study cited, the species is listed, along with the corresponding region or areas, and the anatomical methods used to identify the region. Note that the size and location of areas varies widely between species and corresponding regions are approximate

plane. In chimpanzees with a prominent HG, the orientation and appearance of the core is more similar to that found in humans (Hackett *et al.*, 2001). The core in these cases is confined to the HG. These findings highlight the variable relationship of the core region to the surface landmarks. The anatomical variability is more problematic for functional studies in which delineation of the core and belt regions is important for interpretation of experimental results. Functional imaging and electrophysiological approaches have been broadly used to study activity in auditory cortex (for reviews, see Hall *et al.*, 2003; Scott and Johnsrude, 2003). However, since auditory stimulation tends to activate core and belt regions, it has been difficult to precisely dissociate their respective contributions, especially given the anatomical variability between subjects (Seifritz *et al.*, 2002; Lehmann *et al.*, 2006).

Flanking the core region on the anteromedial and posterolateral sides of the TTG are two distinct regions that are likely to comprise part of the auditory cortex of humans and apes. The anterior region, interposed between the core and circular sulcus of the insula, is a region with distinctive architecture that most closely corresponds to the medial belt region of monkeys. Although variably named by different investigators (e.g., area 52 of Brodmann) (Figure 3), the various architectonic descriptions of this region are remarkably similar. The planum temporale (PT) occupies the superior temporal plane posterolateral to the TTG. Aside from the TTG, the expansion of the PT is perhaps the clearest differences in the gross morphology of the superior temporal lobe among primates. Compared to monkeys, the PT and STG appear to be greatly expanded in apes and humans. Accurately accounting for this expansion poses a significant challenge, because comparative studies are lacking. With respect to the PT, most descriptions have noted significant architectonic heterogeneity, consistent with the presence of at least two subdivisions in apes and humans (Figure 3). Brodmann (1908, 1909) identified area 42 and part of area 22 on the human PT, and while details vary between investigators, subsequent reports have generally not departed greatly from this interpretation (Figure 3, Table 1).

The rotation of the core in apes and humans suggests that the PT may contain parts of the core and parabelt regions of monkeys (Figure 3). Anatomical support for this hypothesis includes evidence that belt areas corresponding to CM and CL cap the core region posteromedially in both chimpanzees and humans (Hackett *et al.*, 2001). Most recently, areas possibly corresponding to the lateral belt and parabelt of monkeys were identified in the human PT adjacent to the core on the TTG (Sweet *et al.*, 2005). These assignments were made on the basis of position, relative to the core region, and architectonic similarities between species. While further comparative studies are needed to validate and extend these findings, it follows that a significant portion of the STG (area 22) would have no clear homologue among monkeys, apes, and humans. That is, if the PT contains most of the lateral belt and parabelt regions identified in monkeys, then most of the STG of apes and humans is comprised of cortex with no clear homologue in monkeys. Since there have been no comparative studies of the STG among these primates, correspondence remains an open question.

4.06.6 Conclusions and Directions for Future Research

Anatomical and functional studies suggest that certain elements of the monkey model of auditory cortex are directly applicable to apes and humans. The homology of the core region is the most well established at present, and homologies among the medial and lateral belt regions appear likely. Undoubtedly, further comparative studies will be needed to identify other similarities and differences in the organization of auditory cortex across taxonomic groups. For architectonic studies, progress will depend on the establishment of anatomical profiles to distinguish cortical fields. Functional studies may help to validate the anatomical predictions through the discovery of common physiological features, such as tonotopic organization. While it is not expected that the anatomical and functional features will be identical among areas identified as homologous, it is likely that many corresponding areas will be revealed, with the possibility that additional areas have been added in apes and humans. The differences in auditory cortex organization are expected to contribute to well-known differences in the perception and production of speech and music among primates, and may also reveal clues about the evolution of these abilities.

4.07 The Evolution of the Sweetness Receptor in Primates

D Glaser, University of Zürich, Zurich, Switzerland

Glossary

acesulfame K	A saccharin-type sweetener with a sweetness potency about 200 times that of sucrose (see sweetness potency entry in the glossary).
alitame (ALT)	A dipeptide-type sweetener with a potency of 2000.
Asp-	Side chain of a specific aspartate residue; recognition site of the sweet taste receptor.
aspartame (APM)	First sweet-tasting dipeptide discovered, with a potency of about 200.
bernadame	Guanidine-type sweetener with a potency of about 200 000.
Glu-	Side chain of a specific glutamate residue; recognition site of the sweet taste receptor.
G-proteins	Family of intracellular proteins that bind receptor complexes and mediate a cell surface receptor (for instance, sweet taste receptor) to intracellular responses.
interaction sites	Parts of a sweet molecule interacting with the recognition sites of the sweetness receptor.
interaction points	Each interaction site is made up of two interaction points or interaction subsites (with the exception of the D-site, where there is only one interaction point).
lugduname	Guanidine-type sweetener, the most potent sweetener ever described, with a potency of about 225 000.
Lys-	Side chain of a specific lysine residue; recognition site of the sweet taste receptor.
monellin	Protein isolated from the fruits of an African plant *Dioscoreophyllum cumminsii*, with a potency of about 2250 (about 100 000 times on a molar basis).
MPA theory	Multipoint attachment theory: a model to explain the interactions of sweet molecules with sweet taste receptors in humans.
neotame (NTM)	A dipeptide-type sweetener with a potency of about 10 000.
recognition sites	Specific side chains of some amino acids forming the sweet taste receptor and assumed to be able to interact with sweet molecules.
Ser-	Side chain of a specific serine residue; recognition site of the sweet taste receptor.
sucrononate	Guanidine-type sweetener with a potency of about 200 000.
sweetness potency	Sweetness potencies are given for humans on a weight basis relative to a 2% sucrose solution.
thaumatin	Protein isolated from the berries of an African plant *Thaumatococcus daniellii* with a potency of 5500 (100 000 on a molar basis).
umami	Taste typically represented by monosodium glutamate (umami is a fifth taste quality in addition to sweet, sour, salty, and bitter, and is derived from the Japanese word meaning deliciousness).
Val-	Side chain of a specific valine residue; recognition site of the sweet taste receptor.

4.07.1 The Importance of the Sense of Taste

The intake of energy is vital for life for animals and humans and is a key determinant in the evolution of animals from primitive to more advanced levels. For most animals, visual and/or olfaction senses are initially essential in finding nutritional energy. Later the sense of taste remains a powerful controlling system of food intake. The importance of the gustatory system is observed in regulation of food intake, recognition and distinction of food substances, and

protection of the body from toxic substances. In many species, the sense of taste is also involved in other functions, such as increase in sexual excitation (i.e., for many insects), or in allowing and regulating the co-habitation of different species of animals and plants (exudates play a regulatory role in interspecific interactions), or, as in humans, in increasing pleasure (see The Evolution of Sensory and Motory Systems in Primates, The Development and Evolutionary Expansion of the Cerebral Cortex in Primates, Organization and Correspondence of the Auditory Cortex of Humans and Nonhuman Primates, The Vomeronasal Organ and Its Evolutionary Loss in Catarrhine Primates, Evolution of Taste).

4.07.2 Classification of the Order Primates

Primates have stimulated more interest than any other group, as humans are ranked in this mammalian order. Primates are represented by following main groups: suborder Prosimmii, with the infraorders Lemuriformes, Lorisiformes, and Tarsiiformes; suborder Anthropoidea, with the infraorders Platyrrhini (the New World simians with the Callitrichidae and Cebidae) and Catarrhini (the Old World simians with the superfamilies Cercopithecoidea (one family cereopithecidae) and the Hominoidea with three families Hylobatidae (lesser apes), Pongidae (great apes), and Hominidae (humans)). A simplified classification is given in Figure 1.

The history of the order Primates began in late Cretaceous times, about 65 Mya. There have been several lively current disputes anticipating primate origins as early as 80 Mya, but up to now there has been no clear evidence for this suggestion. Future fossil discoveries will probably clarify this divergence in the timescale.

4.07.3 Early Greek Theories of Taste Sensations

Until about 10 000 years BC, humans were little more than successful predators living according to the law of the jungle and surviving as they were well adapted to it. Direct evidence about primate diets is exceedingly rare in prehistoric records. But archeologists have dug up tools and food residues, making it possible to sketch an outline of the diet of prehistoric humans. Indications exist that, in relation to sweet substances, about 50 000 years BC humans were cultivating the date palm in southern Mesopotamia. The date palm probably supplied one of the first sweet compounds (81% sucrose dry weight) to humans. Furthermore, the Stone Age paintings (over 20 000 years old) in the caves of Arana in southern Spain depict an individual collecting honey from a bee's nest. Few facts are available in relation to sweet substances in human diet before 3000 BC, the approximate date of the first written records. With the emergence of the early Greek philosophers are found the first written records on taste sensation

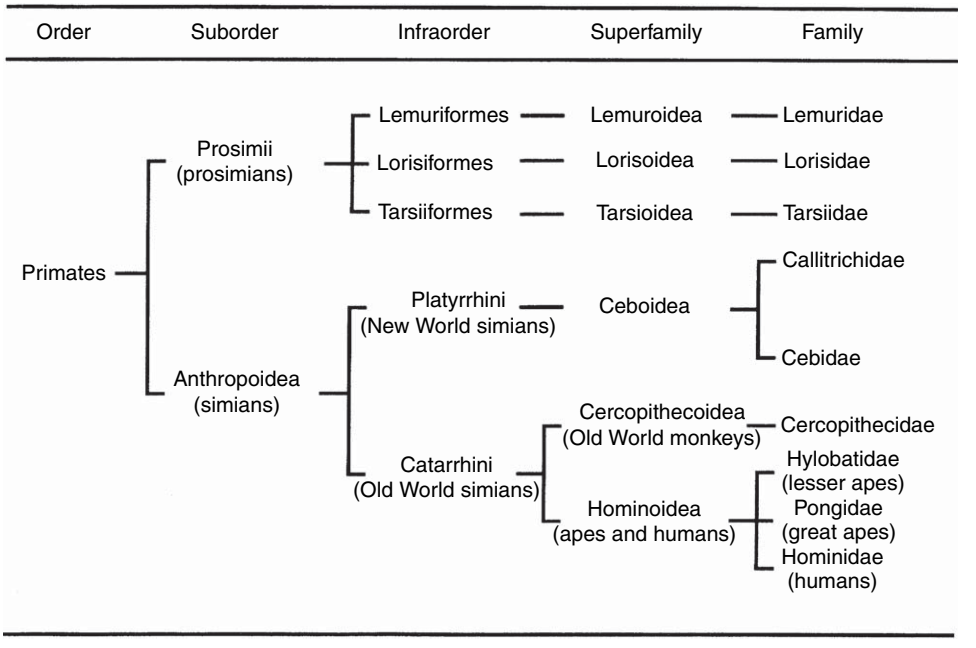

Figure 1 A simplified classification of the order Primates.

(Burnet, 1975): the concept of canals ("Perception is due to the meeting of an element in us with the same element outside") was prevalent. However, Alkmaion (*c.* 500 BC) first connected pores with sensation ("It is with the tongue, however, that we distinguish the tastes") and he suggested the concept that the sensation reaches the brain through these pores.

Influenced by the Pythagorean (532–497 BC) ideals concerning opposites (even–uneven, right–left, hot–cold, black–white, finite–infinite, wet–dry, male–female, good–bad, love–hate), Alkmaion mentions the opposites of sweet–bitter. At this time, the Pythagorean teaching on the battle of the opposites and their fusion into harmony continued to influence biology. In the fifth and fourth centuries BC, probably instigated by Empedokles (*c.* 495–435 BC), the doctrine of the four bodily humors (blood, phlegm, choler, and melancholy) was created in connection with humoral pathology. This further evolved to produce the doctrine of the four basic or primary qualities (probably credited to Zenon, *c.* 490–430 BC). Later, Aristotle (384–322 BC) expresses himself diplomatically: "The types of taste are – as are colours – simple opposites; sweet–bitter, following these two oily and salty; as intermediates pungent, astringent, sour, prickly." Aristotle proposes the existence of two opposites, instead of four, but recognizes the existence of intermediate qualities. However, it is difficult to arrange the Aristotelian terms, oily and salty, as well as the intermediates – pungent, astringent, sour, prickly – on a straight line. This shows how difficult it is to describe the characteristics of taste in an accurate semantic way.

Nowadays, we generally refer to the four primary qualities of taste as sweet, sour, salty, bitter, and in modern times, umami, and it is possible to depict this in a three-dimensional spherical model (Figure 2) (Haefeli and Glaser, 1985). More details of the development of models on taste qualities are given by Glaser (1999).

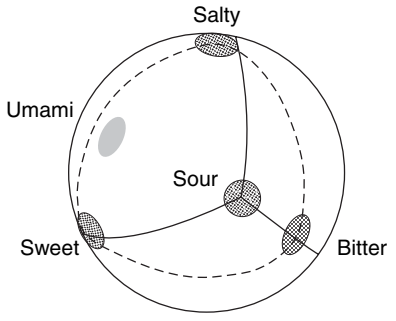

Figure 2 Areas of the spherical model represent diversity within the qualities of taste. This is in contrast to Henning's tetrahedron, where only one point represents a different taste quality. Reproduced from Glaser, D. 1999. The evolution of taste perception. In: Low-Calorie Sweeteners: Present and Future (*ed.* A. Corti), vol. 85, pp. 18–38. Karger, with permission from Karger, Basel.

4.07.4 Sweet Receptor Theories

As mentioned above, Alkmaion discussed pores in connection with taste, while Empedokles wrote that "Perception, then, is due to the meeting of an element in us with the same element outside." This takes place when the pores of the sensory organ are neither too large nor too small for the effluences constantly emitted by all things (Burnet, 1975).

Democritus (460–370 BC) was one of the first originators of the atomic theory of nature: he explained that various taste qualities resulted from the shapes of the atoms (now molecules) in different taste compounds. For example, he attributed sweetness to medium-sized spherical shapes entering special pores, bitterness to small spherical shapes attached with hooks, saltiness to big, aspherical shapes, and sourness to angular shapes.

It was only much later that the concept proposed by Democritus was substantiated by the German chemist Emil Fischer in the following sentence: "Visually speaking, I would say that the enzyme and glucoside must fit together as lock and key, in order to chemically act upon one another." The validity of this concept continues to stand today.

Among basic tastes, the sweet taste has attracted wide attention with regard to its importance to the taste of food. How a molecule binds to the receptor on the microvilli of a taste bud and initiates a sensory effect will be discussed here for sweetness in different steps.

An important step was that of Shallenberger and Acree's (1967) bipartite hydrogen-bonding principle, or the AH–B system, in which "the initial chemistry of the sweet taste response must be analogous to concerted and antiparallel intermolecular hydrogen bonding with a chemically and sterically commensurate receptor." Both A and B are negatively charged atoms in suitable geometrical proximity. A is a hydrogen-bond donor, while B is an acceptor. This bipartite binding was thought to be all that is required to elicit the sensation of sweetness.

Through a second step, a tripartite binding site completed the two hydrogen bonds. Kier (1972) proposed the existence of a third binding site, a hydrophobic site capable of cooperating with the AH–B system.

Later van der Heijden *et al.* (1979) tried to locate the distances of the AH–B moiety from this third binding site. The distance between this new site and A was estimated to be approximately 5.5 nm, and the distance to B approximately 3.5 nm. This third binding site was designated as X by Kier (1972), y by

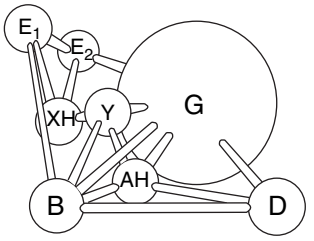

Figure 3 Spatial arrangement of the eight interaction sites of sweetening compounds of the initial MPA model, with four high-affinity sites: B, an anionic group; AH, hydrogen-bond donor group; G, hydrophobic group; and D, hydrogen-bond acceptor group. Four secondary sites are designated as Y, E_1, and E_2 sites, hydrogen-bond acceptor ligands, and XH is a hydrogen-bond donor group. Reproduced from Glaser, D. 1999. The evolution of taste perception. In: Low-Calorie Sweeteners: Present and Future (*ed.* A. Corti), vol. 85, pp. 18–38. Karger, with permission from Karger, Basel.

Shallenberger and Lindley (1977), δ by van der Heijden *et al.* (1979) and later G by Tinti and Nofre (1991).

A fourth step was suggested by Tinti *et al.* (1982), studying structure–activity relationships in the suosan series. These researchers found that an NO_2 or a CN group attached to an aromatic ring (such as a phenyl group) was an essential feature for a high-potency sweetener. They designated this hydrogen-bond acceptor group (such as NO_2/CN) as the D-site. Following this finding, structurally different sweeteners were reviewed by these authors, who proposed a multipoint attachment (MPA) theory of sweetness reception (Figure 3) (Tinti and Nofre, 1991).

4.07.5 Extensive Research of Primate Taste Responses to Sweeteners Started in 1966

In 1966, I started testing nonhuman primates with sweet compounds at the primate facilities of the Anthropological Institute of the University in Zürich, Switzerland. At first, the main point of interest was the animals' sensitivity to sweet compounds in comparison with that of humans. Later, interest focused on the diversity of taste responses and the mechanistic relationships between a sweet substance and the sweet taste receptor.

The first interesting result in the order of Primates was found with thaumatin, a protein isolated from the berries of the African plant *Thaumatococcus daniellii* Benth., which humans find tastes intensely sweet (on a molecular basis, about 100 000 times sweeter than sucrose). Neither the Prosimii – including *Tarsius* – nor the South American primates tested (Figure 1) showed any behavioral and/or electrophysiological responses to this protein. Only the Cercopithecidae, the Hylobatidae, and the Pongidae responded to this compound in the same way as humans and preferred it (Glaser *et al.*, 1978). Later it was found (Glaser *et al.*, 1992) that aspartame (APM), the first discovered sweet-tasting dipeptide with a potency of about 200, induces a behavior similar to that of thaumatin, i.e., there is a clear dichotomy within the order Primates at the same intersecting line. A third compound, the new high-potency non-nutritive sweetener neotame (NTM) (Nofre and Tinti, 2000), which has a sweetness potency about 10 000 times that of sucrose, confirms the intersecting line found with thaumatin and APM.

4.07.6 The Multipoint Attachment Theory

Since its first presentation, the MPA model (Tinti and Nofre, 1991) has been modified and improved to integrate more structure–activity relationship results in sweetening agents and new observations on the sweet taste reception of primate species.

The new model comprises 10 fundamental interaction sites that are counterparts of 10 opposite recognition sites contained in the sweetness receptor.

Because the sweetness receptor has a proteinaceous structure – it is probably a member of the family of seven-pass transmembrane receptors coupled to a G-protein – it is assumed according to the MPA theory that the recognition sites are represented by the side chain of certain amino acids comprising the sweet taste receptor. The sweetening agents are thus able to interact with some of these recognition sites arranged around the central cavity inside the transmembrane receptor protein.

These recognition sites are assumed to be made up of an aspartate or glutamate residue (Asp-1 or Glu-1), a lysine residue (Lys-2), another aspartate or glutamate residue (Asp-3 or Glu-3), five threonine residues (Thr-4, Thr-5, Thr-6, Thr-7, Thr-9), a valine residue (Val-10) behind Thr-4 and under Thr-5, and a serine residue (Ser-8), comprising only one recognition site and designated as the D-site (Figure 4).

Nine of the recognition sites are dual-interaction subsites (or interaction points); thus the number of attachment points between a sweet molecule and the receptor may be high (up to 19 points) (Glaser *et al.*, 2000). Note, however, that a molecule may elicit a sweet taste while interacting through a notably lower number of these interaction points.

Considering in detail Primates (Figure 5), we find only G_1- and G_4-recognition subsites in the entire

infraorder Platyrrhini (all the New World monkeys). In species of the suborder Prosimii (Lemuridae and Lorisidae) the G_1-, G3-, and G4-recognition subsites are found, and it is only in the Catarrhini (Cercopithecidae, Hylobatidae, Pongidae, and Hominidae) that all four G-recognition subsites are found on the receptor surface. Moreover, if we look at the E-points, we find only the E_1- and E_4-recognition subsites in the Callitrichidae (a family of New World monkeys). In the Cebidae (the other family of New World monkeys), we find the E_1-, E_2-, and E_4-recognition subsites. The suborder Prosimii possesses the E_1-, E_3-, and E_4-recognition subsites and again only the Catarrhini possesses all four E-recognition subsites. The mutations observed in the primate sweetness receptors concern only the G_2-, G_3- and E_2-, E_3-steric recognition subsites.

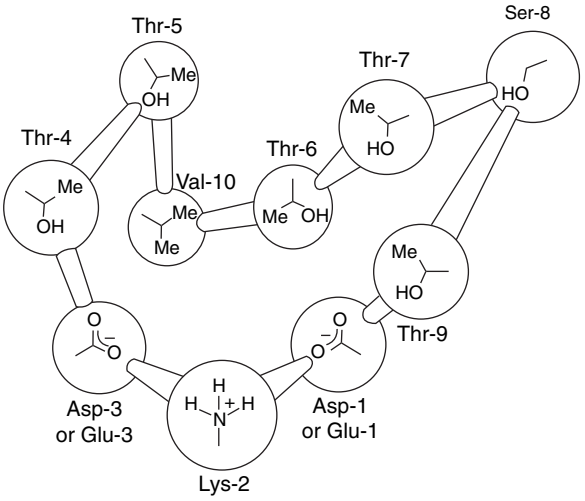

Figure 4 The MPA model of the human sweetness receptor. The spheres of the model represent the approximate spatial positions of the different functional groups that may be involved in the interactions of the human receptor with various natural or artificial sweeteners. Reproduced from Glaser, D., Wanner, M., Tinti, J.-M., and Nofre, C. 2000. Gustatory responses of pigs to various natural and artificial compounds known to be sweet in man. *Food chem.* 68, 375–385, Elsevier.

Initially designed for human sweetness reception, the MPA model proved useful to understand better sweet taste reception by considering the presence or absence of a given recognition site for a specific primate species.

Figure 6 shows the interaction points of the first-known sweet-tasting dipeptide APM (which is only sweet in all Catarrhini) in comparison with another dipeptide-like sweetener, alitame (ALT), which is about 2000 times sweeter than sucrose in humans and which, in contrast to APM, elicits a sweet taste in all primates investigated (Glaser *et al.*, 1996). APM interacts with the receptor through the G_1-, G_2-, and G_4-steric recognition subsites. The G_3-steric interaction subsite is therefore postulated to be the special

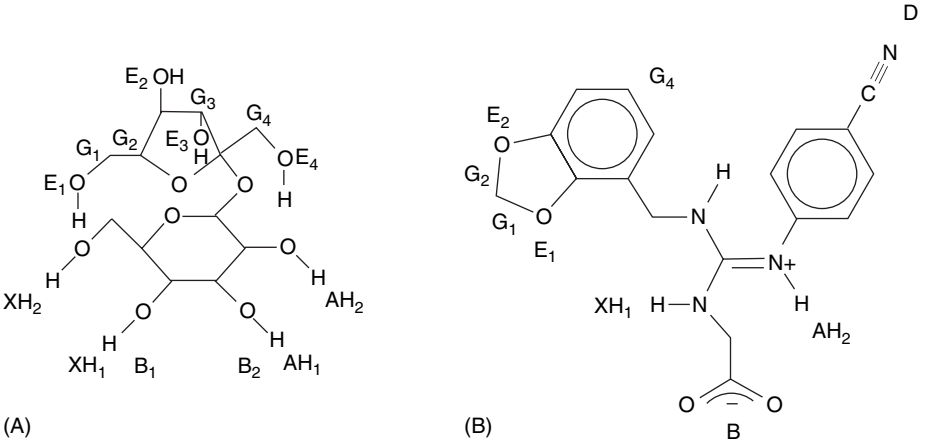

Figure 7 Interaction subsites for (a), naturally occurring sucrose and, in comparison, (b), lugduname, a guanidine derivative, the most potent artificial sweetener known to date, which has a potency 225 000 times that of a 2% sucrose solution. Reproduced from Glaser, D. 1999. The evolution of taste perception. In: Low-Calorie Sweeteners: Present and Future (*ed.* A. Corti), vol. 85, pp. 18–38. Karger, with permission from Karger, Basel.

feature allowing ALT to be sweet in all the primate species tested. The interaction subsites for naturally occurring sucrose and lugduname are illustrated in Figure 7.

4.07.7 Why Are Such a Large Number of Attachment Points Necessary?

We must focus our attention not only on the naturally occurring sweeteners that have been discovered in more than 30 different classes of plants, but also on the enormous number of artificial sweet compounds found in the course of extensive research. All of these sweetening agents belong to more than 25 chemical structural classes (Table 1) and are all coupled to a high biological diversity of animal responses. One way of understanding this diversity is to speculate that there are many receptors (such as, for olfaction), and each family of sweeteners interacts with a different type of receptor. A possible second way is to contemplate that a unique basic receptor exists.

In this second hypothesis, the receptor contains multiple recognition sites, and each sweetener is able to interact with a specific number of these recognition sites. Differences in sweet taste recognition between primate species can thus be easier explained as resulting from evolutional changes (i.e., adapting to environmental conditions) of a common sweet taste receptor ancestor, changes occurring through the mutation or deletion of an existing recognition site or in the apparition of a new one. The many gustatory experiments performed with primates have supported this second approach.

To give just one example, consider the observations with Lemuridae (Prosimii from Madacascar). *Lemur catta* prefers the amino acids glycine and D-tryptophan while *Hapalemur griseus occidentalis* prefers glycine and shows no taste reaction to D-tryptophan. These

Table 1 Sweeteners can be found among diverse chemical structural classes

1. Amino acids (D-tryptophan)
2. Dipeptides (ALT, APM, ampame)
3. Proteins (thaumatin, monellin)
4. Monosaccharides (fructose)
5. Oligosaccharides (sucrose)
6. Polyols (xylitol)
7. Saccharins (saccharin)
8. Urea derivatives (dulcin, suosan)
9. Guanidines (sucrononate, lugduname)
10. Sulfamates (Na-cyclamate)
11. Acesulfames (acesulfame K)
12. Flavonoids (hesperitin)
13. Dihydrochalcones (NHDHC)
14. Nitroanilines (P 4000)
15. Oximes (perillartine)
16. Diterpenes (stevioside)
17. Triterpenes (glycyrrhizic acid)
18. Sesquiterpenes (hernandulcin)
19. Steroid saponins (osladin)
20. Isocoumarins or diphenyls (phyllodulcin)
21. Halogenated hydrocarbons (chloroform)
22. Metal salts (beryllium chloride)
23. Trihalogenated benzamides
24. Malonic diesters
25. Thioureas
26. Anilides

Reproduced from Glaser, D. 1999. The evolution of taste perception. In: Low-Calorie Sweeteners: Present and Future (*ed.* A. Corti), vol. 85, pp. 18–38. Karger, with permission from Karger, Basel.

gustatory differences between primate species can be understood using the MPA theory (Nofre *et al.*, 1996). All our gustatory data support the assumption that a single sweet taste receptor exists in a given primate species – including humans – a receptor that was however subjected to mutations and variations across the millions of years of primate evolution.

4.07.8 Conclusions

Thanks to our knowledge of the MPA model, we can provide a key that allows us to increase our understanding of biodiversity of taste responses and to trace the phylogeny of the sweet receptors in the order Primates. In the course of development from the most ancestral group toward the Cercopithecoidea and Hominoidea, the capability to taste thaumatin, APM, and NTM must have evolved after the South American Platyrrhinai had spilt off. At what point this change occurred is difficult to say, but it may be assumed that this feature is connected with the occurrence of the first catarrhine primates, i.e., 35–38 Mya, with the first confirmed findings of the Catarrhini (*Oligopithecus*) during the Oligocene (Figure 8).

There are indications, however, that this ability evolved specifically in the Catarrhini. All primate species that we tested, whose origin can be traced

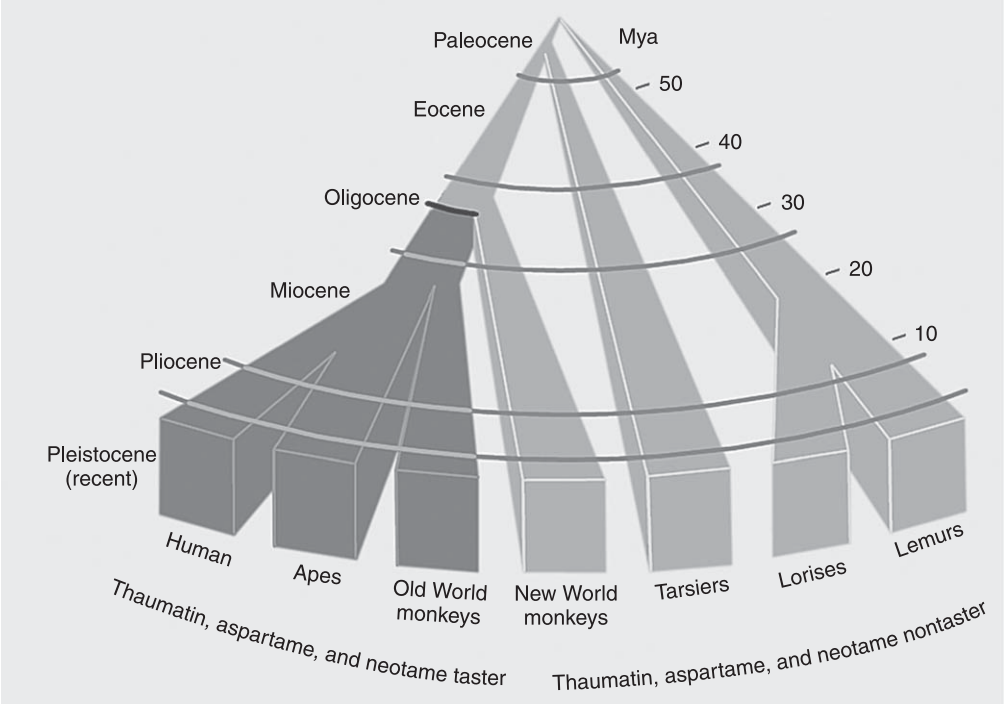

Figure 8 The radiation within the order Primates of tasters and nontasters of thaumatin, aspartame, and neotame. Reproduced from Glaser, D. 2002. Specialization and phyletic trends of sweetness reception in animals. *Pure Appl. Chem.* 74, 1153–1158, with permission from IUPAC.

back to the Cretaceous, Eocene, or Paleocene period, show no response to thaumatin, APM, or NTM (Glaser *et al.*, 2000; Glaser, 2002). All our new and previous data (Nofre *et al.*, 1996, 2002; Tinti *et al.*, 2000) demonstrate that the Catarrhini – the Old World simians – including humans are a compact group and that their sweetness receptor evolved >35–38 Mya in the Oligocene (Glaser *et al.*, 1978, 1992). The Catarrhini possesses the most advanced type of sweetness receptor compared to that of the Callitrichidae, which is considered to be a more primitive sweet taste receptor.

Generally, animals' feeding habits and behavior have been classified into various categories such as carnivorous, omnivorous, and phytophagus, but many species are not highly restricted in their natural diets. Seasonal and/or daily variations sometimes considerably shift feeding habits. Additional efforts in studying comparative gustatory physiology could be helpful to clarify the evolution of further mammalian sweet receptors in connection with feeding habits and other behaviors in the animal kingdom.

4.08 The Loss of Olfactory Receptor Genes in Human Evolution

S Rouquier and D Giorgi, Institute of Human Genetics, CNRS, Montpellier, France

Glossary

apes Great apes comprise chimpanzees, bonobos, gorillas, and orangutans.

cluster A gene cluster is a genomic region containing similar genes and resulting mostly from tandem duplications.

duplication Creation of two copies of a DNA segment in the genome. A tandem duplication results in the duplication of DNA segments (or genes) in close proximity to each other in a given region of a chromosome.

frameshift mutation A mutation that causes a change in the reading frame of a protein-coding region, leading in general to protein inactivation.

G-protein-coupled receptors (GPCR) Seven transmembrane domain receptors that need both ligand binding and coupling to intracellular G-proteins for their activation.

macrosmates and microsmates Animals that either rely (macro-) or do not rely (micro-) on the sense of smell and therefore display high or low olfactory ability.

nonsense mutation A mutation that causes the introduction of a stop codon leading to a premature termination of the encoded protein. This type of mutation results most of the time in protein inactivation.

nonsynonymous mutation (or substitution) A nucleotide change in a codon that changes the encoded amino acid, as opposed to a synonymous mutation that does not change the nature of the encoded amino acid.

Old World monkeys Monkeys from Africa and Asia. New World monkeys are native to America.

open reading frame (ORF) DNA sequence translatable into protein. For known proteins such as olfactory receptors, the initiation Met and the termination stop codon that limit the ORFs are also searched to define a potentially functional gene.

orthologues Genes that are conserved between species and that lie generally in syntenic regions. The sequence similarity is the result of the speciation process.

paralogues In a single organism, paralogues are homologous genes originating from the duplication of an ancestral gene.

positive selection Selection for an advantageous gene.

pseudogene Nonfunctional DNA segment that shares sequence homology with a functional gene. Different processes may lead to the generation of pseudogenes. They generally contain disrupted ORFs.

purifying selection (or negative selection) Removal of an allele or a gene from a population through natural selection.

synteny Synteny conservation arises when DNA regions of different species contain a series of homologous genes (orthologues) in the same order.

4.08.1 Introduction

Olfaction, or the sense of smell, is an ancient sensory system that together with taste enables an organism to detect chemicals in the external environment. Olfaction is present in most species such as insects, worms, fish, amphibians, birds, and mammals. It is essential for survival by permitting the location of food, mates, and predators, although in humans, olfaction is often viewed as an esthetic sense capable of triggering emotion and memory. In mammals, the sense of smell is mediated by two main sensory organs that are located in the nasal cavity: the main olfactory epithelium (MOE), which binds odorants, and the vomeronasal organ (VNO), which is responsible for pheromone detection. This review will focus on genetic aspects of the conscious perception of odors mediated by the MOE. In terrestrial vertebrates, odorants are volatile chemicals of various classes (aliphatic, cyclic, aromatic, etc.). The olfactory perception starts when odorants bind to olfactory receptors (ORs) that are expressed on cilia of the dendrites of olfactory sensory neurons (OSNs), which emerge in the MOE. This interaction induces the activation of a transduction pathway that involves a G-protein-dependent elevation of cyclic 3′, 5′ adenosine monophosphate (cAMP) opening ion channels that in turn results in the transmission of action potentials to specialized glomeruli localized in the olfactory bulb. Sensory inputs are then transmitted to the olfactory cortex where the information is integrated to result in the sensation of smell. A number of reviews have been published on the principles of olfaction (Moulton, 1967; Keverne, 1999; Krieger and Breer, 1999; Laurent, 1999; Mombaerts, 1999, 2001a, 2004a; Mori *et al.*, 1999; Firestein, 2001; Gaillard *et al.*, 2004a).

During the past 6 years, different studies on the evolution of the OR genes in mammals have pointed out the reduction of the functional fraction of the OR gene repertoire during primate evolution leading to a restricted set of functional OR genes in humans (see Evolution of Vertebrate Olfactory Subsystems). These observations led to the hypothesis that the size of the functional OR repertoire reflects the olfactory needs and hence the olfactory capacity/ability of an organism.

This review is an overview on the subject by comparing data obtained by the analysis of the OR subgenome of different primate species with respect to that of mouse and dog.

4.08.2 Olfactory Receptors

4.08.2.1 Receptors

OR genes were first identified in rat (Buck and Axel, 1991) 16 years ago and subsequently in numerous other species. The OR multigene family (see below) encodes proteins 300–350 amino acids in length that belong to the G-protein-coupled receptor (GPCR) superfamily. They share structural features (Figure 1) common to the GPCRs such as seven hydrophobic transmembrane domains (7TM or heptahelical structure) and other characteristics described elsewhere (Liu *et al.*, 2003). Nevertheless, ORs possess specific characteristics such as a long extracellular loop 2 and consensus motifs (for example, MAYDRYVAIC at the end of TM3 and the beginning of intracellular loop 2). Some motifs are specific to mammalian ORs and others are signatures for the mouse subgroup and class I and class II ORs (Liu *et al.*, 2003), which are the two main OR classes defined by sequence comparison. Class I comprises fishlike ORs thought to bind water-soluble odorants, whereas class II contains mammal-like ORs that bind volatile odorants. Transmembrane domains 3, 4, and 5 are hypervariable and are part of the odorant-binding pocket by analogy with other 7TM proteins (Fuchs *et al.*, 2001). Most of the vertebrates and fish possess similar ORs, whereas insects (*Drosophila melanogaster*) and worms (*Caenorhabditis elegans*) possess very specific OR

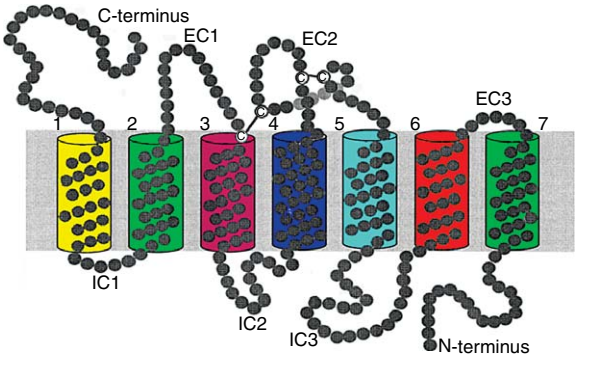

Figure 1 Schematic diagram of an olfactory receptor. The seven transmembrane domains (1–7) are represented embedded in the membrane. Extracellular (EC) and intracellular (IC) loops are indicated as well as the three disulfide bridges.

repertoires that do not share significant sequence homology with any other animal class (Gaillard *et al.*, 2004a).

Classically, on the basis of their sequences, ORs are grouped into protein families (>40% amino acid identity) and subfamilies (>60%).

4.08.2.2 Genes

Although structural features, mode of expression, and gene organization are common to ORs of most species, we will refer to terrestrial mammalian ORs in the next part of this review.

Since the first cloning of OR genes in rat (Buck and Axel, 1991), a plethora of genes have been identified using PCR-based (polymerase chain reaction) approaches with degenerate primers derived from the conserved regions of OR genes. More recently, the complete sequencing of the genome of different species has provided a complete picture of the OR gene repertoire to be drawn. Mammals possess approximately 1000 OR genes that are responsible for the expression of the corresponding receptors. ORs display enough diversity to ensure the detection of thousands of odorants using a combinatorial code (Malnic *et al.*, 1999; Mori *et al.*, 1999; Firestein, 2001; Young and Trask, 2002) to translate complex odorant stimuli into a subtle odor perception. OR genes are expressed mainly in the olfactory epithelium but also in spermatozoa where they appear to be key elements for sperm chemotaxis and the fertilization process (Parmentier *et al.*, 1992; Vanderhaeghen *et al.*, 1993; Spehr *et al.*, 2003). In olfactory neurons, OR genes are expressed in a monoallelic fashion since each OSN expresses only one single OR allele (maternal or paternal) (Chess *et al.*, 1992, 1994; Chess, 1998a, 1998b). This particular expression requires a negative feedback mechanism since the expressed receptor inhibits the expression of the other ORs (Serizawa *et al.*, 2003; Lewcock and Reed, 2004; Li *et al.*, 2004; Mombaerts, 2004b).

OR genes are composed of an intronless coding region of approximately 1kb preceded by a variable number of noncoding 5′ exons (1–4, encompassing up to >15kb) and terminated by a short 3′ end (~1.5kb) containing a polyadenylation signal (Sosinsky *et al.*, 2000). It has been shown that ORs could be alternatively spliced (among the different 5′ nontranslated exons), giving rise to different transcripts encoding the same receptor that might reflect a tissue-specific expression, but no obvious regulatory motifs have been identified (Asai *et al.*, 1996; Sosinsky *et al.*, 2000; Lane *et al.*, 2001).

4.08.3 OR Gene Organization

4.08.3.1 OR Gene Clusters

After the identification of the first OR genes, a number of genomic analyses have been performed to elucidate their organization in the genome by physical mapping. More recently, the complete genome sequencing of diverse species has allowed different groups to perform the precise analysis of the distribution of OR genes in whole genomes.

OR genes are organized in clusters, i.e., genomic regions containing OR genes duplicated in tandem. The first well-studied cluster was located on human chromosome *17p13.3* (Ben-Arie *et al.*, 1993; Glusman *et al.*, 1996, 2000; Sosinsky *et al.*, 2000; Fuchs *et al.*, 2001; Lapidot *et al.*, 2001; Menashe *et al.*, 2002). Other regions were also investigated thereafter (Trask *et al.*, 1998a, 1998b; Brand-Arpon *et al.*, 1999; Lane *et al.*, 2001, 2002; Mefford *et al.*, 2001; Younger *et al.*, 2001; Amadou *et al.*, 2003). OR clusters may contain from 2 to 138 genes (for review, see Gaillard *et al.*, 2004a) with, in general, no non-OR genes interspersed. The human *17p13.3* cluster spans approximately 440kb and contains 17 OR genes (Sosinsky *et al.*, 2000). The average size of human OR clusters is approximately 300kb in a range 100kb to 1Mb with the largest greater than 3Mb. Some of them may contain more than 100 OR genes (Glusman *et al.*, 2001; Zozulya *et al.*, 2001). The OR repertoire is the result of multiple rounds of gene duplication to generate the first ancestral clusters that were subsequently duplicated in multiple locations in the genome (Glusman *et al.*, 2001). Duplications of entire and large genomic segments between chromosomes have been termed segmental duplication (Ohno, 1970; Ohno *et al.*, 1968; Eichler, 2001; Friedman and Hughes, 2001a, 2001b; Bailey *et al.*, 2002a, 2002b; Samonte and Eichler, 2002; van Geel *et al.*, 2002) in contrast to the duplication of a single gene or a whole genome (the tetraploidization process). As a consequence of the dynamics of OR cluster formation, genes lying in the same locus or cluster are closely related (pertaining to the same family), but this does not exclude the possibility that different families may be represented in a single locus. Given that approximately 1000 OR genes (3–5% of all genes) are devoted to olfaction, the OR repertoire is the largest gene family in the genome of mammals and occupies as much as 30Mb, i.e., 1% of the genome.

4.08.3.2 Distribution of the OR Gene Repertoire in Humans

The first picture of the OR gene distribution in the human genome was established before the human

genome was sequenced (Rouquier *et al.*, 1998b). The authors utilized a combination of fluorescence *in situ* hybridization (FISH) analysis, using consensus OR probes to identify the different OR loci on metaphase chromosomes, and the PCR cloning of a number of OR genes, using as templates individual chromosomes sorted by flow cytometry and degenerate OR primers (Ben-Arie *et al.*, 1993) derived from the most conserved OR regions (TM2 and TM7). This analysis showed that:

1. OR genes are distributed in more than 50 loci on virtually all chromosomes except chromosomes 20 and Y.
2. OR genes are not evenly distributed but are preferentially located in subtelomeric regions, which are known as sites for genetic recombination/transposition, and to a lesser extent into pericentromeric regions.
3. Sequence analyses indicate that the OR family expanded by inter- and intrachromosomal duplications.
4. Approximately 70% of the genes are nonfunctional pseudogenes, i.e., whose coding region (open reading frame or ORF) is disrupted by deleterious mutations such as frameshift mutations (insertions or deletions that change the right reading frame in any part of the protein) or nonsense mutations (introducing stop codons leading to truncated proteins).

This latter observation was unexpected and led the authors to hypothesize that there is a parallel between a reduced sense of smell (humans are considered as microsmatic with respect to macrosmatic dogs or rodents) and a reduction in the functional fraction of the OR repertoire. In the same study, it was demonstrated that for some OR pseudogenes, the same mutations were conserved between humans and chimpanzees, meaning that the pseudogenization process occurred before the two species diverged.

Other work confirmed and detailed these data, particularly on the telomeric nature of the OR loci and their role as founders of the present repertoire (Trask *et al.*, 1998a, 1998b; Linardopoulou *et al.*, 2001; Mefford *et al.*, 2001; Mefford and Trask, 2002). At the same time, after sequencing the human genome was nearly complete, two major studies (Glusman *et al.*, 2001; Zozulya *et al.*, 2001) used database mining and sequence analysis to precisely establish a complete genomic map of the OR gene repertoire and its evolutionary origin as well as the sequence of all the OR genes. ORs are distributed in 17 families and dispersed in more than 50 chromosomal locations. OR pseudogenes represent approximately 63% of the gene repertoire, resulting in a functional set of approximately 350 genes. A surprising characteristic of the human repertoire is the presence of a cluster of fishlike class I ORs on chromosome 11. This cluster contains approximately 102 class I ORs, and 52% of them are pseudogenes compared to the more than 75% for the class II, meaning that these genes probably have a functional significance and are not evolutionary relics as was previously supposed. This cluster is actually the ancestral cluster of the whole OR gene repertoire. It first duplicated locally to generate a tetrapod-specific class II OR cluster that in turn was duplicated to the long arm (q arm) tip of chromosome 1 (Figure 2). This chromosome 1 cluster was then duplicated in multiple locations in the genome to generate the complete OR repertoire (Giorgi *et al.*, 2003; Glusman *et al.*, 2001; Zozulya *et al.*, 2001; Gaillard *et al.*, 2004a). Chromosome 11 is therefore the ancestral chromosome of the OR gene repertoire and it contains nine clusters and accounts for approximately 42% of the total number of OR genes. Two databases have compiled these results (for review see Mombaerts, 2001b): the Human Olfactory Receptor Data Exploratorium (HORDE) and the Olfactory Receptor DataBase (ORDB). Other analyses were then published which gave slightly different results (Niimura and Nei, 2003; Malnic *et al.*, 2004). In these publications, the authors count 339–388 intact OR genes and 297–414 pseudogenes, for a total of 636–802 genes located in approximately 51 loci, indicating that 47–52% are pseudogenes. Nevertheless, analyses of the HORDE database tend to consider 1100 human OR genes or more with a pseudogene count comprised in the 63–67% range (Safran *et al.*, 2003; Olender *et al.*, 2004). However, the pseudogene count could be higher since only OR genes with a disrupted ORF were scored, suggesting that nonsynonymous mutations (nucleotide mutations, in general on the first and second base of a codon, that produce amino acid changes that do not disrupt the ORF) could lead to nonfunctional ORs. For example, it has been shown that the replacement of the Arg residue of the DRY motif led to nonfunctional ORs (Gaillard *et al.*, 2004b) and that this change was found in 11% of human ORs (Young *et al.*, 2002), suggesting that the functional human OR repertoire could be at least 11% lower than the theoretical count, leading to approximately 300 functional human genes. As we will see further, among terrestrial mammals, humans possess the highest pseudogene content. For unknown reasons, segmental duplication events have even expanded the human OR 7E gene family

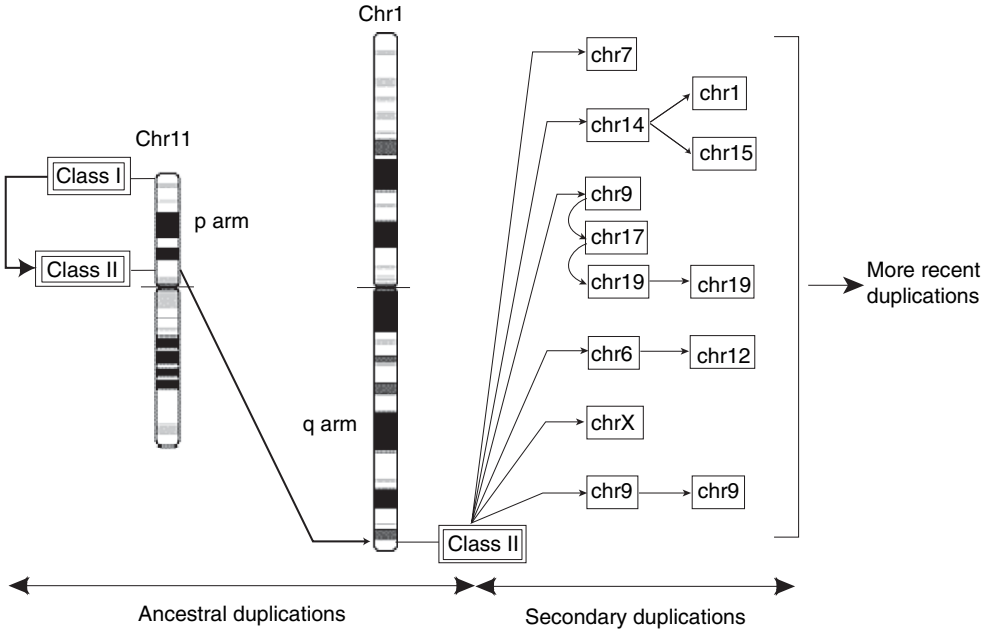

Figure 2 Generation of the OR gene repertoire in the human genome. The ancestral clusters are double boxed. On chromosome 11, the initial duplication of the class I cluster that generated the first class II cluster is indicated. Class II repertoire originated from the duplication of the chromosome 11 class II cluster on chromosome 1, followed by a series of other duplications on other chromosomes. Adapted from Glusman, G., Yanai, I., Rubin, I., and Lancet, D. 2001. The complete human olfactory subgenome. *Genome Res.* 11, 685–702.

that contains approximately 88 genes with a pseudogene count of more than 92% in more than 35 genomic regions (Newman and Trask, 2003). The pseudogenization process accelerated in the human lineage, since it has been shown that humans accumulated OR pseudogenes about fourfold faster than any other species tested (Gilad *et al.*, 2003b).

4.08.3.3 The OR Gene Repertoire in Mouse and Dog

The OR gene repertoire was also investigated thereafter in two macrosmate species (good smellers): the mouse and the dog. These observations are particularly interesting when compared to those of humans, who are considered poor smellers.

4.08.3.3.1 Mouse The mouse offers several advantages for studying ORs:

1. It is a laboratory animal widely used for *in vivo* studies.
2. It is a macrosmatic mammal.
3. Its genetics is known and many mutant mouse lines are available.
4. Its genome is entirely sequenced.

Different studies have shown that the mouse MOE was compartmentalized in four different zones in which different sets of ORs were randomly expressed (Ressler *et al.*, 1993, 1994; Vassar *et al.*, 1993, 1994; Strotmann *et al.*, 1994). The first study of the mouse OR gene repertoire (Sullivan *et al.*, 1996) used 21 OR genes expressed in the four zones of the MOE to study OR gene distribution by genetic analysis. The authors found that OR genes are clustered in multiple loci that lie in paralogous regions generated by duplications. This model predicted what was later shown by database mining and sequence analysis. However, if database searching revealed that mouse ORs are organized in the genome similarly to humans, some important differences emerged (Young *et al.*, 2002; Zhang and Firestein, 2002). Indeed, the mouse genome contains approximately 1500 OR sequences (compared to ~960 in humans) and only 20% are pseudogenes, giving a functional repertoire in mice approximately three times larger than that of humans. Mice possess more than 850–1200 intact ORF-containing genes that map to only 46 genomic locations with very few to subtelomeric or centromeric bands. Also, the mouse gene repertoire seems more compact (less divergence between genes) than in humans, suggesting a rapid evolution/degeneration of the human

repertoire. Most of the characteristics found in humans were also found in mouse, that is:

1. OR genes are distributed on all chromosomes except 12 and Y in a number of subfamilies (228).
2. Roughly 140 class I OR genes are present on chromosome 7 in a region that is syntenic to human chromosome 11.
3. Most clusters are found at syntenic human locations, indicating that they predate primate–mouse divergence (Young *et al.*, 2002).

Another recent study (Godfrey *et al.*, 2004) presented similar data, i.e., approximately 1200 genes among which 24% are pseudogenes. As previously shown, the authors point out that most of the subfamilies are encoded by genes at a single chromosomal locus. As a result of the repertoire evolution/specialization, 22 subfamilies (29 ORs) are found only in humans, whereas 84 (177 ORs) are present only in mouse, and 150 are common to both species.

4.08.3.3.2 Dog Dogs also present several advantages for studying molecular genetics and olfaction. They were domesticated recently (~10000 years ago) and the numerous strains that present readily different morphotypes, sizes, and behaviors are the result of selective breeding, leading to the selection of particular genotypes that are valuable models for the study of genetic diseases (Ostrander *et al.*, 2000; Ostrander and Kruglyak, 2000; Ostrander and Comstock, 2004). On the other hand, all dogs are considered as macrosmatic animals even if they display a great heterogeneity in behavioral traits. The olfactory sensitivity of dogs is empirically known to be much higher than that of humans (Marshall *et al.*, 1981; Smith *et al.*, 2001). For example, trained animals are able to find hidden objects (drugs, explosives, food) or buried people after natural disasters such as avalanches or earthquakes (Ashton and Eayrs, 1970; Komar, 1999).

Different reasons have been proposed to explain the differences between the olfactory performance of dogs and humans. First, dogs have a MOE surface up to 20 times larger than that of humans (Moulton, 1967; Moulton *et al.* 1970; Issel-Tarver and Rine, 1997). This implies that the population of olfactory neurons is larger and might express a higher number of ORs, allowing the animal to develop a better olfactory sensitivity. Second, the brain structures devoted to olfaction, particularly the olfactory bulb, are substantially larger than in microsmatic primates (Stephan *et al.*, 1988). Third, as in the case of mouse, one might expect a high number of functional OR genes.

The dog OR repertoire was first studied by genomics and hybridization studies to assess whether dog OR genes were similar to those of human and mouse, also organized in clusters lying in syntenic regions to mouse, and conserved during evolution (Issel-Tarver and Rine, 1996, 1997; Carver *et al.*, 1998). The complete analyses came recently from the first release of the dog genome sequence (Quignon *et al.*, 2003; Olender *et al.*, 2004). The dog OR repertoire contains approximately 1200 OR genes that are distributed on 24 chromosomes ($n=39$) in 37 loci, and the fraction of pseudogenes is estimated to be 12–18%, similar to the range found in mouse. It seems that this percentage corresponds to the lower value in the gene repertoire of good smellers. Fishlike class I ORs occupy approximately 19% of the repertoire compared to approximately 12% in humans and mouse. The same 17 families are found, and 34 subfamilies are specific to dogs.

In summary, the OR repertoires of humans, mice, and dogs are composed of homologous receptor genes that are organized similarly in the genome. The main information is that there is a striking difference between macrosmates and microsmates, i.e., a higher number of OR genes with a low pseudogene content in macrosmates so that the functional repertoire of macrosmates is more than three times larger than that of microsmates. This difference correlates with the olfactory performance of these species.

4.08.4 Evolution of the OR Gene Repertoire

Starting from the observations cited above, it was interesting to determine whether the loss of functional genes (above the threshold of 20% pseudogenes) was specific to humans and if it was possible to trace the pseudogenization process during evolution. This study naturally focused on primates, since apes (higher primates) were not thought to rely on their sense of smell as mice or dogs do. Preliminary observations showed that some deleterious mutations were conserved from macaque (Old World monkey) to humans, suggesting that particular OR pseudogenes predated the divergence of these species (Rouquier *et al.*, 1998b). At the same time, the analysis of an OR cluster located on human chromosome 3 indicated that orthologous loci were found in syntenic regions of apes (chimpanzee, gorilla, and orangutan), suggesting a similar genomic organization (Trask *et al.*, 1998a, 1998b; Brand-Arpon *et al.*, 1999;

see The Evolution of Neuron Types and Cortical Histology in Apes and Humans). The study of a particular OR gene located on human chromosome 11 revealed a conservation among apes and a localization in syntenic regions. A prominent feature is that it was recently inactivated in humans (pseudogene) by a single deleterious stop mutation (Rouquier *et al.*, 1998a). This mutation was found in all the human populations tested, suggesting that it appeared during the divergence of humans from other apes 4–5 Mya. This observation indicated that the human OR repertoire is still evolving. Later, functional studies showed that the human gene probably incurred additional nonsynonymous mutations (Gaillard *et al.*, 2002, 2004a). The complete analysis in apes of the evolution of the OR gene cluster localized on chromosome *17p13.3* in humans has made it possible to analyze the dynamics of the evolutionary process (Sharon *et al.*, 1998, 1999). A comparison between OR genes in the cluster (paralogues) and between orthologous pairs of the different species indicated that in addition to duplications, gene conversion events are responsible for the evolution of the OR repertoire in the different species. Furthermore, this cluster contains 40% pseudogenes in humans and ape species, with some pseudogenes common to all species. From these observations, the decline of the OR repertoire seems to have occurred approximately 10 Mya before apes diverged. A survey of the OR gene repertoire of different primate species has permitted subsequent evaluation of the pseudogene content in most primate species (Rouquier *et al.*, 2000). This study indicated an increase of the pseudogenization process in humans (pseudogenes represent 70% of the OR gene repertoire), with respect to apes (~45%), Old World monkeys (~27%), and New World monkeys (2%), whereas prosimian lemurs also have a high pseudogene content (~37%) (see the phylogenetic tree in Figure 3). Although this sampling was biased by the PCR primers used for pulling out the OR genes, the general information indicated that there is a progressive loss of functional OR genes from Old World monkeys to humans. Humans present an acceleration in the pseudogenization level with more than 60% pseudogenes. In contrast, New World monkeys seem almost devoid of pseudogenes. This limit between New World monkeys and higher primates parallels that observed for pheromone detection, i.e., New World monkeys are the latest primates to possess an intact and functional VNO, the site of expression of pheromone receptors (see Giorgi and Rouquier, 2002 and references therein), whereas higher primates do not possess this organ. New World monkeys seem to rely heavily on olfaction by using both a VNO-mediated pheromone detection and an olfactory system similar to that of mice or dogs. A more accurate analysis (Gilad *et al.*, 2004) has been done recently on 19 primate species. The results are summarized in Figure 3. Actually, New World monkeys and lemurs have the lowest pseudogene content (~15–20%), similar to that of mice, whereas there is a striking acceleration in OR pseudogenization from Old World monkeys to humans. Surprisingly, the authors report that among New World monkeys, the howler monkey presents a pseudogene count similar to Old World monkeys (Figure 3). Remarkably, the howler monkey is the only New World monkey to possess full trichromatic vision, as do Old World monkey and apes. The authors suggest that the decline of the olfactory repertoire occurred concomitant with the acquisition of trichromatic vision. This observation is very interesting in terms of selective pressure and olfactory needs with respect to vision, and is in accordance with the studies cited above, but one cannot rule out that this could be coincidental. Another study from the same group compared the evolutionary forces that shaped the olfactory repertoires of humans and chimpanzees (Gilad *et al.*, 2003a). In both species, OR pseudogenes evolve neutrally, whereas intact OR genes are submitted to purifying selection in chimpanzees and to positive selection in humans. The authors suggest that selective pressure acted differently because of differences in lifestyle that led to different sensory needs. However, a recent article using the first release of the chimpanzee genome refuted the previous findings on the selective pressures, i.e., there may be a purifying selection over half the repertoire in humans and chimpanzees but no general positive selection (Gimelbrant *et al.*, 2004). Nonetheless, the very recent comparison of the OR repertoire of human and chimpanzee has allowed a refinement of these data (Gilad *et al.*, 2004). First, the OR pseudogene fraction in the human and chimpanzee is 56% and 50%, respectively, or 51% and 41% if the large 7E subfamily that contains only pseudogenes is excluded from the analysis. The number of OR genes in chimpanzee is approximately 26% higher than in human. Second, several subfamilies are either specific to chimpanzee or to human, and some genes are under positive selection in either species, and would therefore be likely candidates for adaptations, as a result of species-specific sensory requirement.

4.08.5 Conclusions

Olfaction requires the binding of odorants to specific receptors (ORs). ORs are encoded by the largest

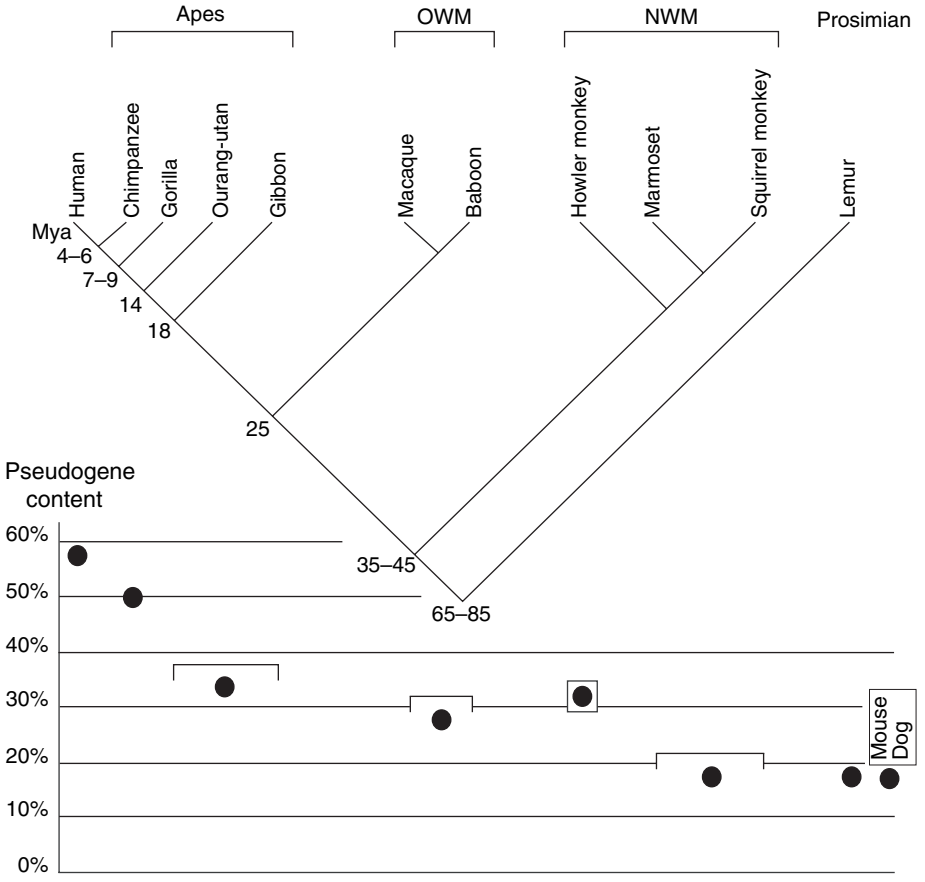

Figure 3 Schematic phylogeny tree (top panel) of the main primate branches used in the study of OR repertoire evolution. The times of divergence are indicated in Mya. OWM, Old World monkeys; NWM, New World monkeys. Lower panel, pseudogene content of the OR repertoire of the species indicated above. The dot for howler monkey is squared. Mouse and dog are indicated for comparison. Adapted from Gilad, Y., Wiebe, V., Przeworski, M., Lancet, D., and Paabo, S. 2004. Loss of olfactory receptor genes coincides with the acquisition of full trichromatic vision in primates. *PLoS Biol.* 2, E5.

multigene family (~1000 members) in the genome of mammals and occupies as much as 1% of the genome. However, there is a rapid decline in the functional fraction of the repertoire in primates, with humans having more than 55% nonfunctional pseudogenes. The pseudogenization process occurred mostly during primate evolution when Old World monkeys and higher primates diverged from New World monkeys. In parallel, genome analyses of macrosmatic mice and dogs revealed a higher number of OR genes with a pseudogene fraction of 20% or less leading to approximately three times more functional ORs than in humans. Although the functional repertoire is reduced in higher primates, most of the OR subfamilies are represented, suggesting that they probably sense the same odor spectrum as mice or dogs but with a reduced sensitivity. Obviously, the decline of the OR repertoire has been correlated to the olfactory ability of the different species. Higher primates are considered as poor smellers compared to dogs, and there is a strong parallel with their OR gene repertoire, even if genes are not the only cause of their reduced olfactory capacities. Indeed, selective pressure has played a major role. For example, when humans developed vision, bipedal posture (verticalization), and language, olfaction was relegated as a secondary need for survival (Shepherd, 2004). However, a number of psychophysical studies comparing the olfactory performance of different species such as primates, dogs, or rodents assume that humans display similar olfactory ability to the other species and sometimes even better, suggesting that humans (and higher primates) do not have a reduced sense of smell (Laska *et al.*, 2000, 2004). However, most of these studies use the sniffing of individual odorants and the data between species are probably very difficult to compare and control. Even if individual measures are likely correct, their interpretation when comparing species may be not an exact reflection of their respective olfactory performance (Giorgi and Rouquier, 2000). It is indeed

difficult to imagine humans detecting hidden explosives or people buried under two meters of snow by their sense of smell, even after intensive training.

4.09 The Vomeronasal Organ and Its Evolutionary Loss in Catarrhine Primates

K P Bhatnagar, University of Louisville, Louisville, KY, USA
T D Smith, Slippery Rock University, Slippery Rock, PA, USA

Glossary

accessory olfactory bulb	A miniature, somewhat disorganized, but discreet, part of the forebrain, situated in a posterodorsal position within the olfactory bulb itself. It is the first site in the central nervous system to receive the vomeronasal neuroepithelial projections.
anthropoid	Taxa of the hyporder Anthropoidea, comprising New World monkeys, Old World monkeys, apes, and humans.
catarrhines	Taxa of the infraorder Catarrhini, comprising Old World monkeys, apes, and humans.
cercopithecoid	Old World monkeys.
haplorhine	Primates of the suborder Haplorhini, which include catarrhines, platyrrhines, and tarsiers.
hominoid	Apes and humans.
platyrrhine	Taxa of the infraorder Platyrrhini, comprising the New World monkeys.
receptor-free epithelium	Vomeronasal organ epithelium that is a columnar (frequently pseudostratified and/or ciliated) epithelium, but no receptor neurons.
strepsirrhine	Among primates, taxa of the suborder Strepsirrhini, comprising lemurs and lorises.
vomeronasal neuroepithelium	Vomeronasal organ epithelium that contains receptor neurons.
vomeronasal organ	Bilateral, peripheral receptor organs for the accessory olfactory (vomeronasal) system, a neural system linked to perception of mammalian pheromones.

4.09.1 The Vomeronasal Organ

4.09.1.1 Introduction

The vomeronasal organ (VNO) is a tetrapod innovation that functions in pheromonal and other chemosensory functions (see Evans, 2003; Halpern and Martínez-Marcos, 2003). Two functional categories of VNO are found in mammals: (1) chemosensory, with elements summed up as a VNO complex, and (2) a nonchemosensory homologue as in chimpanzee or humans (Smith *et al.*, 2001a, 2002). A generalized mammalian VNO complex comprises: (1) an epithelium arranged around a lumen; (2) a lamina propria containing blood vessels, glands, nerve fascicles (VNN), paravomeronasal ganglia; and (3) a cartilaginous or osseous capsule (Figures 1a, 1b, 1i, and 2a–2d). The tubular border comprises a ventromedial microvillar receptor neuroepithelium (VNNE) and a dorsolateral, ciliated receptor-free epithelium (RFE; Figure 1b). Posteriorly, the vomeronasal lumen ends blindly, but anteriorly it either leads to the nasopalatine duct, or opens directly into the nasal vestibule. The nerve fascicles ascend

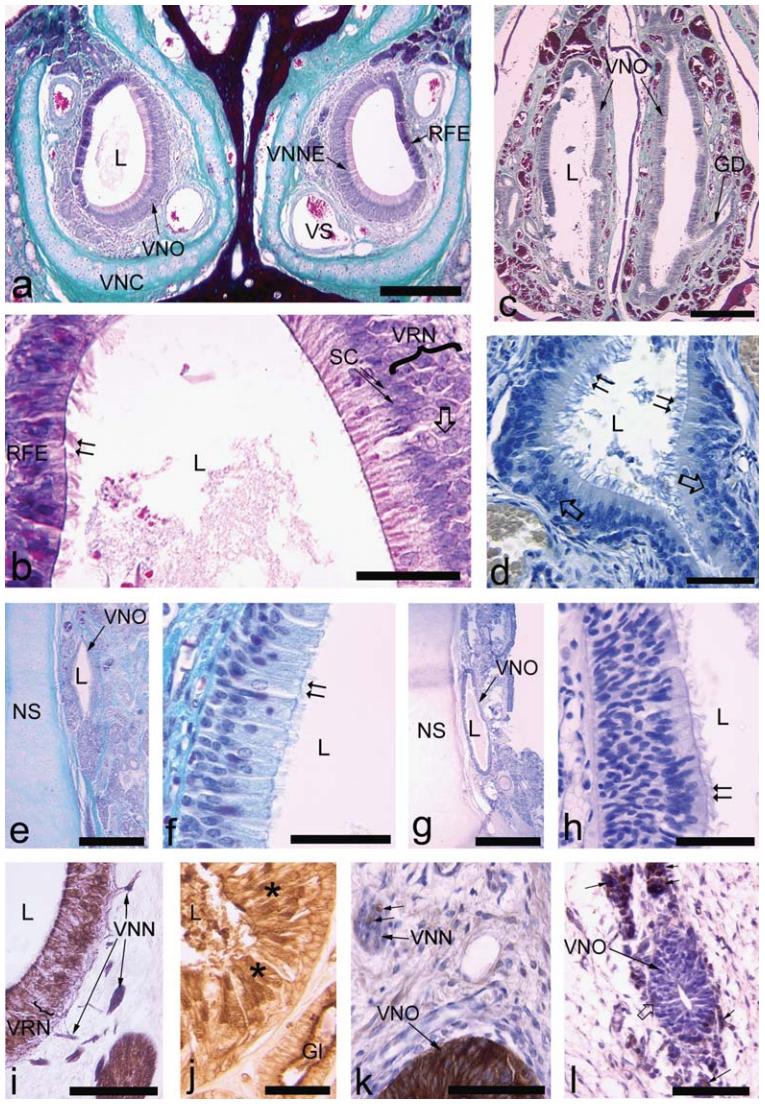

Figure 1 The vomeronasal complex of strepsirrhines such as *Cheirogaleus medius*, a, includes VNO, complete with VNNE (medially) and RFE (laterally), venous sinuses (VS), VNN, glands, and a surrounding capsule (vomeronasal cartilage, VNC). b, The RFE of this species is ciliated (double arrows) while the VNNE possesses an apical row of supporting cell nuclei (SC) and multiple rows of vomeronasal receptor neurons (VRN), which possess round, pale nuclei (open arrow). In adult platyrrhines (c, *Saguinus oedipus*), the medial/lateral differentiation of the epithelium is not evident, and at high magnifications (d) VRN (open arrows) and microvilli (double arrows) can be detected on all sides. In chimpanzees (*Pan troglodytes*, e) and humans (g), VNO homologues are found in an atypical position, displaced superiorly from the base of the nasal septum (NS) and devoid of a cartilaginous capsule. The VNO epithelium in chimpanzees (f) and humans (h) is pseudostratified, columnar, ciliated (double arrows). Reactivity of VNOs with lectins such as UEA-1 (i–l) differs among primates. VRN and VNN are highly reactive in strepsirrhines (i, neonatal *Eulemur macaco*), whereas in humans the mucins of cells resembling goblet cells (*) are strongly reactive (j, 2-year-old child). Presumptive neuron bodies in the VNO and within VNN are UEA-1-reactive in perinatal tamarins (k, *Saguinus geoffroyi*) and fetal humans (l, 9.5-week-old fetus). GD, gland duct; L, lumen. Scale bars: a, 250 μm; b, 50 μm; c, 500 μm; d, 70 μm; e, 500 μm; f, 50 μm; g, 1 mm; h, 50 μm; i, 100 μm; j, 50 μm; k, 70 μm; l, 70 μm.

in the nasal septal mucosa and reach the accessory olfactory bulb (AOB) through the cribriform plate. The AOB is found dorsally on the main olfactory bulb itself (Bhatnagar and Meisami, 1998).

The conclusion that the VNO mediates sociosexual behavior in mammals is supported by track-tracing studies in rodents showing vomeronasal connections to the amygdala and hippocampus and experimental removal of the VNO or VNN lesions (see Halpern and Martínez-Marcos, 2003). It is experimentally demonstrable that similar functions exist for the VNO of strepsirrhine primates (Aujard, 1997), although evidence for such behavioral links in New World monkeys is equivocal thus far. Among mammals, the VNO has been tied to the *Flehmen* behavior (see Evans, 2003, for review); among primates, this has only been observed in *Lemur catta* (Bailey, 1978). Other possible functions have not

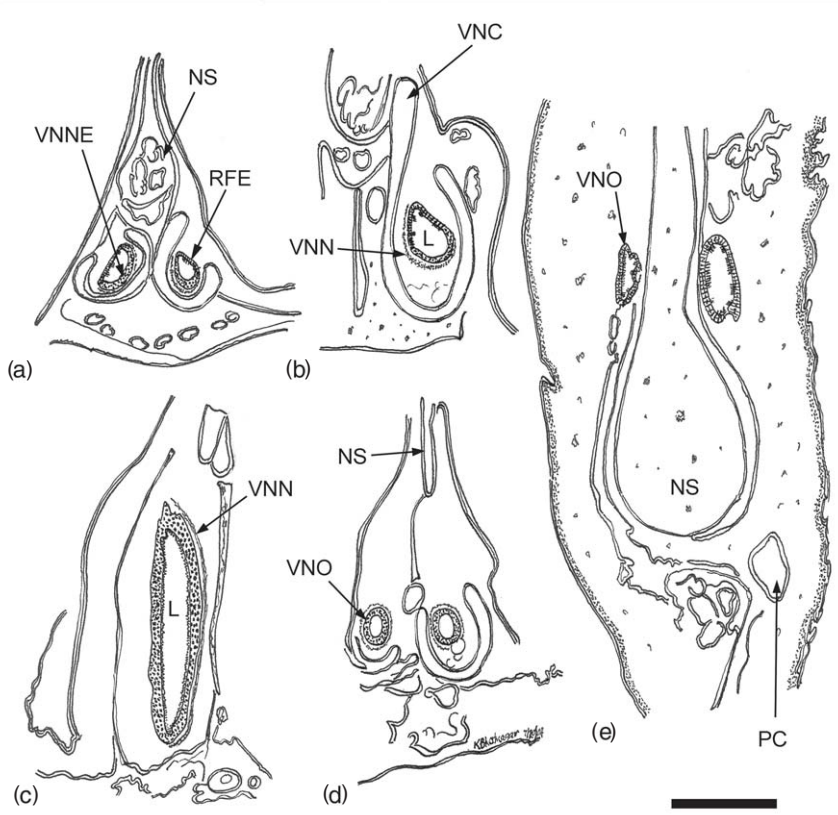

Figure 2 Schematic representations, via camera lucida tracings, of the vomeronasal complex in various primates. Strepsirrhines all have a complete vomeronasal complex (a, *Cheirogaleus medius*; b, *Otolemur crassicaudatus* (left side only)), including VNOs that possess a RFE, VNNE, VNN, and a surrounding vomeronasal cartilage (VNC). Platyrrhines (c, *Saguinus oedipus* (right side only); d, *Callithrix jacchus*) have VNOs with VNNE on all sides and possess VNN and a capsule. Catarrhines either lack a VNO entirely or possess a vestigial tubular VNO that lacks VNNE or VNN (e, *Pan troglodytes*). In such cases, the VNO is spatially separated from the paraseptal cartilages (PC), reduced homologues of the VNC. NS, nasal septum; L, lumen of VNO. Scale bar: 1 mm.

been carefully considered as yet (see Halpern and Martínez-Marcos, 2003). In humans and chimpanzees, the nonchemosensory homologue of the VNO likely serves as a secretory channel, funneling gland secretions to the nasal cavity (Smith *et al.*, 2002).

4.09.1.2 VNO Variability in Mammals

A functional VNO complex is seen in marsupials, rodents, phyllostomid bats, primates except the catarrhines, and all other mammals except the whales. Among placental mammals, taxa of entire suborders likely possess a functional VNO (e.g., species of Rodentia and Carnivora) i.e., with axonal connections to the forebrain (see Halpern and Martínez-Marcos, 2003). The order Chiroptera, in contrast, is characterized by extreme inter- and intrafamilial variations in the VNO complex (Bhatnagar and Meisami, 1998). In primates, such extreme variations have not been reported within families, but are likely to exist at subordinal taxonomic levels (see below).

4.09.2 The Primate VNO

4.09.2.1 Strepsirrhine VNO Complex

Although some of the 23 genera within this order remain uninvestigated, positive evidence of a functional accessory olfactory system exists for every family in this suborder (Schilling, 1970; Stephan *et al.*, 1982; Smith *et al.*, 2001a). Variations of the VNO within Strepsirrhini may only involve epithelial differences. The thickest VNNE is observed in the VNO of cheirogaleids such as *Microcebus murinus* (Schilling, 1970), *Phaner furcifer* (see Evans, 2003), and *Cheirogaleus medius* (T. D. Smith, unpublished observations; Figures 1a and 1b). *Cheirogaleus medius* exhibits a VNNE comprising multiple rows of receptor neurons reminiscent of the VNNE of

rodents. The RFE comprises pseudostratified, columnar, ciliated epithelium. Departures from this morphology have so far included mainly VNNE thickness and lack of cilia in some strepsirrhines (T. D. Smith, unpublished observations). In any event, it can be assumed that all strepsirrhines are endowed with a functional VNO complex.

4.09.2.2 Haplorhine VNO Complex

4.09.2.2.1 Platyrrhines and tarsiers An AOB has been reported in 13 of the 16 platyrrhine genera (Stephan *et al.*, 1982), and tarsiers. Switzer *et al.* (1980) noted an accessory olfactory formation (AOF/AOB) in several strepsirrhines and New World haplorhines, and the through course of the dorsal part of the lateral olfactory tract in relation to the AOF. Switzer *et al.* (1980) have considered the through condition as derived and the under condition of the AOF as primitive (see Evolution of the Neural Circuitry Underlying Laughter and Crying, Evolution of Vertebrate Olfactory Subsystems).

In all platyrrhines studied to date, VNOs have a VNNE (e.g., Smith *et al.*, 2001b, 2003a), although in adults the overall epithelial distribution in the VNO differs from that of strepsirrhines. Adult tarsiers have similar VNO traits. In contrast, our studies on prenatal and perinatal primates have revealed a similar partitioning of sensory and nonsensory divisions of the VNO epithelium among strepsirrhines, some platyrrhines, and tarsiers (Smith *et al.*, 2003a, 2003b; Dennis *et al.*, 2004). Thus, some haplorhines have a transient progression from the primitive VNO morphology to an atypical morphology common to adult platyrrhines and tarsiers (i.e., the VNO lumen is bordered by VNNE on all sides). We hypothesized that the adult morphology of tarsiers and platyrrhines probably reflects that of a haplorhine common ancestor (Smith *et al.*, 2003b). This altered VNO morphology could represent a synapomorphy of Haplorhini (see hypothetical node 'a' on the cladogram shown in Figure 3).

4.09.2.2.2 Catarrhine VNO complex Of the 65 genera of extant primates, 27 (40%) belong to catarrhines, most of which are confined to Africa, Asia, Southeast Asia, and associated islands. Whereas not many catarrhines have been examined by serial sectioning of the nasal septum for VNO presence/absence, 41 extant primate genera were studied for the presence/absence of an AOB (Switzer *et al.*, 1980; Stephan *et al.*, 1982; Table 1); of these, 13 genera (all catarrhines) lacked an AOB. The implication is clear: no extant catarrhines possess a functional accessory olfactory system. Interestingly, the lack of an AOB does not preclude the presence of a nonfunctional VNO (see below). However, two hominoids that possess VNOs are known to lack an AOB (Stephan *et al.*, 1982; Bhatnagar *et al.*, 1987) or VNN in the lamina propria (Bhatnagar and Smith, 2001; Smith *et al.*, 2002). Given this and other data on the VNO itself (see below), the adult hominoid VNO is an atavistic, nonchemosensory vestige.

Until recently, the VNO was reported to be postnatally absent in all apes (Jordan, 1972; Loo, 1973). Then, Smith *et al.* (2001a, 2002) reported homologous structures in postnatal chimpanzees. This has not been investigated in the other hominoids, although it was vaguely suggested that VNO homologues exist perinatally in other hominoids as well (cf. Evans, 2003). Regarding the presumptive hominoid VNO (Figures 1e–1h and 2e), which we hypothesize to be similar in morphology for all hominoids at some postnatal stage, there are positional and microstructural deviations from all other primates. First, the VNO is positionally displaced to a superior (dorsal) position relative to what is seen in any other primate VNO (Figures 1f, 1h, and 2c). The homology of this structure with the VNO of other mammals becomes apparent by comparing late embryos (Smith and Bhatnagar, 2000). Instead of a chemosensory neuroepithelium, a ciliated, pseudostratified columnar epithelium is found (Figures 1f and 1h) (Bhatnagar and Smith, 2001; Smith *et al.*, 2001a, 2001b, 2002).

4.09.2.3 Overview: Morphological Variants of the VNO in Primates

Smith *et al.* (2001b, 2003a) have listed five morphological variants of the primate VNO, including:

1. well-developed sensory epithelium (see description of strepsirrhine VNOs, above);
2. interrupted sensory epithelium (Figures 1c and 1d);
3. sensory epithelium only (Figure 2d);
4. displaced VNOs (Figures 1e–1h); and
5. VNO absence.

Although not all species have been examined, extant catarrhines have been found to exhibit either displaced vestigial VNOs (in at least some hominoids) or none at all (in all Old World monkeys).

4.09.2.4 VNO Functionality in Primates

4.09.2.4.1 Functional categories of VNO

4.09.2.4.1.(i) Chemosensory VNO As long as components of a VNO complex are present (see Figures 1 and 2, Table 1), we have defined it anatomically as a functional (chemosensory) VNO. Even

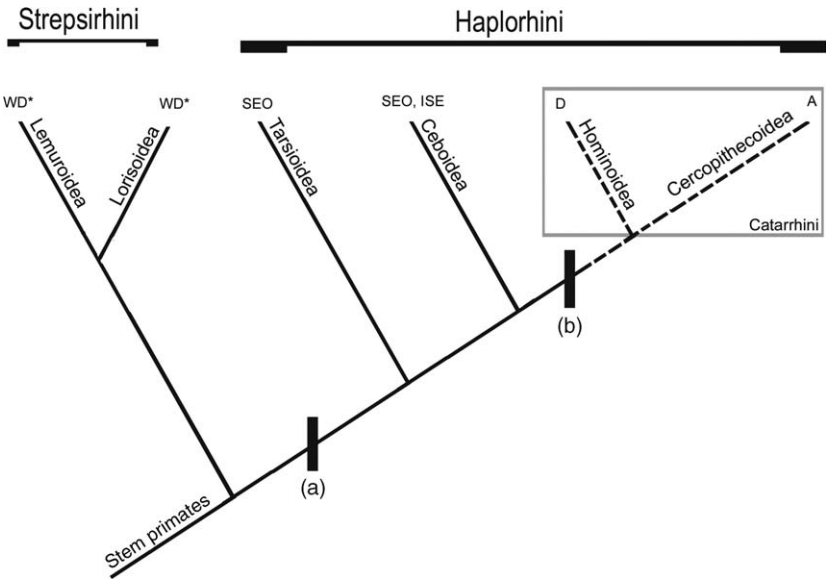

Figure 3 Cladogram based on strepsirrhine-haplorhine subordinal taxonomy (see Fleagle, 1999) showing the distribution of VNO morphologies among extant primates. All strepsirrhines possess well-developed (WD) VNOs with a neuropeithelium and RFE, as in most mammals. Extant tarsioids and ceboids possess VNO epithelium that is either sensory alone (SEO) or sensory epithelium interrupted by patches of RFE (ISE, interrupted sensory epithelium). In the extant Catarrhini (box), at least two hominoids possess a superiorly displaced, nonchemosensory VNO homologue (D), whereas all adult cercopithecoids appear to lack a VNO entirely (A). Node (a) indicates a proposed synapomorphy of Haplorhini (presumably including stem catarrhines), the absence of a distinct RFE. Node (b) indicates a proposed synapomorphy of Catarrhini, the loss of a VNNE. * Experimental evidence for VNO function is firm only for strepsirrhines.

though isolated chemoreceptor cells are distributed sparsely throughout the nasal cavity, the category of chemosensory VNO is distinguished by the presence of a VNNE with connections to the AOB. This stands in contrast to the sparse cells with neuronal characteristics described in the human VNO (Witt *et al.*, 2002). It must be emphasized that functionality is frequently assumed for platyrrhines; there is no anatomical evidence to refute this. However, experimental evidence that the VNO functions similarly in platyrrhines as in strepsirrhines is presently lacking (Table 1).

4.09.2.4.1.(ii) Nonchemosensory VNO In the adults of a few catarrhine VNOs examined (e.g., human, chimpanzee), only a ciliated duct has been observed. This duct clearly drains glandular secretions to the nasal chamber, but lacks a VNNE (Smith *et al.*, 2002). Similar situations are anticipated in the other catarrhines that have not been studied carefully, at least in other hominoids.

4.09.2.4.2 Evidence for VNO functionality among extant primates The basic evidence for postnatal VNO functionality is the presence/absence of the VNO itself or the AOB. Although cercopithecoids lack both, the persistence of the VNO homologue in humans, for instance, has fueled much controversy (see Bhatnagar and Smith, 2001; Wysocki and Preti, 2004). Yet several lines of evidence (Table 1) indicate two generalizations: (1) all strepsirrhines possess a chemosensory VNO that functions, at least in part, in pheromone reception; (2) no extant catarrhines possess chemosensory VNOs as adults. Platyrrhines possess all neural structures essential for VNO chemoreception (Figures 1c, 1d, 2c, and 2d), yet immunohistochemical and experimental evidence only promote more questions regarding the true nature of VNO function in these monkeys (Table 1).

This discussion is limited to postnatal functionality. The role of the prenatal primate VNO as a pool of migratory neurons has been explored little (see Evans, 2003), and such cells are poorly known in nonhuman primates. However, it is clear that cells reactive to neuronal markers (Smith *et al.*, 2004) or lectins such as *Ulex-europeanus-1* (Evans and Griogorieva, 1994; T. D. Smith and K. P. Bhatnagar, unpublished data; Figure 1i–1l) are found in the VNO lamina propria and vomeronasal and terminal nerves of prenatal and infant primates.

4.09.2.5 Phylogenetic Implications

4.09.2.5.1 Fossil evidence The VNO complex is a soft tissue structure and therefore extracting fossil evidence is not easy. Interesting speculation has centered on Eocene primates and inferences about their rhinarial (soft tissue of external nose) and upper lip

morphology (Beard, 1988), although this has no direct bearing on VNO loss in Catarrhini. Recently, Rossie (2005) described a potential correlate of VNO function that is discernible based on osteology. Primates possessing a chemosensory VNO have a system of turbinals (from anterior to posterior, marginoturbinal–atrioturbinal–maxilloturbinal) that span from the margin of the bony nasal aperture to the nasal fossa proper. In this continuous series, muscles that attach to the most anterior turbinal (marginoturbinal) can affect airflow throughout the entire ventral (inferior) meatus, and therefore can affect access of nonvolatile chemostimuli, which preferentially travel in the ventral meatus. The nasal aperture of the nasopalatine duct, which provides a nasal access route to the VNO, is also located in the inferior meatus. Rossie (2005) noted that extant catarrhines have lost the atrioturbinal and thus, this path of chemostimulus access no longer exists. However, the continuous system of turbinals is present in some oligocene catarrhines (e.g., *Aegyptopithecus*), which may provide an important clue to the timing of VNO loss in cercopithecoids (Rossie, 2005).

4.09.2.5.2 Genetic evidence Among primates, genetic evidence supports the anatomical findings for the lack of a functional vomeronasal system in all catarrhines (Liman and Innan, 2003; Zhang and Webb, 2003). Most recently, such studies have focused on genes relating to function of the *TRPC2* ion channel, considered critical for accessory olfactory system functionality. Liman and Innan (2003) described evidence that an accumulation of mutated *TRPC2* genes has occurred since the divergence of catarrhines and platyrrhines, a finding consistent with the anatomical evidence (Dennis *et al.*, 2004; Table 1). Zhang and Webb (2003) asserted that *TRPC2* ion channels, and V1R pheromone receptors, were impaired about 23 Mya in primate evolution, before hominoids and Old World monkeys diverged. These findings have been interpreted as evidence supporting the hypothesis that sociosexual cues are detected via trichromatic color vision in Old World monkeys, and pheromonal communication is thus largely superfluous (and replaced) for this purpose. However, it is likely that some pheromonal communication occurs in catarrhine primates (Wysocki and Preti, 2004), even in the absence of a functioning vomeronasal system. Thus, functions usually attributed to this system are likely mediated by the main olfactory system in humans and other catarrhines.

4.09.3 Conclusions and Future Directions

Multiple lines of evidence are consistent with the hypothesis that the catarrhine VNO became nonfunctional (in pheromonal communication) prior to the divergence of the cercopithecoid and hominoid lineages (Smith *et al.*, 2001a, 2001b; Zhang and Webb, 2003; Rossie, 2005). At present, we speculate that the cercopithecoid-hominoid common ancestor possessed a VNO vestige similar to that seen in extant chimpanzees and humans (Smith *et al.*, 2001a, 2002). However, further investigation of the other extant hominoids (gibbons, orangutans, gorillas) is needed. If absent in these taxa (as previously claimed by Jordan, 1972; Loo, 1973), it would indicate that a postnatal VNO was lost in parallel in Old World monkeys and some hominoids.

4.10 The Evolution of the Cerebellum in Anthropoid Primates

J K Rilling, Emory University, Atlanta, GA, USA

Glossary

afferents	Incoming connections.
cerebellar vermis	The narrow, middle zone between the two hemispheres of the cerebellum.
dentate nucleus	The most lateral and largest of the cerebellar deep nuclei.
efferents	Outgoing connections.
hominid	Any living or extinct habitually bipedal hominoid, including members of the genus *Homo* and *Australopithecus*.
hominoid	Any living or extinct ape or human.
neocortex	A uniquely mammalian type of cerebral cortex involved in perception, thought, and reasoning, and consisting of six cytoarchitectonic layers.
premotor cortex	An area of cortex anterior to motor cortex, corresponding to Brodmann's area 6, that is involved in motor planning.

4.10.1 Anatomy of the Cerebellum

Much like the cerebrum, the cerebellum (Figure 1) consists of cortical gray matter overlying white matter within which lie subcortical nuclei, known as the cerebellar deep nuclei (Figure 2). However, in contrast to the six-layered cerebral cortex (see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates), the cerebellar cortex has only three layers. Within it, Purkinje cells are responsible for integrating excitatory and inhibitory inputs and providing output to the cerebellar deep nuclei, which in turn send projections out of the cerebellum (Figure 3). Thus, most cerebellar efferents originate in the deep cerebellar nuclei. In contrast to the cerebral cortex, cerebellar cortex is cytoarchitectonically homogenous and intercortical connectivity is minimal.

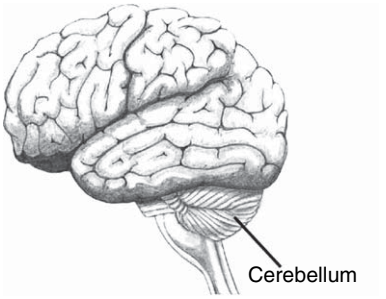

Figure 1 Location of cerebellum in lateral view of human brain. Reproduced from Memory Loss and the Brain. Copyright © Ann L. Myers/Memory Loss and the Brain.

The cerebellum is composed of four different anatomical regions: the flocculonodular lobe (or vestibulocerebellum), the vermis, the intermediate hemispheres, and the lateral hemispheres. The flocculonodular lobe is on the ventral surface of the cerebellum, abutting the brainstem. The vermis occupies the midline of the cerebellum and is separated from the cerebellar hemispheres by longitudinal furrows on either side. The intermediate portion of the hemispheres is just lateral to the vermis and just medial to the lateral portion of the hemispheres (Figure 3).

4.10.2 Cerebellar Connectivity and Function

4.10.2.1 The Flocculonodular Lobe

The flocculonodular lobe receives input from the primary vestibular afferents and projects back to the vestibular nuclei. This portion of the cerebellum

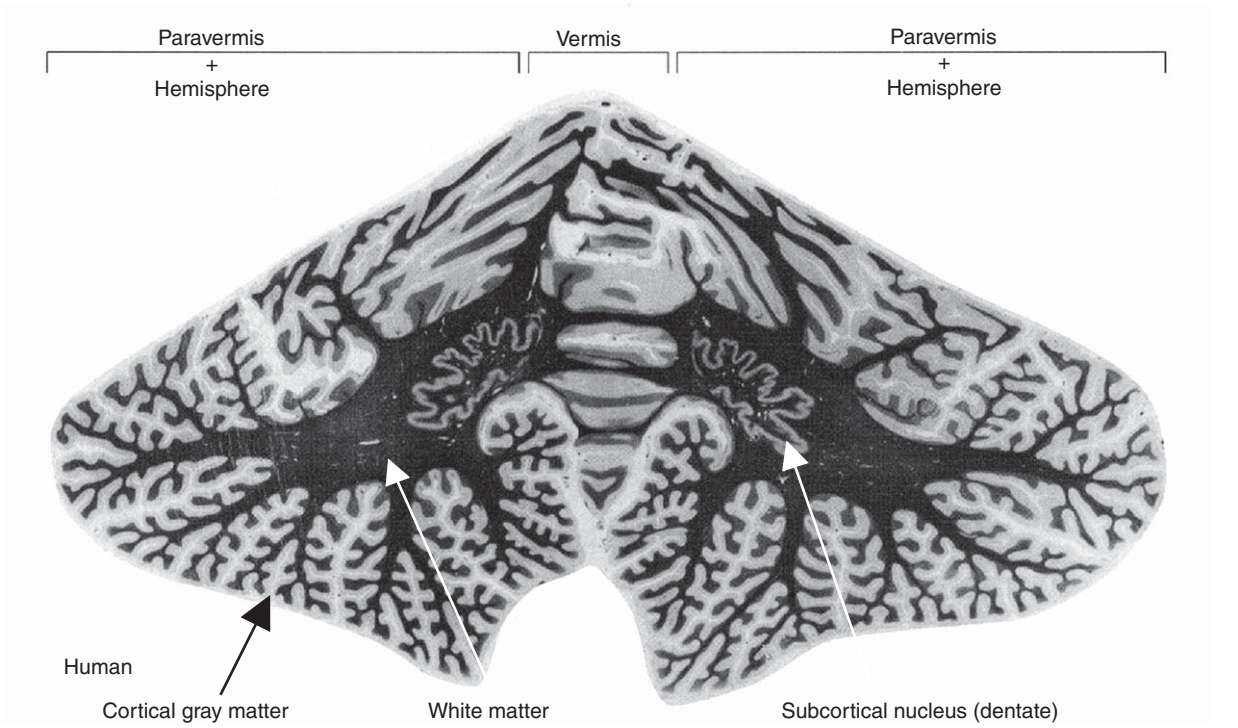

Figure 2 Cerebellar anatomy. Reproduced in full from Altman, J. and Bayer, S. A. 1997. Development of the Cerebellar System in Relation to Its Evolution, Structure and Functions. CRC Press.

governs eye movements and body equilibrium during stance and gait.

4.10.2.2 The Vermis

The primary sources of input to the cerebellar cortex of the vermis are the spinocerebellar tracts, which carry somatosensory information from axial and proximal body parts. This information is relayed from the cortex of the vermis to the most medial of the deep cerebellar nuclei: the fastigial nucleus. All of the deep cerebellar nuclei have both ascending (to midbrain, thalamus, and cortex) and descending (to brainstem and spinal cord) efferents. Fastigial efferents are predominantly descending, projecting to brainstem nuclei that control proximal muscles of the body and limbs (see Figure 3).

4.10.2.3 The Intermediate Hemispheres

The spinocerebellar tracts are also the primary source of input to the cortex of the intermediate hemispheres. The intermediate hemispheres relay information to the interposed cerebellar nuclei (globose and emboliform), which send both ascending and descending efferents to nuclei involved in coordination of distal limb muscles. The ascending projections reach the magnocellular portion of the red nucleus, which gives rise to the rubrospinal tract. Two somatotopic maps of the body are found in the cortex of the vermis and intermediate hemispheres (see Figure 3).

4.10.2.4 The Lateral Hemispheres

In contrast to the vermis and intermediate hemispheres, the lateral hemispheres receive little somatosensory input from the periphery. Instead, the main source of afferents to the cortex of the lateral hemispheres is the cerebral cortex. In macaques, these corticopontocerebellar fibers originate in motor, premotor, posterior parietal, cingulate, and prefrontal cortex and project to the lateral cerebellar hemispheres by way of the pontine gray matter (Brodal, 1978; Glickstein *et al.*, 1985; Schmahmann and Pandya, 1997). Output from the lateral hemispheres is directed to the most lateral of the deep cerebellar nuclei, the dentate nucleus. Most of the dentate's efferents ascend to either the parvicellular portion of the red nucleus or the ventrolateral thalamus, which in turn projects to motor, premotor, prefrontal, and posterior parietal cortices (Kelly and Strick, 2003), thereby forming a loop that links lateral cerebellar and cerebral cortex. Based on tract-tracing studies, Strick and colleagues have introduced the notion of closed cerebellar loops in which inputs from cerebral cortical areas are spatially segregated in both cerebellar cortex and the dentate nucleus. For example, projections from motor (e.g., BA4) and nonmotor (e.g., BA46) cortex

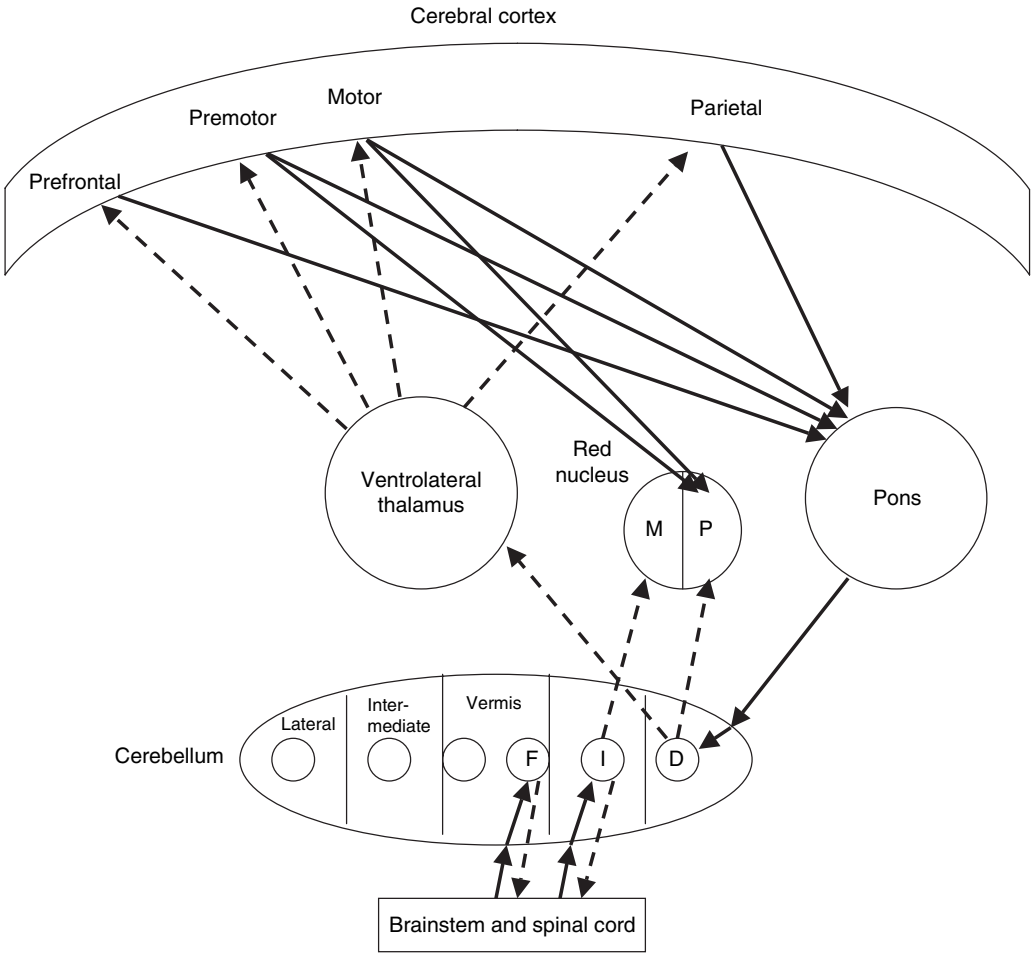

Figure 3 Schematic of cerebrocerebellar system showing prominent cerebellar afferents (solid lines) and efferents (dashed lines). M, magnocellular portion of red nucleus; P, parvicellular portion of red nucleus; F, fastigial nucleus; I, interposed nucleus; D, dentate nucleus.

have distinct, nonoverlapping representations in the cerebellum, both in the cortex (where they enter) and in the dentate nucleus (where they exit). Specifically, motor cortex projects to lobules IV–VI and nonmotor area 46 projects to crus II. In the dentate, the motor domain is dorsal and the nonmotor domain is ventral (Dum and Strick, 2003). The existence of these closed cerebellar loops is consistent with the suggestion that corticocortical projections are absent within the cerebellar cortex (Braitenberg *et al.*, 1997), in stark contrast to the cerebral cortex (see Figure 3).

Consistent with these anatomical data, evidence from neurological patients and functional neuroimaging experiments suggests that the lateral cerebellum of humans has both motor and nonmotor functions. Motor-related functions of the cerebellum include fine motor coordination, motor planning, and motor learning (Ghez and Thach, 2000). The cerebellum has also been implicated in a bewildering array of nonmotor functions, including sensory discrimination, spatial cognition, visuospatial problem solving, attention and attention switching, procedural learning, verbal working memory, verb generation, verbal fluency, lexical retrieval, syntax, semantic and phonological word retrieval, syntactic processing, and abstract reasoning (Dow, 1988; Leiner *et al.*, 1989; Courchesne *et al.*, 1994; Allen *et al.*, 1997; Desmond and Fiez, 1998; Schmahmann, 1998; Ghez and Thach, 2000; Rapoport *et al.*, 2000; Marien *et al.*, 2001). It seems unlikely that all of these processes can be subsumed under a single overarching function that the cerebellum performs. More likely, as originally suggested by Snider (1950), the cerebellum may be "the great modulator of neurologic function." That is, it improves the skilled performance of any cerebral area to which it is linked by two-way neural connections (Leiner *et al.*, 1989). Connections with motor areas would increase the speed and skill of movement and connections with cognitive areas would improve the speed and skill of cognition.

4.10.3 Comparative Cerebellar Anatomy

Evidence with respect to the evolution of the primate cerebellum (see Primate Brain Evolution in Phylogenetic Context) comes mainly from cross-species, comparative studies of living primate brains. Some of these studies are based on postmortem specimens (Stephan *et al.*, 1981), whereas others are based on MRI scans obtained from living primates (Rilling and Insel, 1999). Each data set has both advantages and disadvantages. The primary advantage of the postmortem sample is that it permits analysis of microscopic cytoarchitecture, which cannot be observed in MRI scans. On the other hand, the *in vivo* MRI scans (Figure 4) were obtained from healthy (not old or sick) animals and do not suffer from shrinkage artifacts caused by the postmortem tissue fixation process. Using these data sets, various authors have compared both the size and the histology of the cerebellum and its component structures across the primate order. Below is a summary of what these comparisons have revealed.

To begin with, Figure 5a illustrates variation in absolute cerebellum volume across a sample of 11 anthropoid primate species. At least some of this variation is likely attributable to variation in body weight, since most structures are larger in larger animals. Furthermore, the cerebellum is in close contact with the body surface, receiving somatosensory information from the periphery and modulating descending motor systems that control movement, so that we might expect cerebellar size to track body size. As can be seen in Figure 5a in which species are listed in ascending order of body weight, there is indeed a relationship between body weight and cerebellar volume. In fact, for the sample of 44 anthropoid primates in the Yerkes MRI data set, (log) body weight explained 87% of the variance in (log) cerebellar size ($r = 0.93$, $p < 0.001$; Figure 5b). Figure 5a demonstrates that the human cerebellum is larger than expected for a primate of our body weight. This is confirmed by Figure 5b in which cerebellar volume is plotted against body weight and a least-squares regression line is fit through the data. Much of the unexplained variance can be attributed to the human data points, which lie well above the prediction based on the regression line.

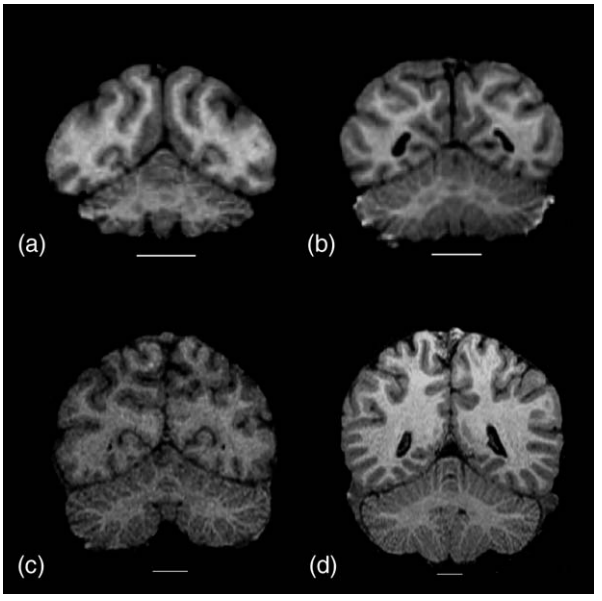

Figure 4 MRIs of primate cerebella. Coronal MRI through the cerebellum of: a, rhesus macaque; b, gibbon; c, chimpanzee; and d, human. Reproduced from Rilling, J. K. and Insel, T. R. 1998. Evolution of the cerebellum in primates: Differences in relative volume among monkeys, apes and humans. *Brain Behav. Evol.* 52, 308–314, with permission from Karger.

Is the cerebellum unusual in this respect or are other human brain structures also disproportionately large relative to body weight? In fact, the cerebellum is second only to the neocortex, albeit a distant second, in terms of its size relative to body size (Stephan *et al.*, 1988). The fact that the neocortex and cerebellum are the two structures that enlarged most relative to body size in humans, coupled with the existence of extensive connections between the two, suggests the possibility that the neocortex and cerebellum have evolved in tandem as a coordinated system (Barton and Harvey, 2000). Using the method of independent contrasts to eliminate the effect of common inheritance, Barton and Harvey showed that this is indeed the case for primates. Cerebellar contrasts are significantly correlated with neocortex contrasts, and this relationship is stronger than that of cerebellar contrasts and other major brain divisions, such as the medulla, mesencephalon, and diencephalon. In a subsequent analysis, Whiting and Barton (2003) demonstrated correlated evolution in other components of this cerebrocerebellar system among primates. For example, after partialing out evolutionary change in the size of the rest of the brain, they found that evolutionary changes in the size of the pons were positively correlated with changes in the size of both neocortex and cerebellar cortex. In other words, the corticopontocerebellar system that provides input to the cerebellum appears to evolve in concert. There was no significant correlation between pons and the deep cerebellar nuclei, in accord with the lack of direct connectivity between these two structures. On the other hand, there was a strong positive correlation between relative contrasts in deep cerebellar nuclei and relative contrasts in the thalamus, to

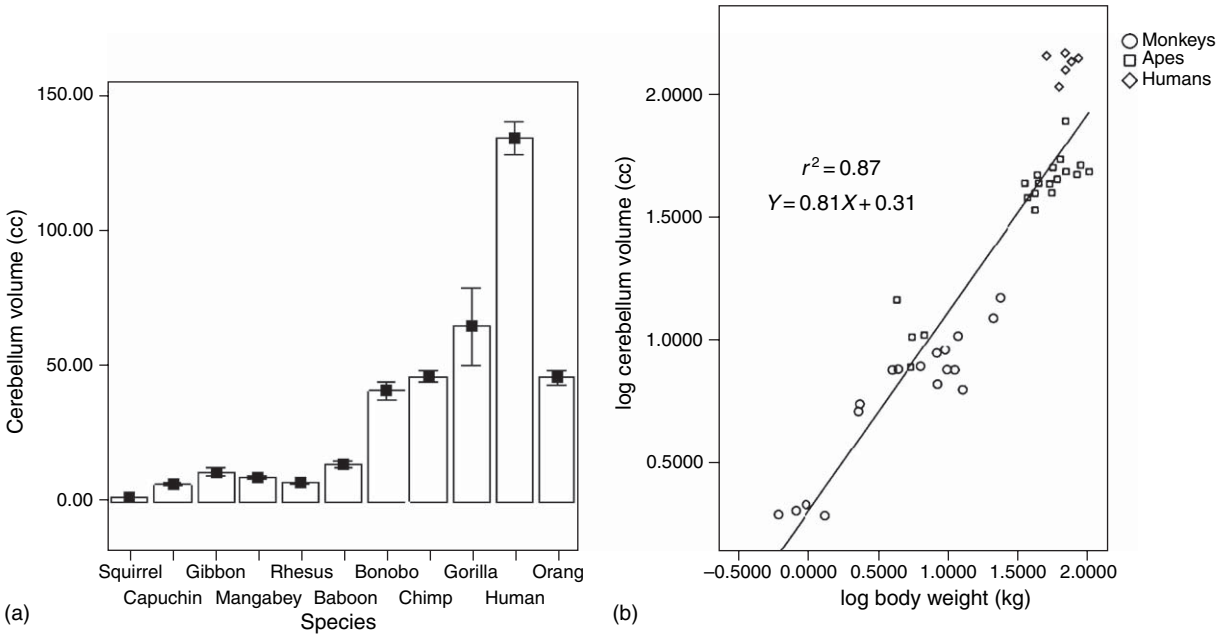

Figure 5 Comparison of cerebellum volume in anthropoid primates. a, Mean absolute cerebellum volume from MRI scans in 11 anthropoid primate species, in ascending order of body weight. Note that the gorilla body weight is low for the MRI data set because it is based on one small female and one subadult male. Error bars are ±1 SE. b, Regression of log cerebellum volume against log body weight, with least squares regression line fit through the entire sample.

which the nuclei send much of their output en route to the neocortex (see Figure 3).

4.10.4 The Ape Cerebellum Is Not an Allometrically Enlarged Monkey Cerebellum

Despite this tendency for the cerebrocerebellar system to evolve as a coordinated whole, it is clear that the relationship between the two structures was altered with the evolution of hominoids (Rilling and Insel, 1998; Semendeferi and Damasio, 2000). When cerebellum volume is regressed on cerebral cortex volume for anthropoid primates, there is a clear grade shift between apes and monkeys, indicating that apes have larger cerebella for any given cerebrocortical volume (Figure 6), and this difference is concentrated in the cerebellar hemispheres as opposed to the vermis (MacLeod *et al.*, 2003). Important differences between apes and monkeys are also found in cerebellar components. Matano and Hirasaki (1997) regressed the volume of the dentate nucleus on the volume of the medulla oblongata for a sample of 26 anthropoid primate species (from Stephan *et al.*, 1981) and found that apes have relatively larger dentate nuclei than monkeys. This was equally true of greater and lesser apes; however, there was an interesting difference between the two in the relative size of the interposed nucleus, which

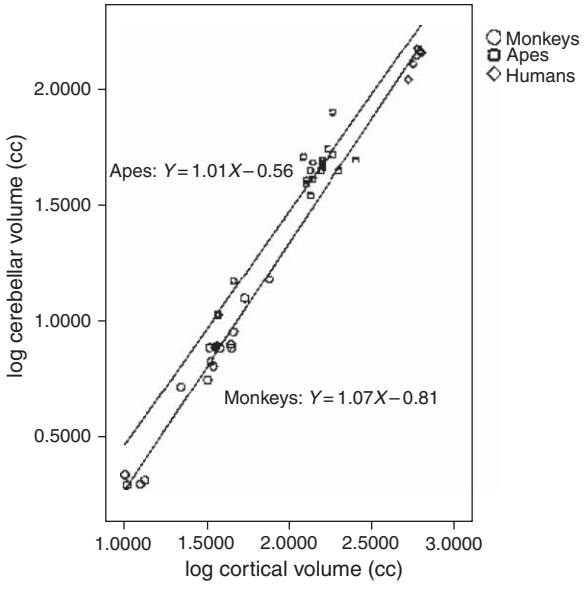

Figure 6 Comparison of cerebellum volume relative to cerebral cortical volume in anthropoid primates. Regression of log cerebellum volume on log cerebral cortical volume, with separate least-squares regression lines fit through the monkey and ape data. Human data points are plotted but not included in either regression. Data are from Rilling and Insel (1998, 1999).

was found to be markedly larger in lesser apes. This raises the possibility that Hylobatidae and Pongidae independently evolved to a similar grade of overall cerebellar development.

Given the anatomical connections between the cortex of the lateral cerebellar hemisphere and the dentate nuclei, the larger relative size of the ape dentate suggests that the expansion of the cerebellar hemispheres in apes may be concentrated in the lateral, rather than intermediate portion of the hemisphere. Detailed comparisons of the dentate nuclei reveal further differences between monkey and hominoid cerebella. On the basis of morphological, histological, embryological, histochemical, and pathological evidence, the dentate nucleus is thought to consist of two parts: an older dorsomedial and newer ventrolateral part (Dow, 1988) (Figure 7). Among anthropoid primates, the ventrolateral part is unique to humans and apes (Leiner *et al.*, 1991). Based on neuropsychological and neurophysiological evidence, Leiner *et al.* (1991) argue that the ventrolateral dentate sends output to nonmotor regions of the frontal lobe by way of the ventrolateral thalamus. This hypothesis will require further testing, perhaps with noninvasive *in vivo* methods such as diffusion tensor imaging (DTI) that allow visualization of white matter fiber tracts. However, if the hypothesis proves accurate, then the emergence of the ventrolateral dentate in hominoids could reflect a qualitative shift toward increased cerebellar involvement with cognition by virtue of connections with nonmotor frontal lobe regions.

What might be the functional significance of the elaborated cerebellum in hominoids? As suggested above, the enlarged ape cerebellum might improve the functioning of all cortical regions with which it is connected. One cortical target of lateral cerebellar efferents is motor and premotor cortex, and it has been argued that apes have a greater complexity of movement than monkeys (Povinelli and Cant, 1995; MacLeod *et al.*, 2003). Also compatible with this augmentation of function in motor and premotor cortex is Ott's observation that, in contrast to apes and humans, baboons apparently lack presyntactical motor planning, the ability to modify current movements based on awareness of movements to follow (Ott *et al.*, 1994). Other skills that apes excel at relative to monkeys are also likely to be dependent on the motor and premotor cortex. For example, when reaching for an object, apes and humans exhibit more complex preshaping of their hand compared with monkeys (Christel, 1993; Christel *et al.*, 1998). In addition to these differences in motor-related functions, apes and monkeys also possess numerous cognitive differences. It is conceivable that cerebellar augmentation of prefrontal function could be involved in apes' putative capacity for self-awareness (Gallup, 1970), components of theory of mind (Tomasello *et al.*, 2003), and capacity for symbolic thought (Tomasello and Call, 1997). Each of these abilities is known to depend upon prefrontal cortex in humans (Deacon, 1997; Frith and Frith, 1999; Gusnard *et al.*, 2001; Gallagher and Frith, 2003).

4.10.5 Is the Human Cerebellum an Allometrically Enlarged Ape Cerebellum?

The human cerebellum is remarkably larger than the ape cerebellum, even after adjusting for differences in body weight (Figure 5). In fact, it is 2.8 times larger than expected for a nonhuman primate of equivalent body weight. Humans also have a larger dentate nucleus for their body size than apes (Matano and Hirasaki, 1997), and the difference is concentrated in the ventrolateral portion of the nucleus (Matano, 2001). Matano (2001) measured the area of the dorsal and ventral halves of the dentate in gorillas, chimps, and humans and calculated a ratio of ventral to dorsal areas in each species. The average human ratio (2.11) was much larger than the average ape ratio (1.64), indicating expansion of the ventral half in humans.

Although there are certainly absolutely more cerebrocerebellar connections in humans compared with apes, the degree of connectivity in humans is

probably less than what would be expected for an ape brain of human size. This is because humans fall below the ape regression line of cerebellar volume against cortical volume (Figure 6). This indicates that either (1) humans have small cerebella for their cortex size or (2) humans have large cortices for their cerebellar size. In fact, the existing data support the latter possibility given that the human cerebral cortex is disproportionately large when regressed on other brain structures, and the cerebellum is not disproportionately small when regressed on other brain structures (Deacon, 1988; Rilling and Insel, 1999). This result suggests that some of the cortical regions that expanded in humans did not maintain the degree of connectivity with the cerebellum that is found in apes or that cortical expansion was concentrated in regions that do not receive many cerebellar efferents. A likely candidate is temporal cortex, which is not intimately connected with the cerebellum and known to have expanded extra-allometrically in humans (Rilling and Seligman, 2002). Prefrontal cortex, when defined cytoarchitectonically, is also disproportionately large in humans (Passingham, 1973; Deacon, 1997; Preuss, 2000).

What could be the functional significance of the enlarged cerebellar hemispheres and ventrolateral dentate in humans? One possibility is accurate overhand throwing, which likely represented a strong selective pressure throughout our hunting and gathering past (Isaac, 1987; Calvin, 1993). Accurately throwing rocks and projectiles may have been crucial for hunting and scavenging prey, predator defense, and intergroup hostilities. Another possibility is that the enlarged human cerebellum supports fine motor coordination involved in the manufacture and use of tools (see Neurological Specializations for Manual Gesture and Tool Use in Humans). Humans are superior to apes in terms of manual dexterity. However, it is also clear that the cerebellum does indeed take on a cognitive role in humans, being involved in a wide range of mental operations (as discussed above). Leiner *et al.* (1993) have emphasized its role in language in view of neuropsychological evidence and hypothesized connections with BA44 (Broca's area). One attractive possibility is that the human cerebellum is involved in a more global augmentation of frontal lobe function that extends to cognitive domains beyond language.

4.10.6 Conclusion

1. Compared with monkeys, apes have larger cerebellar hemispheres for their brain size.
2. The dentate nucleus, the cerebellar deep nucleus that receives input from lateral cerebellar cortex, is also relatively larger in apes than in monkeys and relatively larger in humans than in apes.
3. The ventrolateral portion of the dentate, which may project to nonmotor regions of frontal cortex that are involved in higher cognition, is reportedly absent in monkeys and more developed in humans than in apes.
4. Although the human cerebellum is large relative to body size, the human cerebral cortex is even larger. Consequently, we have a large cerebral cortex for our cerebellum size, and the relative degree of cerebrocerebellar connectivity is probably reduced in humans compared with apes.
5. Given evidence for cerebellar connections with both motor and higher-order association cortex, the above differences in cerebellar anatomy among monkeys, apes, and humans could support motor and cognitive specializations of the three groups.

corticofugal Axonal projections from the cerebral cortex to subcortical targets.

corticospinal Axonal projections from the cerebral cortex to the spinal cord.

interaction torques Undesired forces generated by the movement of one body part on another part.

motor cortex (1) Primary motor cortex; (2) any part of frontal cortex directly involved in motor control, including premotor cortex.

motor pool A group of motor neurons in the spinal cord or brainstem projecting to a muscle.

nonprimary motor cortex Parts of the motor cortex other than the primary motor cortex, sometimes synonymous with premotor cortex.

orofacial Of the mouth and face, including the lips and jaw.

platyrrhines New World primates.

premotor cortex Cortex between the prefrontal cortex and the primary motor cortex, sometimes (but not always) excludes medial motor areas, such as the supplementary motor cortex.

primary motor cortex Abbreviated M1, sometimes called area 4, the motor strip, the precentral motor cortex, or simply the motor cortex.

propriospinal Systems of axonal projections connecting different segments of the spinal cord.

prosimians A group of primates that includes lemurs, lorises, bush babies, and tarsiers.

shoulder girdle A group of muscles that position the shoulder joint relative to the vertebral column.

4.11.1 Cortex for Central Control of Movement

The primate motor cortex comprises the primary motor cortex (M1) and several nonprimary motor areas (Figure 1; see The Evolution of Motor Cortex and Motor Systems). Among the latter, the ventral premotor cortex (PMv) appears to occupy a particularly pivotal place (Dum and Strick, 2005). Of the areas projecting directly to both the spinal cord and M1, PMv has the most interconnections with the prefrontal cortex (red arrow in Figure 1b). Much current thinking about PMv focuses on the neurophysiology of mirror neurons, cells that show similar activity regardless of whether a monkey performs an action or observes a similar one (Ferrari *et al*., 2003). This article, however, concentrates on information from other disciplines: comparative and connectional neuroanatomy, cortical stimulation, comparative morphology, and comparative psychology. Sections below briefly outline some findings from each of these fields in turn, followed by a summary, discussion, and conclusion.

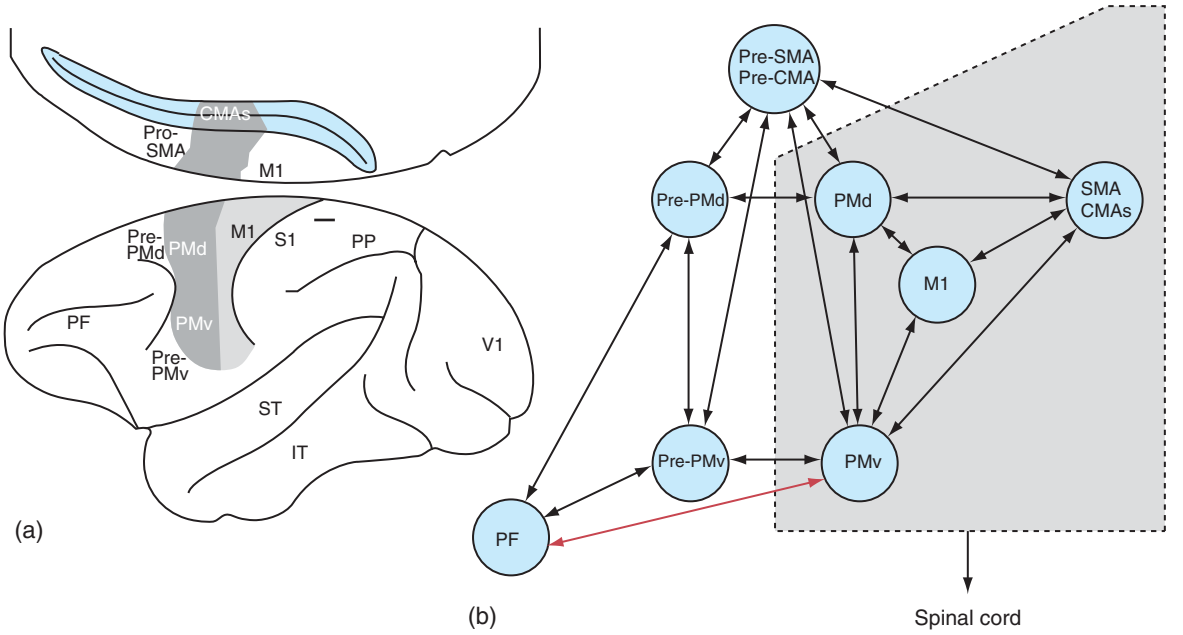

Figure 1 Motor cortical areas in macaque monkeys, their interconnections, and their direct outputs to the spinal cord. a, Brain drawing showing a left hemisphere; rostral is to the left. Ventral is down for the lateral surface of the hemisphere, but up for the medial surface, shown as if reflected at the top. The cingulate sulcus is shown opened to its fundus. b, The connectivity chart has thick lines suggesting stronger and functionally more important connections. The red arrow emphasizes the direct projection from the prefrontal cortex to PMv, which other spinally projecting motor areas (those in the shaded box) lack, at least to the same extent. CMAs, cingulate motor areas; IT, inferior temporal cortex; M1, primary motor cortex; PF, prefrontal cortex; PMd, dorsal premotor cortex; PMv, ventral premotor cortex; PP, posterior parietal cortex; Pre-PMd and Pre-PMv, areas rostral to PMd and PMv, which do not project directly either to the spinal cord or to M1; S1, somatosensory areas; SMA, supplementary motor area; ST, superior temporal cortex; V1, primary visual cortex. Data mainly from Dum, R. P. and Strick, P. L. 2005. Motor areas in the frontal lobe: The anatomical substrate for the central control of movement. In: Motor Cortex in Voluntary Movements (*eds.* A. Richle and E. Vadia), pp. 3–47. CRC Press.

4.11.2 Comparative Neuroanatomy

In their comparative study of the corticospinal system, Nudo and Masterton (1990a) found that corticospinal projections originate from three zones, which they called regions A, B, and C. Figure 2 shows the distribution of retrogradely labeled corticospinal neurons in a prosimian, a platyrrhine (New World) primate, and a catarrhine (Old World) primate. Nudo and Masterton examined two prosimians – lesser bush babies (Figure 2, top) and slow lorises; two New World monkeys – squirrel monkeys (Figure 2, middle) and common marmosets; and three Old World monkeys – green, cynomolgous, and rhesus (Figure 2, bottom) monkeys. They could identify region C, which corresponds to PMv, in each of the seven primates species they studied, but not in any of the other 15 mammals. Accordingly, they concluded that PMv's corticospinal projection evolved in stem primates and was a primate innovation.

When Nudo and Masterton (1990b) examined some possible functional correlates of region C, they found little relationship with manual dexterity and only a slightly stronger one with hand–eye coordination, evaluated in terms of whether an animal can easily view its hand or forepaw. Instead, they identified a robust relationship between the relative extent of region C and an animal's lifestyle, i.e., where it typically lives, sleeps, and eats. Nudo and Masterton (1990b) concluded that "the relative size of Region C depends mostly on an arboreal habit, both in nesting and in foraging" and suggested that

> It is the arboreal life-style of primates that may have provided the selective pressure for the origin and expansion of Region C . . .. The best clue is to be found in some motor trait necessitated by an arboreal life and more closely related to hand–eye coordination than to digital dexterity (Nudo and Masterson, 1990b, pp. 596–597).

4.11.3 Connectional Neuroanatomy

Corticospinal projections originate from neurons in several frontal and parietal areas (Figures 1 and 2) and PMv contains approximately 5% of these neurons in both macaque and capuchin monkeys (Dum and Strick, 2005). By far, most of PMv's corticospinal axons terminate in upper segments of

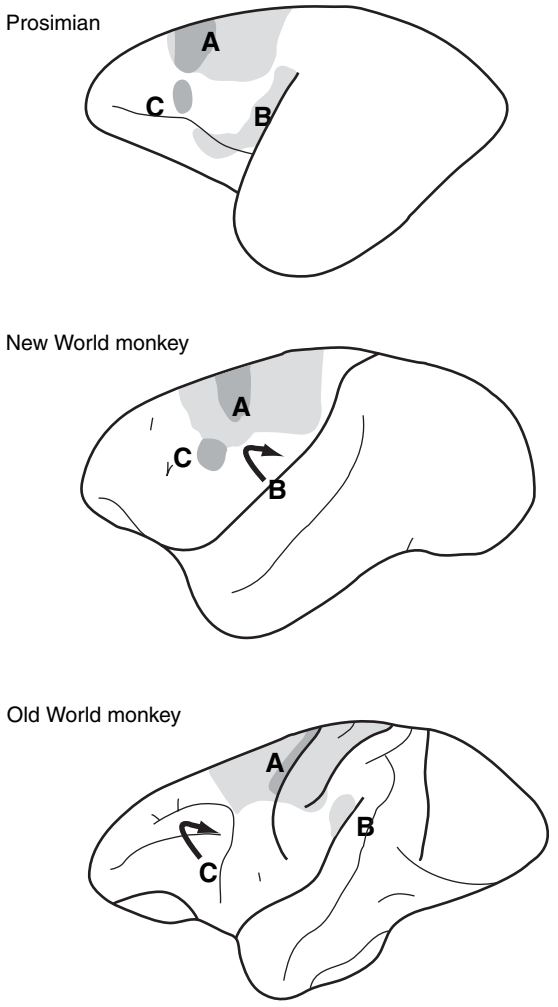

Figure 2 Corticospinal region C. Drawings of left hemispheres show the locations of three major zones of corticospinal neurons: regions A, B, and C. Rostral, left; dorsal, up. Region C, which corresponds to PMv, appears only in primates and is situated lateral to the main source of corticospinal projections, region A. Region A corresponds to the primary motor cortex, the dorsal premotor cortex, certain somatosensory areas, and posterior parietal area 5. Region B corresponds to other somatosensory areas. Reproduced from Nudo, R. J. and Masterton, R. B. 1990. Descending pathways to the spinal cord. III: Sites of origin of the corticospinal tract. *J. Comp. Neurol.* 296, 559–583, with permission from Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

the cervical spinal cord, which have motor neurons with four principal functions: control of head orientation via neck muscles, control of the shoulder girdle, regulation of inspiration, and tongue stabilization.

In addition to its projection to the spinal cord, PMv sends strong corticofugal projections to the brainstem, including to the facial nucleus, the medullary reticular formation, and the parvocellular red nucleus. PMv's projection to the facial nucleus targets motor pools controlling lower face muscles, specifically those of the lip and jaw. PMv, M1, and the caudal cingulate motor areas share a similar pattern of terminations in the facial nucleus, with PMv and M1 sending the densest projections. Neurons projecting to the facial nucleus and spinal cord are intermingled within PMv, with a predominance of the former (Morecraft *et al*., 2004). Thus, PMv projects predominantly to the facial nucleus, less but still significantly to the upper cervical spinal cord, and only weakly to other spinal segments.

Several neuroanatomists have studied connections among the various motor areas, mostly in macaques, but also in capuchins, owl monkeys, and galagos (Kaas, 2004). In capuchins and macaques, six premotor areas have been identified on the basis of connections with M1, including PMv. In galagos and owl monkeys, four to six premotor areas have been identified, also including PMv. An overview of the connections among the motor areas (Figure 1b) indicates that PMv serves as a key node in the network connecting the prefrontal areas, on the one hand, with M1 and the dorsal premotor areas, on the other. The identification of a ventral premotor area projecting to M1 in a prosimian primate, in two New World monkeys, and in Old World monkeys suggests that PMv had evolved by the time of the earliest primates (Preuss, 1993).

4.11.4 Cortical Stimulation

In rhesus monkeys, Graziano *et al*. (2002) inserted electrodes into PMv to electrically stimulate parts of it for periods of up to 1 s. This stimulation evoked a coordinated set of movements that included closure of the hand, smooth movement of the hand to the mouth at a speed appropriate for feeding, and mouth opening (Figure 3b). When the monkey's head could move, it rotated into alignment with the hand. Figure 3a shows the region from which such movements were evoked (blue shading), as well as the nearby regions generating other complex actions (gray shading). Graziano *et al*. concluded that PMv controls a particular class of behavior, one related to bringing the hand to the mouth during feeding.

4.11.5 Comparative Morphology

On the basis of fossil evidence, Bloch and Boyer (2002) extended earlier work by Cartmill (1974) and Martin (1990) to conclude that the first true primates appeared approximately 55 Mya as specialized graspers. In their view, stem primates evolved these and other specializations to feed on flowers, nectar, and tender leaves, which develop on the

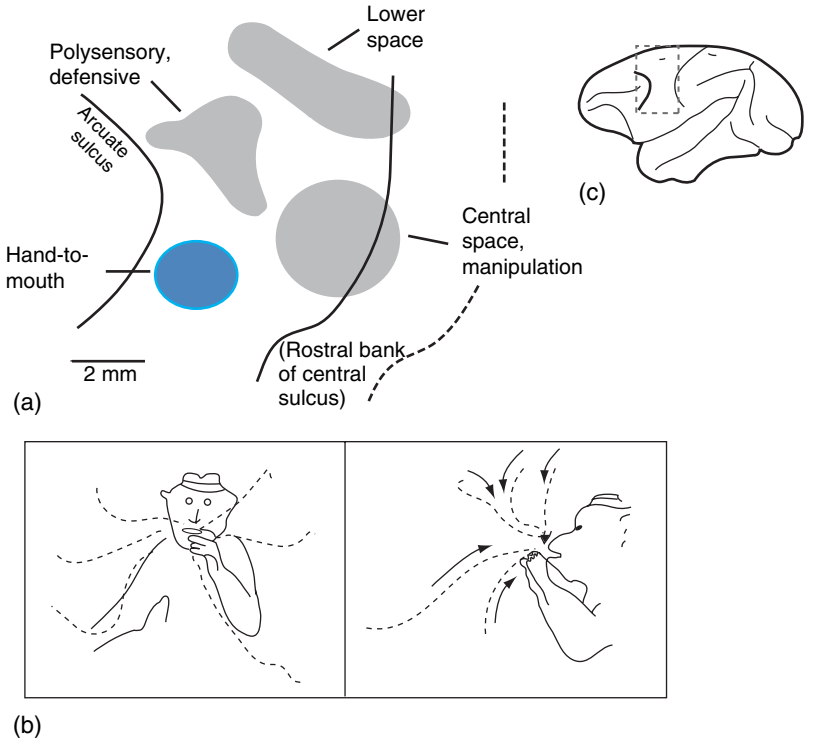

Figure 3 a, Regions of the frontal cortex from which complex, ethologically relevant movements can be evoked by long trains of electrical pulses. Note particularly the region, shaded in blue, ventral to the arcuate sulcus labeled hand-to-mouth. This region corresponds to PMv and contains the corticospinal neurons illustrated in Figures 1 and 2. The solid curved lines indicate the locations of the arcuate sulcus (left) and the central sulcus (right). The dashed line to the right represents the fundus of the central sulcus. b, Each dash shows the hand's position at a given point in time, as the electrical stimulation brings the monkey's hand to its mouth. c, Left hemisphere of a macaque brain; the boxed region (dashed lines) is shown expanded in (a). a, Courtesy of M. S. Graziano. b, Reproduced from Graziano, M. S. A., Taylor, C. S., and Moore, T. 2002. Complex movements evoked by microstimulation of precentral cortex. *Neuron* 34, 841–851, copyright 2002, Cell Press, with permission from Elsevier.

distal branches of trees. Bloch and Boyer also concluded that this specialized reaching and grasping ability preceded the capacity for advanced leaping and frontally directed eyes. Figure 4 shows their image of these extinct animals. Other paleontologists view the first true primates as more insectivorous and more visually oriented than the frugivorous species studied by Bloch and Boyer. Notwithstanding this ongoing debate, the feeding technique of the earliest primates probably involved visually guided reaching and grasping in an arboreal niche, whether primarily for insects, as emphasized by some, or for food items mainly available in the fine-branch niche, as emphasized by Bloch and Boyer.

The work of Radinsky (1979) also bears on these issues. He prepared fossil endocasts, which allowed him to examine sulcal patterns in extinct primates, and concluded that

> The fossil record of primate endocasts suggests that expansion of neocortex in general, expansion of visual cortex, and

Figure 4 A depiction of visually guided reaching movements in an early primate. Reconstruction of an extinct primate, genus *Carpolestes* (meaning fruit robber), drawn by Douglas M. Boyer. Reproduced from Sargis, E. J. 2002. Paleontology: Primate origins nailed. *Science* 298, 1564–1565, with permission from D. M. Boyer.

> possibly also reduction in the olfactory bulbs, had begun by 55 million years ago. ... Endocasts of some of the oldest known anthropoids suggest that by 25 to 40 million years ago, expansion of visual cortex and reduction in olfactory bulb size had progressed further, and was within the modern anthropoid range. Further, ... the central sulcus had appeared by that time, at least in Old World anthropoids. In both anthropoids and prosimians, expansion of frontal lobes lagged behind that of the rest of the brain (Radinsky, 1979, p. 22).

According to Radinsky, then, when the first true primates appeared approximately 55 Mya, the expansion of visual cortex had begun, but it took another 15–30 million years to reach an approximation of its modern state (see The Evolution of Visual Cortex and Visual Systems). Several researchers have suggested that binocular vision drove the expansion of the visual system in primates, and, if this is so, then the findings of Bloch and Boyer (2002) led to the idea that unimanual reaching preceded the rotation of the orbits into the more frontal orientation of anthropoid primates. This later development, then, probably led to increasing reliance on binocular depth information for reaching and a concomitant expansion of the visual cortex.

4.11.6 Comparative Psychology

MacNeilage *et al.* (1987), using the methods of comparative psychology, also proposed particular ways in which the earliest primates adapted their motor system to an arboreal environment (see The Evolution of Sensory and Motor Systems in Primates). They noted that modern prosimians are specialized for unimanual predation and supported the idea that life in a fine-branch, arboreal niche led to this adaptation. MacNeilage *et al.* further suggested that adaptation to this niche involved hemispheric specialization. Specifically, they argued for a left-hand (right hemisphere) specialization for visually guided movements, along with a right-hand (left hemisphere) specialization for postural support, as illustrated in Figure 4.

4.11.7 Consilience

To sum up the preceding sections, evidence from comparative morphology and psychology indicates that the earliest primates adapted to a fine-branch, arboreal niche that involved unimanual feeding (Figure 4). Cortical stimulation of PMv results in a coordinated movement of the hand toward the mouth, along with reorientation of the head (Figure 3). Evidence from comparative neuroanatomy indicates that PMv and its corticospinal projection first appeared in the earliest primates and correlates in extent with an arboreal life (Figure 2). And evidence from connectional neuroanatomy shows that PMv preferentially projects to spinal segments that control head and shoulder movements, brainstem nuclei that control the lips and jaw, and key cortical areas involved in making decisions and taking action, including the prefrontal cortex, the dorsal and medial premotor areas, and M1 (Figure 1).

4.11.8 Command and Control

If PMv evolved as an adaptation to an arboreal life of grasping fine branches and unimanual feeding, to which aspects of that life did it contribute most? The findings summarized here militate against certain possibilities. For example, specializations for hind limb grasping, leaping, and postural support would likely involve projections to the lumbar spinal cord. PMv sends very few axons there in macaque monkeys. Instead, PMv's corticofugal projections point to a role in controlling mouth, face, and head movements. If propriospinal systems in the upper cervical spinal cord contribute to reaching and grasping, then PMv's corticospinal efferents might also be important for these functions. Thus, the neuroanatomy suggests that PMv's contribution to movement has more to do with controlling the upper body than with controlling either the legs or the trunk and perhaps this was the case in the earliest primates, as well.

What does the upper part of the body need to do for unimanual feeding in a fine-branch niche? Two factors seem especially important: (1) coordination of head orientation with the hand movements that bring food to the mouth and (2) compensation for passive movements caused by the instability of distal tree branches and the food items on those branches, compensation for interaction torques produced by reaching and the forces involved in separating food items from their source, and compensation for Coriolis forces that accompany rotational movements as the hand reaches to grasp food.

As for the first factor, PMv's corticofugal projections – to the facial nucleus and to the upper cervical spinal cord – seem well suited to coordinate head and mouth movements with those of the hand. Unlike terrestrial quadrupeds, which often use whole-body movements to bring their mouths to food, unimanual feeding on a platform composed of fine, distal branches would require more flexible control of head orientation during feeding. Among other advantages, the ability for flexible reorientation of the head during feeding would minimize changes in the body's center of mass and the resulting instability that such body shifts would cause.

As for the second factor, consider the motor-control problems posed by swaying branches, undulating food items, and Coriolis forces. The last concept requires some explanation. When primates reach to a target in the outside world, as their body axis rotates, their body's rotation appears to cause a force on the limb that is proportional to the velocity of the hand's movement toward the target and the angular velocity of the rotation. To make a straight movement relative to the outside world, a reacher will have to curve its hand trajectory relative to itself, in the direction opposite to the body's rotation, and thus must exert the forces necessary to do so. When Coriolis forces are considered together with swaying branches that displace the reacher's body and targets that also move, it seems clear that unimanual reachers in an arboreal niche face major problems in motor control. One possible solution to these problems is to keep the position of the shoulder joint stable relative to the outside world. PMv might control movements of the shoulder girdle through its projections to the upper cervical spinal cord and thus compensate for body displacements, at least to some extent. This solution seems less important and less robust than a second one: continuously compute the location of the hand relative to the target and modify ongoing motor commands as the movement progresses – until the hand reaches the target.

PMv appears to play an important role in the latter solution. In a model of reaching and pointing in primates, Shadmehr and Wise (2005) pointed to neurophysiological studies indicating that PMv computes a difference vector, which corresponds to the distance and direction of the hand from the target of a reaching movement. The hand represents one among many kinds of controlled objects, collectively called end effectors, which include not only hands or parts of hands, but also tools such as remotely controlled cursors. Kakei *et al*. (2001) have shown that when macaque monkeys use wrist movements to control a cursor on a video screen, PMv's neuronal activity reflects the direction from the cursor's current position to the target. Importantly, it does so in terms of an extrinsic coordinate frame, based on vision, rather than an intrinsic coordinate frame, based on the joint-angle changes needed to reach the target. Along the same lines, Schwartz *et al*. (2004) have shown that a population of PMv cells reflects what the monkey sees in terms of a target's trajectory more than what the monkey does in terms of its hand's trajectory. These and other data support the idea that PMv contributes to the computation of a difference vector, which the motor system uses to drive the hand (or some other end effector) to a target. This computation appears to be fundamental to the primate way of reaching.

The primate way of reaching also involves using the difference vector to compute the next motor command and doing so in vision-based coordinates. Shadmehr and Wise (2005) called this component the next-state planner and the available evidence indicates that the primate motor system uses vision-based coordinates not only for guiding movements to visible targets, but also for guiding movements to acoustically localized targets and targets that cannot – even in principle – be seen, such as the back of a reacher's head. The dependence on vision-based coordinates leads to the counterintuitive prediction that the primate motor system must update its estimation of both hand and target position whenever the reacher makes an eye movement and there is evidence for such updating (see Shadmehr and Wise, 2005). Furthermore, if the target drifts as the movement progresses or if some external force passively repositions the reacher – both likely occurrences in a fine-branch niche – a motor system based on the difference vector and a next-state planner will adjust the hand's trajectory smoothly and accurately by continuously updating its computation of the difference vector until the hand reaches its target. This mechanism sometimes goes by the name autopilot control and it is fundamental to the primate way of reaching.

At first glance, the idea that PMv represents a difference vector for reaching movements seems at odds with a role in grasping or unimanual feeding. Indeed, orienting the head, bringing food to the mouth, reaching, and grasping differ in many important ways. They may, however, share a mechanism involving the difference vector. For example, when the head or face serves as the end effector, it could be pointed with a mechanism much like that involved in reaching. The fingers also are end effectors and grasping might involve similar computations, at least in part.

4.11.9 Communication

The capability for enhanced control of the head and orofacial musculature for feeding might also have served social signaling. MacNeilage (1998) has proposed that Broca's area and nearby regions such as PMv originally evolved to control feeding movements, but later came to underlie social communication, including language. According to his idea, motor programs that

evolved to control chewing and licking were later modified for use in lip smacks, tongue movements, and teeth-based noises that many primates use for social signaling. Along these lines, Ferrari *et al.* (2003) have reported that PMv neurons discharge during the observation or production of ingestive and communicative oral movements. PMv's projection to the motor nuclei that control the lips and jaw accords with MacNeilage's idea. Its projection to the upper cervical spinal cord does so, as well, because of the relationship between head orientation and social communication. The sender benefits from pointing his or her head toward an intended recipient – for both acoustic and orofacial signals – to focus acoustic energy, present the sender's face in the desired orientation, and avoid sight-line obstructions.

MacNeilage (1998) has further proposed that motor programs used in feeding served as a medium for the messages conveyed by voiced syllables framed in cycles of mandibular oscillations. PMv's projection to the upper cervical spinal cord, which has motor pools that regulate inspiration and stabilize the tongue, could have contributed to that development. In macaque monkeys, electrical stimulation of PMv evokes responses in muscles that lengthen and either tense or relax the larynx (Hast *et al.*, 1974), which supports the idea that PMv contributes to the control of vocal gestures.

4.11.10 Conclusions

The findings and ideas summarized here (see also Preuss, 1993) suggest that PMv evolved in the earliest primates as an adaptation for unimanual feeding in a fine-branch, arboreal niche. As such, its functions probably involved coordinating head orientation and orofacial movements with bringing food to the mouth, visually guided reaching and grasping, and postural support with the nonreaching arm and hand. PMv's projections to the facial nucleus and upper cervical spinal cord probably served these functions from the first.

Later, these same neural systems may have supported various forms of conspecific communication, as well as tool use. Reaching, when transformed into pointing, is fundamentally a communicative gesture. The control of head orientation contributes to both voiced and unvoiced social signaling and primates employ orofacial movements for a wide variety of signals. Finally, a mechanism for controlling reaching and grasping movements based on the computation of a difference vector provides a straightforward preadaptation for tool use, and neuroimaging studies by Chao and Martin (2000) point to PMv as a key contributor to such praxic functions in humans.

4.12 Specializations of the Cortical Microstructure of Humans

J DeFelipe, L Alonso-Nanclares, J Arellano, I Ballesteros-Yáñez, R Benavides-Piccione, and A Muñoz, Instituto Cajal (CSIC), Madrid, Spain

Glossary

aspiny or sparsely spiny nonpyramidal cells Constitute the typical interneurons but show a great variety of morphological, biochemical, and physiological characteristics. Their axons are found near the parent cell, but some have prominent axonal collaterals that run in the horizontal or vertical dimension (ascending and/or descending). Most of them appear to be GABAergic. They are found in all cortical layers and constitute the majority of interneurons and approximately 15–30% of the total neuron population.

basic microcircuit Repeating stereotypical circuit of neurons, composed by elementary operative units in which all elements of the cortex are represented.

GABA γ-amino-butyric acid, is the most abundant inhibitory transmitter in the CNS.

interneurons Short-axon cells or neurons whose axon does not leave the cortex (15–30% of the total neuron population).

macrocolumn The basic processing unit consisting of a cylinder of cortical tissue with a width that varies according to the spread of the specific individual afferent fibers entering the cortex (300–600 μm in diameter, depending on the cortical area and/or species). This macrocolumn is commonly referred to simply as a 'column'.

minicolumn The basic modular subunit in the cortex representing the smallest functional unit of cortical organization, the ensemble of several minicolumns making up the macrocolumns. These minicolumns are formed by a group of vertically oriented interconnected cells that are contained in a vertical cylinder of tissue of approximately 25–50 μm in diameter (depending on the cortical area and/or species).

pyramidal cells Constitute the vast majority of projection neurons, and located in all layers except layer I. They are characterized by the pyramidal or triangular shape of the soma and the presence of a prominent apical dendrite (70–85% of the total population). These neurons are glutamatergic and represent the main source of cortical excitatory synapses.

spiny nonpyramidal cells Constitute the typical neurons of the middle cortical layers (especially layer IV), comprising a morphologically heterogeneous group of neurons. Spiny nonpyramidal cells are excitatory (probably glutamatergic)

neurons whose axons are distributed within layer IV or in the layers above or below that in which their parent cell bodies are located.

4.12.1 Introduction

The great expansion and the differentiation of the neocortex constitute two major events during the evolution of the mammalian brain. Thus, it is particularly interesting to ascertain how the human neocortex has evolved to endow us with the capacity of speech and thought – faculties that distinguish humans from other mammals. In other words, the crucial question remains: what is special about the neocortex of humans and how does it differ from that of other species? Since the very earliest studies of the neocortex two main streams of thought were established. The first holds that the differences in the human neocortex are only quantitative, while the second holds that in addition to quantitative differences, important qualitative variations also exist. Santiago Ramón y Cajal made some of the most important earlier contributions to the study of the cerebral cortex organization. He beautifully summarized this subject as follows:

> At that time, the generally accepted idea that the differences between the brain of [nonhuman] mammals (cat, dog, monkey, etc.) and that of man are only quantitative, seemed to me unlikely and even a little offensive to human dignity [...] language, the capability of abstraction, the ability to create concepts and finally, the art of inventing ingenious instruments [...] do [these facets] not seem to indicate (even admitting fundamental structural correspondences with the animals) the existence of original resources, of something qualitatively new which justifies the psychological nobility of *Homo sapiens*? Microscope at the ready, I then launched with my usual ardor to conquer the supposed anatomical characteristic of the king of Creation, to reveal these enigmatic strictly human neurons upon which our zoological superiority is founded (Cajal, 1917; translated by J. DeFelipe).

Among other authors, Cajal tried to apply the same reasoning that was followed when comparing the structures in different functional regions of the cerebral cortex to the study of comparative anatomy between species. In this way he hoped to determine whether it was possible to explain functional specialization through structural specialization:

> [...] for example, if an organizational detail is found exclusively in or is particularly exaggerated in the visual cortex, we will be justified in suspecting that it has something to do with [cerebral visual function]. Conversely, if an anatomical detail is repeated equally in all cortical regions, we will be justified in assuming that it is devoid of specific functional significance and instead is of more general [significance] (Cajal, 1899a).

Thus, Cajal and other authors thought that it was essential to carry out comparative histological studies to see whether any structural peculiarities existed in the human cerebral cortex that might yield a key to specific human behaviors. How Cajal changed his general scheme of neuronal classification when he studied the cortex of small mammals (rabbit, rat, and mouse) and after examining the human cortex is shown in Figure 1 (Cajal, 1917). In this way he reached the following conclusion:

> [...] my investigations showed that the functional excellence of the human brain is intimately linked to the prodigious abundance and unwonted wealth of forms of the so-called neurons with short axon (Cajal, 1917).

However, as stated above, other researchers did not necessarily support these observations. A good

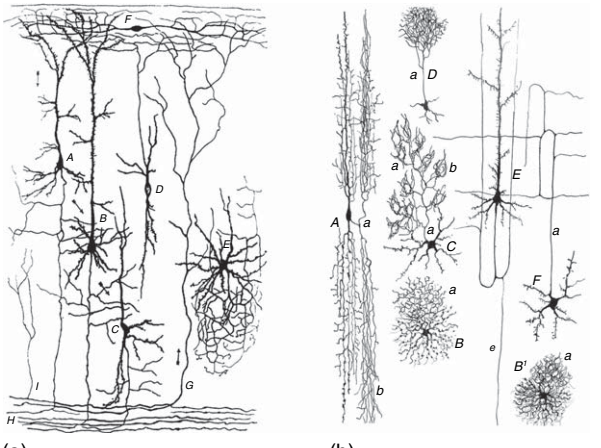

Figure 1 a, The principal cellular types based on the works of Cajal (1890–1894) on the cerebral cortex of small mammals (rabbit, guinea pig, rat, and mouse). A, pyramidal cell of medium size; B, giant pyramidal cell; C, polymorphic cell; D, cell whose axon is ascending; E, cell of Golgi; F, special cell of the molecular layer; G, fiber that terminates freely in the thickness of the cortex; H, white matter; I, collateral of the white matter. b, The principal cellular types based on the works of Cajal (1899–1902) on the human cerebral cortex. A, bitufted cell; B, dwarf cell with short axon; C, basket cell; D, dwarf cell with axon resolving into a tuft; E, pyramidal cell with arciform collateral branches ("small pyramidal cell characterized by an axon that is almost completely exhausted in giving rise to very long arciform and recurrent collaterals"); F, cell with ascending axon dividing into very long horizontal branches. Cajal (1917); referring to this figure, he says, "These cellular elements, particularly the first [A], second [B], fourth [E] and sixth [F], are extremely numerous and can be considered unique to the human cerebrum." – a, Reproduced from Cajal, S. R. 1894. The Croonian Lecture: La fine structure des centres nerveux. *Proc. R. Soc. Lond.* 55, 444–468, with permission. Copyright Herederos de Santiago Ramón y Cajal. b, Reproduced from Cajal, S. R. 1917. Recuerdos de mi vida, vol. 2. Historia de mi labor científica. Moya, with permission. Copyright Herederos de Santiago Ramón y Cajal.

reflection of the scientific thought at the time (against the idea of the qualitative differences between humans and other species) is provided by a disciple of Cajal, Rafael Lorente de Nó, who wrote the following:

> And by comparing our illustrations [regarding the mouse cerebral cortex] with those of our master (Cajal, 1899a, 1899b, 1900, 1901, 1911) that refer to the human cerebral cortex, it is difficult to find a detail that characterizes the latter. Neither the existence of special cells nor more [cortical] layers – qualities which are attributed to the human cortex – can be verified. Rather, we only note that in the [human cortex] there are a greater number of cells, but this in no way departs from the fundamental architectural plan (Lorente de Nó, 1922).

An important factor underlying the idea of the basic uniformity of the neocortex is its rather uniform appearance in Nissl stained sections, despite its functional diversity. Indeed, with the exception of some cortical regions such as the primary motor and visual areas, most of the areas are difficult to distinguish. This point was emphasized by Bailey and von Bonin (1951): "After long and careful study of the human isocortex the main impression we have retained is that vast areas are so closely similar in structure as to make any attempt at subdivision unprofitable, if not impossible."

Therefore, the notion that cortical information processing should be performed through ensembles of neurons organized into small, multiple, repeating microcircuits is both reasonable and attractive. The functional differences between the various cortical areas in different species or within the same species could be explained as the result of their different connections with afferent projection systems and efferent target structures. Thus, it is generally thought that the complexity of the neocortex increases in larger brains during evolution due to the addition of microcircuits with the same basic structure. As a result, it has been considered unlikely that new types of neurons or other fundamental differences would exist. In this article we shall discuss certain features of the neocortex that have been identified through comparative microanatomical studies that emphasize the differences between the human neocortex and that of other mammals. We will see that the human neocortex shows unique specialization, likely to be crucial for human cortical function.

4.12.2 Neuronal Components of the Neocortex

According to the collective work of a number of laboratories (reviewed in Peters and Jones, 1984), the neuronal components of the neocortex can be summarized as follows. The neurons can be divided into three major groups: pyramidal cells, spiny nonpyramidal cells, and aspiny nonpyramidal neurons. 'Pyramidal cells' are the most abundant cortical neurons (70–85% of the total population), constituting the vast majority of projection neurons, and they are located in all layers except layer I. These neurons are glutamatergic and represent the main source of cortical excitatory synapses. They are frequently subdivided according to their projection site. 'Spiny nonpyramidal cells' are, with some exceptions, short-axon cells (spiny interneurons) that are located in the middle layers (especially in layer IV). Various types of spiny nonpyramidal cells are recognized on the basis of their dendrite morphology, axonal arbors, and laminar connections. The typical spiny nonpyramidal cell (granule cells of layer IV) is an excitatory spiny stellate cell, and this cell type is considered by a number of authors to be a modified pyramidal cell. However, there is relatively little information about this group of cells and we will not deal with these cells in detail in the present article. 'Aspiny nonpyramidal neurons' are short-axon cells with smooth dendrites or dendrites that have only sparse spines (smooth interneurons). They are found in all layers, and represent the vast majority of short-axon cells and 15–30% of the total population of neurons although they show a wide morphological variety. Most smooth interneurons express GABA and are the main source of cortical inhibitory synapses. The different types of smooth interneurons are characterized by their particular synaptic connectivity and the expression of a variety of other neurotransmitters, neuroactive peptides, and calcium-binding proteins (reviewed in DeFelipe, 1993; Kawaguchi and Kubota, 1997; Somogyi *et al.*, 1998; Gupta *et al.*, 2000; Markram *et al.*, 2004; DeFelipe *et al.*, 2005). These attributes confer great functional diversity on them.

4.12.3 Cortical Circuits: Widely Shared Features of Connectivity

At present, there is little information on the detailed synaptic connectivity of pyramidal neurons and smooth interneurons (reviewed in DeFelipe *et al.*, 2005). However, these connections follow relatively simple rules: pyramidal cells establish synapses with the somata and dendrites of smooth interneurons, and with the dendritic spines (mainly) and shafts of pyramidal cells, avoiding the somata of these neurons. Smooth interneurons establish synapses with the somata and dendrites of other smooth

interneurons, and with all regions of pyramidal cells (dendrites, soma and, in some cases, the axon initial segment). Furthermore, interneurons do not necessarily form synapses exclusively with other particular types of neurons, nor are their synapses restricted to pyramidal or nonpyramidal cells, or to a single postsynaptic region. However, they do generally show a preference for certain postsynaptic partners. Thus, on the basis of the preferred postsynaptic region of the pyramidal neurons, four different groups of interneurons can be recognized (Figure 2):

- *Axo-dendritic cells (AD cells).* Cells forming synapses only (or almost only) with dendrites (shafts and spines).
- *Axo-somatodendritic cells (ASD cells).* Cells forming multiple synapses with both the dendrites and somata, but with a preference for somata.
- *Axo-dendrosomatic cells (ADS cells).* Cells forming multiple synapses with both the dendrites and somata, but with a preference for dendrites.
- *Axo-axonic or chandelier cells (CH cells).* Cells forming synapses with only the initial axon segment.

With the exception of chandelier cells that establish synapses exclusively with the axon initial segment of pyramidal cells, the other types of interneurons examined so far form synapses with both pyramidal cells and other smooth interneurons (Figure 2). The synaptic connections of large or classical basket cells, chandelier cells and double bouquet cells are three examples of smooth interneuron types that are morphologically and neurochemically well characterized, and that can be considered as common components of cortical circuits in primates (Figure 3). Each type innervates different regions of the pyramidal cell: large basket cells form synapses with the soma and proximal and distal dendrites (shafts and spines); chandelier cells with the axon initial segment; and double bouquet cells with the basal and apical collateral dendrites (shafts and spines). Regarding the subcortical and long-range corticocortical afferent systems, they generally establish synapses with dendrites of both pyramidal and smooth interneurons, avoiding the cell bodies of pyramidal neurons (reviewed in White, 1989). However, it has been shown that some subcortical afferents may form multiple contacts (synapses or appositions) with the somata and

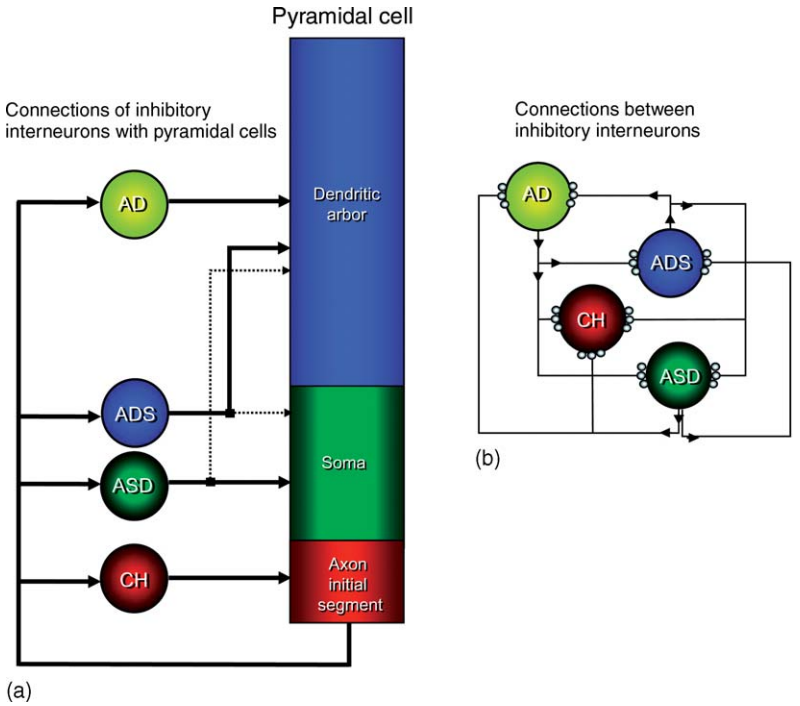

Figure 2 a, Illustration of the synaptic relationships between interneurons and pyramidal cells. Four different groups of interneurons can be recognized: axo-dendritic cells (AD cells); axo-dendrosomatic cells (ADS cells); axo-somatodendritic cells (ASD cells); and chandelier cells (CH cells). b, Illustration of the connections between interneurons. All interneurons are presumably connected with other interneurons, except CH cells, which only connect with pyramidal neurons. The connections between the same types of cells (for example, AD cells with AD cells) are not included for simplicity.

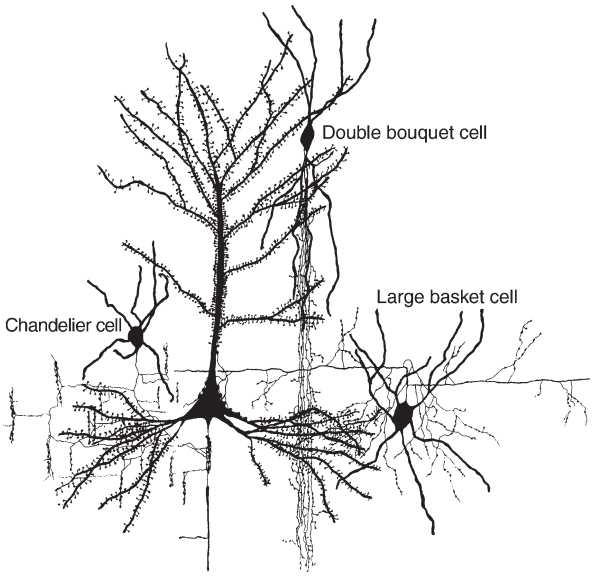

Figure 3 Illustration of the synaptic relationships between double bouquet cells, chandelier cells, and large basket cells with pyramidal cells. These cells constitute the best morphologically and chemically characterized types of aspiny nonpyramidal neurons. From DeFelipe, J. and Fariñas, I. 1992. The pyramidal neuron of the cerebral cortex: Morphological and chemical characteristics of the synaptic inputs. *Prog. Neurobiol.* 39, 563–607.

proximal dendrites of certain smooth interneurons (DeFelipe *et al.*, 1991; Freund and Gulyás, 1991).

4.12.4 Elementary Units of Operation: Macrocolumns and Minicolumns

Rafael Lorente de Nó was the first to propose that the cerebral cortex is composed of elementary operative units in which all elements of the cortex are represented. He conceived these units as small cylinders formed by vertical chains of neurons that crossed all cortical layers and had specific afferent fibers along their axes (Lorente de Nó, 1938). In the 1950s, Mountcastle was the first to provide physiological evidence for the columnar organization in the somatic sensory cortex of the cat and monkey (Mountcastle, 1957; Powell and Mountcastle, 1959). This organization was later investigated both anatomically and physiologically, and confirmed in a number of cortical areas by numerous investigators. Of these, the studies of Hubel and Wiesel in the visual cortex of the cat and monkey were the most detailed and convincing, corroborating the notion of this organization (for reviews see Hubel and Wiesel, 1977; Mountcastle, 1978, 1997; Jones, 1983, 2000a; Buxhoeveden and Casanova, 2002). Mountcastle proposed two types of vertical organization: the macrocolumn and the minicolumn (Mountcastle, 1978, 1997). The macrocolumn is the basic processing unit and consists of a cylinder of cortical tissue the width of which varies according to the spread of the specific individual afferent fibers entering the cortex (300–600 μm in diameter, depending on the cortical area and/or species). This macrocolumn is commonly referred to simply as a 'column' and is therefore the equivalent to the elementary cortical unit of operation of Lorente de Nó. In contrast, the minicolumn is the basic modular subunit in the cortex, representing the smallest functional unit of cortical organization, the ensemble of several minicolumns making up the macrocolumns. These minicolumns are formed by a group of vertically oriented interconnected cells that are contained in a vertical cylinder of tissue of approximately 25–50 μm in diameter (depending on the cortical area and/or species). Accordingly, Mountcastle (1997) defined the macrocolumn as a complex information processing and distributing unit that links a number of inputs to a number of outputs via overlapping internal processing chains (minicolumns).

The number of neurons within a strip of tissue with similar dimensions to a functional minicolumn (30 μm wide by 25 μm thick from the pial surface to the white matter) was counted by Rockel *et al.* (1980) in the motor, somatic sensory, visual, frontal, parietal, and temporal regions of the mouse, rat, cat, monkey, and human. The absolute number of neurons found in all areas and in all species was approximately 110, with the exception of the binocular part of area 17 of the monkey and human where there were approximately 2.5 times more neurons. In addition, earlier electron microscope studies had found that the proportion of neurons that could be characterized as pyramidal and nonpyramidal neurons through their ultrastructure was the same in various cortical areas of the monkey, rat, and cat (Sloper, 1973; Tömböl, 1974; Sloper *et al.*, 1979; Winfield *et al.*, 1980). These observations led Rockel and his colleagues to propose that the intrinsic structure of the neocortex is essentially more uniform than previously thought, and that differences in cytoarchitecture and function reflect different extrinsic connections. To date, these studies have had a strong influence and have provided much of the support for the dominant idea that the cerebral cortex is composed of multiple, small, repeating microcircuits and that the variations between cortical areas and species are insignificant, if we disregard the differences in the afferent and efferent connections (e.g., Douglas and Martin, 2004). However, we will see that there are a number of findings that strongly suggest this to be a gross oversimplification.

4.12.5 Observations That Challenge the Uniformity of the Neocortex

4.12.5.1 Distribution of Neurons

The uniform number of neurons within a narrow vertical piece of neocortical tissue from the pial surface to the white matter reported by Rockel *et al.* (1980) could not be confirmed in the mouse, rat, cat, or human (e.g., Beaulieu and Colonnier, 1989; Beaulieu, 1993; Skoglund *et al.*, 1996; DeFelipe *et al.*, 2002a). These later studies took advantage of more powerful quantitative methods that had been developed, such as the dissector method of Sterio (1984). In this way, differences in the number of neurons in cubes of 50 μm wide by 50 μm thick were identified from layer I to layer VI in the human, rat, and mouse (Figure 4). Furthermore, the conclusion that the proportion of pyramidal and nonpyramidal neurons was the same in various cortical areas of the monkey, rat, and cat based on electron microscope studies (Sloper, 1973; Tömböl, 1974; Sloper *et al.*, 1979; Winfield *et al.*, 1980) has been challenged. This is because it is frequently difficult to unequivocally identify pyramidal and nonpyramidal cells at the electron microscope level and also because the size of the samples analyzed with the electron microscope was relatively small. Since most nonpyramidal neurons are smooth GABAergic interneurons (Houser *et al.*, 1984; DeFelipe, 1993), the introduction of immunocytochemical techniques to visualize neurons expressing GABA or its synthesizing enzyme GAD has made it possible to obtain a more accurate picture of the proportion of aspiny nonpyramidal neurons. Using this approach in the rat, it was found that GABAergic cells represent no more than 15% of the total population in all cortical areas and layers II–VI (e.g., Meinecke and Peters, 1987; Beaulieu, 1993; Micheva and Beaulieu, 1995; Gabbott *et al.*, 1997). In the macaque monkey, they constitute 20% in the visual cortex and up to 25% in other cortical areas, even reaching up to 34–44% in supragranular layers of certain areas of the macaque and human (Hendry *et al.*, 1987; Beaulieu *et al.*, 1992; Gabbott and Bacon, 1996; del Río and DeFelipe, 1996). Therefore, there are clear differences between the rats and primates in terms of the proportion of smooth interneurons.

It is important to emphasize that there are more than 4500 mammalian species, but the vast majority of

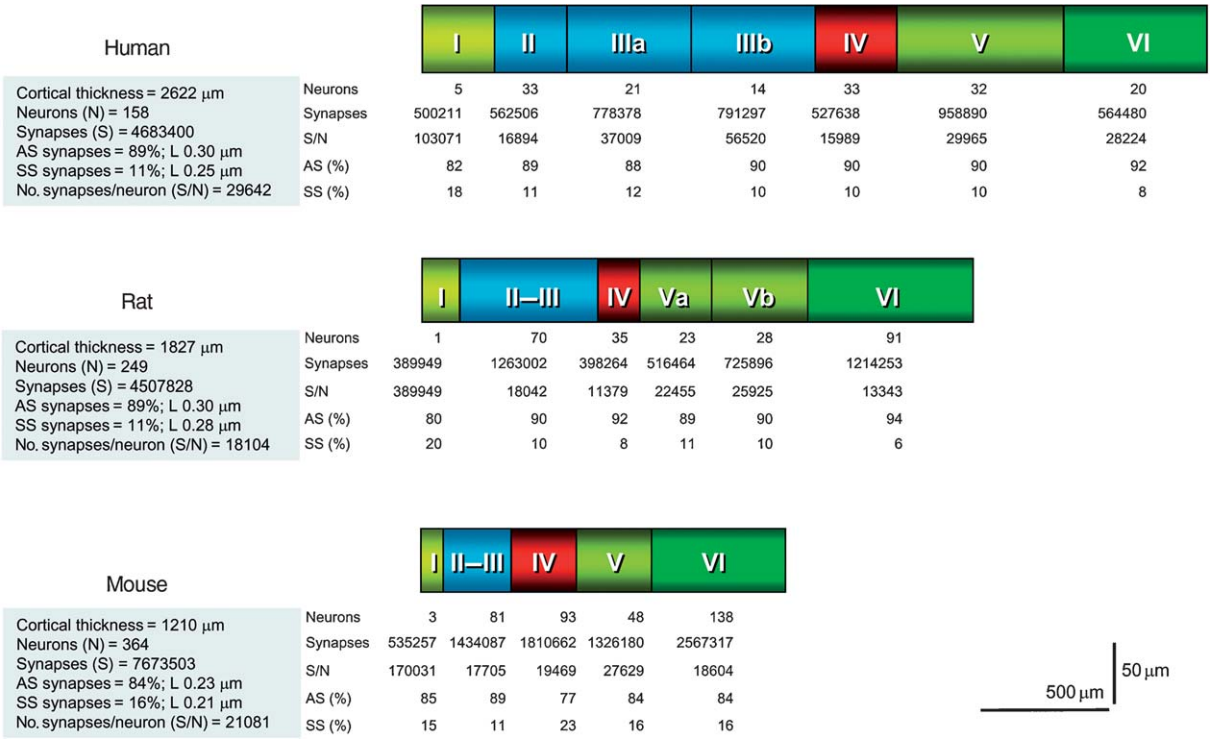

Figure 4 Comparison of the thickness of layers, number of neurons, and of the synaptic profiles within cubes of cortical tissue (50 μm wide by 50 μm thick) from the pial surface to the white matter in the human (anterolateral temporal cortex; T2-T3), rat (hindlimb area of the somatosensory cortex), and mouse (barrel cortex). L, cross-sectional length of synaptic junctions; AS, asymmetrical synapses; SS, symmetrical synapses. Values taken from DeFelipe, J., Alonso-Nanclares, L., and Arellano, J. I. 2002a. Microstructure of the neocortex: Comparative aspects. *J. Neurocytol.* 31, 299–316.

studies of cortical microstructure have been performed in the mouse, rat, cat, and monkey, and to a lesser extent in the human. Furthermore, researchers are often amazed, not only by the great variety of brain sizes and external topographies (Figure 5), but also by the variety of different cortical structures observed in the neocortex of some more 'exotic' species such as elephants, pigmy shrew, manatees, platypus, dolphins, giraffes, or apes (e.g., Haug, 1987; Reep *et al.*, 1989; Stolzenburg *et al.*, 1989; Glezer *et al.*, 1988, 1993; Hof

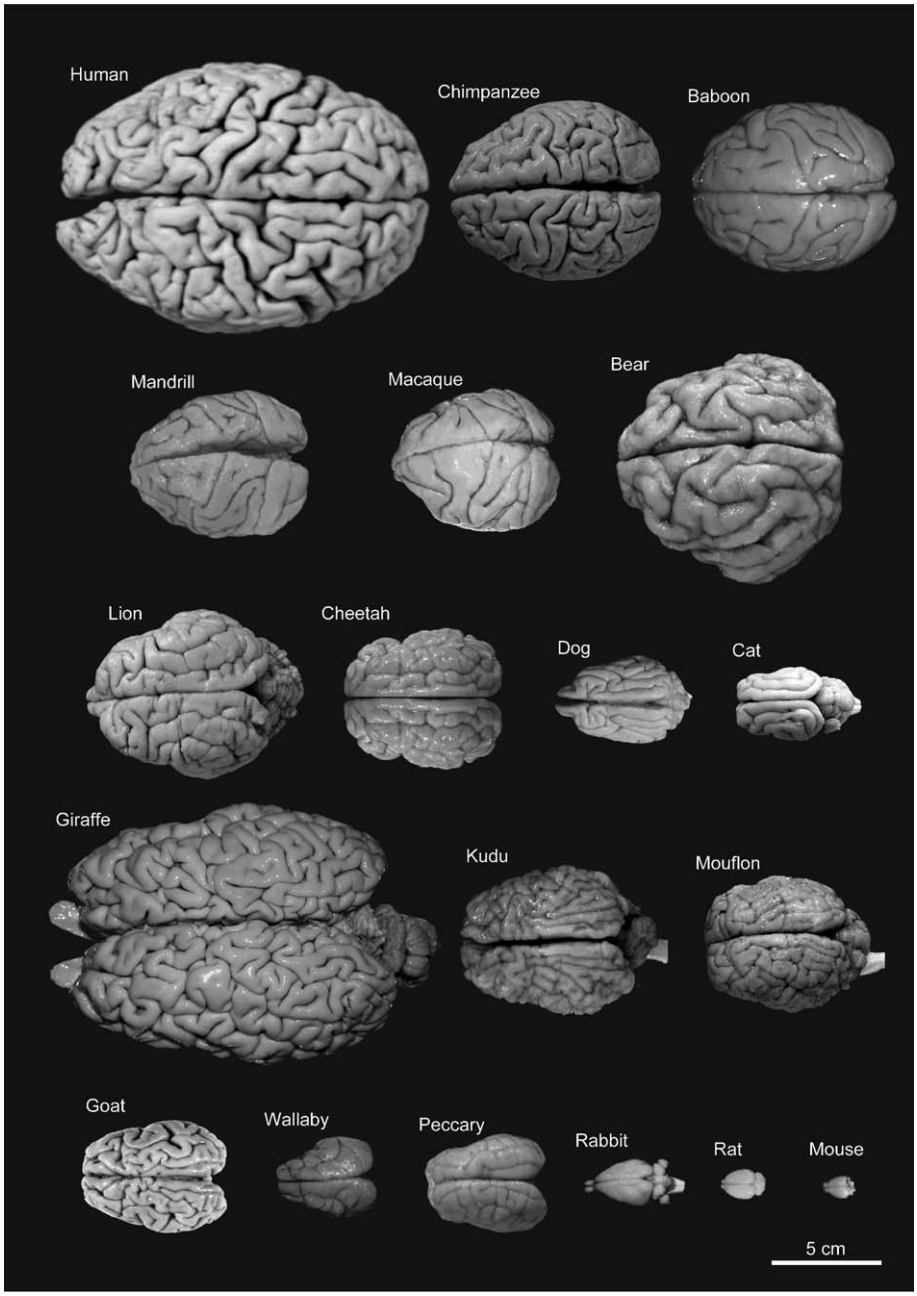

Figure 5 Photographs and weights in grams of the brains of different species. Primates: human (*Homo sapiens*, 1176 g), chimpanzee (*Pan troglodytes*, 273 g), baboon (*Papio cynocephalus*, 151 g), mandrill (*Mandrillus sphinx*, 123 g), macaque (*Macaca tonkeana*, 110 g). Carnivores: bear (*Ursus arctus*, 289 g), lion (*Panthera leo*,165 g), cheetah (*Acinonix jubatus*, 119 g), dog (*Canis familiaris*, 95 g), cat (*Felis catus*, 32 g). Artiodactyls: giraffe (*Giraffa camelopardilis*, 700 g), kudu (*Tragelaphus strepsiceros*, 166 g), mouflon (*Ovis musimon*, 118 g), ibex (goat, *Capra pyrenaica*, 115 g), peccary (*Tayassu pecari*, 41 g). Marsupials: wallaby (*Protemnodon rufogrisea*, 28 g). Lagomorphs: rabbit (*Oryctolagus cuniculus*, 5.2 g). Rodents: rat (*Rattus rattus*, 2.6 g), mouse (*Mus musculus*, 0.5 g). Scale bar: 5 cm. The chimpanzee brain was kindly supplied by Dr. Dean Falk. The rest of nonhuman brains were from material used in Ballesteros-Yáñez, I., Muñoz, A., Contreras, J., Gonzalez, J., Rodriguez-Veiga, E., and DeFelipe, J. 2005. The double bouquet cell in the human cerebral cortex and a comparison with other mammals. *J. Comp. Neurol.* 486, 344–360.

et al., 1999, 2000; Preuss, 2000, 2001; Preuss and Coleman, 2002; DeFelipe *et al.*, 2002a; DeFelipe, 2005). For example, Dexler (1913) found aggregations of neuronal cell bodies that he called 'basal Rindenkerne' (deep cortical clusters) in layer VI of the cerebral cortex of dugongs. Similar clusters of neurons were also found in the cerebral cortex of manatees in a region that Reep *et al.* (1989) called the 'cluster cortex'. This atypical cytoarchitecture has not been described in any other species, suggesting that it is a unique trait of the Sirenia (Reep *et al.*, 1989; see also Johnson *et al.*, 1994). Similarly, in layer II of the giraffe, instead of the typical, more or less homogeneous distribution of neurons, prominent small clusters of neurons exist, whereas this layer is very dense and thin in the platypus (DeFelipe *et al.*, 2002a; DeFelipe, 2005). Indeed, considerable differences have been observed in the neuron density between species. For instance, in the somatosensory cortex of the insectivorous white-toothed pygmy shrew (*Suncus etruscus*), whose brain weight is only 0.062 g, the neocortex is only 409 μm thick and there are approximately 170 000 neurons per mm^3. In contrast, the brain of the European mole (*Talpa europaea*) weighs 1.02 g, the neocortex is 1192 μm thick and there are only 40 000 neurons per mm^3 (Stolzenburg *et al.*, 1989). These densities are 7 and 1.6 times greater than in the human temporal cortex (24 186 neurons per mm^3; DeFelipe *et al.*, 2002a). It is sometimes frustrating to note how little attention has been paid to such comparative studies in spite of their importance for understanding the organization of the neocortex.

In conclusion, there is no 'basic' number or proportion of pyramidal cells and smooth interneurons, shared by all mammals, in a given minicolumn of tissue from layer I to layer VI. In addition, it is likely that as more studies are performed in different mammalian species, more differences will be found with regard to what we currently conceive as basic aspects of neocortical organization. This is important to bear in mind, particularly when one attempts to apply the data regarding cortical circuitry obtained from a given area of a particular species to another species.

4.12.5.2 Proportion of Interneurons

The variety of smooth interneurons is largely based on the diverse morphological, molecular, and physiological characteristics that they show (e.g., Cajal, 1911; Lorente de Nó, 1922; Jones, 1975; Szentágothai, 1975; Fairén *et al.*, 1984; Valverde, 1985; DeFelipe, 1993; Lund *et al.*, 1994; Kawaguchi and Kubota, 1997; Somogyi *et al.*, 1998; Gupta *et al.*, 2000; Markram *et al.*, 2004; DeFelipe *et al.*, 2005). Indeed, we still do not know how many different types of smooth interneurons exist but it is likely to reach the hundreds. If we consider the size of the minicolumn and estimate the number of neurons within a vertical strip of tissue 50 μm wide by 50 μm thick from the pial surface to the white matter (the approximate size of a minicolumn), we obtain a total number of 158 neurons in the human temporal cortex, and 249 and 364 neurons in the rat and mouse somatosensory cortex, respectively (Figure 4; DeFelipe *et al.*, 2002a). As discussed above, in primates and rodents approximately 25% and 15% of neurons are GABAergic and consequently, there would be 40, 37, and 55 smooth interneurons in these minicolumns, respectively. These numbers appear to be too low to include all types of such interneurons. Therefore, it seems likely that several types of microcircuits must exist that can be distinguished by their neuronal components.

As discussed elsewhere (DeFelipe, 2005), the axonal arborization of the vast majority of smooth interneurons surpasses the size limit of the minicolumn, and thus it would perhaps be more appropriate to consider the number of smooth interneurons within macrocolumns. The macrocolumn is approximately 500 μm wide by 500 μm thick from the pial surface to the white matter and within this, there would be a total number of 15 854, 24 885, and 36 395 neurons (DeFelipe *et al.*, 2002a). Considering the percentages of GABAergic neurons outlined above, in these macrocolumns there would be a total of 3963, 3733, and 5459 smooth interneurons in the human, rat, and mouse neocortex, respectively. These numbers do appear to be sufficiently large to include all types of smooth interneurons within the macrocolumn. Now the question arises as to whether the same types of smooth interneurons can be found in all macrocolumns or whether certain types are excluded from some macrocolumns at the expense of an increased number and proportion of other types.

Since the proportion of GABAergic neurons in the primate cortex is higher than in nonprimate mammals, three nonmutually exclusive events may have occurred during evolution (DeFelipe *et al.*, 2002a). First, the number of all types of interneurons already present in nonprimate mammals might have increased in general. Alternatively, an increase in the number of certain types of interneurons may have occurred. Third, new types of interneurons may have been generated during the evolution of the primate cortex.

There are a number of studies that have demonstrated interspecies variation in the distribution, number, morphology, and neurochemical characteristics of both pyramidal cells and smooth

interneurons, supporting the theory of the evolutionary diversity of neurons (e.g., Campbell and Morrison, 1989; Lewis and Lund, 1990; Glezer *et al.*, 1993, 1998; del Río and DeFelipe, 1997a; Nimchinski *et al.*, 1999; Hof *et al.*, 1999, 2000; Elston *et al.*, 1999a, 1999b, 2001, 2005a, 2005b; Dombrowski *et al.*, 2001; Preuss and Coleman, 2002; Ballesteros-Yáñez *et al.*, 2005). For example, the basal dendritic arbor of pyramidal cells displays remarkable differences in terms of size, number of bifurcations, and spine density between homologous cortical areas of different species (reviewed in Elston, 2003a, 2003b; see also Specialization of the Neocortical Pyramidal Cell during Primate Evolution). Since each dendritic spine appears to establish at least one excitatory synapse, these differences indicate the existence of species variations in the cortical circuits established by pyramidal cells. Regarding interneurons, there are a number of interesting examples (DeFelipe, 2002) of which we have selected three cases: the neurons expressing tyrosine hydroxylase (TH), the chandelier cells, and the double bouquet cells.

4.12.5.2.1 Neurons expressing TH TH is the rate-limiting enzyme in catecholamine synthesis. Catecholaminergic fibers are widely distributed throughout the nervous system, yet neurons expressing TH are restricted to certain regions of the brain and spinal cord, including the cerebral cortex (reviewed in Smeets and Gonzalez, 2000). In the neocortex, the laminar distribution of TH-positive neurons is distinct between different species (Figure 6), as is the co-expression of GABA (or GAD). These TH-positive neurons are relatively numerous and are found mostly in layers V and VI of the human neocortex (Benavides-Piccione and DeFelipe, 2003). In contrast, there are no or very few neurons, depending on the cortical area, which express TH in the macaque monkey neocortex (Kohler *et al.*, 1983; Lewis *et al.*, 1988) (Figures 6a and 6b). In the neocortex of certain cetaceans, TH-positive neurons are mainly confined to layer I (Hof *et al.*, 1995). The relatively few TH-positive neurons in the rat can be found in all the cortical layers, yet are most abundant in layers II and III. In addition, the majority of TH-positive neurons in the rat cortex co-express GABA or GAD (Kosaka *et al.*, 1987), whereas only approximately 50% contain GABA in the human neocortex (Gaspar *et al.*, 1987; Hornung *et al.*, 1989; Kuljis *et al.*, 1989; Trottier *et al.*, 1989). This finding is striking because it is thought that most smooth interneurons are GABAergic (Houser *et al.*, 1984) and, therefore, they appear to represent a special type of interneuron particularly abundant in the human neocortex. TH-positive neurons in the human neocortex constitute a subpopulation of smooth interneurons that may include Martinotti cells (or cells with an ascending axon) but not double bouquet cells, chandelier cells, or basket cells (Benavides-Piccione and DeFelipe, 2003).

4.12.5.2.2 Chandelier cells The chandelier cell is a type of smooth interneuron that is distinguished by the short vertical rows of boutons at the terminal portions of its axon (Ch terminals) that resemble candlesticks (Szentágothai and Arbib, 1974). In a variety of species including humans, Ch terminals have been shown to only innervate the axon initial segments of pyramidal cells with which they form symmetrical synapses. Indeed, they represent the major or sole source of synapses on the axon initial segments of pyramidal cells (e.g., Somogyi, 1977; Fairén and Valverde, 1980; Peters *et al.*, 1982; Somogyi *et al.*, 1982; Freund *et al.*, 1983; DeFelipe *et al.*, 1985, 1989a; del Río and DeFelipe, 1994; Gonchar *et al.*, 2002; for a review see DeFelipe and Fariñas, 1992). It seems clear that a given chandelier cell does not form synapses with the initial axon segment of any pyramidal cell it comes across, since the number of pyramidal neurons within the axonal plexus of a chandelier cell is higher than the number of chandelier cell axon terminals. Indeed, only a small proportion of pyramidal cells were innervated by impregnated chandelier cells in layers II and III of area 4 of the monkey, up to 20% (DeFelipe *et al.*, 1985). Until 1989, it was only possible to visualize these neurons by the Golgi method or using intracellular injections of horseradish peroxidase (e.g., Szentágothai, 1975; Jones, 1975; Somogyi, 1977; Fairén and Valverde, 1980; Somogyi *et al.*, 1982; Peters *et al.*, 1982; Freund *et al.*, 1983; DeFelipe *et al.*, 1985; Marin-Padilla, 1987). Because of the inconsistency of the Golgi method and the difficulties in performing intracellular injections in these neurons, their distribution across the cerebral cortex was not studied. However, since they can now be identified by immunocytochemical detection of the calcium-binding protein, parvalbumin (DeFelipe *et al.*, 1989a), their distribution, synaptic connectivity, and neurochemical characteristics can be investigated in detail. As a result, chandelier cells or Ch terminals have been visualized using a variety of antibodies, including antibodies against calbindin (del Río and DeFelipe, 1997a; Arellano *et al.*, 2004), corticotropin-releasing factor (Lewis *et al.*, 1989; Lewis and Lund, 1990), GABA transporter GAT-1 (DeFelipe and González-Albo, 1998; Woo *et al.*, 1998), or against the polysialylated forms of the cell-surface glycoprotein NCAM (PSA-NCAM) (Arellano *et al.*, 2002).

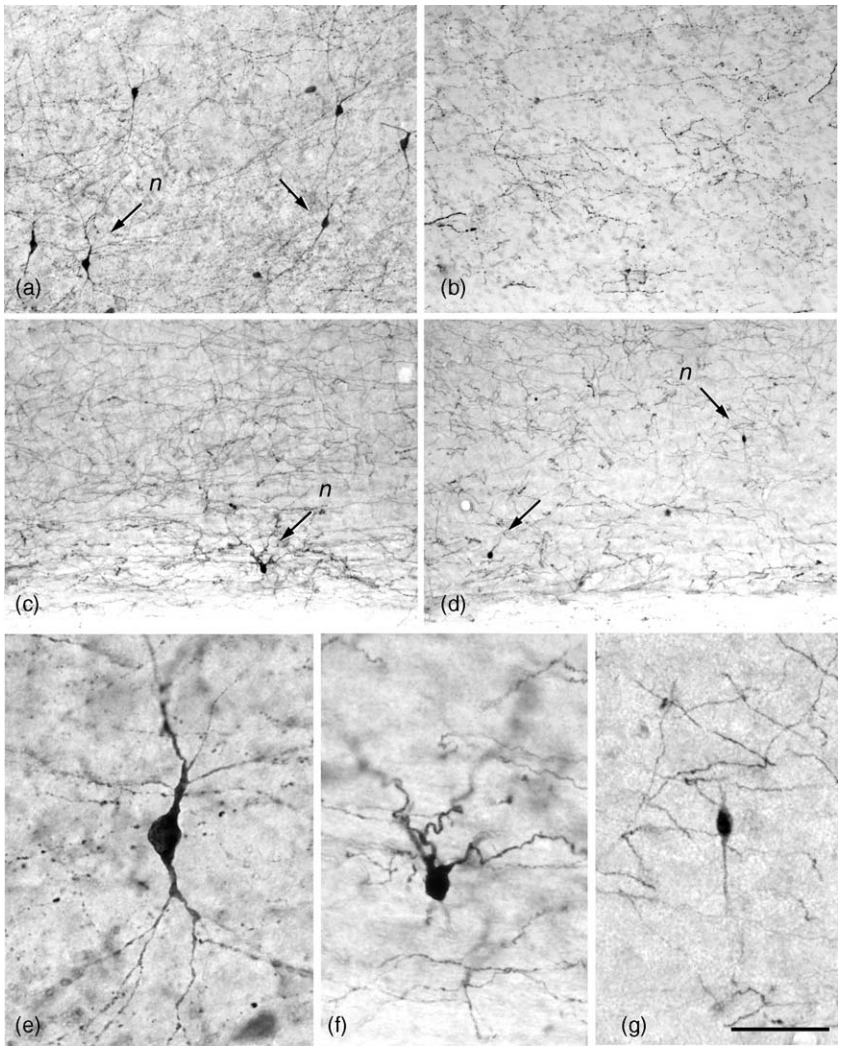

Figure 6 Low-power photomicrographs of TH immunostaining in the temporal cortex of the human (anterolateral temporal lobe) (a), macaque (area TE) (b), somatosensory cortex of the gerbil (c), and somatosensory cortex of rat (d), extending from lower part of layer V to the white matter. e–g, High-power magnification of the TH-positive neurons indicated (*n*) in (a), (c), and (d), respectively. TH-immunoreactive neurons are relatively abundant in the human compared to other species where only occasional cells were found except in the macaque monkey, where no TH-positive neurons were observed in the lateral temporal cortex. Scale bar: a–d, 160 μm; e–g, 40 μm.

On the basis of these and other immunocytochemical studies, chandelier cells can be chemically defined as GABAergic cells that contain parvalbumin and calbindin but not the calcium-binding protein calretinin, and which contain the neuropeptide corticotropin-releasing factor but not other neuropeptides such as cholecystokinin, somatostatin, neuropeptide Y, vasoactive intestinal polypeptide, and tachykinins (reviewed in DeFelipe and Fariñas, 1992; DeFelipe, 1997, 1999).

The most general, prominent and complete staining of Ch terminals is obtained with immunocytochemistry for parvalbumin and GAT-1 (DeFelipe and González-Albo, 1998). Parvalbumin-positive Ch terminals are present throughout layers II–VI of the human temporal neocortex and they are particularly prominent in layers V and VI (del Río and DeFelipe, 1994; Arellano *et al.*, 2002). However, the expression of other substances varies across species and across cortical areas and layers. Therefore, chandelier cells are chemically heterogeneous. For example, using antibodies against corticotropin-releasing factor to examine the prefrontal and occipital cortex of *Macaca mulatta, Macaca fascicularis*, and *Saimiri sciureus*, Lewis and Lund (1990) only found labeled Ch terminals in the *S. sciureus* and mainly in layer IV of the prefrontal cortex. Calbindin immunocytochemistry

labels a small subpopulation of Ch terminals located mainly in layers V and VI of the human neocortex, but not in other species including the macaque monkey (del Río and DeFelipe, 1997a; DeFelipe *et al.*, 1999b). Furthermore, in the human temporal neocortex the majority of parvalbumin-positive Ch terminals are immunostained for PSA-NCAM in layers II and III, whereas in deeper layers Ch terminals expressing PSA-NCAM are only occasionally found (Arellano *et al.*, 2002). In the temporal cortex of the macaque (area TE), the distribution of Ch terminals containing parvalbumin is different to that observed in the human temporal neocortex, since they are observed mainly in layers II–IV in the macaque and only very sparsely in layers V and VI (DeFelipe *et al.*, 1999b; Figure 7). But what is the meaning of this lack of immunostaining? In some cases, it certainly does not mean that chandelier cells are not present since double-labeling immunocytochemistry clearly shows the contrary. For example, the lack of PSA-NCAM immunostaining in layer VI in the human temporal neocortex does not mean that there are no Ch terminals in this layer because they are prominently stained for parvalbumin. Rather, these observations suggest that the neurochemical characteristics, and therefore the functional properties of chandelier cells, vary considerably between cortical layers, areas, and species.

Nevertheless, differences of a more fundamental nature regarding chandelier cells exist. Since chandelier cells innervate only the axon initial segment of pyramidal cells, the existence of pyramidal cells whose axon initial segment lacks synapses indicates that they are not innervated by chandelier cells. By examining the synaptology of the axon initial segment of corticothalamic projecting pyramidal cells in layer VI of the cat visual cortex, only one or two axo-axonic synapses were found to be established and, therefore, they were not postsynaptic targets of chandelier cells (Fariñas and DeFelipe, 1991). In summary, it appears that the axon initial segment of pyramidal cells may or may not be innervated by chandelier cells and that when it is innervated, chandelier cells may show a wide variety of molecular characteristics depending on the cortical layer, area, and species.

4.12.5.2.3 Double bouquet cells The French term 'double bouquet cell' (bitufted cell in English) was given by Cajal (1899a) to describe a variety of morphologically distinct interneurons in the human cerebral cortex. One of these cells is characterized by its long, descending, vertically bundled axon, which crosses several cortical layers. However, instead of giving a different name to this particular cell type, such as, for example, Szentágothai who called them "cells with horsetail-shaped axons," Jones "type 3," and Valverde who used "cells with axons forming vertical bundles" (Szentágothai, 1973, 1975; Jones, 1975; Valverde, 1978, 1985), a number of authors, including ourselves, have preferred to apply the term 'double bouquet cell' only to those neurons with axons forming such vertical bundles irrespective of their somato-dendritic morphology (DeFelipe, 2002). The axonal arbors of these cells, generally termed double bouquet cell axonal 'bundles' or 'horse-tails', are the source of a large number of GABAergic inhibitory synapses on small dendritic shafts and dendritic spines within a very narrow column of cortical tissue (Somogyi and Cowey, 1981; DeFelipe *et al.*, 1989b, 1990; de Lima and Morrison, 1989; Peters and Sethares, 1997).

As with chandelier cells, neither the Golgi method nor intracellular injections are adequate techniques for examining the distribution or chemical characteristics of these cells. However, thanks to the introduction of calbidin immunocytochemistry (Hendry *et al.*, 1989; DeFelipe *et al.*, 1989b, 1990), it is possible to study their distribution, synaptic connectivity, and neurochemical features in detail. At present, double bouquet cells can be

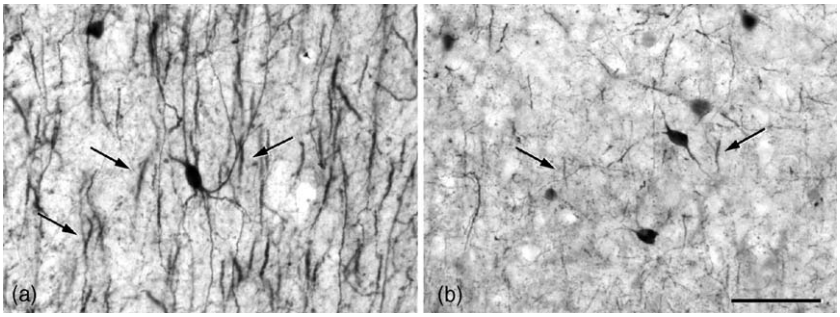

Figure 7 Low-power photomicrographs from human (a) and macaque (b) temporal cortex to illustrate the pattern of immunostaining for parvoalbumin in layer VI. Note how numerous the parvoalbumin-positive chandelier cell axon terminals are (some of them indicated by arrows) in the human compared to the macaque. Scale bar: 70 μm.

neurochemically defined as GABAergic interneurons that are immunoreactive for calbindin, certain subpopulations also expressing the calcium-binding protein calretinin and the peptides somatostatin and tachykinin. In contrast, these cells never contain other peptides or parvalbumin, nor do they appear to express markers for nitric oxide expressing neurons (Somogyi *et al.*, 1981; de Lima and Morrison, 1989; DeFelipe *et al.*, 1989b, 1990, 1999b; DeFelipe and Jones, 1992; del Río and DeFelipe, 1995, 1997b; DeFelipe, 1997; Benavides-Piccione and DeFelipe, 2003).

Double bouquet cells in the human and macaque monkey are very numerous and regularly distributed (Figure 8). Therefore, they are considered to be a key element in the microcolumnar organization of the cerebral cortex, acting on groups of pyramidal cells located in different layers within the minicolumns (DeFelipe *et al.*, 1990; Favorov and Kelly, 1994a, 1994b; del Río and DeFelipe, 1995; Peters and Sethares, 1997; DeFelipe, 1997, 2002, 2005; Jones, 2000a). Indeed, it has been shown that the radial fasciculi (bundles of myelinated axons originated from vertical aggregates of pyramidal cells or pyramidal cell modules) and double bouquet axons overlap on a one-to-one basis (del Río and DeFelipe, 1997b; Peters and Sethares, 1997; Ballesteros-Yáñez *et al.*, 2005). This microcolumnar organization has been demonstrated in the visual, somatosensorial, auditory, and temporal cortex of the macaque monkey, as well as in the human prefrontal, motor, somatosensory, temporal, and visual cortex (DeFelipe *et al.*, 1990, 1999b; Peters and Sethares, 1997; del Río and DeFelipe, 1997b; Ballesteros-Yáñez *et al.*, 2005). In addition, using immunocytochemistry for calbindin we found double bouquet cell horse-tails in a variety of nonprimate species but not in rodents (mouse and rat), lagomorphs (rabbit), and artiodactyls (goat) (Ballesteros-Yáñez *et al.*, 2005). Double bouquet cell axonal horse-tails were identified in the frontal, parietal, and occipital regions of carnivores (cat, cheetah, lion, and dog), although that they were mainly restricted to the occipital cortex, rarely existing in the parietal and frontal cortical regions studied (Ballesteros-Yáñez *et al.*, 2005). We also found that there are many fewer of these neurons in carnivores than in humans (and monkeys). In the neocortex of many species, including rodents, lagomorphs, and artiodactyls, some vertically oriented calbindin-positive axons have been identified but these did not present the typical axonal arbors of double bouquet cells. While it is possible that these cells are present but not stained for calbindin in these species and cortical regions, it is unlikely since they have not been observed using any of the other known markers for double bouquet cell axons as far as we are aware.

Since the proportion of GABAergic neurons is higher in primates than in rodents, we proposed that the presence of double bouquet cells may be at least partly responsible for the higher proportion of GABAergic cells in primates (DeFelipe, 2002; DeFelipe *et al.*, 2002a). It is known that distinct

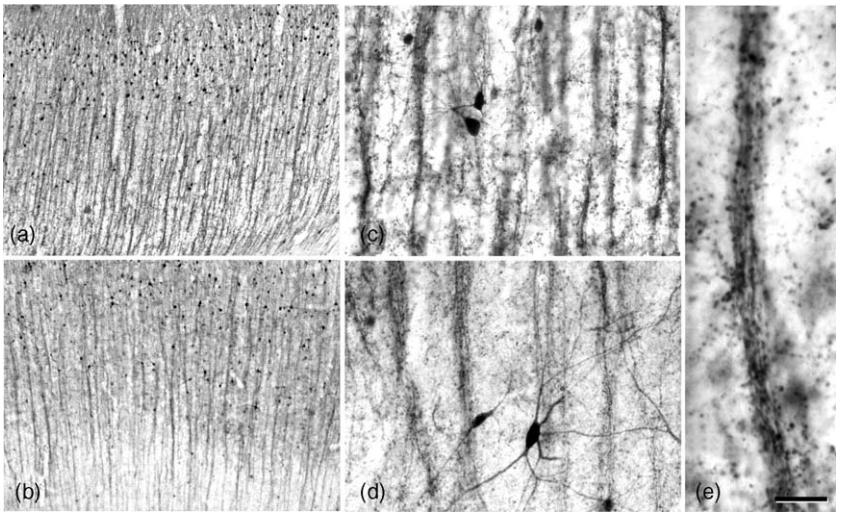

Figure 8 Low-power photomicrographs from the human occipital (area V2) (a) and temporal (anterolateral temporal lobe) (b) cortex immunostained for calbindin, illustrating how numerous double bouquet cell axons (horse-tails) are in the human cortex. (c) and (d) are higher magnifications of (a) and (b), respectively, to show immunoreactive neurons and double bouquet cell horse-tails. e, Example of a double bouquet cell horse-tail (temporal cortex) at a high magnification. subtypes of interneurons may derive from different telencephalic subdivisions (Anderson *et al.*, 2002; Xu *et al.*, 2004; for a review see Xu *et al.*, 2003) and it is possible that the interspecies differences in the types of interneuron might reflect species-specific programs of GABAergic neurogenesis. For example, the existence of two lineages of human cortical GABAergic neurons has been proposed (Letinic *et al.*, 2002). One lineage, which expresses the transcription factors Dlx1/2 and Mash1, makes up 65% of the GABAergic neurons. These cells originate in the ventricular and subventricular zones of the dorsal telencephalon and migrate radially across the intermediate zone to the cerebral cortex. The other lineage, the remaining 35% of GABAergic neurons, express Dlx1/2 but not Mash1, and these cells originate in the ganglionic eminence of the ventral telencephalon from where they migrate tangentially across the intermediate zone to the cerebral cortex. However, all or almost all GABAergic neurons in rodents originate in the ganglionic eminence and migrate tangentially to the cerebral cortex (Tan *et al.*, 1998; Anderson *et al.*, 1999; Marin and Rubenstein, 2003; Xu *et al.*, 2003). As double bouquet cells are very numerous, to the extent that double bouquet axons and pyramidal cell modules generally overlap on a one-to-one basis, it is possible that double bouquet cells of the primate cortex might originate in the ventricular/subventricular zone from the GABAergic lineage expressing Dlx1/2 and Mash1. These neurons may migrate radially along common pathways as radial units, or as the ontogenetic columns that form the pyramidal cell modules (Rakic, 2002). Thus, we suggest that this could be a mechanism by which the complementary microcolumnar organization of double bouquet cells and pyramidal cell modules might originate in the neocortex of primates (DeFelipe, 2002, 2005). In conclusion, while double bouquet cells may be an important element in the microcolumnar organization of primates, this is not necessarily the case in other mammalian species. Differences in the abundance and distribution of double bouquet cells appear to reflect fundamental differences in the cortical microorganization between primates and other species.

4.12.5.3 Synaptology of the Neuropil

Differences and similarities in synaptic density have been reported in various cortical areas and species (see below). However, it is often difficult to interpret these findings because the number of specimens studied and the extension of the cortex examined is frequently relatively small. Moreover, in many studies the different cortical layers have not been examined systematically. Other considerations, such as the age of the individuals may also differ considerably between studies and this information is often not available. This is particularly important since changes in the density of synapses may occur during puberty and throughout adulthood, depending on the cortical area, layer, and species examined (reviewed in Rakic *et al.*, 1994; see also Bourgeois *et al.*, 1994; Poe *et al.*, 2001; DeFelipe *et al.*, 1997, 2002a, 2002b). Furthermore, there is no general consensus for the method of counting synapses and, therefore, it is often difficult to compare data obtained in different laboratories (DeFelipe *et al.*, 1999a). Nevertheless, we shall review some of these issues and compare them with the data we have obtained from the study of the morphology and density of synapses in the thin neuropil (i.e., avoiding the somata of neurons and glia, blood vessels, large dendrites, and myelinated axons) of the mouse visual and somatosensory cortex (area 17 and barrel cortex, respectively), the rat hindlimb area, and the human anterolateral temporal cortex (Brodmann's areas 20 and 21; DeFelipe *et al.*, 2002a). In later studies, we also examined the morphology and density of synapses in relation to their depth in the cortex (from layer I to layer VI), in the adult mouse (3 months old) and rat (5 months old), and in human (normal cerebral cortex obtained from surgically resected brain tissue from three male individuals of 24, 27, and 36 years of age). We applied the same methods to quantify synapses in the thin neuropil, and the neuronal density was also calculated to compare and estimate the number of synapses per neuron in each cortical layer and species. Data from the mouse visual cortex were not used for statistical comparisons and, therefore, unless otherwise specified, the mouse cortex refers to the barrel cortex. In addition, we have included data from unpublished electron microscope studies of the temporal cortex (area TE) of two female adult macaque monkeys in this article. This material was only used to estimate the percentage of multiple synapses.

4.12.5.3.1 Morphology of synapses A consistent finding in all cortical areas and species is that there are two major morphological types of synapses, Gray's (1959) type I and type II synapses that correspond to the asymmetrical and symmetrical types of Colonnier, respectively (Colonnier, 1968; see also Colonnier, 1981; Peters, 1987; Peters *et al.*, 1991; Peters and Palay, 1996). The hallmark for distinguishing these two types of synapses is the postsynaptic density, which is prominent in

asymmetrical synapses and thin in symmetrical synapses. In general, the axons of pyramidal cells (and to a lesser extent spiny stellate cells) are the major source of asymmetrical synapses, as well as the thalamocortical fibers and other main subcortical afferent systems. Most symmetrical synapses originate from the GABAergic interneuron population. Since pyramidal and spiny stellate cells, thalamocortical fibers and most extrathalamic subcortical afferent fibers are excitatory and GABA is an inhibitory neurotransmitter, asymmetrical synapses are excitatory and symmetrical synapses inhibitory (for reviews, see Houser *et al.*, 1984; White, 1989; Peters *et al.*, 1991; DeFelipe and Fariñas, 1992; Peters and Palay, 1996; Conti and Weinberg, 1999; Jones, 2000b; Amitai, 2001). Synaptic size also plays an important role in determining the functional properties of synapses (Mackenzie *et al.*, 1999; Schikorski and Stevens, 1999; Takumi *et al.*, 1999; Kubota and Kawaguchi, 2000; Lüscher *et al.*, 2000). For example, larger synapses seem to contain a greater number of postsynaptic receptors (Mackenzie *et al.*, 1999) and are associated with a greater number of docked synaptic vesicles (Schikorski and Stevens, 1999).

It is important to bear in mind that the vast majority of asymmetrical synapses originate from the cerebral cortex itself, through the local axonal arborization of pyramidal cells (and spiny stellate cells), and from the distal axonal arborization of corticocortical projecting pyramidal cells. This idea comes mainly from the study of thalamocortical axon terminals, which contribute only a small proportion of asymmetrical synapses although they represent a major subcortical afferent system to the cortex. It has been estimated that even in the layers to which the thalamocortical fibers predominantly project, they only represent 5–10% of asymmetrical synapses (Peters, 2002), although other quantitative studies showed this percentage to be higher. For example, LeVay and Gilbert (1976) used electron microscope autoradiography to quantify geniculocortical terminals and synapses in the cat visual cortex and they found the percentage of thalamocortical synapses in layer IV to be about 20%. Similarly, following lesion-induced degeneration (White, 1978) or in studies of anterograde transport of the lectin, *Phaseolus vulgaris leucoagglutinin*, to label and quantify thalamocortical terminals in the mouse barrel cortex (Keller *et al.*, 1985), approximately 20% of the asymmetrical synapses in layer IV were formed by thalamocortical axon terminals (reviewed in White, 1989). Thus, the differences between species in the density and the size of asymmetrical and symmetrical synapses reflect how similar or dissimilar their intrinsic excitatory and inhibitory circuits are in general.

In most electron microscope studies, the percentage of asymmetrical and symmetrical synapses varied between 80–90% and 20–10%, respectively in all the cortical areas and species examined (e.g., Blue and Parnavelas, 1983; Rakic *et al.*, 1986; Zecevic *et al.*, 1989; Schüz and Palm, 1989; Zecevic and Rakic, 1991; Beaulieu *et al.*, 1992, 1994; Bourgeois *et al.*, 1994; Beaulieu and Colonnier, 1985, 1989; Micheva and Beaulieu, 1996; DeFelipe *et al.*, 1997, 2002a, 2002b; White *et al.*, 1997; Marco and DeFelipe, 1997). Therefore, as a general rule excitatory circuits predominate over inhibitory circuits, a predominance that is imposed mainly by the axons of pyramidal cells. The fact that there are approximately 10% more inhibitory neurons in the macaque and human compared to the rat, but the percentage of asymmetrical and symmetrical synapses in the human and rat cortex is the same (89% asymmetrical and 11% symmetrical; DeFelipe *et al.*, 2002a), suggests that human inhibitory interneurons (the main source of symmetrical synapses) and pyramidal neurons (the main source of asymmetrical synapses) have axons with fewer and more synaptic boutons, respectively.

A given axon terminal forms an asymmetrical or symmetrical synapse with either one (single synapse), or with two or more postsynaptic elements (multiple synapses). As shown in Table 1, it appears that axon terminals originating from different types of cortical cells or from the thalamus give rise to different proportions of multiple synapses. Therefore, we have examined the proportion of multiple synapses in the neuropil of the human, macaque, rat, and mouse. Whereas the large majority of axon terminals establish single synapses with a postsynaptic element in the four species examined (human, 99.7%; macaque, 99.3%; rat, 99%; mouse, 97.6%), notable differences between species were found in certain layers (Table 2). For example, the greatest proportion of multiple synapses in the human, rat, and mouse were observed in layer IV (0.7% in the human, 1.6% in the rat, and 4.5% in the mouse), whereas in the macaque the highest proportion was found in layer IIIb (0.9%). In layer I, no axon terminals were seen to establish multiple synapses in the human cortex, whereas in the macaque, rat, and mouse multiple synapses contributed 0.8%, 0.7%, and 0.9%, respectively. Although small, these percentages represent a large number of synapses. For instance, in layer IV of the human temporal cortex, rat hindlimb area, and mouse barrel cortex there are 8 million, 29 million, and 173

Table 1 Examples of multiple synapses formed by identified axons in various species and cortical areas

Type of cell or axon	*Species, cortical area*	*No. synaptic axon terminals examined, type of synapse*	*% multiple synapses*[a]	*Reference*
Golgi-impregnated interneuron with axonal arcades (layers II–III)	Cat, visual cortex (area 17)	152, symmetrical	7	DeFelipe and Fairén (1988)
Tachykinin-immunoreactive terminals (layers II, III, V, VI)	Macaque monkey, somatic sensory cortex (areas 1 and 2), motor cortex (area 4)	312, symmetrical	11	Jones *et al.* (1988)
Intraaxonally injected geniculocortical axon (parvicellular axons; layer IV C)	Macaque monkey, visual cortex (area 17)	150, asymmetrical	16–37	Freund *et al.* (1989)
Intraaxonally injected geniculocortical axon (magnocellular axons; layer IV C)	Macaque monkey, visual cortex (area 17)	173, asymmetrical	35	Freund *et al.* (1989)
Calbindin-immunoreactive double bouquet cell axons (layer III)	Macaque monkey, somatic sensory cortex (areas 3a and 1)	237, symmetrical	16	DeFelipe *et al.* (1989b)
Tachykinin-immunoreactive double bouquet cell axons (layer III)	Macaque monkey, primary auditory cortex	277, symmetrical	16	DeFelipe *et al.* (1990)
Intracellularly injected cluth cells (layers IV, V)	Cat, visual cortex (area 17)	269, symmetrical	22	Kisvárday *et al.* (1985)
PHA-L labeled corticocortical axons (layers III, IV)	Cat, visual cortex (area PMLS)	182, asymmetrical	4	Lowenstein and Somogyi (1991)
Intracellularly injected large basket cells (layer III)	Cat, visual cortex (area 17)	155, symmetrical	11	Somogyi *et al.* (1983)

[a]Number of single axon terminals forming synapses with two or more postsynaptic profiles (percentage). These numbers must be considered as an underestimate since the percentages were obtained from single electron microscope sections: a synaptic junction can be observed in approximately 5–8 sections, whereas an axon terminal of 1 μm of diameter for example, can be followed in approximately 16 sections (60 nm thick).

Table 2 Percentages of multiple synapses in the neocortex of the human, macaque, rat, and mouse

million multiple synapses per mm^3, respectively. These quantitative observations suggest that there are significant differences in the proportion or types of axons that establish multiple synapses in the different cortical areas or species.

4.12.5.3.2 Cross-sectional length of synaptic junctions In most electron microscope studies, the cross-sectional length of synaptic junctions in all cortical areas and species studied so far varies between 0.20 and 0.40 μm. (e.g., Blue and Parnavelas, 1983; Beaulieu and Colonnier, 1985, 1989; Schüz and Palm, 1989; Glezer and Morgane, 1990; Beaulieu *et al.*, 1992, 1994; Huttenlocher and Dabholkar, 1997; White *et al.*, 1997; DeFelipe *et al.*, 1997, 2002a,

2002b; Marco and DeFelipe, 1997). A comparison of the mean cross-sectional length of synaptic junctions in the various cortical layers between the human, rat, and mouse (DeFelipe *et al.*, 2002a), revealed that the mean cross-sectional length when all layers were considered was 0.30, 0.30, and 0.23 μm for asymmetrical synapses, and 0.25, 0.28, and 0.21 μm for symmetrical synapses, respectively (Figure 9 and Table 3). Nevertheless, the mean cross-sectional length of asymmetrical synapses was significantly shorter in all layers of the mouse cortex when compared to the human and rat. No significant differences were found between humans and rats except in layer V of the human where asymmetrical synapses were shorter (0.27 μm) compared to layer Va (0.31 μm) and Vb (0.30 μm) of the rat. With regards to symmetrical synapses,

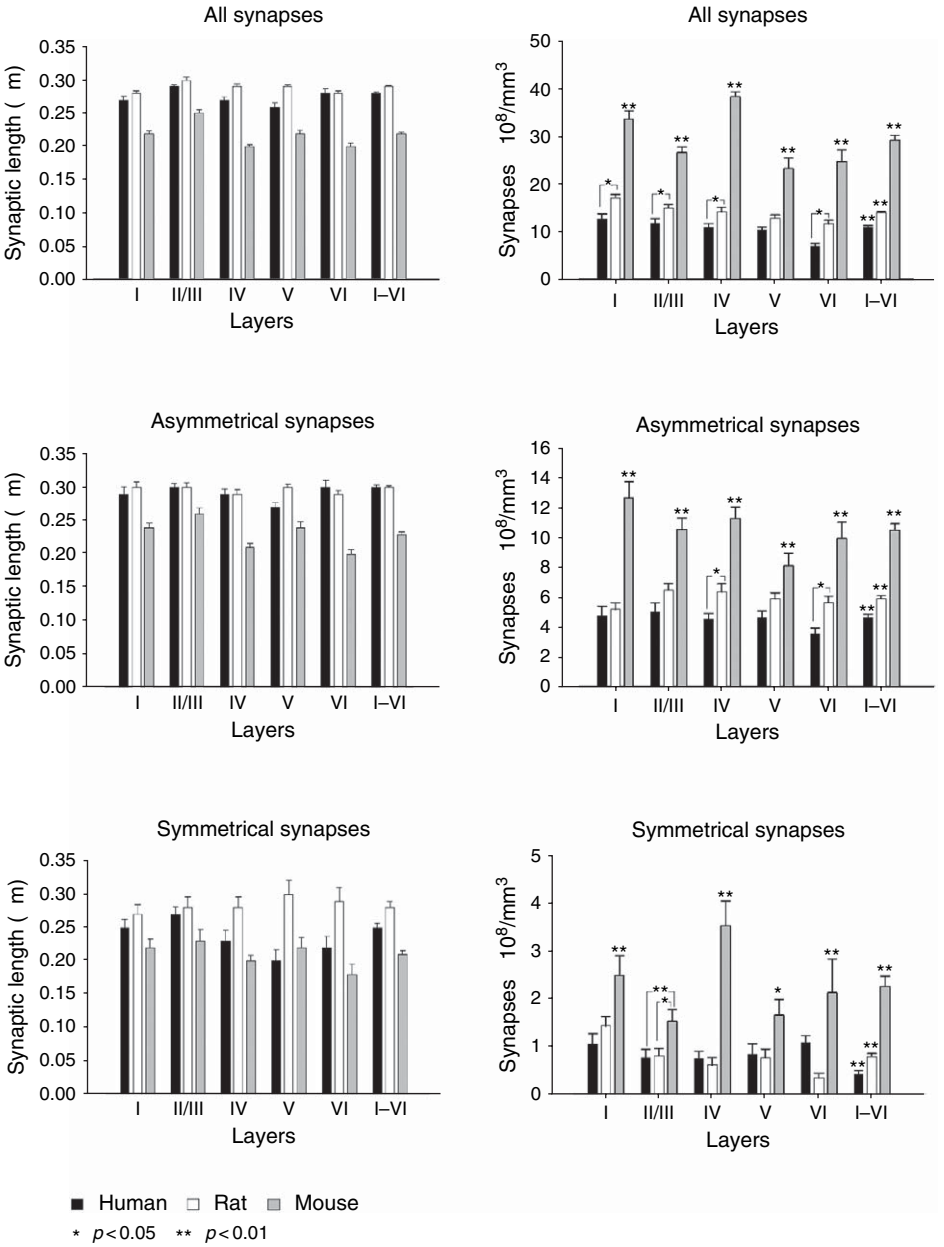

Figure 9 Comparison of the mean cross-sectional lengths (± s.e.m.) and densities of synaptic profiles between human, rat, and mouse. Density values obtained in layers II, IIIa, and IIIb of human, and layers Va and Vb of rat were recalculated according to the relative thickness of these layers to estimate the representative values of layers II–III and V, respectively. Number of synapses per neuron	29 821	18 015	21 983	

Data from mouse visual cortex were not used for statistical comparisons with data from mouse barrel cortex, nor with the rat and human cortex.

All synapses include asymmetrical, symmetrical, and uncharacterized synapses.

Reproduced from *J. Neurocytol.*, vol. 31, 2002a, pp. 299–316, Microstructure of the neocortex: Comparative aspects, DeFelipe, J., Alonso-Nanclares, L., and Arellano, J. I., table 1. With kind permission of Springer Science and Buisness Media.

significant differences were found between human and rat in layers IV, V, and VI (Figure 9). In summary, it is remarkable that in spite of the great differences in brain size between human, rat, and mouse, there are relatively small differences in the mean cross-sectional length of synaptic junctions, although significant laminar differences can be observed between the different species.

4.12.5.3.3 Density of synapses As far as we know, Cragg (1967) was the first author to perform comparative ultrastructural studies of the neocortex. He pointed out that there was relatively little variation in synaptic density between cytoarchitectonically and functionally different regions such as the motor and visual cortex of the mouse and monkey (between 6 and 9×10^8 synapses per mm^3). Later, Colonnier and colleagues also argued that the numerical density of synapses was relatively constant throughout the cortical layers, as well between different cortical areas and different species (see O'Kusky and Colonnier, 1982; Beaulieu and Colonnier, 1989). These observations were confirmed by others, such as Schüz and Palm (1989) who failed to detect systematic differences between layers or different cortical regions in the mouse, including areas 6, 8, and 17. Similarly, Rakic and colleagues emphasized the remarkable small variation they found in the neuropil of all cortical layers in diverse regions of the rhesus monkey neocortex (15–20 synaptic profiles per 100 μm^2), including the motor cortex, somatosensory cortex, prefrontal cortex, and visual cortex (Rakic *et al.*, 1986; see also Zecevic and Rakic, 1991). Furthermore, similar data was obtained from the human visual, auditory, and prefrontal cortex by Huttenlocher and Dabholkar (1997).

O'Kusky and Colonnier (1982) hypothesized that this uniformity in synaptic density probably reflects an optimal number of synapses, and that it may be due to some limiting metabolic or structural factor (see also Rakic *et al.*, 1986). However, as discussed previously (DeFelipe *et al.*, 2002a), the problem with this hypothesis is that the estimates of synapse number were made with very different techniques and did not always apply stereological methods. In addition, most comparisons are only qualitative and not based on statistical analysis. Therefore, one must be careful when comparing data from different authors because it may lead to uncertain conclusions. This is clearly demonstrated in the study of Beaulieu *et al.* (1992, 1994), who found significant differences in the number of synapses per volume between certain layers of both the rat and monkey visual cortex by applying the dissector method and statistical comparisons.

In our comparative studies of human, rat, and mouse tissue (DeFelipe *et al.*, 2002a), we detected a lower synaptic density in the human (1094 million per mm^3), than in the rat (1397 million per mm^3), and mouse (2931 million per mm^3) when all layers were considered (Table 3). In most layers, these differences between the three species were statistically significant (Figure 9). The amazingly high density of synapses found in the mouse barrel cortex when compared to the human (Figure 10) and rat was not due to a peculiarity of the barrel cortex as the mouse visual cortex also had a very high density (2519 million per mm^3; Table 3). The transmitter released at synaptic or nonsynaptic sites may diffuse a certain distance and act on other synaptic contacts or on extra-synaptic receptors ('volume transmission'; for a review see Agnati and Fuxe, 2000). Hence, the density of synapses may represent a very significant factor in the diffusion of chemical signals and, therefore, species differences in synapse density may indicate differences in volume transmission. In general, a number of significant differences have been found in the density of synapses depending on the layer and species, particularly when asymmetrical and symmetrical synapses are analyzed separately (Figure 9). We conclude that the density of synapses is not uniform throughout the cortex and that there are laminar specific differences between different cortical areas in different species. Thus, if an optimal number of synapses for cortical circuits does exist, it must be species and laminar specific.

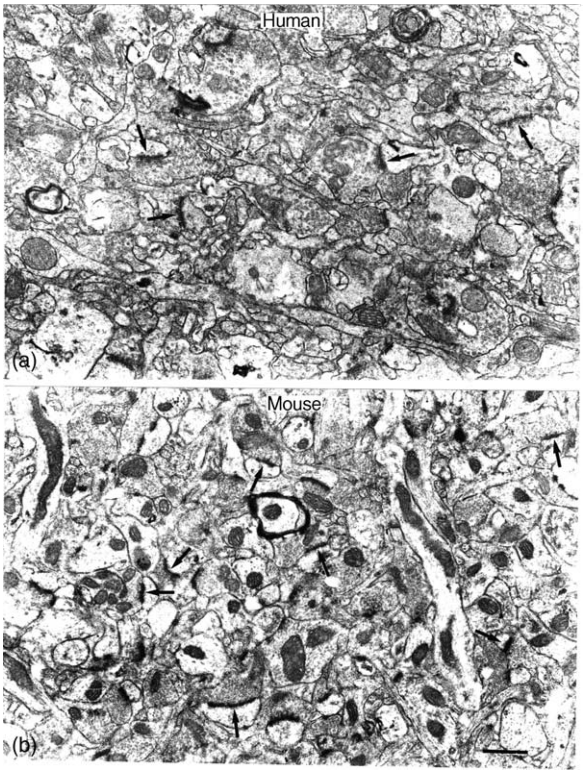

Figure 10 Electron micrographs illustrating the thin neuropil from layer IIIa in the human temporal cortex (a), and layer II/III of the mouse barrel cortex (b). Note the higher density of synapses (some of them indicated by arrows) in the mouse cortex. Scale bar: 0.5 μm. Reproduced from *J. Neurocytol.*, vol. 31, 2002a, pp. 299–316, Microstructure of the neocortex: Comparative aspects, DeFelipe, J., Alonso-Nanclares, L., and Arellano, J. I. With kind permission of Springer Science and Buisness Media.

4.12.5.4 Number of Synapses per Neuron

In terms of connectivity, it is difficult to interpret the comparisons of synaptic density between species because the thickness and neuronal density in different layers and species differ (Table 3; Figure 4). Therefore, to examine possible differences in connectivity between species it is more appropriate to compare the values obtained by dividing the synaptic density by the corresponding neuronal density. Nevertheless, there are a number of considerations that must be borne in mind. First, the number of synapses per neuron in a given layer is not an accurate estimate of the number of synapses received by neurons in that layer, since dendrites, particularly of pyramidal cells, may cross several layers. Second, axon terminals in a given layer do not necessarily originate from local neurons; they may come from neurons located in other layers, or from other cortical areas or subcortical nuclei. Third, the number of synapses per neuron obtained simply by dividing the synaptic density of the neuropil by the neuronal density is an overestimate because the volume occupied by neurons, glia cells, blood vessels, and neuropil is usually not taken into account. Thus, the synapse/neuron ratio should be taken as a useful parameter to compare between cortical layer, areas, and species in terms of 'general' connectivity (DeFelipe *et al.*, 2002a).

Cragg (1967) compared the number of synapses per neuron in the motor and visual areas of the mouse and macaque monkey, and found species differences in the relationship between neuronal density and number of synapses per neuron. For example, in the motor cortex, the density of neurons was lower and the number of synapses per neuron was much greater in the monkey than in the mouse (16.1×10^6 neurons per cm^3; 60 000 synapses per neuron vs. 64.4×10^6 neurons per cm^3; 13 000 synapses per neuron). On the other hand, the neuron density was higher in the visual cortex where the synapse per neuron ratio was

lower in the monkey than in the mouse (110.3×10^6 neurons per cm^3; 5600 synapses per neuron vs. 92.4×10^6 neurons per cm^3; 7000 synapses per neuron). An inverse relationship between neuronal density and the number of synapses per neuron was also observed for individual layers of the macaque visual cortex (O'Kusky and Colonnier, 1982), corroborating the findings of Cragg. However, O'Kusky and Colonnier's estimates were approximately 60% lower than Cragg (2300 synapses per neuron) in the macaque visual cortex, probably due to the different methods used. O'Kusky and Colonnier suggested that a limiting factor was responsible for this inverse relationship, and that neurons receiving more synapses would have more complex dendritic trees, thereby increasing the distance between their cell bodies. In contrast, neurons receiving fewer synapses would have a less-complex dendritic tree, allowing them to be more densely packed. According to Cragg (1967), the origin of this idea is based on the old histological studies of Franz Nissl (1860–1919) and Constantin Von Economo (1876–1931). Nissl pointed out that cortical neurons were more crowded in the mole and dog than in humans. Based on this observation, Von Economo proposed that the richer the fiber plexus was between neurons the more they would be separated, increasing the opportunity for neuronal interactions. Thus, the wider separation of neurons in humans compared to other species could be taken as an indication of a greater refinement of the connections between neurons.

We examined this issue in the human, rat, and mouse and found that the principle of the inverse relationship between neuronal density and the number of synapses per neuron in general held true in the human when compared with the rat and mouse, but not when comparing the rat with the mouse (Figure 11). Additionally, when specific layers were compared, this rule was applicable to all layers in the rat, but not to the human or mouse. Similarly, there was no common pattern between species or within a given species with respect to the distribution of synapses per neuron when considering asymmetrical and symmetrical synapses (Figure 11). Instead, there were impressive laminar differences not only between certain layers of the human and mouse when compared to the rat, but also between the human and mouse.

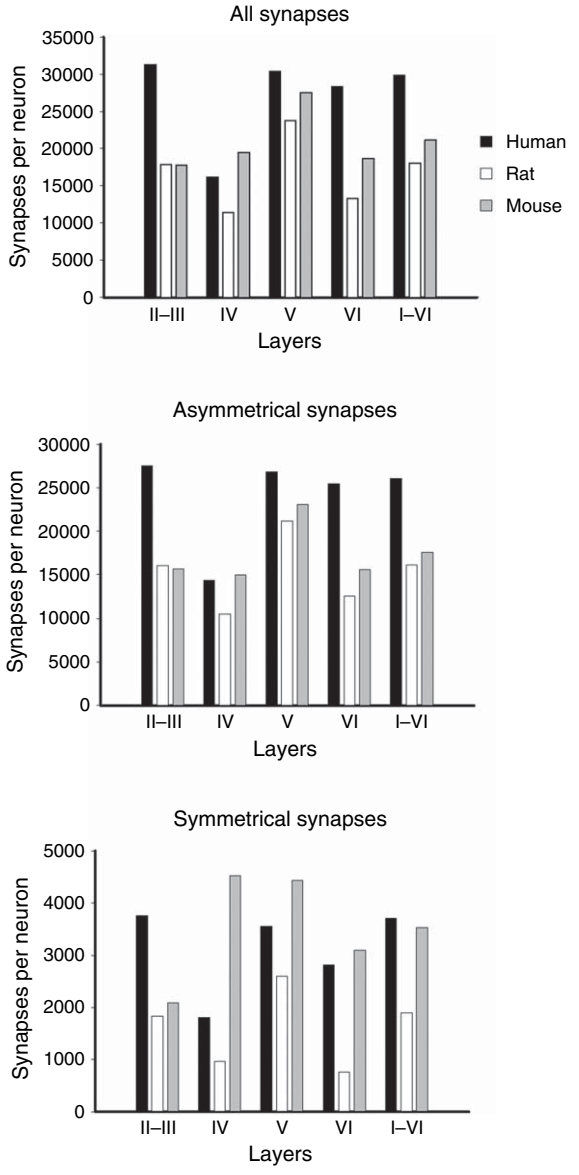

Figure 11 Graphs showing the number of synapses per neuron in the human, rat, and mouse. The values obtained in layers II, IIIa, and IIIb of human, and layers Va and Vb of rat were recalculated according to the relative thickness of these layers to estimate the representative values of layers II, III, and V, respectively. 4.12.6 Concluding Remarks

In summary, there are variations between species in terms of the density of neurons, as well as in the proportion of GABAergic interneurons, the synaptology in the neuropil and in the number of synapses per neuron. Furthermore, certain subtypes of interneurons are lacking or greatly modified in some species. The specific similarities between the human, rat, and mouse, and other species with respect to the types of cortical neurons and the percentage, length, and density of asymmetrical and symmetrical synapses, and in the number of

synapses per neuron, might be considered as the common features of cortical organization. The differences that can be observed probably indicate evolutionary adaptations of excitatory and inhibitory circuits to particular functions.

4.13 Specialization of the Neocortical Pyramidal Cell during Primate Evolution

G N Elston, The University of Queensland, Brisbane, QLD, Australia

4.13.1 Introduction

4.13.1.1 The Study of Brain Evolution

The study of the evolution of the brain poses an innate problem: soft tissue is rarely preserved in fossil specimens. Natural endocasts of brains reveal aspects of gross structure, such as overall size, and occasionally it is possible to identify particular sulci – allowing speculation regarding the expansion of the cortical lobes during brain evolution. Differences in the size of brain endocasts and, in particular, the region of neocortex anterior to the lunate sulcus, have been interpreted by some as a measure of the evolution of cognitive abilities of hominids (Figure 1; see Oakley, 1949; Dart, 1956; Eiseley, 1957; Tobias, 1981; Gray and Thompson, 2004 for reviews). However, there has been a dramatic increase in complexity in material culture with little change in brain size during the past 300 000 years or so. Moreover, there is some evidence to suggest that the cerebrum in modern humans is actually smaller than in his predecessors (see Tobias, 1995; Henneberg, 1998; Manger, 2005a for reviews). Thus, advances in cognitive abilities of humans, as evidenced by the increasing complexity of material culture, may be explained by something that cannot be gleaned from the fossil record – specializations in microstructure of the brain.

The study of the evolution of the primate brain is thus largely restricted to extant species. By systematically investigating internal features of the brains of different species, inferences can be made about the evolution of these structures (see Kaas, 1989, 1995; Northcutt and Kaas, 1995; Northcutt, 2002 for reviews). We have adopted such an approach to study the evolution of microcircuitry in the primate brain. Here we review presently available data on pyramidal cell structure in the primate cortex, how regional and species differences in pyramidal cell structure may influence patterns of connectivity and, in turn, the functional complexity and computational abilities of the circuits they form. Data sampled from homologous cortical areas among species reveal interesting trends in the evolution of the pyramidal cell phenotype in different regions of brain. The structure of pyramidal cells in the primary visual area (V1) is relatively similar in prosimian galagos, New World and Old World monkeys, and the baboon, despite more than a fivefold difference in the cortical surface area occupied by V1 in these primates (Brodmann, 1913; see Elston and Garey, 2004 for a translation). Pyramidal cells in granular prefrontal cortex (gPFC), on the other hand, have markedly different phenotypes in the different primate species: those

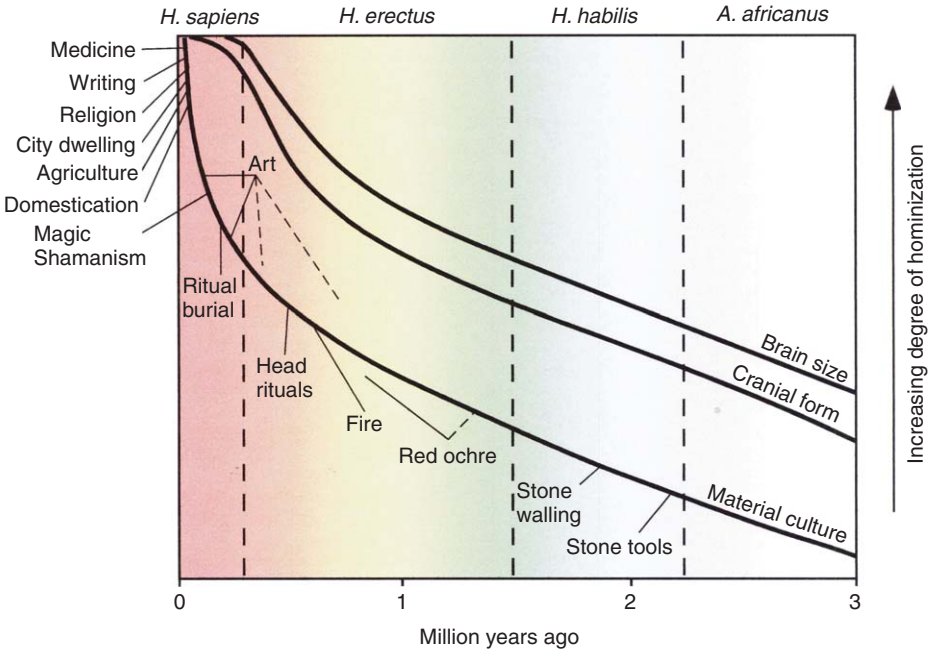

Figure 1 Schematic illustrating the evolution of cranial form and brain size in relation to the level of sophistication of cognitive abilities during the past three million years of human evolution. Note in particular that there was a sharp increase in brain size in *H. erectus* beginning ~500 kya, which coincided with the first record of the mastery of fire, ritualization, and the beginnings of art. However, more recently, there has been a dramatic increase in the level of sophistication of cognitive abilities in *H. sapiens*, as evidenced by the domestication of animals, implementation of agricultural practices, city dwelling, writing, and the practice of medicine, which has occurred without notable increase in brain size. Modified from Tobias, P. V. 1981. Evolution of the human brain, intellect and spirit. In: 1st Abbie Memorial Lecture, pp. 5–70. The University of Adelaide.

in the prosimian galago are relatively simple, in monkeys are progressively more complex, in the baboon yet more complex, and those in human are the most complex of all pyramidal cells studied to date. Based on regional and species differences in the pyramidal cell phenotype, it is possible to postulate some new theories on specialization of circuit structure in neocortical evolution. The data suggest not one simple rule, but various trends, which may differ according to the cortical region in question or which species are included for comparison. A better understanding of the evolution of specialized cortical function in primates will only be possible by encompassing this diversity in structure and function. While this 'unwelcome revolution' will no doubt be unpalatable to some (see Preuss, 2001 for a review), the inevitability of the necessity to perform systematic quantitative comparative studies will, no doubt, become increasingly more apparent with each new species included for study. This becomes even more obvious when comparing the evolution of cortical circuitry between primates and nonprimates, for which some preliminary data are presented. Differences in the size and location of specific cortical areas within a given species (Figure 2, Table 1), and possible differences in cortical microstructure, further complicate the story but are not considered further here. For a translation of Brodmann's (1913) in-depth review of individual variation in cortical organization, the reader is referred to Elston and Garey (2004).

4.13.1.2 Cortical Microcircuitry

As students we are often told that the mammalian cerebral cortex comprises distinguishable cortical layers, six in total. Within these cortical layers reside particular populations of neurons (glia are often neglected), which make particular types of projections. Patterns of afferent inputs are usually stereotyped, inevitably terminating in layer IV. The mammalian cerebral cortex is clearly far more diverse than this standard 'plan' would suggest (see Rockland, 1997 for a critical review; see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates). The most eminent authorities in comparative cytoarchitecture disputed the number and nomenclature of cortical layers for decades, yet this is poorly acknowledged by many contemporary scientists (see Garey, 1994 for a translation of Brodmann's, 1909 original monograph). This is more than just a matter of historical accuracy, as acknowledgment of the diversity in cytoarchitecture of the mammalian cerebral cortex is a fundamental step if the discipline of neuroscience is to forge ahead. Without this most basic of acceptances, we cannot hope to make any inferences regarding the evolution of the mammalian cerebral cortex, much less the evolution of specialized cortical functions such as vision, somatosensation, and intellect. To accept the cortical uniformity hypothesis is to accept that cortex has not evolved. In the following sections we set out how we have attempted, and only just begun, to quantify aspects of cortical microstructure systematically across the cerebral cortex of mammals. We have done so by focusing on the pyramidal cell, the most abundant neuronal type in the cerebral cortex.

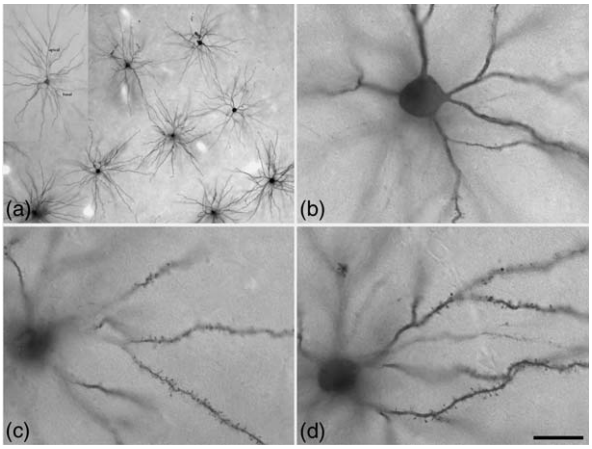

Figure 3 Photomicrographs of neocortical pyramidal cells that were injected with Lucifer Yellow and processed for a diaminobenzadine (DAB) reaction product. Note the characteristic features of a pyramidal cell as seen in the transverse section (inset in (a)), including the prominent apical dendrite and the basal skirt of dendrites. Cells in panels (a–d) were injected in tangential sections. In each instance, cells are injected close to the top of the section so as to include the entire basal skirt of dendrites (250 μm thick sections), while at the same time leaving enough space between the top of the section and the cell body to allow visualization of the proximal portion of the apical dendrite. Upward of 100 cells can be injected in individual sections (a), which can then be studied at high power (b–d) to quantify dendritic branching pattern, spine density, and the size of the cell bodies.

4.13.1.3 What Is a Pyramidal Cell?

Pyramidal cells are distinguished by their prominent apical dendrite and basal dendritic tree (Figure 3). They comprise ~70–90% of all neurons in cortex. Pyramidal cells form rich plexuses of connections, often called intrinsic lattices or

horizontal patches, within cortical areas. They form nearly all corticocortical connections, both ipsi- and contralateral, as well as most subcortical connections. Pyramidal cells also contain the excitatory neurotransmitter glutamate: their discharge directly facilitates cortical activity, rather than inhibiting it. Arguably, pyramidal cells are the principal neurons of the cerebral cortex, generating nearly all cortically initiated excitation (see Feldman, 1984; Jones, 1984; DeFelipe and Fariñas, 1992; Nieuwenhuys, 1994; Elston and DeFelipe, 2002; Valverde, 2002 for reviews).

Different subtypes of pyramidal cells have been reported based on different aspects of their morphology, for example, inverted pyramidal cells, those whose axons project into the white matter, and those whose axons are restricted to the gray matter. In addition, pyramidal cells have been subdivided according to their neurochemical content and receptor subunit profiles (del Rio and DeFelipe, 1994; Preuss *et al.*, 1997; Gabernet *et al.*, 1999; González-Albo *et al.*, 2001; Hof *et al.*, 2001). It has also been proposed that pyramidal cells are not genetically fated to have their characteristic morphology. According to this theory, all variants of spiny neurons from the typical pyramidal cell to the typical spiny stellate cell are derived from a common precursor (Valverde, 1988). Here, the focus is on the discussion of pyramidal cells to the 'typical' pyramidal cell of unknown neurochemical content observed in mature primate cortex. As a prelude to studying specializations in pyramidal cell structure that have occurred during the evolution of different primate species we first set out how pyramidal cell structure varies in the cerebral cortex in a single species, the macaque monkey, and outline how specialization in cell structure may influence functional capabilities and, in turn, behavioral complexity.

4.13.2 Phenotypic Variation of Neocortical Pyramidal Cells

4.13.2.1 The Macaque Monkey

The macaque monkey is the most widely studied primate model in neuroscience. The primary objective of the study of the macaque brain is to better our understanding of the human brain. The normal mature macaque brain is clearly smaller than the normal mature human brain, and its cortex is arguably less differentiated. Estimates vary somewhat, but Old World monkeys, to which the macaque monkeys belong, separated from the lineage that led to contemporary humans ~25 Mya (Figure 4). Since this time sakis and a host of monkey species (e.g., titi, marmoset, tamarin, spider, howler, woolly, capuchin, squirrel, and owl monkeys) have branched from a common New World ancestor, while colobus monkeys, langurs, guenons, and

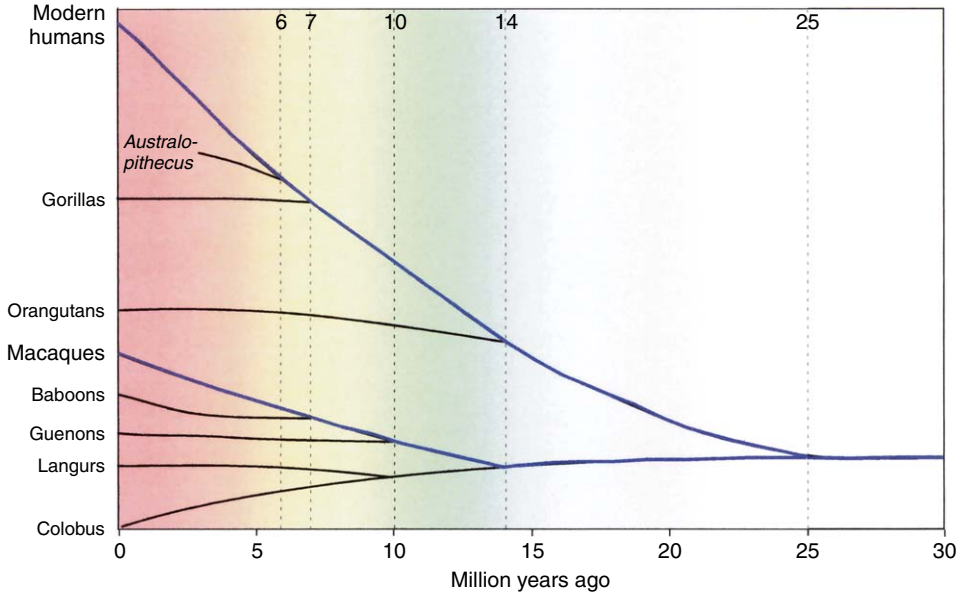

Figure 4 Schematic illustrating the evolution of different groups of primates. Note in particular the time at which the lineages leading to present-day humans and macaque monkeys (solid blue lines) diverged – 25 Mya. Note also that since this time all Old World and New World anthropoids have evolved from a common ancestor (~14 Mya), present-day orangutans and gorillas diverged from the human lineage (~14 and 7 Mya, respectively), and various hominids have evolved and become extinct (labeled *Australopithecus*). Modified from Dawkins, R. 2004. The Ancestor's Tale. A Pilgrimage to the Dawn of Life. Weidenfeld & Nicolson.

macaques have branched from a common Old World ancestor. Gibbons, chimpanzees, and gorillas have also evolved in this time. During a much shorter period of time (~6 million years), various hominids have evolved and become extinct (e.g., *Homo habilis, H. erectus, H. habilis, Africanis africanis, A. afarensis, A. biosei,* and *A. robustus*). Clearly enough time has passed for aspects of both the macaque and human brains to evolve their own unique specialized structure and functions. Indeed, studies of macaque monkeys (of which there are 20 species) reveal differences in their preferred habitats and behavior. Some macaques are reportedly highly social, gregarious foragers, whereas others are more circumspect in their interactions with conspecifics, some are terrestrial while others are arboreal, and some are obligate rainforest dwellers while others have adapted to living in human urbanizations (Nowak, 1999). Macaques that live on the Rock of Gibraltar have become expert robbers, relieving unsuspecting tourists of breakfast, lunch, and dinner. So adept have these monkeys become in their newfound trade that they are able to survive atop an otherwise barren rock almost completely devoid of food. Others, such as the Japanese macaque, have learned the pleasure of indulging in hot springs, spending hours bathing in steaming hot water while snow falls around them. Even more pronounced differences are seen in human behavior: hundreds of volumes have been published by anthropologists in which differences in behavior among human populations/cultures have been documented in painstaking detail. Nonetheless, in terms of the structure and function of the neocortex, the macaque monkey has become the most widely studied and best understood of primates. While acknowledging the problems associated with transferring findings from the macaque brain to that of humans, it is because the macaque monkey brain is the most extensively researched and best understood of all primate brains that much of my earlier work was focused on this animal.

4.13.2.1.1 Visual cortex The areas of the cerebral cortex that contain neurons involved in some form of visual processing are perhaps the most thoroughly explored in the macaque brain (see The Evolution of Visual Cortex and Visual Systems). Prior to the 1970s, most studies were restricted to the striate, or primary (V1), visual area. Since then, there has been an explosion in the number of studies in, and our understanding of, extrastriate visual cortex. Application of new techniques such as electrophysiological mapping and imaging, and the development of specialized tracers, have revealed that visual processing is much more complex than previously thought, involving up to half of the cortex and as many as 30 different areas (Figure 5). Various theories have been presented for the existence of so many visual cortical areas, and how visual stimuli are processed by neurons within these areas (see Kaas, 1987, 2000; Weller, 1988; Felleman and Van Essen, 1991; Rosa, 1997 for reviews). In addition, many theories have been proposed regarding the recruitment and interaction of neurons in these different cortical areas during particular visual tasks. Two of the most popular models include the quasihierarchical model and the distributed processing model. In the quasihierarchical model, visual inputs to cortex are processed through a series of cortical areas. These areas are not necessarily organized into a strict hierarchy, but there is some form of serial processing through select visual areas. In the distributed processing model, visual processing occurs in multiple cortical areas, but not necessarily in any form of hierarchy. That is not to say, however, that the two theories are mutually exclusive. Mountcastle, for example, highlighted how hierarchies may exist within a distributed system (Mountcastle, 1995).

New methods of quantification (e.g., Elston and Rosa, 1997, 1998, 2000; Elston, 2001) have revealed marked, systematic differences in pyramidal cell structure (cortical circuitry) in these different visual areas (Figures 6–8). Briefly, there is a trend for increasingly more complex pyramidal cells with progression from V1 to the second visual area (V2) and visual areas in the parietal (the lateral intraparietal area, LIP, and cytoarchitectonic area 7a) and temporal (the fourth visual area, V4, the middle temporal area, MT, cytoarchitectonic areas, TEO and TE, and the superior temporal polysensory area, STP) lobes. The increase in the size of the dendritic tree, coupled with a concomitant increase in the number of dendritic branches and spine density, results in a progressive doubling in our estimates of the total number of spines in the basal dendritic trees of pyramidal cells through V1, V2, V4, and TEO (Figure 8). The functional implications of these specializations in pyramidal cell structure in functionally related cortical areas are discussed in Section 4.13.2.2.

4.13.2.1.2 Sensorimotor cortex Like visual cortex, somatosensory and motor cortex in the macaque monkey has been divided into a number of highly interconnected cortical areas (Figure 9). Based on patterns of connectivity, neuronal response properties, and, more recently, imaging studies, several theories have been put forward regarding normal function across, and cooperativity

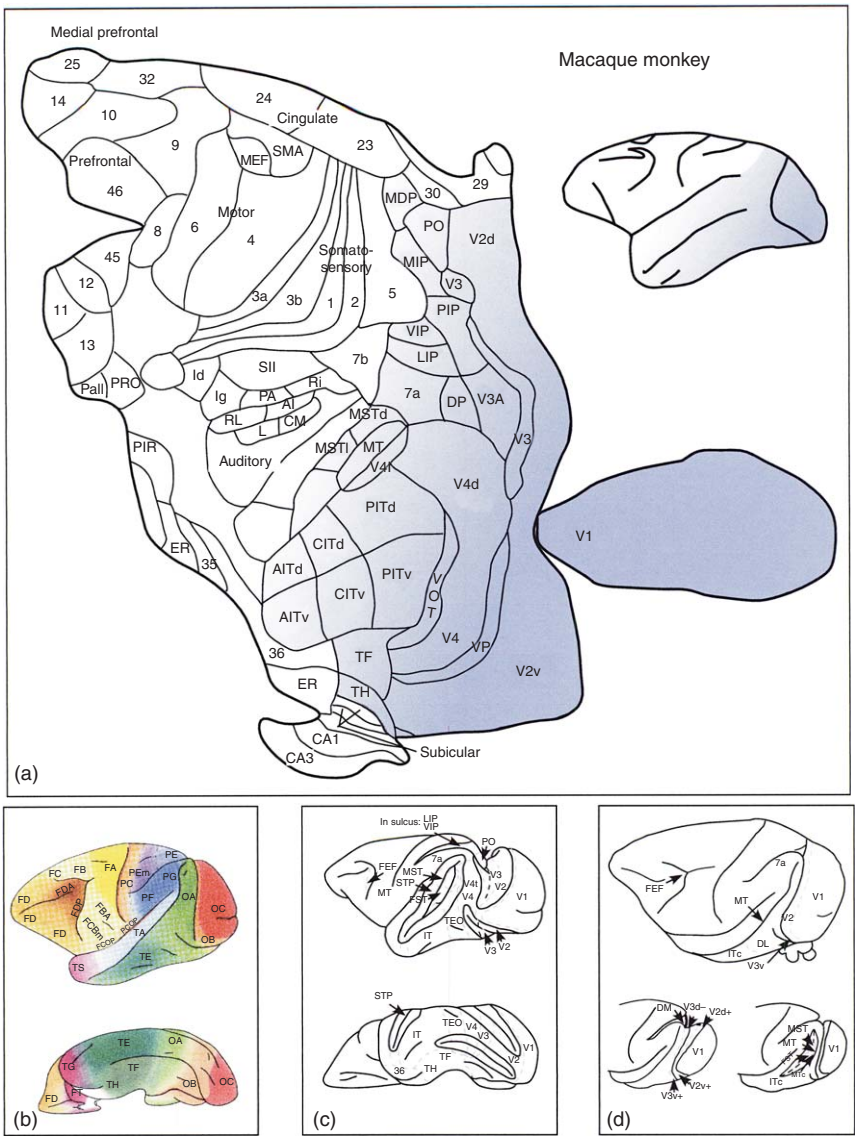

Figure 5 Schematic illustrating how different authors have divided visual cortex of the macaque monkey (blue shading). Note that the entire occipital lobe and a large portion of the temporal and parietal lobes contain neurons responsive to visual stimuli. Neurons in PFC, such as area 8 (the FEF) are also involved in visual processing (not shaded).1, 2, 3(a, b), 4, 5, 6, 7(a, b), 8, 9, 10, 11, 12, 13, 14, 23, 24, 25, 29, 30, 32, 35, 36, 45, 46, cytoarchitechtonic areas; 1 and 2, somatosensory cortex; 3b, primary somatosensory area (SI); 4, primary motor area (MI); 5, somatosensory association; 6, premotor cortex; 7a, visual association; 7b, somatosensory association; 8, includes the frontal eye field; 9, dorsolateral prefrontal cortex; 10, medial prefrontal cortex; 12 and 46, dorsolateral prefrontal cortex; 13, orbital prefrontal cortex (12 orbital); 23, posterior cingulate cortex; 24 and 32, anterior cingulate cortex; A, auditory; A1, primary auditory; AIT, anterior inferotemporal; CA1 and CA3, hippocampus; CIT, central inferotemporal; CM, caudomedial; d, dorsal; DL, dorsolateral area (caudal division); DM, dorsomedial; DP, dorsoparietal; ER, entorhinal; FA, FB, FC, FD, FBA, FCBM, PEM, FDA, FDP, FCOP, PCOP, TG, TS, PC, FF, PG, PF, cytoarchitectonic areas; CAs architechtonic areas; FEF, frontal eye field; FST, fundus of the superior temporal area; IT, inferotemporal cortex; Id, insular dysgranular; Ig, insular granular; L, lateral auditory; LIP, lateral intraparietal; MDP, mediodorsal parietal area; MEF, medial eye field; MIP, medial intraparietal area; MSTd, dorsal middle superior temporal; MSTl, lateral middle superior temporal; MT, middle temporal area; OA, OB, OC, and PE, cytoarchitectonic areas; PA, periamygdaloid; Pall, periallocortex; PIP, posterior intraparietal area; PIR, piriform; PIT, posterior inferotemporal; PO, parieto-occipital; PrCO, precentral opercular; PRO, proisocortex; Ri, retroinsular; RL, rostrolateral auditory cortex; SII, second somatosensory area; SMA, supplementary motor area; STP, superior temporal polysensory area; TE, TF, and TH, cytoarchitectonic areas; v, ventral; V1, primary visual area; V2, second visual area; V3, third visual area; V4, fourth visual area; VIP, ventral intraparietal; VOT, ventral occipitotemporal; VP, ventroposterior. a, Modified from Felleman, D. Figure 6 Drawings of the basal dendritic trees of layer III pyramidal cells in the primary (V1), second (V2), and fourth (V4) visual areas, as well as cytoarchitectonic area TEO of the macaque monkey. Each cell has a dendritic tree the size of which approximates the average for all neurons sampled in each cortical area. In addition to differences in the size of the dendritic trees, there are also differences in the number of branches and the total dendritic length for the different cells. Cells are skeletonized, dendritic diameters and spine density are not illustrated. Modified from Elston, G. N. and Rosa, M. G. P. 1998a. Morphological variation of layer III pyramidal neurones in the occipitotemporal pathway of the macaque monkey visual cortex. *Cereb. Cortex* 8, 278–294.

among, these different cortical areas (e.g., Mishkin, 1979; Pons *et al.*, 1987, 1992; Felleman and Van Essen, 1991; Passingham, 1997; Geyer *et al.*, 2000). By injecting large numbers of pyramidal cells in some of these different cortical areas, it has been possible to demonstrate marked and systematic differences in their size, branching complexity, and spine density. More specifically, two trends of increasing morphological complexity have been revealed with progression from the central sulcus to adjacent cortical areas (Figure 10). There is a systematic increase in the size of the dendritic trees of pyramidal cells, their branching complexity, and spine density within their basal dendritic trees, with caudal progression from the primary somatosensory area on the posterior wall of the central sulcus (area 3b) to the rostral bank of the intraparietal sulcus (area 5) and the exposed rostral portion of the inferior parietal lobule (area 7b). There is also an increase in the size of the dendritic trees of pyramidal cells, their branching complexity, and the total number of spines within their basal dendritic trees, with rostral progression from the primary motor area on the anterior wall of the central sulcus (area 4) to the exposed lateral portion of the precentral gyrus (area 6 or premotor cortex). These differences in size, branching complexity, and spine density result in appreciable differences in our estimates of the total number of spines in the basal dendritic tree of the average cell in each cortical area (Figure 11).

4.13.2.1.3 Cingulate cortex A study of the literature reveals little agreement regarding the functions performed in cingulate cortex, nor the number and location of cortical areas contained therein (Figure 12). Some have attributed higher cognitive and emotional functions to the anterior cingulate cortex and vegetative functions to posterior cingulate cortex (Allman *et al.*, 2001), whereas others have claimed the reverse (e.g., Baleydier and Mauguiere, 1980). In a recent series of studies in which cortical activity was recorded in awake behaving monkeys by fMRI, Dreher and colleagues revealed that neurons in anterior cingulate cortex, unlike those in posterior cingulate cortex, are often co-activated with gPFC during cognitive tasks (Dreher and Berman, 2002; Dreher and Grafman, 2003). Various other studies have also demonstrated 'executive' or cognitive function in the anterior cingulate, including error detection and reward-based decision-making (Gemba *et al.*, 1986; Carter *et al.*, 1998; Bush *et al.*, 2002; Shidara and Richmond, 2002; Hadland *et al.*, 2003).

While it is well known that these two different regions of cingulate cortex can be distinguished by their cytoarchitecture, particularly the granular layer, relatively little is known of possible differences in their microcircuitry. In order to investigate this, layer III pyramidal cells were injected in the posterior cingulate gyrus (area 23 of Brodmann). Their structure was compared with that of cells injected in the anterior cingulate gyrus (Brodmann's area 24). These investigations revealed

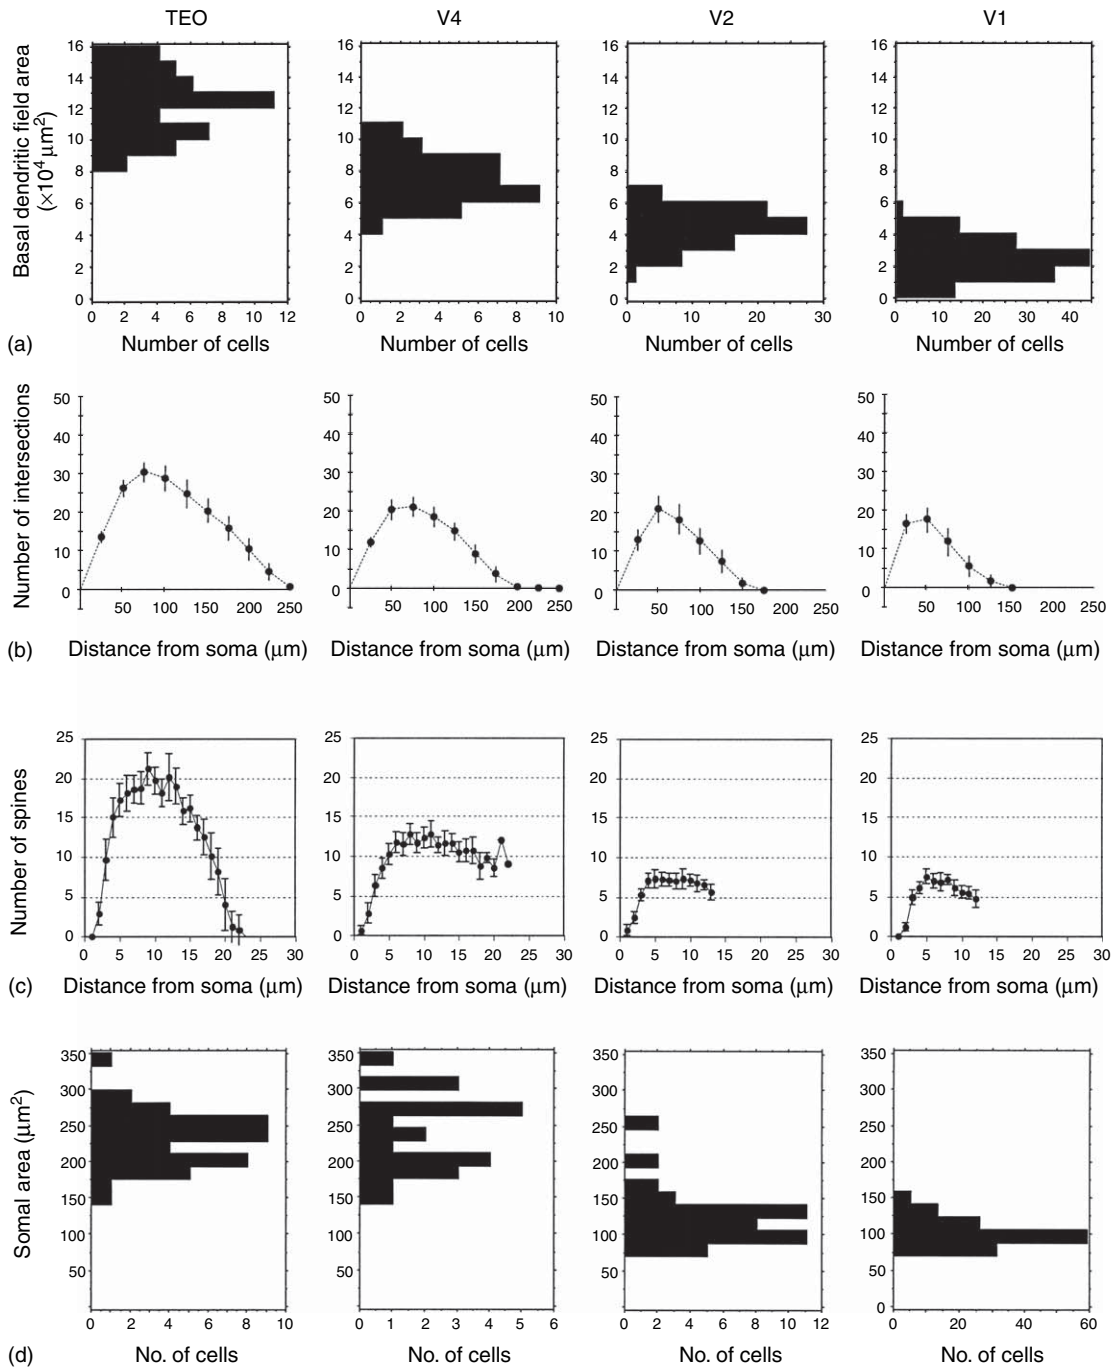

Figure 7 a, Frequency histograms of the size of the basal dendritic trees of layer III pyramidal neurons in the primary (V1), second (V2), and fourth (V4) visual areas, as well as cytoarchitectonic area TEO in the macaque monkey. The average size of the basal dendritic tree of layer III pyramidal neurons increases with rostral progression through the visual areas. b, Sholl analysis of dendritic trees of layer III pyramidal neurons in V1, V2, V4, and TEO yields a graphical representation of the complexity of the basal dendritic fields of layer III pyramidal neurons. Neurons in V1 had a similar branching complexity to those in V2, neurons in V4 had more complex basal dendritic fields than those in V1 or V2, and neurons in area TEO had the most complex basal dendritic trees. c, Plots of spine densities along basal dendrites of pyramidal neurons in V1, V2, V4, and area TEO in the macaque monkey. Twenty horizontally projecting basal dendrites were selected randomly from neurons in each region to determine if there was any difference in spine density. Spine density, which was calculated per 10 μm segment of dendrite, varied as a function of distance from the soma to the distal tips of the dendrites. Peak spine density was relatively low for neurons in V1 and V2, slightly higher in V4, and greatest in area TEO. d, Frequency histograms of somal areas of layer III pyramidal neurons in V1, V2, V4, and area TEO in the macaque monkey. Note there is an overall increase in the size of the cell bodies with rostral progression through these visual areas. Error bars = standard deviations. Modified from Elston, G. N. and Rosa, M. G. P. 1998a. Morphological variation of layer III pyramidal neurones in the occipitotemporal pathway of the macaque monkey visual cortex. *Cereb. Cortex* 8, 278–294.

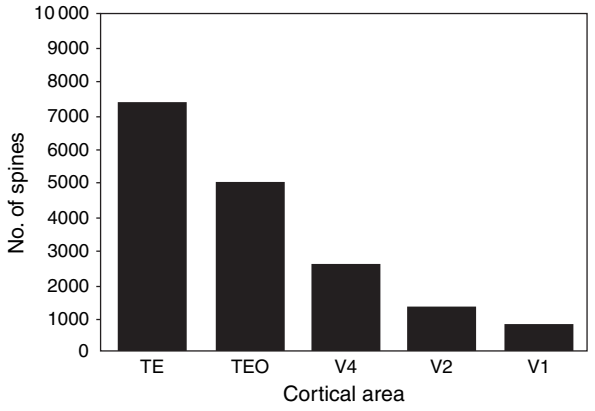

Figure 8 Plot illustrating differences in the estimates of the total number of spines in the basal dendritic trees of layer III pyramidal cells in cortical visual areas of the macaque monkey. Estimates were made by summing the product of average number of dendritic intersections per successive 25 μm annulus derived from Sholl analysis and the average spine density for the corresponding region in the dendritic tree. TE and TEO are cytoarchitectonic areas; V1, primary visual area; V2, second visual area; V4, fourth visual area. Data taken from Elston, G. N. and Rosa, M. G. P. 1998a. Morphological variation of layer III pyramidal neurones in the occipitotemporal pathway of the macaque monkey visual cortex. *Cereb. Cortex* 8, 278–294.

that pyramidal cells in the anterior cingulate gyrus were considerably larger, more branched, and more spinous than those in the posterior cingulate gyrus (Figure 13). Estimates of the total number of spines in the basal dendritic tree of the average cell reveal a twofold difference between cells in the anterior and posterior cingulate gyri (Figure 14). Moreover, pyramidal cell structure in the anterior cingulate gyrus more closely approximates that of cells in the gPFC, than does that of cells in the posterior cingulate (see discussion below).

4.13.2.1.4 Prefrontal cortex Exactly what constitutes 'prefrontal' cortex (PFC) has been interpreted in many ways. Some classify it as cortex that receives projections from the medial dorsal nucleus of the thalamus, whereas others distinguish the PFC by cytoarchitecture (see Fuster, 1997 for a review). Here, as intended by Brodmann (1913), the term is used to only include granular cortex anterior to the central sulcus (Figure 15). To avoid confusion here, this region is referred to as the gPFC. Regional differences in cytoarchitecture and patterns of corticocortical connectivity have been used to subdivide macaque gPFC in various ways (e.g., Vogt and Vogt, 1919; Walker, 1940; Barbas and Pandya, 1989; Preuss and Goldman-Rakic, 1991a, 1991b; Petrides, 1998; Petrides and Pandya, 1999, 2001; Pandya and Yeterian, 2000) (Figure 15). Broadly speaking, these different areas have been grouped into the lateral, medial, and orbital regions.

The gPFC has been the focus of intensive investigation because of its involvement in executive functions such as conceptual thinking, prioritizing and planning (see Goldman-Rakic, 1996; Fuster, 1997; Barbas, 2000; Petrides, 2000; Miller and Cohen, 2001 for reviews). Our understanding of the types of functions performed by neurons in the different regions within gPFC, and how other cortical regions participate in specific tasks, is growing rapidly with the advent of new methodologies (see Quintana and Fuster, 1999; Passingham *et al.*, 2000; Rolls, 2000; Fuster, 2001; Funahashi and Takeda, 2002 for reviews). For example, orbital and medial gPFC are involved in emotional behavior and the processing of taste, reward, memory, affect, and motivation. The lateral gPFC provides cognitive support to the temporal organization of behavior, speech, and reasoning and is involved in executive control of voluntary motor movements. As in other regions, gradients characterized by different patterns of connectivity and functions have also been reported in the gPFC (Goldman-Rakic, 1987; Petrides, 1987, 1991; Barbas, 1992; Wilson *et al.*, 1993; Barbas *et al.*, 1999; Pandya and Yeterian, 2000). What is clear from these studies is that because of the complexity of functions performed by neurons in gPFC, and the difficulty in quantifying neuronal responses to specific executive tasks, our understanding of prefrontal function is likely to lag behind that of sensory cortex for some time to come.

By injecting large numbers of pyramidal cells in different regions of gPFC, and relating these findings back to those of pyramidal cell structure in other cortical regions, new information may emerge related to executive cortical functions performed in different areas in the gPFC. One of the advantages of the cell injection approach is that it is not fraught with the methodological problems of anesthetic state, training, attention, or stimulus specificity associated with electrophysiological mapping and/or imaging studies. The investigations of pyramidal cells in gPFC revealed that they are highly branched and spinous relative to those in many other cortical regions (compare Figures 7, 10, 13, and 16). For example, cells in the frontal eye field (FEF) were the most branched of all cells studied in the cerebral cortex of the macaque monkey (Elston, 2000; Elston *et al.*, 2006b). In addition, estimates of the number of dendritic spines in their dendritic trees revealed that they are more spinous than their counterparts in other cortical areas (Figures 8, 11, 14, and 17). In particular,

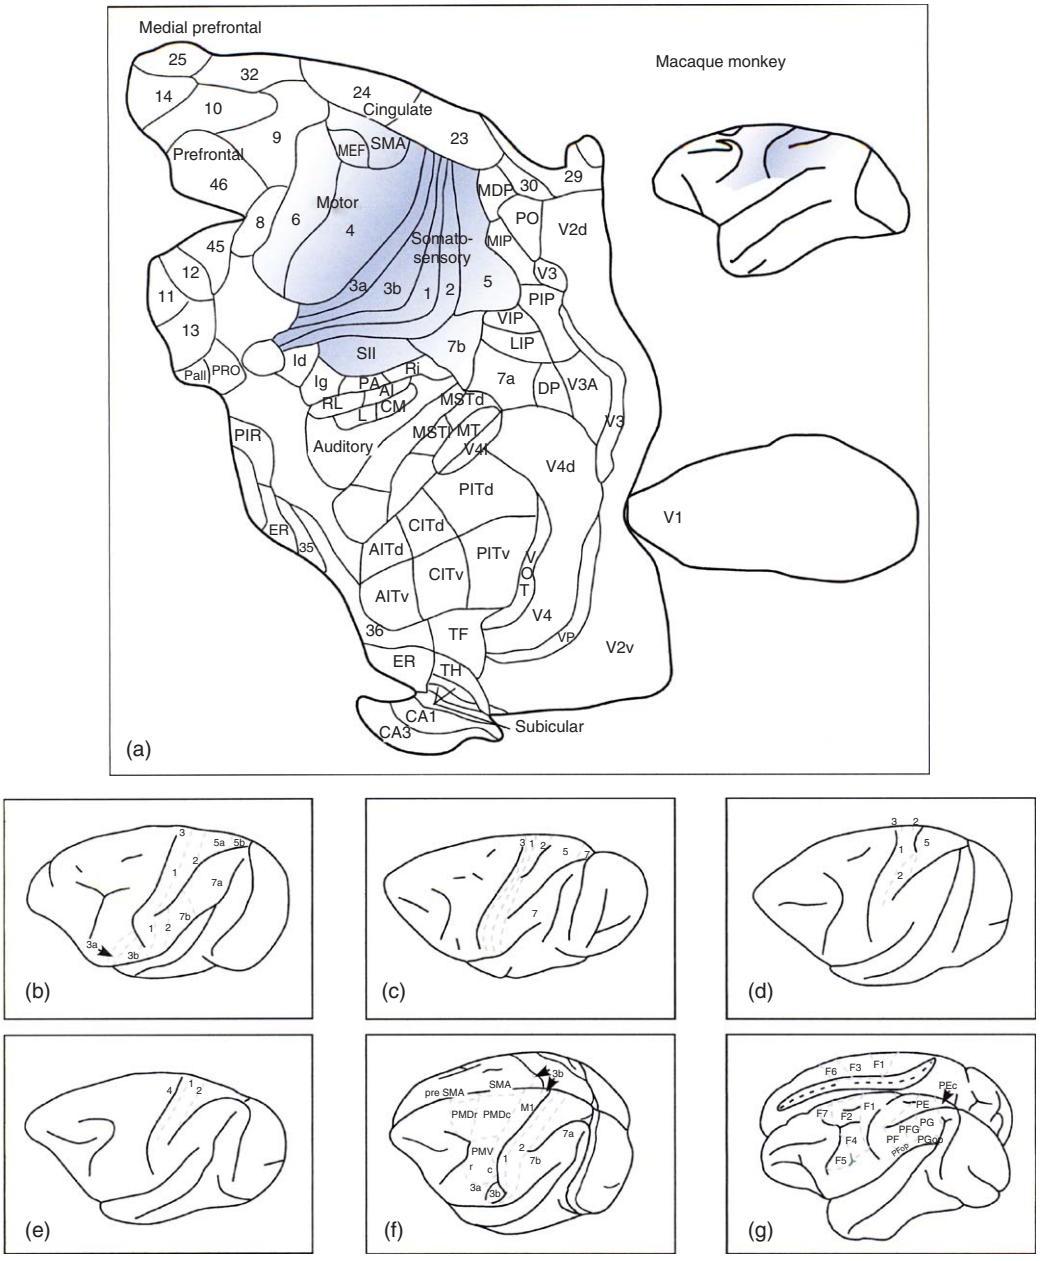

Figure 9 Schematic illustrating divisions in the sensorimotor cortex of the macaque monkey (blue shading) according to different authors. pyramidal cells in dorsolateral area 9d are considerably more spinous than those in visual, auditory, somatosensory, motor, and cingulate cortex (cf. Elston and Rosa, 1997, 1998a; Elston *et al.*, 1999a, 2002, 2005a, 2006b; Elston and Rockland, 2002). Up to a 16-fold difference has been demonstrated in the number of spines in the basal dendritic trees of populations of pyramidal cells in V1 and the gPFC (Elston, 2001). That is not to say, however, that all pyramidal cells in gPFC are highly branched and spinous relative to those in other cortical regions. For example, those in prefrontal area 10 are less spinous than those in inferotemporal cortex (IT) and the anterior cingulate gyrus (Elston *et al.*, 2005a). Some interpretations of the functional consequences of these regional differences in pyramidal cell structure are discussed in the following section.

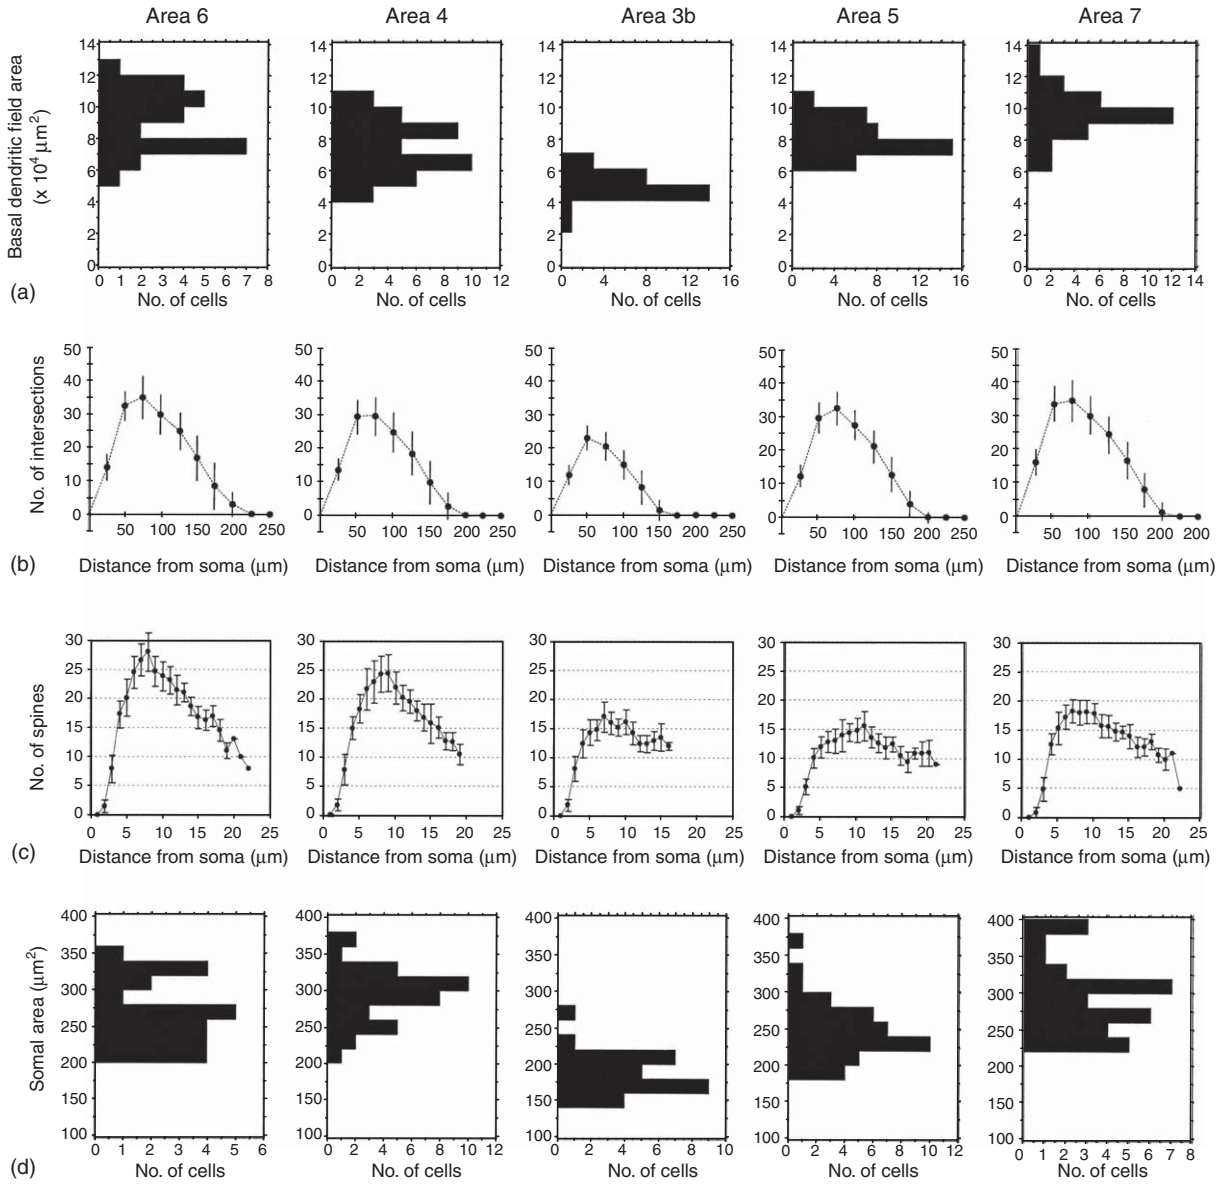

Figure 10 a, Frequency histograms of the size of the basal dendritic trees of layer III pyramidal neurons in the primary somatosensory area (3b), cytoarchitectonic somatosensory areas 5 and 7, the primary motor area (Brodmann's area 4), and premotor cortex (area 6). b, Graphs of the results of Sholl analysis of the basal dendritic trees of pyramidal neurons in sensorimotor areas. c, Plots of the proportion of dendritic spines, as a function of distance, in the basal dendritic trees of layer III pyramidal neurons in the above areas. d, Frequency histograms of somal areas of pyramidal neurons in areas 3b, 4, 5, 6, and 7. 4.13.2.2 Regional Specialization in the Pyramidal Cell Phenotype in the Macaque Monkey Cortex: Functional Interpretations

Neurons in different cortical regions are characterized by different response properties. That is not just to say that neurons in visual cortex discharge when presented with visual stimuli, those in somatosensory cortex discharge when presented with tactile stimuli, or those in auditory cortex discharge when presented with auditory stimuli, and so on. These modality specific aspects of their discharge selectivity are inevitably determined by the source of their inputs, originating from the retina, body surface, and cochlea, respectively. More specifically, neurons in different cortical regions are characterized by different discharge properties when presented with their respective stimuli. For example, while cells in V1 have been classified as 'simple' and 'complex' (Pettigrew and Daniels, 1973; Sillito, 1977; Kato *et al.*, 1978; Nelson and Frost, 1985; Reid *et al.*, 1991; Ferster *et al.*, 1996), in general the temporal duration of neuronal discharge following presentation of a stimulus is short by comparison with neurons in IT. More specifically, neurons in V1 are characterized by phasic discharge, whereas those in IT are characterized by tonic discharge when presented with a visual stimulus (Fuster and Alexander, 1971; Fuster and Jervey, 1981, 1983; Ashford and Fuster, 1985; Miller *et al.*, 1993; Miyashita *et al.*, 1993a, 1993b; Figure 18). Studies of the discharge properties of neurons in parietal cortex, such as somatosensory/visual association area 7, also reveal that the cells continue to discharge tonically for a relatively long time after presentation of a specific stimulus (Gnadt and Andersen, 1988; Koch and Fuster, 1989; Colby *et al.*, 1996; Constantinidis and Steinmetz, 1996; Zhou and Fuster, 1996, 1997; Chafee and Goldman-Rakic, 1998). This tonic activity, however, desists if a distractor is presented. Neurons in dorsolateral gPFC differ from those in association areas of the parietal and temporal lobes in that they continue to discharge tonically even when distractors are presented (Fuster and Alexander, 1971; Fuster, 1973; Fuster *et al.*, 1982; Funahashi *et al.*, 1989, 1993; Miller, 1999; Leung *et al.*, 2002). This persistence in tonic discharge despite presentation of distractors is widely believed to be important for executive functions performed by neurons in gPFC (see Fuster, 1997; Miller and Cohen, 2001; Wang, 2001; Elston, 2003b for reviews). Further evidence for regional variation in the functional characteristics of cortical circuitry comes from the work of Murayama *et al.* (1997), who demonstrated that tetonic stimulation led to long-term potentiation in TE but long-term depression in V1, and Shinomoto *et al.* (2005), who showed that neurons in area TE have characteristically different interspike intervals to those in medial motor areas.

The data on the structural complexity parallel these differences in neuronal discharge properties. Cells in V1, which are characterized by phasic discharge following stimulus presentation, have a relatively simple structure; those in association areas of the parietal and temporal lobes, which are characterized by tonic activity, that is, interrupted by presentation of distractors, have intermediate structural complexity while those in dorsolateral gPFC, which are characterized by tonic discharge properties that are sustained during presentation of distractors, have the most complex structure (Figure 18). The parallel between complexity in pyramidal cell structure and discharge properties makes it likely that the two are related: structure subserving function. Moreover, cortical circuits composed of pyramidal cells of different complexities will be characterized by different patterns of connectivity, resulting in different computational abilities. This theory departs from the popular belief that functional specialization in the cerebral cortex is attributed solely to the source of inputs. How differences in pyramidal cell structure may influence the computational capabilities of the circuits the cells comprise, is discussed below. Different aspects of the structure/function relationship are discussed at the cellular and systems levels.

4.13.2.2.1 Cellular level Many aspects of dendritic tree structure can be identified that may influence neuronal function (see White, 1989; Koch, 1999; Mel, 1999; Spruston *et al.*, 1999; Magee, 2000; Häusser and Mel, 2003 for reviews). Three of these features – size, branching pattern, and number/distribution of inputs, are considered here. Pyramidal cells characterized by a large dendritic tree extend over a wider region of cortex than cells with smaller tree (Sholl, 1956). In macaque visual cortex, there is a successive increase in both the size of the dendritic tree and the receptive field size for neurons in visual areas V1, V2, V4, and TEO (cf. Hubel and Wiesel, 1974; Dow *et al.*, 1981; Van Essen *et al.*, 1984; Burkhalter and Van Essen, 1986; Felleman and Van Essen, 1987; Schein and Desimone, 1990; Boussaoud *et al.*, 1991; Roe and T'so, 1995; Elston and Rosa, 1998a). Similarly, pyramidal cells have progressively larger dendritic trees through somatosensory areas 3b, 5, and 7, with a parallel increase in their receptive field size (Huntley and Jones, 1991; Pons *et al.*, 1992; Elston and Rockland, 2002). Differences in the size of the dendritic tree of pyramidal cells in motor cortex (area 4) and premotor cortex (area 6) also parallel differences in their motor fields (Mitz and Wise, 1987; Luppino *et al.*, 1991; Donoghue *et al.*, 1992; Elston and Rockland, 2002). In visual cortex, the differences in the size of the dendritic tree, coupled with receptive field map compression, result in more than a 100-fold difference in the region of the visual map sampled by individual pyramidal cells in V1 and cytoarchitectonic area TEO (Elston and Rosa, 1998a). Moreover, the size of the dendritic tree of layer III pyramidal cells and the size of neural receptive fields are significantly correlated in visual areas V1, V2, V4, and TEO (Figure 19). The largest cells reported so far in the macaque monkey cortex are those in the anterior cingulate gyrus. These cells sample a region of cortex, on average, eight times larger than that sampled by cells in V1.

In addition to determining the physical area of cortex from which neurons sample inputs, the size of the dendritic tree will influence its geometrical relationship with input axonal arbors. Supragranular pyramidal cells receive inputs from multiple sources (see Rockland, 1997 for a review). Here we focus on the sampling geometry between layer III pyramidal cell dendritic trees and the intrinsic lattice of axons, which arise from supragranular pyramidal cells (Rockland and Lund, 1982, 1983; Rockland *et al.*, 1982; McGuire *et al.*, 1991). In visual cortex, these intrinsic horizontal axonal patches are successively larger in V1, V2, V4, and cytoarchitectonic area TEO (Lund *et al.*, 1993; Fujita and Fujita, 1996), their size paralleling that of the dendritic tree of layer III pyramidal cells (Figure 19). Likewise, the size of these intrinsic horizontal patches increases through the primary somatosensory area

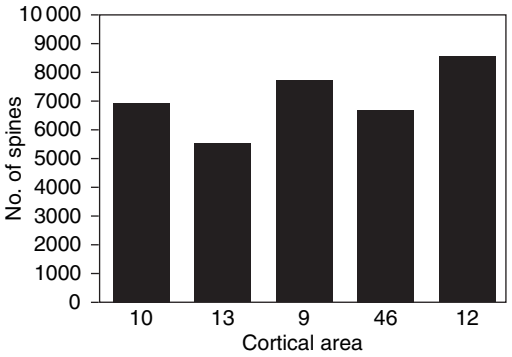

Figure 17 Plot illustrating differences in the estimates of the total number of spines in the basal dendritic trees of layer III pyramidal cells in granular prefrontal areas of the macaque monkey. 9d, dorsal subdivision of cytoarchitectonic area 9; 10, cytoarchitectonic area 10; 12vl, ventrolateral subdivision of cytoarchitectonic area 12; 13, cytoarchitectonic area 13 (also known as area 12 orbital); 46vr, ventral rostral subdivision of cytoarchitectonic area 46. Data taken from Elston, G. N., Benavides-Piccione, R., Elston, A., Manger, P., and DeFelipe, J., unpublished observations.

(area 3b) to areas 5 and 7 (Juliano *et al.*, 1990; Lund *et al.*, 1993) just as the dendritic trees of the cells in these areas become larger (Elston and Rockland, 2002). This parallel between dendritic tree size and intrinsic axonal patch size is also present in motor areas 4 and 6 (Lund *et al.*, 1993; Elston and Rockland, 2002). Studies of the intrinsic axonal patches in IT and dorsolateral gPFC reveal a different pattern. In these cortical regions, the axon patches are more diffuse, extending over much larger regions of cortex (Kritzer and Goldman-Rakic, 1995; Pucak *et al.*, 1996; Melchitzky *et al.*, 1998, 2001; Tanigawa *et al.*, 2005). This geometrical relationship between the size of pyramidal cell dendritic trees and the topography of the intrinsic horizontal lattice of projections reportedly influences the sampling geometry between the intrinsic axons originating from supragranular pyramidal cells and their dendritic trees (Figure 19), cells in cortical areas in which the size of the dendritic trees match the size of the

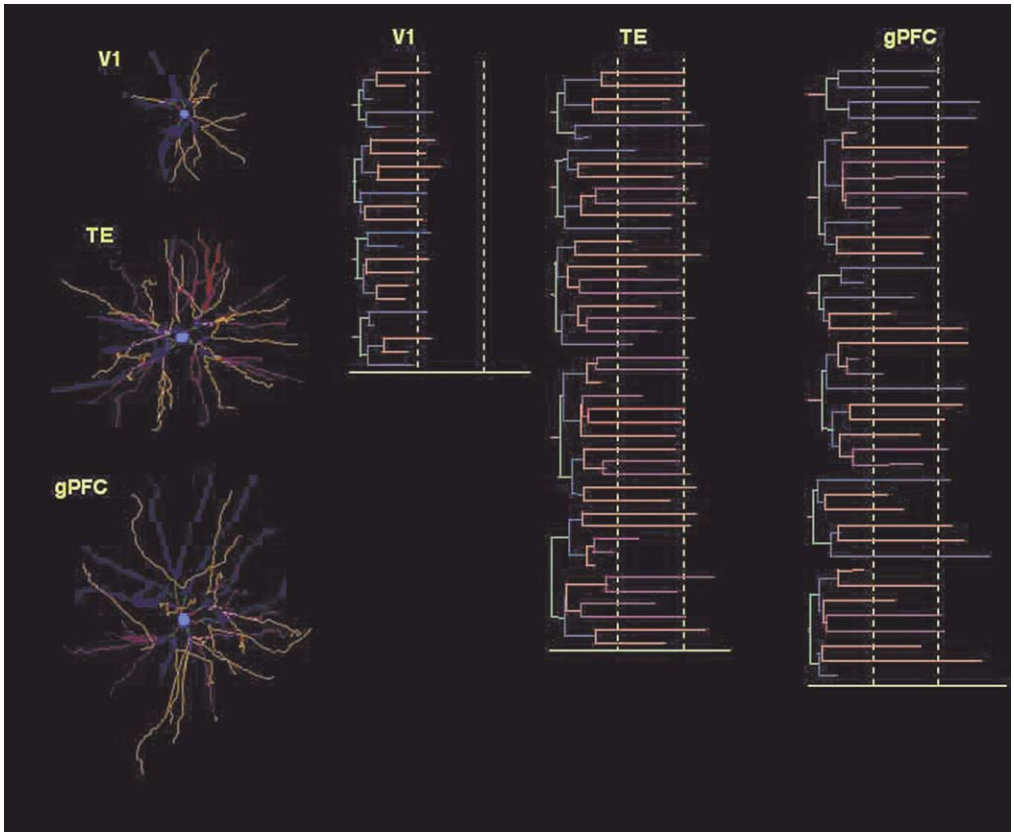

Figure 18 Drawings of pyramidal cells (skeletonized images of the basal dendritic tree in the tangential plane) located in layer III of the primary visual area (V1), IT (cytoarchitectonic area TE), and the dorsolateral gPFC and their respective dendograms. Note the difference in the number of 1° (red), 2° (green), 3° (blue), 4° (orange), and 5° (purple) dendrites, the number of separate compartments supported by the 1° dendrites (three, four, and five in V1, TE, and gPFC, respectively) and differences in the total dendritic length of the illustrated cells. Cells were chosen by virtue of their having a dendritic tree with a size approximating the average of that for each cortical area.

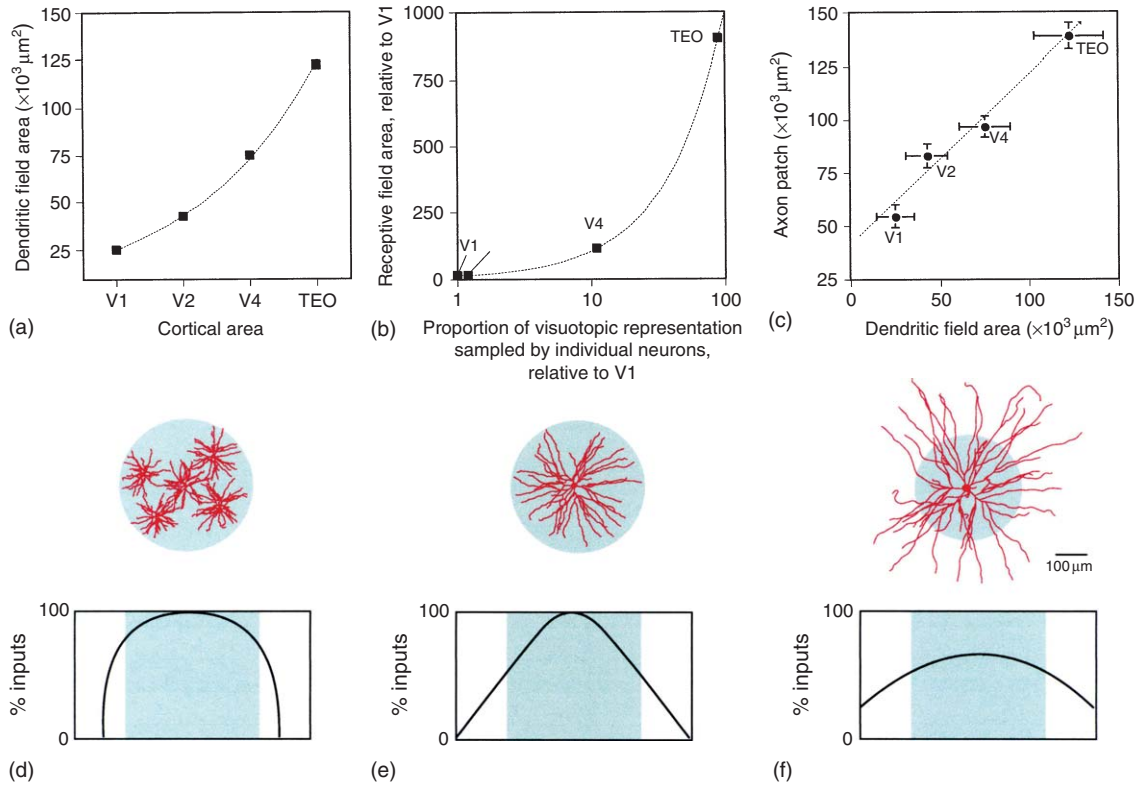

Figure 19 Schematics illustrating (a), the trend for pyramidal cells to have progressively larger dendritic trees through the primary, second, and fourth visual areas (V1, V2, and V4, respectively) and cytoarchitectonic area TEO of the macaque monkey; (b), the relationship between the size of the dendritic trees and the receptive fields of these same cells; (c), the relationship between the size of the basal dendritic trees of these pyramidal cells and the size of the intrinsic axonal patches; and (d, e), different sampling strategies between pyramidal cell basal dendritic trees and the intrinsic axonal patches. In (d), the dendritic trees of pyramidal cells are smaller than the axonal patches from which they receive inputs, meaning that a large population of cells potentially sample from the same source. Maximum connectivity (e) may be achieved if the basal dendritic trees are the same size as the axonal modules. There is greater potential for mixing of inputs (f) when the pyramidal cell dendritic trees are larger than the axonal patches from which they sample. Injected cells, and receptive field sizes selected for comparison, were sampled from the central 5° in the visual field. Data for receptive field sizes taken from Hubel and Wiesel (1974), Dow *et al.* (1981), Van Essen *et al.* (1984), Burkhalter and Van Essen (1986), Felleman and Van Essen (1987), Schein and Desimone (1990), Boussaoud *et al.* (1991), Roe and T'so (1995). Data on the size of the basal dendritic trees taken from Elston and Rosa (1998a), and data on the size of the intrinsic axonal patches taken from Amir *et al.* (1993), Lund *et al.* (1993). The figures related to sampling strategies were modified from Malach (1994).

axonal patches have maximum potential to sample all inputs from a single source, whereas cells that have dendritic trees that are larger than the intrinsic axonal patches are likely to sample more divergent sources (see Malach, 1994; Elston, 2003a for reviews).

Marked differences in the number of dendritic spines, each of which receives at least one asymmetrical synapse (Colonnier, 1968; Jones, 1968; Peters and Kaiserman-Abramof, 1969), the presynaptic terminals of which contain the excitatory neurotransmitter glutamate (DeFelipe *et al.*, 1988; Kharazia and Weinberg, 1993), means that pyramidal cells in different cortical areas integrate different numbers of inputs over the region of cortex from which they extend. For example, in visual cortex, there is a successive doubling in the number of spines (excitatory inputs) in the dendritic trees of pyramidal cells in V1, V2, V4, and TEO. Layer III pyramidal cells in macaque area TE, contain, on average, more than 11 times the spines in their basal dendritic trees than those in macaque V1, while cells in area STP contain, on average, more than 13 times the spines than those in V1 (Elston *et al.*, 1999a). Similar trends are reported in somatosensory areas 3b, 5, and 7, although the extent of the interareal differences is less than that reported in visual cortex. Pyramidal cells in the gPFC have, on average, as many as 20 times more spines than those in V1. These differences cannot be accounted for by the differing size of the dendritic trees of pyramidal

cells, but reflect variations in the density of spines within the dendritic tree. For example, the dendritic trees of cells in the dorsolateral gPFC are smaller than those in IT but they contain more dendritic spines.

The differences in the density of dendritic spines along the dendrites of pyramidal cells may also influence various aspects of the integration of inputs along the dendrites. For example, the peak spine density along dendrites of pyramidal cells in TE is more than three times higher than that found in V1 (Elston *et al.*, 1999a). These differences in spine density are likely to influence local summation of postsynaptic potentials (EPSPs), cooperativity between inputs, and propagation of potentials (Shepherd *et al.*, 1985; Frick *et al.*, 2004). Regional differences in the morphology of spines (Elston *et al.*, 1999a, 1999b; Benavides-Piccione *et al.*, 2003; Konur *et al.*, 2003) may also influence their functional properties (see Harris and Karter, 1994; Shepherd, 1998; Koch, 1999; Tsay and Yuste, 2004 for reviews). For example, the volume of the spine head is reportedly correlated with the postsynaptic density. This correlates with the number of receptors and the potential for current to pass through the membrane, and the number of docked vesicles on the postsynaptic terminal, which reflects both quantity and probability of release of neurotransmitter (Harris and Stevens, 1989; Nusser *et al.*, 1998; Schikorski and Stevens, 2001).

In addition, specialization in the branching structure of pyramidal cells in different cortical regions allows varying degrees of compartmentalization of these inputs within their dendritic trees. Modeling studies have demonstrated how the number of branches in, and the distribution of receptors throughout, the dendritic tree of pyramidal cells may influence its functional capacity: cells with the same number of inputs distributed throughout dendritic trees with different numbers of branches have different functional capacities (Mel, 1992, 1993; Poirazi and Mel, 2000). Cells that sample more inputs in dendritic trees with more complex branching patterns have even greater functional capacities (Figure 20). Thus, in visual cortex, cells in area TEO or TE are likely to have greater functional capacities than those in V1, for example. Similarly, neurons in somatosensory area 7 or premotor cortex are likely to have greater functional capacity than those in areas 3b and 4, respectively. Nowhere is this potential greater than in dorsolateral gPFC, which contains the most branched and spinous of all cells studied. While this remains theoretical (Koch *et al.*, 1982; Rall and Segev, 1987; Shepherd and Brayton, 1987; Koch, 1999), compartmentalization has been demonstrated empirically in the retina (Taylor *et al.*, 2000) and auditory brainstem (Agmon-Snir *et al.*, 1998).

4.13.2.2.2 Systems level Cortical function, whether it be processing of visual information, somatosensation, audition, motor planning, emotion, or executive functions, never occurs solely in a small group of clustered neurons, nor in neurons restricted solely to a single cortical area. Imaging studies in particular have revealed how much of the cerebral cortex may be recruited during a particular sensory stimulus presentation, memory task or cognitive task (see Paulesu *et al.*, 1997; Passingham, 1997; Friston, 2001 for reviews). Ensembles of neurons are recruited across multiple areas for any given task, although, importantly, not all neurons within these different areas are necessarily activated. Neurons located within a particular cortical area can be involved in multiple overlapping circuits, which are activated during specific functions (both within and between cortical areas). Some ways in which specialization in pyramidal cell structure may influence cortical processing at the level of the single cortical area (areal) and/or across multiple cortical areas (multi-areal) are discussed here.

We have already seen in Figure 19 how differences in the size of intrinsic axonal patches result in different sampling strategies for individual neurons in visual, somatosensory, association, and gPFC. In addition, differences in the spacing and lateral extent of these intrinsic patches result in different patterns of connectivity in different cortical areas (Figure 21). For example, the intrinsic patches in V1 are closely spaced and restricted to the immediate surroundings of the injection site, whereas those in visual areas such as TEO and TE are more widely spaced and extend over larger regions of cortex. In topographically organized cortex, this equates to a larger proportion of the topographic representation being sampled by individual neurons. In visual cortex, the differences in the spacing of the intrinsic patches, coupled with compression of the visual map, result in a much larger proportion of the visual scene being sampled by individual neurons in TEO than, for example, in V1. Not surprisingly, these principles also hold true in somatosensory cortex: center-to-center spacing of intrinsic axonal patches increases through areas 3b, 5, and 7, paralleling differences in the receptive field properties of neurons in these areas. In gPFC, the intrinsic axonal 'patches' extend over even larger expanses of cortex. Although the gPFC is not topographically organized in the same way as the visual, somatosensory, and motor cortices, different authors have reported various forms of systematic

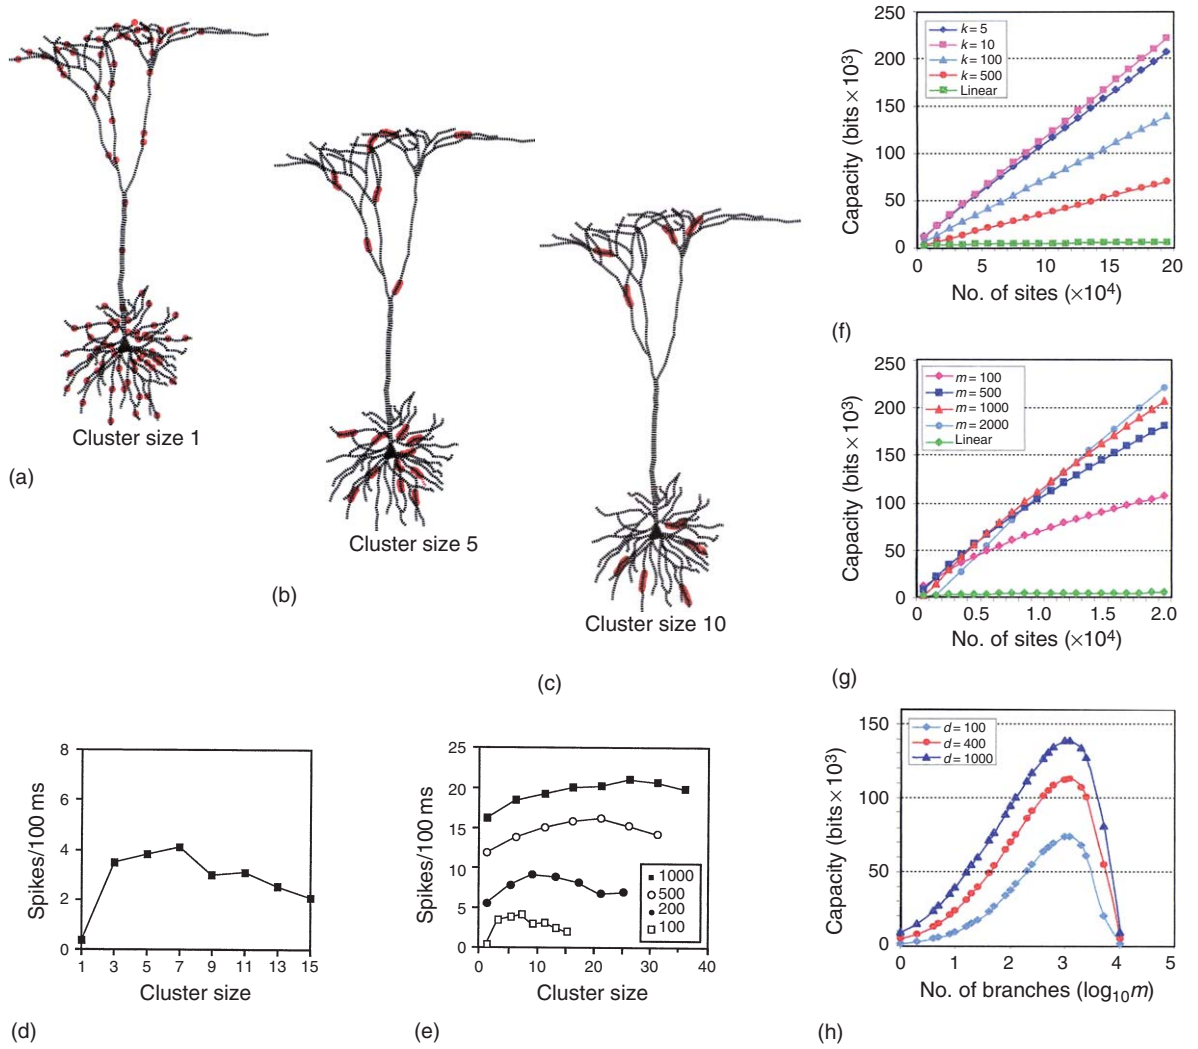

Figure 20 a–c, Drawings of a neocortical pyramidal cell that has a constant number of synchronously active excitatory inputs (red circles) distributed throughout the dendritic tree in different cluster sizes. d, Pyramidal cells receiving different numbers of synchronously active excitatory inputs will be characterized by different saturation levels for cells. e, Increasing the number of inputs (with a set cluster size) also increases the number of spike discharges. The 'capacity' (measured in bits) of a cell of fixed branch length, or total number of branches, increases with an increase in the number of sites (f–h). An increase in either branch length (*k*) or branch count (*m*) results in increasing 'capacity' with an increase in the number of sites ((f) and (g), respectively). The 'capacity' of a cell of fixed size (h), increases to a peak with an increase in the number of branches, before decreasing to values expected by linear models. Adapted from Mel, B. W. 1993. Synaptic integration in an excitable dendritic tree. *J. Neurophysiol.* 70, 1086–1101; Poirazi, P. and Mel, B. 2000. Impact of active dendrites and structural plasticity on the storage capacity of neural tissue. *Neuron* 29, 770–796.

topography across cortex (Funahashi *et al.*, 1989; Wilson *et al.*, 1993; Ó Scalaidhe *et al.*, 1997; Compte *et al.*, 2000). Thus, the more widespread patterns of axon connections in supragranular cortex potentially allow cross-communication between these fields. Unfortunately, studies of the supragranular intrinsic connectivity in cingulate cortex of the macaque monkey are lacking. It will be of great interest to see if any latticework exists and how it compares with that reported in other cortical regions.

As mentioned previously, there are various theories related to multi-areal processing, including hierarchical and distributed models (see Felleman and Van Essen, 1991; Mountcastle, 1995 for reviews). Common to both models is the concept that ensembles of neurons in multiple cortical areas may be co-activated for any given task. How regional differences in pyramidal cell structure could influence processing within these different models has been covered in detail elsewhere (Elston, 2002, 2003b). Briefly, within hierarchical models, the flow of visual inputs along a pathway allows individual neurons within progressively 'higher' areas to process inputs from a

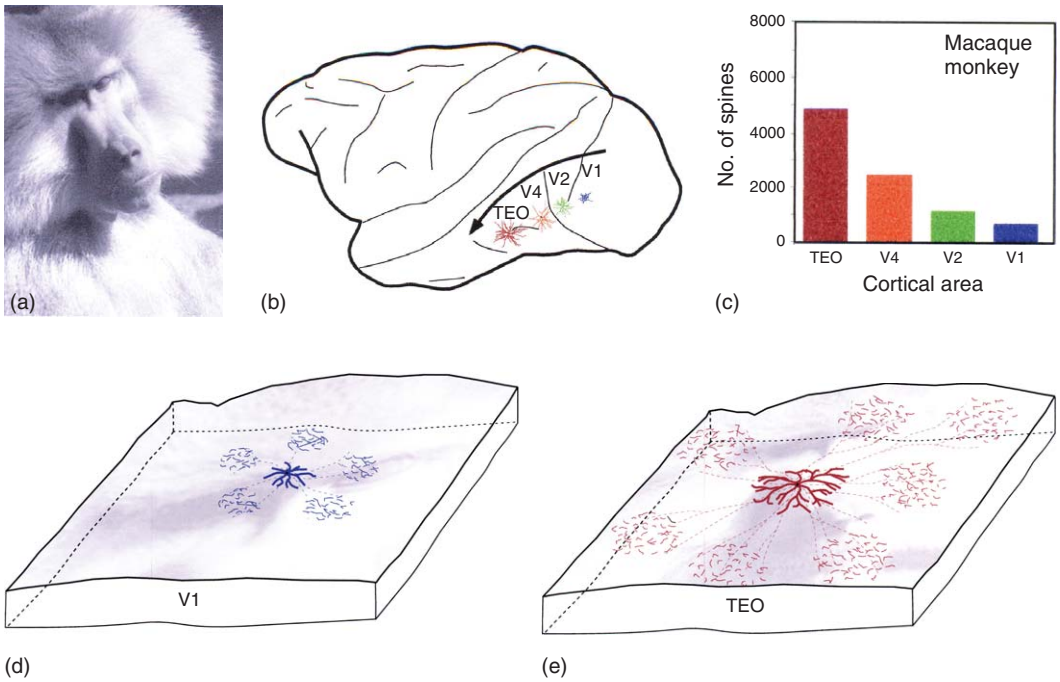

Figure 21 Schematic illustrating various aspects of sampling topography of supragranular pyramidal cells in the primary visual area (V1) and cytoarchitectonic area TEO. A typical visual stimulus is illustrated in (a). Different aspects of the visual stimulus are processed in multiple cortical areas, including the primary, second, and fourth visual areas (V1, V2, and V4, respectively) and cytoarchitectonic area TEO (illustrated in (b)). Cells have progressively larger dendritic trees with anterior progression through these four cortical areas. They also become progressively more branched and spinous, resulting in dramatic differences in the number of spines (putative excitatory inputs) in their dendritic trees (c). In addition to the increase in size, branching complexity, and number of spines in their basal dendritic trees, there is a progressive increase in the size and center-to-center spacing of intrinsic horizontal axonal clusters in the supragranular layers of these cortical areas (c and d). In V1 (d), the intrinsic axonal clusters are relatively small and are tightly grouped, whereas in cytoarchitectonic area TEO (e), these axonal clusters are less uniform, generally larger, and extend over a larger region of cortex (in absolute size). These features, coupled with the visuotopic compression in these cortical areas (e.g., the relative absolute size of the baboon face in (d) and (e)), result in patterns of connectivity that encompass markedly different proportions of the visual scene.

proportionately larger region of the visuotopic map. The potential advantage of such 'serial reconstruction' of the visual scene is conceptually straightforward in the occipitotemporal (OT) pathway where neurons in successively higher visual areas distinguish more complex features (see Felleman and Van Essen, 1991; Gross *et al.*, 1993; Tanaka, 1996; Elston, 2002; Fujita, 2003 for reviews). Within a distributed system, co-activation of ensembles of highly spinous pyramidal cells in association areas may be important for binding sensory perceptions (see Singer and Gray, 1995; Llinás and Paré, 1996 for reviews). In addition, there is a greater potential for re-entrant sampling in circuits composed of neurons that integrate large numbers of excitatory inputs and are highly interconnected than in circuits composed of sparsely interconnected neurons that sample relatively few inputs (see Wang, 2001 for a review). Thus, cooperativity of ensembles of pyramidal cells of varying phenotype in different cortical areas potentially leads to a richness in diversity of, and functional cohesiveness in, cortical function not attainable in cortex composed of the same basic repeated, or canonical, circuit.

4.13.2.2.3 Circuits and memory formation Multiple converging criteria, including cortical damage (both, that inflicted by foreign objects and that which results from internal insult such as calcification or hemorrhage), experimental ablation studies, electrophysiological recording, imaging, and theoretical studies, reveal that memories are stored across large expanses of cortex, including but not exclusive to neocortex (see Fuster, 1995 for a review). While this remains a highly controversial field of investigation, there is widespread agreement that the hypothesis proposed by Hebb (1949) is fundamental to the storage of memory – that is, put simply, synapses are strengthened through use. Considerable advances have been made in our understanding of the molecular mechanisms involved at the synaptic level (e.g., see Kandel, 2001 for a review). Here we focus on the implications of synaptic reinforcement at the neural/circuit level.

During the last few years, there has been a resurgence of interest in Hebbian-type reinforcement at the circuit level (see Mel, 2002; Chklovskii *et al.*, 2004 for reviews). Of particular interest here is the distinction made between 'weight-based' learning and 'wiring-based' learning. Put simply, weight-based learning refers to the synaptic reinforcement of a pre-existing synapse (in series), whereas wiring-based learning refers to the establishment of a new synaptic contact by association (in parallel) (see Chklovskii *et al.*, 2004). How this bears relevance to the regional difference in pyramidal cell structure reported here becomes clear when we focus on the word 'association'. In particular, are cortical circuits composed of neurons with quantifiably different associative potential characterized by differing memory capacities? Intuitively, the answer is yes but let us consider how.

Typically, the associative potential of a neuron is measured by the number of inputs it can sample. As we have seen, pyramidal cells in V1 contain, on average, ~600 spines (putative excitatory inputs) in the basal dendritic trees. Those in gPFC contain, on average, more than 10 000 spines in their basal dendritic trees. Based on what is known of intrinsic connectivity in V1 and the gPFC (e.g., McGuire *et al.*, 1991; Melchitzky *et al.*, 1998, 2001), 20–30% of inputs received by pyramidal cells in both these cortical regions originate from neighboring pyramidal cells (excitatory). By way of example, lets assume that cells in V1 are connected with 200 local pyramidal cells, whereas those in the gPFC are connected with 3000 neighboring pyramidal cells. Application of these numbers to a wiring-based model makes it clear that there is a greater potential for association in the gPFC. Extension of this logic to include multiple synapses across three or more levels reveals how the associative potential of a circuit is ramped up, particularly in the gPFC. The exponential increase in the associative potential in a multi-neuron circuit in the gPFC soon eclipses that in V1 as successive synaptic steps are added to the circuit (eqn [1]). Applying this logic, based on what is known of the structure of neurons, reveals intermediate levels of association in IT and parietal association cortex, as well as cingulate cortex:

$$\begin{aligned}\text{V1: } & 200 \times 200 \times 200 \times 200 \times 200 \times \ 200 \ldots n \\ \text{gPFC: } & 10\,000 \times 10\,000 \times 10\,000 \times 10\,000 \\ & \times 10\,000 \times 10\,000 \ldots n.\end{aligned} \qquad [1]$$

Equation [1], as simple as it is, serves to illustrate several points. First, note the different associative potentials of neurons interspersed throughout a cortical circuit. In this equation, we have illustrated the magnitude of this difference through a series of six neurons, up to n. Even in this crude example of a cortical circuit, there is a 1.5×10^{10}-fold difference in associative potential in those first six steps even when assuming a strict serial order. However, as we know, parallel and reciprocal connections are common in the cerebral cortex. Thus, this simple equation also serves to illustrate, or prompt, the question, how many neurons are included in a memory circuit in the neocortex? The answer is simple, we do not know – certainly, more than two but less than 10 billion. We leave it to the reader to calculate the difference in associative potential in circuits composed of 100 or more cells in V1 and the gPFC.

Of course, this is a grossly oversimplified representation of memory. Memories are not coded entirely within a single cortical area. Imaging studies have revealed that neurons may be active in many widely distributed cortical areas during memory recall. Thus, another level of complexity in trying to determine the associative potential in a memory circuit is conspicuous by its absence in eqn [1]. How many neurons of different associative potentials (from different cortical areas) are incorporated in a given memory engram? The scope of this discussion falls outside this review; however, we would like to point out one other aspect of neuron structure that adds further complexity to the above.

As outlined above (Section 4.13.2.2.1), the functional capacity of individual neurons is influenced by their branching structure. In turn, the branching structure of, and the distribution of ion channels throughout, the dendritic trees of neurons will influence the association potential of the circuits they comprise. More specifically, the structure of the dendritic tree determines both the number of computational subunits, and their geometric interface with other neurons (Williams and Stuart, 2002; Krapp and Gabbiani, 2005; Nolan *et al.*, 2004). Differences in the distribution of inputs throughout the dendritic trees of pyramidal cells, as exemplified by their different branching structure, may result in a difference of up to two orders in magnitude in the memory storage capacity (Poirazi and Mel, 2000).

4.13.2.2.4 More on the structure/function relationship Many investigators have made a concerted effort over the years to detect possible structural abnormalities in the cerebral cortex associated with specific pathologies. Although the scope of this body of work is beyond the thrust of this review, it is worth drawing the readers attention to

some examples where a parallel has been demonstrated between cortical microstructure and psychopathogy. This growing body of evidence suggests that structural modifications to pyramidal cell structure observed in senescence, mental disorder, and disease are cause rather than effect. For example, the decrease in dendritic branching and spine loss with aging is paralleled by a decline in cognitive ability (Scheibel *et al.*, 1975, 1976; Huttenlocher, 1979; Jacobs and Scheibel, 1993; Jacobs *et al.*, 1997; de Brabander *et al.*, 1998). The impoverished structure of pyramidal cells in the brains of individuals with Down syndrome and Fragile X reflect their diminished cognitive abilities (Marin-Padilla, 1976; Suetsugu and Mehraein, 1980; Takashima *et al.*, 1981; Hinton *et al.*, 1991). Decreased branching structure and number of dendritic spines have been reported in schizophrenia, which are thought to be responsible for altered mental functions (Garey *et al.*, 1998; Glantz and Lewis, 2000; Kalus *et al.*, 2000; Black *et al.*, 2004; Cullen *et al.*, 2006). Dendritic atrophy has also been reported in Rett syndrome (Cornford *et al.*, 1994). In addition, manipulation of sensory inputs to the cerebral cortex results in plastic changes in microcircuitry – new dendrites grow, dendritic spines form, and synapses are established, which are not present in the intact animal (e.g., Valverde, 1967, 1968). Neuronal and circuit function is consequently changed. Such dendritic growth, spinogenesis, and synaptogenesis observed in the adult (e.g., Elston and DeFelipe, 2002; Churchill *et al.*, 2004; Tailby *et al.*, 2005) is thought to consolidate immediate functional changes observed in the cerebral cortex following damage to sensory inputs (e.g., Merzenich *et al.*, 1983a, 1983b; Calford and Tweedale, 1988; Kaas *et al.*, 1990; Pons *et al.*, 1991; Gilbert and Wiesel, 1992). Moreover, pyramidal cells in experimental animals reared in an enriched environment have a more complex structure (Figure 22) and the animals perform better on behavioral tasks, than animals that have been reared in a nonenriched environment (Volkmar and Greenough, 1972; Globus *et al.*, 1973; Greenough *et al.*, 1973; Floeter and Greenhough, 1979; Withers and Greenough, 1989; Dierssen *et al.*, 2002) (Figure 22). For in-depth reviews the reader is referred to articles by Huttenlocher (1991), Harris (1999), Kintsova and Greenough (1999), Wooley (1999), Irwin *et al.* (2000), Jones (2000), Kaufmann and Moser (2000), Calford (2002), Elston and DeFelipe (2002), Dierssen *et al.* (2003), and Kaas *et al.*

(2003). See also DeFelipe and Jones (1988) for a translation of Cajal's works (1894a, 1894b).

4.13.2.2.5 Summary of the structure/function relationship In summary, systematic areal specializations in cortical circuitry are likely to influence various aspects of visual processing. The small pyramidal cells in V1, and the circuits they form, allow high-fidelity sampling of the visual scene, the relatively small number of inputs they integrate, and their patterns of connectivity, being instrumental in determining their phasic discharge properties. V1 circuit structure is specialized to subserve rapid processing of a constantly changing visual scene, allowing quick reset time for processing saccadic inputs. In other words, V1 circuitry is specialized to fire and flush. The integrative ability and patterns of connectivity of the larger, more branched, and more spinous pyramidal cells in visual areas in IT provide an anatomical substrate for the global integration of the visual scene. Each neuron's ability to sample a large number of excitatory inputs is central to the sustained tonic activity reported in these cells, which is widely believed to be important for visual memory. The more branched, more spinous pyramidal cells in the gPFC sample, the larger the number of excitatory inputs in a smaller volume of cortex than those in IT, potentially facilitating greater recurrent excitation necessary to sustain tonic discharge even when presented with distractors.

4.13.3 Comparative Data on the Pyramidal Cell Phenotype in the Primate Brain

In a bid to begin to understand something of the evolution of cortical microcircuitry in the primate brain, pyramidal cell structure has been quantified in multiple cortical areas in a diverse range of species. More specifically, pyramidal cell structure has been studied in visual, sensorimotor, cingulate, and gPFC of human and nonhuman, New World and Old World, simian and prosimian primates. Where possible, we have attempted to study pyramidal cells in homologous cortical areas. Where there is uncertainty regarding homology, analogous or corresponding cortical regions have been selected for study. These investigations have always been focused on pyramidal cells in a homologous cortical layer (layer III, unless otherwise stated). In a bid to minimize sampling error, studies have concentrated on the same hemisphere (left) of brains taken from individuals of the same sex (male) of similar developmental age (all sexually mature but not aged). In addition, the cell injection techniques and the methods of quantification have been standardized across all studies. In nearly all species, data have been sampled from two or more cases.

4.13.3.1 Visual Cortex

Visual cortex has been mapped extensively in a number of primate species. Data from the laboratories of Allman, Kaas, Rosa, and Zeki, in particular, reveal the presence of V2, MT, and a number of other extrastriate visual areas in the temporal and parietal lobes of the cerebral cortex of primates (Zeki, 1969a, 1969b, 1971, 1977, 1978, 1980; Allman and Kaas, 1971a, 1971b, 1975, 1976; Kaas *et al.*, 1972; Allman *et al.*, 1973, 1979; Kaas and Lin, 1977; Sesma *et al.*, 1984; Weller *et al.*, 1984; Zeki and Shipp, 1989; Rosa *et al.*, 1993, 1997; Rosa and Schmid, 1995; Rosa and Elston, 1998; Rosa and Tweedale, 2000; Lyon and Kaas, 2002; Lyon *et al.*, 2002). These studies have paved the way for cell injection studies of pyramidal cells in a number of different visual areas in species other than the macaque monkey. In particular, studies of pyramidal cell structure have been focused on occipitotemporal (OT) visual areas. As a basis for comparison, pyramidal cells have been studied in well-documented visual areas in the galago (bush baby), marmoset, and owl monkey. In addition, the study of pyramidal cells has been extended to the OT cortex of the baboon and vervet monkey (savannah guenon), for which detailed maps do not exist but data are available regarding the size of V1. Comparison of these data with those obtained from the OT cortex of the macaque monkey reveals several interesting trends. In all species included for investigation, both simian and prosimian, New World and Old World, diurnal and nocturnal, there was a trend for pyramidal cells with progressively larger, more spinous-basal dendritic trees with anterior progression through the OT cortex (Figure 23). Moreover, the relative extent of the difference among cell structure in OT areas differs between species.

These species differences in the extent of the trend for pyramidal cells with progressively larger, more spinous basal dendritic trees through OT visual areas do not result from a random increase in cell complexity in a given cortical area. Nor do they occur as a result of scaling of the cerebrum: cells in the primary visual areas have remarkably similar structure in all species despite up to a fivefold difference in the size/cortical surface area of V1 (Table 2). Instead, the

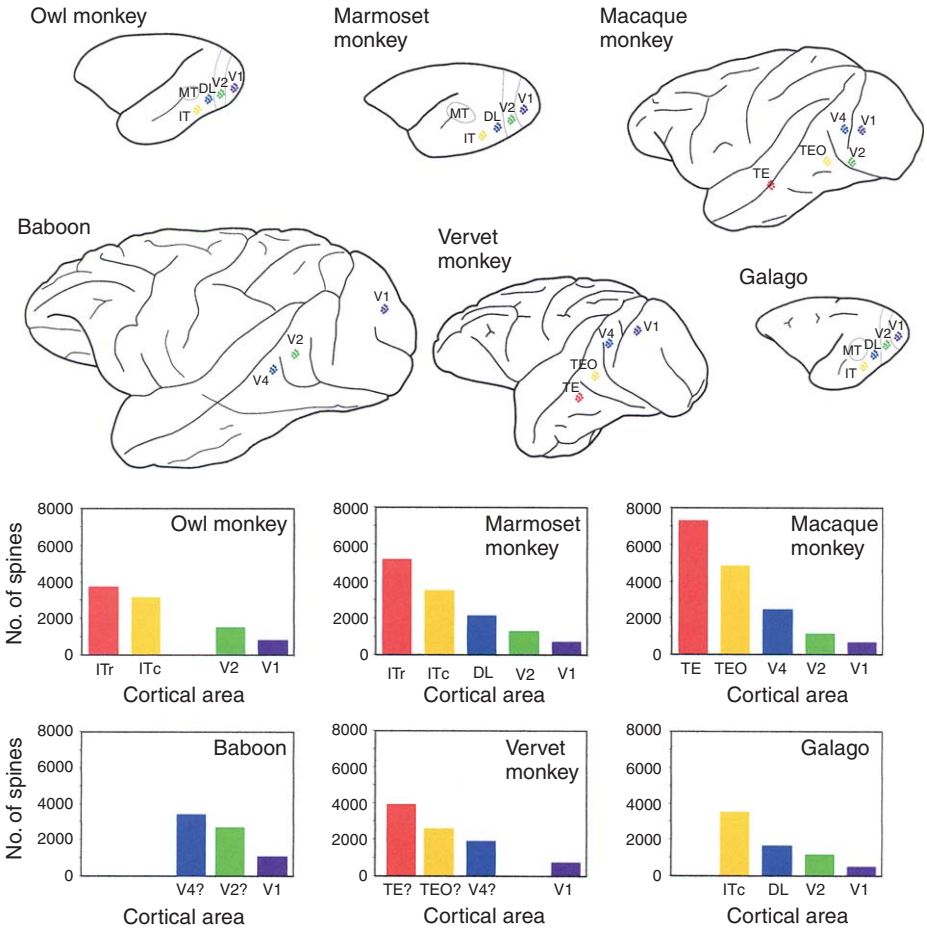

Figure 23 Schematic illustrating the location from which neurons were sampled (colored dots) in the OT cortex of the left hemisphere of the galago, owl monkey, marmoset monkey, macaque monkey, vervet monkey, and baboon, and the corresponding bar graphs of the estimates of the total number of spines in the basal dendritic trees of layer III pyramidal cells in cortical visual areas. Although we have not sampled from all cortical areas in OT cortex of all six species, and there is confusion regarding the homology of cortical areas in the temporal lobe, there is a clear and consistent trend for more spinous cells with anterior progression through OT cortex. In addition, the relative extent in the number of dendritic spines (putative excitatory inputs) in the basal dendritic trees of these cells differs between species. Despite large variations in the size of the primary visual area (V1) between species, there is remarkable consistency in the number of spines in their basal dendritic trees. The same is not true, however, for cortical areas in the temporal lobe. There is a parallel between the size of the temporal lobe (the degree to which it has expanded) and the extent of the increase in the number of spines in the dendritic trees of cells. Schematics of the different brains are not drawn to scale. DL, dorsolateral area; IT, inferotemporal cortex; MT, middle temporal area; TE and TEO, cytoarchitectonic area; V1, primary visual area; V2, second visual area; V4, fourth visual area. Data taken from Elston and Rosa (1998a), Elston *et al.* (1999b, 2005b, 2005e, 2005j), and Elston (2003c).

species differences are primarily manifest in IT. The extent to which pyramidal cells become larger and more spinous with anterior progression through OT cortex appears to reflect the expansion of the temporal lobe. A plot of the estimates of the total number of spines in the basal dendritic trees of layer III pyramidal cells in OT visual areas reveals a progressive increase in the number of spines as a function of increasing distance from the occipital pole (Figure 24).

4.13.3.2 Sensorimotor Cortex

Like visual cortex, sensorimotor cortex has been studied extensively in a number of primate species. Based on Brodmann's observations, motor cortex has expanded to different degrees in different primate species. While still controversial, it has been proposed that new cortical areas have differentiated in premotor cortex during its expansion. For example, Watanabe-Sawaguchi *et al.* (1991) identified a new cortical area, area 6aγ, in premotor cortex of the baboon, which they claim is not present in the macaque or vervet monkeys. Area 6aγ reportedly has cytoarchitectonic characteristics intermediate between the more posterior 'area 6' and anterior area 8. However, studies in the prosimian galago suggest that it shares a similar complement of motor areas with monkeys (Wu *et al.*, 2000), despite the fact that the lineages that led to these present-day

Table 2 Relative proportion of cortical volume occupied by granular prefrontal and precentral cortex in a number of different species

	Species	*Total cortical volume (mm^3)*	*Granular prefrontal cortex (gPFC)*	*Agranular precentral cortex*	*gPFC[a] agranular precentral cortex (frontal lobe)*	*Primary visual area*

[a]Included as a primate in the original table (see Pettigrew *et al.*, 1989 for a review).
[b]Labeled as a rodent in the original table.
Modified from Brodmann, K. 1913. Neue Forschungsergebnisse der Grosshirnrindenanatomie mit besonderer Berücksichtigung anthropologischer Fragen. *Gesselsch. Deuts. Naturf. Artze.* 85, 200–240.

species have been separated for a longer period of time than those leading to present-day baboons and macaque monkeys (see Figure 4).

As in visual cortex, investigations of the sensorimotor cortex revealed consistent trends for pyramidal cell specialization, but the extent of these specializations varies among species. For example, comparison of the dendritic trees of layer III pyramidal cells in sensorimotor cortex of the macaque monkey, the vervet monkey, and the baboon reveal a common trend for increasing cell complexity with posterior progression from the central sulcus through somatosensory areas and with anterior progression from the primary motor area to premotor cortex. As in visual cortex, these estimates reveal dramatic differences in the total number of spines in the dendritic trees of pyramidal cells in sensorimotor areas, with up to a fivefold difference reported in the vervet monkey (Figure 25).

What is also clear from Figure 25 is that pyramidal cells in sensorimotor cortex of the macaque monkey are considerably more spinous than those in corresponding cortical areas in either the baboon or vervet monkey. For example, based on estimates of the total number of spines in the basal dendritic tree of pyramidal cells in area 6, cells in the macaque monkey are approximately twice as spinous as those in the other two species. However, several caveats need to be considered when interpreting these data. First, neurons in the macaque monkey were sampled from the forelimb/hand representation, whereas those in the vervet monkey and baboon were sampled more dorsally, probably in the trunk representation (cf. Jones *et al.*, 1978; Matsumura and Kubota, 1979; Waters *et al.*, 1990; Huntley and Jones, 1991; Manger *et al.*, 1996, 1997). Sampling cells from these different topographic representations is likely to influence the data, particularly in view of forelimb dexterity in primates. Second, the age of some of the animals included in these investigations was unknown: differences in age may influence both the branching structure

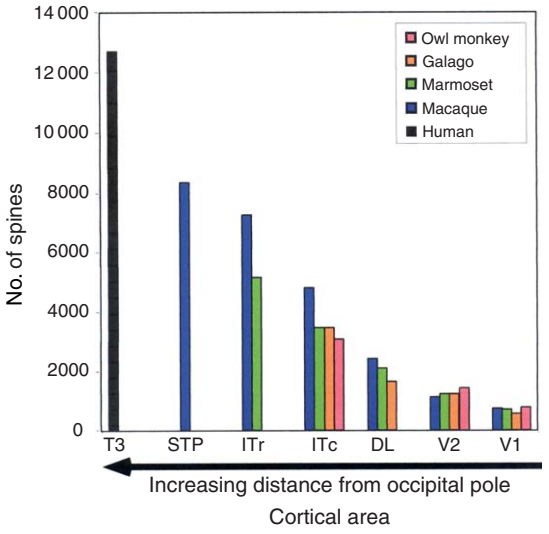

Figure 24 Plots of the estimates of the total number of spines in the basal dendritic tree of the 'average' pyramidal cell in OT cortical areas in the galago, the owl monkey, the marmoset monkey, the macaque monkey, and human. The number of spines in the basal dendritic tree of the 'average' pyramidal cell is calculated by summing the product of the mean spine density and mean number of dendritic branches over successive 25 μm annuli across the entire dendritic tree of all neurons sampled in a given cortical area. Note the general trend toward an increase in the number of dendritic spines in the basal dendritic trees of pyramidal cells in species with progressively larger temporal lobes. These data, however, should not be interpreted as suggesting that pyramidal cells become increasingly more complex in cortical areas anterior to those illustrated. Our unpublished observations suggest that there is a decrease in the number of spines in the basal dendritic trees of pyramidal cells in close proximity to the temporal pole, much the same as reported in the frontal pole (Elston *et al.*, 2001). Data taken from Elston and Rosa (1998a), Elston *et al.* (1999b, 2005b, 2005e, 2005j), and Elston (2003c).

and the number of dendritic spines. Third, some of the animals included for study were raised in animal colonies (macaque and vervet monkeys), whereas others (baboons) lived in the wild. All of these variables have been shown to influence pyramidal cell structure (Greenough *et al.*, 1973; Scheibel *et al.*, 1975, 1976; Huttenlocher, 1979; Cupp and Uemura, 1980; Huttenlocher *et al.*, 1982; Nakamura *et al.*, 1985; Huttenlocher and de Courten, 1987; Anderson and Rutledge, 1996; Huttenlocher and Dabholkar, 1997; Jacobs *et al.*, 1997; Dierssen *et al.*, 2002). Nonetheless, studies in the cingulate cortex of these same animals (see below) reveal similar numbers of spines in the dendritic trees of pyramidal cells in corresponding cortical areas, suggesting that the differences reported here in sensorimotor cortex (macaque monkey versus baboon and vervet monkey) are likely to be attributable to the body-part representations from which the data were sampled, rather than any other reason.

4.13.3.3 Cingulate Cortex

Although cingulate cortex is often considered to be a primitive structure (Sanides, 1970; MacLean, 1989), comparison of this region of cortex across different primate species reveals dramatic variation in its size. For example, the cingulate gyrus in the Chacma baboon is at least five times longer than that in the marmoset monkey, and more than double the width, while that in humans may be more than 10 times longer than that in the marmoset. There are remarkably few studies that have explored the functional implications of these differences, even at the gross level (see Allman *et al.*, 2001 for a review). Although the data are relatively limited, a picture is beginning to emerge with respect to specialization in pyramidal cell structure in the cingulate gyrus in primates (Figure 26). For example, there is a consistent trend for larger, more branched, and more spinous pyramidal cells in the anterior cingulate gyrus than in the posterior cingulate gyrus (Brodmann's areas 24 and 23, respectively). Estimates of the total number of spines in the basal dendritic tree of pyramidal cells in area 24 are remarkably similar between the Chacma baboon and the macaque and vervet monkeys, as are those for cells in area 23. In addition, in all three species, pyramidal cells in the anterior cingulate gyrus are considerably larger, more branched, and more spinous than those in other visual, somatosensory, and motor cortical areas sampled from the same cases (cf. Figures 23, 25, and 26). In future studies, it will be of interest to study pyramidal cell structure in the cingulate cortex of great apes, particularly in view of the presence of specialized spindle cells reported in humans and chimpanzees (Nimchinsky *et al.*, 1999; Hayashi *et al.*, 2001; see Role of Spindle Cells in the Social Cognition of Apes and Humans).

4.13.3.4 Prefrontal Cortex

The gPFC has become greatly expanded in some primates, particularly in humans (Table 2, Figure 27). Because of this relatively recent and rapid expansion, many researchers have concluded that the gPFC is important in executive functions such as planning, prioritizing, and conceptualizing. This view, however, is not without its critics. For example, Semendeferi and colleagues suggest, based on imaging data, that there is no relative difference in the size of the frontal lobe in humans and great apes (Semendeferi *et al.*, 2002). However, more extensive studies in which gPFC was identified and quantified reveal differences in both the absolute size of gPFC in different primate species and its size relative to the frontal lobe. In addition, contrary to the claims of the above authors,

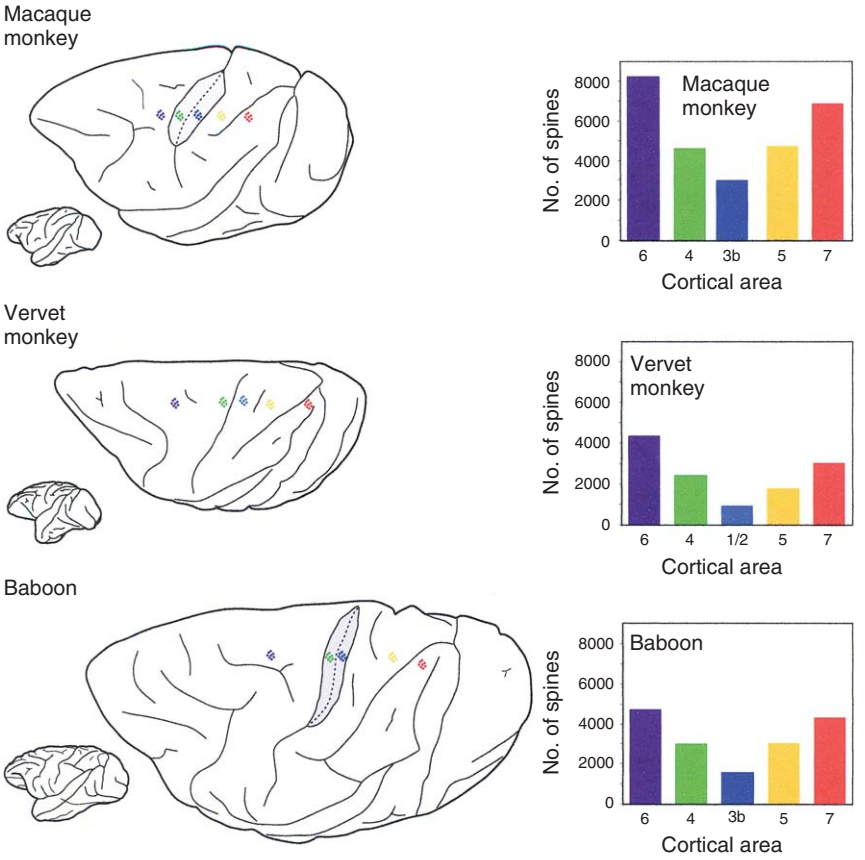

Figure 25 Schematic illustrating the location from which neurons were sampled (colored dots) in the sensorimotor cortex of the left hemisphere of the macaque monkey, vervet monkey, and baboon, and the corresponding bar graphs of the estimates of the total number of spines in the basal dendritic trees of layer III pyramidal cells in these areas. Note the consistent trend toward more spinous cells with anterior progression from the primary motor area (area 4) to premotor cortex (area 6) in all three species. Note also the consistent trend for progressively more spinous cells with posterior progression through somatosensory areas from the central sulcus to the angular gyrus. As seen from the graphs, the estimate of the number of dendritic spines (putative excitatory inputs) was higher for cells in the macaque monkey than in either the baboon or vervet monkey (across all cortical areas studied). These differences are probably due to the different body-part representations that were sampled in the different species: those in the macaque monkey were likely to have been sampled in the forelimb/hand representation whereas those in the other species were likely to have been sampled in the trunk/hindlimb representations (see Elston *et al.*, 2005g, for a discussion). Schematics of the different brains are not drawn to scale. Data taken from Elston and Rockland (2002) and Elston *et al.* (2005d, 2005g).

gPFC has been identified and quantified in the brains of different great apes: gPFC occupies 52.7% of the frontal lobe in the chimpanzee and 83.2% in humans (corresponding to 11.3% and 29% of the total cerebral surface area, respectively; Brodmann, 1913). Schoenemann *et al.* (2000) have argued that in humans there is no correlation between the size of the brain and cognitive abilities in different individuals of the same family.

Studies of pyramidal cell structure in the gPFC of different primate species are beginning to provide new insights into how microcircuitry in this region has evolved in different species, and how it may vary within a species (Elston *et al.*, 2006a). While there is still the greatest confusion and controversy regarding the number and locations of prefrontal cortical areas in different species, and any potential homology between these areas, the study of neuronal structure in corresponding cortical regions of different species (Figure 28) is beginning to reveal some common trends between species, as well as some interesting differences (see Do All Mammals Have a Prefrontal Cortex?). In all three species in which pyramidal cell structure has been quantified across multiple cortical areas in the gPFC (Chacma baboon and macaque and vervet monkeys), marked regional variation in the branching of, and number of spines in, the basal dendritic trees was observed. Unlike in visual, somatosensory, motor, and cingulate cortex, regional differences in pyramidal cell structure between cortical areas within the gPFC varied between cases 'for each species'. For example, the consistency in the trends for progressively more branched, spinous neurons through a selection of

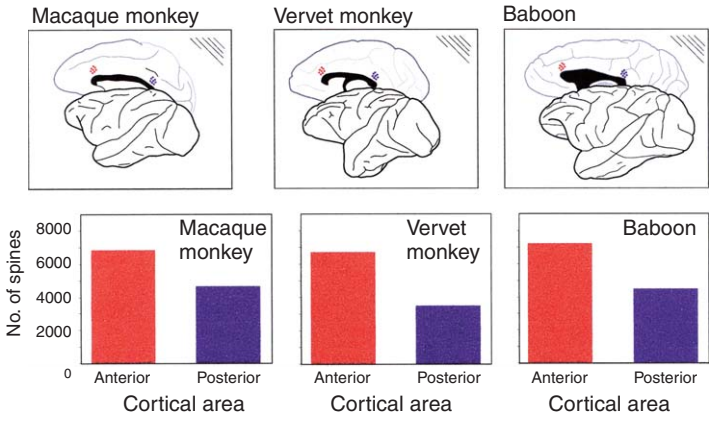

Figure 26 Schematics illustrating regions of cingulate gyrus from which neurons were sampled (colored dots) in the macaque monkey, vervet monkey, and baboon, and bar graphs of the estimates of the number of spines in the basal dendritic trees of pyramidal cells located in these areas. In all three species, cells were injected in the caudal region of the cingulate gyrus, dorsal to the splenium and in the rostral cingulate gyrus, caudal to the genu (Brodmann's areas 23 and 24, respectively). In all three species there was a consistent trend toward more spinous pyramidal cells in the anterior cingulate gyrus than in the posterior cingulate gyrus. Cells in the anterior cingulate gyrus of the baboon were slightly more spinous than those in the corresponding region in the macaque monkey, which, in turn, were more spinous than those in the vervet monkey. Schematics of the different brains not drawn to scale. Data taken from Elston *et al.* (2005a, 2005c, 2005f).

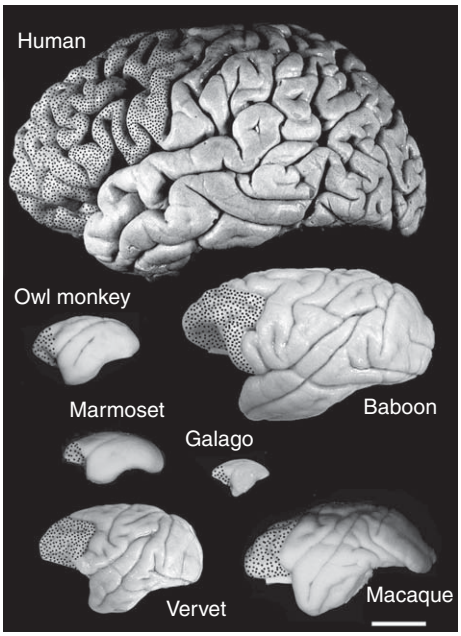

Figure 27 Photomicrographs of the lateral aspect of the left cerebral hemisphere of the human, baboon, macaque monkey, vervet monkey, owl monkey, marmoset monkey, and the galago illustrating the relative differences in the extent of gPFC (stipple). According to Brodmann (1913), gPFC occupies 29% of the total cortex in human, considerably more than in the baboon (10.3%), macaque (11.3%), guenon or vervet monkey (9.2%), and marmoset (8.9%). While Brodmann did not include the galago and owl monkey in his studies, data published by others (Preuss and Goldman-Rakic, 1991c; Preuss *et al.*, 1996) indicate that the galago has the smallest gPFC of all species included here; that of the owl monkey is intermediate between the marmoset monkey and the vervet monkey. Scale bar: 2 cm.

cortical areas (e.g., V1, V2, V4, and TEO in visual cortex, areas 3b, 5, and 7 in somatosensory cortex, or areas 23 and 24 in cingulate cortex) were not always observed in the gPFC. Nonetheless, despite this inter-individual variation, cells in gPFC were characterized by a relatively complex structure (i.e., the gPFC contained among the most complex of all cells studied in the cerebral cortex, but their location differed between species and between individuals).

These data suggest that the functional characteristics of neurons, and the computational abilities of the circuits they form, differ between the medial, orbital, and dorsolateral gPFC within a given species. In addition, the comparative data suggest that corresponding regions of the gPFC across species are characterized by different functional abilities. In the following section, regional and species differences in the pyramidal cell phenotype are related to cortical volume/surface area.

4.13.4 Specialization of the Pyramidal Cell during Cortical Evolution

We have already seen how pyramidal cell structure may vary considerably in corresponding, if not homologous, cortical areas in different primate species. However, we have not yet compared these data with the size of the different cortical areas, which are known to differ between the various primate species (Figures 29 and 30). This is clearly the next logical step in establishing any trends for specialization of

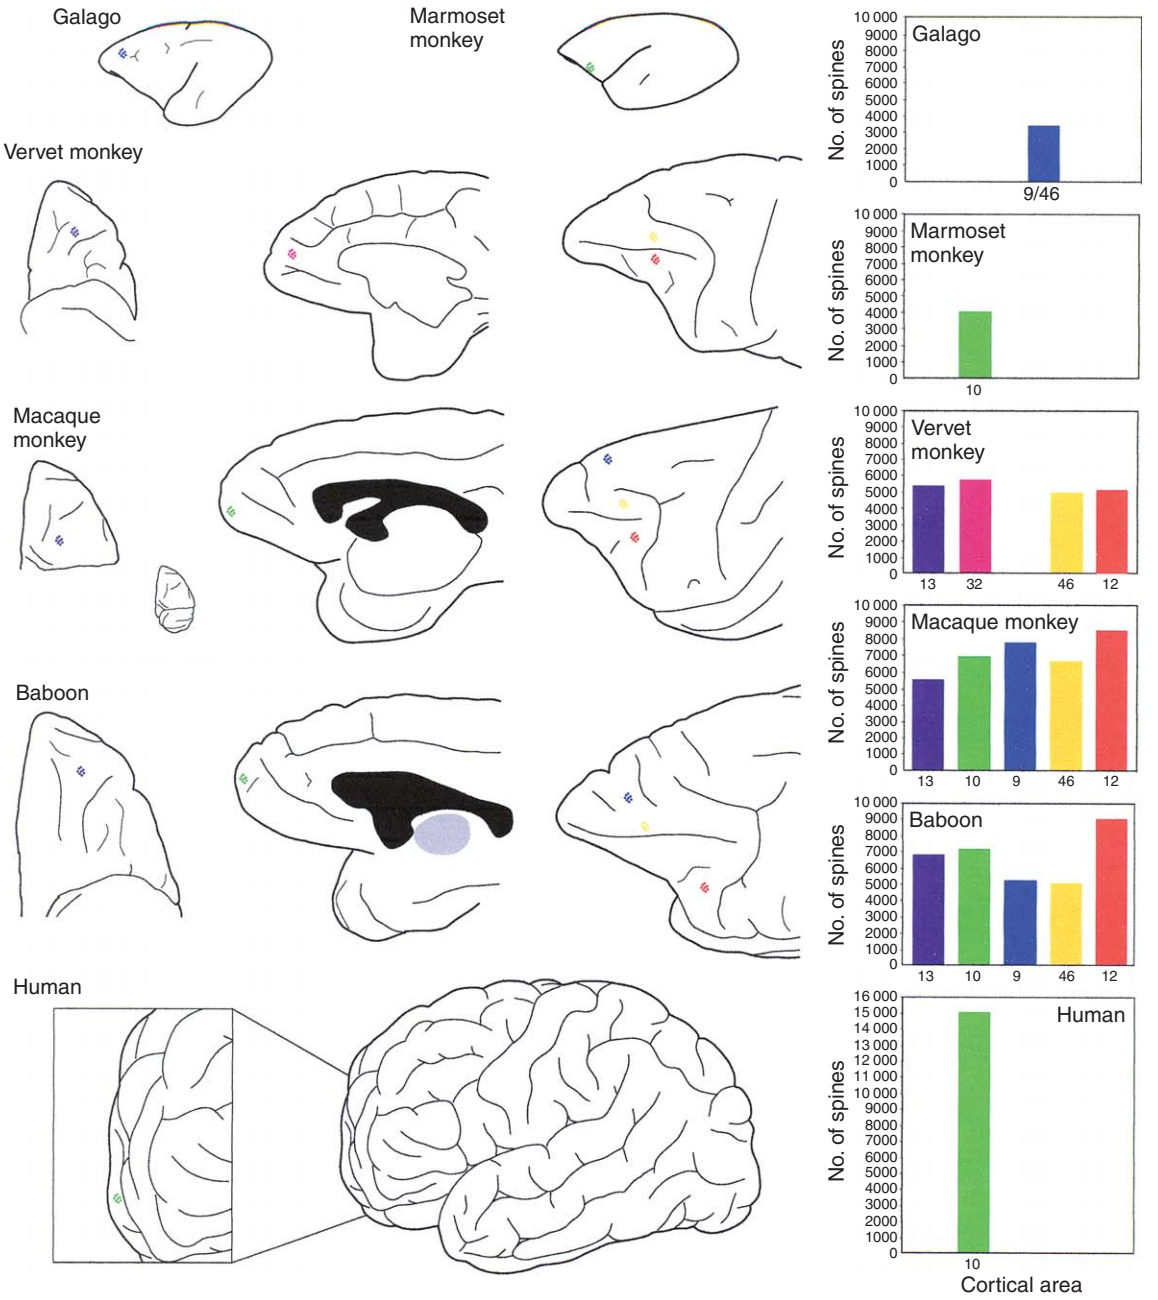

Figure 28 Schematic illustrating the location from which neurons were sampled (colored dots) in the gPFC of the left hemisphere of the marmoset, macaque and vervet monkeys, as well as the galago and the baboon. Despite the greatest of confusion with regard to the number, location, and homology of cortical areas in the gPFC in primates, we have attempted to inject cells in specific cortical regions to allow meaningful comparisons across species. While we have been unable to inject cells in the same cortical regions in all species, we have sampled large numbers of cells in gPFC of at least three species (macaque monkey, vervet monkey, and the baboon). These data are compared with those sampled from the galago and the marmoset monkey. Cells were injected in the dorsolateral, orbital, and medial prefrontal cortex in the macaque monkey, vervet monkey, and the baboon. They were sampled from the dorsolateral gPFC in the galago, and orbital gPFC in the marmoset monkey. Cells injected in corresponding regions are color coded. Bar graphs of the estimates of the total number of spines in the basal dendritic trees of layer III pyramidal cells in gPFC of these different species are illustrated on the left. While the picture is by no means complete, several trends can be gleaned from these data. Note, in particular, the lack of consistency in the trends reported here, as compared with those in visual, somatosensory, motor, and cingulate cortex. Also note the relative species differences for particular cortical areas, for example, areas 12 and 46 in the macaque monkey, vervet monkey, and baboon. Data taken from Elston *et al.* (2001, 2005i, 2006a, unpublished observations).

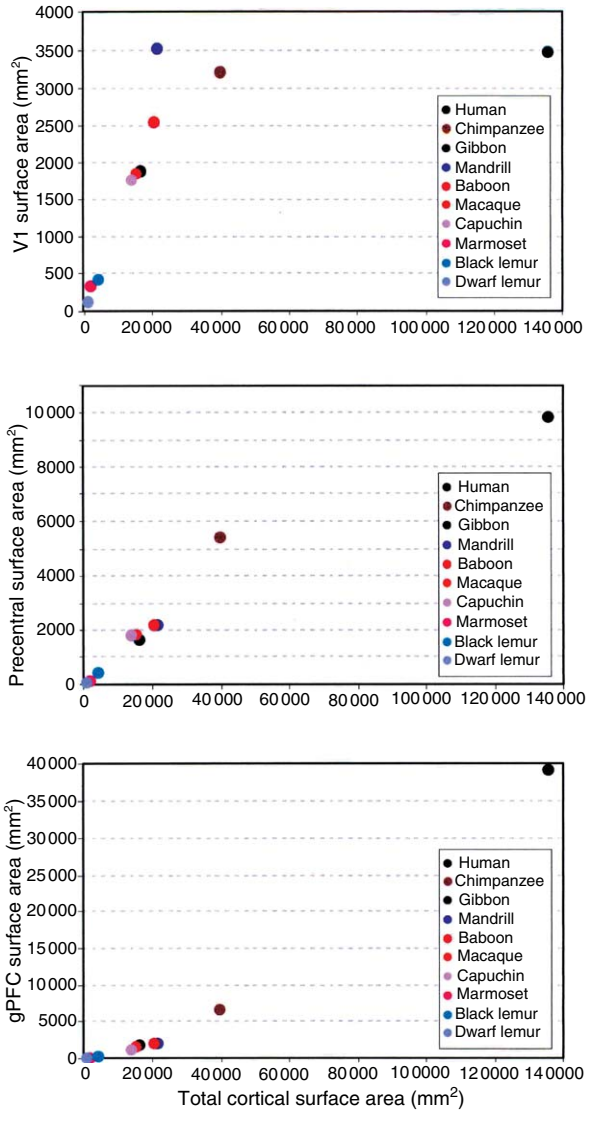

Figure 29 Plots of Brodmann's (1913) data on the cortical surface area of the primary visual area (V1), motor cortex (precentral agranular cortex), and the gPFC in the human, chimpanzee, gibbon, mandrill, baboon, macaque monkey, capuchin monkey, marmoset monkey, black lemur, and dwarf lemur. Note the relative differences in the cortical surface area of V1, precentral (motor), and gPFC in the different species, particularly in the nonhuman species. Note also that V1, precentral (motor) cortex, and gPFC are disproportionately large in the human.

the pyramidal cell phenotype associated with the volumetric increase in the cortical mantle during the evolution of the cerebral cortex. This is of particular importance as it might provide insights into the evolution of specialized cortical functions in different species.

At least three principles may act in concert to determine the pyramidal cell phenotype (and regional specializations thereof) in the mammalian cerebral cortex: laws of form, phylogenetic constraints, and species adaptations (see Gould, 2002; Manger, 2005b for reviews). It remains to be determined how each of these principles influences the pyramidal cell phenotype and to what extent they may interact in different mammalian orders. If we restrict the scope of this discussion to primates, interspecies differences in pyramidal cell structure may parallel the relative degree of expansion of particular cortical areas, lobes, the cortical mantle, or the entire brain. Alternatively, patterns of connectivity may dictate pyramidal cell structure, irrespective of volumetric differences in brain size. Both of these possibilities relate to laws of form (see also Section 4.13.4). Another possibility is that variation in pyramidal cell structure may reflect species-specific specializations that occur irrespective of size and patterns of connectivity. Any or all of these possibilities may vary between different mammalian orders. Indeed, preliminary findings in rats and mice suggest that trends observed in primates are not necessarily observed in rodents (e.g., Benavides-Piccione *et al.*, 2006; Ballesteros-Yáñez *et al.*, 2006).

We are now exploring these issues systematically among rodent species (e.g., Elston *et al.*, 2006b). Establishing which of these possibilities has occurred is essential if we are to better understand how phylogeny may predetermine specialized cortical function. Importantly, regional and species differences in pyramidal cell structure contradict one of the central assumptions of the prevailing dogma related to brain size and intelligence: the bigger the brain the more intelligent the species/individual (cf. Jerison, 1973). Clearly, any such relationship between brain size and functional ability fails if the different brains are composed of circuits with different functional capabilities.

In a bid to study the brain size/pyramidal cell phenotype issue further, it is necessary to study pyramidal cell structure in homologous cortical areas of multiple species with different-sized brains. We immediately run into a problem; that is, with the exception of the primary sensory areas and the primary motor area, there is little agreement in the literature regarding the homology of different cortical areas – particularly when comparing among mammalian orders. This is not an inconsequential problem, nor is it an insurmountable problem. One solution immediately presents itself – study all cortical areas at least in a handful of species. This, perhaps, is not as ridiculous a suggestion as it may seem. A team of investigators numbering less than usually observed in a molecular biology laboratory could sample $>10\,000$ cells in the space of a few days from a single brain, at 50 or so cells per cortical area, which is a lot of cortical areas, enough to more than satisfy even the most complex human brain

maps thus far presented. For the present, I, and more recently with the help of Ruth Benavides-Piccione, have been sampling as many cells as possible in the cerebral cortex of a selection of primate species. Although the data are by no means complete, we have sampled sufficient numbers of cells to make some cross-species comparisons.

Here we focus on data obtained from V1, V2, and gPFC of the human, baboon, macaque monkey, vervet monkey, owl monkey, marmoset monkey, and galago (Figure 31). We focused on these areas because there is widespread agreement about the size and location of V1 and V2 in these primate species. Moreover, Brodmann (1913) published a monograph in which he included quantitative data on the size of the gPFC of these species. While the means by which Brodmann determined the size of these cortical regions probably lead to inaccuracies, any sources of error are likely to be standardized across the species he investigated. Thus, while the absolute sizes of these different cortical regions as reported by Brodmann may be erroneous, the relative difference in their sizes should be reasonably accurate – arguably more accurate than that obtained by drawing data from multiple laboratories using different methodologies.

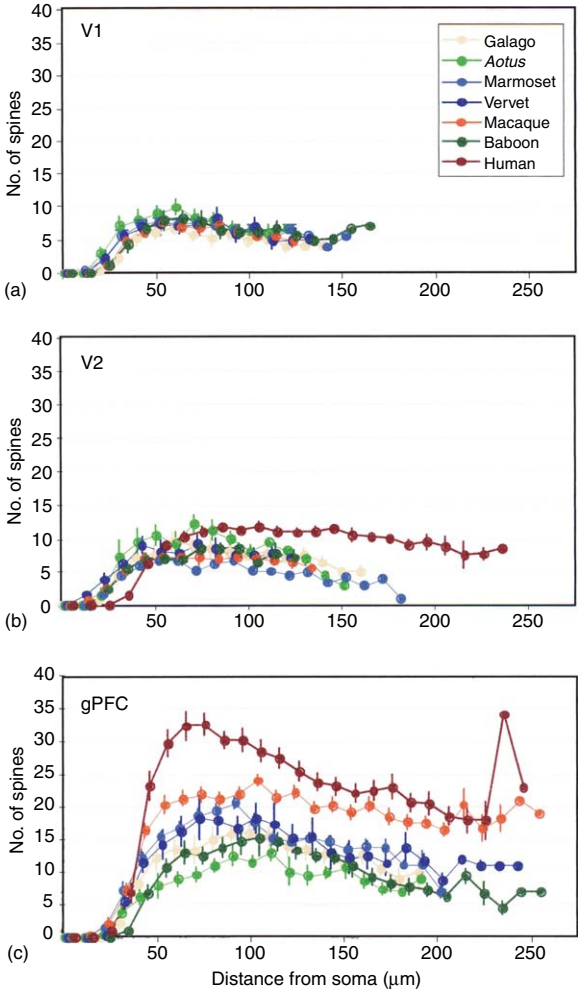

Figure 30 Plots of the spine density along randomly selected dendrites in the basal dendritic trees, as a function of distance from the cell body, of layer III pyramidal cells sampled in (a), the primary visual area (V1); (b), the second visual area (V2); and (c), the gPFC in the human, baboon, macaque monkey, vervet monkey, marmoset monkey, owl monkey (*Aotus*), and galago. Note the differences in the profiles in the different cortical regions. Spine densities along the basal dendrites of pyramidal cells in V1 and V2 are tightly grouped, with those in V2 being, on average, higher than those in V1. In gPFC, however, there are impressive differences among the species. Data taken from Elston *et al.* (2001, 2005c, 2005d, 2005e, 2005i).

Comparison of the size of the basal dendritic trees of pyramidal cells with the cortical surface area occupied by areas V1, V2, and gPFC reveals a trend for larger cells with absolute increase in the size of the cortex (Figure 31a). Based on these data, it might be tempting to conclude that dendritic tree size scales with the absolute size of the cortical area. However, notably, the data also reveal that dendritic trees in a given cortical area, such as V1 or V2, may be larger in a species in which this cortical area occupies a smaller absolute size than another species. Moreover, the size of the dendritic trees of pyramidal cells in the human gPFC does not reflect the dramatic difference in the absolute size of this region (note the difference of two orders of magnitude in the absolute size of human gPFC). To further explore this issue, we compared our estimates of the total number of spines in the basal dendritic tree of the 'average' neuron in each cortical area with the absolute size of the cortical area. As each dendritic spine represents one putative excitatory input, different trends observed in such a plot would suggest different degrees of connectivity among populations of pyramidal cells. Indeed, these plots reveal marked differences in the relationship number of putative excitatory inputs received by pyramidal cells and the absolute size of the cortical area between visual cortex and gPFC (Figure 31b). Of particular note, the slope of the linear regression for the gPFC data is considerably steeper than that for either V1 or V2. Not only do these data suggest that pyramidal cells in these different regions sample different numbers of excitatory inputs, but the rate of spine acquisition during the evolutionary expansion of gPFC far exceeds that in visual cortex. To test whether this effect could be attributed to the increasing size of the dendritic trees of the neurons, the total number of spines in the dendritic tree was plotted against tree size (Figure 31c). These plots reveal progressive increase in the slopes of the linear regression lines from V1 to V2 to gPFC. In addition, there is an extraordinary amount of variance in the gPFC data,

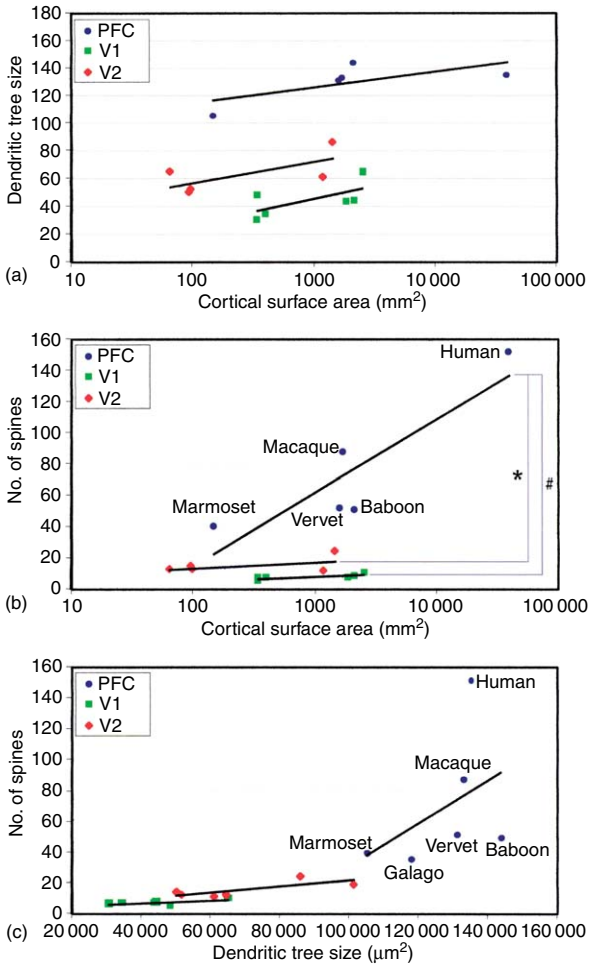

Figure 31 Plots of (a), the size; and (b), the number of spines in the basal dendritic trees of pyramidal cells in the gPFC, primary (V1), and second (V2) visual areas versus the surface area of each cortical area. c, Plot of the number of spines versus the size of the basal dendritic trees of pyramidal cells in the gPFC, V1, and V2. Moderated multiple regression revealed a significant difference between the slopes of regression lines of gPFC and V2 for comparisons between total number of spines in the dendritic trees of pyramidal cells versus cortical surface area ($F_{change}(1,6) = 6.19$, $p < 0.05$). Significance was approached for the comparison between the total number of spines in the dendritic trees of pyramidal cells versus cortical surface area for gPFC and V1 ($F_{change}(1,7) = 5.20$, $p < 0.057$). Data taken from Elston *et al.* (1999a, 1999b, 2001, 2005b, 2005e, 2005i, 2005j, 2006a) and Elston (2003c, 2003d).

which is not present in either V1 or V2 (see also Table 3).

Although only restricted to three cortical areas/regions, these data reveal that the extent to which different aspects of pyramidal cell structure (size, branching pattern, and number of spines) vary in different species depends on the cortical region studied. Note that the trend observed for gPFC differs from that for V1 and V2 for plots of the total number of spines in their dendritic trees and either the size of their basal dendritic trees or the size of the cortical area (Figures 31b and 31c). It has been suggested that these relative differences in pyramidal cell structure in the gPFC of different species endow the neurons, and the circuits they comprise, with different functional capabilities (i.e., compartmentalization within their dendritic trees, the number and diversity of inputs sampled, the potential for recurrent connectivity, and differences in memory storage capacity). Moreover, it has been suggested that species differences in executive functions of the gPFC such as conceptualizing, planning, and prioritizing result from differences in the pyramidal cell phenotype (Elston *et al.*, 2006a; see also Cajal, 1894a).

4.13.5 How Complex Can Pyramidal Cells Become?

Based on these data, one might conclude that pyramidal cells could evolve increasingly more complex branching structures as the cortex continues to expand. The obvious question, then, is how complex can pyramidal cell structure become? In theory, at least, the dendritic trees could contain so many branches that they almost form a solid sphere. However, considering principles of connectivity, this is unlikely. For example, if the dendrites became too densely packed, there would be a decrease in the amount of space available for axons to pass through the dendritic tree. Presumably, then there is an optimal space-filling characteristic for the dendritic tree to maximize both the number of inputs they can receive and the number of inputs that can pass in close proximity to form synapses (see Ringo, 1991 for a discussion).

In order to investigate the space-filling characteristics of the dendritic trees of pyramidal cells in different cortical areas/species, a systematic study of their fractal values has been initiated (Elston and Jelinek, 2001; Jelinek and Elston, 2001, 2003; Zietsch and Elston, 2005). Fractal analyses (Figure 32) allow the objective determination of the complexity, or space-filling capacity, of dendritic trees (see Jelinek *et al.*, 2005 for a review). The entire dendritic tree is defined by a single number, the fractal value, which can be correlated with other anatomical variables (e.g., the size of, or estimates of the asymmetry or the total number of spines in, the dendritic tree, or the size of the cortical area in which they are located). Fractal analyses were used to quantify the dendritic trees of pyramidal cells in V2, inferotemporal cortex (ITr or TE) and gPFC of human, baboon, macaque monkey, vervet monkey, owl monkey, marmoset monkey, and galago (Figure 33). These

BDFA, basal dendritic field area; CSA, cortical surface area; DF, fractal value; TNS, total number of spines in the basal dendritic tree. Reproduced from Elston, G. N., Benavides-Piccione, R., Elston, A., *et al.* 2006a. Specializations of the granular prefrontal cortex of primates: Implications for cognitive processing. *Anat. Rec.* 288A, 26–35, with permission from John Wiley & Sons, Inc.

plots reveal several interesting features related to areal and species specializations in the branching pattern of these cells. First, there is a degree of heterogeneity in the branching structure of pyramidal cells in all three cortical regions. Second, space filling is greater for cells in IT than in V2 in all species except the baboon. Third, between-species variability in the space filling of the dendritic trees is most notable in gPFC. Fourth, in V2 and IT there is no systematic correlation between the space-filling capacity of the dendritic trees of pyramidal cells and volumetric differences in the cortical area in the cerebrum of the different species. Finally, in gPFC there is a systematic increase in the space-filling characteristics of the dendritic trees of pyramidal cells that parallels the increase in the absolute size of this region in different species. These data suggest that optimal space-filling characteristics of pyramidal cells may differ between cortical areas and possibly between species for a given cortical area. These findings were confirmed dramatically by comparing the fractal value of cells with the size of the cortical area in which they were located (Figure 34). The trend for increasing space filling during expansion of the cortical area, which was present in V1 and gPFC, was clearly not present in V2. Instead, cells in V2 appear to occupy a progressively smaller volume of the neuropil within their dendritic tree in species in which this cortical area occupies a progressively larger absolute size (Figure 34a). In addition, it is clear from Figure 34b that there has been a disproportionate increase in the number of spines contained within the dendritic trees of pyramidal cells in the gPFC as these neurons have become more branched.

Based on the data presented in Figures 33 and 34, it might be reasonable to conclude that pyramidal cells in the gPFC in Old World anthropoids (humans and macaques in particular) will become increasingly more branched if this region continues to expand. Replotting the data on the fractal dimensions of cells reported in Figure 33 reveals a trend for increasingly more complex branched structure with increasing size of the dendritic trees (Figure 35). However, the trends in the data plotted in Figure 35 suggest that pyramidal cells, particularly those in the gPFC of humans, are reaching an upper limit of branching complexity (i.e., the regression slope reaches a plateau somewhere between 1.5 and 1.6). What this means in terms of prefrontal function in future humans is obviously highly speculative. It could be argued, for example, that increasing branching complexity would result in increased connectivity and, thus, greater functional capabilities (see Section 4.13.2.2). Alternatively, it is possible that the space-filling relationship between axonal input and recipient dendritic trees in human gPFC has already reached stasis at an optimal point and increasing the branching (space filling) of dendritic trees could only occur by decreasing the volume of neuropil occupied by other processes (and/or cells), resulting in decreased functional complexity. What can be said with some degree of

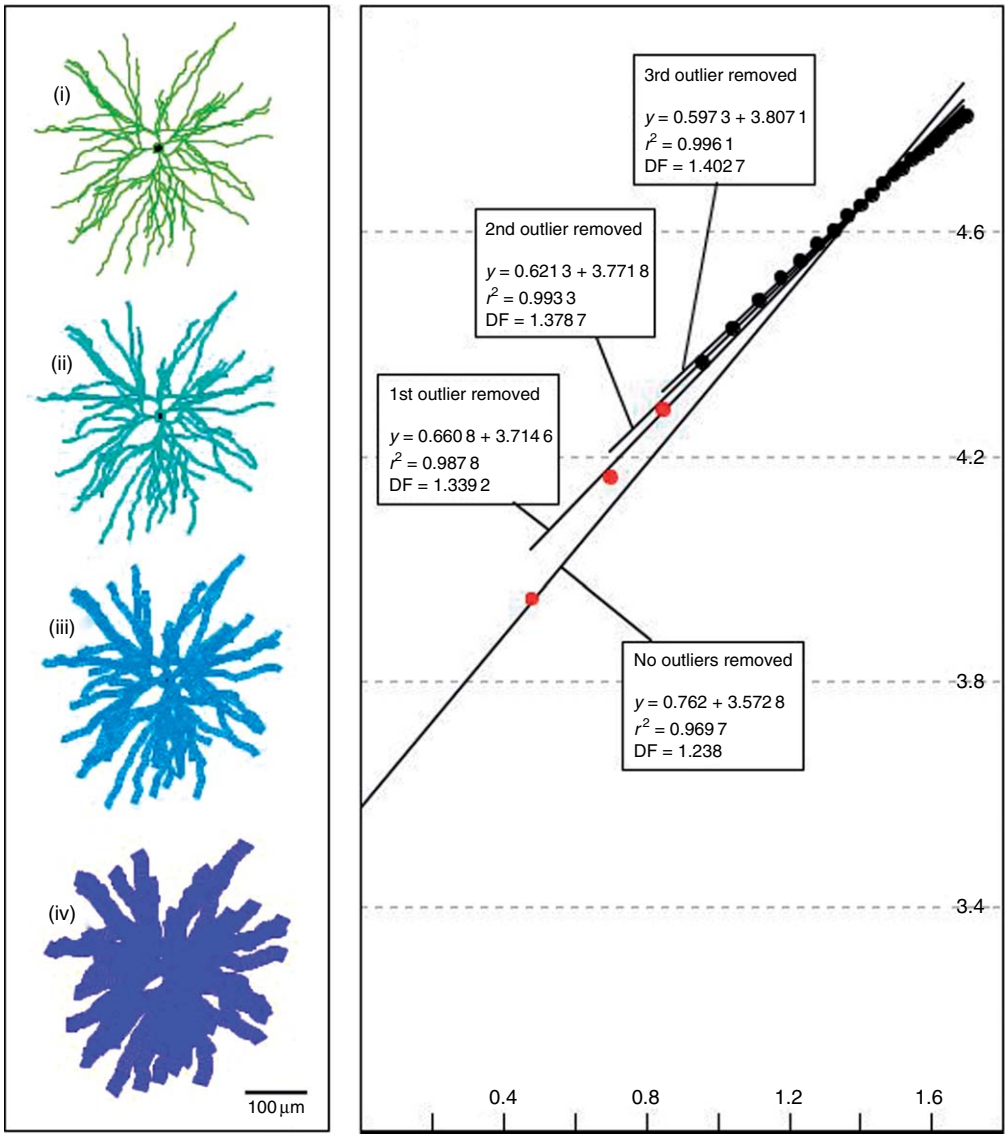

Figure 32 Schematic illustration of the methodology used in determining the fractal values (DFs) of the dendritic trees of pyramidal cells. Drawings of cells are digitized and the dendrites reduced to a thickness of one pixel (a(i)). Circles of increasing diameter are drawn over each pixel along the skeletonized dendrites (a(ii–iv)) and the percentage coverage within the dendritic tree calculated. The process is repeated 26 times and the data plotted (b). Outliers are then removed from the data set (colored dots) to reach a significance >0.95 and the fractal value calculated. Data taken from Elston, G. N. and Rosa, M. G. P. 1998b. Complex dendritic fields of pyramidal cells in the frontal eye field of the macaque monkey: Comparison with parietal areas 7a and LIP. *Neuroreport* 9, 127–131.

certainty is that differences in density and distribution of cells/neurites in the neuropil in different cortical areas/species makes it likely that optimal connectivity will be achieved by cells with dendritic trees characterized by different space-filling characteristics. Although untested, the data suggest that such an optimal connectivity is likely to vary appreciably between cortical areas. If true, this is a radical departure from present thinking on the ubiquity and uniformity of column structure in the cerebral cortex (see Mountcastle, 1997).

4.13.6 A New Model for Circuit Specialization during Cortical Evolution

The cerebral cortex differs in volume by more than 10 000-fold in extant mammals (see Stephan *et al.*, 1981; Hofman, 1985, 1988; Kaas, 1989; Krubitzer, 2000; Kaas and Collins, 2001; Northcutt, 2002 for reviews). These differences in volume do not adhere strictly to any cladistic variable, as dramatic differences in the volume of the cerebral cortex can be found within any given order or family, even between

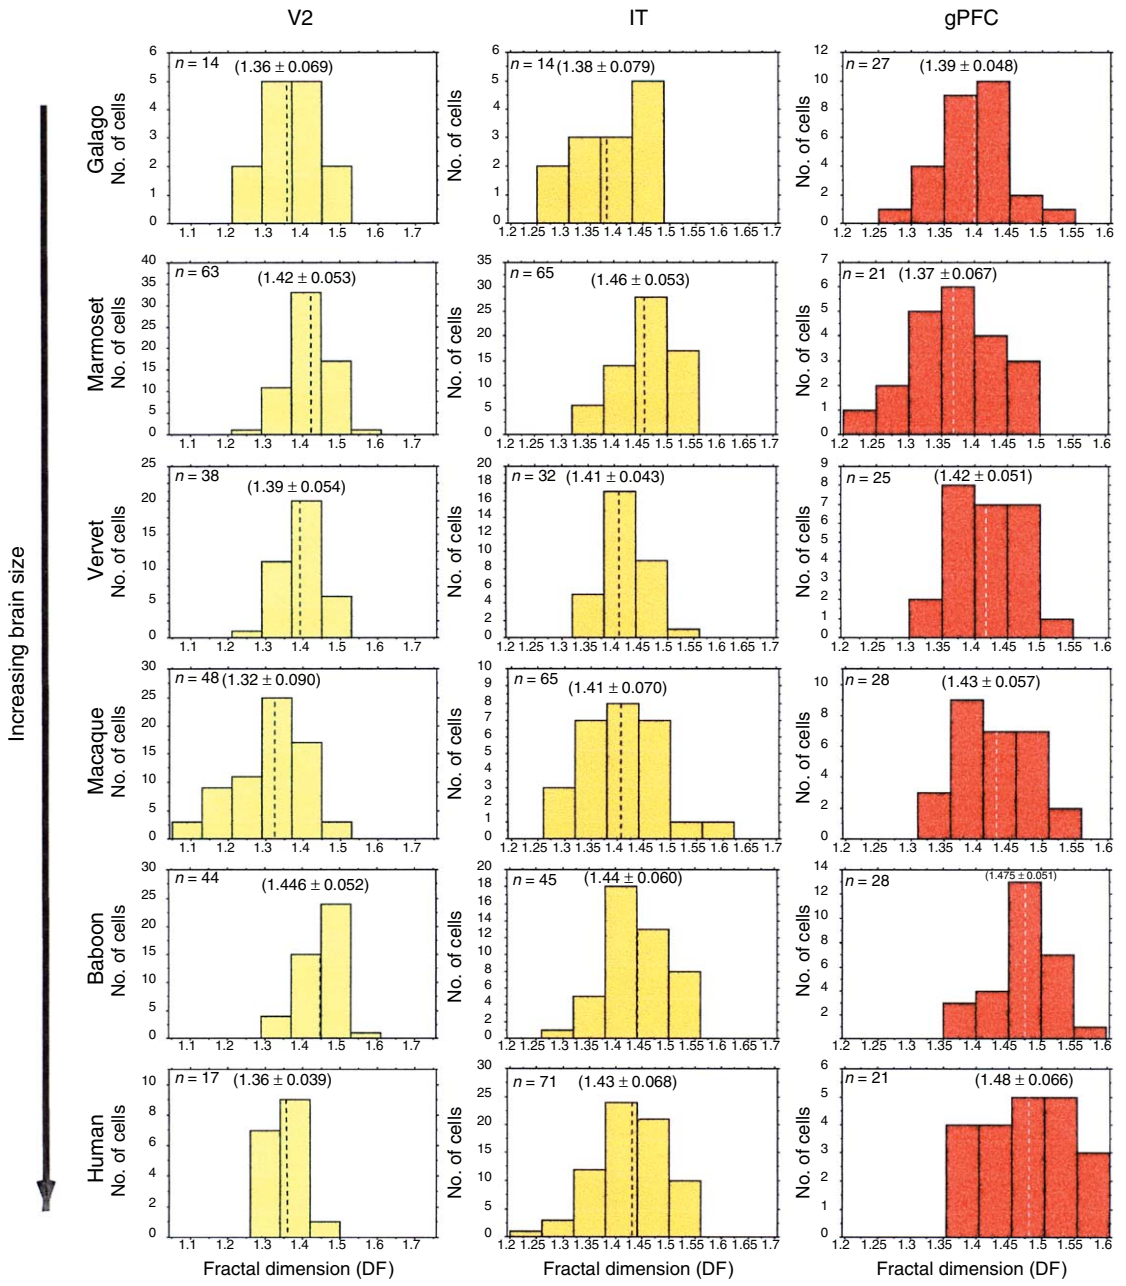

Figure 33 Frequency histograms of the fractal values (*DFs*) of the basal dendritic trees of layer III pyramidal cells in the second visual area (V2), inferotemporal cortex (IT), and granular prefrontal cortex (gPFC) of the marmoset monkey, galago, vervet monkey, macaque monkey, baboon, and human. Note there is no consistent change in the average *DF* (dashed line) with respect to brain size in either V2 or IT. There is, however, a trend for increasing *DF* (branching complexity) with increasing size of the gPFC. Mean ± SD illustrated in brackets. Modified from Elston, G. N. and Zietsch, B. 2005. Fractal analysis as a tool for studying specialization in neuronal circuitry: The study of the evolution of primate cerebral cortex and human intellect. *Adv. Compl. Syst.* 8, 217–227.

subspecies (e.g., pygmy marmoset and common marmoset, greater and lesser galagos). Notwithstanding this variability, comparisons of the brain volume of large numbers of individuals suggest that the cerebrum has expanded in some species, remained relatively constant in others, and possibly shrunk in yet other species. Narrowing the scope to primates, it is generally accepted that a common ancestor of extant primates had a relatively small cerebral cortex, which has become larger in different species. If you have read this far you may have already come to the realization that I do not believe that there is a common or unifying principle regarding specialization in pyramidal cell structure and brain size/cerebral volume.

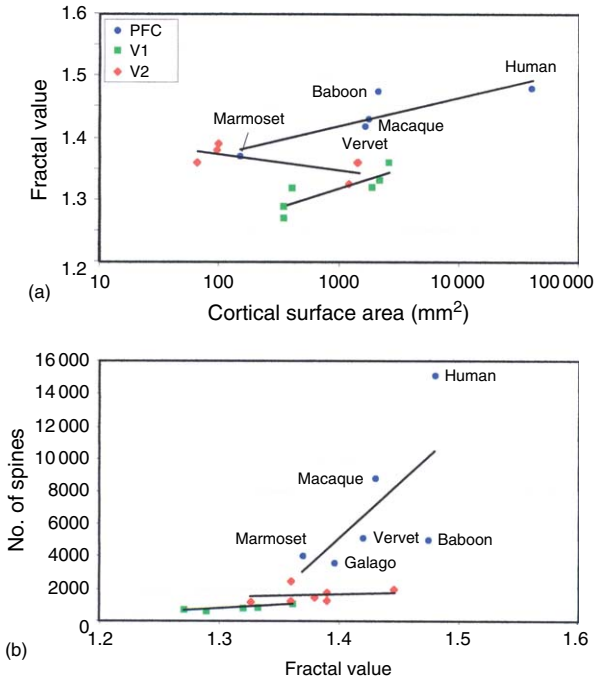

Figure 34 Plots of (a), the fractal value of the basal dendritic trees of pyramidal cells in the gPFC, primary (V1), and second (V2) visual areas versus the size of each cortical area; and (b), the number of spines versus the fractal value of the basal dendritic trees of pyramidal cells in gPFC, V1, and V2. Moderated multiple regression revealed a significant difference between the slopes of regression lines of gPFC and V2 for comparisons between the fractal values versus cortical surface area ($F_{change}(1,6) = 8.71$, $p < 0.05$). Note in (a) the negative slope generated by regression analysis, suggests that as V2 has undergone expansion in these species there has been a decrease in the space-filling capacity of the basal dendritic trees. Note also the radical increase in the number of spines in gPFC as cells have increased their space-filling capacity. Reproduced with permission from Elston, G. N. and Zietsch, B. Advances in Complex Systems, Vol. 8, Nos. 2–3, (2005) 217–227 © World Scientific Publishing Company.

Instead, the data on pyramidal cell structure suggest that evolutionary and developmental features that act in concert to shape the mature neuronal phenotype are likely to vary in different cortical regions and species. In the previous sections, the discussion was focused, in particular, on V1, V2, and gPFC, for which there are systematic and standardized data. Here we extend the discussion to include other regions of the cerebral cortex, and review data from the archontan tree shrew (a close relative of primates).

Based on data obtained from the occipital, parietal, temporal, and frontal lobes of primates, two different outcomes were proposed during evolutionary expansion of cortex: (1) expansion whereby mature cortex contains pyramidal neurons of similar structure or (2) expansion whereby mature cortex contains pyramidal neurons of increasingly complex structure (Elston *et al.*, 2005j). Evidence can be gleaned for both outcomes. For example, the total cortical volume occupied by V1 varies between primates, with as much as a fivefold difference reported between macaques and marmosets (Brodmann, 1913), yet layer III pyramidal cells have a remarkably similar number of spines in these species. Evidence for expansion of cortex by the addition of progressively more complex pyramidal cells comes from the temporal lobe: there is a consistent and dramatic increase in the number of spines in the dendritic trees of pyramidal cells as a function of absolute distance from the occipital pole (Figure 24). Comparison of the gPFC data in the galago, marmoset monkey, vervet monkey, macaque monkey, baboon, and human suggests a general trend for increasingly more spinous pyramidal cells as this region as a whole has undergone cortical expansion (Figure 36).

Quantification of pyramidal cell structure in the tree shrew (Elston *et al.*, 2005h) has revealed at least three other possibilities with respect to specialization in the pyramidal cell phenotype during the evolution of cortex: (1) an increase in complexity in the structure of pyramidal cells with little or no cortical expansion; (2) an increase in complexity in the structure of pyramidal cells during reduction in cortical size; and (3) a decrease in complexity in the structure of pyramidal cells during cortical expansion (Figure 37). These possibilities arise from the V1 data, but are not exclusive to striate cortex. In the first scenario, pyramidal cells in V1 have become more structurally complex even though the cortical area has undergone little or no expansion. In the second scenario, pyramidal cells in V1 have become more structurally complex and V1 has reduced in size. These outcomes would require that the structurally simple pyramidal cell phenotype in primate V1 is the apomorphic state while that seen in tree shrew V1 is a specialization. Such an interpretation requires that V1 in a common ancestor of tree shrews and monkeys was of a size similar to that in the tree shrew in the first scenario, or larger than that in the tree shrew in the second scenario. The third possibility is that the relatively complex pyramidal cell phenotype reported in tree shrew V1 could be the apormorphic state and that reported in primates a plesiomorph. That is to say, the less complex pyramidal cell structure is a specialization in primate V1. It remains unclear which of these scenarios may have occurred. On the one hand, it could be argued that relatively simple pyramidal cell phenotype is a primitive feature, as suggested by Cajal's observations in reptiles, amphibians, birds, and mammals (Cajal, 1894a, 1894b), and that observed in tree shrews is a plesiomorphy. On the

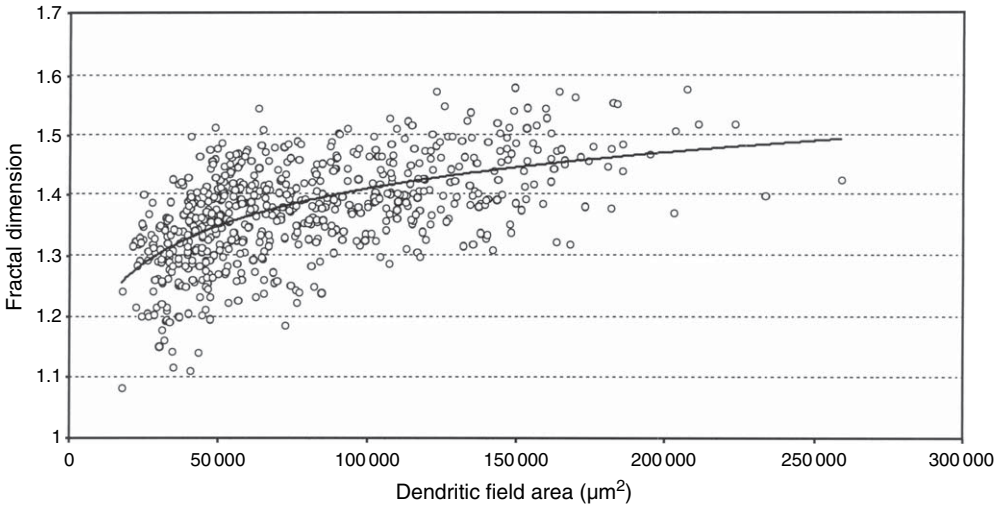

Figure 35 Plot of the fractal value (dilation method) versus the size of the dendritic tree of over 600 layer III pyramidal cells sampled from the primary, second, fourth, dorsolateral inferotemporal (caudal and rostral subdivisions), cytoarchitectonic areas TEO and TE, and gPFC of human, baboon, macaque monkey, vervet monkey, owl monkey, marmoset monkey, and galago. Note the lack of linear correspondence between the size and branching complexity of pyramidal cells. Instead, there is a plateau in the fractal value (branching complexity) of pyramidal cells with increasing size. The average fractal value of neurons varies between different cortical areas, suggesting that of their space-filling characteristics (and constraints) differ. We have proposed that the space filling of the dendritic trees of pyramidal cells is influenced during evolution, maturation, and adult experience, and varies according to the functional demands placed upon the cells. Data taken from Elston, G. N. and Zietsch, B. 2005. Fractal analysis as a tool for studying specialization in neuronal circuitry: The study of the evolution of primate cerebral cortex and human intellect. *Adv. Compl. Syst.* 8, 217–227.

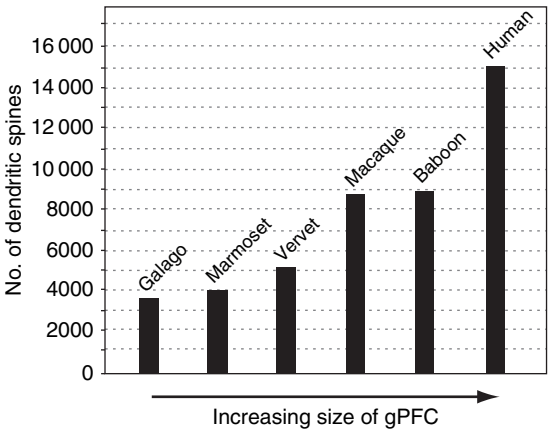

Figure 36 Estimates of the total number of spines in the basal dendritic tree of the 'average' pyramidal cell in gPFC in the young adult galago, marmoset monkey, vervet monkey, macaque monkey, Chacma baboon, and human. Note that there is a trend for a systematic increase in the total number of spines in the basal dendritic tree of pyramidal cells with increasing size of gPFC.

other hand, it could be argued that as Scandentia radiated prior to the emergence of the galago and New World and Old World monkeys, complex cell structure is likely to be a primitive feature. Clearly, further comparative studies are required, particularly if we are to determine whether any of these trends may be phylogenetically constrained.

4.13.7 A Note on Possible False Positives through Sampling Bias

It could be argued that interareal heterogeneity of cell structure reported in the cell injection studies could be attributed to us having sampled different subpopulations of pyramidal cells in the different cortical areas. For example, even within a given cortical layer, there may exist different populations of pyramidal cells of markedly different structure. Perhaps the best example of such intralaminar variation in pyramidal cell structure is that reported for cells that have different types of axonal projections. For example, pyramidal cells that form intrinsic projections have a notably different structure from those that make corticocortical projections, which in turn differ from those that send their axons to subcortical structures (Klein *et al.*, 1986; Schofield *et al.*, 1987; Hallman *et al.*, 1988; Hübener and Bolz, 1988; Hübener *et al.*, 1990; Vogt Weisenhorn *et al.*, 1995; Matsubara *et al.*, 1996). To address this issue, V1-projecting and MT-projecting neurons in different cortical areas of the marmoset monkey were specifically targeted for intracellular injection and their structures compared (Elston and Rosa, 2000, 2006). In particular, the fluorescent tracer Fluoro-emerald (FE) was injected into V1 or MT in different animals, and FE-labeled cells were then injected intracellularly with Lucifer

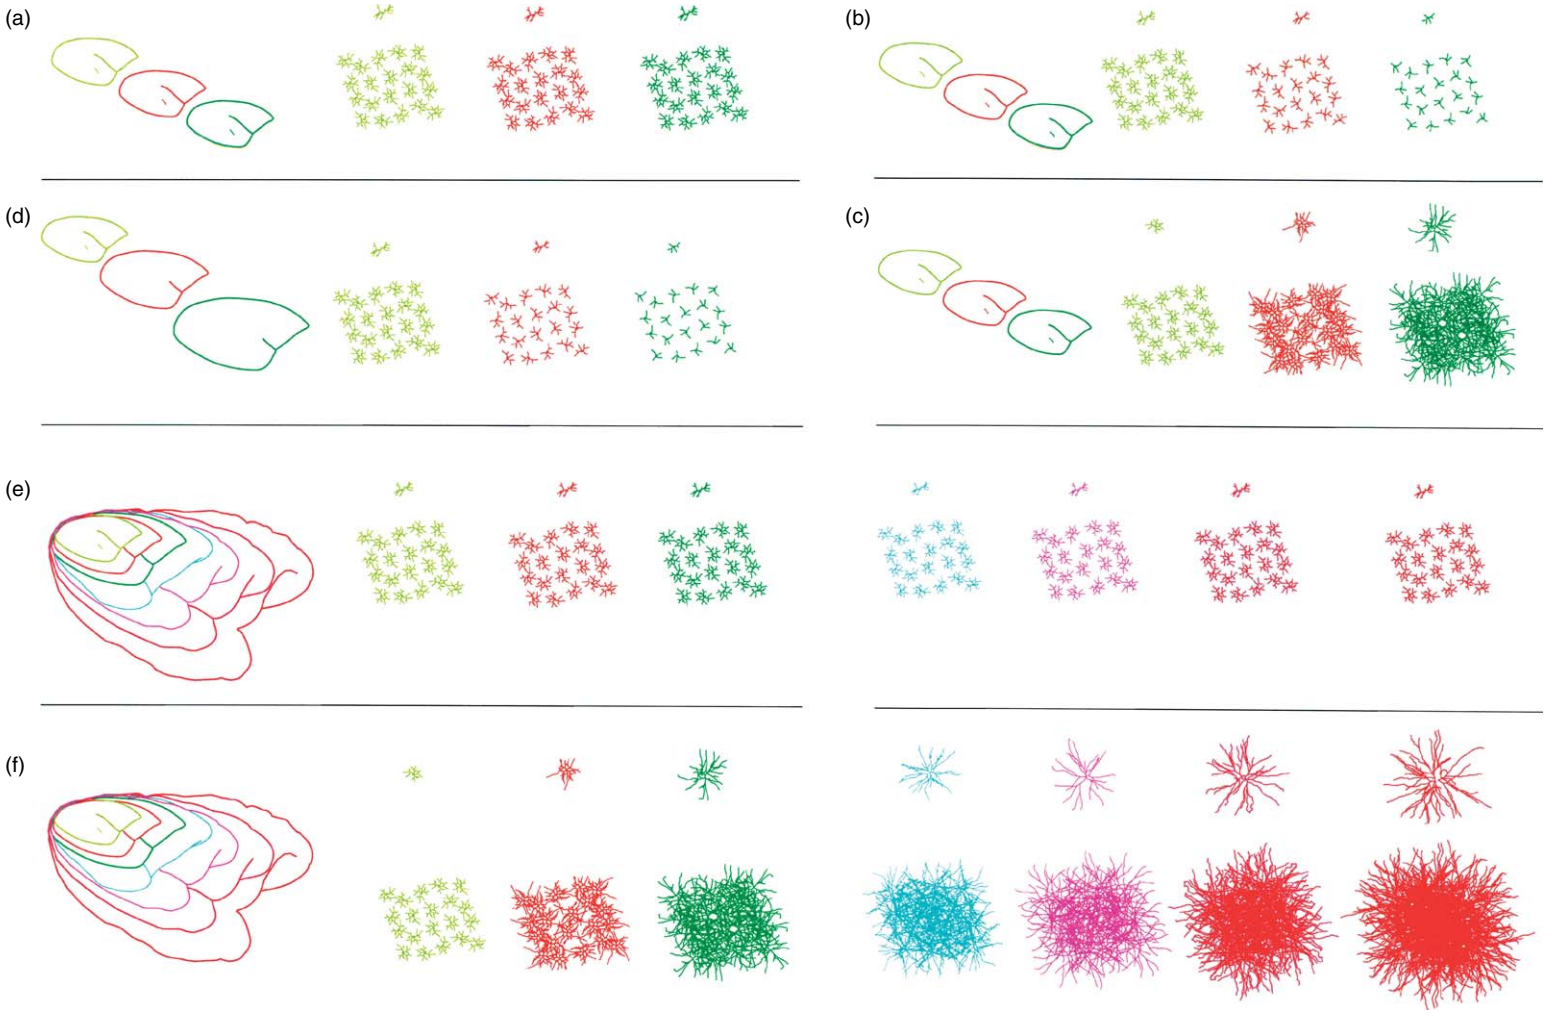

Figure 37 Schematic illustrating some possible specializations in pyramidal cell structure during the evolution of the cerebrum. In (a–c) there is no volumetric increase in the cerebrum but neurons either (a), retain the same structure; (b), become less complex; or (c), become more complex. In (d–f) the cerebrum has undergone a volumetric increase during its evolution and neurons either become less complex (d); retain the same structure (e); or become more complex (f). Note that pyramidal cell density is constant in all illustrated scenarios. Differences in dendritic coverage, especially visible in (f), are attributed solely to increasing size and branching complexity of the basal dendritic tree. Differences in cell density that may occur during the evolution of cortex result in three possible outcomes for each scenario illustrated here (increasing, decreasing, or constant neuron density).

Yellow. Thus, two distinct populations of neurons were studied, feed-forward and feedback, in multiple visual areas. In total, 242 feed-forward and 124 feedback cells from five animals were investigated (Figure 38).

We found that the morphology of both feed-forward and feedback extrastriate neurons varied systematically between cortical areas, paralleling previous findings for randomly labeled cells (Elston *et al.*, 1996, 1999b). For example, MT-projecting cells in V2 were smaller and less spinous than those in dorsolateral cortex (DL), which, in turn, were smaller and less spinous than those in IT. V1-projecting cells in V2 were smaller and less spinous than those in DL, which, in turn, were smaller and less spinous than those in IT (Figure 39). MT-projecting cells in V1 were the exception to the rule; however, these cells are located in a specialized sublamina in V1 (layer IIIC of Hassler, 1966) (Spatz, 1977; Tigges *et al.*, 1981; Diamond *et al.*, 1985; Shipp and Zeki, 1989; Elston and Rosa, 1997) not present in extrastriate cortical areas. In a similar series of experiments on the cat, Vercelli and Innocenti (1993) reported systematic variation in callosally projecting pyramidal cells in different visual areas. They concluded that the structure of pyramidal cells is determined by the cortical area in which they are located rather than the type of projections they

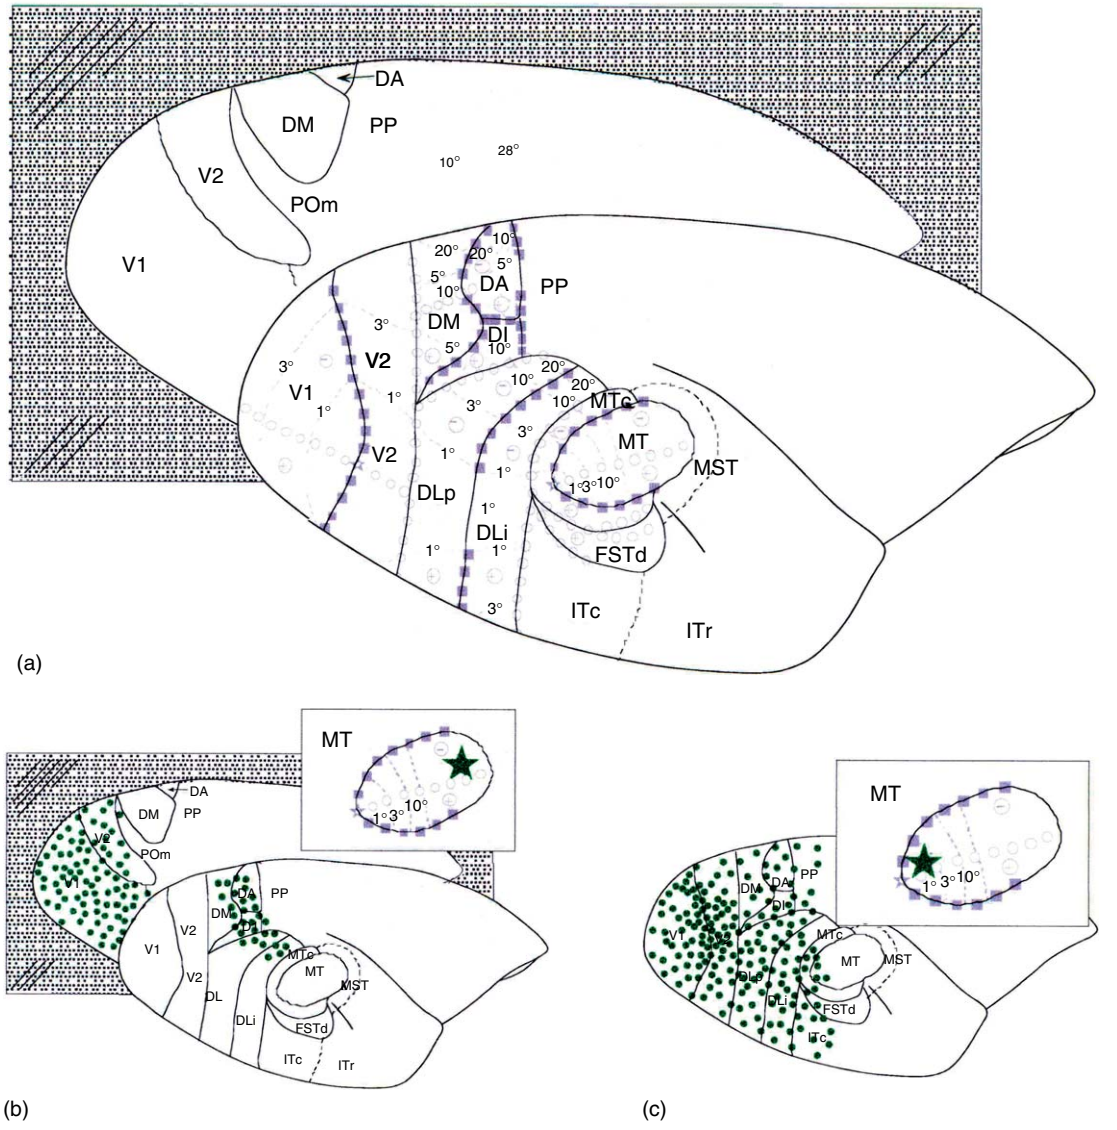

Figure 38 Schematics illustrating placement of injections (green star) of Fluoro-emerald into the area MT in two different cases. MT-projecting neurons (green dots) were labeled in the first (V1), second (V2), inferotermporal (IT) cortex, dorsolateral (DL), dorsomedial (DM), dorsointermediate (DI), dorsoanterior (DA), and the posterior parietal (PP) areas, as well as in the middle temporal crescent (MTc), the fundus of the superior temporal area (FST), and IT.

form. Thus, regional variation in pyramidal cell structure appears not to be attributed to sampling different subpopulations of these cells in different cortical areas, but rather reflects fundamental differences in cortical circuitry. This finding adds further support to the view that pyramidal cell structure in any given cortical area is specialized for its local functional requirements.

In addition, these experiments revealed that the size, branching complexity, spine density, and cell body size of cortical pyramidal cells is not necessarily correlated with the length of their axonal projection. More specifically, it was found that the cells making the longest feed-forward projection to area MT had the smallest, least branched, and least spinous dendritic trees, and the smallest cell bodies. Moreover, cells in V2, which made the second-longest projections, had only a slightly more complex structure than those in V1, but less complex structure than those in DL that projected a shorter distance (Figure 40). These findings challenge classic ideas regarding the relationship between cell body size and length of

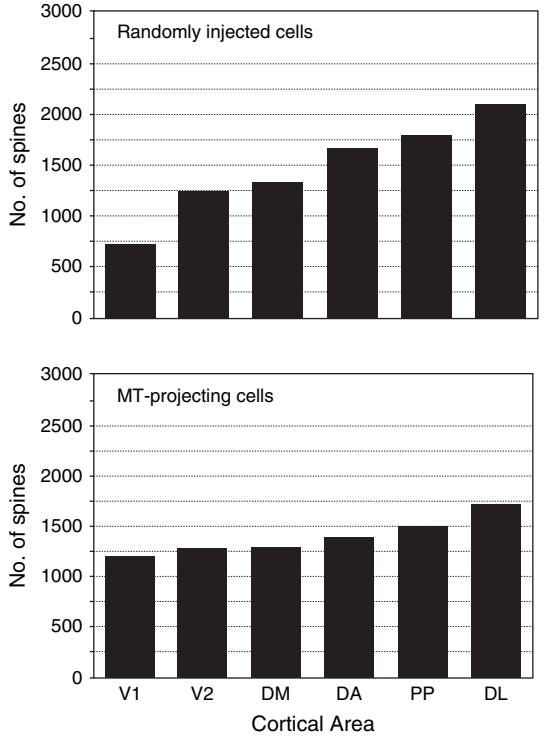

Figure 39 Plots of estimates of the total number of spines in the basal dendritic tree of the 'average' randomly injected (upper) and corticocortical projection (lower) layer III pyramidal cells in the primary, second, dorsomedial, dorsoanterior, posterior parietal, and dorsolateral visual areas (V1, V2, DM, DA, PP, and DL, respectively) in the marmoset monkey. Data for both randomly injected and corticocortical projecting cells were restricted to those in the central visual representations of the different cortical areas ($<5^\circ$ eccentricity). Note the trend for progressively more spinous cells through the same complement of cortical areas (note that visual areas are arranged in the same order along the *x*-axis in both graphs). Note also the difference in the V1 data: it has been well documented that the subpopulation of cells in V1 that project to MT are larger and more branched than non-MT-projecting cells in the same sublamina. The overall similarities in the estimates of the total number of spines in the basal dendritic trees of layer III pyramidal cells yielded by the different methods (random injection and retrogradely labeled cells), notwithstanding the difference in V1, is quite remarkable given that the calculations are influenced by the size and branching structure of the dendritic trees as well as the spine density along individual dendrites (see Elston, 2001). Differences in any one of these three variables can easily result in a doubling or tripling in the estimates of the total number of spines.

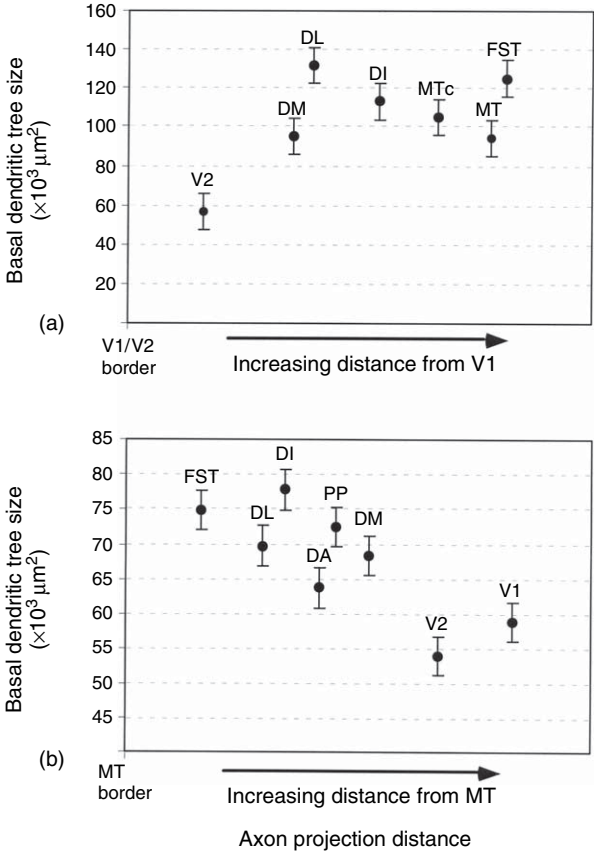

Figure 40 Plots of the estimates of the total number of spines in the basal dendritic tree of the average projection neuron in the first (V1), second (V2), third (V3), dorsolateral (DL), dorsomedial (DM), dorsointermediate (DI), and dorsoanterior (DA) areas, as well as in the middle temporal crescent (MTc), the fundus of the superior temporal area (FST), inferotemporal (IT) and the posterior parietal area (PP). Data are illustrated for the V1-projecting (a) and MT-projecting (b) cells, as a function of distance from projection site. Note that while it could be argued from the V1-feedback projecting data (a) that there is a rough correspondence between the size of the dendritic trees and the length of the axons they project, this is clearly not the case for MT-projecting cells. These data provide further evidence that regional differences in pyramidal cell structure are determined according to the functional requirements of the cells therein, over any other variable.

axonal projection, and dendritic tree size and length of axonal projection. For corticocortically projecting pyramidal cells, this appears not to be the case. Our unpublished data in the giraffe also reveal that these traditional theories related to cell body/dendritic tree size and length of axonal projection do not apply to neocortical pyramidal cells that form subcortical projections. For example, pyramidal cells in layer V of the primary motor area of the giraffe have a similar structure to those in layer III in its primary visual area (Elston, Elston, Badlangana, and Manger, unpublished observations).

4.13.8 The Paradox in the Frontal Lobe

Based on the data presented in visual cortex and somatosensory cortex, it may be tempting to assume that there is a correlation between complexity in pyramidal cell structure and a hierarchy in cortical pathways (see Section 4.13.2.2). However, data from the macaque monkey, the vervet monkey, and the baboon reveal that cells in area 4 (the primary motor area), which is generally considered to be the end of a cortical motor decision–execution pathway (Jones, 1986; Geyer *et al.*, 2000), are smaller and less branched than those in area 6. Moreover, cells in area 6 are less branched, and less spinous than those in dorsolateral gPFC, which are involved in purposive motor movements. Thus, in this proposed pathway, pyramidal cells become smaller, less branched, and less spinous with progression through successive levels involved in purposive motor movements (Figure 41). Of course, it could be argued that pyramidal cell structure reflects the functional complexity of neurons in these cortical areas (i.e., cells in gPFC are involved in the planning and initiation of purposive movements based on incoming sensory information and juxtaposing this with motivation and necessity to actuate a particular movement, whereas those in area 4 'merely' execute the movement).

One possible explanation can perhaps best be presented with an analogy from the physical world – nuclear power. We have seen how neurons in gPFC have a complex structure and, in dorsolateral gPFC, these cells are characterized by tonic discharge sustained over long periods of time. If these cells were to project directly out of the cerebral cortex to initiate motor movements, the muscles that they stimulate would likely be in a state of tonic spastic paralysis and would quickly fail. Even if these neurons were to project from gPFC to the efferent cells (area 4), they would be likely to cause tonic spastic paralysis, as cells in area 4 would be constantly stimulated. However,

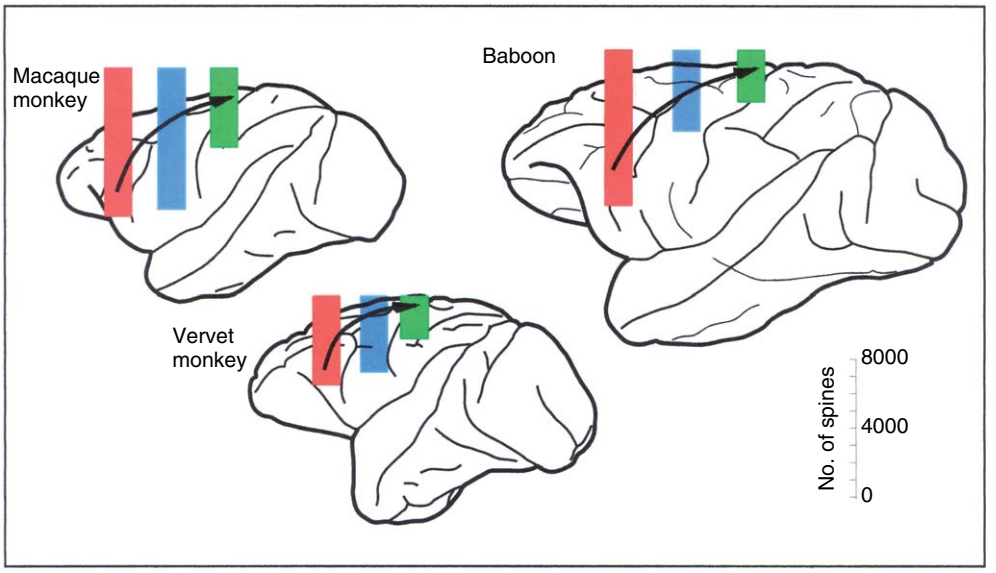

Figure 41 Schematic illustration highlighting phenotypic variation in the structure of pyramidal cells involved in voluntary motor movements in the vervet monkey, the macaque monkey, and the baboon. Cells in dorsolateral prefrontal cortex (area 12, red), which are involved in the initiation of purposive motor movements, are larger, more branched, and more spinous than those in premotor cortex (area 6, blue), which are larger, more branched, and more spinous than the effector cells in the primary motor area (area 4, green). Cortical areas included here represent only a few areas involved in purposive motor planning. In future studies, it will be worthwhile to quantify pyramidal cell structure in other cortical areas such as the supplementary motor area and motor areas on the medial wall.

if these highly active neurons in gPFC project through a series of cortical areas, each composed of cortical circuitry with less recurrent feedback and, thus, a decreased ability to sustain tonic activity, there may be more control over the efferent signals. In terms of the nuclear power analogy, cells in gPFC are like hot rods, while circuitry in the supplementary/premotor and the primary motor cortex act as progressively cooler water baths, reducing the self-sustaining activity to controllable levels before the activation of motor movement (efferent signal or output current). Differences in the threshold of neurons between motor areas (e.g., Wu *et al.*, 2000) provide evidence for their different 'energy states'. As pyramidal cells in gPFC have become more complex, as in the baboon and human, their patterns of connectivity have become more complex, resulting in more recurrent excitation and more powerful sustained activity – hence the expansion of motor cortex and the inclusion of more synaptic steps between area 4 and gPFC (i.e., premotor cortical areas) to modulate purposive motor movements. Clearly, more remains to be discovered regarding the implications of regional variation in cell structure and processing within cortical pathways involved in purposive motor movements, particularly in view of the results of studies that suggest distributed cortical processing (see Jones, 1986; Kaas, 1990; Paulesu, *et al.*, 1997; Calvert, 2001 for reviews).

4.13.9 Summary

Marked differences in pyramidal cell structure in different cortical areas of the primate cerebral cortex, and between corresponding cortical regions in different primate species, are likely to result from different evolutionary trends, development, and adult experience. Behavioral advantages endowed by specialization in pyramidal cell structure, by influencing the functional capacity of individual neurons and the computational power of the circuits they comprise, are likely to act as important selective pressures during the evolution of species. There is no unifying principle that determines phenotypic specialization in pyramidal cell structure in the primate cerebral cortex. Different evolutionary pressures appear to have resulted in different trends in the occipital, parietal, temporal, and frontal lobes among species.

Acknowledgments

Supported by grants from the Australian National Health and Medical Research Council and the McDonnell Foundation. Thanks go to Dr. Ruth Benavides-Piccione who has helped with the marathon 13-day, 24-hour-a-day experiments required to sample some of these data; to Alejandra Elston, Brendan Zietsch, Laura Ferris, Haidee Peréz, and Jeydi Perera who have helped reconstruct many of these cells and assisted with preparation of some of the figures; to Rowan Tweedale and Paul Manger for proofreading and to many colleagues who have generously provided tissue for these experiments and intellectual input. Dedicated to Prof. Jack Pettigrew, FRS, who has given me the support and complete freedom to follow my scientific endeavours during the past 15 years at the Vision, Touch and Hearing Research Centre.
