4.14 The Development and Evolutionary Expansion of the Cerebral Cortex in Primates

P Rakic, Yale University School of Medicine, New Haven, CT, USA
D R Kornack, University of Rochester Medical Center, Rochester, NY, USA

Glossary

anthropoid primates The group of primates that includes monkeys, apes, and humans.

bromo-deoxyuridine Also called BrdU; an analogue of thymidine, one of the four bases of DNA. When applied to dividing cells, BrdU is incorporated into newly replicating DNA during the S-phase of the cell cycle. Thus labeled, dividing cells and their progeny can be identified using immunohistochemical procedures. See 'tritiated thymidine'.

corticogenesis The process by which the cerebral cortex grows and develops.

cytoarchitectonic areas Regions of cerebral cortex distinguished by differences in the relative prominence of particular cellular layers or the size or packing density of the resident cells.

GABAergic neurons Neurons that synthesize and release GABA as a neurotransmitter.

ganglionic eminence A mound of dividing neural precursors situated on the floor of the lateral ventricles in the embryonic forebrain.

GFAP Glial fibrillary acidic protein; a cytoplasmic protein that can be used to identify radial glial cells in the developing primate brain.

gliogenesis The process by which new glial cells are generated from dividing cells.

gliophilic cells Migrating cells that preferentially use glial cells as a migratory substrate. Compare with 'neurophilic cells'.

gyrencephalic Characterized by the presence of convolutions. Compare with 'lissencephalic'.

isocortex The part of the cerebral cortex characterized by having six horizontal layers of neurons.

lissencephalic Characterized by the absence of convolutions, e.g., a relatively smooth cortex. Compare with 'gyrencephalic'.

local circuit neurons Neurons with relatively short axonal projections that predominantly use GABA as an inhibitory neurotransmitter.

neocortex The part of the cerebral cortex characterized by having six horizontal layers of neurons. The prefix 'neo' confers the idea that this was the part of the cerebral cortex to appear most recently during cortical evolution.

neurogenesis The process by which new neurons are generated from dividing neural precursor cells.

neurophilic cells Cells that migrate preferentially along other neurons and their axons, in particular. Compare with 'gliophilic cells'.

telencephalon The part of the embryonic brain that will develop into the cerebral cortex, striatum, and olfactory bulbs of the adult forebrain.

tritiated thymidine A radioactive form of thymidine, one of the four bases of DNA. When applied to dividing cells, tritiated thymidine is incorporated into newly replicating DNA during the S-phase of the cell cycle. Thus labeled, dividing cells and their progeny can be identified using autoradiographic procedures. See 'bromo-deoxyuridine'.

4.14.1 Introduction

The mechanisms underlying the evolutionary expansion of the cerebral cortex are central to our understanding of the potential and limits of our mental capacity. Since the time of its origin in a mammalian ancestor, perhaps 250 Mya, the neocortex has undergone expansion in both relative and absolute size independently in several mammalian radiations. This expansion is particularly apparent in anthropoid primates, including humans, in which the neocortex comprises up to 80% of the brain mass. The expansion occurs primarily in surface area rather than in thickness. Further, the neocortex is parcellated into different cytoarchitectonic areas, which have increased in number, size, and complexity during cortical evolution.

Our insights into the evolution of the neocortex have traditionally come from physical anthropology and comparative anatomy (e.g., Ariëns Kappers *et al.*, 1936; Herrick, 1948; Nauta and Karten, 1970; Armstrong and Falk, 1982; Kaas, 1988; Jerison, 1991; Preuss, 1993; Butler, 1994; Northcutt and Kaas, 1995). More recently, genetic, molecular, and cellular mechanisms by which the cerebral cortex might have evolved have begun to be scientifically explored (e.g., Simeone, 1998; Smith Fernandez *et al.*, 1998; Caroll, 2003; Pruess *et al.*, 2004). The present article is an attempt to interpret some of these recent advances in our understanding of cortical development within the context of neocortical evolution. Examining the embryonic development of living species for clues about possible mechanisms underlying evolution is a well-established approach in evolutionary biology (e.g., Haeckel, 1879; Gould, 1977; Gerhart and Kirschner, 1997; Richardson *et al.*, 1997; Striedter, 1997, 1998). Recent advances in developmental neurobiology provide new insights into possible genetic and cellular mechanisms at a level of analysis that was previously unattainable.

The most notable feature of the cerebral cortex in all species, particularly in primates, is its parcellation into distinct laminar, radial, and areal domains (Rakic and Singer, 1988; Mountcastle, 1997) (see The Role of Transient, Exuberant Axonal Structures in the Evolution of Cerebral Cortex, Cerebral Cortical Folding Patterns in Primates: Why They Vary and What They Signify). The neocortex consists of six basic cellular layers, each having distinct neuronal organization and connections: layers 5 and 6 contain neurons that project to subcortical structures, layer 4 contains local circuit neurons, and layers 2 and 3 are composed mostly of neurons that project to other cortical areas, both ipsilaterally and contralaterally. The neocortex is also organized into radial (vertical) groups of neurons that are linked synaptically in the vertical dimension and share common functional properties. This radial arrangement of cortical neurons is unquestionably a fundamental principle of cortical organization that reflects its unique developmental history (Rakic and Singer, 1988; Mountcastle, 1997). Furthermore, the neocortex is parcellated into structurally and functionally distinct cytoarchitectonic areas, which increased in number, size, and proportion during the evolution of bigger brains (Brodmann, 1909). Recent re-examination of cortical parcellation by modern hodological, cytochemical, and physiological methods indicates that the definition as well as the border assignments of areas in the cortex may be more complex than previously thought by Brodmann and others. Nonetheless the principle of functional localization remains the same (Felleman and Van Essen, 1991).

The origin and evolution of the cerebral cortex is among the most fundamental questions in biology. Answers to this question may in turn provide long-sought answers to the questions of who we are, where we come from, and where we might be going. This subject can be approached from the standpoint of (1) its origin from phylogenetically older structures, (2) the expansion of its size following its emergence, and (3) the parcellation and elaboration of the neocortex into functionally and structurally specialized domains, or cytoarchitectonic maps. We will interpret various aspects of cortical development within the context of cortical evolution. In particular, we will focus on those cellular events that most likely underwent evolutionary modifications to build a larger and more parcellated cortex.

4.14.2 Neocortical Origins

The origin of the neocortex in vertebrate evolution has been a focus of interest to evolutionary biologists for more than a century (Darwin, 1871). Although the neocortex is recognized as a neural structure unique to mammals, its possible evolutionary antecedents and its homologues in the brains of other vertebrates are still disputed (see reviews by Northcutt, 1981; Butler, 1994; Northcutt and Kaas, 1995; Karten, 1997; Striedter, 1997; Smith Fernandez *et al.*, 1998). Perhaps the most frequently stated hypothesis is that the mammalian neocortex developed as an enlargement of the reptilian dorsal pallium (e.g., Herrick, 1948; Northcutt, 1981). Another frequently mentioned concept, although no longer tenable, is that the neocortex is an elaboration of the olfactory system (Ariëns Kappers *et al.*, 1936). One attractive hypothesis, proposed

in the early 1970s, was based on the comparative anatomy of neuronal organization, and suggested that the neocortex may have originated from two sources of cells from lower parts of the neuraxis (Nauta and Karten, 1970; Karten, 1997). The basic idea is based on comparative anatomical studies that suggest that the lateral pallium, or general cortex, of amphibians, birds, and reptiles may be homologous to the six-layered mammalian neocortex (reviewed in Northcutt, 1981). The basic tenet of this dual origin hypothesis is that during evolution, the expansion of the lateral pallium was associated with displacement of the archicortex (hippocampal formation) and the paleocortex (piriform cortex) toward the medial wall of the telencephalon (Figure 1). Furthermore, it was suggested that the lateral pallium was simultaneously transformed from a simple neural structure into a more complex six-layered mammalian cortex.

It is not clear how the predecessors of the neurons that eventually form the neocortex arose during evolution. One possibility is that during evolution, the neuroblasts of the dorsal ventricular ridge (DVR) of ancient reptiles shifted into the lateral pallium and provided additional cells for the six-layered neocortex (Nauta and Karten, 1970). Not everyone is convinced that the DVR has a homologue in the mammalian telencephalon or that the isocortex originates in topographically different pallial compartments (e.g., Aboitiz, 1999). Nevertheless, according to Nauta and Karten's model, the mammalian neocortex is formed by contributions from two distinct populations of founder cells. Results from studies of chimeric mice give implicit support for the dual origin hypothesis, and in addition indicate that the two phylogenetically discrete populations remain segregated during ontogeny as the separate laminar and radial clones within the mammalian cerebral cortex (Kuan *et al.*, 1997). This example illustrates how experimental methods in developmental biology may provide new insights into evolutionary questions. As elaborated below, neuroembryology provides not only new evidence to evaluate existing hypotheses, but can also generate new ideas of how the cortex may have evolved. An instructive example is the radial unit hypothesis of cortical expansion (see below).

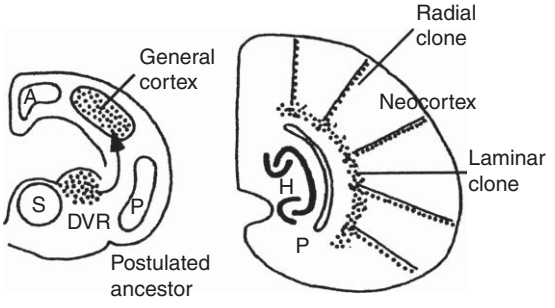

Figure 1 Comparative studies suggest that during evolution the general cortex of a mammalian ancestor expanded and propelled the archicortex (A; hippocampus, H) and the paleocortex (P; pyriform cortex, P) toward the medial wall of the telencephalon. It has also been postulated that neuroblasts of the dorsal ventricular ridge (DVR) located in the dorsal striatum (S) migrated and incorporated into the general cortex in ancestral mammals to result in the modern six-layered isocortex (Nauta and Karten, 1970). One possible explanation of the coexistence of radial and laminar clones in the mouse cerebral cortex is that these two phylogenetically distinct populations of cells remain ontogenetically segregated and are allocated differently. From Kuan *et al.* (1997), modified after Nauta and Karten (1970).

4.14.3 Key Events in Cortical Development

Because the embryonic development of living species can provide clues about possible mechanisms underlying its evolution, we will first briefly review major developmental events that lead to the formation of the cerebral cortex. We will describe primarily the timing and sequence of cellular events that occur in the macaque monkey, since the focus of this review is on cortical evolution in primates.

At the beginning of the second month of gestation in rhesus monkeys and humans, the process of differential cell proliferation causes the anterior-most end of the embryonic neural tube to balloon outward, forming a pair of telencephalic vesicles, which will become the future cerebral hemispheres (Sidman and Rakic, 1982). It is within the dorsal walls of these vesicles that the neocortex forms. It was initially suspected from observations in human embryos, by using classical methods, and later confirmed by the tritiated thymidine autoradiographic technique, that the neurons of the mammalian neocortex are generated only during a restricted period of early development, the period of neurogenesis. Unlike most species that have been examined, in which cortical neurogenesis lasts until birth or shortly thereafter, primates, including humans, acquire their full complement of cortical neurons before the last trimester (Rakic and Sidman, 1968; Sidman and Rakic, 1973; Rakic, 1974, 1988b). Some recent studies using bromo-deoxyuridine labeling and immunocytochemistry reported that new neurons continue to be generated and incorporated into the neocortex of macaque monkeys and rodents well into adulthood (Gould *et al.* 1999, 2001). However, subsequent studies by other groups of investigators using the same experimental methods have been unable to replicate these findings. Despite finding new neurons

in other areas known to be neurogenic in adulthood, i.e., the hippocampal dentate gyrus and lateral subventricular zone, convincing evidence for neurogenesis in adult neocortex was not observed (Magavi *et al.*, 2000; Kornack and Rakic, 2001; Rakic, 2002; Keketsu *et al.*, 2003; Ehninger and Kempermann, 2003). Thus, it appears that in all mammals investigated, neocortical neurogenesis is normally restricted to early developmental periods.

The initial concept that cortical neurons migrate from the place of their origin near the cerebral ventricle to their final destinations in the overlying cortex was discovered about a century ago, based on the exquisite observations and ingenious interpretation of human embryonic tissue sections stained with the classical histological methods. The critical finding was that mitotic figures (which signify cell division) are situated among neuroepithelial cells along the lumen of the cerebral ventricles (i.e., the ventricular zone, at the time called germinal layer or matrix) and are virtually absent in the overlying developing cortical plate, situated below the pial surface (His, 1874). The use of the autoradiographic method confirmed the fact that cortical neurons are not generated within the cortex itself, but rather are generated deep in the brain, near the surface of the cerebral ventricle (Angevine and Sidman, 1961; Sidman and Rakic, 1973; reviewed in Rakic, 1974, 1982, 1988b, 2006) (Figure 2). His' proposal regarding the noncortical site of dividing precursor cells in developing human cortex was eventually proven by using tritiated thymidine in one of the first applications of live tissue slice preparations (*in vitro*) in developmental biology (Rakic and Sidman, 1968). The majority of the supravitally labeled cells in the wall of the human fetal cerebrum were situated close to the ventricular surface, although some could also be found in the intermediate zone (IZ, prospective white matter) and marginal zone (MZ, prospective layer 1). Recent immunohistochemical analysis of the human telencephalon at early embryonic stages (30–37 postconceptual days) revealed that some abventricular mitosis occurs even before the onset of neurogenesis in the local ventricular zone (Bystron *et al.*, 2006). However, the developing cortical plate itself was found to be basically devoid of divisions until the beginning of gliogenesis (Rakic and Sidman, 1968). In primates, as in other mammalian species, progenitors of cortical neurons are confined to the narrow ventricular zone, where they form a transient pseudostratified epithelium, i.e., the ventricular zone (Rakic, 1972). Dividing cells in the ventricular zone are attached to each other at the ventricular surface by their endfeet and have radial

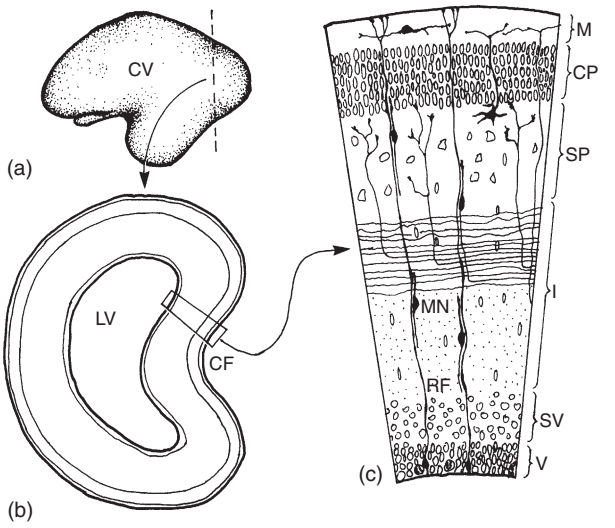

Figure 2 The cytological organization of the primate cerebral wall during the first half of gestation. a, The cerebral vesicle (CV) of a 60- to 65-day-old monkey fetus is still smooth and lacks the characteristic convolutions that will emerge in the second half of gestation. b, A coronal section across the occipital lobe at the level indicated by a vertical dashed line in (a). The lateral ventricle (LV) at this age is still relatively large and only the identification of the incipient calcarine fissure (CF) marks the position of the prospective visual cortex. c, A block of the tissue dissected from the upper bank of the calcarine fissure. At this early stage, one can recognize six embryonic layers from the ventricular surface (bottom) to the pial surface (top): ventricular zone (V); subventricular zone (SV); intermediate zone (I); subplate zone (SP); cortical plate (CP); and marginal zone (M). Note the presence of migrating neurons (MN) moving along radial glial fibers (RF), which span the full thickness of the cortex. The early afferents from the brainstem, thalamus, and other cortical areas invade the cerebral wall and accumulate in the subplate zone, where they make transient synapses before entering the cortical plate (Rakic, 1990).

processes that protrude toward the pial surface and into the outer cell-free marginal zone (Figure 2c). At later stages, particularly in primates, increasingly larger proportions of neurons are produced in the subventricular zone. Although in rodents virtually all interneurons of the neocortex are imported from ganglionic eminence within the basal telencephalon (reviewed in Marin and Rubenstein, 2001), in the human, most cortical interneurons originate in the subventricular zone of the dorsal telencephalon within a given area (Letinic *et al.*, 2002). This is particularly evident in the primary visual cortex (area 17), which in Old World primates, such as macaque and human, contains a significantly larger number of interneurons than the adjacent areas (Rakic, 1976; Smart *et al.*, 2002; Lukaszewicz *et al.*, 2005). The cells originating from the subventricular zone population in humans comprise about two-thirds of the neocortical GABAergic neurons; the remaining third originate from the ganglionic eminence, similar to rodents.

Besides harboring progenitors, the ventricular and subventricular zones contain a population of elongated radial glial cells that span the entire embryonic cerebral wall, from the ventricular to the pial surface (Rakic, 1972; Schmechel and Rakic, 1979a; Levitt *et al.*, 1981). This class of non-neuronal cells is present transiently in all mammals, but is particularly prominent in the large primate telencephalon (Schmechel and Rakic, 1979b; deAzevedo *et al.*, 2003; Zecevic, 2004; reviewed in Rakic, 2003). The radial glial fibers, which connect ventricular and pial surfaces, elongate as the cerebral wall widens (Schmechel and Rakic, 1979a). Postmitotic neurons produced in succession within the proliferative zones migrate outward along radial glial fascicles and traverse the intermediate and subplate zones before entering the developing cortical plate (Figure 2c). Radial glial scaffolding is considered to be essential for the preservation of positional information among cells within the protomap of the ventricular zone after they migrate to the suprajacent cortical plate, which, in primate brain, shifts as the hemispheric surface becomes more convoluted (Figure 3; Rakic, 1978). In addition to their role in providing a scaffold for radial neuronal migration, recent evidence indicates that radial glia can also directly produce

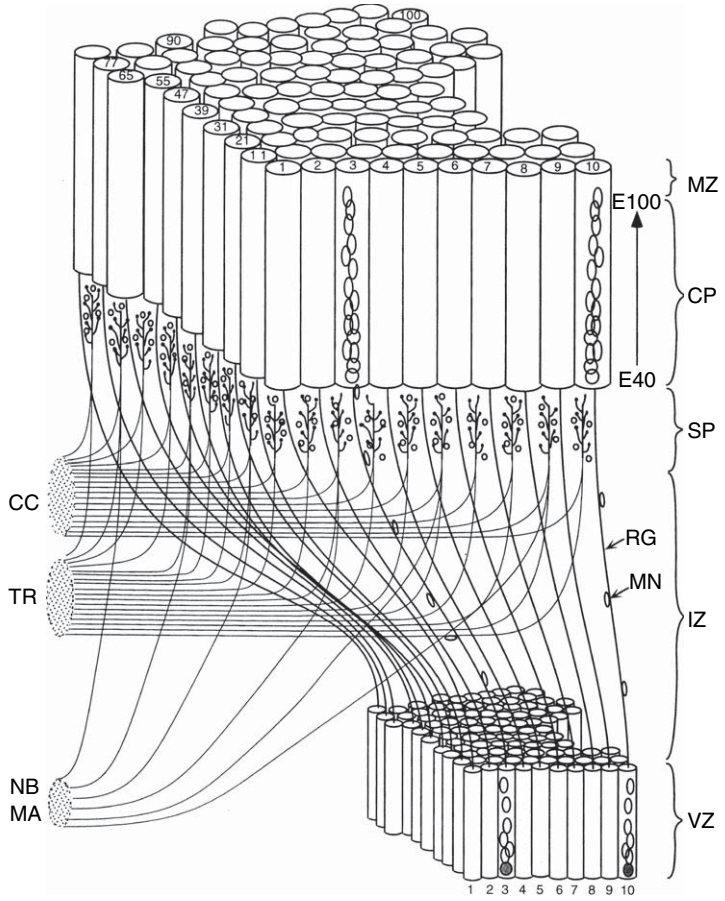

Figure 3 A three-dimensional illustration of the basic developmental events and types of cell–cell interactions occurring during early stages of corticogenesis, before formation of the final pattern of cortical connections (Rakic, 1988b). This drawing emphasizes radial migration, a predominant mode of neuronal movement that, in primates, underlies the elaborate columnar organization of neocortex. After their last division, cohorts of migrating neurons (MN) first traverse the intermediate zone (IZ) and then the subplate zone (SP) where they have an opportunity to interact with waiting afferents arriving sequentially from the nucleus basalis (NB) and monoamine subcortical centers (MA), from the thalamic radiation (TR), and from several ipsilateral and contralateral corticocortical bundles (CC). After newly generated neurons bypass the earlier generated ones, situated in the deep cortical layers, they settle at the interface between the developing cortical plate (CP) and marginal zone (MZ) and eventually form a radial stack of cells that share a common site of origin but are generated at different times. For example, neurons produced between embryonic day E40 and E100 in radial unit no. 3 follow the same radial glial fascicle and form ontogenetic column no. 3. Although some cells, presumably neurophilic, may detach from the cohort and move laterally, guided by an axonal bundle, most are gliophilic, i.e., have an affinity for the glial surface, and strictly obey constraints imposed by transient radial glial cell scaffolding. This cellular arrangement preserves relationships between proliferative mosaic of the ventricular zone (VZ) and the corresponding protomap within the subplate zone and cortical plate, even though the cortical surface in primates shifts considerably during the massive cerebral growth during mid-gestation. (For details see Rakic, 1972, 1988b.)

postmitotic neurons (Noctor *et al.*, 2001; Rakic, 2003; Gal *et al.*, 2006). The relative number of $GFAP^+$ and $GFAP^-$ precursors changes systematically over the course of cortical neurogenesis (Levitt *et al.*, 1983).

Upon entering the cortical plate, most neurons settle in an orderly inside-out temporospatial gradient, such that the earliest-born neurons form the deepest layer and successively later-born cells make progressively more superficial layers (Rakic, 1974). This inside-out gradient of laminar formation was initially discovered in rodents using tritiated thymidine autoradiography. Subsequent exposure of a series of macaque embryos to tritiated thymidine at different embryonic stages *in vivo* that were sacrificed postnatally, indicated that the inside-to-outside sequence is even more pronounced in the larger, gyrencephalic, and more slowly developing monkey neocortex, which is similar in size, shape, and cellular composition to the human (Rakic, 1974, 1988b). The reason for this pattern is not clear, but one hypothesis is that earlier generated neurons provide some information to the later generations, since genetic and/or environmental interference with sequential development has serious behavioral consequences (reviewed in Caviness and Rakic, 1978; Rakic, 1988a).

Although some postmitotic neurons do not obey radial constraints (Rakic *et al.*, 1974; Schmechel and Rakic, 1979b; Misson *et al.*, 1991; Rubenstein *et al.*, 1994; Ware *et al.*, 1999) and a selective population undergoes tangential, neurophilic modes of movement (Rakic, 1990; O'Rourke *et al.*, 1992; Ware *et al.*, 1999), the majority of neurons in a given column of the cortex are generated in the underlying sectors of the ventricular zone and migrate radially by gliophilic interactions (Rakic, 1978; Luskin *et al.*, 1988; Nakatsuji *et al.*, 1991; Parnavelas *et al.*, 1991; Tan and Breen, 1993; Rakic, 1995a; Tan *et al.*, 1998). Early divergence of basic cell types has been confirmed using the retroviral gene transfer method, which enables the study of cell lineages in the developing mammalian telencephalon, including primates (Luskin *et al.*, 1988; Kornack and Rakic, 1995). The use of the retroviral gene transfer method to trace cell lineages in the fetal monkey shows that even in the large convoluted primate cerebrum, clones of neurons in the cortex remain in strict radial alignment (Kornack and Rakic, 1995). Neural stem cells can also be tagged by the retroviral gene transfer method and their phenotype and migratory pattern followed in slices of postmortem human fetal tissue (Letinic *et al.*, 2002). Postmitotic neurons that are confined to a radial pathway exhibit a strong affinity for the radial glial cells (Rakic, 1972, 1978, 1988a; Gadisseux *et al.*, 1990). The class of migrating cells that use a glial substrate are termed gliophilic, in contrast to neurophilic cells, which move preferentially along axonal pathways (Rakic, 1990). The identity of surface molecules that provide differential adhesion between migrating neurons and glial fibers is being actively investigated (reviewed in Hatten and Mason, 1990; Rakic *et al.*, 1994; Rakic, 1997). In the context of the present article, it is sufficient to state that this cellular system may be an essential prerequisite for building a cerebral cortex as a sheet of radial columns intersected by horizontal layers of isochronously generated neurons.

4.14.4 The Radial Unit Hypothesis

The first step in cortical evolution is the increase in the number of its constituent cells. Since this increase precedes the formation of connections, it is the primary and essential change that has occurred during evolution. In addition, the manner by which a larger number of postmitotic cells migrates from proliferative ventricular zone to become deployed in the cortical plate as a sheet rather than a lump (as they do, for example, in the neostriatum) is crucial for understanding cortical expansion during evolution (Rakic, 1995b). The interpretation of the data on kinetics of cell production and their allocation in the embryonic telencephalon has led to the postulate of the radial unit hypothesis of cortical development and evolution (Rakic, 1988b).

The radial unit hypothesis postulates that the developing cortical plate basically consists of arrays of ontogenetic columns. The dynamic cellular events that underlie the development of this organization in the embryonic cerebral wall are presented schematically in Figure 3. Autoradiographic studies of neuronal origin indicate that neurons within a given radial column originate from several clones (polyclones) that share the same birthplace, migrate along a common pathway, and settle on top of each other within the same ontogenetic column (Rakic, 1988b). This has been confirmed by retroviral lineage tracing experiments in primates (Kornack and Rakic, 1995), rodents (Reid *et al.*, 1995) and in chimeric and transgenic animals (Nakatsuji *et al.*, 1991; Tan and Breen, 1993; Soriano *et al.*, 1995). Progenitor cells within the individual radial units that generate neurons destined for the cortical plate are coupled by specialized junctions that allow for intercellular communication (Bittman *et al.*, 1997). These radial units may form the developmental basis of

functional columns or modules that are observed in the adult cerebral cortex (Szenthágothai, 1978; Eccles, 1984; Mountcastle, 1997). However, the relation of ontogenetic columns to functional columns of the adult cortex remains to be defined.

According to the radial unit hypothesis, tangential (horizontal) coordinates of cortical neurons are determined by the relative position of their precursor cells in the ventricular zone, whereas their radial (vertical) position is determined by the time of their origin (Rakic, 1988b). Moreover, the number of the ontogenetic columns determines the size of the cortical surface, whereas the number of cells within the columns determines the thickness. Therefore, questions about the evolution of cortical size and thickness become translated into questions about developmental regulation of total cell number, and how this regulation was modified during evolution.

4.14.5 Cortical Expansion

Even cursory comparison of cerebral hemispheres among different mammalian species reveals dramatic differences in the number of cortical neurons and overall size of cortical surface. For example, surface area of the neocortex in mouse, macaque monkey, and human has an approximate ratio of 1:100:1000, respectively, whereas the thickness barely varies by factor of two (Blinkov and Glezer, 1968). The difference in the size of the neocortex between human and macaque monkey is particularly instructive as their basic cytoarchitectonic and hodological organization are rather similar (Polyak, 1957; Shkol'nik-Yarros, 1971). Thus, it appears that in the 23 Mya since macaque monkeys and humans diverged from a common ancestor (Fleagle, 1988), the cerebral cortex of these two Old World primate species has undergone different rates of expansion in cell number and cortical surface without a significant increase in the thickness of the cortical mantle.

According to the radial unit hypothesis, the increase in the cortical surface without a comparable increase in its thickness during mammalian evolution can be accounted for by changes in the proliferation kinetics of founder cells in the ventricular zone that increase the number of radial units without significantly changing the number of neurons within each unit (Rakic, 1995b). How was this expansion initiated and, once established, how was it preserved? How does one explain that approximately 15-fold more postmitotic cells in humans (compared to macaques) are generated and deployed to form a thin, regular sheet? This question can be further extended to the approximately 100-fold difference between the surface of the mouse and monkey neocortex.

4.14.5.1 Determinants of Neuron Number

Theoretically, total neuronal number in the cortex is determined by five basic parameters:

1. the number of founder cells;
2. the duration of the cell-division cycle;
3. the number of successive cell cycles during the period of neurogenesis;
4. the modes of cell division; and
5. selective cell death.

Recent progress in understanding the relevance of these parameters and their genetic control to cortical expansion is described below.

4.14.5.1.1 Kinetics of cell division The length of the cell cycle is a major determinant of the number of cells produced because it determines the total number of successive cell divisions that elapse over the entire period of neurogenesis. Accordingly, to gain insight into which parameters were modified during the evolution of larger cortices, we measured the length of the cell cycle of progenitor cells that generate neurons of the primary visual cortex in fetal macaque monkeys and compared it to cell cycle measurements in the smaller-brained mouse. Surprisingly, we found that the duration of the cell cycle in monkeys is as much as five times longer than that in the mouse neocortex (Kornack and Rakic, 1998). Nevertheless, due to the greatly extended duration of cortical neurogenesis in primates (60 days in monkeys compared to 6 days in mice), substantially more successive rounds of cell division elapse during neurogenesis in monkeys than in mice. Specifically, the generation of cortical cells in monkeys requires at least 28 successive rounds of cell division in the ventricular zone, in contrast to the much smaller cortex of mice, which is produced by only 11 mitotic cycles. Moreover, in contrast to the progressive slowing of the cycle described in rodents (Caviness *et al.*, 1995), the rate of cell division accelerates during neurogenesis of the enlarged cortical layers in monkeys (Kornack and Rakic, 1998). This evolutionary amplification in the number of successive cell-division cycles that generate cortical cells could account for the expansion of monkey cortical surface and the hypercellularity of upper layers in the monkey visual cortex (Kornack, 2000). One question is whether the difference in the laminar width between cortical regions, such as observed between striate (area 17) and extrastriate

(area 18) in primates, is a result of an increased production of cells destined for these areas in the subjacent proliferative zones or is due to an increase in cell death of postmigratory neurons. This difference could be predicted from previous studies showing that area 17 develops some of its specific cytological properties even if deprived from the thalamic input (Rakic, 1988a; Rakic *et al.*, 1991). It has also been shown that cell cycle duration in the ventricular zone subjacent to areas 17 and 18 is different at the time when the supragranular layers (i.e., layers 2 and 3) are being generated (Kornack and Rakic, 1998; Lukaszewicz *et al.* 2005). Thus, evolutionary modification of the duration and number of progenitor cell divisions has contributed to both the expansion and laminar elaboration of the primate neocortex. Uncovering the genes and cellular signals that control the length of cell cycle and duration of neurogenesis in ontogeny may provide clues to how these changes have occurred during evolution. Progress has already been made in identifying particular genes and signaling molecules that influence proliferation during cortical development in the mouse. For example, deleting the gene for the winged helix transcription factor, *BF-1*, decreases the proliferation of progenitor cells in the forebrain and results in greatly reduced cerebral hemispheres (Xuan *et al.*, 1995), whereas overexpression of *p27* can increase the number of cortical cells generated (Lukaszewicz *et al.*, 2005; Tarui *et al.*, 2005).

4.14.5.1.2 Modes of cell division In addition to the length of the cell cycle and the total duration of neurogenesis, the mode of cell division that produces (1) two equal progenitors (symmetric, nonterminal mode), (2) one progenitor and one postmitotic cell (stem or asymmetrical mode), or (3) two postmitotic cells (symmetric, terminal mode) can also significantly influence the total output of the proliferative ventricular zone (Kornack and Rakic, 1995; Rakic, 1995b). Since, as reviewed above, the entire cortical plate is created by neurons generated in the ventricular zone, the way they are generated may have profound consequences on their allocation in the cortex. In the macaque monkey, which has a 165-day gestation, before the 40th embryonic day (E40), all cells in the ventricular zone are dividing symmetrically: each progenitor produces two additional progenitor cells during each mitotic cycle (Rakic, 1988b). With each extra round of symmetric divisions, the number of founder cells in this phase doubles the number of progenitor cells, resulting in an exponential increase in the size of ventricular zone (Figure 5a). Conceivably, a slight prolongation of this phase of telencephalic development of proliferation could be indirectly responsible for the large surface enlargement of the cerebral cortex (Rakic, 1995b).

After E40 in macaque monkeys and approximately E42 in humans, some progenitor cells begin to produce postmitotic neurons that leave the ventricular zone, differentiate into neurons, and never divide again (Rakic, 1974, 1985). Autoradiographic and retroviral analyses of the patterns of cell division indicate that, after E40, many precursors begin to divide asymmetrically (Rakic, 1988b; Kornack and Rakic, 1995) (Figures 4a and 5b). This mode of division, also known as stem cell division, produces one daughter cell that is permanently postmitotic, and the other, which continues to divide or dies. The postmitotic cell that will become a neuron detaches from the ventricular surface and begins to migrate toward the pial surface, eventually settling in the cortical plate (Figures 4a and 5b). The other daughter cell remains attached to the ventricular surface by the endfoot and usually continues to divide, producing an additional pair of unequal cells: one progenitor and one postmitotic neuron that departs for the cortical plate. This pattern of

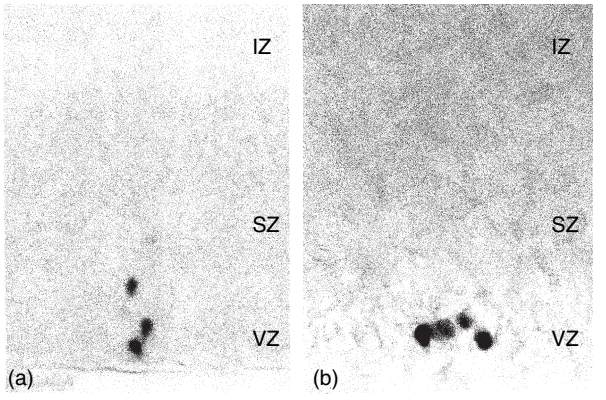

Figure 4 The distribution of retrovirally labeled cell clones in the inner cerebral wall of a fetal monkey near the end of corticogenesis, 3 weeks after an intraventricular injection of retroviral vectors carrying the histological marker gene, *lac z*. These distribution patterns of labeled cells provide evidence for the coexistence of two distinct modes of cell division in the proliferative ventricular zone (VZ), i.e., asymmetric and symmetric. a, The radial alignment of these three clonally related cells suggests that they are the offspring of an asymmetrically dividing progenitor. The innermost cell, near the ventricular surface, is most likely the progenitor that produced, in sequence, the outer two sibling cells, which are migrating outward toward the developing cortical plate. b, Clonally related cell clusters that remain in the VZ are most likely progenitor cell cousins that are the offspring of a symmetrically dividing progenitor. Note the lateral displacement of the resultant progenitors. SZ, subventricular zone; IZ, intermediate zone, Modified from Kornack, D. R. and Rakic, P. 1995. Radial and horizontal deployment of clonally related cells in the primate neocortex: Relationship to distinct mitotic lineages. *Neuron* 15, 311–321.

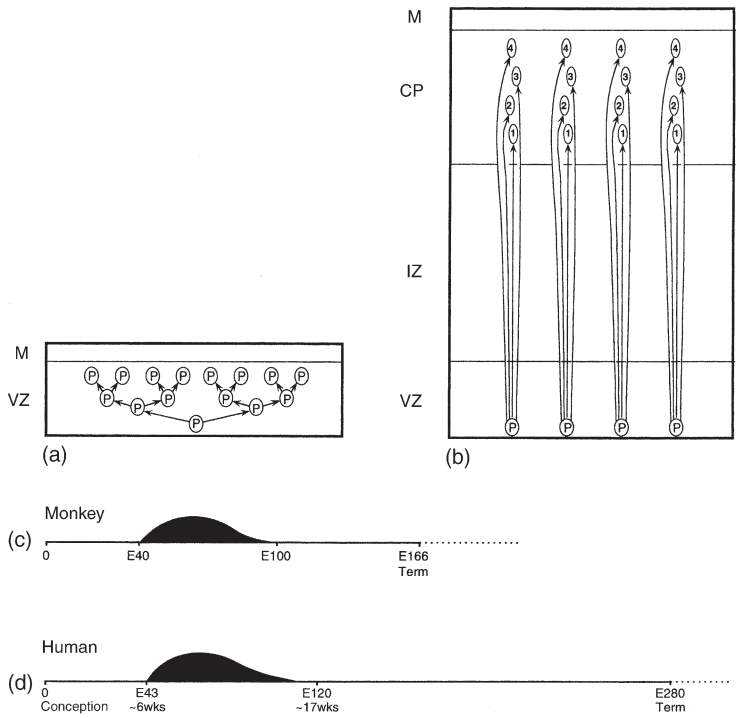

Figure 5 a, A schematic model of symmetric cell divisions, which predominate before the 40th embryonic day (E40). At this early embryonic age, the cerebral wall consists of only the ventricular zone (VZ), where all cells proliferate and the marginal zone (M), where some of them extend their radial processes. Symmetric division produces two progenitors (P) during each cycle and causes rapid horizontal lateral spread. b, A model of asymmetric or stem division, which becomes predominant in the monkey embryo after E40. During each asymmetric division, a progenitor (P) produces one postmitotic neuron that leaves the ventricular zone and another progenitor that remains within the proliferative zone and continues to divide. Postmitotic neurons migrate rapidly across the intermediate zone (IZ) and become arranged vertically in the cortical plate (CP) in reverse order of their arrival (1, 2, 3, 4). c, A diagrammatic representation of the time of neuron origin in macaque monkey. The data are obtained from the ^{3}H-thymidine autoradiographic analyses (Rakic, 1974). d, An estimate of the time of neuron origin in the human neocortex based on the number of mitotic figures within the ventricular zone, supravital DNA synthesis in slice preparations of fetal tissue and the presence of migrating neurons in the intermediate zone of the human fetal cerebrum. Based on Rakic (1978) and Rakic and Sidman (1968).

cell division in the monkey fetus proceeds during the next 30–60 days depending on the cortical area (Rakic, 1974, 1976, 1982). The number of cells contributing to each column depends on the duration of the period of corticogenesis and length of the cell cycle.

After the onset of cortical neurogenesis in primates (Kornack and Rakic, 1995) as well as other mammals (Caviness *et al.*, 1995; Chenn and McConnell, 1995; Mione *et al.*, 1997; Gall *et al.*, 2006), many precursors continue to divide symmetrically (Figure 4b). During the course of neurogenesis, this mode appears to be gradually supplanted by the asymmetric mode until the ventricular zone becomes exhausted as a source of cortical neurons and neurogenesis ceases (Rakic, 1988b; Caviness *et al.*, 1995; Rakic, 1995b; Kornack and Rakic, 1998; Kornack, 2000). However, the retrovirus gene transfer method of labeling clonally related cells in both rodent and primate embryos supports the hypothesis that neurons produced by a single asymmetrically dividing stem cell migrate radially and settle in the same ontogenetic column (Luskin *et al.*, 1988; Misson *et al.*, 1991; Kornack and Rakic, 1995; Reid *et al.*, 1995). It should be emphasized that even neurons produced from symmetrical division that become distributed over several columns, after their terminal division, nevertheless appear to migrate radially and settle within the same layer (Kornack and Rakic, 1995; Rakic, 1995a). The elimination of the isochronously dividing cells by low doses of ionizing radiation in monkey embryos at different stages of development supports this concept (Algan and Rakic, 1997). Specifically, irradiation of monkey embryos before E40 results in a decrease in cortical surface with little effect on its thickness, whereas irradiation after E40 deletes individual layers and reduces cortical thickness without an overall decrease in total surface.

To summarize, the kinetics of mitotic activity in the macaque ventricular zone can be divided into

two broad phases: (1) the phase before E40, when the most of the founder cells of the prospective cerebral cortex are formed, and (2) the phase of ontogenetic column formation, which proceeds mainly by asymmetric and terminal symmetric divisions that begin after E40 and continue until the completion of corticogenesis in a given region (Rakic, 1988b). The duration of the first phase, and of the cell cycle, determines the number of radial units and, indirectly, the size of cortical areas. The duration of the second phase regulates the number of neurons within each ontogenetic column. It is also during this second phase that the laminar phenotype of generated neurons is determined (reviewed in McConnell, 1995). It was proposed that the switch between the two phases of cortical development may be triggered by the activation of putative regulatory genes that control the mode of mitotic division in the ventricular zone (Rakic, 1995b). This activation is initiated within the telencephalon prior to the arrival input from the periphery.

Several lines of evidence from experimental manipulation as well as the pathogenesis of particular cortical malformations in humans suggest that these two phases can be separately affected: a deficit occurring during the first phase produces a cortex with a small surface area but normal or enlarged thickness (lissencephaly), whereas a defect during the phase of ontogenetic column formation produces a thin cortex with a relatively normal or larger surface size (polymicrogyria). This has been put to the test in mice in which neuronal production has been increased through an acceleration in the production of proliferative units (Chenn and Walsh, 2003).

4.14.5.1.3 Programmed cell death An additional, though frequently neglected, mechanism that may be involved in the control of cell production in the ventricular zone is the extent of apoptosis, or programmed cell death (PCD). Several lines of evidence support the notion that PCD is an active, inherently regulated phenomenon of selective cell elimination that is clearly distinct from cell necrosis, which occurs in response to harmful mechanical or chemical injuries (Kerr *et al.*, 1972). Although PCD has been considered a major factor contributing to the formation of the vertebrate brain (Glucksman, 1951), current research has focused on histogenetic cell death occurring at late developmental stages where it is primarily involved in eliminating incorrect axonal connections (Cowan *et al.*, 1984; Rakic, 1986; Oppenheim, 1991). Relatively little attention has been paid to the reports documenting sporadic cell death in the ventricular zone (e.g., Rakic, 1972) or more massive elimination of cells that fail to migrate away from the proliferative centers, prior to formation of any connections (Rakic and Sidman, 1973).

Recently, the use of methods that identify dying cells by labeling the exposed ends of their fragmented nuclear DNA suggests that early apoptosis may be much more widespread than generally assumed (Blaschke *et al.*, 1996). The possibility of studying this issue in mammals at the cellular/molecular level has dramatically increased in the past few years with the identification of regulatory genes that regulate PCD (Ellis and Horvitz, 1986). Because biologically important molecules tend to be conserved during evolution, we can use the same genes that were identified, for example, in *Drosophila* or the nematode, *Caenorhabditis. elegans*, and examine their function in mice. We can, for example, delete, overexpress, underexpress, or differentially express genes as nerve cells are produced or allocated. This can be illustrated by our recent work on genes controlling apoptosis in the mouse (Kuida *et al.*, 1996, 1998; Haydar *et al.*, 1999). We have reduced apoptosis by inactivating genes for caspase 3 and caspase 9, which must be expressed for a cell to die. In mice lacking both copies of the gene, apoptosis is reduced in the cerebral ventricular zone at early stages, during production of the founder progenitor cells. The main finding, relevant to the expansion of cortical size, is that in accord with the radial unit hypothesis, a larger-than-normal number of founder cells resulted in a cortex with an increased surface area and the formation of convolutions. By this single gene mutation, a lissencephalic mouse cortex was transformed into a gyrencephalic cerebrum, which is usually a hallmark of larger brains, as if there was a recapitulation of evolution. In this instance, the mutation resulting in more cortical neurons was not good for the homozygous mice; most of the mice died before birth. However, during evolution over millions of years, numerous mutations that increase the number of founder cells by either changes in the kinetics of proliferation or cell death could occur, and at some point supernumerary cells may have formed functionally useful connections that have helped in the survival of the species. Although the developmental mechanisms underlying the natural occurrence and patterning of cortical gyri in other species remain largely unknown, several theories have been proposed, which are beyond the scope of this review (Welker, 1990; Armstrong *et al.*, 1995; Van Essen, 1997). This experiment with apoptotic genes addresses this issue and illustrates the remarkable power of molecular and developmental neurobiology: here we used a gene

identified in a nematode worm that may help us understand principles of cortical development that could be extrapolated to primate evolution. In summary, the size of the cortex results from interactions of genes involved in progenitor proliferation and genes that cause the death of some of those progenitors.

4.14.5.2 Implications of the Radial Unit Hypothesis for Cortical Expansion

The radial unit hypothesis of cortical development provides a useful framework for understanding cortical expansion during evolution: the larger the number of radial units in a given species, the larger the surface of the neocortex (e.g., Figure 3). The radial unit hypothesis predicts that the difference in cortical surface area between two species depends on the difference in the number of founder cells generated during the first phase of unit formation (Rakic, 1995b). As is evident from Figure 5, during this phase, each round of symmetric cell divisions could double the number of founder cells, whereas, during the second phase, when asymmetrical divisions begin to predominate, each additional mitotic cycle adds only a single neuron to a given ontogenetic column. Indeed, in the monkey, the second phase begins 4 weeks later than it does in the mouse (E40 and E11, respectively). Thus, although the length of the cell cycle at the onset of neuron production is about twice as long in primates as that in mice (Kornack and Rakic, 1998), the size of the proliferative pool at the comparable embryonic stages is much larger in monkey than in mouse. However, it takes only a few days to account for the difference of an order of magnitude of cortical expansion between monkey and human (Figures 5c and 5d). If the length of the cell cycle in these two Old World primates is comparable, a delay in the onset of the second phase of a few days that allows three to four extra rounds of mitosis would result in a 23-fold to 24-fold increase in founder cells, which would generate an 8–16 times larger number of columns and therefore the proportionally larger cortical surface (Figure 5c and 5d). In contrast, a 20-day longer duration of the second phase in human compared to monkey (E100 and E120) would add only about 10 more cells per ontogenetic column. Assuming that each column consists of about 100 neurons (Rakic, 1988b), such an addition would increase cortical thickness by only 10%. These numbers, as well as the descriptions of developmental events, are oversimplifications of more complex cellular processes that occur during this developmental period. For example, this model does not take into account the possible changes in the proportion of symmetrical cell divisions during the second phase, the growth in size of individual neurons, the contribution of glial cells and myelin, or the rate of cell death, all of which may also influence surface expansion to different extents in each species. However, these developmental and structural differences are relatively minor between the two Old World primate species that we selected for comparison. The enlargement of the number of radial units must be the most prominent and decisive evolutionary factor.

The developmental events described here indicate that the evolutionary expansion of the neocortex in primates could be attributed, to a large extent, to a change in genetic mechanisms that control the onset, cessation, rate, and/or mode of cell division (Rakic, 1995b). According to the proposed model, the species-specific size of the cortex is determined at early stages by the pool of founder cells before corticogenesis starts, and before there is any input from the periphery. Although the evolutionary construction of the mammalian brain may require as many genes as were needed for all morphogenetic and metabolic functions in phyletic history (John and Gabor Miklos, 1988), a small modification of a regulatory gene or genes may have played a significant role in the evolutionary expansion of the neocortex, as has presumably occurred in other bodily systems (Medawar, 1953). Therefore, the explanation for cortical expansion between mammalian species rests predominantly upon the process of heterochrony whereby changes in the timing of developmental events increases the number of founder cells and consequently the surface of the cortical plate (Rakic, 1995b; Kornack and Rakic, 1998).

4.14.6 The Protomap Hypothesis of Cortical Parcellation

In addition to expanding more than 1000 times in surface area during evolution, the neocortex also became divided into more complex and more distinct cytoarchitectonic maps by both the differential growth of existing areas and the introduction of novel ones. For example, compared to small-brained mammals (e.g., insectivores, rodents), large-brained primates, including macaque monkeys and humans, display a larger number as well as more pronounced differences between cytoarchitectonic features, distribution of neurotransmitter receptor complements, and neuronal circuitry (Rakic and Singer, 1988). How might such differences emerge? Again, to get some insight into how this could have occurred during evolution, we have devised

scenarios based on advances in understanding ontogenetic development.

As predicted by the radial unit hypothesis and the data reviewed above, the initial number of proliferative units that generate prospective cortical columns in a given species is likely to be set up early in embryogenesis by a few regulatory genes that control cell production. However, the final pattern and relative size of cytoarchitectonic subdivisions of the neocortex are probably regulated by a different set of genes and, in addition, it must be coordinated through reciprocal cell–cell interactions with various afferent systems. Ten years ago, one of us proposed a protomap hypothesis of cortical parcellation (Rakic, 1988b). This hypothesis postulates that intersecting gradients of molecules might be expressed across the embryonic cerebral cortex that guide and attract specific afferent systems to appropriate cortical regions where they can interact with the responsive set of cells. The prefix 'proto' indicates the malleable character of this primordial map, as opposed to the generally accepted *tabula rasa* hypothesis, which considers the cortical plate as an undifferentiated primordium that is shaped and subdivided entirely by afferents, as advocated effectively by Otto Creutzfeldt in the mid-1970s (Creutzfeldt, 1977). However, in the past decade, there has been increasing evidence of differential gene expression across the embryonic cerebral wall that indicates prospective subdivisions of the neocortex. Some of these molecules may be expressed in a region-specific manner before and/or independently of the input (Kuljis and Rakic, 1990; Barbe and Levitt, 1991; Arimatsu *et al.*, 1992; Ferri and Levitt, 1993; Cohen-Tannoudji *et al.*, 1994; Levitt *et al.*, 1997; Acampoa *et al.*, 1999; Donoghue and Rakic, 1999a, 1999b; Gitton *et al.*, 1999a, 1999b; Rubenstein and Rakic, 1999). This independence is supported by finding that animals devoid of input from periphery (as in experimentally induced and congenital anophthalmia) nevertheless develop region-specific cytoarchitecture and appropriate local and topographic connections (Kaiserman-Abramof *et al.*, 1989; Kuljis and Rakic, 1990; Kennedy and Dehay, 1993; Rakic and Lidow, 1995; Bourgeois and Rakic, 1996; Miyashita-Lin *et al.*, 1999; Grove and Fukuchi-Shimogori, 2003; reviewed in special issues of *Cerebral Cortex*: Rubenstein and Rakic, 1999; O'Leary and Borngasser, 2006).

There is an emerging body of evidence for the existence of areal differences in the duration and rate of cell production in the macaque ventricular zone that can be detected prior to overt cell differentiation (Rakic, 1976; Dehay *et al.*, 1993). Finally, regional differences in the embryonic cerebral wall (either in the subplate or cortical plate) seem to be capable of attracting axons that originate from distinct diencephalic nuclei (Kostovic and Rakic, 1990; De Carlos and O'Leary, 1992; Agmon *et al.*, 1995; Letang *et al.*, 1998). This selective attraction may be due a gradient of recognition molecules distributed across the cerebral wall (Boncinelli *et al.*, 1993; O'Leary and Koester, 1993; Bulfone *et al.*, 1995; Simeone, 1998; Acampora *et al.*, 1999; Donoghue and Rakic, 1999a, 1999b).

It should be emphasized that these hypothetical primordial protomaps merely provide an oriented blueprint and a biological potential that, in turn, is translated into a species-specific archetype of neural connections through reciprocal interactions between interconnected levels. Numerous studies have shown that perturbation of afferent connections and local circuitry result in changes within these regions (e.g., O'Leary and Stanfield, 1989; Rakic, 1981, 1988b; Rakic *et al.*, 1991; Algan and Rakic, 1997), implicating cellular connectivity as a necessary but not sufficient determinant of regional specification. These interactions begin before birth (Rakic, 1981) and therefore may be influenced by spontaneous electrical activity (Shatz, 1996). However, numerous experimental studies in the developing brain indicate that basic species-specific topology develops autonomously and that neural activity may play more of a permissive rather than an instructive role (reviewed in Chair, 1999). Therefore, input from sensory receptors at the periphery may not be essential for the establishment of basic species-specific connections (Kuljis and Rakic, 1990; Rakic, 1995b).

In the primate visual system, such interactions continue until the time of puberty (Bourgeois and Rakic, 1993), when most structural and biochemical properties become stabilized through visual stimulation from the environment. Such interactions are bidirectional, i.e., from photoreceptors at the periphery toward the central structures in the cortex, and back from the cortex toward the retina. Disruption, or even a short delay in a single communication step in either direction may cause a cascade of reactions affecting heterogeneous cell classes, leading to an abnormal organization of the entire system and, consequently, to abnormal function (Hubel *et al.*, 1977; Rakic, 1983; Bourgeois and Rakic, 1996; Shatz, 1996). Thus, once connected with the appropriate input, neurons at each visual center may have a species-specific response, depending on the complement of genes that become differentially expressed.

The enlargement of cortical surface area or even the differential expansion of the individual areas in

themselves is not sufficient to account entirely for the elaboration of cortical connectivity that occurred during evolution (Rakic, 1995b). The increase in cortical surface by the introduction of new radial units, as well as the expansion and elaboration of areas, provides only an opportunity for creating novel input/target/output relationships with other structures that, if heritable, may be subject to natural selection. The new synaptic relationships resulting from these neuronal interactions may be adverse or neutral, or may enhance the capacity for behavioral adaptation. As pointed out by Jacob (1977), a new structural feature does not have to be optimal, but must be good enough to provide a survival advantage for the species. For example, reducing mortality by advantages of increased cognitive capacity and thereby prolonging the sexually active period of individuals with a larger cortex might improve their lifetime reproductive success and propagate this trait. Although the introduction of novelty in evolution by the process of heterochrony has been proposed to explain morphological changes of non-neural organs of the body (Alberch *et al.*, 1979), understanding the role of heterochrony in the phylogenetic development of the brain presents special problems because of the complex interplay among multiple epigenetic factors that regulate gene expression during development (Edelman, 1988; Purves, 1988; Changeux and Chavaillon, 1995; Rakic, 1995b). During the genesis of the cerebral cortex, such cellular interactions probably play a more significant role than in any other organ, and this, as well as the paucity of crucial comparative developmental studies, is perhaps why progress in this field has been slow.

In summary, modern developmental neurobiology provides insight into how the cerebral cortex develops and how it may have evolved. The genes and morphoregulatory molecules that control the production, migration, and appropriate allocation of neurons to their final positions within the developing cortical plate are being identified at a rapid rate and their functions tested both *in vitro* and *in vivo* in transgenic animals. The data suggest that the early stages of corticogenesis determine the species-specific size and basic pattern of organization that set the stage for the formation of the final pattern of synaptic connections whose functional values are then tested by natural selection.

4.15 Brain Size in Primates as a Function of Behavioral Innovation

S M Reader, Utrecht University, Utrecht, The Netherlands

Glossary

behavioral innovation	A novel learned behavior not previously found in the population.
social learning	Learning from another animal or its products.

4.15.1 Introduction: What is Behavioral Innovation?

A behavioral innovation can be operationally defined as "a new or modified learned behavior not previously found in the population" (Reader and Laland, 2003b). Thus, innovations are novel, learned acts. The focus on learned acts excludes accidental, one-off behaviors and emphasizes behavior patterns more likely to be consequential to the animal. The focus on innovations as novel to the group rather than the individual distinguishes the creation of a novel behavior pattern (innovation) from social acquisition of the new behavior. This definition contrasts with that used in the human innovation literature (e.g., Rogers, 1995), which considers socially acquired novel behavior patterns as innovations.

Innovation taps into what many consider an important aspect of cognitive sophistication: the flexibility to try and learn something new (Eysenck, 1995; Reader and Laland, 2003a). Innovators must depart from an established behavioral repertoire and locate a novel problem to be solved or a novel solution to an old problem (Kummer and Goodall, 1985; Reader and Laland, 2003b). Innovation therefore combines problem solving with the tendency to seek new solutions or new problems. The 'problems' solved may range in apparent cognitive complexity, from inclusion of a new item in the diet to the use of novel tools. Thus, innovation is likely to involve a number of underlying cognitive, perceptual and motivational processes, and perhaps also a variety of neural substrates (Greenberg, 2003; Reader and Laland, 2003b). This broad definition of innovation is deliberate, and is appropriate at this early stage of investigation in order to encourage research demarcating innovation into its possible component processes on the basis of empirical data, rather than on arbitrary distinctions such as perceived cognitive complexity (Reader and Laland, 2003b).

Innovation is of significance to several research fields. To the psychologist, understanding innovation is an important part of understanding learning and problem solving. To the social learning theorist, a complete understanding of the spread of novel behaviors through groups will also involve an understanding of how the novel behavior arises in the first place. To the ecologist, shifts to novel resources, novel habitats, or novel mate choice preferences are of great theoretical and applied interest (Sol, 2003; Sol *et al*., 2005). To the evolutionary biologist, of interest are the potentially dramatic evolutionary consequences of such innovations, particularly, perhaps, when innovations spread by social learning (Wyles *et al*., 1983; Nicolakakis *et al*., 2003; Sol, 2003; West-Eberhard, 2003). Innovation itself may be under natural, sexual, and cultural selection, and Baldwin (1896) raised the possibility that adaptive behavioral innovations may lead to selection favoring unlearned versions of the same behavior (for supporting theoretical models and human data, see Holden and Mace, 1997; Ancel, 1999; West-Eberhard, 2003).

Moreover, innovation can provide a useful measure of behavioral flexibility. For taxa like primates and birds, where there is a history of reporting deviations from the established population

behavioral repertoire, one can count the number of reports of innovation for large numbers of species (Lefebvre *et al.*, 1997; Reader and Laland, 2002). With appropriate correction for possible confounding variables (such as research effort) we have a general index with which we can examine the evolution and evolutionary consequences of one aspect of behavioral flexibility. In particular, we can examine the neurological, cognitive, and ecological correlates of innovation. Such analyses can provide useful clues for the role of behavioral flexibility in brain evolution, the co-evolutionary history of cognitive capacities, and the ecological pressures favoring an innovative strategy.

4.15.2 Innovation and Cognitive Evolution

The comparative studies of nonhuman primates described below are detailed fully by Reader and Lefebvre (2001), Reader and Laland (2002), Reader (2003), and Reader and MacDonald (2003), and examples of the innovations collated can be found in Reader and Laland (2001). For exposition, we present figures of across-species data, with each datum representing one species. However, such across-species analyses are potentially flawed if species show similar characteristics to each other because of common ancestry, not independent evolution, thereby violating the assumption of data independence (Harvey and Pagel, 1991). We employed the independent contrasts technique to account for this difficulty (Felsenstein, 1985; Purvis and Rambaut, 1995). Such techniques assume that while two species may be similar to each other because of common ancestry, the differences between them represent independent evolution (Harvey and Pagel, 1991).

4.15.2.1 Neurological Correlates of Innovation

The brain does not evolve as a unitary structure (Barton and Harvey 2000; see Mosaic Evolution of Brain Structure in Mammals). Thus, it is sensible to focus on the brain areas thought to be involved in the psychological processes of interest. In the case of primate innovation, these are generally thought to be the neocortex and striatum, together the so-called 'executive brain' (Oakley, 1979; Jolicoeur *et al.*, 1984; Keverne *et al.*, 1996). Figure 1 shows that there is a correlation between relative executive brain volume and innovation rate: species with large executive brains relative to their body size are more frequently reported as innovators. The relative brain measure used in Figure 1 is the ratio of executive brain to brainstem volume. Note that there is debate over the most appropriate methods for taking body size into account in comparative brain studies (Deaner *et al.*, 2000). We did not find relationships between innovation and every alternative measure of relative executive brain volume (Reader and Laland, 2002). However, the relationship remained significant when body mass was included in a multiple regression with innovation rate and executive brain ratio, suggesting that the correlation is not due to the confounding effect of body mass (Reader and Laland, 2002).

These results are consistent with the idea that cognitive capacity and brain volume are linked, if the reasonable assumption is made that innovation rate is a measure of cognitive capacity (see also Section 4.15.2.2). These correlational data do not, however,

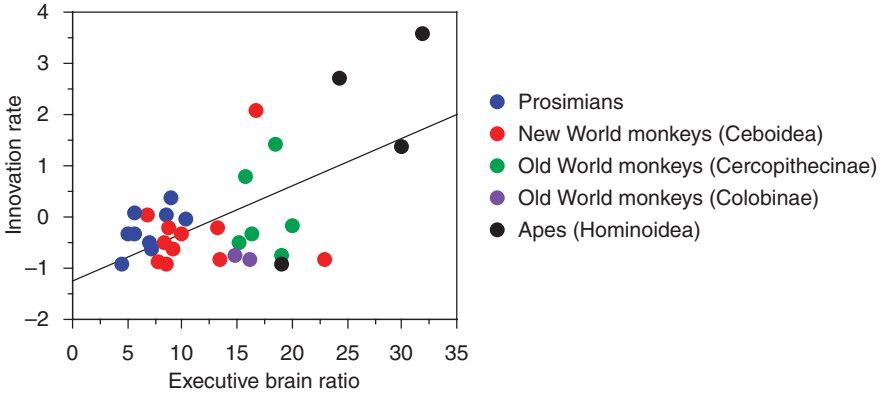

Figure 1 Innovation rate and relative executive brain ratio (executive brain volume/brainstem volume) are correlated. Innovation rate was corrected for differences in research effort by taking the residuals from a natural log-log plot of innovation rate against research effort, thus corrected innovation rate can take positive and negative values. For exposition the figure shows across-species data, with colored symbols indicating taxa. Independent contrast analysis gave similar results (Reader and Laland, 2002). Adapted from Reader, S. M. and Laland, K. N. 2002. Social intelligence, innovation and enhanced brain size in primates. *Proc. Natl. Acad. Sci. USA* 99, 4436–4441.

allow us to distinguish between innovation as an adaptation, an exaptation, or a nonadaptive byproduct of another selection pressure that promoted brain enlargement. Moreover, the fact that innovation correlates with brain volume casts scant light on the neuropsychological processes underlying innovation: the question of why neural volume and cognitive capacity should be linked remains open (Bolhuis and Macphail, 2001; Deary, 2001).

4.15.2.2 Cognitive Correlates of Innovation

Social learning and tool use frequencies can be collated from published literature in the same manner as innovation frequency. Innovation rate correlates with both social learning and tool use frequency (Figure 2; Reader and Laland 2002). These relationships remain significant when the confounding effect of executive brain volume is taken into account: executive brain ratio correlates with both social learning and tool use rates (Reader and Laland, 2002). While tool use and innovation can be identified by observational studies, observational reports of social learning must be treated with caution (Galef, 1992; Reader and Laland, 2002). Innovation rate also correlates with performance in laboratory individual learning tasks, though the number of species available for analysis was small and no attempt was made to correct for phylogenetic relationships (Riddell and Corl, 1977; Reader and MacDonald, 2003). Notwithstanding these caveats, we have evidence for different cognitive measures evolving together, which would suggest that they are all part of one general intelligence or that these 'intelligences' are modular but the modules have evolved together (Fodor, 1983; Tooby and Cosmides, 1989; Byrne and Whiten, 1997).

4.15.2.3 Social and Ecological Correlates of Innovation

Many socioecological factors may favor an innovative brain, and the factors favoring brain enlargement have received considerable attention (see The Evolution of Encephalization). Social intelligence hypotheses, for example, focus on dealing with the rapidly changing social world, with more advanced cognitive abilities evolving to cope with the demands of social living, to gain information from others, and create unpredictability in personal behavior – unpredictability that may be key in outwitting other individuals (Byrne and Whiten, 1988). Ecological intelligence hypotheses instead emphasize the role of variables such as foraging ecology in determining brain evolution (Milton, 1988).

The selection pressures favoring innovation specifically have not received the same attention as those favoring brain enlargement. Innovation may be beneficial in both social and ecological domains. For example, innovations may be particularly effective methods to deceive or manipulate others (Kummer and Goodall, 1985; Byrne, 2003), and shifts to novel foods or foraging techniques may be vital to animals in impoverished circumstances (Reader and Laland, 2001). Social learning, a component of social intelligence, may be favored in ecologically innovative species if the acquisition of innovations by social means provides a cheaper, more reliable, or less risky alternative to innovating for oneself. The correlation between social learning and innovation rates described above would support this idea. However, such information scrounging by group members will often reduce the benefits of innovation to the innovator. Moreover, although innovations are reported in both social and

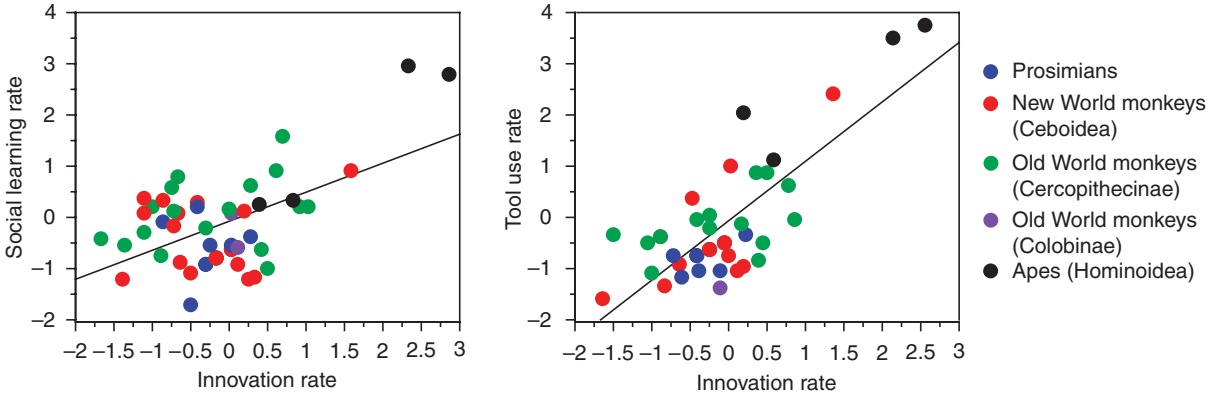

Figure 2 Innovation rate correlates with reported frequencies of social learning ($r^2_{adj} = 0.29$, $p < 0.0001$) and tool use ($r^2_{adj} = 0.60$, $p < 0.0001$). All frequencies are corrected for research effort (see legend, Figure 1). Reanalysis of the data from Reader and Laland (2002), excluding species where social learning, tool use, or innovation were not reported. Relationships remain significant when executive brain ratio is included as a covariate. For exposition the figures show across-species data, with colored symbols indicating taxa. Independent contrast analyses gave similar results (Reader and Laland, 2002).

ecological contexts, very few have been observed spreading through primate groups (Kummer and Goodall, 1985; Reader and Laland, 2001; Laland and Hoppitt, 2003). Thus, the hypothesis that social intelligence and innovation have had feedback effects on each other's evolution remains unproven.

Clues to the circumstances promoting the evolution of innovation might come from observational and experimental studies of when and where animals innovate. If innovation consistently occurs in harsh or marginal habitats (e.g., the edge of the species range; K. MacDonald, personal communication), in changed or poor conditions (e.g., cold periods), or in individuals of poor competitive ability (Reader and Laland, 2001) this might suggest that innovation has an adaptive advantage in conditions of range expansion, climatic variability, or social competition, respectively. In birds, innovative species are known to be more likely to become established when introduced to new habitats than less innovative species (Sol *et al*., 2005). At present, primate analyses do not support a link between climatic variability and innovation rate, nor a correlation between the geographical range of a species and innovation rate (Reader and MacDonald, 2003). Correlations between these variables might have been expected if innovation is prompted by variation in current conditions, or if variable conditions had selected for a propensity to innovate. Social competition clearly has an effect on innovation, and much innovation appears to be performed by peripheral, low-ranking individuals, perhaps limiting the social learning of innovations by the rest of the group (Reader and Laland, 2001).

Social intelligence hypotheses link living in larger or more complex groups with increased cognitive demands (Deaner *et al*., 2000). One line of evidence for social intelligence ideas comes from correlations between primate group size and relative brain volume (Deaner *et al*., 2000). As brain volume is assumed to be an indirect cognitive measure, this begs the question of which cognitive capacities are favored by group life – innovation, deception, and social learning are likely candidates. Such cognitive capacities would be expected to correlate with both group size (group living being the selection pressure favoring their evolution) and relative brain volume. However, in contrast to the above expectations, three behavioral correlates of brain volume do not correlate with social group size: primate social group size does not predict innovation, social learning, or deception rates (Reader and Lefebvre, 2001; Byrne and Corp, 2004; S. M. Reader, unpublished data). If these findings are robust, they raise the question of whether other, as yet unrecognized, cognitive or noncognitive correlates of brain size were favored by group living.

4.15.3 Discussion: Cognitive Convergence – Are Primates Special?

Confidence in the generality of the relationships between innovation and other variables described in primates will be strengthened if they are also found in other animal taxa. Lefebvre *et al*. (1997; see The Evolution of Encephalization) pioneered the study of the co-evolution of brain and innovation in birds, and we can compare findings in birds and primates to examine the evidence for convergent cognitive evolution in two groups that diverged more than 250 Mya (Lefebvre *et al*., 2004; Jarvis and The Avian Brain Nomenclature Consortium, 2005). In both birds and primates innovation rate correlates with the volumes of higher order and multimodal integration brain areas: the mesopallium and nidopallium in birds and the neocortex in primates. Far from being reptilian in size, birds typically have relative brain sizes closer to those of mammals, and show similar cognitive sophistication (Jarvis and The Avian Brain Nomenclature Consortium, 2005). Moreover, in both primates and birds innovation rate correlates with tool use frequency and individual learning measures (Lefebvre *et al*., 2004). The fact that these neural and cognitive associations are observed in two independent groups, and at different taxonomic levels (species were compared in primates, and parvorders in birds), suggests a striking pattern of convergent evolution.

A common assumption to virtually all cognitive explanations for brain enlargement is that large brains afford greater behavioral flexibility. Comparative analyses of innovation allow this assumption to be tested, and have raised the possibility that behavioral flexibility played a pivotal role in the evolution of enlarged brains. What of the future? Understanding the psychological, neural, and genetic processes underlying innovation will be key to improving understanding of the evolution of innovation and behavioral flexibility. It is still not clear what processes underlie innovation in humans and other animals, or whether the same processes are involved in both. For example, do animals actively seek novel solutions to problems, or do they profit from accidents? If the former, what are the determinants of creativity? How do experience, development, and the socioecological environment influence innovativeness? Is innovativeness heritable, and, if so, what are its heritable components? These are all questions amenable to experimental study,

and will be instrumental in understanding how and why brain enlargement and behavioral flexibility are linked.

4.16 Cerebral Cortical Folding Patterns in Primates: Why They Vary and What They Signify

D C Van Essen, Washington University School of Medicine, St. Louis, MO, USA

Glossary

FEF	Frontal eye fields.
LIP	Lateral intraparietal area.
MRI	Magnetic resonance imaging.
MST	Medial superior temporal area.
MT	Middle temporal area.
PALS	Atlas population average, landmark and surface-based atlas.
V1	Visual area V1.

4.16.1 Introduction

As the dominant component of the primate brain, the cerebral cortex is remarkably variable in its pattern of convolutions. Lissencephalic primates, such as the owl monkey and galago, have small brains and only a few shallow cortical sulci. In larger-brained primates, such as the highly gyrencephalic human, most of the cortex is buried in a complex, irregular array of sulci whose pattern is species-specific but also varies markedly from one individual to the next within a given species.

These observations give rise to many questions. Why does the degree of folding vary so much across species, and why does it increase systematically with brain size? What accounts for the variability in the pattern within and across species? What is the relationship between the arrangement of cortical areas and the pattern of folds in any given individual or species?

This article provides a developmental and comparative framework for addressing these questions. Many aspects of cortical folding can be understood in terms of a basic set of developmental processes that include the differentiation into distinct cortical areas, the formation of long-distance connections, and the generation of folds by mechanical tension along these axons. Differences among species may largely reflect the characteristic arrangement of cortical areas and their connections.

4.16.2 Why Is the Cortex Folded?

Cerebral cortex is a thin sheet that surrounds a core of subcortical structures, including various nuclei (e.g., thalamus, basal ganglia), the ventricles, and a surrounding shell of subcortical white matter. The factors regulating the total volume and surface area of the cortex differ in many ways from those regulating the aggregate volume of the subcortical core. Nonetheless, cortical and subcortical development are coupled, insofar as the cortical sheet is effectively shrink-wrapped around the subcortical core. With these points in mind, the correlation between cortical folding and overall brain size can be attributed to several systematic relationships revealed by allometric studies.

1. *Disproportionate cortical expansion.* As overall brain size increases, cerebral cortical gray matter expands disproportionately compared to subcortical nuclei (Jerison, 1982; Hofman, 1989). This differential growth is attributable to a disproportionately extended period of cortical neurogenesis in larger-brained mammals (Finlay and Darlington, 1995; see The Evolution of Sensory and Motor Systems in Primates).
2. *Staying thin.* As cortical volume (V_{cort}) increases, total cortical surface area (A_{cort}) increases much more rapidly than average cortical thickness ($T_{cort} = V_{cort}/A_{cort}$). For example, in comparing human and macaque cerebral cortex, there is a 10-fold difference in surface area but only a

1.5-fold difference in average cortical thickness (Hofman, 1989; see Captured in the Net of Space and Time: Understanding Cortical Field Evolution).

3. *Limited wiring*. White matter underlying cerebral cortex includes axons of long-distance corticocortical connections plus axons associated with corticosubcortical pathways. This subcortical white matter is a very small fraction of total subcortical volume in lissencephalic animals. It increases with total brain size (V_{brain}) much more rapidly than does the volume of cortical gray matter ($V_{WM} \propto V_{brain}^{1.37}$ vs. $V_{cort} \propto V_{brain}^{1.05}$), yet remains less than cortical gray matter volume even in the largest-brained species (Frahm *et al.*, 1982; Hofman, 1989).

To appreciate the implications of these relationships, note that the surface area $A_{subcort}$ bounding the subcortical domains would be minimal if the aggregate volume (subcortical white matter, gray matter, and ventricles) were configured as a perfect sphere, in which case $A_{subcort}^{min} = 4.84\ V_{subcort}^{2/3}$. If cortical surface area is less than this minimum ($A_{cort} < A_{subcort}^{min}$), then a completely smooth cortex would only partially enclose the subcortical components, and the resultant brain would perforce be lissencephalic (Figure 1a). On the other hand, if cortical surface area substantially exceeds the subcortical minimum ($A_{cort} \gg A_{subcort}^{min}$), then the subcortical core must take on an irregular shape, including peaks and valleys that mesh with a folded cortical sheet and thereby achieve an appropriate shrink-wrapping of the cortex (Figure 1b). By this argument, the approximate degree of cortical folding is predictable largely on the basis of the number of neurons, average neuronal size, and average connectivity patterns of major cortical and subcortical domains. This conclusion does not rely on any particular mechanistic hypothesis about the mechanical forces that cause a specific pattern of folds to emerge.

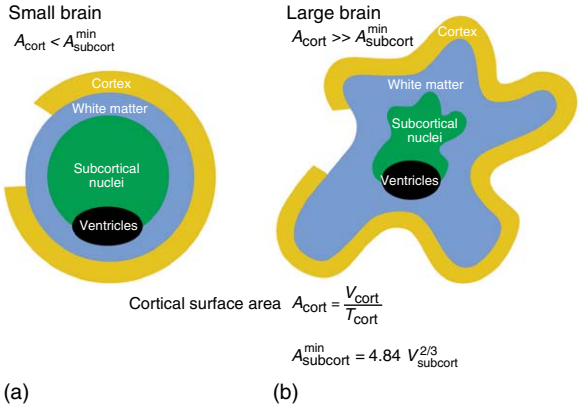

Figure 1 Schematic drawing of cortical and subcortical components in small vs. large brains. a, In lissencephalic brains, subcortical nuclei constitute a large fraction of total brain volume, and the cortical sheet lacks sufficient surface area to completely envelop the subcortical domains. b, In gyrencephalic brains, the increase in cortical surface area greatly outstrips the increase in subcortical nuclei and ventricular domains. Even though subcortical white matter also increases greatly, the surface area of subcortical regions matches cortical surface area only if the subcortical domain is highly nonspherical.

4.16.3 A Tension-Based Hypothesis of Cortical Folding

Five observations set the stage for a general hypothesis for how and where cortical folding occurs. The first four relate to morphogenetic events that occur during embryonic cortical development.

1. Cerebral cortex initially forms as a completely smooth sheet, as a result of neuronal proliferation along the ventricular surface followed by outward radial migration (Rakic, 2003). Each hemisphere is like an inflated balloon, in which elevated intraventricular pressure generated by the production of cerebrospinal fluid keeps the hemisphere inflated (Desmond and Jacobson, 1977; Miller *et al.*, 1987).
2. The cortical sheet becomes regionally specialized into a species-specific mosaic of many distinct cortical areas. This results from a complex set of molecular signaling processes that remain poorly understood (Grove and Fukuchi-Shimogori, 2003).
3. A high percentage of cortical neurons send axons into what becomes the white matter and begin to establish precise long-distance connections that are appropriate for their areal identity (Schwartz *et al.*, 1991; Coogan and Van Essen, 1996).
4. Cortical folding begins around the time that initial long-distance pathways are being established and continues over an extended period of late prenatal and early postnatal maturation, during which time cortical surface area increases rapidly.
5. Neurons grown in tissue culture extend neurites that generate substantial mechanical tension (Dennerll *et al.*, 1988; Lamoureux *et al.*, 1992), suggesting a biologically plausible mechanical force for inducing cortical folds.

   The fifth observation discussed above is of a different type and relates to mechanical forces exerted by axons and dendrites.

If, as seems likely, the axons of cortical neurons generate tension *in vivo* akin to that generated by neurites *in vitro*, then the aggregate forces associated

with long-distance corticocortical pathways would tend to bring strongly interconnected regions closer together, thereby forming a gyral fold in between. In contrast, weakly interconnected regions would lack sufficient strength to force an intervening gyral fold and in many cases would tolerate an intervening sulcal fold that actually increased their separation. This tension-based hypothesis of cortical folding is part of a more general theory of morphogenesis throughout all parts of the nervous system (Van Essen, 1997). A related aspect of this theory is that radially oriented tension along the apical dendrites of pyramidal cells keeps the cortex thin as it grows in volume. This radial anisotropy would make the developing cortex mechanically stiffer along the radial axis and would therefore lead to preferential expansion along the path of least resistance (in the tangential plane). Finally, tension associated with the pathways linking cortex with subcortical structures may keep cortex tightly shrink-wrapped around subcortical structures while having less influence on the specific pattern of folds.

Tension-based cortical folding provides a plausible basis for understanding species differences in folding patterns, as well as individual differences within a species. Alternative models of cortical folding have been proposed (Richman *et al.*, 1975; Smart and McSherry, 1986; Welker, 1990), such as the hypothesis that differential growth of superficial versus deep layers causes buckling of the cortex, but they do not easily account for the specificity of folding patterns. The remainder of this article will focus on evolutionary comparisons that are predicated on tension-based cortical folding.

4.16.4 Folding Patterns in Primates

4.16.4.1 Surface Representations

The diversity of cortical folding patterns in primates is illustrated in Figure 2, using surface reconstructions of the right hemisphere in a monkey (rhesus macaque), great ape (chimpanzee), and human (see also Sereno and Tootell, 2005). The chimpanzee MRI data came from the study of Rilling and Insel (1999), accessed via the fMRI Data Center (see 'Relevant Websites'). Each surface was generated from a structural MRI (top row, coronal slices) using the SureFit segmentation algorithm (Van Essen *et al.*, 2001); surface contours (blue) resulting from the segmentation are overlaid on the MRI slices. Lateral and medial views of the fiducial (3D) surfaces (middle and lower rows of Figure 2) reveal, as expected, progressively greater complexity in macaque, chimpanzee, and human cortex. The pastel colors indicate cortex assigned to different lobes; dark shading indicates sulcal (buried) cortex, determined using an automated method that is part of the SureFit segmentation process.

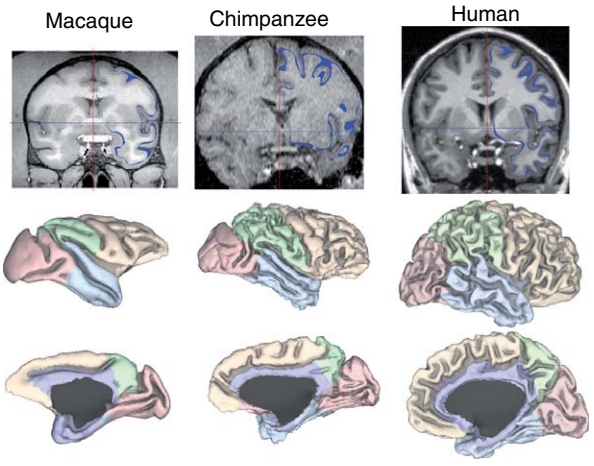

Figure 2 Structural MRI and surface reconstructions of three primate species. The quality of the chimpanzee structural MRI is considerably lower than that for the other species, but a high-quality fiducial surface reconstruction was nonetheless obtained with the aid of extensive manual editing. Data for this and following figures are available at the SumsDB database (see 'Relevant Websites'). The exact views seen in individual panels can be recreated using the scene selection option in WebCaret (no download required) or in Caret (data download required).

The fiducial surface of the macaque has a surface area of 108 cm^2. Chimpanzee cortex is about threefold greater in extent (317 cm^2), and human cortex is another threefold greater (960 cm^2; Van Essen, 2005a; see also Jouandet *et al.*, 1989; Tramo *et al.*, 1995; Van Essen and Drury, 1997). The percentage of buried cortex increases much more modestly (46% in the macaque, 54% in the chimpanzee, and 60% in humans). Regarding different lobes, the frontal lobe can be delineated most precisely and is also of intrinsically high interest. The frontal lobe occupies 26% of macaque cortex but is substantially more dominant in both the chimpanzee (34%) and human (36%), consistent with previous volumetric analyses (Semendeferi and Damasio, 2000).

To compare the arrangement of identified sulci in different species, it is advantageous to view inflated surfaces (with shallow sulci smoothed out) along with flat maps (Figure 3). The inflated surfaces are displayed in oblique dorsolateral and ventromedial views to better visualize the sulcal patterns. Each surface shows a map of sulcal depth, in which darker shades represent more deeply buried regions (i.e., more distant from gyral cortex that forms the cerebral hull). The far right column of Figure 3 shows a population average of 12 individual inflated human right hemispheres that were registered to the PALS surface-based atlas (Van Essen, 2005b). The average sulcal

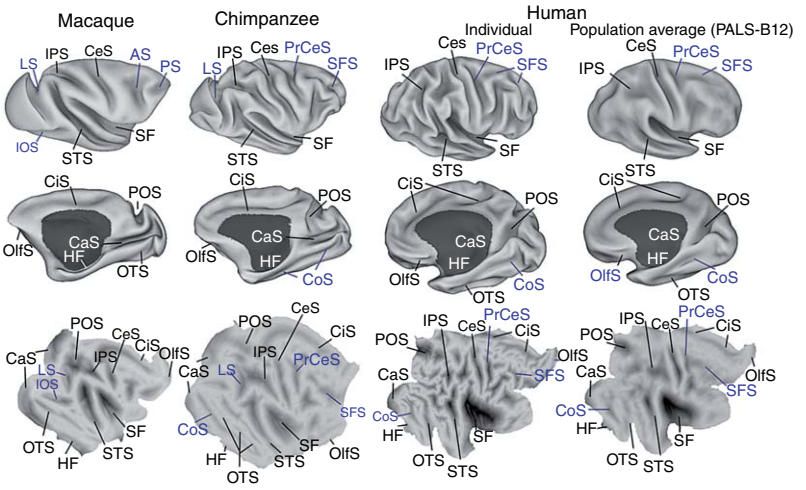

Figure 3 Sulcal depth maps for three primate species on inflated surfaces and flat maps. Inflated maps are viewed from a dorsolateral perspective in the top row and a ventromedial perspective in the middle row. Sulci common to all three species are labeled in black; sulci found in only one or two species are labeled in blue. Note that the posterior half of the occipitotemporal sulcus in the chimpanzee is located more medially than the human OTS and instead has a trajectory more like that of the collateral sulcus. Other examples of interspecies differences in geographically corresponding sulci are noted in the main text. PrCeS, precentral sulcus; SFS, superior frontal sulcus; CoS, collateral sulcus.

depth displayed on the PALS atlas is blurry in regions of high variability and has higher contrast in regions of low variability. Individual variability in the pattern of convolutions is well known to be much less in the macaque. In the chimpanzee, the degree of variability appears to be intermediate, based on visual inspection of published brain photographs and drawings (Holloway *et al.*, 2003; Gannon *et al.*, 2005).

4.16.4.2 Geographic Correspondences

Sulci that have a common location, orientation, and general shape in different species can be considered geographically corresponding. It is common practice in such cases to assign the same name, even though geographic correspondence does not imply that the sulci contain the same set of functional areas. Indeed, examples of functional noncorrespondence are discussed in Section 4.16.4.3.

Ten major sulci are present in all three species, based on geographic correspondence (Figure 3). Four of these are visible from the dorsomedial views in the top row of Figure 3: the central (CeS), superior temporal (STS), and intraparietal (IPS) sulci plus the Sylvian fissure (SF). Of these, the human IPS is the most variable across individuals (thus appearing blurred in the average sulcal depth map) and on average differs markedly from the chimpanzee and macaque. Six common sulci are visible from ventromedial views (middle row of Figure 3): the cingulate (CiS), parieto-occipital (POS), calcarine (CaS), occipitotemporal (OTS), and olfactory (OlfS) sulci, plus the hippocampal fissure (HF). Of the remaining four major sulci in the macaque, one (the lunate sulcus, LS) is prominent in both the macaque and chimpanzee but is typically absent in humans (and even when present is not prominent). The remaining three are the inferior occipital (IOS), arcuate (AS), and principal (PS) sulci, which cannot be unambiguously identified in either chimpanzee or human cortex (see below). The collateral sulcus is prominent in the chimpanzee and human, but is absent in the macaque.

Table 1 Size of individual sulci as percent of total cortex

Sulcus	*Macaque*	*Chimpanzee*	*Human*
Superior temporal	7.9%	5.9%	4.0%
Sylvian fissure	6.8	6.5	9.2
Calcarine	6.7	3.2	1.8
Intraparietal	4.0	3.3	3.8
Cingulate	2.5	3.0	3.4
Central	2.4	4.1	3.1
Parieto-occipital	2.1	2.7	2.1
Hippocampal fissure	1.9	0.5	0.4
Occipitotemporal	1.6	0.5	1.7
Olfactory sulcus	0.07	0.1	0.5
Total surface area	108 cm^2	317 cm^2	960 cm^2

Table 1 shows the size of each sulcus as a percentage of total cortical surface area and reveals marked interspecies variability in the relative sizes of sulci. Most notably, the STS is the largest sulcus in the macaque (8% of fiducial surface area), slightly larger than the SF (7%), and several times larger than the central sulcus (2.4%). In contrast, the STS in humans (4%) is less than half the size of the SF (9%) and is only about one-third larger than

the central sulcus (3%). Results for the chimpanzee are intermediate, as the STS (6%) is slightly smaller than the SF (6.5%) and half again larger than the central sulcus (4%). The STS extends more dorsally relative to the SF in the macaque than it does in humans, consistent with its greater relative size. The calcarine sulcus is also notably variable. It is the third largest sulcus in the macaque (7%, slightly smaller than the SF), whereas it is the sixth largest (3%) in the chimpanzee and the tenth largest in humans (2%). The calcarine sulcus also varies in shape, having a characteristic T-shaped posterior bifurcation in the macaque and chimpanzee that is lacking in humans.

4.16.4.3 Relation between Folds and Cortical Areas

A central issue in understanding the significance of cortical folding is the degree to which geographically corresponding sulci (sharing a common name) also correspond functionally (i.e., contain a similar collection of cortical areas). Reasonably good functional correspondences are demonstrable for a few sulci, such as the central sulcus (which contains somatosensory area 3 and motor area 4) and the calcarine sulcus (which contains area V1). The situation is more complex for the Sylvian fissure, which contains primary auditory and gustatory areas in both humans and macaque. In view of its larger relative size, the human Sylvian fissure may contain many areas that are absent in the macaque. For some sulci, such as the STS discussed below, the mismatch between geographic and functional correspondence may be even more severe.

Before discussing additional specific examples, it is useful to note that in general our understanding of the identity and arrangement of distinct cortical areas remains fragmentary in all primate species, even the intensively studied macaque monkey. The total number of distinct cortical areas in the macaque may be around 100 (Lewis and Van Essen, 2000; Van Essen, 2004). However, a reasonable consensus regarding areal identity and location exists for only a minority of these candidate areas; for most of parietal, temporal, and prefrontal cortex, several competing partitioning schemes remain in widespread use. In the chimpanzee, there are very few studies of cortical partitioning schemes for using modern architectonic approaches to reassess the classic partitioning scheme of Bonin and Bailey (1950). In humans, the total number of cortical areas may be substantially larger than in the macaque (perhaps as many as 200), but for most regions of cortex, there are major uncertainties regarding the basic layout of areas (Van Essen, 2004, 2005a). Human visual cortex shows striking similarities to the macaque in the topographic organization of early areas (especially V1–V3 and middle temporal (MT)) but pronounced species differences are evident in several nearby visual regions (Grill-Spector and Malach, 2004; Van Essen, 2004, 2005a). In general, speculations about candidate homologies between macaque and human are fraught with uncertainty and controversy for most regions of cortex.

Despite these caveats, interesting comparative insights can nonetheless be gleaned by focusing on a few select regions and areas of occipitotemporal, parietal, and frontal cortex. In each of these regions, current evidence points to major differences between macaque and human cortex in terms of functional organization and relationship of function areas to folding patterns.

If cortical connectivity patterns are the primary determinants of cortical folding patterns, is it possible to work backward and infer the arrangement of cortical areas and their connections by precisely analyzing the exact pattern of cortical folds? Unfortunately, finding the inverse solution is not feasible, as many possible connection patterns could give rise to virtually identical folding patterns. Nevertheless, analysis of folding patterns does provide some constraints on what are the most likely general connectivity patterns. In this regard, it is useful to include the chimpanzee in a discussion of relationships between areas and folding patterns despite the paucity of direct evidence about its functional organization.

4.16.4.3.1 Gyral folds along the V1/V2 border V1 is the largest cortical area in the macaque, occupying 10 cm^2 (10% of neocortex). In the chimpanzee, V1 is more than twice as large as in the macaque (25 cm^2) and thus nearly as large in percentage size (8%; see Figure 4 legend for details). Human V1 is about the same absolute size as in the chimpanzee (24.0 ± 4.9 cm^2; range 14.4–33.6 cm^2, Andrews *et al.*, 1997; 21 cm^2, Stensaas *et al.*, 1974) and thus is much smaller in percentage size (average 2.5%). In macaque and human cortex, neighboring area V2 is nearly as large as V1 and has a mirror-symmetric topographic organization (Van Essen *et al.*, 1986; Dougherty *et al.*, 2003), so it is likely that these characteristics also apply to chimpanzee V2. In the macaque and other primates where connectivity has been studied, V1 and V2 are powerfully interconnected (Felleman and Van Essen, 1991); it seems likely that this generalizes to humans and great apes.

The perimeter of area V1 runs along a largely continuous gyral ridge in all three species (Figure 4). In the macaque (Figures 4a and 4d), this gyral ridge adjoins five major sulci (the calcarine, parieto-occipital, lunate, inferior occipital, and occipitotemporal sulci). The pattern is similar in the chimpanzee, except for the absence of an inferior occipital sulcus (Figures 4b and 4e; see also Holloway *et al.*, 2003). In humans, V1 is largely contained within the calcarine sulcus (Figure 4c) and the surface area of V1 is correlated with the size of the calcarine sulcus in different individuals (Andrews *et al.*, 1997). The absence of a prominent lunate or inferior occipital sulcus (Figure 4f) is thus correlated with the more restricted relative extent of human V1.

In all three species, folding of occipital cortex in general brings topographically corresponding loci in V1 and V2 into close proximity. Hence, it is indicative of compact wiring in this region, and it is consistent with tension-based cortical folding. The interspecies differences in folding in this region may reflect differences in connectivity and/or organization of nearby extrastriate areas.

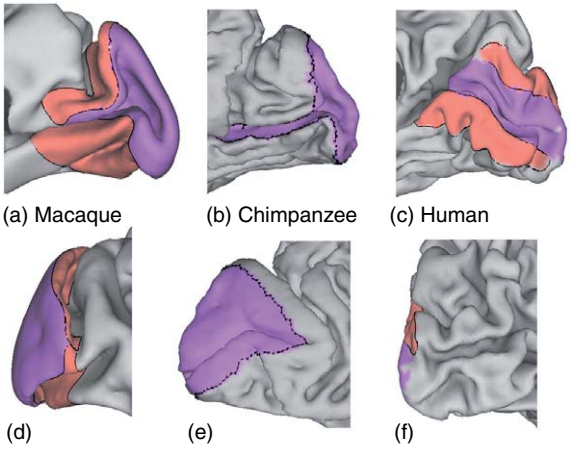

Figure 4 Relationships of areas V1, V2, and MT to folding patterns. For the chimpanzee, V1 was drawn on the surface map based on selected histological sections illustrated by Holloway *et al.* (2003).

4.16.4.3.2 Area MT and a functional mismatch in the STS MT is a small visual area that has been identified in many primates by its distinctive myeloarchitecture and/or functional specialization for motion processing (Born and Bradley, 2005). In the macaque, MT is located on the posterior bank of the STS (red in Figures 5a and 5d), whereas in humans MT+ (MT plus part of the medial superior temporal (MST) complex) is situated several centimeters posterior to the STS (Figures 5c and 5f). The more posterior location of human MT may in part be attributed to the more medial disposition of V1 and the smaller relative size of the STS. However, it is also striking that the region between MT and primary auditory cortex (on the posterior bank of the Sylvian fissure, light blue in Figure 5) is greatly expanded in humans compared to the macaque (Van Essen, 2005a). This region, including the human STS, includes cortex involved in multisensory processing (Beauchamp, 2005) and in specialized processing for tool-related functions (Lewis, 2006). In the chimpanzee, cortical folding in lateral occipitotemporal cortex (Figures 5b and 5e) is similar to that in the macaque, with the STS lying immediately anterior to the lunate sulcus. Hence, it is plausible to suggest that chimpanzee MT may lie on the posterior bank of the STS (i.e., more like the macaque than the human location).

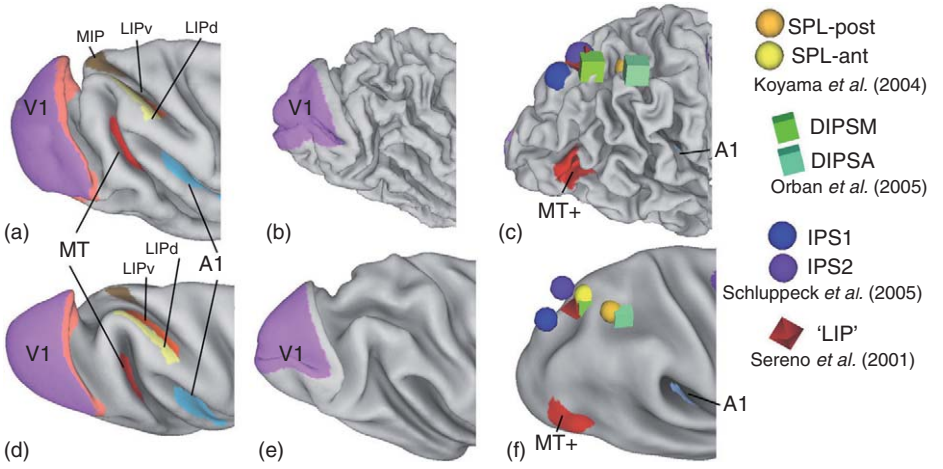

Figure 5 Relationship of selected occipitotemporal and parietal areas to folding patterns. SPL, superior parietal lobe; DIPSM, dorsal intraparietal sulcus area medial; DIPSA, dorsal intraparietal sulcus area anterior; LIP, lateral intraparietal area.

4.16.4.3.3 Parietal cortex and a functional mismatch in the IPS In the macaque, parietal areas associated with vision are located in the inferior parietal lobule, lateral and posterior to the fundus of the IPS. The most intensively studied parietal areas, LIPd and LIPv (Figures 5a and 5d, often considered together as LIP) can be activated during saccade and attention-shift tasks as well as by passive visual stimulation in both single-unit and fMRI studies. In human fMRI studies, a variety of vision-related tasks activate parietal cortex, but mainly the superior parietal lobule, medial to the fundus of the IPS. Figure 5c shows the stereotaxic coordinates for the centers of some of these regions, including attention- and delayed-saccade-related areas IPS1 and IPS2 (Schluppeck *et al.*, 2005; Silver *et al.*, 2005); saccade-related SPL-post and SPL-ant regions (Koyama *et al.*, 2004); attention-related area LIP (Sereno *et al.*, 2001); and motion-related regions DIPSM and DIPSA (Orban *et al.*, 2005). Most of these studies have suggested a potential homology between macaque areas LIPd/v and one or more of the vision-related regions identified in Figure 5. Given the complexity and diversity of these data, it is premature to argue strongly for a homology at the level of individual areas. Nonetheless, it seems plausible that the clusters of human and macaque parietal visual areas have a common evolutionary origin and are thus homologous at a regional level (Orban *et al.*, 2004). If so, an important implication is that the fundus of the IPS in the macaque (the boundary between visual and somatosensory domains) corresponds not to the human IPS fundus but rather to a more medial strip within the superior parietal lobule. This in turn would signify that cortex of the inferior parietal lobule has expanded disproportionately in the human lineage compared to the macaque. Morphologically, the chimpanzee parietal lobe is intermediate but arguably closer to the macaque pattern than to the human pattern (e.g., the postcentral sulcus is only modest in extent). Hence a plausible speculation is that the relative expansion of the human inferior parietal lobule occurred mainly after the split from the chimpanzee lineage.

4.16.4.3.4 Differential expansion of prefrontal cortex In the macaque, dorsal frontal cortex contains only two sulci (the arcuate and principal sulci) that run approximately orthogonally to one another (Figures 6a and 6d). The chimpanzee and human both have a much more complex folding pattern (commensurate with their larger relative size) that includes precentral and superior frontal sulci as well as major folds in dorsolateral prefrontal cortex.

The frontal eye fields (FEF) represent a key functional landmark for the frontal lobes, analogous in this respect to area MT in occipitotemporal cortex. In the macaque, FEF is centered in area 8 on the anterior bank of the arcuate sulcus (Bruce *et al.*, 1985); neuroimaging studies suggest that there may be two saccade-related foci plus a partially overlapping pursuit-related region (Baker *et al.*, 2006), but also that FEF may extend posteriorly into area 6 (Koyama *et al.*, 2004). In humans, several studies have identified FEF activations centered mainly in area 6 in and near the anterior bank of the precentral sulcus (Corbetta *et al.*, 1998; Koyama *et al.*, 2004; Hagler and Sereno, 2006; Figures 6c and 6f). Because the human precentral sulcus is much farther posterior in the frontal lobe than is the arcuate sulcus in the macaque, it suggests a disproportionate expansion of prefrontal cortex in

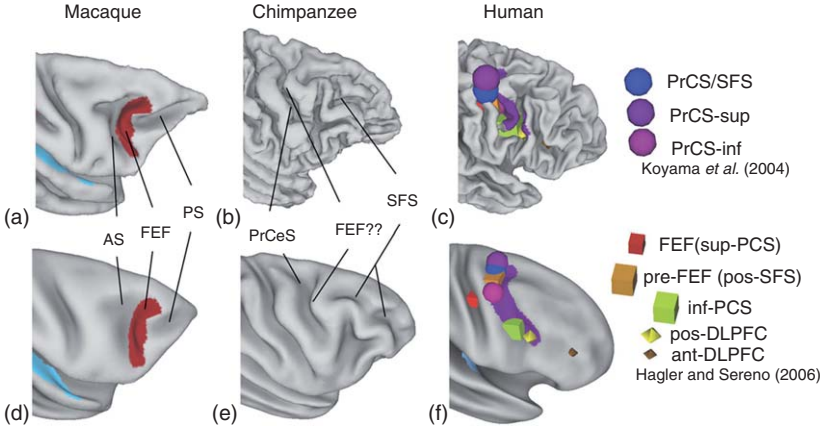

Figure 6 Relationship of selected frontal areas to folding patterns. PCS, PrCeS, and PrCS, precentral sulcus; DLPFC, dorsolateral prefrontal cortex.

humans (Van Essen *et al.*, 2005). Recently, Hagler and Sereno (2006) reported additional maps of visual working memory in more anterior regions (DLPFC in Figures 6c and 6f).

For the chimpanzee, one interesting hypothesis is that the expansion of the frontal lobe relative to the macaque occurred primarily in dorsolateral prefrontal cortex. By this scenario, the chimpanzee precentral and superior frontal sulci may be equivalent to the macaque arcuate and principal sulci, respectively, and the chimpanzee FEF may be located on the anterior bank of the precentral sulcus (identified as FEF?? in Figures 6b and 6e). However, this is only one of many plausible hypotheses regarding the evolution of frontal cortex in great apes.

4.16.5 Concluding Remarks

The central thesis of this article is that cortical folding may be a natural consequence of a tension-based mechanism for achieving compact wiring of cerebral circuits and that species differences in folding patterns can be related to the arrangement of cortical areas and their connections. While the discussion has focused on three representative primates, the hypothesis is generally applicable to all gyrencephalic primates. For example, cortical folding in the New World cebus monkey is remarkably similar to patterns in the Old World macaque even though their common ancestor was presumably lissencephalic (Rosa *et al.*, 2000). This type of evolutionary convergence could occur if brain size increased in both monkey lineages without dramatic changes in the mosaic of cortical areas. In other mammalian orders, there is great diversity in the general layout of cortical folds, suggestive of large differences in areal organization and connectivity.

Within a given species, it is well documented that the absolute size of a given cortical area can vary by twofold or more in the normal population (Andrews *et al.*, 1997). From the perspective of tension-based cortical folding, variability of this magnitude in the size of areas as well as connectivity patterns can account for variability in the pattern of folds, especially in balkanized regions where folding reflects competitive interactions among many small areas. In addition, specific neurological or psychiatric disease conditions such as Williams syndrome are associated with specific folding abnormalities that may reflect developmental effects on the size and/or connectivity of specific cortical areas (Van Essen *et al.*, 2006). In general, the mosaic of cortical areas and connectional patterns specified genetically and by early developmental interactions may be the primary determinants leading to a unique pattern of folds in any given individual.

The analyses illustrated in this article include qualitative evaluations based on simple visual inspection plus several quantitative measurements carried out on cortical surface models. Another useful strategy for interspecies comparisons involves surface-based registration between species, in which candidate areal homologies provide landmarks to constrain the registration. This allows the implications of any set of proposed homologies to be examined objectively, by assessing the alignment of geographic and/or functional data in intervening regions. Surface-based registration has been successfully carried out between macaque and human cortex using several combinations of candidate landmarks (Van Essen *et al.*, 1998, 2004; Astafiev *et al.*, 2003; Denys *et al.*, 2004; Orban *et al.*, 2005). The availability of chimpanzee surface models will allow the chimpanzee to be registered to both the macaque and the human atlas surfaces. Such comparisons will become of even greater interest if it eventually becomes feasible to carry out *in vivo* functional neuroimaging and/or postmortem architectonics on chimpanzees or other great apes.

As a final note, readers interested in viewing the data used in this study or in carrying out additional analyses can take advantage of the fact that all of the data sets are freely available in the SumsDB database (see 'Relevant Websites'). The data can be viewed online using the WebCaret visualization tools, without the need to download data or software. Alternatively, the data sets can be downloaded for visualization and analysis using Caret software.

4.17 Cortical Commissural Connections in Primates

R W Doty, University of Rochester School of Medicine and Dentistry, Rochester, NY, USA

4.17.1 Introduction

Following its appearance some half a billion years ago, bilaterality has been established as the organizational plan for the vast majority of animal life. This inevitably includes the brain, and the requirement for intercommunication of the right and left halves to achieve a unity of action (Doty, 2003). There is thus a deep evolutionary history of interhemispheric communication, and the forebrain commissures in primates reflect this stability. In their first-order anatomy, development, and characteristic sites of termination, they are typically mammalian. Aside from the variation with overall size of the brain, the primary organization of the primate commissures offers little to suggest evolutionary modulation. However, at the detailed level of the origin and termination of their intracortical components, there is substantial variance across primate species. These differences are also compounded, at least in macaques and humans, by a wide interindividual variance, to the degree that the pattern of callosal versus acallosal zones in the cortex of macaques has been characterized as a 'callosal fingerprint' (Van Essen *et al.*, 1982; see Figure 1). Here, evolution may be at work, but it will be an arduous task to delineate the species from the individual variation. Such analysis has only recently begun, so that designating species characteristics at the microlevel awaits much more extensive analysis than is presently available.

A review by Cumming (1970) traces the history of work and thought concerning the corpus callosum (CC) through the nineteenth and early twentieth centuries, and Tomasch (1954), in his landmark paper, provides a valuable appraisal of the state of knowledge of the corpus callosum (CC) just prior to the revolution wrought by the 'invention' of the split-brain procedure (Myers and Sperry, 1953). A number of other reviews will be helpful to provide a background for the present material (Doty and Negrão, 1973; Elberger, 1982; Cusick and Kaas, 1986; Innocenti, 1986; Aboitiz and Montiel, 2003).

4.17.2 Components of the Forebrain Commissural System

The forebrain commissures of primates consist of the CC, anterior commissure (AC), hippocampal commissure, and the basal telencephalic commissure (LaMantia and Rakic, 1990b). Evolutionary distinctions of primates versus other mammals are immediately at hand in this list since: (1) unlike the case in most eutherian mammals, where the AC is primarily an interhemispheric pathway for the olfactory system, in macaques, at least, the few olfactory fibers are concentrated in the basal telencephalic commissure, that abuts the anterior dorsal portion of the AC (LaMantia and Rakic, 1990b); (2) again, contrary to the case so far known in most mammals (Van Groen and Wyss, 1988), the dorsal hippocampal commissure has very limited connections to cornu ammonis, and instead includes substantial

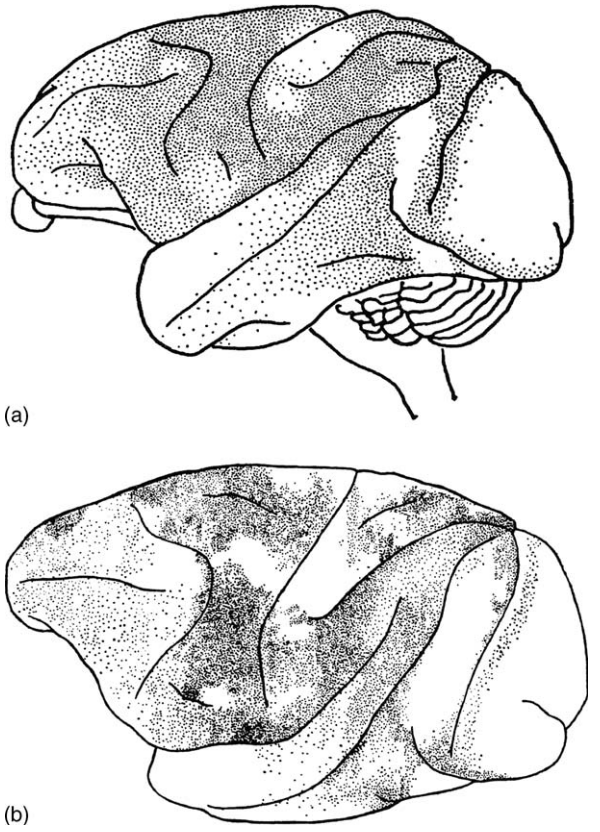

Figure 1 Two examples of the degeneration of terminals in macaque neocortex following total transection of the corpus callosum. The differences in (a) versus (b) can be ascribed not only to slight variation in procedures between the two laboratories, but to the uniqueness of the pattern between individual animals, as noted by Van Essen *et al.* (1982). The paucity of distribution to the inferior temporal lobe, however, is mostly attributable to its being the terminus for fibers of the AC. The degree and nature of the interdigitation between callosal and anterior commissural fibers remains to be determined, but there does seem to be some overlap. a, Reproduced from Myers, R. E. 1965. Organization of forebrain commissures. In: Ciba Foundation Study Group No. 20 – Functions of the Corpus Callosum (*ed.* E. G. Ettlinger), p. 142. Little Brown. b, Reproduced from Karol, E. A. and Pandya, D. N. 1971. The distribution of the corpus callosum in the rhesus monkey. *Brain* 94, 471–486, Oxford University Press.

connections from entorhinal cortex, presubiculum, and parahippocampal gyrus (Amaral *et al.*, 1984; Pandya and Seltzer, 1986; Demeter *et al.*, 1985, 1990).

Axons of the dorsal hippocampal commissure constitute only about 0.4% of the forebrain commissural total in macaques (*c.* 270000 fibers), the basal telencephalic commissure 0.3% (193000 fibers). This compares with 5.3%, 3.15 million fibers, in the AC, and 56 million in the CC (LaMantia and Rakic, 1990a, 1994).

In macaques, the hippocampal commissure lacks the ability to support interhemispheric transfer of learned visual discriminations. Two animals were prepared with CC, AC, and optic chiasm transected, sparing the hippocampal commissure (Rosene and Doty, unpublished observations). Intactness of the latter was confirmed by MRI and by retrograde axoplasmic transfer. One hemisphere was trained to distinguish a rewarded from a nonrewarded projected image, and the other hemisphere was then tested on its ability to learn the discrimination. In a series of 25 such discrimination tests, there was no evidence that the second hemisphere benefited from the learning by the first. In view of this failure to contribute significantly to interhemispheric visual transfer, and the small number of fibers composing the hippocampal and basal telencephalic commissures, they will be ignored in the remainder of this review, and the term 'forebrain commissures' will refer only to the CC and AC.

4.17.3 Evolutionary Stability of the Forebrain Commissures

Despite the differences just noted between primates and most eutheria, the CC and AC are highly similar across the mammalian order in their development and ultimate connections. Primates share with marsupials and other mammals four characteristic features:

1. In its fetal development, the human CC utilizes a series of proteins, for example, Robo/Slit, that hark back to the evolutionary origin of bilaterality and paired, symmetrical brains (Mineta *et al.*, 2003; Doty, 2003), a system that guides the commissural fibers in their 'six points of decision' as they migrate across the midline (Richards *et al.*, 2004; Ren *et al.*, 2004).
2. The forebrain commissures are unmyelinated at birth, progress gradually with myelinization as juveniles, but still leave a substantial proportion of interhemispheric fibers unmyelinated in adults.
3. Developmentally, the initial number of fibers is far greater than of those which ultimately survive ('exuberance').
4. Interconnection is avoided between one striate cortical area and the other.

4.17.3.1 Exuberance and Myelinization

In the marsupial wallaby, Ashwell *et al.* (1996) found that the total number of fibers in the AC and fasciculus aberrans peaked at about 63 million on postnatal day 148, and was down to 22 million in adults. Similarly, Berbel and Innocenti (1988)

report 67 million fibers in the cat CC at postnatal day 4, 32 million in adults. For macaques, the figures are 108 million fibers in the CC at birth, 56 million in the adult (LaMantia and Rakic, 1990a), and for the AC 11 million fibers becoming 3.3 ± 0.5 million in adults (LaMantia and Rakic, 1994). The phenomenon is dramatic in the tree shrew. Retrogradely labeled peristriate, CC neurons first become detectable at 7–9 days of age, peak in number by day 13, and 2 days later are reduced by 94% (Kretz and Rager, 1992).

This exuberant growth sends commissural axons into cortical areas and laminae from which they will ultimately be lost. Thus, the proliferation provides an inventory of fibers from which subsequent selective elimination sculpts the connectivity in the milieu of postnatal conditions (e.g., Innocenti, 1986; Shang *et al*., 1997). Indeed, there is a substantial body of studies examining how callosal connections are modulated by rearing conditions, lesions, etc. (e.g., Dehay *et al*., 1991; Meissirel *et al*., 1991; Sanchez *et al*., 1998; Reed *et al*., 2002). For the cat it has been shown that some of the neurons along the 17/18 border, that shed their CC axons during the postnatal period, survive to maintain intracortical association fibers (Innocenti *et al*., 1986).

Myelinization occurs postnatally, and has been followed electrophysiologically in cats as an increase in the complexity of the callosally evoked potential and its gradually diminishing latency (Grafstein, 1963). Myelinization, however, remains incomplete even in adults. Using electron microscopy, for the wallaby only 56–62% of AC fibers are myelinated (Ashwell *et al*., 1996). For the CC of the rat the figure is 54% (Seggie and Berry, 1972), rabbit 55% (Swadlow, 1985), cat 43–60% (Fleischhauer and Wartenberg, 1967; Koppel and Innocenti, 1983), macaque 70–94%, depending upon region of the callosum (LaMantia and Rakic, 1990b; Swadlow *et al*., 1980). For humans, with light microscopy and three brains of 50-year-old males, Tomasch (1954) estimated that the lowest proportion of myelinated fibers was in the genu, but the number, 60%, was little different from the remainder of the CC. He recognized that the histological procedure might have removed the myelin from fibers that were only lightly coated. Using electron microscopy on the brain of a 41-year-old human male, Aboitiz *et al*. (1992) found 84% myelinated in the genu, 95% elsewhere, that is, similar to the situation in macaques. On the other hand, the electron microscopic study of Olivares *et al*. (2001) on horse, cow, dog, cat, rabbit, and rat found a high degree of similarity for these species at about 70% myelinated in the splenium of young adults.

4.17.3.2 Avoidance of Striate Cortex

Striate cortex lacks interhemispheric connections in marsupials (Granger *et al*., 1985; Heath and Jones, 1971; Putnam *et al*., 1968; Sheng *et al*., 1990), as is true in most mammals. There is an exception in the case of species with laterally placed eyes, such as the tree shrew (Bosking *et al*., 2000), hedgehog (Gould and Ebner, 1978), squirrel (Gould, 1984), and rabbit (Swadlow and Weyand, 1981), where the CC makes homotopic connections with the striate representation of the ipsilateral visual field. The question has never been addressed as to what happens in these species when ocular vergence occurs, bringing different regions of visual space into correspondence. Interestingly, these CC connections ignore the orientation preference that characterizes later stages of intrastriatal processing (Bosking *et al*., 2000). Perhaps because primates have the largest binocular visual fields among mammals (Heesy, 2004), the decussation of the optic pathway is more complete, rendering this callosal input into striate cortex redundant, perhaps a true case of evolution in the primate callosal system. This singular absence of CC input to striate cortex in primates has been consistently noted, beginning with Beevor (1891) on the marmoset, van Valkenburg (1913), Clarke and Miklossy (1990) for human, and Bailey *et al*. (1941) for the chimpanzee. As shown in Figure 1, the finding is equally consistent in macaques (e.g., Curtis, 1940; McCulloch and Garol, 1941; Myers, 1962; Jacobson and Marcus, 1970; Karol and Pandya, 1971; Van Essen *et al*., 1982; Dehay *et al*., 1988; Chalupa *et al*., 1989), and squirrel monkeys (Gould *et al*., 1987). In the owl monkey, and particularly in galago (Newsome and Allman, 1980; Weyand and Swadlow, 1980; Cusick *et al*., 1984; Beck and Kaas, 1994), callosal cells and terminals are found farther into striate cortex, away from the representation of the vertical meridian, than in higher primates.

4.17.3.3 Other Acalossal Areas

A somewhat similar CC avoidance (Figure 1) is present for motor and somatosensory areas representing the hand and foot in primates, as well as other mammals (e.g., Karol and Pandya, 1971; Vogt and Pandya, 1978; Jones *et al*., 1979; Jones and Hendry, 1980; Killackey *et al*., 1983; Cusick and Kaas, 1986; Killackey and Chalupa, 1986; Rouiller *et al*., 1994; but see Iwamura, 2000). While striate cortex is the prime example of an acallosal cortical area, it and the distal extremities are by no means the only such areas. Indeed, the density of callosal cells and terminals varies widely

across the cortex, to give a patchy appearance in most mammals, including human (Clarke and Miklossy, 1990) and macaque (Figure1; Myers, 1962; Karol and Pandya, 1971; Cusick and Kaas, 1986). The variance in this pattern is so great that Van Essen *et al*. (1982), on the basis of the situation in macaques, propose that the distribution constitutes a 'callosal fingerprint' unique to each individual. The significance of these numerous acallosal regions in relation to those that receive forebrain commissural input remains essentially unexamined.

4.17.4 Protracted Course of Myelinization

As noted above, a rather large proportion of axons in the forebrain commissures remains unmyelinated. Yakovlev and Lecours (1967; Lecours, 1975), using the Weigert stain for myelin in human brains, found a continuing increase in CC myelinated fibers into the third decade. Data from MRI are consonant with this, a continuing increase in cross-sectional area of the human CC being seen from age 4 into the mid-20s (Giedd *et al*., 1996, 1999; Keshavan *et al*., 2002; Pujol *et al*., 1993; Rauch and Jenkins, 1994; Schaefer *et al*., 1990). Children were 2 years old before interhemispheric comparisons were behaviorally evident (Liégeois *et al*., 2000; see Primate Brain Evolution in Phylogenetic Context, Brain Size in Primates as a Function of Behavioral Innovation).

This exceedingly slow pace of myelinization presents something of a puzzle. What functional increment may be provided by the newly myelinated fibers, and how is this increment consolidated with existing circuitry? This problem is analogous to that of the continuing appearance of new neurons in the dentate gyrus throughout life (e.g., Kornack and Rakic, 2001), and possibly related through the generation of new oligodendrocytes. This protracted myelinization is not limited to the CC, but is seen in various cortical areas into the fifth decade (Kaes, 1907, cited by Lecours, 1975). The data of Aboitiz *et al*. (1996) are also compatible with an increase in fiber size and myelinization of the CC into middle age.

4.17.5 Laminar Organization and Regional Variance

Here is a point where evolution may enter, in the details of distribution of CC and AC cells and terminals. The variance exists not only in the commissural density from one to another functional area, but in the cortical laminae involved, and whether the projection is homo- or heterotopic. While a few examples are available, overall the data are far from sufficient to support any clear evolutionary theme.

Throughout the mammalian order, the primary site of CC and AC neurons is layer 3, with a sizable population in layer 5; and termination is typically directed to layer 4. The cells of origin are mostly pyramids, often slightly larger than adjacent cells forming ipsilateral connections (Innocenti, 1986). In macaque prefrontal cortex, the CC neurons have 34% and 25% longer apical and basilar dendrites compared to ipsilaterally projecting pyramidal cells, dendritic length being independent of whether the neuron lies supra- (75%) or infragranular (25%) (Soloway *et al*., 2002).

There is a clear tendency for grouping of the interhemispheric cells and terminations to form pseudocolumns (Bugbee and Goldman-Rakic, 1983; Cusick *et al*., 1984; Goldman-Rakic and Schwartz, 1982; Innocenti, 1986; Johnson *et al*., 1989; Jones *et al*., 1979; Schwartz and Goldman-Rakic, 1984). The CC connections that are homotopic are generally reciprocal, and tend to differ in their laminar locations compared to heterotopic projections. All this is well summarized and reviewed by Innocenti (1986). That heterotopic CC connections can be extremely diverse is shown by the example of fibers from a limited region of the right human inferotemporal lobe projecting into both Wernicke's and Broca's areas on the left (Di Virgilio and Clarke, 1997).

The ispi- and contralateral exchange between the ascending stages of visual processing in macaques provides a cogent illustration of the rich detail in such relations (Kennedy *et al*., 1986). 'Feedforward' connections are defined as those progressing from earlier to later stages of processing, and 'feedback' as occurring in the opposite direction; these exist for both ipsi- and contralateral projections. For instance, feedforward connections passing ipsilaterally from the border of striate cortex into area MT arise primarily from layer 3, with some input from layer 5, all projecting to layer 4. The ipsilateral feedback from MT to striate, on the other hand, arises primarily from layer 5, with some input from layer 3, and terminates in layers 3 and 6 of the striate cortex. Callosal input in the feedforward, heterotopic mode, from striate border to MT, is similar to that ipsilaterally: it too terminates sharply in layer 4 of MT, but arises exclusively from layer 3. The homotopic terminals of the callosal cells in the contralateral border area of the striate cortex avoid layer 4 contralaterally, and instead are limited to layers 3 and 5, rather similar to the ipsilateral feedback format. The heterotopic projections of the

callosal cells, also all in layer 3, forming the striate border and projecting into visual area 2, terminate much more diffusely, in all layers except 4, and strongly favor the cytochrome oxidase loci (see also Preuss and Kaas, 1996; Olavarria and Abel, 1996).

Distinct patterns are thus formed as to layer of origin and termination that depend upon the relations of the cortical areas involved. The pattern described by Kennedy *et al.* (1986) for macaques, as they discuss, differ from those found in New World monkeys and, particularly, from galago.

4.17.6 Subcortical Involvement

As is the case for marsupials (Heath and Jones, 1971), primates have extensive crossed connections between cortex and striatum, via the AC and fasciculus aberrans in the first and the CC in the latter. As is so far known, these crossed corticostriatal connections in primates emanate only from frontal and motor cortical areas, and seem to be absent from sensory areas (Jones *et al.*, 1977). For area 6, the contralateral projection to the putamen and head of the caudate nucleus is as numerous as is that ipsilaterally, with smaller contralateral numbers from area 8, and rare from area 4. All arise from lamina 5 (Jones *et al.*, 1977). McGuire *et al.* (1991) show that the ipsi- and contralateral projections are largely in register. They found that the CC projection from the area of the principal sulcus was weaker than ipsilaterally, but for the supplementary motor area (6?) and area 4 the density and extent of projection from the two sides were roughly equal, and directed mainly at the putamen.

There has been some dispute concerning the reality of crossed corticothalamic projections, but Dermon and Barbas (1994) have resolved this by showing that such connections proceed only from 'transitional' cortex, that is, cortex not being eulaminate in having six clearly developed laminae and a distinct layer 4. Thus, areas 13, 32, 24, and 25 have contralateral projections into ventralis anterior, medialis dorsalis, and the intralaminar nuclei. These crossed connections are reciprocated from these thalamic nuclei to the transitional cortex, but send no crossed connections to eulaminate cortical areas. It bears note that in the rat, Negyessy *et al.* (1998) demonstrated that these crossed corticothalamic fibers were primarily collaterals of the ipsilaterally projecting fibers.

Another instance of crossed projection can be found in the dorsal raphé. When striate cortex of macaques was unilaterally, but liberally, loaded with HRP, at any given level of the dorsal raphé 10–45% of the labeled neurons were contralateral to the injection (Doty, 1983). Thus, both sides of the raphé project to both striate cortices, but whether this is a case of collateralization remains to be examined.

4.17.7 Phrenology of the CC

The shape and area of the human CC in midline cross section is variable. The shape has been extensively studied, and assigned correlation with a rather wide number of variables, such as sex, various talents, handedness, and schizophrenia (see Smith, 2005). What is often overlooked is just how extreme the variation is, not just for the forebrain commissures, but for the human central nervous system generally. For instance, Andrews *et al.* (1997) demonstrated a twofold variation in the central visual system, commensurate at the different stages, for example, a small lateral geniculate nucleus was correlated with a small striate area. When examining the cross-sectional area of the human AC, Demeter *et al.* (1988) noted a sevenfold range, that was not related either to brain weight or cross-sectional area of the CC. Such variability in the AC may have a functional equivalent in that some patients undergoing transection of the CC, with sparing of the AC, can effect a degree of interhemispheric transfer of visual information, whereas others cannot (McKeever *et al.*, 1981), unlike macaques that have been uniformly capable of interhemispheric mnemonic transfer via the AC in the absence of the CC (Doty *et al.*, 1994).

A correspondingly large variation is found in the size of the human CC (e.g., Aboitiz *et al.*, 1996; Rauch and Jenkins, 1994; Jancke *et al.*, 1997; Giedd *et al.*, 1999). However, evidence for a clear sexual difference in form is often contradictory (Smith, 2005), although the midline cross-sectional area in human females is commonly smaller, corresponding to smaller average brain size. In a series of consecutive births of human males and females, 100 each, Hwang *et al.* (2004) found no gender differences in total area of the CC or its subregions. In line with many studies, Scamvougeras *et al.* (2003) observed a 1.5-fold variation in cross-sectional area for 14 monozygotic twins, twofold for 12 dizygotic twins, and concluded that heredity accounted for 94% of this size variance.

Even among eight macaques, the range is almost twofold, 55–95 million μm^2; but the smaller CC, from an animal only 2 years old, had 54.7 million axons, compared with the 17-year-old macaque with the largest CC that had only 36.9 million

(LaMantia and Rakic, 1990b). This, and other comparisons in their table, shows not only the great variation in area, but also that the area is not necessarily well correlated with the number of fibers.

4.17.8 Effect of Brain Size on the CC, and Its Consequences

As the number of neurons in a brain increases, and the neurons necessarily become farther apart, the volume devoted to the axons required to maintain a given level of interconnectivity between the neurons increases faster than does the volume devoted to the neurons *per se* (Ringo, 1991). The result is that the proportion of white versus gray matter increases as a function of brain volume, evident in a diverse series of primates including humans (Luders *et al.*, 2002; Rilling and Insel, 1999b; Striedter, 2005). This effect extends to the CC, where cross-sectional area is proportionately less the larger the brain, thus providing a clear example of evolution modulating interhemispheric connectivity (de Lacoste and Woodward, 1988; Olivares *et al.*, 2000; Rilling and Insel, 1999a; Striedter, 2005). Not only does the proportionate number of cross-connections diminish as the brain enlarges, the distance that they must traverse necessarily also increases. Thus, unless the diameter of the interhemispheric fibers were to keep pace with the greater distance in the larger brain, the time required for interhemispheric communication inevitably increases (Ringo *et al.*, 1994). The consensus is that the mean diameter of fibers in the CC is essentially constant among species (see Olivares *et al.*, 2001), and the average time for transmission across the CC must thus increase in step with size of the brain. In the human brain, this temporal delay for interhemispheric transmission offers a sufficient penalty that intrahemispheric computations are likely to be significantly more efficient than bihemispheric calculations, so that each hemisphere develops an intrahemispheric modus operandi, that is, hemispheric specialization reflects the solution to this problem (Ringo *et al.*, 1994).

It may be asked why the diameter of the CC fibers does not increase *pari passu* with size of the brain, but augmenting the diameter does itself require space that increases the distance for communication, etc. (Ringo, 1991). However, in so far as it has been examined, species with larger brains do have a few exceptionally large CC fibers that are absent in species with smaller brains. The best example is that of Olivares *et al.* (2001). In their series of rat, rabbit, cat, dog, cow, and horse, only the latter had a population of heavily myelinated fibers with a diameter of 1 μm or more in the splenium. A similar population of conspicuously large splenial fibers has also been observed in humans (Shoumura *et al.*, 1975) and macaques (Glickstein and Whitteridge, 1976), presumably subserving rapid integration of the two halves of the visual field.

It should be emphasized that whereas the temporal delay in interhemispheric communication with increasing brain size may be the root cause of hemispheric specialization, it has nothing to do with which hemisphere forms what manner of specialization. Handedness is a frequent index of hemispheric specialization, or dominance, in humans, but whether right or left need have no necessary relation to the forebrain commissures.

4.17.9 What Do the Forebrain Commissural Pathways Do?

4.17.9.1 Electrophysiology

The basic data derive almost entirely from experiments on cats and rodents. The classical observations of Asanuma and Okamoto (1959), on antidromically identified cells of the CC and pyramidal tract in the anesthetized cat, established that stimulation of the CC could inhibit the discharge of PT cells driven by peripheral nerve stimulation, after a latency of some 20–30 ms. Although subsequent work has shown that the vast majority of CC terminals are excitatory, disynaptic inhibition is a very common feature. Less than 1% of the CC fibers in the frontal areas of the cat and rat are GABAergic, the remainder being ostensibly glutamatergic (e.g., Conti and Manzoni, 1994; Fabri and Manzoni, 2004; Kumar and Huguenard, 2001; Cissé *et al.*, 2003).The functionally inhibitory influence of the CC is exemplified by the suppression that it exerts upon the discharge of units in V4 of macaques when the field of view impinges upon the visual field opposite to that activating the units (Desimone *et al.*, 1993). An inhibitory component remains a factor in the interpretation of many callosal effects. However, the details of the neuronal interplay in relation to the behavioral effect of the commissural influence remain largely unexplored, and beyond the scope of the present review.

4.17.9.2 Behavior

As is well known, it took a surgical trick, the split-brain preparation of Myers and Sperry (1953), to begin defining the behavioral contribution of the forebrain commissures. The ingenious feature was

to sever the optic chiasm, thereby allowing easy limitation of visual input to one or the other hemisphere, with subsequent complete or partial transection of the forebrain commissures to test the nature of interhemispheric communication. The loss of half or more of the visual input to each hemisphere in this procedure is commonly ignored and, so far as is known, is not relevant to the analyses performed. In split-brain patients (Gazzaniga *et al*., 1962), of course, the chiasm remains intact, and the addition of observations on humans greatly augmented the depth of understanding concerning interhemispheric communication (Doty, 1999).

A summary of this now vast literature cannot be attempted here but, instead, several examples are offered to suggest the range of the effects observed.

4.17.9.2.1 Transcortical monitoring by the amygdala This series of experiments in macaques (Figures 2 and 3) tested whether the amygdala in one hemisphere can communicate with the visual system of the other hemisphere across the splenium of the CC (Doty *et al*., 1973). Surprisingly, the result demonstrated that there is a continual intercomunication between these entities despite limitation of exchange to this restricted route, thus revealing a remarkable depth in the capability of interhemispheric processes.

Downer (1962) and Horel and Keating (1969) had already shown in split-brain macaques that the amygdala in one hemisphere could communicate commissurally with the visual system in the other. The procedure was thus modified to produce a blind hemisphere by severing the optic tract on one side, and surgically removing the amygdala in the other hemisphere (Figure 2; Doty *et al*., 1973). The forebrain commissures were then transected save for 5 mm of the splenium, around which a snare was placed. Macaques so treated retained an entirely normal reaction to the human presence, fleeing consistently and expertly when approached within a 3×5 m enclosure. When, however, under local anesthesia, the snare was pulled, transecting the remaining CC fibers and eliciting a blink, the animal was immediately transformed in its visual appraisal (Doty *et al*., 1973). Rather than fleeing the human presence, it endeavored to smell the approaching human hand (Figure 3), typical of the Klüver–Bucy syndrome (Bucy and Klüver, 1955). It struggled fiercely if seized, and leapt about the perches in the room with its previous agility. It is thus apparent that when only the splenium was intact, the 'seeing hemisphere', that lacked an amygdala, was continually in communication with the amygdala in the 'blind' hemisphere. The interesting question, still unapproached, is the direction of that interchange: whether the amygdala scans the activity callosally transmitted into its 'blind' visual system, or whether the signal crossing the splenium already contains the

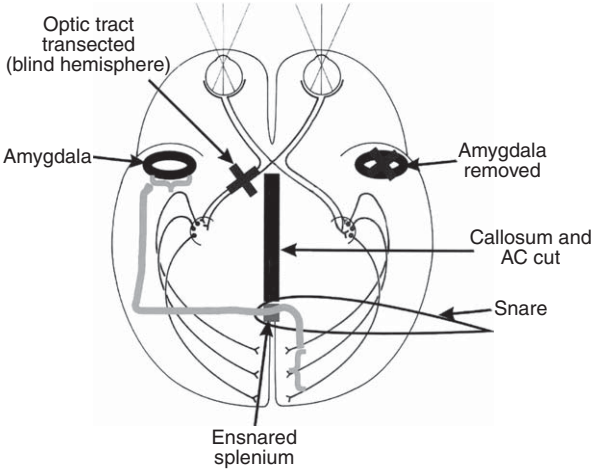

Figure 2 Schema for demonstrating the interhemispheric communication between amygdala and the cortical visual system in macaques. The amygdala has been removed on one side (also interrupting the AC), and the optic tract has been transected on the other, blinding that hemisphere. All of the CC has been cut save for 5 mm of the splenium, around which a snare has been passed. The thick gray line represents the putative path connecting the 'seeing' visual hemisphere with the contralateral amygdala. When the snare is pulled, transecting the remaining connections via the CC, interruption of that pathway then precludes the animal from visually judging the threat of human presence, that was fully manifest prior to pulling the snare (see Figure 3). Based on experiments of Doty, R. W., Negrão, N., Yamaga, K. 1973. The unilateral engram. *Acta Neurobiol. Exp. (Wars.)* 33, 711–728.

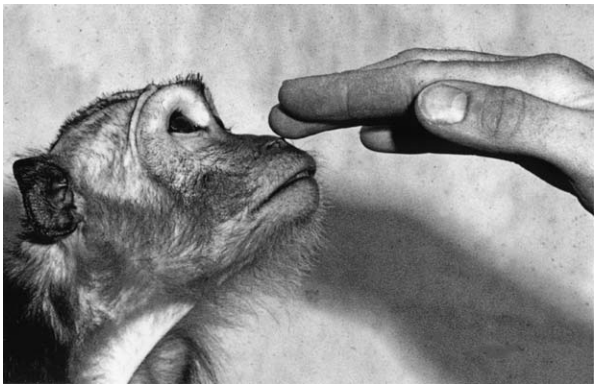

Figure 3 Macaque manifesting Klüver–Bucy syndrome a few minutes after interruption of the cortical visual–amygdalar interhemispheric path, as per Figure 2. Prior to this disconnection, the human hand would have been severely bitten, were it so available, in contrast to the olfactory exploration illustrated here. Visuomotor coordination retained its usual dexterity, in that the animal leapt skillfully from one perch to another, and were it touched or seized, it still reacted with full aggression and resistance. After Doty, R. W., Negrão, N., and Yamaga, K. 1973. The unilateral engram. *Acta Neurobiol. Exp. (Wars.)* 33, 711–728.

code for alerting the amygdala. The most remarkable feature remains the flexibility of the visual/emotional interhemispheric paths, that maintain a link that would seem to be redundant in normal circumstances.

4.17.9.2.2 Memory In everyday life, items are continually falling first within one visual field, and a moment later the next. The basic question is thus whether the memory traces formed by the input via one hemisphere/visual field are recognized in the other hemisphere/visual field, a process requiring interhemispheric transmission. Tested with a continuous series of words or intermingled nonverbalizable images, human subjects displayed essentially no differences in subsequent recognition regardless of which visual field or type of stimulus was used for the second viewing (Kavcic and Doty, 2002). At delays of 1–2 min, however, there was an interesting paradox. When words were first viewed via the left visual field/right hemisphere, they were subsequently better recognized via the right visual field/left hemisphere in these right-handed subjects, suggesting that the more secure linguistic memory trace had been established contralateral to the input, in the linguistically more facile hemisphere.

This question of which hemisphere actually holds the memory trace is difficult to assess, given the near-perfect efficiency of commissural communication and, in humans, the pronounced specialization of the individual hemispheres. It can, however, be addressed in macaques, where the commissural transmission can be blocked or eliminated. When intact macaques learned to respond to electrical excitation of striate cortex in one hemisphere, they unhesitantly responded to such stimulation of the contralateral striate cortex, so long as the AC or CC was intact (Doty *et al*., 1973). However, there was a dramatic dichotomy between the CC and AC in this regard. Using the 'snare' procedure alluded to above, it was arranged that only the splenium or the AC was intact during the training to excitation of striate cortex. In all the cases, the learned response was readily elicited from excitation of the contralateral striate cortex without further training. When the splenial snare was pulled, to complete the transection of the commissures, the response to contralateral stimulation was abolished, while excitation of previously untrained loci on the 'trained' side was unaffected.

The latter result encouraged the idea that the engram in this case was strictly unilateral, and suggested that the mnemonic role of the CC might be to restrict memory traces to a single hemisphere, thereby doubling the mnemonic storage capacity of the brain compared to that were engrams to be allowed bilaterality. So long as the commissures were intact, one hemisphere could activate the memory trace held unilaterally by the other. Unexpectedly, and still inexplicably, the situation was exactly the opposite on the nine animals in whom the AC remained intact during training, all of the CC having been severed (Doty *et al*., 1973). In this case, pulling the AC snare to complete the severance of the forebrain commissures had no effect upon the learned responses elicited by excitation of the contralateral, 'untrained' striate cortex, and they proceeded immediately upon first testing, without further training. Presumably, the critical difference lies in the fact that the AC serves the inferior temporal lobe, wherein an engram would have been induced from the input provided by the AC, but it would, of course, also have to be made accessible to the input via the 'untrained' striate cortex.

The unilateral engram via the CC may be unique to cases where the stimulus originates in the cortex, bypassing normal sensory pathways. Using normal visual input, Ringo (1993) demonstrated an unequivocal bilaterality of the memory trace. He used a delayed matching-to-sample task with split-chiasm macaques, retaining only AC or splenium of the forebrain commissures. Formation of or access to memory traces was restricted to one or the other hemisphere by mild tetanization of the corresponding medial temporal lobe during either the encoding or retrieval stages. If tetanization proceeded in opposite hemispheres during encoding and retrieval, performance was reduced to essentially chance levels. By manipulating the sequence of encoding and retrieving by the two hemispheres in relation to the tetanization, it could be shown that a unilateral trace was accessible from the other hemisphere. If only one eye/hemisphere viewed the target image, and during retrieval via the other eye/hemisphere the original hemisphere was tetanized, accuracy of retrieval was still above chance. Controls indicated that in the 5–10 s interval between encoding and retrieval the engram had in that case been passed to the initially nonviewing hemisphere, that is, created a bilateral engram. This was true with either the CC or AC.

A further example of mnemonic processing by macaques with split chiasm and possessing only the AC or the splenium for interhemispheric communication used memory for six visual targets, that were subsequently to be distinguished from nontarget items on each set of trials (Lewine *et al*., 1994). The critical point was that the target items were randomly distributed between (presented to) the hemispheres, as were the tests. So long as either the splenium or AC was intact, the hemispheric

distribution of targets and tests for accuracy was close to that of the intact animal, and, as expected, the reaction time was linearly related to the total number of targets held by the two hemispheres together. In other words, the commissures were extremely efficient in unifying the mnemonic load and the processing required. Once the commissures were totally severed, to produce a split-brain animal, the reaction time reflected the mnemonic load only of the hemisphere being queried; surprisingly, however, the accuracy of either hemisphere reflected the total mnemonic load held by the two hemispheres together.

This latter indication of subcortical participation in mnemonic processing was further examined in two split-brain macaques (Kavcic *et al*., 2000): first, to determine whether the two hemispheres could each acquire a memory trace when visual stimuli were presented to each simultaneously, and second, to assess the degree of hemispheric dominance when they were given a conflicting choice. Unexpectedly, it was found that when the two hemispheres viewed different images simultaneously, testing either hemisphere alone for recognition of 'its' image was consistently less accurate than when the repetition of the images was simultaneous and binocular. The interpretation follows that, while parallel processing by the two hemispheres is achieved at a high level, there is an additional factor. The binocularly acquired trace somehow predominates and, when one component is lacking upon monocular viewing, the distinction is noted as a less accurate match. Thus, even in the absence of the forebrain commissures, subcortical processes are in play to yield, in so far as possible, a bilaterally unified memory trace. Support for such supposition comes from observations by Marcel (1998) on human patients with unilateral loss of the geniculo calcarine pathway. When viewing Kanizsa illusory contour figures, part of which fell into the blind visual field, they nevertheless could make the appropriate decision as to the nature of the figure, amalgamating the subcortical component with that available through the intact side of their visual system. In other words, here too there was a unification of features available via bilaterally disparate channels, one of which required access at subcortical levels.

A further feature of subcortical exchange was displayed by the two split-brain macaques when consistently contradictory stimuli were employed (Kavcic *et al*., 2000). In the course of a running recognition task with colored images, the first viewing of an item, NEW, would be given to, say, the right hemisphere and, several trials later, that item would again appear for the right hemisphere, now as OLD, while simultaneously the left hemisphere viewed an item that for it was NEW. Prima facie, the situation is wholly ambiguous, one hemisphere cued to judge OLD, the other NEW. One animal 'solved' the situation by responding correctly to what the dominant hemisphere was viewing, gradually consolidating this behavior over the course of several days. The other animal remained confused. Throughout this testing period, it was the OLD stimulus that was always rewarded. The situation was then reversed, so that the stimulus always rewarded in this conflict situation was NEW. Over the course of some 200 trials, interspersed with other tests for several weeks, both animals were gradually able to effect a subcortical 'negotiation', whereby the hemisphere viewing an OLD image deferred 80% of the time to its mate if it was concurrently viewing a NEW image. This was achieved at some cost to accuracy, normally *c*. 90%, when the situation was such that both hemispheres were viewing an OLD image. There is thus a form of learning that can be effected between the hemispheres independently of the forebrain commissures. It is hypothesized that much of this interchange passes via the superior colliculus.

4.18 The Hominin Fossil Record and the Emergence of the Modern Human Central Nervous System

A de Sousa and B Wood, The George Washington University, Washington, DC, USA

Glossary

anatomically modern human — Hominin fossil evidence that cannot be distinguished from the skeletal remains of contemporary modern humans.

brain specific mass — The average density of the brain.

brain tissue volume — The volume of the brain itself (i.e., brain volume minus the volume of the CSF within the ventricles of the brain and the volume of any meninges and cranial nerves that may adhere to the brain).

brain volume — Usually defined as the sum of the volume of the whole brain (including the ventricles) plus the leptomeninges (i.e., the arachnoid and pia mater).

clade (Gk. clados = *Branch)* — A grouping of taxa that contains no more and no less than all the descendants of the group's most recent common ancestor.

encephalization (syn. cephalization, céphalisation) — The process by which, for a given taxon, relative brain size becomes larger than predicted from the general scaling relationship between brain size and body size.

encephalization quotient (EQ) — The ratio of the observed brain size over the expected brain size, based on a general scaling relationship.

endocranial cast — A natural or artificial cast that uses the walls, roof, and floor of the cranial cavity as a mold.

endocranial volume (syn. cranial capacity, endocranial capacity)	The volume of the endocranial cavity. This is the sum of brain volume plus the volumes of the meninges, the extracerebral CSF (i.e., the CSF outside the ventricles), the intracranial (but extracerebral) vessels, and the cranial nerves within the cranial cavity.
hominin (L. homin = *Man)*	Vernacular for a species (or an individual specimen belonging to a taxon) within the tribe Hominini (e.g., *Paranthropus boisei* is a hominin taxon and KNM-ER 1470 is a hominin fossil cranium).
meningeal vessels	The meningeal arteries and veins that supply blood to, and drain most of the blood from, the neurocranium and the dura mater.
petalia	The greater anterior, posterior, or lateral protrusion of one cerebral lobe relative to the other.
suture (L. sutura = *A Seam)*	Fibrous joint between two bones of the cranial vault. The fibrous tissue in these joints gradually disappears as the bones fuse together.
virtual endocast	3-D digital cast of the neurocranial cavity, created using 2-D computed tomography slices.

4.18.1 Introduction

This article focuses on what the fossil evidence for human evolution can tell us about the evolution of the modern human central nervous system (CNS). Its scope is the hominin clade, which extends in time from the hypothetical common ancestor of chimpanzees and modern humans, via the appearance of the first hominins (*c.* 8–5 Mya), to the emergence a little over 190 kya ago of anatomically modern humans. We use the term 'hominin' for modern humans and all extinct species that are more closely related to modern humans than to any other living taxon, and the term 'panin' for living chimpanzees and all extinct species that are more closely related to chimpanzees than to any other living taxon.

The first section reviews the ways in which the fossil and archeological records can be used to help reconstruct the CNS of extinct hominin taxa. The second section reviews the relationships of modern humans, and outlines the organization of the hominin fossil record. The third section reviews each of the fossil hominin species. It uses a relatively speciose hominin taxonomy, but it also indicates how the same fossil evidence would be arranged if it were grouped into a smaller number of more inclusive taxa. Brief descriptions of each taxon are provided. There are two reasons why this section concentrates on the craniodental evidence. The first relates to the relative durability of the hard tissues of the head and neck of higher primates. Because they are generally hard and dense, they tend to preserve in larger numbers than do the bones of the limbs and trunk. This means that most species are defined on the basis of a set of distinctive craniodental traits. The second reason is that because, in this article, we focus on how the quality and scope of the fossil evidence for each taxon can contribute to our knowledge about the recent evolutionary history of the modern human CNS, this inevitably means emphasizing the cranial evidence. The fourth section of the article summarizes trends in the evolution of the hominin CNS. It summarizes the differences between the CNSs of modern humans and chimpanzees, and makes predictions about the CNS of the common ancestor of chimpanzees and modern humans. It addresses, among others, the following questions:

1. When did hominin brain size begin to increase beyond the levels we see in contemporary nonhuman higher primates?
2. At what stages in hominin evolution do we see grade shifts in brain morphology?
3. Were changes in brain size and shape restricted to our own genus, or did they occur in other hominin genera?

4.18.2 How can Fossil Evidence Be Used to Reconstruct the Recent Evolution of the Modern Human CNS?

4.18.2.1 Fossil Evidence Relevant for Reconstructing the Size and Shape of the Brain

The biggest obstacle to understanding the evolution of the human CNS is that the CNS is not preserved in the hominin fossil record. However, inferences can be made about the size and shape of the CNS from natural endocasts, from the fossilized morphology of the neurocranium, the cranial base, and the axial skeleton. Endocasts and neurocranial fossils convey information about the size, shape, external convolutional morphology, and blood supply of the brain. Cranial base morphology contains information about the brainstem, and the cranial

nerves and blood vessels that perforate it. Finally, the neural canal conveys information about the spinal cord which extends in adult modern humans from the atlas (C1) to the first (usually) or second lumbar vertebras. Across primate species, the cross-sectional area of the vertebral canal provides an indication of spinal cord dimensions – particularly in its most rostral aspect, but less so more caudally where a greater proportion of the canal is devoted to spinal nerves (MacLarnon, 1995).

Although endocasts look remarkably brain-like, an endocast is not a fossil brain, but rather a cast of the neurocranial cavity. A natural endocast is formed during fossilization as the cranial cavity fills with fine sediments that enter through the various foramina and fissures that perforate the floor of the cranial cavity. Similarly, a synthetic endocast is made by stopping these perforations and then lining the inner surface of the endocranial cavity with quick-drying latex. Once dry, the thin layer of flexible latex can be peeled off the endocranial surface and removed through the foramen magnum. It is also possible to create a three-dimensional (3-D) digital cast of the neurocranial cavity, called a virtual endocast, and this has become the method of choice for investigating delicate and/or fragmentary fossils (e.g., Falk *et al.*, 2005; Zollikofer *et al.*, 2005). Endocasts potentially preserve details of the convolutional morphology of the surface of the cerebral and cerebellar hemispheres that are imprinted through the three layers of meninges (from outside in: the dura, arachnoid, and pia mater). In addition, endocasts preserve the imprints of blood vessels and skeletal sutures.

Convolutional details are not always well preserved. The differential imprinting of convolutional detail may be due to taphonomy, the relative size of the brain, and the effects of ontogeny. In general, natural endocasts produce more details than synthetic endocasts. Falk (1980a) proposed two explanations for this: (1) natural endocasts may begin to form before the dura mater has fully disintegrated, so that any details present on it, but absent on the endocranial surface of the inner table of the neurocranium, are preserved; and (2) synthetic endocasts are often produced from crania that have been reconstructed from fragments, and the process of reconstruction can introduce morphological noise. The relatively small-brained *Australopithecus* endocasts are usually more detailed than endocasts made from crania assigned to larger-brained later *Homo* taxa. It is noteworthy that, for various groups of mammals, those with the largest brains within that group tend to produce the least-detailed endocasts, although this pattern does not hold true for absolute brain size across major groups (Radinsky, 1972, p. 176). This is related to the fact that endocranial volume increases more rapidly than brain size increases within primates (Martin, 1990, pp. 365, 392). The intensity of gyral impressions is also related to ontogeny. In modern humans there are few or no impressions on the endocranial aspect of the cranial vault before 1 year (Du Boulay, 1956). Gyral impressions are probably most marked during adolescence, and with increasing age basal markings become more prominent whereas vault impressions become fainter (Connolly, 1950, p. 291).

The convolutional details of endocasts are notoriously difficult to interpret (Symington, 1916; Holloway, 1966). A feature might be the impression of a sulcus, or a blood vessel, or a skeletal suture, or it might be an artifact, and observers might offer genuinely different interpretations of what the same feature represents (Connolly, 1950; Falk, 1980a). For example, over the last three decades, Holloway and Falk have been providing often conflicting interpretations of the same endocasts. Only a handful of researchers study the details of endocast morphology, and both Falk and Holloway have called on other paleoanthropologists to join the debate (Falk, 1987; Holloway *et al.*, 2004a).

Not all researchers are convinced that the detailed morphology of endocasts has functional relevance. Many paleoneurologists take it for granted that sulci delimit functional or somatotopic cortical areas (see Radinsky, 1972, and references therein). However, it has become clear that the primate brain exhibits a substantial amount of intraspecific variability in sulcal anatomy and cytoarchitectural boundaries (Geyer *et al.*, 2001; Rademacher *et al.*, 2001). In some cases, the relationship between sulcal landmarks and functional areas is maintained within a species (Holloway *et al.*, 2003), but in others it varies within species (Sherwood *et al.*, 2003). It might not be possible to make detailed interpretations of brain function from endocasts alone.

Information about fossil hominin brain evolution is not limited to the hard-tissue fossil record. Natural endocasts are a form of trace fossil that record, often in unusual detail, the endocranial morphology of an individual. Archeologists also claim that artifacts reveal information about the evolution of the hominin CNS. Tools, art, and other artifacts found in association with hominin remains provide direct evidence of the capacity of a species for specific behaviors, something that fossils cannot reveal.

The combination of paleontological and archeological evidence provides more insight into the brain function of fossil hominins than either of these two lines of evidence could generate on their own.

4.18.2.2 Data Interpretation

In a specimen of an extant taxon, the size and shape of the brain can be estimated from either the brain itself or, indirectly, from cranial measurements. In a fossil specimen, measurements are taken from either an endocast (natural or synthetic) or from a fossil neurocranium. In general, the same measurement methods are used for endocasts and whole brains, and similar methods are applied to extant and fossil neurocrania. However, there are several reasons why data taken from contemporary taxa and data taken from fossil specimens might not be comparable and suggestions have been made to correct for the discrepancies.

First, it is important to appreciate that the volume of an endocast is the volume of the neurocranial cavity (i.e., endocranial capacity or endocranial volume). Endocranial volume includes not only the volume of the brain, but also the space occupied by meninges, extracerebral cerebrospinal fluid (CSF), and cranial nerves.

Second, all fossils, including endocasts and cranial fossils, are imperfect representations of the hard tissues they represent. Problems include incompleteness and plastic deformation. Incomplete fossils require that assumptions are made about the size and shape of the missing parts, and deformation may be difficult to detect when the form of the undeformed brain is unknown. Matrix can fill and widen cracks, expanding the size of the fossil beyond the size of the original bone. Virtual methods have recently been developed to correct for such deformation.

Third, even well-preserved fossils present sampling problems that affect interspecific comparisons. For example, we do not know the chronological age of individual fossils, yet if the individual is immature it may be necessary to estimate the size of the equivalent adult. However, ontogenetic age is difficult to estimate even in extant animals, let alone in a fossil species for which we will never have a satisfactory reference sample. In addition, sexual dimorphism may introduce substantial variation in brain volume within a species. In hominin species with a sparse fossil record, overrepresentation of a particular sex might give an inaccurate impression of the species' true mean and range of brain size.

4.18.2.3 Brain Size Measures and Estimates

The brain sizes of fossils can be obtained from a variety of methods that vary in their accuracy and precision. For example, de Miguel and Henneberg (2001) reviewed the brain size estimates for OH 5 cited in the literature and found that for this relatively complete *Paranthropus boisei* fossil cranium 15 different endocranial volume estimates are given ranging from 500 to 750 cm^3. Holloway (1983b) has devised a useful system for indicating the reliability of endocranial volume measurements which uses a letter code for the method used and a number code for the reliability of the measurement.

4.18.2.3.1 Measurements of the volume of a brain or of a solid endocast by water displacement The preferred way to determine the volume of a brain or an endocast, natural or artificial, is by water displacement according to Archimedes' principle. For extant species this is done using postmortem brains, but how well does this method measure brain size? For postmortem samples, one or more of the following confounding factors needs to be taken into account: time from death to measurement, time from death to fixation, fixation method and preparation prior to measurement, whether the leptomeninges and CSF are included, adequacy of dissection, and shrinkage. For example, what Stephan and others (Stephan *et al.*, 1970, 1988; Stephan, 1981) call brain weight includes meninges, hypophysis, and any nerves still attached to the brain (Heiko Frahm, personal communication). Similarly, the largest brain mass data sets for modern humans (Dekaban and Sadowsky, 1978) and chimpanzees (Herndon *et al.*, 1999) include leptomeninges and CSF in the brain mass estimates. Jerison (1973) estimates that the effect of including or excluding variables such as these can cause measurements to differ by as much as 20%.

Holloway *et al.* (2004a, 2004b) found that weighing the water displaced by an endocast was a more consistent method than measuring its volume. Volumes measured using artificial endocasts might be underestimates of the true volume because endocasts are likely to have undergone shrinkage (Gingerich and Martin, 1981; Broadfield *et al.*, 2001).

4.18.2.3.2 Measurements of the volume of the endocranial cavity

4.18.2.3.2.(i) Packing methods Packing methods involve filling the cranial cavity with small particles such as mustard seed, sintered glass beads, or shotgun pellets, and then determining the volume of the packing material. Different types of fillers can produce slightly different endocranial volume estimates (Miller, 1991). For fossil crania, packing methods are sometimes preferred over water displacement of a latex endocast because the problem of endocast shrinkage is avoided. However, because of

variation in techniques for settling the packing material, these methods almost certainly underestimate the true endocranial volume (Gould, 1978, 1996).

4.18.2.3.2.(ii) Filling methods Filling methods are like packing methods, but involve a fluid rather than a solid. Uspenskii (1954) describes a method in which a rubber balloon is put into the cranial cavity and then filled with water. Similar values (mean difference 1.67 cm^3) were obtained with this method and with water displacement, but packing with millet seed resulted in smaller (mean difference 65.4 cm^3) values than those obtained using the balloon method (Uspenskii, 1954).

4.18.2.3.3 Estimating volumes from slices

4.18.2.3.3.(i) Cavalieri's principle Using Cavalieri's principle, it is possible to produce an unbiased estimate of total brain volume from measurements of the cross-sectional area of a sample of brain sections (Stephan, 1981, p. 3; Gundersen and Jensen, 1987). Cavalieri's principle can be used to determine brain volume from actual and virtual brains. Serial sections of brains mounted onto slides undergo shrinkage as a result of fixation and embedding, so volume measurements determined from slide-mounted sections need to be corrected accordingly. In early papers, the effect of shrinkage was overlooked. Stephan (1981) advised researchers to generate an individual conversion factor (C_{ind}) for a brain with known mass and known volume:

$$C_{ind} = \frac{\text{Volume of fresh brain}}{\text{Serial section volume}}.$$

Stephan (1981, p. 4) list conversion factors for specific types of fixation, ranging from 1.54 to 2.4. Aside from mismeasurement due to shrinkage, the only disadvantage with using sections as opposed to water displacement is that the former estimates volume, rather than measuring it. However, what the estimate loses in precision it may gain in accuracy, since imaging makes it possible to be sure that only brain tissue is included.

4.18.2.3.3.(ii) In vivo *MRI* Magnetic resonance imaging (MRI) has recently begun to be applied to comparative samples of living hominoid species in order to obtain volumes of both entire brains and particular brain regions (e.g., Rilling and Insel, 1999; Semendeferi and Damasio, 2000; Sherwood *et al.*, 2004). Comparison of MRI volumes with volumes obtained by water displacement have established that as few as 5–6 MRI slices per brain are enough to yield reliable estimates of mean brain volume, with a coefficient of error (CE) of approximately 5% (Mayhew and Olsen, 1991). The CE decreases as the number of slices increases (e.g., for 28 slices, CE < 1%).

There are several advantages to using *in vivo* MRI volumes over autopsy brain volumes. *In vivo* MRI brain volumes avoid biases inherent to using autopsy brains; for example, autopsy brain samples overrepresent aged individuals. *In vivo* MRI volumes are not affected by changes in brain volume due to the elapsed time between death and measurement or fixation. Peters *et al.* (1998) compared the results of cross-sectional studies in which human brain volumes were obtained either *in vivo* by MRI (or nuclear magnetic resonance, NMR) or from autopsy brains. They found large discrepancies between the means of the different samples (even in cases in which the same method was used), but they did not identify the way in which the autopsy and MRI volumes differed.

4.18.2.3.3.(iii) Postmortem MRI Peters *et al.* (2000) compared estimates of brain volume obtained from MRI and from water displacement in autopsy specimens. They found that provided thin MRI slices (1–1.25 mm) were used, MRI volumes did not differ significantly from water displacement volumes. However, MRI volumes were found to be overestimates when thicker slices (5 mm) were used.

4.18.2.3.3.(iv) CT slices and virtual endocasts A widely applicable and noninvasive way in which to accurately estimate fossil endocranial volumes is by using two-dimensional (2-D) computed tomography (CT) slices. It is possible to use these slices to obtain an endocranial volume in two ways which yield similar results: (1) either directly using Cavalieri's principle, or (2) through the construction of virtual endocasts (e.g., Conroy *et al.*, 1998). Increasingly popular, a 3-D virtual endocast is a 3-D model of the fossil constructed from the 2-D CT slices (Zollikofer *et al.*, 1998; Tobias, 2001; Zollikofer, 2002). For matrix-filled skulls, thresholding to distinguish between local object densities is the method used to separate the walls of the fossil neurocranium from the matrix at their interface (Conroy and Vannier, 1985; Conroy *et al.*, 1990; Zollikofer *et al.*, 1998). Fragmentary specimens are completed using mirror-imaged parts from the opposite side (e.g., Conroy *et al.*, 2000a), or scaled parts from another specimen (e.g., Zollikofer *et al.*, 1998). Once the virtual cranium has been created (e.g., Zollikofer *et al.*, 2005), it is possible to create a

virtual endocast. If there is uncertainty about the dimensions, several potential endocrania are created to establish a range of endocranial volumes, from which a most likely endocranial volume can be determined (Conroy *et al.*, 2000b). The virtual endocast technique was tested on 10 *Homo sapiens* crania whose endocranial volumes were measured using a mustard seed filler; it was found that the difference between the measured and virtual endocast volumes was around 2% (Conroy *et al.*, 1998).

4.18.2.3.4 Measuring incomplete endocasts

4.18.2.3.4.(i) Partial endocast method Tobias (1964, 1971, p. 64) introduced a method for estimating endocranial volume. The method, which has become known as the partial endocast method, involves taking a complete endocast with known endocranial volume, reducing it to the anatomy preserved in the fossil of interest, and then determining what proportion of the complete endocast is represented by the reduced endocast. This provides a conversion factor to estimate complete endocranial volume for the specimen for which there is only a partial endocast. This method was originally used to determine the volume of OH 7, the type specimen of *H. habilis*, and its large endocranial capacity (estimated by the partial endocast method to be 675–680 cm^3; Tobias, 1964), was one of the reasons given for including the new taxon in the genus *Homo* (Leakey *et al.*, 1964). This spawned a debate revolving around the reliability and taxonomic implications of the original estimate, in which alternative methods to determine endocranial volumes from partial endocasts were suggested (Pilbeam, 1969; Wolpoff, 1969, 1981; Holloway, 1983d; Vaisnys *et al.*, 1984).

4.18.2.3.4.(ii) Reconstructed endocast method Synthetic and natural endocasts are typically reconstructed using plasticene to fill in missing areas. If only small parts of bilateral structures are missing on one side the necessary reconstruction does not require much guesswork. Holloway (1973, 1975) distinguishes between minimal plasticene reconstruction (method A) and extensive plasticene reconstruction involving close to half the total endocast (method B). Endocast reconstruction should be re-evaluated as additional fossils are discovered, and new, improved, methods should be applied to existing endocasts, not just to newly discovered evidence. Holloway's method involves making one endocast reconstruction based on comparisons with specimens belonging to the same hypodigm, or to members of different fossil hominin hypodigms (e.g., *P. robustus* and *P. boisei*) with brains that are similar in size and shape. Reconstructions made independently by different researchers provide a test of reliability. For example, the differences between the endocranial volumes of Holloway's (914 cm^3) and Broadfield's (921 cm^3) reconstructions of the Sambungmacan 3 calvaria are minimal (Broadfield *et al.*, 2001).

4.18.2.3.5 Extrapolations from ecto- and endocranial linear metrics

Several formulas have been suggested to estimate brain volume from linear dimensions of the endocranial cavity of crania, or endocasts. MacKinnon *et al.* (1956) compared linear measurements of the cranial cavity taken from radiographic images to mustard seed endocranial capacities for 52 modern human crania. They devised the following formula, which predicts endocranial volume with an error of 0.62% (0.87 cc in a 1400 cc cranium):

$$V = 0.51[1/2(LHW - LBW)],$$

where L is endocast length from frontal pole to occipital pole, W is maximum width (usually taken at the level of the superior aspect of the temporal), B is the distance from bregma to basion, and H is the distance from vertex to the deepest portion of the cerebellar lobes.

Holloway (1973, p. 450) applied this formula to endocasts, but he replaced the value of 0.51 with f, a variable determined for each taxon:

$$V = f[1/2(LHW + LBW)].$$

It is not advisable to calculate endocranial volume from external head or cranial measurements. Simmons (1942) found that crania with similar external perimeter measurements had different internal capacities, and Wickett *et al.* (1994) found that head perimeter measurements were not significantly correlated with total brain size. Bookstein *et al.* (1999) found that some of the factors responsible for the differences between the external and the internal cranial form were independent, so the inability of external head dimensions to accurately predict endocranial volume is not surprising. Further, there are particular problems with applying formulas designed for modern humans on fossil hominins. Formulas that have been developed to estimate modern human endocranial volume, such as those of Welcker (1885), Pearson (1926), and Manouvrier (1898), do not provide accurate estimations of the cranial capacity of fossils (Olivier and Tissier, 1975). Olivier and Tissier (1975) developed formulas specifically designed for archanthropians and paleoanthropians, but the fact that members of the taxon *H. heidelbergensis* fall into both

categories suggests that the reliability of this approach is dependent on having a satisfactory taxonomy.

4.18.2.4 Comparing Different Types of Measurements and Estimates

Brain size can be measured as a volume or as a weight (or mass). European authors tend to use weight whereas American authors tend use mass, but in most cases these terms are used interchangeably. For consistency we will refer to masses in grams (g) and volumes in cubic centimeters (cm^3).

4.18.2.4.1 Brain tissue mass from brain mass Measurements reported as brain mass from autopsy brains typically include the leptomeninges (i.e., the arachnoid and pia mater) as well as whatever CSF remains in the ventricles (Peters *et al.*, 1998). Volumes taken from MRI or stained sections measure brain tissue volume from which the volume of the meninges and the CSF are excluded (Peters *et al.*, 1998). This is comparable to the net brain volume calculated by adding up brain volumes for various brain components (e.g., Stephan, 1981). In modern humans, the meninges and CSF are estimated to contribute an additional 183 g for males and 132 g for females (Peters *et al.*, 1998). Thus, for male modern humans:

$$\text{Brain tissue mass (g)} = [\text{Brain mass (g)}] - 183,$$

and for female modern humans:

$$\text{Brain tissue mass (g)} = [\text{Brain mass (g)}] - 132.$$

4.18.2.4.2 Brain mass from brain volume For a sample of 78 adult human brains, the brain tissue was found to have an average specific mass of 1.032 g cm^{-3} (Zilles, 1972). Thus,

$$\text{Brain mass (g)} = [\text{Brain volume } (cm^3)] \times 1.032.$$

The specific mass of the brain has also been determined by comparing rodent brain weights with volumes to give an average specific mass of 1.036 g cm^{-3} (Stephan, 1960). Thus,

$$\text{Brain mass (g)} = [\text{Brain volume } (cm^3)] \times 1.036.$$

This suggests that brain mass is *c.* 3% larger than brain volume (but see Jerison's argument below).

4.18.2.4.3 Brain volume from endocranial volume Brain volume and endocranial volume (= cranial capacity) are not identical. Endocranial volume is larger as it also includes meninges, CSF, and cranial nerves. Few data are available for actual brain volume and endocranial volume from the same specimen because it is difficult to remove the brain from the brain case without causing damage to either. Novel imaging techniques could improve our understanding of this relationship, although in practice different techniques are used to visualize soft (MRI) and hard (CT) tissues.

Pickering (1930) found a correlation between nonfixed brain volume as determined by water displacement and endocranial volume measured with mustard seed in a sample of 29 modern humans, using the following conversion formula ($r^2 = 0.805$):

$$\text{Brain volume} = (\text{Endocranial volume}) \times 0.8598.$$

In other words, approximately 14% of the endocranial volume does not represent brain volume.

4.18.2.4.4 Brain mass from endocranial volume Count (1947) suggested a value of 0.876 g cm^{-3} for brain mass/endocranial volume, so that:

$$\text{Endocranial volume } (cm^3) = [\text{Brain mass (g)}] \times 1.14,$$
$$\text{Brain mass (g)} = [\text{Endocranial volume } (cm^3)] \div 1.14.$$

Ruff *et al.* (1997) used an equation that acknowledged the allometric nature of the relationship between endocranial volume and brain mass (see Martin, 1990). Ruff *et al.* derived brain mass from endocranial volume using a regression based on brain masses from Stephan *et al.* (1970) and cranial capacities from Martin (1990) for 27 primate species ($r^2 = 0.995$):

$$\text{Brain mass (g)} = 1.476 \times [\text{Endocranial volume } (cm^3)]^{0.976}.$$

Jerison (1973, p. 30) does not recommend converting endocranial volumes into brain volumes or brain masses. Apparently, the specific gravity of the mammalian brain ranges from 0.9 to 1.1; for example, brain mass (in g) is approximately 5% larger than endocranial volume in insectivores (Bauchot and Stephan, 1967), whereas brain mass (in g) is approximately 3% smaller than endocranial volume in a cat (Jerison, 1973).

4.18.2.5 Indices for Estimating and Comparing the Relative Sizes of Brains

The relationship of brain size to body size, analyzed by Snell (1891), was the basis of Dubois' index of

cephalization (Dubois, 1897), which related brain size to (1) body size and somatic functions, and (2) the encephalization of psychic functions. Jerison and Martin have further investigated the relationship between brain size and body size, and have made contributions to the most widely used measure of relative brain size, the encephalization quotient.

4.18.2.5.1 Encephalization quotient Some researchers (e.g., Jerison, 1973; Martin, 1990) do not consider absolute brain size to be an appropriate way to compare the mental capacities of different species. Nor is it useful to compare the brain/body ratio, because this ratio decreases with increasing body size. The solution has been to plot log brain mass on log body mass, from which is derived the allometric formula:

$$E = kP^{\beta},$$

where E is brain size, P is body size, k is the allometric coefficient, and β is the allometric exponent. It has been suggested that different taxonomic groups tend to have a similar value for β (reflecting a consistent functional relationship), but different values for k (reflecting different grades; Martin, 1981). This is usually expressed as the log-transformed linear equation:

$$\log E = \log k + \beta(\log P).$$

The key variable β is typically referred to as the scaling coefficient.

For all mammals, Jerison (1961, 1973) observed that the relationship between brain size and body size was described by the equation

$$\text{Brain mass} = 0.12 \times (\text{Body mass})^{2/3}.$$

Jerison developed Dubois' proposal for an equation to quantify encephalization (Dubois, 1897), and derived what he referred to as the encephalization quotient (EQ):

$$\text{EQ} = (\text{Brain mass})/[0.12 \times (\text{Body mass})^{2/3}].$$

Encephalization occurs when there is a departure from the general relationship between brain size and body size. Encephalization occurs in mammals and birds, but is rare in other vertebrates. Encephalization is explained by Jerison's (1973) additive theory of brain size: $E = E_v + E_c$, where E is brain size, E_v is brain size determined by body size, and E_c is associated with improved adaptive capabilities. According to his theory, if $E_c = 0$, then the brain is of a size sufficient for somatic maintenance. If one assumes there is a relationship between brain size and neuron number, and if $E_c > 1$, then the brain has extra neurons designated to deal with extracorporeal pressures. The presence of extra neurons is referred to as encephalization.

A scaling coefficient value of 2/3 (or 0.66) was suggested for several sets of mammals (Snell, 1891; Jerison, 1955, 1961, 1973; Gould, 1975), but a later study suggested that a scaling coefficient of 3/4 (or 0.75) is more appropriate (Martin, 1981). Based on this, Ruff *et al.* (1997) used the following equation to generate EQ in hominins:

$$\text{EQ} = \text{Brain mass}/[11.22 \times (\text{Body mass})^{3/4}].$$

A scaling coefficient of approximately 3/4 (i.e., 0.78) was also described for a comprehensive sample of primates (Bauchot and Stephan, 1969), although subsets of primates have a wider range of values. The scaling coefficient of nonhuman hominoids (i.e., the apes) is much lower (e.g., EQ = 0.58; Bauchot and Stephan, 1969).

4.18.2.5.2 Other standards for brain size comparison Although brain size is most often considered in relation to body mass, other standards for comparing brain size have been used. Some authors suggest that the scaling relationship between brain mass and body mass is a surrogate measure for some underlying variable (e.g., Harvey and Krebs, 1990). CNS or CNS-related standards of comparison are sometimes preferred because they vary less intraspecifically, and measure brain versus nervous system information flow. All standards have advantages and disadvantages.

Krompecher and Lipak (1966) were the first to suggest scaling brain size against the mass of another CNS structure (the spinal cord); subsequently, Passingham (1975) scaled brain mass to a CNS-related structure (the foramen magnum). The latter method has the advantage that it uses a hard-tissue structure that is occasionally preserved in the hominin fossil record. The absolute size of the spinal cord gives an indication of total neuronal input and output to the brain. In fact, an index of brain size to nonbrain CNS size provides a direct measure of Jerison's extra neurons. On the other hand, it has been suggested that body mass is better for use in scaling relationships precisely because, unlike the CNS or CNS-related structures, it is independent of brain mass (Stephan *et al.*, 1988). Radinsky (1967) suggested that foramen magnum area was a good estimate of body size, although it is less variable within a species than is body mass. However, others have suggested that foramen magnum area is linked more closely with brain size than with overall body size (Jerison, 1973; Gould, 1975; Martin, 1981). In fact, the relationship of the size of a

given CNS or CNS-related structure to body mass is variable. For example, the relationship between body size and foramen magnum/medulla size may be strongly influenced by specializations such as adaptation to water (Stephan and Dieterlen, 1982; Stephan and Kuhn, 1982).

Finally, it has been suggested that CNS structures make better standards because they vary less within a species than body mass does (Radinsky, 1967). One reason why body mass varies so much is that it comprises several components, including muscle mass and adipose tissue, which are themselves variable (Pitts and Bullard, 1968). Muscle tissue, which is well innervated, and other components of fat-free mass scale more closely to CNS mass than does the mass of the less well-innervated adipose tissue (Schoenemann, 2004). This finding has implications for certain questions about the scaling of brain size to body size. For example, the difference between male and female brain mass might be partially explained by the fact that male body mass contains proportionally more muscle (Manouvrier, 1903; Ankney, 1992; Gould, 1996). Along these lines, when scaled to fat-free mass, it has been suggested that the very muscular Neanderthals would have much smaller relative brain size than would modern humans (Schoenemann, 2004).

4.18.2.5.3 Measure of brain organization: A/S ratio Scaling brain size to other appropriate parts of the CNS gives a direct indication of the size of the brain in relation to the amount of input and output. Hebb (1949) advocated replacing brain/body size comparisons with an A/S (association cortex/primary sensory cortex) ratio, since the primary sensory areas are related to input from an animal's surroundings, whereas association areas are involved in higher-level cognitive processing. This procedure is also advocated by Holloway, who discussed in detail the problems associated with basing intelligence on brain/body size relationships (Holloway, 1968, 1979; Holloway and Post, 1982).

4.18.2.6 Major Lines of Fossil Evidence for CNS Evolution, Plus Other Endocranial Morphology

Particular attention is paid to fossil anatomy that can be used to make inferences about the functional anatomy of the CNS. In addition, non-CNS related aspects of endocranial morphology are included.

4.18.2.6.1 CNS-related fossil evidence The categories described below are the major lines of evidence that can be used to infer CNS evolution from the hominin fossil record. Their comparative contexts are data from extant primates from the endocranium and brain, and from the vertebral column and spinal cord. There is a dearth of data about the CNS of extant hominoids, so most inferences should be treated as preliminary. The extant hominoid data tend to be based on very small samples (e.g., one or two individuals per species, and often the same individuals are used in several studies), and, with respect to the cerebral cortex, rely on gross morphological landmarks as proxies for functional regions (see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates).

4.18.2.6.1.(i) Absolute and relative brain size Sample mean EQs are calculated using the formula of Ruff *et al.* (1997), which is based on Martin (1981), and using the calculation for estimating brain mass from endocranial volume of Ruff *et al.* (1997), based on Martin (1990). A list of endocranial volumes used here is available from the authors upon request; mean body mass estimates are from Skinner and Wood (in press). For more information, see Section 4.18.2.5.1.

4.18.2.6.1.(ii) Left occipital right frontal (LORF) petalia This asymmetrical pattern, with a wider and more posteriorly protruding left occipital pole, and a wider right frontal lobe, is typical of modern humans, and is statistically significantly related to right-handedness; that is, left-handed and ambidextrous people are more likely to be symmetrical or have the opposite pattern (Le May, 1976). Although petalias are also common in great apes (Le May, 1976; Le May *et al.*, 1982), they are less frequent than in humans and rarely involve both the frontal and the occipital lobes (Holloway and de Lacoste-Lareymondie, 1982).

4.18.2.6.1.(iii) Orbital surface of frontal lobe The orbital surface of the frontal lobe is blunt and expanded in modern humans. In contrast, it is beaked and pointed in African apes. This region corresponds to cytoarchitectural area 10, which is involved in planning future actions, abstract thinking, and undertaking initiatives (Semendeferi *et al.*, 2001). A regression of nonhuman primate area-10 volumes against brain volumes shows that humans have a larger than expected area-10 volume, but the residual (6%) is less striking than for other regions (Holloway, 2002).

4.18.2.6.1.(iv) Fronto-orbital sulcus The fronto-orbital (or orbitofrontal) sulcus typically incises the orbitolateral border of the frontal lobe of African apes, but is rarely present on modern human brains (Falk, 1980b). Due to the opercular

expansion of the frontal lobe in humans, this sulcus has probably been shifted so far posteriorly that it now comprises the anterior limiting sulcus of the insula, giving modern human brains a distinctly shaped lateral edge of the frontal lobe (Connolly, 1950, p. 330). The human frontal lobe (Semendeferi *et al.*, 1997; Semendeferi and Damasio, 2000) and its cortex (Semendeferi *et al.*, 2002) have volumes expected for an ape of similar brain size. It has been suggested that the human prefrontal cortex is larger than expected for a primate with a similar sized brain (Deacon, 1997), and that it has a higher than expected white/gray matter ratio (Schoenemann *et al.*, 2005), but these inferences are not reliable (Semendeferi *et al.*, 2002; Sherwood *et al.*, 2005). Note, however, that even if the frontal lobe did not become relatively larger, it is still possible for the prefrontal cortex to become relatively larger within it.

4.18.2.6.1.(v) Broca's cap region Broca's cap as seen on endocasts represents portions of Brodmann areas 47 and 45 (Broadfield *et al.*, 2001). Broca's cap overlaps with (but does not exactly correspond to) Broca's language area. Broca's area corresponds to the Brodmann cytoarchitectural areas 45 and 44 (respectively, 'pars triangularis' and 'pars opercularis' of the inferior frontal gyrus) (Aboitiz and Garcia, 1997). In the majority of modern humans, the left hemisphere is dominant for language (see The Evolution of Language Systems in the Human Brain), and Broca's region on the left hemisphere is asymmetrically enlarged in comparison to the contralateral areas 45 and 44 (Amunts *et al.*, 1999). Although an enlarged Broca's cap is a characteristic of modern humans, it does occur, albeit more rarely, in apes (Holloway, 1996). Questions persist about whether the African ape Broca's area homologue exhibits modern humanlike asymmetry (Holloway, 1996; Cantalupo and Hopkins, 2001; Sherwood *et al.*, 2003). Investigators have drawn attention to modern humanlike Broca's cap asymmetry in fossil hominin endocasts, in particular to those specimens in which the left side is larger than its homologue on the right. They also describe overall size and convolutional detail, particularly in fossils where only one hemisphere is present. Because an asymmetry in which the left Broca's area is larger than the right (L > R) is related to right-handedness is a characteristic of most modern humans, attention is drawn to cases in which Broca's area L > R asymmetries are found along with LORF L > R asymmetries.

4.18.2.6.1.(vi) Temporal poles Modern human endocasts have anteriorly expanded, laterally pointed temporal poles (Falk *et al.*, 2005), in contrast to African apes, which have rounded temporal poles. In modern humans, the anterior lateral temporal pole, particularly in the left hemisphere, is involved in human face recognition and naming (Damasio *et al.*, 1996; Grabowski *et al.*, 2001). The corresponding monkey area, TG, also functions in visual learning and recognition (Horel *et al.*, 1984; Nakamura and Kubota, 1995).

4.18.2.6.1.(vii) Lunate sulcus

4.18.2.6.1.(vii).(a) Primary visual cortex reduction The lunate sulcus (LS) is within the secondary visual area, close to the anterior border of the primary visual cortex. Modern humans have a more posteriorly located primary visual cortex than do the great apes. Most modern human brains lack an LS, but when present it is situated more posteriorly than it is in the great apes. A regression of occipital lobe volumes against mean brain volumes from small samples of diverse primate species suggests that modern humans have substantially less (−121%) primary visual cortex than expected for a nonhuman primate of similar brain size (Holloway, 1992). Although chimpanzees typically have a relatively larger primary visual cortex than do modern humans, a minority of chimpanzees show repositioning of the LS to a more modern humanlike posterior position (Holloway *et al.*, 2003). Holloway *et al.* (2003) used this point to argue that the hypothetical panin–hominin common ancestor must also have had within its population individuals with reduced primary visual cortices, so you would expect this condition in early hominins such as *Australopithecus afarensis*. The LS may be unique among the cortical sulci visible on endocasts in that it might provide information about the proportion of cortex allocated to distinct functional categories, and provides an estimate of the aforementioned ratio of association to sensory cortex (Holloway, 1966, 1968).

4.18.2.6.1.(vii).(b) Parietal expansion The posterior location of the LS indicates relative reduction of the primary visual cortex and relative expansion of the posterior parietal association cortex. The posterior parietal lobe is concerned with several aspects of sensory processing and sensorimotor integration (Lynch, 1980; Hyvarinen, 1981). The superior parietal lobule subcomponent is involved in visuomotor tasks, including finger movements (Shibata and Ioannides, 2001). The inferior parietal lobule subcomponent is involved in language and calculation abilities, and it is greatly expanded in humans compared to monkeys (Simon *et al.*, 2002). Derived modern human behaviors involving the posterior

parietal lobe include enhanced social behavior, including communication, tool-making, and tool use (Holloway *et al.*, 2004a). Bruner *et al.* (2003) suggested that the unique globular shape of the neurocranium of *H. sapiens* is related to an additional expansion of the parietal lobe in modern humans. Bruner (2004) associated the manufacture of more sophisticated tools and refined language ability with this difference.

4.18.2.6.1.(viii) Posterior cranial fossa A cerebellar quotient (CQ = actual/predicted value) was obtained when recent modern human cerebellar volume (determined from posterior cranial fossa volume) was regressed against brain volume (determined from endocranial capacity) minus cerebellar volume (Weaver, 2001, 2005). Extant hominoid brain data suggest that the modern human cerebellum is smaller than would be expected for an ape of similar brain size (Rilling and Insel, 1998; Semendeferi and Damasio, 2000). The difference between modern human and great ape relative cerebellar volumes is statistically significant, although less dramatic when considered along with the range of inferred relative cerebellar volumes found within the hominin fossil record (Weaver, 2005). The cerebellum of modern humans is relatively larger than that of some earlier hominins, perhaps because its size is linked to the complexity of cognitive functions (Weaver, 2005).

4.18.2.6.1.(ix) Thoracic vertebral canal Differences in thoracic vertebral canal size between humans and nonhuman primates have been related to unique aspects of breathing in human speech (MacLarnon, 1993). The thoracic part of the vertebral canal and the spinal cord segments which it encases (in modern humans, T2–S2) are enlarged in modern humans compared with nonhuman primates. It is inferred that this difference is due to an increase in the size of the anterior horns of the spinal cord and of nerves stemming from the segments which innervate the mid or lower trunk region. Some of these nerves innervate intercostal muscles and a set of abdominal muscles that are responsible for the fine control of breathing in modern human speech (Campbell, 1968, 1974; Gould and Okamura, 1974). Modern human speech involves long, punctuated, and modulated utterances (Draper *et al.*, 1959; Campbell, 1968; Hixon and Weismer, 1995), which require respiratory control mechanisms far beyond those necessary for nonhuman primate vocalizations. For example, it appears that in modern human speech the exhalatory portion of the breathing cycle is extended (Borden and Harris, 1984); this is in contrast to primate vocalizations, which drop in pitch during their duration (MacLarnon and Hewitt, 1999, 2004). MacLarnon and Hewitt (1999) explored several alternate hypotheses for increased thoracic vertebral canal size in humans, including postural control for bipedalism, endurance running, and parturition, but found that none were congruent with the fossil and neurological evidence.

4.18.2.6.2 Other endocranial morphology Endocasts preserve information about cranial venous sinuses and meningeal arteries. These may have taxonomic significance, although there is no evidence that their morphology is related to brain function (Holloway *et al.*, 2004a).

4.18.2.6.2.(i) Cranial venous sinuses Modern humans, apes and most hominins have a dominant transverse-sigmoid cranial venous sinus system. In contrast, a subgroup of hominin taxa have a dominant occipital/marginal (O/M) sinus system; that is, the occipital and marginal sinus complex is enlarged, and the transverse and sigmoid sinus complex is reduced (Falk and Conroy, 1983). The functional relevance of variations in the cranial venous sinus system is not clear. The radiator hypothesis (see Constraints on Brain Size: The Radiator Hypothesis) interprets the cranial blood drainage specializations of hominin taxa as an epigenetic adaptation to bipedalism (Falk, 1986, 1990). These specializations include an enlarged O/M sinus system, multiple hypoglossal canals, and augmented emissary vein foramina. African apes have none of these anatomical features, except multiple hypoglossal canals. Within the hominin clade, different combinations of these traits occur. Both *Au. afarensis* and *Paranthropus* (*P. boisei* and *P. robustus*) have high frequencies of an enlarged O/M sinus system, and the latter has high frequencies of posterior condyloid foramina and multiple hypoglossal canals, but low frequencies of mastoid and parietal foramina. There is a trend in the hominin clade toward the modern human condition (e.g., an increase in the number of mastoid and parietal foramina in *H. erectus* and later *Homo*), and a decrease in the frequencies of an O/M venous sinus system (in *Au. africanus* and *Homo*). Multiple hypoglossal canals are found in *Pan* and generally within the hominin clade. Braga and Boesch (1997a) investigated the incidence of these venous channels in African apes and hominins. They did not find statistically significant differences between *Paranthropus* and African apes with respect to the frequency of condylar canals, nor did they find statistically significant differences between

Paranthropus, *Australopithecus*, and African apes with respect to the frequency of divided hypoglossal canals, mastoid canals, and parietal and occipital foramina. Further, they suggest that, if differences did exist, these would probably be due to differences in brain size between African apes and hominins. The statistical arguments are set out in subsequent papers (Braga and Boesch, 1997b; Falk and Gage, 1997).

4.18.2.6.2.(ii) Meningeal arteries Descriptions of meningeal vessels are confused by the fact that several descriptive systems have been used to categorize the patterns of these vessels, and homologies between the vascular systems of different species are uncertain (see Falk, 1993; Grimaud-Herve, 1997; Holloway *et al.*, 2004a). Meningeal vessels are meningeal arteries and veins that supply blood to the neurocranium and also to the dura mater (Holloway *et al.*, 2004a). Of the three components of the meningeal arterial system (anterior, middle, and cerebellar), the middle has undergone the greatest change in hominin evolution (Falk, 1993; Grimaud-Herve, 1994; Holloway *et al.*, 2004a). In modern humans, the middle meningeal artery is divided into an anterior (bregmatic) branch which primarily supplies the frontal region, and a posterior (lambdatic) branch which primarily supplies the parietal region (Netter, 1997). In addition, there is an obelic (middle) branch, which varies in its relationship to the other two branches, and which serves as the basis for Adachi's (1928) simplistic classification of human meningeal artery configurations. This system has influenced paleoanthropologists, but it is not applicable to nonhuman taxa because it assumes that meningeal arteries enter the middle cranial fossa through its floor, which is the case for nearly all modern humans. In the great apes some or all of the meningeal arteries may enter through the back of the orbit (Falk, 1993).

4.18.3 The Hominin Fossil Record

4.18.3.1 Defining Hominins

Molecular biology has revolutionized our knowledge of the relationships within the great ape clade of the Tree of Life. Relationships between organisms can now be pursued at the level of the genome instead of having to rely on morphology (traditional hard- and/or soft-tissue anatomy, or the morphology of proteins) for information about relatedness. Comparisons of the DNA of organisms have been made using two methods. In DNA hybridization, all the DNA is compared, but at a relatively crude level. In DNA sequencing, the base sequences of comparable sections of DNA are determined and then compared. The results of hybridization (e.g., Caccone and Powell, 1989) and sequencing studies of both nuclear and mtDNA (e.g., Bailey *et al.*, 1992; Horai *et al.*, 1992; Gagneux and Varki, 2001; Wildman *et al.*, 2002, 2003) are virtually unanimous in suggesting that modern humans and the African apes are more closely related to each other than any of them is to the orangutan. They also suggest that modern humans and modern chimpanzees, i.e., commom chimpanzees and bonobos, both (belonging to the genus *Pan*) are more closely related to each other than either is to the gorilla (Miyamoto *et al.*, 1987; Sibley and Ahlquist, 1987; Goodman *et al.*, 1990, 1998; Goodman, 1999; Salem *et al.*, 2003; Wildman *et al.*, 2003; Ruvolo, 2004; but see Ruano *et al.*, 1992; Deinard and Kidd, 1999; Barbulescu *et al.*, 2001). Phylogenetic analysis of genome-wide gene expression profiles of the anterior cingulate cortex (ACC) also supports these relationships (Uddin *et al.*, 2004).

Thus, if we accept that the hominin twig of the Tree of Life may extend back in time to *c.* 8 Mya, and that the earliest unambiguous hominin is probably *Au. anamensis* (see below), then between 8 and 4 Mya we would expect to find primitive hominin and primitive panin taxa, and close to 8 Mya we should expect to see evidence of the common ancestor of panins and hominins. Not all of these primitive taxa, be they hominins, panins, or members of another clade, are direct ancestors of modern humans and chimpanzees. Some will belong to extinct panin and hominin subclades and it is also possible there were major clades for which we have no living representative.

4.18.3.2 Terminology

Paleoanthropologists have differed, and still do differ, in the way they classify the higher primates. We have tried to avoid using technical terms, but some are necessary in order to understand the implications of the different classifications. Linnean taxonomic categories immediately above the level of the genus (i.e., the family, the subfamily, and the tribe) have vernacular equivalents that end in 'id', 'ine', and 'in', respectively. In the past, *H. sapiens* has been considered to be distinct enough to be placed in its own family, the Hominidae, with the other great apes grouped together in a separate family, the Pongidae. Thus, modern humans and their close fossil relatives were referred to as

'hominids', and the other great apes and their close fossil relatives were referred to as 'pongids' (Table 1).

However, this scheme is inconsistent with the overwhelming evidence that modern humans and chimpanzees are more closely related to each other than either is to the gorilla or to the orangutan. Some researchers advocate combining modern humans and chimps in the same genus (e.g., Wildman *et al.*, 2003), which, according to the rules of zoological nomenclature, must be *Homo*. We adopt a less radical solution. The taxonomy we prefer lumps all the great apes including humans into a single family, the Hominidae (Table 1), and recognizes three subfamilies within the Hominidae: Ponginae for the orangutans, Gorillinae for the gorillas, and Homininae for modern humans and chimpanzees. The latter subfamily is broken down into two tribes: Panini (or panins) for chimpanzees, and Hominini (or hominins) for modern humans. The latter is further broken down into two subtribes: one, Australopithecina, which includes only extinct hominin genera; and the other, Hominina, for the genus *Homo*, which includes the only living hominin taxon, *H. sapiens*. Thus, modern humans are hominids (family), hominines (subfamily), and then hominins (tribe). Modern humans and all the fossil taxa judged to be more closely related to modern humans than to chimpanzees are called hominins; the chimpanzee equivalent is panin. We use 'australopith' when we refer to taxa belonging to the subtribe Australopithecina.

Table 1 A traditional taxonomy and a modern taxonomy that take account of the molecular and genetic evidence that chimpanzees are more closely related to modern humans than they are to gorillas. Extinct taxa are given in bold type

Traditional taxonomy
Superfamily Hominoidea (hominoids)
- Family Hylobatidae (hylobatids)
  - Genus *Hylobates*
- Family Pongidae (pongids)
  - Genus *Pongo*
  - Genus *Gorilla*
  - Genus *Pan*
- Family Hominidae (hominids)
  - **Subfamily Australopithecinae (australopithecines)**
    - **Genus *Ardipithecus***
    - **Genus *Australopithecus***
    - **Genus *Kenyanthropus***
    - **Genus *Orrorin***
    - **Genus *Paranthropus***
    - **Genus *Sahelanthropus***
  - Subfamily Homininae (hominines)
    - Genus *Homo*

Modern taxonomy
Superfamily Hominoidea (hominoids)
- Family Hylobatidae (hylobatids)
  - Genus *Hylobates*
- Family Hominidae (hominids)
  - Subfamily Ponginae
    - Genus *Pongo* (pongines)
  - Subfamily Gorillinae
    - Genus *Gorilla* (gorillines)
  - Subfamily Homininae (hominines)
    - Tribe Panini
      - Genus *Pan* (panins)
    - Tribe Hominini (hominins)
      - **Subtribe Australopithecina (australopiths)**
        - **Genus *Ardipithecus***
        - **Genus *Australopithecus***
        - **Genus *Kenyanthropus***
        - **Genus *Orrorin***
        - **Genus *Paranthropus***
        - **Genus *Sahelanthropus***
      - Subtribe Hominina (hominans)
        - Genus *Homo*

4.18.3.3 Organizing the Hominin Fossil Record

The classification of the hominin fossil evidence is a controversial topic. Some researchers favor recognizing relatively few taxa, whereas others think that more species and genera are needed to accommodate the observed morphological diversity. We use a relatively speciose (or splitting) taxonomy, but we also provide an example of a less-speciose (or lumping) taxonomy so that readers can appreciate how the evidence for human evolution would look if interpreted in a different way. The taxa included in the two taxonomies are listed in Table 2. Some of the taxon names are used in different senses in the speciose and less-speciose taxonomies. When we refer in the text to the hypodigm (the fossil evidence referred to that taxon) of one of these taxa in the speciose taxonomy we generally use the less-inclusive interpretation of the taxon, *sensu stricto* (*s.s.*). To save space we omit the *sensu stricto* if we are not making a particular distinction between members of the taxon *sensu lato* and members of the taxon *sensu stricto* (e.g., *Au. afarensis* means *Au. afarensis, s.s.*). When we refer to the same taxon in the more inclusive taxonomy (i.e., the hypodigm is larger), the Linnean binomial is followed by *sensu lato* (e.g., *Au. afarensis sensu lato* or *Au. afarensis s.l.*). This indicates that we are using the taxon name in a 'looser' sense. Table 2 demonstrates how the less-speciose taxonomy maps onto the more-speciose one.

The temporal spans of the taxa in the speciose taxonomy are illustrated in Figure 1. The age of the first and last appearances of any taxon in the fossil record (called the first-appearance datum, or FAD, and last-appearance datum or LAD) almost certainly underestimate the temporal range of the

Table 2 Speciose (splitter) and less-speciose (lumper) hominin taxonomies and skeletal representation of the taxa in the speciose taxonomy

Speciose taxonomy	*Age (Mya)*	*Type specimen*	*Crania*	*Dentition*	*Axial*	*Upper limb*	*Lower limb*

Skeletal representation key: X, present; ff, fragmentary specimens; ?, taxonomic affiliation of fossil specimen(s) uncertain.

taxa. Nonetheless, FADs and LADs provide an approximate temporal sequence for the hominin taxa. The heights of the columns of those taxa with good, well-dated, fossil records (e.g., *Au. afarensis* and *P. boisei*) are a reasonable estimate of the temporal range of those taxa, but the heights of other columns marked with an asterisk (e.g., *S. tchadensis* and *Au. bahrelghazali*) reflect uncertainties about the age of the taxon because either the sample size is too small, or because the estimates of temporal range are not reliable.

For various reasons it is very unlikely that we have a complete record of hominin taxonomic diversity, particularly in the pre-4-Mya phase of hominin evolution. This is because intensive explorations of sediments of this age have been conducted for less than a decade, and because these investigations have been restricted in their geographical scope. Thus, the fossil evidence we are working with in the early phase of hominin evolution is almost certainly incomplete. More taxa are likely to be identified. We should bear this in mind when formulating and testing hypotheses about any aspect of hominin evolution, especially the evolution of bipedalism. We have not used lines to connect the taxa because the constraints of existing knowledge suggest that there are only two relatively well-supported subclades within the hominin clade, one for *Paranthropus* taxa, and the other for post-*H. ergaster* taxa belonging to the *Homo* clade. Without more well-supported subclades it is probably unwise to try to identify specific taxa as ancestors or descendants of other taxa.

4.18.3.4 Review of Individual Hominin Fossil Taxa

Each hominin taxon is placed in one of six informal grades (Huxley, 1958) based on a combination of brain and postcanine tooth size and on inferred

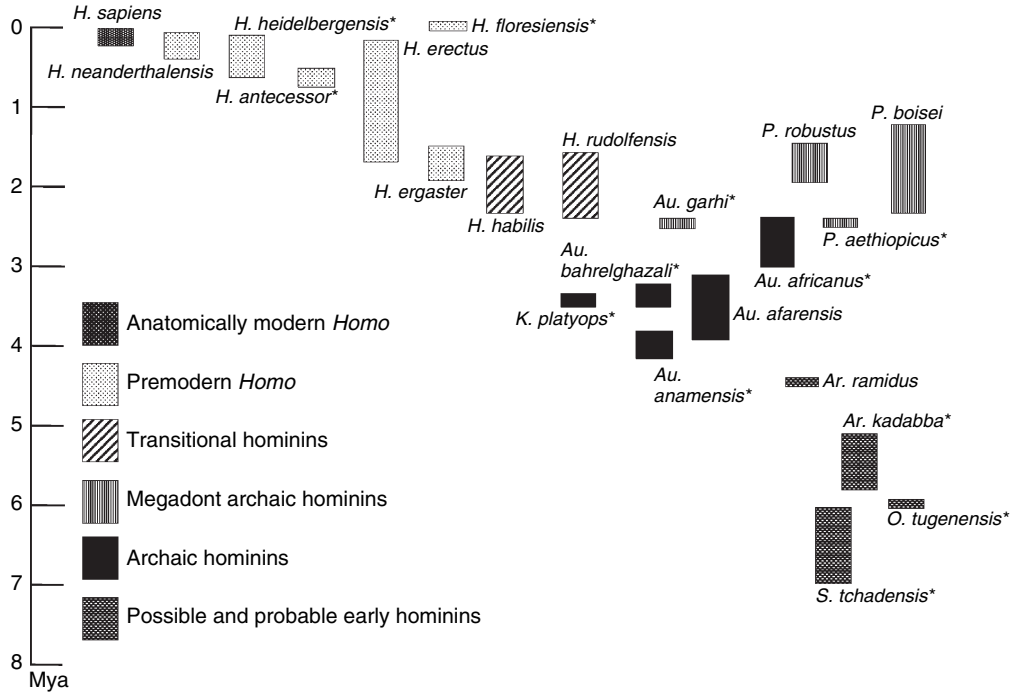

Figure 1 Speciose hominin taxonomy.

locomotor mode. The six grades are: possible and probable primitive hominins (PH); archaic hominins (AH); megadont archaic hominins (MAH); transitional hominins (TH); premodern *Homo* (PMH); and anatomically modern *Homo* (AMH) (Figure 1). Several taxon samples are too small to do other than make an informed guess about the grade of the taxon. Within each grouping, the taxa are listed in order of their first appearance in the fossil record.

Unless homoplasy (shared morphology not derived from the most recent common ancestor) is more common than we anticipate, there is little doubt that recent hominin taxa (i.e., post-*H. ergaster* taxa in group PMH) are more closely related to modern humans than to chimpanzees. These taxa all have absolutely and relatively large brains, they were obligate bipeds, and they have small canines, slender jaws, and small chewing teeth. However, the closer we get to the split between hominins and panins the more difficult it is to find features we can be sure fossil hominins possessed and fossil panins, or taxa in any other closely related clade, did not. In the early stages of hominin evolution it may be either the lack of panin features or relatively subtle differences in the size and shape of the canines, or in the detailed morphology of the limbs, that mark out hominins.

We are conscious that many readers might be unfamiliar with the details of the hominin fossil record, so we provide basic information about the morphology of each taxon. The formal way to cite a taxon name is to give the Linnean binomial, followed by the name(s) of the authors and the date of the paper that introduced the taxon. Conventionally, this citation is not placed in parentheses. However, when a taxon has been moved from its initial genus, the original reference is placed within parentheses followed by the revising reference: for example, *Homo erectus* (Dubois, 1892) Weidenreich, 1940. Further details about most of the taxa and a more extensive bibliography can be found in Wood and Richmond (2000). Recent relevant reviews of most of these taxa can be found in Hartwig (2002) and Wood and Constantino (2004).

4.18.4 Review of Hominin Taxa

4.18.4.1 Possible and Probable Primitive Hominins

This category includes one species, *Ardipithecus ramidus*, which is almost certainly a member of the hominin clade, one species, *Sahelanthropus tchadensis*, which is a possible hominin, and two species, *Ardipithecus kadabba* and *Orrorin tugenensis*, which may be hominins.

Taxon name. Sahelanthropus tchadensis Brunet *et al.*, 2002.

Temporal range. *c*. 7–6 Mya.

Initial discovery. TM 266-01-060-1 – an adult cranium; Toros-Menalla, Chad, 2001 (Brunet *et al*., 2002).

Type specimen. As above.

Source(s) of the evidence. Toros-Menalla, Chad, Central Africa.

Nature of the evidence. A distorted cranium, although an attempt to correct the distortion has been made in a virtual reconstruction (Zollikofer *et al*., 2005), plus several mandibles and some teeth.

Characteristics and inferred behavior. Cranial: A chimp-sized animal displaying a novel combination of primitive and derived features. Much about the base and vault of the cranium is chimp-like, but the relatively anterior placement of the foramen magnum, the presence of a supraorbital torus, the lack of a muzzle, the small, apically worn canines, the low, rounded molar cusps, the relatively thick tooth enamel, and the relatively thick mandibular corpus (Brunet *et al*., 2002) suggest that *S. tchadensis* does not belong in the *Pan* clade. Postcranial: No evidence. Conclusion: It is either a primitive hominin, the common ancestor of hominins and panins, or it belongs to a separate clade of hominin-like apes.

CNS-related fossil evidence. The endocranial volume is estimated to be between 350 and 370 cm^3, the smallest of any adult hominin, and within the range of extant chimpanzees.

Taxon name. *Orrorin tugenensis* Senut *et al*., 2001.

Temporal range. *c*. 6.0 Mya.

Initial discovery. KNM LU 335– left mandibular molar tooth crown; Tugen Hills, Baringo, Kenya, 1974 (Pickford, 1975).

Type specimen. BAR 1000'00 – fragmentary mandible; Tugen Hills, Baringo, Kenya, 2000 (Senut *et al*., 2001).

Source(s) of the evidence. The relevant remains come from four localities in the Lukeino Formation, Tugen Hills, Kenya.

Nature of the evidence. The 13 specimens include three femoral fragments.

Characteristics and inferred behavior. Cranial: The discoverers admit that much of the critical dental morphology is "ape-like" (Senut *et al*., 2001, p. 6). Postcranial: The femoral morphology has been interpreted (Pickford *et al*., 2002; Galik *et al*., 2004) as suggesting that O. *tugenensis* is an obligate biped, but some researchers interpret the radiographs and CT scans of the femoral neck as indicating a mix of bipedal and nonbipedal locomotion. Conclusion: O. *tugenensis* could prove to be a hominin, but it is more likely that it belongs to another part of the adaptive radiation that included the common ancestor of panins and hominins.

CNS-related fossil evidence. None.

Taxon name. *Ardipithecus kadabba* Haile-Selassie *et al*., 2004.

Temporal range. 5.8–5.2 Mya.

Initial discovery. ALA-VP-2/10 – partial mandible; Alayla, Western Margin, Middle Awash, Ethiopia, 1997.

Type specimen. As above.

Source(s) of the evidence. Middle Awash and Gona, Ethiopia.

Nature of the evidence. Mandible, teeth, and postcranial evidence.

Characteristics and inferred behavior. Cranial: The upper canine and lower first premolar morphology is less ape-like than that of O. *tugenensis*, but more ape-like than that of *Ar. ramidus*. The researchers who found it suggest that it closely approaches the extant and fossil ape condition (Haile-Selassie *et al*., 2004, p. 1505); they also suggest that the morphology of the canine–premolar complex of *S. tchadensis*, O. *tugenensis*, and *Ar. kadabba* is so similar that they may belong to one genus, or even one species (Haile-Selassie *et al*., 2004). Postcranial: *Ar. kadabba* has been suggested to be a biped on the basis that the shape of the proximal articular surface of the fourth proximal phalanx of the foot resembles that of *Au. afarensis*, but similar morphology may also be found in the quadrupedal African apes. Conclusion: *Ar. kadabba* is probably a member of an extinct clade closely related to hominins and panins.

CNS-related fossil evidence. None.

Taxon name. *Ardipithecus ramidus* (White *et al*., 1994) White *et al*., 1995.

Temporal range. *c*. 4.5–4.4 Mya.

Initial discovery. ARA-VP-1/1 – right M^3; Aramis, Middle Awash, Ethiopia, 1993 (White *et al*., 1994). (NB: if a mandible, KNM-LT 329, from Lothagam, Kenya, proves to belong to the hypodigm, then this would be the initial discovery.)

Type specimen. ARA-VP-6/1 – associated upper and lower dentition; Aramis, Middle Awash, Ethiopia, 1993 (White *et al*., 1994).

Source(s) of the evidence. A site called Aramis in the Middle Awash region of Ethiopia. A second suite of fossils, including a mandible, teeth, and postcranial bones, recovered in 1997 from five localities in the Middle Awash, that range in age from >5.7 to 5.2 Mya were initially allocated to this taxon (Haile-Selassie, 2001), but they were

subsequently transferred to *Ar. kadabba* (see above).

Nature of the evidence. The published evidence consists of isolated teeth, a piece of the base of the cranium, and fragments of mandibles and long bones. A fragmented associated skeleton has been found and is being prepared and reconstructed.

Characteristics and inferred behavior. Cranial: The remains attributed to *Ar. ramidus* share some features in common with living species of *Pan*, others that are shared with the African apes in general, and, crucially, several dental and cranial features are shared only with later hominins such as *Au. afarensis*. Its chewing teeth are relatively small, and the thin enamel covering on the teeth suggests that the diet of *Ar. ramidus* may have been closer to that of the chimpanzee than to that of modern humans. Postcranial: Judging from the size of the shoulder joint, *Ar. ramidus* weighed about 40 kg. The position of the foramen magnum suggests that the posture and gait of *Ar. ramidus* was respectively more upright and bipedal than is the case in the living apes. Conclusions: The discoverers initially allocated the new species to *Australopithecus* (White *et al.*, 1994), but they subsequently assigned it to a new genus, *Ardipithecus* (White *et al.*, 1995). Of the hominin taxa in this category, *Ar. ramidus*, is the most likely to be an early hominin.

CNS-related fossil evidence. A crushed cranium has been reported, but no details have been published.

4.18.4.2 Archaic Hominins

This group, which includes all the remaining hominin taxa not conventionally included in *Homo* and *Paranthropus*, subsumes two genera, *Australopithecus* and *Kenyanthropus*. As it is used in this and many other taxonomies, *Australopithecus* is almost certainly not a single clade, but until researchers can generate a reliable phylogeny there is little point in revising its generic terminology.

Taxon name. *Australopithecus anamensis* Leakey *et al.*, 1995.

Approximate time range. *c.* 4.2–3.9 Mya.

Initial discovery. KNM-KP 271 – left distal humerus; Kanapoi, Kenya, 1965 (Patterson and Howells, 1967).

Type specimen. KNM-KP 29281 – an adult mandible with complete dentition and a temporal fragment that probably belongs to the same individual; Kanapoi, Kenya, 1994.

Source(s) of the evidence. Allia Bay and Kanapoi, Kenya.

Nature of the evidence. The evidence consists of jaws, teeth, and postcranial elements from the upper and lower limbs.

Characteristics and inferred behavior. Cranial: The main differences between *Au. anamensis* and *Au. afarensis* relate to details of the dentition. In some respects the teeth of *Au. anamensis* are more primitive than those of *Au. afarensis* (e.g., the asymmetry of the premolar crowns, and the relatively simple crowns of the deciduous first mandibular molars), but in others (e.g., the low cross-sectional profiles, and bulging sides of the molar crowns) they show similarities to *Paranthropus* (see below). Postcranial: The upper limb remains are australopith-like, but a tibia attributed to *Au. anamensis* has features associated with obligate bipedality.

CNS-related fossil evidence. None.

Taxon name. *Australopithecus afarensis* Johanson *et al.*, 1978.

Approximate time range. *c.* 4–3 Mya.

Initial discovery. AL 128-1 – left proximal femur fragment; Hadar Formation, Afar, Ethiopia, 1973 (Johanson and Taieb, 1976).

Type specimen. LH 4 – adult mandible; Laetoli, Tanzania, 1974.

Source(s) of the evidence. Laetoli, Tanzania; White Sands, Hadar, Maka, Belohdelie and Fejej, Ethiopia; Allia Bay, West Turkana, and Tabarin, Kenya.

Nature of the evidence. *Au. afarensis* is the earliest hominin to have a comprehensive fossil record including a well-preserved skull, several crania, many lower jaws, and sufficient limb bones to be able to estimate stature and body mass. The collection includes a specimen, AL-288, that preserves just less than half of the skeleton of an adult female.

Characteristics and inferred behavior. Cranial: It has incisors that are much smaller than those of extant chimpanzees, but the premolars and molars of *Au. afarensis* are relatively larger than those of the chimpanzee. Postcranial: The hind limbs of AL-288 are substantially shorter than those of a modern human of similar stature. The range of body mass estimates is from 25 to >50 kg. The upper limb, especially the hand, retains morphology that most likely reflects a significant element of arboreal locomotion. The size of the footprints, the length of the stride, and stature estimates based on the length of the limb bones suggest that the standing height of adult individuals in this early hominin species was between 1.0 and 1.5 m. Direct evidence of the

locomotion of either *Au. afarensis* or another synchronic hominin comes from the 3.6 Mya hominin footprint trails at Site G in the Laetolil Formation, at Laetoli, Tanzania. If we assume that the skeletal evidence from Hadar and the trace fossil evidence from Laetoli represents one taxon, and if we weigh the primitive and derived characteristics observed in the Hadar pedal remains and in the Laetoli footprints, the form and function of the *Au. afarensis* locomotor system was not modern humanlike.

CNS-related fossil evidence. Endocranial: *Au. afarensis* is represented by at least 15 specimens that preserve endocranial anatomy and some for which endocranial volume can be estimated. The estimated mean adult endocranial volume is 446 cm^3 ($n = 5$; range 387–550). The range is interpreted as reflecting a substantial degree of sexual dimorphism. The average of the two largest crania (probable males) is 125 cm^3 greater than that for the three smallest crania (probable females). These values are larger than the average endocranial volume of a chimpanzee, and if the estimates of the body size of *Au. afarensis* are approximately correct then relative to estimated body mass the brain of *Au. afarensis* is substantially larger than that of *Pan*. The sample mean EQ for *Au. afarensis* is 2.5. Holloway has long argued that the primary visual cortex is relatively reduced in size in *Au. afarensis*, as is apparent in two specimens, AL 162-28 (Holloway, 1983a; Holloway and Kimbel, 1986) and AL 288-1 (Holloway *et al.*, 2004a). However, he allows that another specimen (AL 333-45) may have a proportionately larger, more ape-like, primary visual cortex. Other evidence presented by Holloway *et al.* for brain organization in *Au. afarensis* is ambiguous. There may be evidence of a slight left occipital petalia in one specimen (AL 333-45), but a juvenile specimen (AL 333-105) retains the ape pattern of an inferior frontal orbital sulcus (Holloway *et al.*, 2004a). On the other hand, Falk (1985b) argues that *Au. afarensis* (particularly AL 162-28) has an entirely ape-like sulcal pattern with no evidence of a relatively reduced primary visual cortex, and with an ape-like condition of a cerebellum projecting posteriorly beyond the occipital lobe, a suggestion Holloway and Kimbel (1986) and Holloway *et al.* (2004a) dismiss as a misinterpretation due to the way the fossil was oriented. Vertebral canal: This species is represented by four sets of vertebras. The most complete set of vertebras includes 15 vertebral elements belonging to AL 288-1, of which the thoracic vertebras have been used to make inferences about the spinal cord. *Au. afarensis* retains small (relative to modern human) thoracic vertebral canals in cross-sectional area, suggesting a small thoracic spinal cord, and by inference a lack of fine control of breathing for speech, and thus the lack of a complex vocal language ability (MacLarnon and Hewitt, 1999). Behavioral interpretations: Both Holloway and Falk recognize that the brain of *Au. afarensis* shows some degree of reorganization toward the modern human condition. However, a point of contention between these authors has been the relative location of the LS, and the coincident reduction of the primary visual cortex and expansion of the parietal association cortex cortex. Some *Au. afarensis* brains have a posteriorly placed LS, but some chimpanzee brains also have a posteriorly placed LS (Figure 2b) (Holloway *et al.*, 2003). Holloway *et al.* (2003) argue that the hypothetical panin–hominin common ancestor must also have had within its population individuals with reduced primary visual cortices, so you would expect this condition in early hominins such as *Au. afarensis*.

Other endocranial morphology. Cranial venous sinuses: Eight *Au. afarensis* from Hadar (AL 333-45, Al 333-105, AL 333-114, AL 333-116, AL 162-28, AL 444-2, AL 288-1, and AL 439-1) have an enlarged, and thus presumably dominant, occipital marginal sinus system (Kimbel *et al.*, 2004; Falk *et al.*, 1995). However, LH 21, and probably AL 224-9 and AL 427-1b, lack an enlarged occipital marginal sinus system. Meningeal vessels: Present, but not diagnostic.

Taxon name. *Kenyanthropus platyops* Leakey *et al.*, 2001.

Approximate time range. *c.* 3.5–3.3 Mya.

Initial discovery. KNM-WT 38350 – left maxilla fragment; Lomekwi, West Turkana, Kenya, 1998 (Leakey *et al.*, 2001).

Type specimen. KNM-WT 40000 – a relatively complete cranium but it is criss-crossed by matrix-filled cracks; Lomekwi, West Turkana, Kenya, 1999 (Leakey *et al.*, 2001).

Source(s) of the evidence. West Turkana, and perhaps Allia Bay, Kenya.

Nature of the evidence. The initial report lists the type cranium and the paratype maxilla plus 34 specimens – including three mandible fragments, a maxilla fragment, and isolated teeth – some of which may also belong to the hypodigm, but at this stage the researchers are reserving their judgment about the taxonomy of many of these remains (Leakey *et al.*, 2001). Some of them have only recently been referred to *Au. afarensis* (Brown *et al.*, 2001).

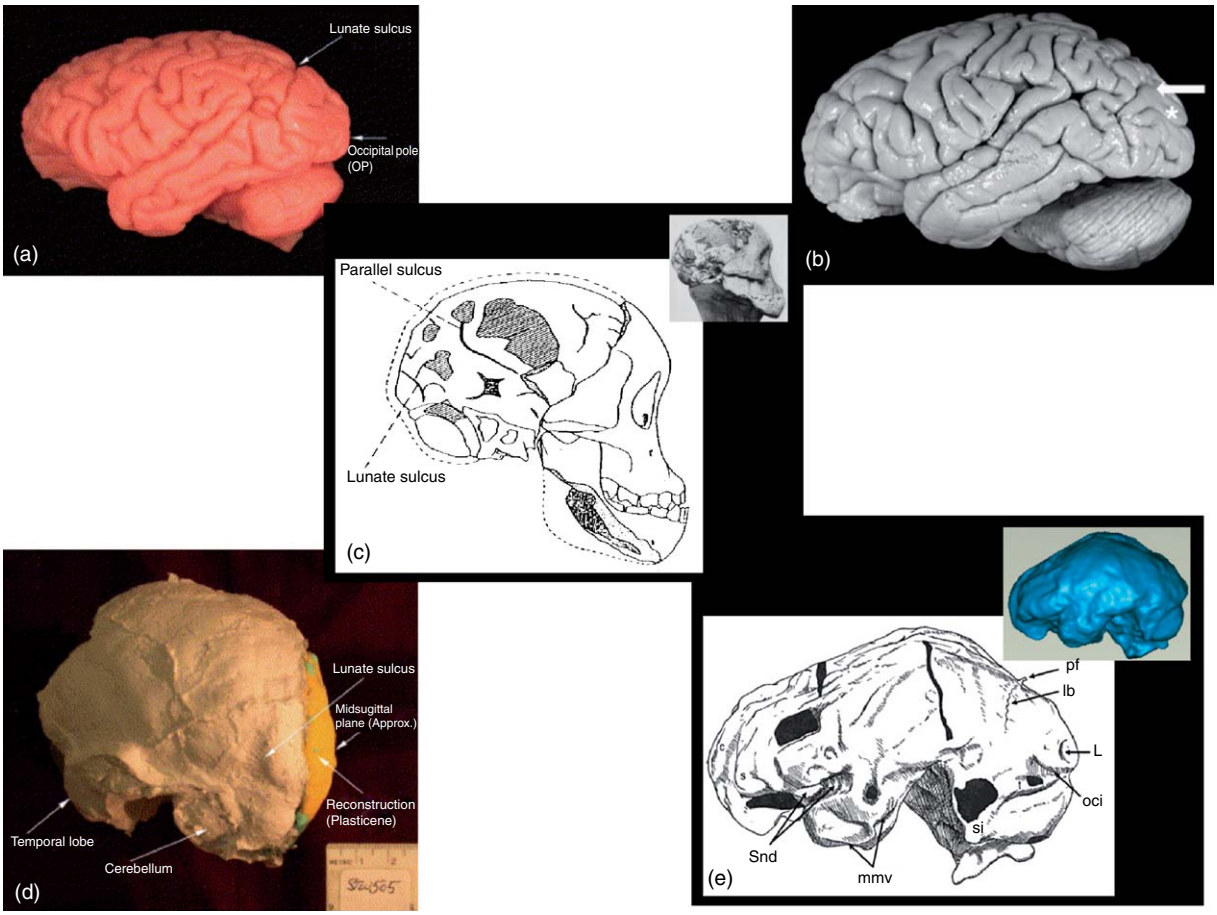

Figure 2 a, Left lateral view of a typical chimpanzee brain cast showing relatively anterior position of the LS (Holloway *et al.*, 2004b). b, Left lateral view of unusual chimpanzee brain with the LS in a more posterior position (* indicates lateral calcarine fissure) (Holloway *et al.*, 2003). c, Right lateral view of a natural endocast and sketch of juvenile *Au. africanus* (Taung) (Dart, 1925). d, Left oblique view of *Au. africanus* (Stw 505) partially reconstructed endocast showing the location of the LS (Holloway *et al.*, 2004b). e, Left lateral view of virtual endocast and sketch of *H. floresiensis* (LB1) showing the location of the LS (Falk *et al.*, 2005). Images are not shown to the same scale. a and d, Reproduced from Holloway, R. L., Clarke, R. J., and Tobias, P. V. 2004b. Posterior lunate sulcus in *Australopithecus africanus:* Was Dart right? *C. The brain of LB1, *Homo floresiensis. Science* 308, 242–245. Copyright 2005 AAAS.

Characteristics and inferred behavior. Cranial: The main reasons why Leakey *et al.* (2001) did not assign this material to *Au. afarensis* are its reduced subnasal prognathism, anteriorly situated zygomatic root, flat and vertically orientated malar region, relatively small but thick-enameled molars, and the unusually small M^1 compared to the size of the P^4 and M^3. Some of the morphology of the new genus, including the shape of the face, is *Paranthropus*-like, yet it lacks the postcanine megadontia that characterizes *Paranthropus*. Postcranial: No evidence. Conclusion: The authors note that the face of the new material resembles that of *H. rudolfensis* (see below), but they rightly point out that the postcanine teeth of the latter are substantially larger than those of KNM-WT 40000. *K. platyops* apparently displays a hitherto unique combination of facial and dental morphology. Some researchers contend that KNM-WT 40000 is an *Au. afarensis* cranium that is distorted by the matrix-filled cracks.

CNS-related fossil evidence. No estimate of endocranial volume is given, although it is apparently australopith-like in size.

Taxon name. *Australopithecus bahrelghazali* Brunet *et al.*, 1996.

Approximate time range. *c.* 3.5–3.0 Mya.

Initial discovery. KT 12/H1 – anterior portion of an adult mandible; Koro Toro, Chad, 1995 (Brunet *et al.*, 1996).

Type specimen. As above.

Source(s) of the evidence. Koro Toro, Chad.

Nature of the evidence. Published evidence is restricted to a fragment of the mandible and an isolated tooth.

Characteristics and inferred behavior. Cranial: Its discoverers claim that its thicker enamel distinguishes the Chad remains from *Ar. ramidus*, and that its smaller mandibular symphysis and more complex mandibular premolar roots distinguish it from *Au. afarensis*. Otherwise, there is too little evidence to infer any behavior. Postcranial: No evidence. Conclusion: This taxon may be a regional variant of *Au. afarensis*.

CNS-related fossil evidence. None.

Taxon name. *Australopithecus africanus* (Dart, 1925).

Approximate time range. *c*. 3.0*–2.4 Mya. *NB: it remains to be seen whether the associated skeleton Stw 573 from Member 2 (Clarke and Tobias, 1995; Clarke, 1998, 1999, 2002) and the 12 hominin fossils recovered from the Jacovec Cavern since 1995 (Partridge *et al.*, 2003) belong to the *Au. africanus* hypodigm. Samples of quartz grains from Member 2 and the Jacovec Cavern have recently been dated to *c*. 4.2–4.0 Mya using ratios of the ^{26}Al and ^{10}Be radionuclides (Partridge *et al.*, 2003).

Initial discovery. Taung 1 – a juvenile skull with partial endocast; Taung (formerly Taungs), now in South Africa, 1924.

Type specimen. As above.

Source(s) of the evidence. Most of the evidence comes from two caves, Sterkfontein and Makapansgat, with other evidence coming from caves at Taung and Gladysvale.

Nature of the evidence. This is one of the best, if not the best, fossil record of an early hominin taxon. The cranium, mandible, and dentition are well sampled. The postcranium and particularly the axial skeleton is less well represented in the sample, but there is at least one specimen of each of the long bones. However, many of the fossils have been crushed and deformed by rocks falling onto the bones before they were fully fossilized.

Characteristics and inferred behavior. Cranial: *Au. africanus* had relatively large chewing teeth and apart from the reduced canines the skull is relatively ape-like. Postcranial: Overall, the postcranial remains of *Au. africanus* suggest that this hominin could engage in both arboreal and bipedal locomotion. The Sterkfontein evidence suggests that males and females of *Au. africanus* differed substantially in body size, but probably not to the degree they did in *Au. afarensis* (see above). Conclusion: This is a hominin with a mixed locomotor mode, part climbing and part bipedal walking.

CNS-related fossil evidence. Endocranial: *Au. africanus* is represented by at least 15 specimens representing the neurocranium, many of which are natural endocasts. *Au. africanus* endocasts are unique among hominin endocasts in that they preserve a great deal of convolutional detail (Falk, 1987). This species has the most studied (and debated) endocast morphology of any fossil hominin species. The estimated mean adult endocranial volume for *Au. africanus* is 460 ($n = 9$; range 428–515). The sample mean EQ for *Au. africanus* is 2.8. An early claim for reorganization of the cerebral cortex, in the form of a relatively reduced primary visual cortex and relatively expanded parietal–occipital association areas, was made by Dart (1925) on the basis of a humanlike posteriorly located LS on the Taung child endocast (Figure 2c). This observation is the focus of a long-standing debate over the identification and location of the LS, including support for Dart's view (Holloway, 1975), one author arguing for a very posterior position (Schepers, 1946), others arguing for an anterior position (Keith, 1931; Le Gros Clark *et al.*, 1936; Falk, 1980b, 1985a), and some noting that it is impossible to know the position with certainty (Le Gros Clark, 1947; Holloway, 1985; Tobias, 1991). The debate over the location of the Taung LS developed into a larger debate between Falk and Holloway about whether brain reorganization preceded brain size increase. On the one hand, Holloway (Holloway, 1975, 1983a, 1984, 1985, 1988b) and Holloway *et al.* (2004a, 2004b) maintain that Taung and other *Au. africanus* specimens demonstrate aspects of humanlike brain organization. Holloway does not maintain that a particular line clearly represents the LS, but states that for Taung there is no good evidence for a LS in a typical anterior pongid position (Holloway *et al.*, 2004a, p. 97). In addition, Holloway *et al.* claim that two other specimens (Stw 505 and Sterfontein Type 3) also show a relative reduction in primary visual cortex size, based on the position of the LS (see Figure 2d) (Holloway *et al.*, 2004a, p. 97). In addition, they find evidence of a humanlike brain morphology associated with right-handedness. Two specimens (Sts 5 and Sterfontein type 2) have Broca's cap regions which demonstrate a trend toward a modern humanlike pattern, and one of these (Sts 5) displays a slight LORF petalia (Holloway *et al.*, 2004a). On the

other hand, Falk (1980b, 1983b, 1985a) maintains and defends her interpretation of a more anterior, ape-like, position for the LS in Taung and other *Au. africanus* individuals. In addition, Falk points to other ape-like features of *Au. africanus* endocasts, most significantly the fronto-orbital sulcus. Falk (1980b) claims that Taung is ape-like in the position and size of the fronto-orbital sulcus at the lateral edge of frontal lobe (but see Holloway, 1981b). Five other *Au. africanus* endocasts (Sts 60, Type 2, Type 3, Sts 58, Sts 1017) are considered to have similar ape-like sulcal patterns, although based on much less evidence (Falk, 1980b). However, Falk *et al.* (2000) have pointed to derived, modern humanlike aspects of *Au. africanus* brain morphology that differentiate this species from *Paranthropus*. The orbital surface of the frontal lobe is blunt and expanded in *Au. africanus* (Sts 5, Stw 505, and see also the more fragmentary Type 2 and Sts 60) just as in *H. sapiens* (Falk *et al.*, 2000). Anteriorly expanded, laterally pointed temporal poles also characterize *Au. africanus* and *H. sapiens* to the exclusion of *Paranthropus* (Falk *et al.*, 2000). Vertebral canal: One set of 15 vertebras (Sts 14) and two individual vertebras (Sts 65, Sts 73) have been referred to this species. *Au. africanus* thoracic vertebral canals have a small cross-sectional area relative to those of modern humans. Behavioral interpretations: In the original description of the type specimen, Dart argued that *Au. africanus* demonstrates humanlike brain reorganization on the basis of the position of the LS. Although Falk does not concede the position of the LS, Falk *et al.* (2000) do agree that in other respects the *Au. africanus* brain has been reorganized relative to African ape brains. There are several examples showing an early start to a trend toward modern humanlike cortical reorganization (Falk *et al.*, 2000). The enlarged orbital surfaces of the frontal lobes in *Au. africanus* are thought to indicate an expansion of area 10 prior to brain size increase. The anterior lateral regions of the temporal poles, which show a modern humanlike expansion in *Au. africanus*, are involved in visual learning and recognition. In addition, *Au. africanus* (Sts 5) is more modern humanlike than ape-like in the size and shape of its olfactory bulbs (Falk *et al.*, 2000). In modern humans, olfactory bulbs are less than half the size of those of the apes. Furthermore, the fraction of functioning olfactory receptor genes is reduced in modern humans relative to apes (Gilad *et al.*, 2003a), a finding that corroborates behavioral data that suggest modern humans do not rely on their sense of smell as much as apes do. Reduction of olfactory bulb size, and corresponding changes in the dependence on smell (Gilad *et al.*, 2003b), may have arisen early in hominin evolution. Falk *et al.* (2000) point to shared morphology in *Au. africanus* and *H. sapiens* to the exclusion of *Paranthropus* as evidence of an *Au. africanus–Homo* lineage, but this is a highly contested proposal (e.g., Johanson and White, 1979). In spite of evidence for brain reorganization, there is no very strong evidence for brain morphology that can be related to language capacity. Moreover, the small vertebral canals in the thoracic region suggest a lack of fine breathing control, and thus the lack of complex vocal language ability. This conclusion is similar to that for *Au. afarensis*.

Other endocranial morphology. Cranial venous sinuses: Most researchers who have studied the cranial venous sinuses of *Au. africanus* suggest that it retains a symplesiomorphic dominant transverse sigmoid sinus and lacks an enlarged O/M sinus (e.g., Sts 5, Sts 19, Sts 26, MLD 1 and MLD 37/38) (Tobias and Falk, 1988; Conroy *et al.*, 1990; Falk *et al.*, 1995). Two exceptions are Taung and Stw 187a, which have evidence for a dominant O/M sinus system (Tobias and Falk, 1988; Kimbel *et al.*, 2004). Falk *et al.* (1995) argue that this unusual feature contributes to the uncertainty of Taung's taxonomic affinity. Holloway *et al.* (2004a) suggest that MLD 1 has an O/M sinus drainage system. Meningeal vessels: Saban (1983) drew distinctions between *Australopithecus* (i.e., *Au. africanus*) and *Paranthropus* (*P. boisei* and *P. robustus*) with respect to the configuration of meningeal vessels, but this interpretation has since been rejected (Falk, 1993; White and Falk, 1999). Saban (1983) showed that two *Au. africanus* specimens (Sts 60, Taung) have middle meningeal vessels that bifurcate into simple anterior and posterior branches, with no middle branch, in contrast to *Paranthropus* in which a middle branch is present.

4.18.4.3 Megadont Archaic Hominins

This group includes hominin taxa included in the genus *Paranthropus* and one other taxon, *Au. garhi*. The genus *Paranthropus* was reintroduced when cladistic analyses suggested that three of the four species in this grade formed a clade. Two genera, *Zinjanthropus* and *Paraustralopithecus*, are subsumed within the genus *Paranthropus*.

Taxon name. *Paranthropus aethiopicus* (Arambourg and Coppens, 1968) Chamberlain and Wood, 1985.

Approximate time range. *c.* 2.5–2.3 Mya.

Initial discovery. Omo 18.18 (or 18.1967.18) – an edentulous adult mandible; Shungura Formation, Omo Region, Ethiopia, 1967.

Type specimen. As above.

Source(s) of the evidence. Shungura Formation, Omo region, Ethiopia; West Turkana, Kenya.

Nature of the evidence. The hypodigm includes a well-preserved cranium from West Turkana (KNM-WT 17000), several mandibles (e.g., KNM-WT 16005), and isolated teeth from the Shungura Formation. No postcranial fossils have been assigned to this taxon.

Characteristics and inferred behavior. Cranial: Similar to *P. boisei* (see below) except that the face is more prognathic, the cranial base is less flexed, the incisors are larger, and the postcanine teeth are not so large or morphologically specialized. When this taxon was introduced in 1968 it was the only megadont hominin in this time range. With the discovery of *Au. garhi* (see below) it is apparent that robust mandibles with similar length premolar and molar tooth rows are being associated with what are claimed to be two distinct forms of cranial morphology.

CNS-related fossil evidence. Endocranial: One almost complete cranium is the only source of information about the CNS of *P. aethiopicus*. The estimated endocranial volume is 410 cm^3 (Walker *et al.*, 1986). Holloway *et al.* (2004a) describe a slight LORF petalial pattern, but no claims of humanlike brain organization have been made. Falk *et al.* (2000) suggest that this specimen retains aspects of ape-like brain morphology not found in *Au. africanus*. The olfactory bulb of *P. aethiopicus* is ape-like in size and shape, in contrast to *Au. africanus* (Falk *et al.*, 2000). *P. aethiopicus* has an ape-like beak-shaped orbital surface of the frontal lobe, in contrast to *Au. africanus* and *Homo*. The *P. aethiopicus* temporal lobe is ape-like in both size and shape and contrasts with the morphology seen in *Au. africanus* and *Homo*, but it shares this trait with other *Paranthropus* taxa (Falk *et al.*, 2000). Holloway (1988a) suggests that the cerebellum of this specimen is chimpanzee-like in that it is posteriorly protruding and laterally flaring, in contrast to the more modern humanlike tucked-under cerebellum of *P. robustus* (SK 1585) and *P. boisei* (OH 5). The ape-like morphology and small brain size are consistent with the conclusion that this species was more ape-like than humanlike in terms of its cognition.

Other endocranial morphology. Cranial venous sinuses: The lack of transverse sigmoid sinus grooves in KNM-WT 17000 is taken (by default) as evidence for an enlarged O/M sinus system in *P. aethiopicus* (Brown *et al.*, 1993).

Taxon name. *Paranthropus boisei* (Leakey, 1959) Robinson, 1960.

Approximate time range. *c.* 2.3–1.3 Mya.

Initial discovery. OH 3 – deciduous mandibular canine and molar; Olduvai Gorge, Tanzania, 1955 (Leakey, 1958).

Type specimen. OH 5 – adolescent cranium; Olduvai Gorge, Tanzania, 1959 (Leakey, 1959).

Source(s) of the evidence. Olduvai and Peninj, Tanzania; Omo Shungura Formation and Konso, Ethiopia; Koobi Fora, Chesowanja, and West Turkana, Kenya; Melema, Malawi.

Nature of the evidence. *P. boisei* has a comprehensive craniodental fossil record. There are several skulls (the one from Konso being remarkably complete and well preserved), several well-preserved crania, and many mandibles and isolated teeth. There is evidence of both large and small-bodied individuals, and the range of the size difference suggests a substantial degree of sexual dimorphism. There are no postcranial remains that can, with certainty, be assigned to *P. boisei*.

Characteristics and inferred behavior. Cranial: *P. boisei* is the only hominin to combine a massive, wide, flat, and face, massive premolars and molars, and small anterior teeth. The face of *P. boisei* is larger and wider than that of *P. robustus,* yet their brain volumes are similar. The mandible of *P. boisei* has a larger and wider body or corpus than any other hominin (see *P. aethiopicus* above). The tooth crowns apparently grow at a faster rate than has been recorded for any other early hominin. The fossil record of *P. boisei* extends across about 1 My, during which there is little evidence of any substantial change in the size or shape of the components of the cranium, mandible, and dentition (Wood *et al.*, 1994). Postcranial: There is, unfortunately, no postcranial evidence that can with certainty be attributed to *P. boisei*.

CNS-related fossil evidence. Endocranial: The *P. boisei* neurocranium is represented by 11 specimens: OH 5 (Olduvai Gorge); Omo L-338Y-6 and Omo-323-1976-896 (Omo Shungura Formation); KGA-10-525 (Konso); KNM-ER 23000, KNM-ER 406, KNM-ER 407, and KNM-ER 732 (Koobi Fora); KNM-CH 304 (Chesowanja); and KNM-WT 13750 and KNM-WT 17400 (West Turkana). The mean adult endocranial volume for *P. boisei* is 488 cm^3 ($n = 10$; range 400–545 cm^3). The sample mean EQ for *P. boisei* is 2.5. Four or five *P. boisei* (KGA-10-525, KNM-ER 23000, KNM-WT 13750, OH 5, and possibly Omo L338Y-6) endocasts have slight LORF petalial patterns (Holloway *et al.*, 2004a). For all other *P. boisei* endocasts, either it is not possible to determine whether a petalia exists,

or this information has not been reported. For one specimen (KNM-WT 17400) the Broca's cap region is larger on the left side than on the right side, but it is not clear whether or not this is due to distortion (Holloway *et al.*, 2004a). Three *P. boisei* have convolutional details in the occipital region, suggesting a reduction in the relative size of the primary visual cortex size (KGA-10-525, KNM-ER 23000, Omo L338Y-6). For all other *P. boisei*, it is either not possible to determine the key occipital landmarks, or this information has not been reported. The temporal lobe of KNM-WT 17400 is ape-like in its size and shape. This contrasts with morphology seen in *Au. africanus* and *H. sapiens*, but it shares this morphology with other *Paranthropus* taxa (Falk *et al.*, 2000). Three *P. boisei* endocasts (KNM-ER 2300, KNM-WT 17400, and OH 5) have a pointed rostral frontal lobe. They share this morphology with *P. aethiopicus* and the great apes, and it contrasts with the condition in *Au. africanus* and modern humans (Falk *et al.*, 2000). Vertebral canal: No evidence. Behavioral interpretations: There is more and better evidence for a more modern humanlike pattern of brain organization in *P. boisei* than in *Au. afarensis*. This may indicate that not only did *Paranthropus* brain size expand over time (Elton *et al.*, 2001), but some brain reorganization may have occurred in this lineage. Certainly, the impact of brain size on brain morphology (e.g., Jerison, 1975) could be a contributing factor to this trend.

Other endocranial morphology. Cranial venous sinuses: The cranial venous sinus system of *P. boisei* has been given much attention. Tobias (1967) first noted that OH 5 had an enlarged occipital marginal sinus system, a trait it shares with most other scorable *P. boisei* specimens: that is, KNM-CH 304 (Gowlett *et al.*, 1981), KNM-ER 23000 (Brown *et al.*, 1993), KNM-ER 407 (Day, 1976), and KNM-ER 732 (Leakey *et al.*, 1972). A probable exception to this is Omo L-338Y-6, because several authors (Rak and Howell, 1978; Holloway, 1981a; Kimbel, 1984; Holloway *et al.*, 2002) have failed to confirm the presence of an enlarged O/M sinus system in this specimen (cf. Falk *et al.*, 1995). The fossil KGA-10-525 lacks an O/M sinus system (Suwa *et al.*, 1997; Holloway *et al.*, 2004a), although it has been suggested that transverse sinus grooves are also missing (Suwa *et al.*, 1997; White and Falk, 1999; cf. Holloway *et al.*, 2004a). Meningeal vessels: Saban (1983) found that *P. boisei* (KNM-ER 407), like *P. robustus*, has three major branches of the middle meningeal vessels: anterior, middle, and posterior. However, Saban found only simple anterior and posterior branches for Omo 338y-6, now considered to belong to *P. boisei*, but originally thought to be an non-megadont australopith (Walker and Leakey, 1988; White and Falk, 1999).

Taxon name. *Paranthropus robustus* Broom, 1938.

Approximate time range. *c.* 2.0–1.5 Mya.

Initial discovery. TM 1517 – an adult, presumably male, cranium and associated skeleton; Phase II Breccia, now Member 3, Kromdraai B, South Africa, 1938.

Type specimen. As above.

Source(s) of the evidence. Kromdraai, Swartkrans, Gondolin, Drimolen, and Cooper's caves, all situated in, or near to, the Blauuwbank Valley, near Johannesburg, South Africa.

Nature of the evidence. The fossil record is similar to but less numerous than that of *Au. africanus*. The dentition is well represented, some of the cranial remains are well preserved, but many of the mandibles are crushed and/or distorted. The postcranial skeleton is not well represented. Research at Drimolen was only initiated in 1992, yet already more than 80 hominin specimens have been recovered and it promises to be a rich source of evidence about *P. robustus*.

Characteristics and inferred behavior. Cranial: The brain, face, and chewing teeth of *P. robustus* are larger than those of *Au. africanus*, yet the incisor teeth are smaller. Postcranial: It has been suggested that the thumb of *P. robustus* would have been capable of the type of grip necessary for stone tool manufacture, but this claim is not accepted by all researchers. The foot retains some arboreal capability, and the pelvic morphology suggests a relatively inefficient system for mass transfer, but the finger curvature is reduced, and it has more modern humanlike limb proportions and foot morphology, evidence that *P. robustus* was a more committed biped than, say, *Au. afarensis*, or *H. habilis* (see below).

CNS-related fossil evidence. Endocranial: The *P. robustus* neurocranium is represented by at least six specimens: four from Swartkrans (SK 1585, SK 46, SK 54, and SK 859), one from Kromdraai (TM 1517), and one from Drimolen (DNH 7). The mean adult endocranial volume is 533 ($n = 4$; range 450–650). The sample mean EQ for *P. robustus* is 3.1. The evidence for modern humanlike aspects of brain morphology is much weaker than for *P. boisei*, in spite of the larger brain size of *P. robustus*. Two or three specimens (SK 1585, SK 859, and possibly SK 54) have slight left occipital petalias, but there is no indication of whether they also have right frontal petalias (Holloway *et al.*, 2004a). It is not possible to tell whether the primary visual cortex is reduced in

SK 1585, SK 54, and SK 859, since for each of these endocasts the location of the LS and the interparietal sulcus cannot be determined with certainty (Holloway, 1975; Holloway *et al.*, 2004a). One *P. robustus* individual (SK 1585) has a beak-shaped frontal lobe and a rounded temporal lobe – ape-like traits shared with other *Paranthropus*, in contrast to the morphology of *Au. africanus* and *Homo* (Falk *et al.*, 2000). Vertebral canal: There are a handful of vertebras associated with this species, none of which are thoracic vertebras, although there is one near-complete axis (SK 854).

Other endocranial morphology. Cranial venous sinuses: All three *P. robustus* specimens with the relevant anatomy preserved demonstrate an enlarged O/M sinus system. These are SK 1585, SK 46, and SK 859 (Tobias, 1967; Holloway, 1972; Kimbel, 1984). Meningeal vessels: Saban (1983) found that one *P. robustus* endocast (SK 1585) had three major branches of the middle meningeal vessels: anterior, middle, and posterior.

Taxon name. *Australopithecus garhi* Asfaw *et al.*, 1999.

Approximate time range. *c.* 2.5 Mya.

Initial discovery. GAM-VP-1/1 – left side of mandibular corpus; Gamedah, Middle Awash, Ethiopia, 1990.

Type specimen. BOU*-VP-12/130 – a cranium; Bouri, Middle Awash, Ethiopia, 1997 (*the prefix ARA was erroneously used in the text of Asfaw *et al.*, 1999).

Source(s) of the evidence. Bouri, Middle Awash, Ethiopia.

Nature of the evidence. A cranium and two partial mandibles.

Characteristics and inferred behavior. Cranial: *Au. garhi* combines a primitive cranium with large-crowned postcanine teeth. However, unlike *Paranthropus* (see above), the incisors and canines are large and the enamel lacks the extreme thickness seen in the latter taxon. Postcranial: A partial skeleton combining a long femur with a relatively long forearm was found nearby, but is not associated with the type cranium of *Au. garhi* (Asfaw *et al.*, 1999); these fossils have not been formally assigned to *Au. garhi*.

CNS-related fossil evidence. The single cranial specimen has an endocranial volume of 450 cm^3, based on water displacement of a plaster model of the reconstructed endocast (reliability A1–A2). Holloway *et al.* (2004a) described the endocast morphology, but there was no evidence of a modern humanlike brain reorganization.

Other endocranial morphology. Meningeal vessels are present, but are not diagnostic.

4.18.4.4 Transitional *Homo*

This group contains two hominin taxa (*H. habilis s.s.* and *H. rudolfensis*) that are conventionally included within *Homo*, but which some researchers (e.g., Wood and Collard, 1999) have suggested might not belong in the *Homo* clade. Until we have the means to generate sound phylogenetic hypotheses about these and other early hominin taxa, it is not clear what their alternative generic attribution should be. Thus, for the purposes of this review, these two taxa are retained within *Homo*, but are referred to as transitional hominins.

Taxon name. *Homo habilis* Leakey *et al.*, 1964.

Approximate time range. *c.* 2.4–1.6 Mya.

Initial discovery. OH 4 – fragmented mandible; Olduvai Gorge, Tanzania, 1959.

Type specimen. OH 7 – partial skull cap and hand bones; Olduvai Gorge, Tanzania, 1960.

Source(s) of the evidence. Olduvai Gorge, Tanzania; Koobi Fora, and perhaps Chemeron, Kenya; Omo (Shungura), and Hadar, Ethiopia, East Africa; perhaps also Sterkfontein, Swartkrans, Cooper's and Drimolen, South Africa.

Nature of the evidence. Mostly cranial and dental evidence with only a few postcranial bones that can be confidently assigned to *H. habilis*.

Characteristics and inferred behavior. Cranial: All the crania are wider at the base than across the vault, but the face is broadest in its upper part. The jaws and teeth are absolutely small, but when related to estimated body mass they are larger than in other later premodern *Homo* taxa. Postcranial: The curved proximal phalanges and well-developed muscle markings on the phalanges of OH 7 also indicate the hand was used for more powerful grasping (such as would be needed for arboreal activities) than is the case in any other species of *Homo*. Conclusion: The jaws and teeth of *H. habilis* are absolutely small, but they are relatively large. Also, postcranial evidence suggests that *H. habilis* was capable of traveling arboreally and bipedally.

CNS-related fossil evidence. Endocranial: The CNS-related fossil evidence for *H. habilis* comprises six crania, two from Koobi Fora (KNM-ER 1813 and KNM-ER 1805), and four from Olduvai Gorge (OH 7, OH 13, OH 16, and OH 24). Brains are larger in *H. habilis* than in *Australopithecus* and *Paranthropus*, with a mean adult endocranial volume of 609 cm^3 ($n = 6$; range 509–687 cm^3). The sample average EQ for *H. habilis* is 3.7. Most of the inferences about derived modern humanlike morphology in this species are controversial, mainly due to poor preservation of the

relevant structures. Falk (1983a) has cast doubt on the allocation of KNM-ER 1805 to *H. habilis* on the grounds that it displays ape-like frontal orbital sulci at the lateral borders of the frontal lobes. The evidence for the petalial pattern in *H. habilis* is weak. Holloway *et al.* (2004a) claim that a single specimen, KNM-ER 1805, has a slight LORF petalial pattern, but the observation of frontal petalia is not reliable because of postmortem deformation (Begun and Walker, 1993; Holloway *et al.*, 2004a). Tobias (1987) makes a case for language ability in *H. habilis*, but this is controversial as much of the derived anatomy he describes for *H. habilis* is not confirmed by other authors, who claim the fossils are too fragmented and distorted to justify these interpretations (Begun and Walker, 1993; Holloway *et al.*, 2004a). Tobias (1987) suggests that OH 24, and probably OH 16 (but there is bone missing), have right frontal petalias. According to Tobias, the morphology of the fragmented of the frontal regions of the OH 7 and OH 16 endocasts is suggestive of a modern humanlike Broca's area, but Holloway *et al.* (2004a) see too few convolutional details to confirm this. The supramarginal angular gyri of the inferior parietal region – corresponding to Brodmann areas 40 and 39, respectively – are well developed in all four Olduvai *H. habilis* specimens (i.e, OH 7, 16, 13, and 24) (Tobias, 1987). Tobias states that these gyri are included in Wernicke's area (although he allows that the area's definition is controversial). In fact, the inferior parietal lobule is probably not part of Wernicke's language comprehension area, which is restricted to the left superior temporal cortex posterior to the primary auditory cortex (i.e., posterior part of Brodmann area 22) (Wise *et al.*, 2001). However, as previously mentioned, the inferior parietal lobule is greatly expanded in humans compared to monkeys, a difference that has been correlated with the development of language and calculation abilities (Simon *et al.*, 2002). Tobias (1987) mentions that in three *H. habilis* specimens (OH 24, OH 13, and OH 7) the superior parietal lobule is well developed, a characteristic also of *Au. africanus* (Dart, 1925; Schepers, 1946). Because the development is greater on the left size, he calls the asymmetry parietopetalia, but note that none of these specimens has the typical modern humanlike LORF petalial pattern. Holloway *et al.* (2004a) do not confirm these asymmetries, and instead they note that OH 7 and OH 24 are distorted and that this makes the identification of parietal petalias questionable, and that in OH 13 inferences about a parietal petalia depend on the way the specimen is orientated. Holloway *et al.* (2004a) do not refer to the placement of the LS or to the size of the occipital lobe in *H. habilis*. However, Begun and Walker (1993) suggest that the occipital lobe in two *H. habilis* specimens (KNM-ER 1813 and KNM-ER 1805) is smaller and less projecting than in KNM-ER 1470, a cranium referred to *H. rudolfensis*. Vertebral canal: Unfortunately, no *H. habilis* thoracic vertebras are available to investigate potentially language-related aspects of spinal cord anatomy in this taxon. Behavioral interpretations: There is no evidence of modern humanlike Broca's cap morphology in *H. habilis*, nor is there any evidence for any reduction in the size of the primary visual cortex. In summary, the original suggestion that *H. habilis* is the earliest hominin with the cognitive capacity for language is no longer supported.

Other endocranial morphology. Cranial venous sinuses: Three specimens (KNM-ER 1813, KNM-ER 1805, and OH 16) demonstrate the usual modern humanlike dominant transverse-sigmoid sinus system. Meningeal vessels: *H. habilis* endocasts for which the morphology is available (KNM-ER 1805, KNM-ER 1813, OH 7) have evidence of three major branches of the middle meningeal artery (Tobias, 1991; Holloway *et al.*, 2004a).

Taxon name. *Homo rudolfensis* (Alexeev, 1986) *sensu* Wood, 1992.

Approximate time range. *c.* 1.8–1.6 Mya.

Initial discovery. KNM-ER 819 – mandible fragment; Koobi Fora, Kenya, 1971.

Type specimen. Lectotype: KNM-ER 1470 – cranium; Koobi Fora, Kenya, 1972 (Leakey, 1973).

Source(s) of the evidence. Koobi Fora, and perhaps Chemeron, Kenya; Uraha, Malawi.

Nature of the evidence. Several incomplete crania, two relatively well-preserved mandibles, and several isolated teeth.

Characteristics and inferred behavior. Cranial: *H. rudolfensis* and *H. habilis* show different mixtures of primitive and derived, or specialized, cranial features. For example, although the absolute size of the brain case is greater in *H. rudolfensis*, its face is widest in its mid-part, whereas the face of *H. habilis* is widest superiorly. The more primitive face of *H. rudolfensis* is combined with a robust mandible and mandibular postcanine teeth with larger, broader crowns and more complex premolar root systems than those of *H. habilis*. The mandible and postcanine teeth of *H. rudolfensis* are larger than one would predict for a generalized hominoid of the same estimated body mass, suggesting that its dietary niche made mechanical demands comparable to those of the archaic

hominins. Postcranial: No postcranial remains can yet be reliably linked with *H. rudolfensis*.

CNS-related fossil evidence. Endocranial – CNS-related data are preserved in three cranial specimens (KNM-ER 1470, KNM-ER 1590, and KNM-ER 3732). *H. rudolfensis* mean adult endocranial volume is 776 ($n = 3$; range 750–825), although when it is related to admittedly crude estimates of body mass (EQ = 3.2) the brain of *H. rudolfensis* is not substantially larger than that of *Paranthropus*, and is smaller than that of *H. habilis*. KNM-ER 1470 has a modern humanlike Broca's region which is expanded on the left side (Tobias, 1975; Falk, 1983a; Begun and Walker, 1993; Holloway *et al*., 2004a), a feature that KNM-ER 3732 probably shares, although distortion obscures the interpretation of the morphology of this region. The clearly delimited, modern humanlike Broca's cap is taken by Holloway (1983c) to be suggestive of both language capacity and right-handedness, although he cautions that chimpanzees may also have well-developed Broca's caps. KNM-ER 1470 has a clear, modern humanlike LORF petalial pattern. Unlike *H. habilis* (KNM-ER 1805), KNM-ER 1470 lacks an ape-like fronto-orbital sulcus on the surface of the frontal lobe (Falk, 1983a). Holloway *et al*. (2004a) found no evidence of an LS or occipital lobe reduction in *H. rudolfensis*. However, Begun and Walker (1993) mention that the occipital lobe in the *H. rudolfensis* specimen KNM-ER 1470 is larger and more projecting than in two *H. habilis* specimens (KNM-ER 1813 and KNM-ER 1805). Vertebral canal: No vertebras are known for this taxon. Behavioral interpretations: *H. rudolfensis* (in particular, KNM-ER 1470) represents the oldest undisputed evidence of modern humanlike brain anatomy and it possesses features suggestive of language ability and right-handedness (Falk, 1983a; Holloway *et al*., 2004a). In support of these interpretations, Toth (1985) has inferred that contemporaneous stone tools were produced by predominately right-handed hominins. Interestingly, there is much more evidence of modern humanlike CNS-related anatomy in *H. rudolfensis* than in *H. habilis*. Also noteworthy, the debate over particular convolutional details lessens with the appearance of *Homo*. This is in part due to the fact that the endocranial convolutions of *Homo* are less obvious than those of archaic hominins. Falk (1980a, 1980b) notes that frontal convolutions should be the focus of endocast studies as these are more visible. This visibility contrasts with the relatively poor preservation of the LS in premodern *Homo* (Falk, 1991).

Other endocranial morphology. Cranial venous sinuses: *H. rudolfensis* does not show any evidence of an enlarged O/M sinus system. Meningeal vessels: One specimen (KNM-ER 1470) has separate anterior, middle, and posterior branches of its middle meningeal artery (Holloway *et al*., 2004a).

4.18.4.5 Premodern *Homo*

The species in this category are all usually assigned to the *Homo* clade. However, at least one species, *H. ergaster*, has a brain size that overlaps with that of archaic and transitional hominins.

Taxon name. *Homo ergaster* Groves and Mázak, 1975.

Approximate time range. *c*. 1.9–1.5 Mya.

Initial discovery. KNM-ER 730 – corpus of an adult mandible with worn teeth; Koobi Fora, Kenya, 1970.

Type specimen. KNM-ER 992 – well-preserved adult mandible; Koobi Fora, Kenya, 1971.

Source(s) of the evidence. Koobi Fora, West Turkana, Kenya; Dmanisi, Republic of Georgia.

Nature of the evidence. Cranial, mandibular, and dental evidence, including a remarkably complete associated skeleton of a juvenile male individual from Nariokotome, West Turkana.

Characteristics and inferred behavior. Cranial: Two sets of features are claimed to distinguish *H. ergaster* from *H. erectus*. The first comprises features for which *H. ergaster* is more primitive than *H. erectus*, with the most compelling evidence coming from details of the mandibular premolars. The second set comprises features of the vault and base of the cranium for which *H. ergaster* is less specialized, or derived, than *H. erectus*. The small chewing teeth of *H. ergaster* imply that it was either eating different food than the australopiths, or that it was preparing the same food extraorally. This could have involved the use of stone tools, or cooking, or a combination of the two. Postcranial: Postcranial similarities to modern humans suggest these hominins were habitual bipeds. Conclusion: Overall, *H. ergaster* is the first hominin to combine modern human-sized chewing teeth with a postcranial skeleton (e.g., long legs, large femoral head, etc.) apparently committed to long-range bipedalism, and to lack morphological features associated with locomotor and postural behaviors related to arboreality.

CNS-related fossil evidence. Endocranial: Relevant fossil evidence for *H. ergaster* comprises three well-preserved crania from Africa (Koobi Fora, and West Turkana), and four crania from

Dmanisi in the Republic of Georgia. The adult mean endocranial volume of the six *H. ergaster* specimens is 762 cm^3, with an average of 851 cm^3 for the three African specimens, and a much lower average of 675 cm^3 for the three Dmanisi specimens with published endocranial volume estimates. The sample average EQ for *H. ergaster* is 2.8. When the Dmanisi specimens (for which no body mass has been estimated) are excluded, the EQ for the three African specimens of *H. ergaster* is 3.1. Convolutional details are known only for the three African specimens. Two specimens have modern humanlike LORF petalial patterns (KNM-WT 15000, KNM-ER 3883), whereas the third specimen (KNM-ER 3733) has a less pronounced asymmetry (Begun and Walker, 1993; Holloway *et al.*, 2004a). All three specimens seem to have a modern humanlike asymmetry of the Broca's cap region, with the evidence for this pattern being clearest in KNM-ER 15000, whereas in the other two East African specimens the morphology in that area is uncertain (Begun and Walker, 1993; Holloway *et al.*, 2004a). Occipital convolutional details are not preserved in any *H. ergaster* cranial specimen. Vertebral canal: The juvenile West Turkana (KNM-WT 15000) skeleton also includes a vertebral column. *H. ergaster* resembles earlier hominins and nonhuman primates in having relatively smaller thoracic vertebral canals than recent humans, suggesting that this hominin did not yet show the expanded canal that has been associated with more precise control of the muscles associated with speech (see entry for *H. neanderthalensis* for a discussion). Behavioral interpretations: Holloway *et al.* (2004a) interpret the cranial findings as clear evidence of right-handedness and language ability. In contrast, evidence from the vertebral canal suggests humanlike increased control of breathing; thus, speech most likely did not yet exist in these hominins. Great apes (Patterson, 1978; Gardner *et al.*, 1989; Shapiro and Galdikas, 1999) and human infants (Bonvillian *et al.*, 1983, 1997; Bonvillian and Patterson, 1999) lack the capacity for vocal language production, but they are able to communicate with hand signals. A study of a deaf sign-language user found that Broca's region maintains its function in nonvocal language (Corina *et al.*, 1999; Corina and McBurney, 2001). Language-related cerebral anatomy might have existed as part of a complex of preadaptations to language, along with a series of cranial modifications seen in *H. ergaster* and *H. erectus* (MacLarnon and Hewitt, 2004). These data suggest that increased nonvocal language ability preceded vocal language.

Other endocranial morphology. Cranial venous sinuses: There is no indication of enlarged O/M sinus system for this taxon. Meningeal vessels: The anterior branch of the middle meningeal artery is especially well developed in *H. ergaster* crania such as KNM-WT 15000 (Begun and Walker, 1993), and KNM-ER 3883 (Holloway *et al.*, 2004a). Anterior branches are characteristically more developed on endocasts of later African fossil *Homo*, including modern humans (Grimaud-Hervé, 1994; Holloway *et al.*, 2004a).

Taxon name. Homo floresiensis Brown *et al.*, 2004.

Approximate time range. c. <90–12 kya.

Initial fossil discovery. LB1 – partial adult skeleton; Liang Bua, Flores Indonesia, 2003 (Brown *et al.*, 2004).

Type specimen. As above.

Sources of the evidence. Liang Bua, Indonesia.

Nature of the evidence. LB1 partial adult skeleton plus cranial and postcranial evidence of a total of at least nine individuals (Morwood *et al.*, 2005).

Characteristics and inferred behavior. Cranial: Cranial morphology suggests a dwarfed *H. erectus*. Similar to *Au. afarensis* in stature and endocranial volume. Postcranial: Femur and pelvic morphologies show affinities to *H. habilis* and *Au. afarensis*. Possibly associated with oldowan-like stone artifacts. Charred bones hint at control of fire.

CNS-related fossil evidence. Endocranium: The endocranial volume estimate of LB 1 is 417 cm^3. The *H. floresiensis* EQ, assuming a body mass of 26 kg, is 3.1; this is within the *Australopithecus* range. For comparison, if one assumes the low-end body mass estimate of 16 kg, the EQ is 4.5, and assuming the given the high-end body mass estimate of 36 kg, the EQ is a mere 2.4 – the smallest of any fossil hominin. All inferences about *H. floresiensis* brain morphology were made by Falk *et al.* (2005), based on observations of both the LB1 fossil neurocranium and a virtual endocast. In endocranial shape, LB1 resembles classic Asian *H. erectus*. LB1 has a LORF petalial pattern. Details are not given, although the Broca's cap region is consistent with modern humanlike morphology (Falk *et al.*, 2005). The endocast lacks ape-like fronto-orbital sulci; these are also absent in *H. rudolfensis*, but they are retained in other (smaller-brained) early hominins such as *H. habilis* and *Au. africanus* (Falk, 1980b, 1983a). The LS is posterior to the lambdoid suture, in a derived position which suggests relative reduction of the primary visual cortex at the expense of enlargement of posterior parietal association areas (Figure 2e). There are a few features in which the

H. floresiensis brain differs from the classic *H. erectus* brain. First, it is inferred that prefrontal cortex in the region of area 10 is expanded and much more convoluted than in *H. erectus* or *Au. africanus* (Falk *et al.*, 2005). This aspect of *H. floresiensis* is significant because the prefrontal cortex is the region of the human brain that has most clearly increased in relative degree of gyrification (Zilles *et al.*, 1988; Rilling and Insel, 1998). Second, LB1 has extremely wide temporal lobes. Interestingly, the temporal lobe is predicted to have undergone more change in the modern human lineage than has any other brain component (Semendeferi and Damasio, 2000), and it is larger in modern humans than predicted for a nonhuman primate of similar brain size (Rilling and Seligman, 2002). Third, the LB1 occipital lobe does not hang over the cerebellum. An occipital lobe that overhangs the cerebellum is a derived feature of *H. erectus* (Falk *et al.*, 2005). Vertebral canal: No description available. Behavioral interpretations: *H. floresiensis* is a dwarfed hominin species in which the size reduction was more pronounced in the brain than the body. In spite of its small absolute and relative brain size, the *H. floresiensis* brain is at least as modern humanlike in its morphology as is the brain of *H. erectus*. Compared to classic *H. erectus*, *H. floresiensis* is more modern humanlike in having a well-developed temporal lobe and increased gyrification of the prefrontal region. Might the specialized brain morphology of *H. floresiensis* relate to the fact that this species has been associated with unusually sophisticated artifacts? At present, it is impossible to know. Many cognitive functions of the prefrontal and temporal regions (e.g., processing of auditory information, language production, higher-order processing of visual information, planning, and memory) are predicted to be emphasized in a species that is associated with stone tools. However, these areas are probably not the ones most involved in the act of stone toolmaking (see Stout *et al.*, 2000). An alternative hypothesis is that in this species the temporal lobe and prefrontal cortex did not become relatively larger; rather, other structures (e.g., primary visual cortex) became relatively smaller more quickly. Domesticated mammals have relatively smaller brains and sensory structures than do their wild counterparts, with the size of the primary visual cortex and eyes being the most reduced – a pattern that is also found in the fossil dwarfed bovid *Myotragus* (Köhler and Moyà-Solà, 2004).

Other endocranial morphology. Cranial venous sinuses: Present, but not diagnostic. Meningeal vessels: The configuration suggests that vessels that originate in the orbit contribute to the supply of the meninges overlying the temporal lobe; this feature is common in apes and found in some *H. erectus* (Falk, 1993; Falk *et al.*, 2005).

Taxon name. *Homo erectus* (Dubois, 1892) Weidenreich, 1940.

Approximate time range. *c.* 1.8 Mya to $<$ 200 kya.

Initial discovery. Kedung Brubus 1 – mandible fragment; Kedung Brubus, Java (now Indonesia), 1890.

Type specimen. Trinil 2 – adult calotte; Trinil, Ngawi, Java (now Indonesia), 1891.

Source(s) of the evidence. Sites in Indonesia (e.g., Trinil, Sangiran, Sambungmachan), China (e.g., Zhoukoudian, Lantian), Africa (e.g., Olduvai Gorge, Melka Kunture), and possibly India (Hathnora).

Nature of the evidence. Mainly cranial with some postcranial evidence, but little or no evidence of the hand or foot.

Characteristics and inferred behavior. Cranial: The crania belonging to *H. erectus* have a low vault, a substantial, more-or-less continuous torus above the orbits, and the occipital region is sharply angulated. The inner and outer tables of the cranial vault are thickened. The body of the mandible is less robust than that of the australopiths and in this respect it resembles *H. sapiens*, except that the symphyseal region lacks the well-marked chin that is a feature of later *Homo* and modern humans. The tooth crowns are generally larger, and the premolar roots of many specimens are more complicated than those of modern humans. All the dental and cranial evidence points to a modern humanlike diet for *H. erectus*. Postcranial: The cortical bone of the postcranial skeleton is thicker than that in modern humans. The limb bones are modern humanlike in their proportions and have robust shafts, but the shafts of the long bones of the lower limb are flattened from front to back (femur) and from side to side (tibia) relative to those of modern humans. There is no fossil evidence relevant to assessing the dexterity of *H. erectus*, but if *H. erectus* manufactured Acheulean artifacts then dexterity would be implicit. The postcranial elements are consistent with a habitually upright posture and obligate, long-range bipedalism.

CNS-related fossil evidence. Endocranial: At least 43 crania or cranial fragments preserve information about the CNS of *H. erectus*. The mean endocranial volume of *H. erectus* is 991 cm^3 ($n = 36$; range 727–1260). The EQ for *H. erectus* is 3.9, and

H.erectus shows aspects of modern humanlike brain organization similar to those described for *H. ergaster*. This taxon shows surprisingly little variability in endocast morphology. Holloway (1980), Broadfield *et al.* (2001), and Holloway *et al.* (2004a) drew attention to the very clear pattern of LORF petalial patterns and modern humanlike asymmetry of the Broca's cap region. There is some suggestion of a right-hander's petalial configuration from all sites with scored fossils (i.e., Olduvai, Ngandong, Sambungmacan, Sangiran, Trinil, Zhoukoudian) (Holloway *et al.*, 2004a). The asymmetries range from slight to strong, and in many specimens the evidence exists for both the left occipital and the right frontal (Ngandong 1, 6, 17, 14; Sangiran 2, 17; Trinil 2, Zhoukoudian III E, III L), although in other specimens there are missing data or there is distortion in either the left occipital or right frontal regions (Ngandong 13; OH 9, 12; Sangiran 4, 10, 12; Zhoukoudian I L; Holloway *et al.*, 2004a). However, Begun and Walker (1993) took a different position with respect to the existence of petalias in the Zhoukodian specimens that they examined. They state that no frontal petalias are evident for Zhoukoudian I L, II, III E, and III L, and no occipital petalias are evident for Zhoukoudian II and III E, although they do allow that occipital petalias are evident for Zhoukoudian I L and III L. Holloway *et al.* (2004a) do not describe the morphology of Zhoukoudian II. Most authors agree that the frontal lobe of *H. erectus* is derived toward the modern humanlike condition. Convolutional details of the frontal lobe are more modern humanlike than ape-like for Sangiran 2 (Ariens Kappers and Bouman, 1939; Weidenreich, 1943; Connolly, 1950). Broca's region is more modern humanlike in *H. erectus* than in earlier hominins. This was first mentioned by Dubois (1897), who noted that the type specimen (Trinil 2) had a fairly well-developed third (=inferior) frontal convolution, the gyrus associated with Broca's area. In fact, the Broca's cap region is enlarged, and/or there is an asymmetry in which the left side is larger and better defined or protrudes more laterally in all scorable specimens (i.e., Ngandong 6 and 14, Sambungmacan 3, Sangiran 2, 3, 10 and 17, Trinil 2, and Zhoukoudian III E) (Holloway, 1980; Grimaud-Hervé, 1994; Holloway *et al.*, 2004a). Holloway *et al.* (2004a) infer that *H. erectus* was capable of rudimentary language and was predominantly right-handed. In the occipital lobe, the LS has been identified in a few specimens (Sangiran 10, OH 12, Trinil 2) and in all it is in a posterior position. A possible exception is Sangiran 2 in which the identification of the LS is uncertain, and the sulcus referred to may actually be a lateral calcarine sulcus in a position that would be unusual in modern humans. The two fossils from Olduvai (OH 9 and OH 12) resemble the Asian specimens in aspects of brain morphology. OH 9 has a strong left occipital petalia like other *H. erectus* and *H. ergaster* (due to missing data, whether or not there was a right frontal petalia cannot be determined). OH 12 has a posterior LS like other *H. erectus* (convolutional details in this region are not preserved in any *H. ergaster* specimen). However, whereas OH 9 is in the upper 50% of *H. erectus* endocranial volume, OH 12 has the smallest *H. erectus* endocranial volume and fits better with *H. ergaster*. The development of three cranial features (the tympanic plate, the bregmatic area of the cranial vault, and the subarcuate fossa) and a comparison of adult *H. erectus* endocranial volumes with that of the Mojokerto child, reveal an ape-like pattern of brain ontogeny for this specimen (Coqueugniot *et al.*, 2004).

Other endocranial morphology. Cranial venous sinuses: Three specimens (Zhoukoudian II, III E, and III L) have dominant transverse-sigmoid sinus systems, and one specimen (Trinil 2) has an O/M sinus system on the left and an enlarged transverse sinus on the right (Falk, 1986). Meningeal vessels: Weidenreich (1938) used a modern human-based system of classification in his description of the Zhoukoudian fossils which overlooked similarities between the *H. erectus* meningeal patterns and that of the apes; but he did note that *H. erectus* was primitive in having fewer ramifications than modern humans. In Falk's re-evaluation of Weidenreich's description of the meningeal vessels (Falk, 1993), she concludes that they are ape-like to the extent that there is a high frequency of the meningeal arteries originating from the orbit rather than the floor. In comparison to modern humans, in Asian *H. erectus* specimens the obelic branch of the middle meningeal artery is more developed, and may have contributions from both the anterior and the posterior branches. Grimaud-Hervé describes three regional patterns. First, it is common for the obelic branch to arise independently as a third major branch in Zhoukoudian endocasts (e.g., Zhoukoudian I L, III E). Second, the obelic branch bifurcates near the origin of middle branch in Trinil 2 and several Sangiran endocasts (e.g., Sangiran 17). Third, in most Ngandong endocasts, the obelic branch derives from the anterior branch but also has a contribution from the posterior branch; the anterior branch is often better developed than the posterior (e.g., Ngandong 3, 7). In the North African *H. erectus* Ternifine 4, a very ramified obelic branch stems from the anterior branch of the

middle meningeal artery (Saban, 1984; Holloway *et al.*, 2004a). The developed anterior branch is said to be typical of African specimens of later taxa, but, as mentioned above, the developed obelic branch is also typical of *H. erectus*. The principal vessel of the anterior branch has posterior ramifications that run parallel to it in *H. erectus*, in contrast to their more oblique orientation in modern humans (Grimaud-Hervé, 1994; see The Evolution of Parallel Visual Pathways in the Brains of Primates).

Taxon name. Homo antecessor Bermúdez de Castro *et al.*, 1997.

Approximate time range. c. 700–500 kya.

Initial discovery. ATD6-1 – left mandibular canine; Level 6, Gran Dolina, Spain, 1994.

Type specimen. ATD6-5 – mandible and associated teeth; Level 6, Gran Dolina, Spain, 1994.

Source(s) of the evidence. Gran Dolina, Atapuerca, Spain.

Nature of the evidence. The partial cranium of a juvenile, parts of mandibles and maxillae, and isolated teeth.

Characteristics and inferred behavior. Cranial: Researchers who found the remains claim the combination of a modern humanlike facial morphology with large and relatively primitive tooth crowns and roots is not seen in *H. heidelbergensis* (see below). The Gran Dolina remains also show no sign of any derived *H. neanderthalensis* traits. Its discoverers suggest *H. antecessor* is the last common ancestor of Neanderthals and *H. sapiens*.

CNS-related fossil evidence. The only *H. antecessor* cranium (ATD-15) has an estimated endocranial volume of 1000 cm^3 (Bermudez de Castro *et al.*, 1997).

Taxon name. Homo heidelbergensis Schoetensack, 1908.

Approximate time range. c. 600–100 kya.

Initial discovery. Mauer 1 – adult mandible; Mauer, Heidelberg, Germany, 1907.

Type specimen. As above.

Source(s) of the evidence. Sites in Europe (e.g., Mauer, Petralona); Near East (e.g., Zuttiyeh); Africa (e.g., Kabwe, Bodo); and China (e.g., Dali, Jinniushan, Xujiayao, Yunxian). Researchers who see distinctions between the African and non-African components of the hypodigm refer to the former as *H. rhodesiensis*.

Nature of the evidence. Many crania but relatively little mandibular and postcranial evidence.

Characteristics and inferred behavior. Cranial: What sets this material apart from *H. sapiens* and *H. neanderthalensis* (see below) is the morphology of the cranium and the robusticity of the postcranial skeleton. Some brain cases are as large as those of modern humans, but they are always more robustly built with a thickened occipital region, an evenly projecting face with large separate ridges above the orbits, unlike the more continuous brow ridge of *H. erectus*. Compared with *H. erectus* (see above), the parietals are expanded, the occipital is more rounded and the frontal bone is broader. The crania of *H. heidelbergensis* lack the specialized features of *H. neanderthalensis* such as the anteriorly projecting midface and the distinctive swelling of the occipital region. *H. heidelbergensis* is the earliest hominin to have a brain as large as anatomically modern *H. sapiens*. Postcranial: the postcranial skeleton of *H. heidelbergensis* suggests that its robust long bones and large lower limb joints were well suited to long-distance bipedal walking.

CNS-related fossil evidence. Endocranial: *H. heidelbergensis* is represented by at least 22 cranial fossils that preserve evidence of the CNS. The mean adult endocranial volume for *H. heidelbergensis* is 1242 cm^3 ($n = 21$; range 880–1450 cm^3). There is an increase in mean endocranial volume compared to *H. erectus* and *H. ergaster*. The EQ for *H. heidelbergensis* is 4.2. For all the specimens, the LS is in the modern humanlike posterior position, according to Holloway *et al.* (2004a). Broken Hill 1 was described by Smith (1928) to have an ape-like LS, but Holloway *et al.* (2004a) disagree with this interpretation. Holloway *et al.* (2004a) describe LORF petalial patterns in most specimens, and very pronounced asymmetrical Broca's regions in some specimens. This is most pronounced in Arago, which has very protruding Broca's caps on both sides. Unfortunately, several specimens are missing entire frontal lobes, and there is no specimen for which all the relevant language/handedness morphology is preserved.

Other endocranial morphology. Cranial venous sinuses: Arago, Broken Hill, and Salé lack an O/M sinus system, although Guomde has an O/M sinus system (on both sides) and Swanscombe has an O/M sinus system on the right, not on the left (Falk, 1986). Meningeal vessels: The anterior branch of the middle meningeal artery is especially developed in African *H. heidelbergensis*. The anterior branch has a few anastomoses in Salé, and more numerous anastomoses in Broken Hill 1. In some European *H. heidelbergensis* (e.g., Swanscombe, Ehringsdorf 9), the anterior branch is more prominent and is the source of the obelic branch (Falk, 1986). In contrast, in one European *H. heidelbergensis* the posterior ramus is just as prominent as the anterior ramus (Falk, 1986).

Taxon name. Homo neanderthalensis King, 1864.

Approximate time range. *c.* >400 or 200–30 kya.

Initial discovery. Engis 1 – a child's cranium; Engis, Belgium, 1829.

Type specimen. Neanderthal 1 – adult calotte and partial skeleton; Feldhofer Cave, Mettmann, Germany, 1856.

Source(s) of the evidence. Fossil evidence for *H. neanderthalensis* has been found throughout Europe, with the exception of Scandinavia, as well as in the Near East, the Levant and Western Asia. Taxonomic note: The scope of the hypodigm of *H. neanderthalensis* depends on how inclusively the taxon is defined. For some researchers the taxon is restricted to fossils from Europe and the Near East that used to be referred to as classic Neanderthals. Others interpret the taxon more inclusively and include within the hypodigm fossil evidence that is generally earlier and less derived (e.g., Steinheim, Swanscombe and Atapuerca (Sima de los Huesos)).

Nature of the evidence. Many specimens are burials and so all anatomical regions are represented in the fossil record.

Characteristics and inferred behavior. Cranial: The distinctive features of the cranium of *H. neanderthalensis* include thick, double-arched brow ridges, a face that projects anteriorly in the midline, a large nose, laterally projecting and rounded parietal bones, and a rounded, posteriorly projecting occipital bone (i.e., an occipital bun). The size and wear on the incisors suggest that the Neanderthals regularly used their anterior teeth as tools, either for food preparation or to grip hide or similar material. Postcranial: Neanderthals were stout with a broad rib cage, a long clavicle, a wide pelvis, and limb bones that are generally robust with well-developed muscle insertions. The distal extremities tend to be short compared to most *H. sapiens*, but Neanderthals were evidently obligate bipeds. The generally well-marked muscle attachments and the relative thickness of long bone shafts point to a strenuous lifestyle.

CNS-related fossil evidence. Endocranial: There are at least 27 neurocranial fossils preserving evidence of the *H. neanderthalensis* CNS. The mean adult endocranial volume for *H. neanderthalensis* is 1404 cm^3 ($n = 27$; range 1172–1740 cm^3). The EQ for *H. neanderthalensis* is 4.7, smaller than that of *H. sapiens*. Neanderthals were often considered to have larger cranial capacities than *H. sapiens*, but this has recently been reconsidered in light of new estimates (Holloway *et al.*, 2004a, pp. 301, 304–305). Holloway *et al.* (2004a) suggest that Neanderthals have an overall modern humanlike brain shape, although there is occipital bunning in many specimens. Similarities with modern human brain shape include broad, round, vertical prefrontal lobes, and wide, full parietal lobes. In contrast, Bruner *et al.* (2003) argue that brain shape in Neanderthals follows archaic (i.e., *H. erectus* and *H. heidelbergensis*) allometric trends for brain size expansion. In contrast, they suggest that modern humans show a different pattern of brain growth that emphasizes expansion of the parietal lobes. Distinct petalias are the norm for Neanderthals. Many have very strong petalias, although not all specimens display the LORF pattern. One of the crania with an atypical petalia (La Ferrassie 1) also has a larger Broca's area on the right than on the left, and in another (La Chapelle-aux-Saints), a usual LORF petalial pattern is combined with a right dominant Broca's area. However, most have a modern humanlike pattern of Broca's area asymmetry.

Holloway *et al.* (2004a) suggest that, in all the Neanderthals they looked at, the LS is posterior to the lambdoid suture, as it is in modern humans. They are most certain about the position of the LS in Monte Circeo I, where it is far posterior to the lambdoid suture. They are uncertain about the identification of, or make indirect inferences about, the location of the LS in Le Ferrassie 1, La Quina 5, Neanderthal, Spy I, and Spy II. In La Chapelle-aux-Saints, Boule and Anthony (1911) had originally suggested the LS was anterior to the lambdoid suture. This was disputed (Symington, 1916; Le Gros Clark *et al.*, 1936), and Holloway *et al.* (2004a) point out that Boule and Anthony (1911) misidentified the LS, and that the real LS is posterior to the lambdoid suture. Holloway *et al.* did not look at the Krapina endocasts in detail, but they suggest that the Krapina specimens have more derived and modern features than Western European Neanderthals. Holloway *et al.* (2004a, p. 235) consider that, in terms of their CNS morphology, *H. sapiens* and *H. neanderthalensis* should only be separated at the subspecific level. Vertebral canal: At least four (Kebara, La Chapelle-aux-Saints, Shanidar 2, Shanidar 3) sets of Neanderthal fossil vertebras provide information about the size of the vertebral canal that transmits the spinal cord. Neanderthals resemble modern humans (and are different from all earlier hominins) in having enlarged thoracic vertebral canals relative to nonhuman primates. Increased muscular control associated with speech may explain the increase in spinal cord size in the Late Pleistocene hominins (MacLarnon and Hewitt, 1999, 2004).

Behavioral interpretations. *H. neanderthalensis* is modern humanlike in terms of its endocranial volume, inferred spinal cord dimensions, and

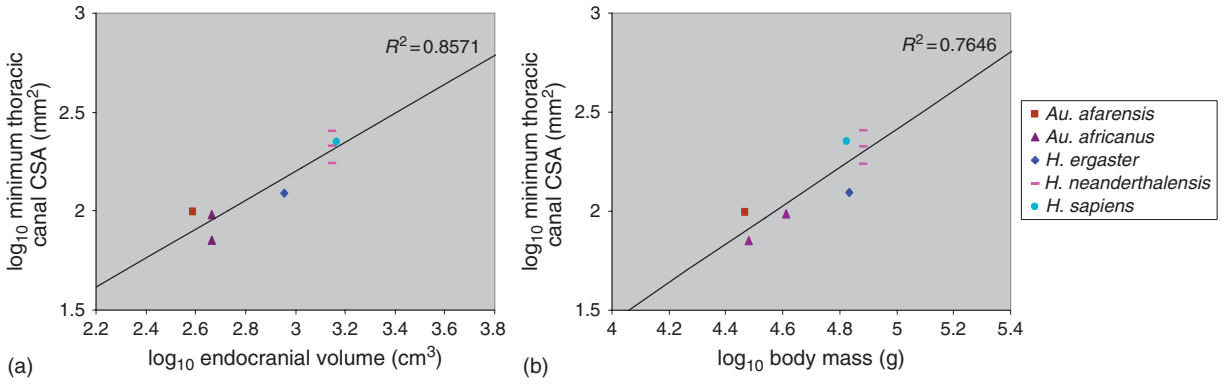

Figure 3 Log–log plots of minimum thoracic vertebral canal cross-sectional area (CSA) versus endocranial volume (a) and body mass (b) for fossil hominin specimens. Fossil hominin endocranial volume sources are available from the authors, by request. Thoracic CSA and body mass data are from MacLarnon and Hewitt (1999) and references therein.

brain organization. This, taken together with anatomy consistent with spoken language, and archeological evidence of complex, possibly symbolic burial behavior, suggests that Neanderthals shared with their early modern human contemporaries many characteristics of modern human cognition. However, no Neanderthal remains are associated with artifacts that can unequivocally be interpreted as art, which would serve as undisputed evidence of symbolic behavior. In contrast, contemporaneous early modern humans are associated with art throughout Europe by the time of Neanderthals last appearance *c*. 28 kya, suggesting that these two hominin taxa differed in terms of culture and cognition (Klein, 1999). The increase in thoracic vertebral canal cross-sectional area from early to late hominins might be explained by the corresponding increase in endocranial volume. The only Neanderthal for which both measures are available, La Chapelle-aux-Saints, has the largest minimum thoracic vertebral cross-sectional area of any primate specimen listed (253 mm^2 at T6) and a very large endocranial volume (1625 cm^3) (MacLarnon and Hewitt, 1999, 2004, p. 188). MacLarnon and Hewitt's conclusions are based on hominin values compared with a thoracic vertebral canal to body size scaling relationship for extant primates. But different taxa have different brain mass to body mass scaling relationships (Holloway and Post, 1982), and the relationship between brain size and spinal cord size is even more variable within large taxonomic groups (MacLarnon, 1995). A within-hominin spinal cord to brain size scaling relationship (or CNS scaling law) could account for the observed variation in spinal cord size (see Figure 3a). Further, the pivotal specimen for the argument of MacLarnon and Hewitt is a single *H. ergaster* specimen – a juvenile for which the growth trajectory is uncertain (see Coqueugniot *et al.*, 2004, and references therein) and for which the small vertebral canal may be pathological (Ohman *et al.*, 2002). This specimen sits on the regression line, and most hominin fossils plot above it (see MacLarnon and Hewitt, 1999; Figure 3b). A best-fit line for thoracic vertebral canal cross-sectional area against body mass for the fossil hominin specimens is much steeper than that for all primates (Figure 3b). Therefore, Neanderthals and modern humans have thoracic vertebral canal cross-sectional areas that fall within the range predicted for a hominin of similar brain size and body mass, although *H. ergaster* has a smaller thoracic vertebral canal cross-sectional area than expected for its body mass.

Other endocranial morphology. Cranial venous sinuses: There is no evidence of an O/M sinus system in any Neanderthal specimen (Falk, 1986). Meningeal vessels: In some Neanderthal crania (Le Moustier, Neanderthal, La-Chapelle-aux-Saints), the posterior branch of the middle meningeal artery is as prominent as the anterior branch (Holloway *et al.*, 2004a). In other Neanderthals (Gibraltar 1 and 2, Teshik Tash 1, Engis 2, La Ferrassie 1, La Quina H 5), the anterior branch is more prominent, and is the source of the obelic branch, as is common in modern humans. Both configurations found in Neanderthals were also found in European *H. heidelbergensis* (Holloway *et al.*, 2004a).

4.18.4.6 Anatomically Modern *Homo*

This category includes all those specimens that lack the autapomorphies of premodern *Homo* taxa, or which cannot be distinguished from living *H. sapiens*.

Taxon name. *Homo sapiens* Linnaeus, 1758.

Approximate time range. *c*. 190 kya to the present day.

Initial fossil discovery. With hindsight, the first recorded evidence to be recovered was the Red Lady of Paviland, found in Wales in 1822–23.

Type specimen. Linnaeus did not designate a type specimen.

Source(s) of the evidence. Fossil evidence of *H. sapiens* has been recovered from sites on all continents except the Antarctic. The earliest absolutely dated remains are from Omo Kibish (McDougall *et al*., 2005) and Herto (White *et al*., 2003) in Ethiopia. Taxonomic note: Researchers who wish to make a taxonomic distinction between fossils such as Florisbad, Omo 2, and Laetoli 18, and subrecent and living modern humans refer the African subset to *H.* (*Africanthropus*) *helmei* (Dreyer, 1935).

Nature of the evidence. Many are burials so the fossil evidence is good, but in some regions of the world (e.g., West Africa) remains are few and far between.

Characteristics and inferred behavior. Cranial: The earliest evidence of anatomically modern human cranial morphology in the fossil record comes from sites in Africa and the Near East. It is also in Africa that there is evidence for a likely morphological precursor of anatomically modern human morphology. This takes the form of crania that are generally more robust and archaic-looking than those of anatomically modern humans yet which are not archaic enough to justify their allocation to *H. heidelbergensis* or derived enough to be *H. neanderthalensis* (see above). Specimens in this category include Jebel Irhoud from North Africa, Omo 2 and Laetoli 18 from East Africa, and Florisbad and Cave of Hearths in southern Africa. There is undoubtedly a gradation in morphology that makes it difficult to set the boundary between anatomically modern humans and *H. heidelbergensis*, but unless at least one other taxon (e.g., *H. neanderthalensis*) is recognized the variation in the later *Homo* fossil record is too great to be accommodated in a single taxon. Postcranial: There are relatively few early *H. sapiens* postcranial fossils.

CNS-related fossil evidence. Endocranial: Early modern *H. sapiens* have a mean endocranial volume of 1463 cm^3 ($n = 79$, range 1090–1880 cm^3). The EQ for early *H. sapiens* is 5.3. The mean brain mass and EQ are within the range of recent modern human values. However, the extreme fossil endocranial volumes (when converted to brain masses, 1133–1799 g) fall outside of the range for a sample ($n > 227$) of recent modern humans aged 20–30 years (1239–1526 g).

Fossil modern humans are essentially modern humanlike in shape and endocranial volume. The Jebel Irhoud crania (Jebel Irhoud 1 and 2) are also considered to be *H. sapiens* but are said to be Neanderthal-like in overall shape; for example, Jebel Irhoud 2 has some occipital bunning, and the Jebel Irhoud 1 cranium is low and broad. The two Jebel Irhoud endocrania show evidence of modern humanlike brain morphology, including a LORF petalial pattern, an asymmetrically enlarged left Broca's area, and a reduced primary visual cortex, plus taxonomic indicators not related to the CNS (mentioned below). As is the case of recent modern humans, the manifestation of the LORF petalia pattern is variable. Cro-Magnon III, Dolni Vestonice 3 – and probably also Combe Capelle, and Brno 3 – have typical LORF petalias. Predmosti 10 has one of the most extreme cases of the right-hander's LORF petalial pattern, but there is no clear evidence of this pattern from the other specimens from the site (Predmosti 3, 4, and 9). Brno II has a reversed, left-hander's pattern of right-occipital and left-frontal petalias. Jebel Irhoud 1 and 2 provide the only evidence of asymmetrically enlarged left Broca's cap regions. The right side of Cro-Magnon III Broca's area is enlarged but the left is not preserved. Fossil and modern *H. sapiens* neurocrania are uniquely globular in shape (Lieberman *et al*., 2002), apparently having overcome constraints which cause *H. neanderthalensis* and archaic (i.e., *H. erectus* and *H. heidelbergensis*) neurocranial shape to plot along the same allometric trajectory (Bruner *et al*., 2003). Expanded temporal and possibly frontal lobes in modern humans possibly contribute to this morphological change (Lieberman *et al*., 2002). More recently, it has been suggested that volumetrically expanded parietal lobes have consequences for overall brain shape which contribute to the characteristic globularity of the human brain (Bruner *et al*., 2003). In comparison to the brains of earlier *Homo*, the modern human brain is shaped such that the anterior and posterior ends seem to approach each other from below. This is related to a decrease in relative endocranial length, a relative shortening of the frontal and occipital poles, and displacement of the cerebellum to a more inferior position (Bruner, 2004). Weaver (2005) suggests that relative cerebellum size differs between fossil modern humans and recent modern humans. The Early to Middle Pleistocene group (*Au. africanus*, *P. boisei*, *H. habilis*, *H. rudolfensis*, and *H. erectus*, *H. heidelbergensis*) does not differ significantly from recent modern humans or from the great apes with respect to CQ values (Weaver, 2005). However, the very low CQ values of the Late Pleistocene group (*H. neanderthalensis* and

H. sapiens) are significantly different from those of the Early to Middle Pleistocene group, the great apes, and from recent humans (Weaver, 2005). The shift toward larger CQ values in recent humans is said to be due to expansion of relative cerebellar size during a time of stasis in encephalization. Weaver suggests the cerebellum became expanded in recent humans to better manage the complex cognitive functions. However, this interpretation assumes that the Late Pleistocene group represents the condition directly ancestral to recent humans. The group with the lowest CQ values are Late Pleistocene hominins, which are all European, and the lowest value in the entire sample is from the Swanscombe specimen (CQ = 0.60). The decrease to the CQ values characteristic of the European Middle–Late Pleistocene group may be due to shared ancestry or geographical convergence, and it may not necessarily indicate the condition which precedes that of recent humans.

Other endocranial morphology. Cranial venous sinuses: Jebel Irhoud 1 and 2, Kanjera 1, and Predmost II and X have evident dominant transverse sinuses and no O/M system (Holloway *et al.*, 2004a). Brno III has an enlarged O/M sinus on the right (its left side is strongly deformed), and Predmost IV has evidence of an O/M sinus system on the right but not on the left. Skhul I has an O/M system on both sides. Meningeal vessels: The number of ramifications and anastomoses is increased from the ape-like level seen in *H. erectus* (Weidenreich, 1943, p. 13) to the characteristic modern human condition (Saban, 1984; Grimaud-Hervé, 1994). The principal vessel of the anterior ramus has posterior ramifications which run parallel to it in *H. erectus*, but which become more oblique inferoposteriorly relative to the more rounded occipital of recent humans (Grimaud-Hervé, 1994). In modern humans, the anterior and obelic branches are more developed, and the posterior branch is less developed – a pattern also seen in KNM-WT 15000. The anterior branch of the middle meningeal artery is well developed in fossil African *H. sapiens*, with numerous anastomoses in Jebel Irhoud (1 and 2) and Omo 2. In some fossil European *H. sapiens*, the obelic branch takes origin from both the anterior and posterior branches (Predmost 3, Predmost 4 left side, Dolni Vestonice 1, 2).

4.18.5 Trends in Hominin CNS Evolution

4.18.5.1 Primitive Brain Morphology

In order to determine whether a morphological feature is primitive or derived within the hominin clade, it is necessary to consider the brain morphology of the most recent hypothetical common ancestor of modern humans and living chimpanzees. The principle of parsimony suggests the panin–hominin ancestor possessed all shared derived features of extant humans and chimpanzees, but it would lack those features acquired solely along either the panin or the hominin lineages. It is difficult to reconstruct the panin–hominin ancestor with certainty with respect to well-represented regions of the hard tissue fossil record, and it is particularly difficult to do so for CNS-related morphology for which the extant and fossil evidence is both sparser and more difficult to interpret. For simplicity, we will assume that the chimpanzee brain is equivalent morphologically to the primitive hominin brain. There is no significant evidence for derived chimpanzee brain morphology which is not also shared with modern humans, although chimpanzees are likely to have evolved CNS autoapomorphies related to species-specific behaviors, which may be brought to light by future hominoid comparative neuroanatomical studies.

4.18.5.2 Modern Human or Hominin Lineage

4.18.5.2.1 Earliest appearance of derived modern human morphology The data suggest that, whereas fully modern human brain morphology only occurs in recent humans, some aspects of modern human brain morphology are present in earlier forms (see Table 3).

The aspect of modern human brain morphology that may have appeared earliest is the reduction of the primary visual cortex, as evidenced by the position of the LS. A posterior LS has been reported for some *Au. afarensis* specimens, but at the least this feature is variable within the taxon. Given the small sample it is difficult to tell whether the *Au. afarensis* brain really is derived in the direction of the modern human brain, or whether it expresses variability similar to that seen in chimpanzees. In contrast, there are several aspects of endocast anatomy derived in the direction of modern humanlike brain reorganization in *Au. africanus*, which has better evidence for a reduced primary visual cortex. In addition, *Au. africanus* shows evidence of: (1) a somewhat expanded, blunt orbitofrontal cortex, (2) anteriorly expanded, laterally pointed temporal poles, (3) an incipient LORF petalial pattern, and (4) a modern humanlike Broca's cap region. Although these features are not as pronounced as in modern humans, they can be interpreted as being derived in the direction of modern humans. The LORF petalial pattern and Broca's cap region

become even more modern in *H. rudolfensis*, the earliest taxon for which there is evidence for humanlike brain organization (there are insufficient data for the other three aforementioned features until later *Homo*). In addition, *H. rudolfensis* is the earliest taxon not to have an orbitofrontal sulcus. Interestingly, there is no good evidence for a modern humanlike LORF petalial pattern and a Broca's cap region in *H. habilis*; indeed, there is evidence of an African ape-like orbitofrontral sulcus. Where data exist, *H. erectus* and *H. ergaster* endocasts tend to share the modern humanlike features that are found in *H. rudolfensis*. *H. neanderthalensis* is the earliest taxon known to have an expanded thoracic vertebral canal. A globular brain due to parietal lobe expansion has been proposed as an autoapomorphy of modern humans (Bruner *et al.*, 2003). An increase in relative cerebellum size from fossil to recent anatomically modern humans might be a final refinement within this species.

4.18.5.2.2 Earliest appearance of increase in absolute and relative brain size Modern human mean brain mass for adults 21–39 years old is 1450 g for males, and 1290 g for females (Figure 4, Table 4) (Dekaban and Sadowsky, 1978). The chimpanzee mean brain weight for adolescents and young adults (7–30 years) is 406 g for males and 368 g for females (Herndon *et al.*, 1999). In both species, average brain mass decreases in older individuals; for example, Dekaban and Sadowsky (1978) reported a 7.4% decrease (approximately 100 g) in modern human brain mass between 20–30 years and 70–80 years. In fact, the mean endocranial volumes from a more typical modern human autopsy data set (average age 65 years) are dramatically different (male = 1308 g, female = 1179 g) (Zilles, 1972). Sex is also an important consideration in brain size comparisons because male and female samples of hominoid taxa have significantly different brain sizes. It is not possible to know the sex of fossil specimens, and statistical methods of sexing are not possible for the small early hominin cranial samples. Therefore, fossil taxa are not assigned to sex, but are compared as whole taxon samples to samples of both sexes of extant taxa. Previously, absolute brain size has been used to determine a cerebral Rubicon criterion for inclusion in the genus *Homo*, variably set between 600 and 800 cm^3 (Leakey *et al.*, 1964). Currently, absolute brain size is thought to lack biological significance, since it does not give an indication of degree of encephalization, or the number of extra neurons (Jerison, 1973; Martin, 1990). However, aspects of brain morphology such as brain component volumes and degree of gyrification scale to absolute brain size (Zilles *et al.*, 1988, 1989; Semendeferi and Damasio, 2000; Semendeferi *et al.*,

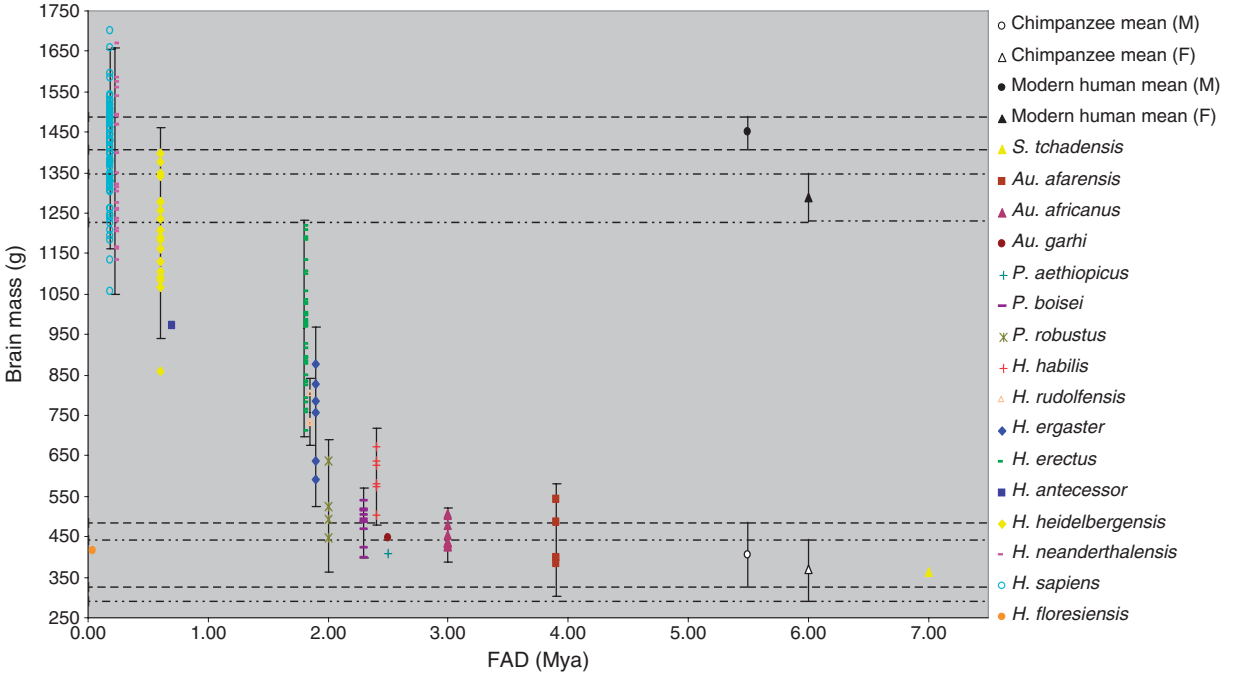

Figure 4 Chimpanzee and recent modern human male and female brain mass means are plotted, with *y*-axis bars and dashed lines showing ranges within two standard deviations. Fossil hominin brain mass individual specimen values are plotted with *y*-axis bars showing range within two standard deviations from the mean. FAD, first-appearance datum. For more information, see Table 4.

[a]Sources: Chimpanzee brain and body mass data for individuals 7–30 years from Herndon *et al.* (1999). Recent modern human brain and body mass data for adults 21–39 years (except minimum and maximum brain mass, which are for 20–30 years) from Dekaban and Sadowsky (1978). In both data sets, brain mass is taken from fresh autopsy specimens and includes brain tissue as well as leptomeninges and CSF. Fossil hominin endocranial volume raw data and sources are available from the authors, by request.

[b]Fossil endocranial volumes were converted into brain masses after Ruff *et al.* (1997).

[c]EQ (encephalization quotient) values after Martin (1981), and Ruff *et al.* (1997). Extant taxon EQ values are means of individual EQ values. Fossil taxon sample mean EQ values are obtained from each taxon's mean brain mass and mean body mass estimates (SD, standard deviation). EQ values obtained by either method are very similar and have been used interchangeably (e.g., Ruff *et al.*, 1997).

2002; Weaver, 2005), an important consideration when investigating the evolution of the brain of modern humans.

The smallest adult hominin brain belongs to the single cranial specimen of *Sahelanthropus*, the earliest possible hominin, and its endocranial volume falls slightly below the female chimpanzee mean. Single specimens of *P. aethiopicus*, *Au. garhi*, and *H. floresiensis* plot around the male chimpanzee mean. The *Au. afarensis* sample is not significantly different from the combined sex sample of chimpanzees ($p = 0.093$), nor from the male chimpanzee sample ($p = 0.456$), although it is significantly larger than the female chimpanzee sample ($p = 0.011$) (all statistical comparisons are derived from a Kruskal–Wallis test of significance). The *Au. africanus* sample is significantly different from the combined sex sample ($p < 0.001$), and the male ($p = 0.001$) and female ($p < 0.001$) subsamples of chimpanzees. However, this does not suggest that the brain size of *Au. africanus* is significantly increased relative to chimpanzees and that of *Au. afarensis* is not; these two groups do not differ significantly from each other ($p = 0.385$). Although the *Au. africanus* mean value (455 g) is only slightly larger than that for *Au. afarensis* (442 g), the range for *Au. africanus* is much smaller than that for the sexual dimorphic *Au. afarensis* (but see Reno *et al.*, 2005 for an alternative interpretation that suggests only modest levels of sexual dimorphism in *Au. afarensis*). *Au. afarensis* attains higher individual brain mass estimates than *Au. africanus*.

Early hominin fossil crania for which endocranial volume and body mass have been reliably estimated are extremely rare, making it impossible to do comparative statistical tests of EQs. However, given that early fossil hominins (e.g., *Australopithecus* and *Paranthropus*) have smaller estimated body masses than chimpanzees (mean body mass 58 kg for males, 43 kg for females; Herndon *et al.*, 1999), any significant increase in relation to chimpanzee brain volume can be assumed to be an increase in both absolute and relative brain size (Table 4). Thus, the increase from the brain size of a chimpanzee-like hypothetical common ancestor to brains the size of those belonging to *Au. afarensis* and *Au. africanus* is evidence of an increase in relative brain size. This finding is further evidenced by the EQ values of *Au. afarensis* (2.5) and *Au. africanus* (2.8), which are well above those for chimpanzees (male EQ = 1.7, female EQ = 1.9), overlapping with those of *Paranthropus* (*P. boisei* EQ = 2.5; *P. robustus* EQ = 3.1), and approximating that of *H. ergaster* (2.8).

By the appearance of *H. rudolfensis* and *H. habilis*, both absolute and relative brain size have clearly departed from the *Pan*-like condition. *H. habilis* is the smallest-brained hominin for which all the specimen values fall outside of two standard deviations of the male chimpanzee mean. *H. habilis* and *H. rudolfensis* are significantly different in brain mass ($p = 0.02$), and the entire range of *H. rudolfensis* values plot above the range of *H. habilis* values. However, when the brain mass data are seen in the light of body mass data, *H. habilis* (EQ = 3.7) is more encephalized than *H. rudolfensis* (EQ = 3.2). Relative brain mass in both *H. habilis* and *H. rudolfensis* is greater than that in *Australopithecus* and *Paranthropus,* and it approaches the values for *H. erectus* (EQ = 3.9).

In summary, although encephalization in the hominin lineage might have begun as early as *Au. afarensis*, it was evident in *Au. africanus* (in parallel to the encephalization of *Paranthropus*, see Section 4.18.5.3) and definitely by the time of the appearance of *H. habilis* and *H. rudolfensis*.

4.18.5.2.3 Appearance of derived modern human CNS morphology in relation to brain size Although there are hints of a trend toward a modern humanlike relative brain size and brain morphology in *Au. afarensis*, there is a lot of variability in the size and morphology of this taxon. Given small samples, one cannot be certain whether or not this variation is different from the variation seen in chimpanzees. Further, the functional and adaptive significance of these features in the early taxa is questionable. Modern humanlike endocranial anatomy in *Au. afarensis* might be a pre-adaptation which only acquires its modern functions in *Au. africanus*, *H. rudolfensis,* or in even later hominins.

Most aspects of modern humanlike endocast morphology make an appearance in *Au. africanus*, but they do not yet show the fully modern form. The reason for their occurrence in this taxon is uncertain, but might be influenced by brain size increase, and it is quite possibly related to exceptional preservation of brain morphology in this taxon. The appearance of several aspects of modern brain morphology in *Au. africanus* complement the fact that this taxon is the first to have a brain size significantly different from chimpanzees. However, as a whole, the *Au. africanus* brain still differs considerably from the modern human brain, and any similarities are not considered sufficient to suggest a modern humanlike cognitive capacity or behavior for *Au. africanus*.

This is in contrast to the more modern humanlike brain morphology of *H. rudolfensis* which is generally taken as evidence of more modern humanlike

cognitive capacities. Most notably, these features are suggestive of language ability and right-handedness, coincident with the first stone tools which apparently were made by right-handed hominins. This is associated with the earliest brain masses outside of what is expected for a chimpanzee, and an EQ higher than that of earlier taxa. However, *H. habilis* has a higher EQ than *H. rudolfensis*, and this later appearing hominin also has brain mass values outside of what is expected for a chimpanzee. It is not yet possible to tell whether the more modern humanlike brain morphology of *H. rudolfensis*, compared to *H. habilis*, is, or is not, size-related.

4.18.5.3 Brain Evolution in Other Lineages

The *P. boisei* mean value (483 g) for estimated brain mass is larger than the value for *P. aethiopicus* (407 g) and somewhat larger than the means for *Au. africanus* (455 g) and *Au. afarensis* (442 g). Further, the majority of the *P. boisei* specimens fall outside of two standard deviations of the male chimpanzee mean. Therefore, it is inferred that *P. boisei* has increased its absolute brain size relative to the primitive condition. The *P. boisei* sample mean is not significantly different ($p = 0.357$) from that of the later occurring *P. robustus* sample, even though the latter attains a much higher maximum value (638 g) and has a much higher mean (565 g). *P. boisei* and *P. robustus* have EQs that are higher than those for male and female chimpanzees. However, the *P. boisei* EQ is smaller than that of *Au. africanus* and is similar to the *Au. afarensis* value. Given the lack of postcranial evidence, one cannot be certain that EQ has increased from *P. aethiopicus* to later *Paranthropus* taxa. These data are, however, consistent with the suggestion of a temporal trend for brain size increase within the *Paranthropus* lineage (Elton *et al.*, 2001).

There is little evidence to suggest modern humanlike reorganization of the *Paranthropus* brain. In particular, slight LORF petalial patterns are found in *P. aethiopicus* and *P. boisei*, and a posteriorly positioned LS has been identified in *P. boisei*. The evidence does not suggest that the *Paranthropus* brain becomes increasingly modern humanlike over time, as is the case for *Homo*. Further, *Paranthropus* retains ape-like beak-shaped orbital surface of frontal lobe and rounded temporal poles, differentiating it from *Au. afarensis* and *H. sapiens*. The modern humanlike endocranial features seen in *Paranthropus* most likely reflect a shared ancestry with the modern human lineage. Similarly, brain size increase in *Paranthropus* is probably the continuation of a trend beginning in a common ancestor of *Paranthropus* and modern humans.

There is presumed to be a decrease in absolute and relative brain size in *H. floresiensis* (Brown *et al.*, 2004), but this trend might also apply to other fossil hominin taxa. *H. floresiensis* had a tiny brain (414 g), with an EQ (3.0) much lower than that of its presumed closest fossil relative, *H. erectus*. Interestingly, its EQ is higher than the one listed here for *H. ergaster* (2.8, includes Dmanisi) and only slightly lower than the EQ for African *H. ergaster* (3.1). Body mass estimates obtained from Dmanisi postcranial remains will refine the *H. ergaster* EQ. Given that *H. ergaster* is thought to have expanded outside of Africa, evidence from the relative brain size alone suggests that it, rather than *H. erectus*, may be the sister taxon of *H. floresiensis*. If so, this would indicate that EQ did not actually decrease in *H. floresiensis*, thereby solving one of the major puzzles of this taxon (Brown *et al.*, 2004). It is noted that *H. floresiensis* possesses much morphology that is derived from the primitive ape-like condition. Several of these features are thought to be found in the most recent *H. floresiensis*–modern human common ancestor (which may also be the most recent *H. erectus*–modern human common ancestor).

Brain size increase and the appearance of some aspects of modern humanlike brain morphology occur in at least two hominin lineages. Both *Paranthropus* and *Homo* have absolutely and relatively larger brains than *Australopithecus*. However, only in *Homo* does brain size increase occur in parallel with the acquisition of modern humanlike brain morphology. Interestingly, *H. floresiensis* provides striking evidence that, even within *Homo*, estimated brain mass and inferred brain morphology can become disassociated.

B Bogin, The University of Michigan-Dearborn, Dearborn, MI, USA

Glossary

adolescence A stage in the human life cycle, covering the 5–8 years after the onset of puberty. The adolescent phase is characterized by a growth spurt in height and weight, virtual completion of permanent tooth eruption, development of secondary sexual characteristics, sociosexual maturation, intensification of interest and practice of adult social, economic, and sexual activities.

adolescent growth spurt The rapid and intense increase and then decrease in the rate of growth in height and weight that occurs during the adolescent stage of the human life cycle.

adrenarche A stage of maturation of the cortex of the human adrenal glands. It typically occurs between ages 6 and 10 years and involves a progressive increase in the production of androgens.

adulthood The stage of the human life cycle that begins at about age 20 years. The prime of adulthood lasts until the end of child-bearing years (late forties) and is a time of homeostasis in physiology, behavior, and cognition. Old age and senescence mark the period of decline in the function of many body tissues or systems during adulthood. This later phase lasts from about the end of child-bearing years to death.

childhood A stage in the human life cycle that occurs between the end of infancy and the start of the juvenile growth period (about the ages 3.0–6.9 years). Children are weaned from breast-feeding (or bottle feeding) but must be provided specially prepared foods and require intensive care by older individuals. Relatively rapid neurological development and slow physical growth and development characterize childhood.

cooperative breeding Also called communal breeding; occurs when nonbreeding helpers raise young produced by dominant breeders. The helpers may be genetic kin of the breeders.

infancy A stage in the life cycle of all mammals when feeding is done by lactation. For human beings, infancy lasts from birth to the end of lactation, usually by age 36 months. Human infancy is characterized by: (1) rapid growth velocity with a steep deceleration in velocity with time, (2) feeding by lactation, (3) deciduous tooth eruption, and (4) many developmental milestones in physiology, behavior, and cognition.

gonadarche Maturation of neuroendocrine system at puberty resulting in a change from inhibition to stimulation of gonadal steroid secretion. This event is also called puberty.

juvenile A stage in the life cycle of most social mammals, including all of the higher primates. The juvenile stage is defined as the time of life when an individual is no longer dependent on adults (parents) for survival, and prior to that individual's sexual maturation. For human beings, the juvenile stage begins after childhood at about 7 years and ends at puberty (gonadarche) at about 9 years for girls and 11 years for boys.

life history theory A field of biology concerned with the strategy evolved by natural selection that an organism uses to allocate its energy toward growth, maintenance, reproduction, raising offspring to independence, and avoiding death. For a mammal, it is the strategy of when to be born, when to be weaned, how many and what type of prereproductive stages of development to pass through, when to reproduce, and when to die.

plasticity The concept that the development of the phenotype is responsive to variations in the quality and quantity of environmental factors required for life. Such variations produce many of the differences in growth, physiology, and behavior observed between individuals or groups of people.

puberty An event of short duration (days or a few weeks) that marks the reactivation of the central nervous system regulation of sexual development. The onset of puberty is accompanied by a dramatic increase in the gonadal secretion of sex hormones. In social mammals, including humans, puberty occurs at end of the juvenile stage.

trade-offs Life history strategies used when competition between two biological or behavioral traits requires a partial allocation of energy or materials to each trait, or complete allocation to only one of several competing traits.

weaning The termination of breast-feeding.

4.19.1 Human Brain and Body Growth

Shown in Figure 1 is the size of the adult brain relative to that of adult body weight for 61 species of the order Primates (data for Old World monkeys, apes, and humans). The curve drawn through the data points is a logarithmic regression fit to the data for all species. All of the monkeys and the three great apes, *Pan* (chimpanzee), *Pongo* (orangutan), and *Gorilla*, lie close to the predicted curve for brain weight/body weight. Human (*Homo*) brain size departs significantly from the predicted curve. It is known that virtually all parts of the human brain enlarged during evolution, especially the size of the neocortex, which comprises about 80% of the mass of the modern human brain (see Brain Size in Primates as a Function of Behavioral Innovation).

At all stages of life after birth, human beings have brains that are significantly larger than expected given the human body size. Human beings grow a large brain by maintaining the rapid rate of fetal brain growth into the postnatal period and extending the time for rapid brain growth to about age 7 years (Figures 2 and 3). In contrast, chimpanzee brain growth slows down greatly after birth and ends by 5 years of age (Vrba, 1998). Human body growth reaches a zenith in the second trimester of pregnancy and then slows precipitously through the third trimester (Figure 4). The rate of human body growth continues to decelerate for the first 3 years after birth, levels off at about 3 years of age, and remains relatively slow until puberty and adolescence when all healthy humans experience a growth spurt in height and weight (Figure 5). No other species of primate or mammal follows this pattern of brain–body growth (Figure 6).

4.19.2 Human Life History

Life history can be defined as the strategy of when to be born, when to be weaned, how many and what

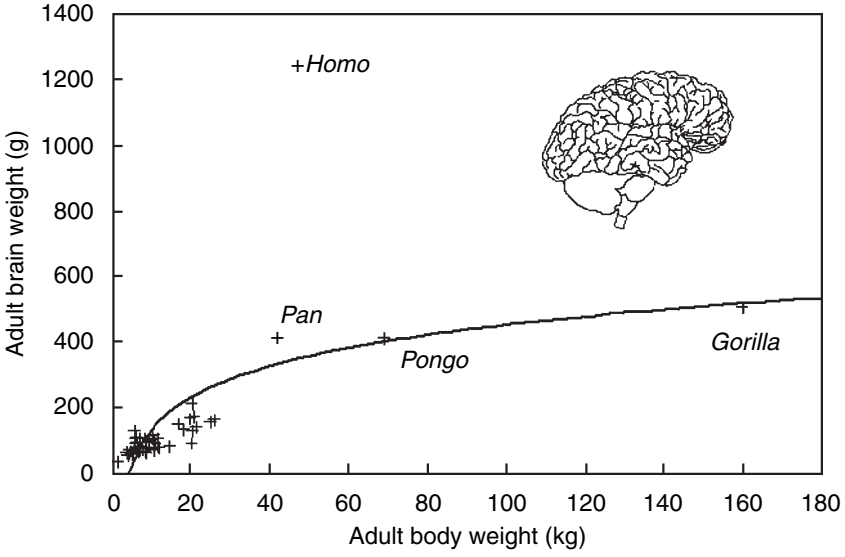

Figure 1 Adult body weight and brain weight plotted for 61 species of Cercopithcidae (Old World monkeys, apes, and people). The curve is logarithmic regression fit to the data for all species. The image is a lateral view of the human brain. Data from Harvey, P., Martin, R. D., and Cluton-Brock, T. H. 1987. Life histories in comparative perspective. In: Primate Societies (*eds.* B. Smuts, D. L. Chency, R. M. Seyfarth, R. W. Wrangham, and T. T. Struhsaker), pp. 181–196. University of Chicago Press.

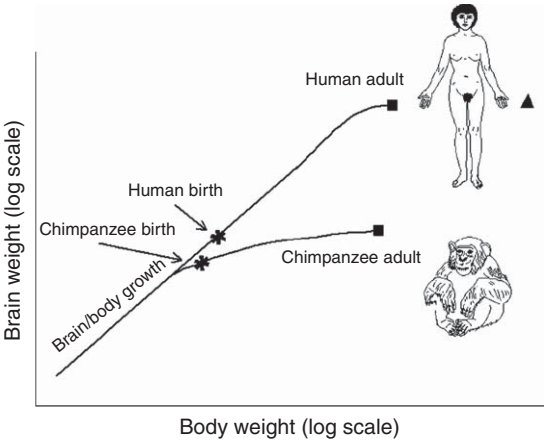

Figure 2 Growth curve for human brain and body compared with the chimpanzee. The length of the human fetal phase, in which brain and body grow at the same rate for both species, is extended for humans. Chimpanzee brain growth slows after birth, but humans maintain the high rate of brain growth during the postnatal phase. In contrast, the rate of human body growth slows after birth. If human brain/body growth rate were equal to the chimpanzee rate, then adult humans would weigh 454 kg and stand nearly 3.1 m tall, indicated by the ▲ symbol. From Bogin (1999) based on the data and concepts of Martin (1983).

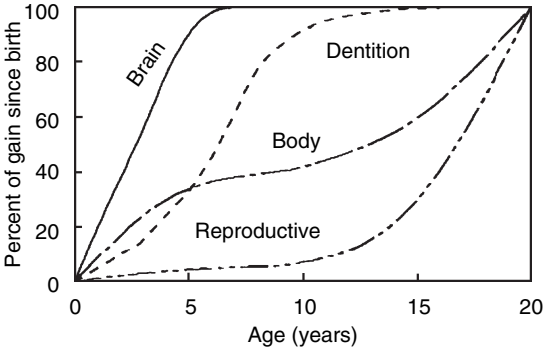

Figure 3 Growth curves for different body tissues (Bogin, 1999). The brain curve is for total weight of the brain (Cabana *et al.*, 1993). The dentition curve is the median maturity score for girls based on the seven left mandibular teeth (I1, I2, C, PM1, PM2, M1, M2) using the reference data of Demirjian (1986). The body curve represents growth in stature or total body weight and the reproductive curve represents the weight of the gonads and primary reproductive organs (Scammon, 1930).

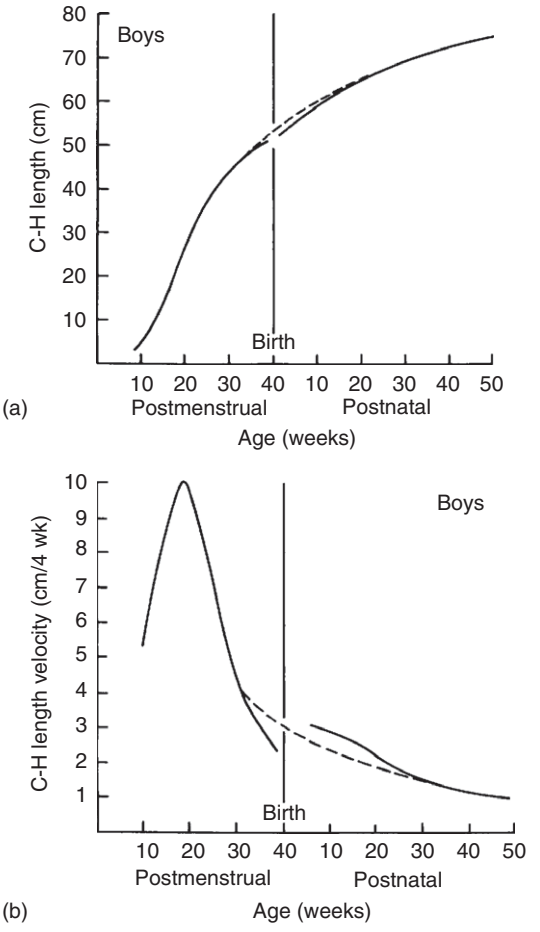

Figure 4 Distance curve (a) and velocity curve (b) for growth in body length (measured as crown-heel (C-H) length) during human prenatal and postnatal life. The figure is diagrammatic, as it is based on several sources of data. The dashed lines depict the predicted curve of growth if no uterine restriction takes place. In fact, such restrictions do take place toward the end of pregnancy and this may impede the flow of oxygen or nutrients to the fetus. Consequently, growth rate slows but rebounds after birth and returns the infant to the size she or he would be without any restriction (Tanner, 1990). Reprinted by permission of the publisher from Fetus into Man: Physical Growth from Conception to Maturity by J. M. Tanner, p. 39, Cambridge, MA: Harvard University Press, Copyright © 1978, 1989, by J. M. Tanner and Cartlemead Publishers.

type of prereproductive stages of development to pass through, when to reproduce and when to die. For a mammal, it is the strategy of when to be born, when to be weaned, how many and what type of prereproductive stages of development to pass through, when to reproduce, and when to die. Living things on earth have greatly different life history strategies, and understanding what shapes these histories is one of the most active areas of research in whole-organism biology.

The majority of mammals have two postnatal life history stages: infancy and adulthood. Highly social mammals such as wolves, wild dogs, lions, elephants, and the primates postpone adulthood by inserting a period of juvenile growth and behavior between infancy and adulthood. Most mammalian biologists define infancy as the stage of life when the offspring are fed by nursing. Adulthood is the stage of life when the individual is capable of reproduction. Juveniles may be defined as "prepubertal individuals that are no longer dependent on their mothers (parents) for survival" (Pereira and Altmann, 1985, p. 236).

Human beings add two new stages of development between birth and adulthood: childhood and adolescence. As can be seen in Figure 5, changes in growth

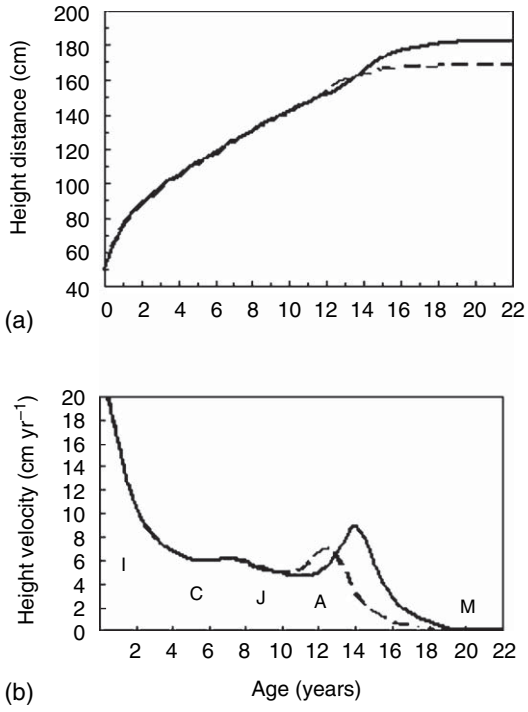

Figure 5 Average distance (a) and velocity (b) curves of growth in height for healthy girls (dashed lines) and boys (solid lines) showing the postnatal stages of the pattern of human growth. The stages of postnatal growth are abbreviated as follows: I, infancy; C, childhood; J, juvenile; A, adolescence; M, mature adult. Data used to construct the curves come from Prader, A 1984. Biomedical and endocrinological aspects of normal growth and development. In: Human Growth and Development (*eds.* J. Borms, R. R. Hauspie, A. Sand, C. Susanne, and M. Hebbelinck), pp. 1–22. Plenum; Bock, R. D. and Thissen, D. 1980. Statistical problems of fitting individual growth curves. In: Human Physical Growth and Maturation, Methodologies and Factors (*eds.* F. E. Johnston, A. F. Roche, C. Susanne), pp. 265–290. Plenum.

rate are associated with each stage of development. Each stage may also be defined by characteristics of the dentition, changes related to methods of feeding, physical and mental competencies, or maturation of the reproductive system and sexual behavior (Bogin, 1999, provides detailed discussion for the following material; more recent references are provided herein).

As for all mammals, human infancy is the period when the mother provides all or some nourishment to her offspring via lactation or some culturally derived imitation of lactation (e.g., formula feeding). During infancy, the deciduous dentition (the so-called milk teeth) erupts through the gums. Motor skills (i.e., what a baby can do physically) develop rapidly during infancy. There is a similar progression of changes in the problem solving, or cognitive, abilities of the infant. Human infancy ends when the child is weaned from the breast, which in preindustrialized societies occurs between 30 and 36 months of age.

The childhood stage encompasses the ages of about 3–7 years. At the beginning of childhood, the body growth rate levels off at about 5–6 cm per year. Brain growth continues at a relatively fast pace (Figure 3). The leveling-off in body growth rate is unusual for mammals, because almost all other species either stop growing or, in the case of social mammals, continue a pattern of deceleration during the juvenile stage (Figure 6).

A suite of additional features defines the childhood stage. These are:

- slow and steady rate of body growth and relatively small body size;
- a large, fast-growing brain;

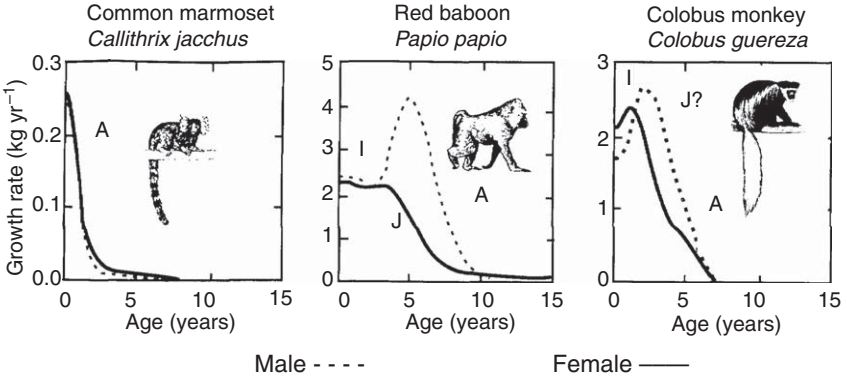

Figure 6 Three nonhuman primate species showing different patterns of postnatal growth in weight. The human pattern of growth differs significantly from each of these species. Marmosets are weaned at 63 days and can breed at 1 year of age (Harvey *et al.*, 1987). Marmoset growth rate shows no postnatal growth spurt and no change in growth rate typical of a juvenile growth stage. Baboons are weaned by 18 months and begin puberty at about 3.5 years for females and 4.5 years for males (Harvey *et al.*, 1987). Baboons have a juvenile growth stage for both males and females, but only males have clear weight growth spurt. Colobus monkeys are weaned at about 13 months and females have their first birth at about 4.6 years of age. Colobus monkeys show a postnatal spurt for both sexes, but it is not clear if there is a juvenile growth stage. The velocity curves are fit to cross-sectional data collected from captive animals. The curves are fit using the statistical estimates based on lowess regression (Leigh, 1994). I, infancy; J, juvenile; A, adult. Reproduced from Leigh, S. R. 1994. Growing up to be a Primate (book review). *Evol. Anthropol.* 3, 106–108, with permission from John Wiley & Sons, Inc.

- higher resting metabolic rate (RMR) of brain relative to body than any other mammalian species;
- immature dentition;
- motor immaturity;
- cognitive immaturity; and
- adrenarche and the midgrowth spurt.

No other mammalian species has this entire suite of features.

The large and fast-growing brain of infants and children is an especially important feature of human biology. The newborn uses 87% of its RMR for brain growth and function. By the age of 5 years, the percent RMR usage is still high at 44%, whereas in the adult human, the figure is between 20% and 25% of RMR. At comparable stages of development, the RMR values for the chimpanzee are about 45%, 20%, and 9%, respectively (Leonard and Robertson, 1994).

The human juvenile stage begins at about 7 years of age. In girls, the juvenile period ends, on average, at about the age of 10, 2 years before it usually ends in boys, the difference reflecting the earlier onset of adolescence in girls. The beginning of juvenility is marked by adrenarche and, in some children, a midgrowth spurt in height (Figure 1). Adrenarche is the progressive increase in the secretion of adrenal androgen hormones (Auchus and Rainey, 2004). Adrenal androgens may launch the growth of axillary and pubic hair. The physical changes induced by adrenarche are accompanied by cognitive and social advances, and there are sexually dimorphic changes in behavior and voice during this stage as well (Wuyts *et al.*, 2003).

By the beginning of the juvenile stage (about age 7 years), the growth in weight of the brain is virtually complete, but much biological and cognitive development of the brain must still take place. (A small increase in brain mass occurs at puberty (Durston *et al.*, 2001; Sowell *et al.*, 2001); myelination and some nerve proliferation continue into adulthood (Bjorklund and Pellegrinni, 2002; Taupin and Gage, 2002).) The energy requirements for brain growth are about 38% of RMR, which is still large as juvenile body weight is relatively small, at about 31% of adult body weight. Energy investment in the juvenile brain may be related to the onset of new behavioral and cognitive competencies. A great deal of learning, physical activity play, and social competition takes place for all juvenile primates (Bogin, 2002). Language and symbolic thinking skills mature rapidly (Locke and Bogin, in press; see The Evolution of Language Systems in the Human Brain) and the 7-year-old individual can perform many basic tasks, including food preparation with little or no supervision. Juveniles can also conceptualize themselves as independent of older people. Energy invested in brain and behavior takes away from energy available for body growth. Indeed, the juvenile stage is characterized by the slowest rate of growth since birth. No energy is used for reproduction, as juveniles are prefertile and immature in terms of both their primary and secondary sexual characteristics.

Human adolescence is the stage of life when social and sexual maturation takes place. Adolescence begins with puberty, or more technically with gonadarche, which is an event of the neuroendocrine system. The current understanding of the control of gonadarche is that one, or perhaps a few, centers of the brain change their pattern of neurological activity and their influence on the hypothalamus (Plant and Barker-Gibb, 2004). The hypothalamus, which has been basically inactive in terms of sexual development since about age 3 years, is again stimulated to produce GnRH (gonadotrophin-releasing hormone). It is not known exactly how this change takes place. As stated above, the production of GnRH by the hypothalamus becomes inhibited by the age of about 2 years. The inhibitor has not been identified but likely is located in the brain and certainly not in the gonads. Human children born without gonads as well as rhesus monkeys and other primates whose gonads have been surgically removed still undergo both hypothalamus inhibition in infancy and hypothalamus reactivation at puberty.

None of these hormonal changes can be seen without sophisticated technology, but the effects of gonadarche can be noted easily as visible and audible signs of sexual maturation. One such sign is a sudden increase in the density of pubic hair. In boys, the deepening of the voice is another sign of puberty. In girls, a visible sign is the development of the breast bud, the first stage of breast development. The pubescent boy or girl, his or her parents, and relatives, friends, and sometimes everyone else in the social group can observe these signs of early adolescence. The adolescent stage also includes sexual dimorphism in body size and composition and the onset of greater interest and practice of adult patterns of sociosexual and economic behavior. These physical and behavioral changes occur with puberty in many species of social mammals. What makes human adolescence unusual among the primates are two important differences. The first is the length of time between age at puberty and age at first birth. Humans take, on average, at least 10 years for this transition. Monkeys and apes take less than 3 years to make the transition from puberty to parenthood. The second human difference is that during this life stage, both boys and girls experience a rapid acceleration in the growth velocity of almost all skeletal

tissue – the adolescent growth spurt. Other primate species may show a rapid acceleration in soft tissue growth, such as muscle mass in many male monkeys and apes. However, unlike humans, other primate species either have no acceleration in skeletal growth or a very small increase in growth rate. The human skeletal growth spurt is unequaled in amount and duration by other species, and when viewed graphically, the growth spurt is a defining feature of human adolescence (Figure 5b).

Adolescence ends and early adulthood begins with the completion of the growth spurt, the attainment of adult stature, and the achievement of reproductive maturity, meaning both the physical and psychosocial maturity needed for successful reproduction. All of these developments coincide, on average, by about age 19 in women and 21–25 years of age in men.

4.19.3 Life History Trade-Offs between the Growth of Brain versus Body Tissues

Perhaps it is best to conceptualize the pattern of life history of a species as a series of trade-offs, or compromises, that an organism makes between principal biological or behavioral traits. Some mammalian life history traits and trade-offs are listed in Table 1. Principal traits for mammals, including human beings, include the timing of birth versus continued fetal development, the length of the lactation stage versus weaning (the cessation of lactation), the size of the brain, the age at first reproduction, and the age at death. A trade-off may be thought of as the competition between two biological or behavioral traits. Stearns says that ". . . trade-offs occur when two traits compete for materials and energy within a single organism . . ." or ". . . when selection for one trait decreases the value of a second trait" (Stearns, 1992, p. 223). An example of the first type of trade-off is competition between organs or tissues of the body during growth. For example, should energy and materials be devoted to growing a large set of muscles and gut or a larger brain? An example of the second type of trade-off is the choice of producing one large offspring or many, smaller offspring.

During human evolution, and in comparison to the evolution of the nonhuman apes, several trade-offs were made. At least four trade-offs are most important to the evolution of brains and bodies. First, grow a large brain early in life, but reduce the rate of body growth after birth. Second, wean infants before the eruption of their permanent teeth, enabling the mother to reproduce more rapidly, but pass-on child care responsibilities to other group members. Third, reduce the size of the gut (stomach and intestines), but divert energy to the growth and maintenance of the brain. Fourth, prolong the total duration of body growth, delay the onset of adult reproduction, but allow for greater plasticity and adaptability in physical development and learning.

Table 1 Life history principal traits and trade-offs

Principals	*Trade-offs*
1. Size at birth	1. Current reproduction vs. future reproduction
2. Brain size	2. Current reproduction vs. survival
3. Growth patterns • Number of life cycle stages • Duration of each stage	3. Number vs. size offspring 4. Parental reproduction vs. growth 5. Brain size vs. body size
4. Age at eruption of first permanent molar	6. Parental health vs. offspring growth
5. Rate of maturation • Age at first reproduction • Age of last reproduction	7. Parental vs. offspring reproduction
6. Size at maturity	
7. Number and sex ratio of offspring	
8. Reproductive investment in each offspring	
9. Length of life • Rate of aging/senescence • Age at death	

This is a partial list of the most important traits. The list is based on the discussion in Cole (1954) and Stearns (1992), who provide additional traits.

4.19.4 Implications for Behavioral and Cognitive Maturation of Human Children

Trade-offs between brain and body growth, combined with early weaning and the short duration of human infancy have several implications. After weaning, the infant enters the childhood stage. Human children require specially prepared foods because of the immaturity of their dentition, the small size of their stomachs and intestines, and the rapid growth and relatively high RMR of their brain. The human constraints of immature dentition and small digestive system necessitate a childhood diet that is easy to chew and swallow and low in total volume. The child's relatively large and active brain, almost twice the size of an adult chimpanzee's brain, requires that the low-volume diet be dense in energy, lipids, and proteins. Children do not yet have the motor and cognitive skills to prepare such a diet for themselves.

Children are also especially vulnerable to predation and disease and thus require protection. Children will not survive in any society if deprived of the care provided by older individuals. So-called wolf children and even street children, who are sometimes alleged to have lived on their own, are either myths or not children at all. My search of the literature finds no case of a child (i.e., a youngster under the age of 6 years) living alone, either in the wild or on urban streets. The dependence of children on older members of the social group creates the need for cooperative breeding, a style of reproduction found in several groups of social insects and mammals (Bogin, in press).

Two of the important physical developmental milestones of childhood are the replacement of the deciduous teeth with the eruption of the first permanent teeth and completion of brain growth in weight (Cabana *et al.*, 1993). First molar eruption takes place, on average, between the ages of 5.5 and 6.5 years in most human populations. Eruption of the central incisor quickly follows, or sometimes precedes, the eruption of the first molar. By the end of childhood, usually at the age of 7 years, most children have erupted the four first molars, and permanent incisors have begun to replace milk incisors. Along with growth in size and strength of the jaws and the muscles for chewing, these new teeth provide sufficient capabilities to eat a diet similar to that of adults. At this stage of development, not only is the child capable dentally of processing an adult-type diet; the nutrient requirements for brain growth also diminish. Moreover, cognitive and emotional capacities mature to new levels of self-sufficiency. Language and symbolic thinking skills mature rapidly (Locke and Bogin, in press), social interaction in play and learning become common, and the 7-year-old individual can perform many basic tasks, including food preparation with little or no supervision (Bock and Sellen, 2002).

4.19.5 Evolution of Human Brains and Life History

Figure 7 is an attempt to represent the evolution of human development, though at present, the only reliable data are associated with *Pan* (chimpanzee) and *Homo sapiens*. Known or estimated adult brain sizes are given at the top of each bar. Smith and Tompkins (1995) calculated estimated ages for the first permanent molar (M1) in other species. Age of eruption of M1 is an important life history event that correlates very highly with other life history events. The fossil taxa named in Figure 7 are meant to represent grades of hominin evolution.

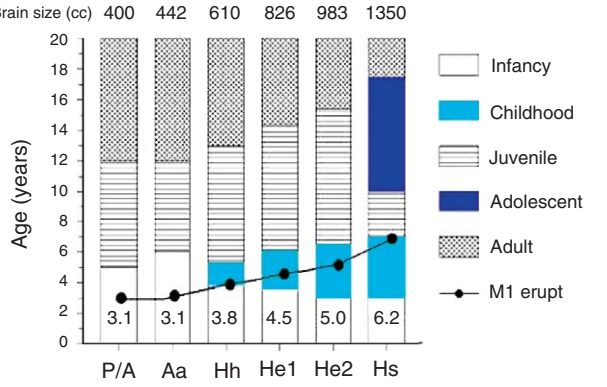

Figure 7 The evolution of hominid life history during the first 20 years of life. P/A, *Pan* and *Australopithecus afarensis*; Aa, *Australopithecus africanus*; Hh, *Homo habilis*; He1, early *Homo erectus*; He2, late *Homo erectus*; Hs, *Homo sapiens*. Mean brain sizes are given at the top of each histogram. Mean age at eruption of the M1 is graphed across the histograms, and identified numerically at the base.

Appearing about 3.9 Mya, *Australopithecus afarensis* shares many anatomical features with nonhominid pongid (ape) species, including an adult brain size of about 400 cc and a pattern of dental development indistinguishable from extant chimpanzees. Therefore, the chimpanzee and *A. afarensis* are depicted as sharing the typical tripartite stages of postnatal growth of social mammals: infancy, juvenility, and adulthood. The duration of each stage and the age at which each stage ends are based on empirical data for chimpanzees. A probable descendent of *A. afarensis* is the fossil species *A. africanus*, dating from about 3 Mya. Achievement of the larger adult brain size of *A. africanus* (average of 442 cc) may have required an addition to the length of the fetal and/or infancy periods. Figure 3 depicts a 1 year extension of infancy.

As the figure indicates, M1 of the chimpanzee erupts at 3.1 years, even though infancy continues for nearly 2 more years. Before 5 years, young chimpanzees are dependent on the mother and will not survive if she dies or becomes unable to provide care and food. After the eruption of M1, they may be able to manage an adult diet, but still must learn how to find and process foods, and it takes time to learn how to open shelled fruits and extract insects from nests. This may be why chimpanzees extend infancy beyond the eruption of M1. It is likely that early hominids, such as *A. afarensis* and *A. africanus*, followed a pattern of growth and development very similar to chimpanzees and also extended infancy for at least 1 year beyond the age of M1 eruption. Analyses of postcranial anatomy and archaeological records suggest a similarity between the behavioral capacities of hominids and extant chimpanzees.

The *H. habilis* grade of hominin evolution follows. At this grade there are delays in dental development and a pattern of femur growth that departed from that of the australopithecines, but resembled the pattern seen in later hominids (Tardieu, 1998). Along with larger adult brain size, all of this indicates a probable childhood stage of growth. This stage may have started after the eruption of M1 and lasted for about 1 year. During childhood, the *H. habilis* youngsters would need to be supplied with special weaning foods. There is archaeological evidence for just such a scenario. *H. habilis* seems to have intensified its production and dependence on stone tools. There is considerable evidence that some of these tools were used to scavenge animal carcasses, especially to break open long bones and extract bone marrow (Potts, 1988). This behavior may be interpreted as a strategy to feed children. Such scavenging may have been needed to provide the essential amino acids, some of the minerals, and especially the fat (as both essential lipids and a dense source of energy) that children require for growth of the brain and body.

A further increase in brain size occurred during the time of *H. erectus*, which began about 1.6 Mya. The earliest adult specimens have mean brain sizes of 826 cc, but many individual adults had brain sizes between 850 and 900 cc. Insertion or expansion of childhood would have provided the time needed for a rapid, humanlike pattern of brain growth. In the time of *H. habilis* and early *H. erectus*, the transition from infancy to childhood took place before M1 eruption. If the new childhood was stolen from infancy, or reduced its length, then *H. erectus* would have enjoyed a greater reproductive advantage than any previous hominid. This seems to be the case, since by the time of *H. erectus* hominin populations increased in size and began to spread throughout Africa and other regions of the world.

Figure 7 also shows later *H. erectus*, with an average adult brain size of 983 cc and a further expansion of the childhood stage. In addition to larger brains (some measuring 1100 cc), the archaeological record for later *H. erectus* shows increased complexity of technology (tools, fire, and shelter) and social organization. These technosocial advances, and a parallel increase in learning, were grafted onto the reproductive value of childhood. By the time of modern *H. sapiens*, the selective value of reproductive efficiency and learning expanded the length of the childhood stage to its current length.

As for when adolescence evolved, it is possible that this stage first appeared in *H. erectus* (Antón and Leigh, 2003; Smith, 2004). Other research indicates that *H. erectus*, later hominids such as *Homo antesesor* (800 000 BP) and *H. heidelbergensis* (400 000–500 000 BP), and even the Neanderthals of 40 000 BP grew up too quickly to have adolescence (Dean *et al.*, 2001; Ramirez-Rossi and Bermudez de Castro, 2004). If so, then adolescence evolved with archaic or modern *H. sapiens* (as depicted in Figure 7). Adolescence may be a product of contemporary brain size and brain function that creates the human world of complex technological, social, and ideological capacities and cultures.

4.20 Constraints on Brain Size: The Radiator Hypothesis

D Falk, Florida State University, Tallahassee, FL, USA

Glossary

Australopithecus	A genus of early hominin with many species, one of which probably gave rise to the human lineage; sometimes called gracile australopithecines.
emissary veins	Veins that pass through apertures (foramina) in the cranial wall and establish communication between the sinuses and veins inside the braincase and the veins external to it.
hominin	Humans and their early bipedal ancestors (excludes apes); what 'hominid' used to mean.
occipital/marginal (O/M) sinus	Route that delivers venous blood to the vertebral plexus of veins and causes a groove on the occipital (O) bone and along the margin (M) of the foramen magnum in some hominins.
Paranthropus	A rugged-looking genus of early hominin that was not ancestral to humans, also called robust australopithecines.
selective brain cooling	A natural mechanism that enables mammals to maintain brain temperature below that of the rest of the body during states of hyperthermia.
transverse/sigmoid sinuses	Cranial venous sinuses that drain blood from the back of the cranium to the jugular veins in most humans.
vertebral plexus of veins	Network of veins surrounding the spinal column that drains significantly more cranial venous blood from upright than supine humans.

4.20.1 Synopsis of Radiator Hypothesis

4.20.1.1 Temperature Sensitivity and Selective Brain Cooling in Humans

The human brain is an exquisitely heat-sensitive organ. According to the noted vascular physiologist, Mary Ann Baker (1979):

> A rise of only four or five degrees C above normal begins to disturb brain functions. For example, high fevers in children are sometimes accompanied by convulsions; these are manifestations of the abnormal functioning of the nerve cells of the overheated brain. Indeed, it may be that the temperature of the brain is the single most important factor limiting the survival of man and other animals in hot environments.

Humans lack the special network of arteries and veins (*rete mirabile*) that helps regulate brain temperature in numerous carnivores and ungulates. The differentially enlarged human brain is especially sensitive to hyperthermia because its high cerebral (compared to resting) metabolic rate generates a relative abundance of heat (Caputa, 2004). One way in which human brain temperature is regulated is through arterial blood that is delivered into the cranium, which is cooler than the brain it supplies. As the arterial blood circulates, it removes heat from the brain, so that venous blood exiting the braincase is warmer than the arterial blood supplying it.

4.20.1.1.1 Role of emissary veins Whole-body cooling takes place when arterial blood is cooled through the effects of evaporation of sweat from the body's surface, a process that also contributes to regulation of brain temperature via its arterial supply. Cabanac and Brinnel (1985) proposed an additional mechanism for selectively cooling the

brain under conditions of intense exercise that results in hyperthermia. Because experimental evidence revealed that blood flows out of the cranium through the mastoid, ophthalmic, and parietal emissary veins in hypothermic subjects but into the braincase in hyperthermic subjects, Cabanac and Brinnel reasoned that venous blood that is cooled at the head's surface through the effects of evaporation on dilated veins is selectively delivered into the braincase under, and only under, conditions of hyperthermia (oral temperature of $37.6 \pm 0.18^{\circ}$ C). The authors noted that innumerable, microscopic emissary veins exist in humans, and demonstrated (by massaging a cadaver's skullcap) that blood is capable of flowing through this network from the outside of the skull to the diploic veins within the cranial bones and then to the inside of the braincase.

The three emissary veins that were used to record direction of blood flow are located at dispersed points of the network that supplies the entire skull: at the face (ophthalmic), behind the ear (mastoid), and at the top back part of the skull (parietal) (Figure 1). Cabanac and Brinnel concluded that when blood flows into the braincase in these three emissary veins, it also does so in the innumerable tiny veins that comprise the entire network. According to this hypothesis, venous blood cooled at the head's surface under hyperthermic conditions flows into the braincase over a dispersed network of tiny veins (the cranial radiator). This is a selective brain cooling mechanism that serves to keep brain temperature in check. Cabanac and Brinnel's hypothesis became controversial among physiologists who claimed that existence of an anatomical network of cranial veins capable of delivering cooled blood into the braincase was speculative. This point will be returned to in Section 4.20.3.

4.20.1.1.1.(i) Patterns of cranial blood flow in apes, hominins, and contemporary people All scorable skulls of robust australopithecines (*Paranthropus*) show traces of an unusual enlarged sinus at the lower back ends of their skulls that routed venous blood from their heads, called the occipital/marginal (O/M) sinus. Curiously, only one other hominin shared this high frequency, namely *Australopithecus afarensis* from Ethiopia (the group to which the famous fossil Lucy belongs). Neither living people nor apes manifest enlarged O/M sinuses to any appreciable degree (Figure 2). Instead, apes and humans drain blood from their heads through another route, the transverse/sigmoid sinus system (Figure 2). (*Paranthropus* skulls may or may not

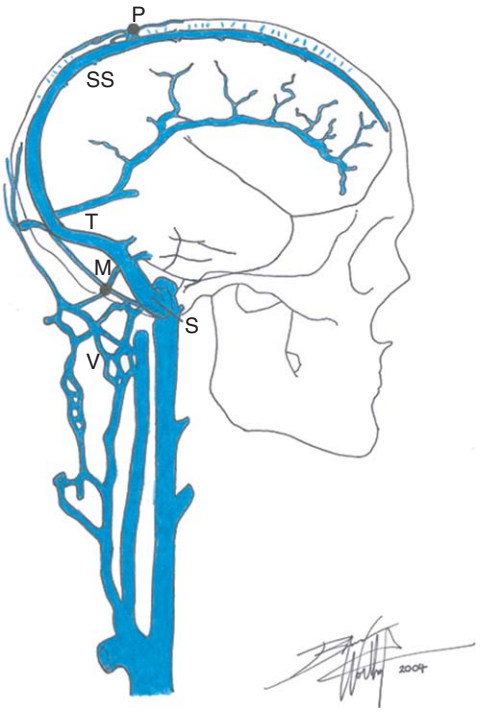

Figure 1 Venous sinuses and parietal (P) and mastoid (M) emissary veins in humans. SS, superior sagittal sinus; T, transverse sinus; S, sigmoid sinus; V, vertebral plexus of veins. Reproduced from Falk, D. Concepts and hypotheses: history of brain evolution, http://www.anthro.fsu.edu/research/falk/braindance.html.

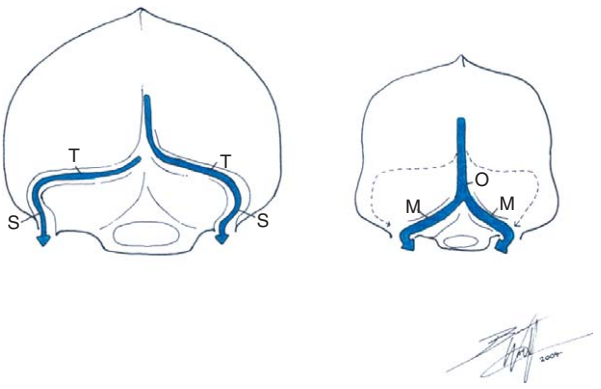

Figure 2 Occipital views of typical cranial venous sinus systems in modern humans (left) and fossil robust australopithecines (*Paranthropus*) and earlier hominins from Hadar, Ethiopia (right). In humans, venous blood exits the skull through the transverse (T)–sigmoid (S) sinuses, which deliver blood to the internal jugular veins. This system may or may not be present in robust and Hadar australopithecines, in which a significant amount of blood is always drained through an enlarged occipital (O)–marginal (M) sinus system that communicates with the vertebral plexus of veins. The O/M system is always present on one or both sides of the latter. Reproduced from Falk, D. Concepts and hypotheses: history of brain evolution, http://www.anthro.fsu.edu/research/falk/braindance.html.

reproduce one or both sides of the transverse/sigmoid route in addition to one or both sides of an enlarged O/M system.) Because the enlarged O/M sinuses that are infrequently found in human cadavers deliver blood to a network of veins around the spinal column (called the vertebral plexus of veins), this is likely to have been an important drainage route for the enlarged O/M sinuses of early hominins.

In order to explore the evolution of cranial blood flow, data were collected on the frequencies of O/M sinuses and mastoid and parietal emissary foramina from skulls of African apes, fossil hominins, and extant humans (Falk, 1986). Apes have low frequencies (appearing in $\leq$25% of specimens) for all three traits (Boyd, 1930). Emissary foramina of *Paranthropus* are equally infrequent but all scorable specimens to date ($n = 11$) have enlarged O/M sinuses (Falk *et al.*, 1995). Humans, on the other hand, have high frequencies of both emissary foramina but very low frequencies for enlarged O/M sinuses. As discussed below, the nonrobust hominins that preceded *Homo* show decreasing frequencies of O/M sinuses and increasing frequencies of parietal and mastoid foramina over time.

4.20.1.1.1.(ii) Relationship of vascular pattern to brain size Figure 3 shows the frequencies of enlarged O/M sinuses and emissary foramina plotted for African apes and various hominins along with their mean cranial capacities (which approximate brain size) expressed as a percentage of the average capacity for extant *Homo sapiens*. The graph reveals that emissary foramina increased in frequency in *Homo* as brain size enlarged over time. These data and experimental evidence that mastoid and parietal emissary veins participate in

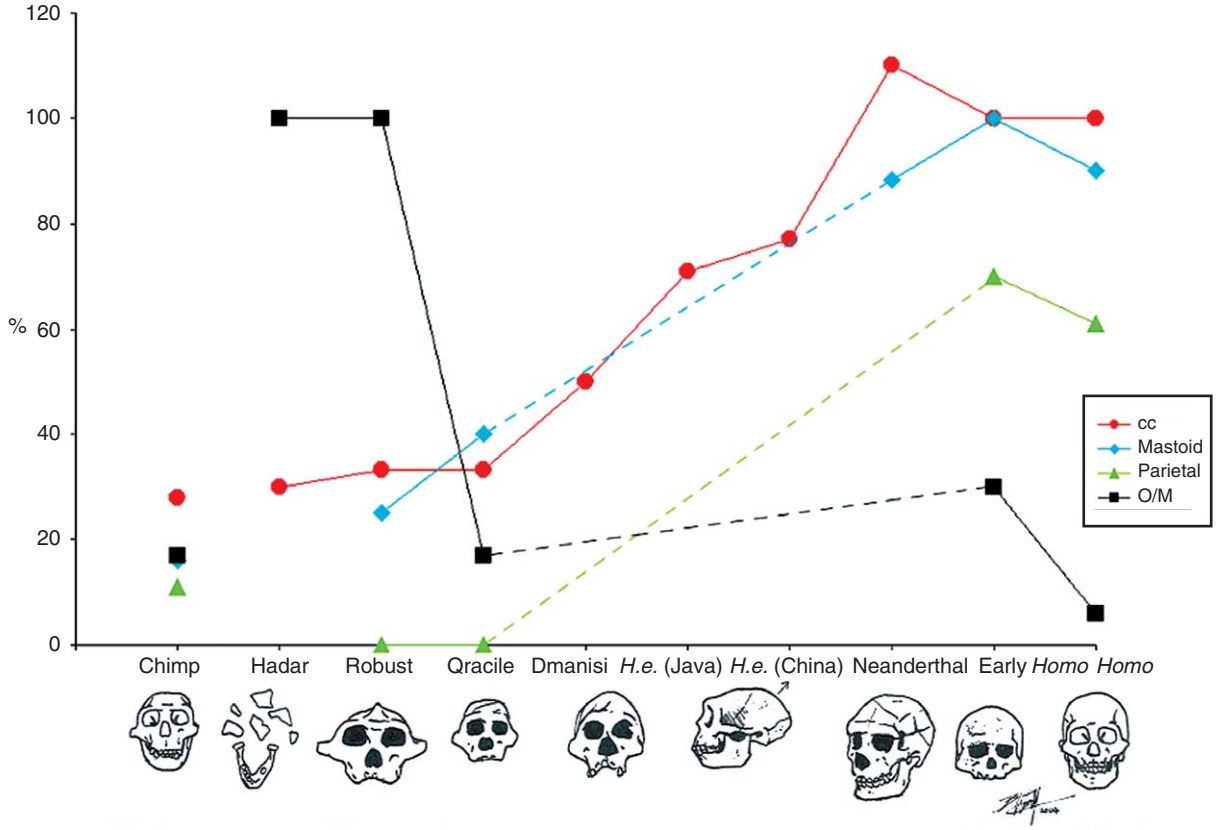

Figure 3 Frequencies of mastoid (blue diamonds) and parietal (green triangles) emissary foramina and enlarged O/M sinuses (black squares) plotted against mean cranial capacities (CCs) expressed as percentages of the 1350 cc mean for modern humans (red circles). Data from Falk (1986), Tobias and Falk (1988), and Falk *et al.* (1995, 2000). Dashed lines indicate fossils that have not been scored; robust = *Paranthropus*, gracile = *Australopithecus africanus*. Chimpanzees are included for comparative purposes; hominins are arranged in approximate chronological order from left to right. In Hadar and robust specimens, O/M is fixed; in the latter emissary foramina occur in low apelike frequencies. The reverse is true for the *Australopithecus* (gracile)–*Homo* lineage in which O/M frequencies fluctuate around those of apes, while those for emissary foramina increase through time in conjunction with brain size. Reproduced from Falk, D. Concepts and hypotheses: History of brain evolution, http://www.anthro.fsu.edu/research/falk/braindance.html.

selective brain cooling in hyperthermic people (Cabanac and Brinnel, 1985) suggest that the wider network of veins that incorporates the two emissary veins increased in size and complexity as cooling requirements became more demanding due to the ongoing enlargement of an evolving brain. Because this network of veins acts to keep brain temperature within check much as an automobile's radiator regulates engine temperature, it has been dubbed a cranial radiator (Falk, 1990).

4.20.1.2 Significance of Bipedalism

Experimental evidence reveals that the vertebral plexus of veins around the spinal column receives significantly more cranial blood when living humans are upright than when they are supine. The enlarged O/M sinuses of an early biped, *A. afarensis*, presumably delivered blood to their vertebral plexuses and have therefore been correlated with the development of upright walking (bipedalism) in that species or its ancestors. Because of their shared enlarged O/M sinuses, it was suggested in 1983 that *A. afarensis* was ancestral to more recent *Paranthropus* (or that the two groups shared a common ancestor) rather than to *Homo* (Falk and Conroy, 1983). The proponents of Lucy as 'the mother of us all' did not take kindly to this suggestion, which nevertheless found support in 1986 with the announcement of the discovery of a remarkably early *Paranthropus* specimen, the Black Skull dated to around 2.5 Mya, which appeared to be a probable descendant of *A. afarensis* (Falk, 1990, 2004a).

Humans do not usually have enlarged O/M sinuses, and appear instead to utilize a network of tiny pathways to deliver blood to their vertebral plexuses when they are standing or walking. The finding that blood drains preferentially to the vertebral plexus (instead of to the jugular veins) in upright but not supine postures (due to hydrostatic and hemodynamic factors) is well documented and has important implications for patients undergoing surgery of the head and neck. The named emissary veins at the back of the head contribute to the routes that drain to the vertebral plexus and, fortunately for paleoanthropology, these veins go through identifiable foramina (Hauser and De Stefano, 1989) that may be observed in fossil skulls (Figure 3). To summarize, both an enlarged O/M sinus system and the cranial radiator channel blood toward the vertebral plexus of veins surrounding the spinal column when individuals are bipedal, but only one of these (the radiator) is involved in selective brain cooling.

4.20.1.2.1 Interaction of bipedalism with climate/solar radiation According to Wheeler (1988), hominins that foraged for food during the heat of the day initially reduced their risk of hyperthermia by behavioral means, namely by maintaining bipedal stances that reduced the amount of body surface exposed to direct sunlight, which allowed them to occupy a noon-day scavenging niche. By the time bipedalism was fully achieved, however, hair had reduced on body surfaces that were no longer exposed to direct radiation from the sun at its zenith, and the newly naked skin and an increased number of cutaneous sweat glands facilitated evaporation and therefore whole-body cooling. Wheeler also suggested that such cooling released a constraint on brain size in *Homo*. Add to this the elaboration of the network of emissary and other small veins that participate in selective brain cooling and one has the radiator hypothesis (Falk, 1990)!

4.20.1.2.1.(i) Two lineages of hominins (Paranthropus, Australopithecus–Homo): *two ways to drain cranial blood* A variety of patchy environments were available to hominins living in Africa during the Plio-Pleistocene, and evidence from dentition and cranial blood flow shows that robust and nonrobust (gracile) australopithecines occupied different niches. *Paranthropus* was a vegetarian who had no need to engage in hunting of game during the heat of the day and therefore no need of a cranial radiator that would kick in during intense exercise. This hominin and its earlier *A. afarensis* relatives from Ethiopia relied on an enlarged O/M sinus system to drain blood from the cranium. Gracile australopithecines and early *Homo*, on the other hand, were more eclectic in their diets and, like living chimpanzees, had a taste for meat. By around 2 Mya, late *Australopithecus* and/or some of its early *Homo* descendants had begun scavenging and hunting on the hot African savanna (Blumenschine, 1987), and cranial radiators began to evolve.

4.20.2 Significance for Understanding Human Encephalization

4.20.2.1 The Cranial Radiator Was a Prime Releaser, Not a Prime Mover of Human Encephalization

During the early development of the network of radiator veins, thermal constraints that had previously kept brain size in check were released by the emergence of selective brain cooling in hominins that were living in niches associated with exposure to intense solar radiation. Consequently, brain size

began to increase in late nonrobust australopithecines and their *Homo* descendants, but remained forever static in *Paranthropus*. The radiator network of veins continued to increase along with brain size during most of *Homo*'s evolution, and today the human brain averages three times the size one would expect for a nonhuman primate of equivalent body size. The radiator network of veins is not hypothesized to have been the 'prime mover' of human brain evolution, i.e., the one trait whose selection was primarily responsible for brain evolution. (Prime mover candidates include hunting, tool production, work, warfare, throwing, language, and Machiavellian intelligence Falk 2004a). Instead, the radiator is viewed as an underlying and dynamic mechanism that helped regulate brain temperature and, as such, released thermal constraints that would otherwise have kept brain size in check in *Homo*, as they had in *Paranthropus*. The radiator is therefore best viewed as a 'prime releaser' (or one of several coordinated physiological releasers), not a prime mover of human brain evolution (see The Evolution of Human Brain and Body Growth Patterns, Evolutionary Specializations for Processing Faces and Objects).

4.20.2.1.1 The prime mover(s) of encephalization and cognitive evolution must be sought elsewhere The radiator hypothesis is purely mechanistic and does not address specific behaviors that may have been favored directly by natural selection as the prime mover(s) of hominin brain evolution. Of all the candidates that have been suggested as prime movers, human-like language may be the most likely because (1) it is not found in other animals and (2) it is germane to many of the advanced cognitive abilities that characterize *Homo sapiens*.

4.20.3 Recent Evidence Bearing on the Hypothesis

4.20.3.1 New Data Are Consistent with the Radiator Hypothesis

4.20.3.1.1 The takeoff in hominin brain size may have begun earlier than previously believed Since the radiator hypothesis was first published in 1990, major changes have occurred in the understanding and interpretation of the hominin fossil record that pertain to brain evolution. Revised cranial capacities for numerous australopithecines and new data for hominins from Dmanisi, Republic of Georgia (Vekua *et al.*, 2002), contradict the traditional view that brain size 'took off' around 2.0 Mya in *Homo* and suggest, instead, that brain size may have begun to increase considerably earlier in the *Australopithecus* ancestors of *Homo* (Falk, 2004b). Such a paradigm shift fits with the radiator hypothesis (Figure 3), and newly discovered skulls offer the opportunity to collect more data pertaining to cranial blood flow.

4.20.3.1.2 New findings regarding early hominin habitats The radiator hypothesis incorporated a controversial assumption that early *Homo* and its direct australopithecine ancestors occupied patchy savanna niches that exposed individuals to risk of hyperthermia from intense solar radiation, and that other hominins, including *A. afarensis* and *Paranthropus*, occupied more wooded, less thermally challenging niches. The assumption that different early hominins occupied different habitats has received recent support from discoveries of 6–7-million-year-old hominins (*Sahelanthropus*, *Orrorin*) that are thought to have lived in forested or wooded habitats rather than savannas. Although it now looks as if bipedalism may not have originated in savanna habitats as previously thought, by around 2 Mya nonrobust hominins were 'standing tall and staying cool' while adding more meat to their diets by scavenging and hunting in thermally stressful savannas. Such a shift to higher quality (and easily digestible) foods at this time is incorporated in the expensive-tissue hypothesis of Leslie Aiello and Pete Wheeler (Aiello and Wheeler, 1995), which postulates a trade-off between metabolically expensive guts and brains, with the former decreasing as the latter increased in mass during hominin evolution. These new data are consistent with the radiator hypothesis' basic assumption that a cranial radiator developed when hominins began to occupy thermally stressful habitats, thus releasing a thermal constraint that had previously kept brain size in check.

4.20.3.1.3 New data for frequency of enlarged occipital/marginal venous sinuses in *Paranthropus* According to the radiator hypothesis, an enlarged O/M sinus occurs in 100% of scorable robust australopithecines. This assertion has met with occasional claims that a particular *Paranthropus* specimen lacks this feature, but in these few cases the specimens have not been complete enough to score (per guidelines published by Tobias and Falk, 1988). When enlarged O/M sinuses were first tallied, seven *Paranthropus* specimens were scorable and all seven had the feature. Today, 11 out of 11 scorable *Paranthropus* specimens have the trait, which lends strong support to the suggestion that enlarged O/M sinuses are, indeed, fixed in *Paranthropus*.

4.20.3.1.4 Anatomical demonstration of the radiator The radiator hypothesis' basic assumption that humans possess an extensive network of tiny veins that participate in selective brain cooling was based on physiological and frequency data collected from a few named emissary veins. Although this assumption was controversial, in 1996 Wolfgang Zenker and Stefan Kubik demonstrated an anatomical basis for a convection process of cooling the brain by evaporation of sweat from the head (Figure 4). Transcranial heat exchange may thus occur between cool venous blood, the CSF (cerebral spinal fluid), and thin-walled subarachnoid and pial arterial branches before they enter the brain. As the authors note, the suggestion that the 'unprecedented vascular bed' shown in Figure 4 may transmit temperature changes to the cerebrospinal compartment, which, in turn, selectively cools the brain is open to physiological verification or falsification.

4.20.4 Summary and Conclusions

4.20.4.1 Physiological Data Such as Those Incorporated in the Radiator Hypothesis Are Beginning to Inform Paleoanthropology

Traditional hypotheses on hominin brain evolution have often included suggestions regarding single behaviors or traits that may have been the prime mover(s) of cognitive evolution targeted by natural selection. Although entertaining, such prime mover hypotheses are extremely speculative and do not lend themselves readily to testing. Physiological hypotheses such as those regarding a cranial radiator and expensive tissue are beginning to emerge in paleoanthropology, and these lend themselves more easily to scientific testing. The radiator and expensive-tissue hypotheses should be viewed as complementary rather than competing. Both incorporate data that suggest the direct ancestors of humans increased their exploitation of resources in open African habitats; and both identify physiological constraints that, when released, permitted brain size to increase.

P R Hof, Mount Sinai School of Medicine, New York, NY, USA

Glossary

allometry Many biological traits scale with overall size in a nonlinear fashion. Such allometric scaling relationships can be expressed by the power function: $Y = bX^a$. The logarithmic transformation of the allometric scaling equation yields: $log\ Y = \log\ b + a\ \log\ X$. The exponent of the power function becomes the slope of the log-transformed function. The slope of this line can then be interpreted in terms of a biological scaling relationship between the independent and dependent variable. Positive allometry refers to a scaling relationship with an exponent that is greater than 1, which means that the structure in question grows disproportionately larger or more numerous with increases in the size of the reference variable. Negative allometry refers to a scaling relationship with an exponent that is less than 1, which means that the structure in question becomes proportionally smaller or less numerous with increases in the size of the reference variable.

chemoarchitecture The microanatomical organization of the cerebral cortex revealed by staining for biochemical substances using techniques such as immunohistochemistry and enzyme or lectin histochemistry.

dysgranular cortex A type of cortex that has a weakly defined layer IV because it is variable in thickness. At points, layer IV seems to disappear because neurons from layers IIIc and Va intermingle.

encephalization A relative measure of a species' brain size that represents the degree to which it is larger or smaller than expected for a typical animal of its body size.

granular cortex A type of cortex that has a clearly identifiable layer IV.

gray level index (GLI) The proportion of an area of reference that is occupied by the projected profiles of all

Nissl-stained elements. This value provides an estimate of the fraction of tissue that contains neuronal somata, glial cell nuclei, and endothelial nuclei versus neuropil. GLI values are highly correlated with the volume density occupied by neurons since glial and endothelial cell nuclei contribute only a very small proportion of the total volume.

hominoid A phylogenetic clade that includes lesser apes (gibbons and siamangs), great apes (orangutans, gorillas, chimpanzees, and bonobos), and humans.

infragranular layers Cortical layers that are deep to granular layer IV, i.e., layers V and VI.

minicolumn Morphologically, minicolumns appear as a single vertical row of neurons with strong vertical interconnections among layers, forming a fundamental structural and functional unit. The core region of the column contains the majority of the neurons, their apical dendrites, and both myelinated and unmyelinated fibers. A cell-poor region, containing dendritic arbors, unmyelinated axons, and synapses, surrounds each column.

neuropil The unstained portion of Nissl-stained tissue, which is comprised of dendrites, axons, and synapses.

supragranular layers Cortical layers that are superficial to granular layer IV, i.e., layers I, II, and III.

4.21.1 Introduction

4.21.1.1 Evolutionary History of the Hominoids

Apes and humans are members of the primate superfamily Hominoidea (Figure 1). Molecular evidence indicates that the hominoid lineage split from the Old World monkeys about 25 Mya (Wildman *et al.*, 2003). The extant representatives of this phylogenetic group include two families. The Hylobatidae comprises gibbons and siamangs, and the Hominidae includes great apes (i.e., orangutans, gorillas, chimpanzees, and bonobos) and humans (Groves, 2001). Living hominoids are distinguished by a suite of shared derived traits that point to the key adaptations of this clade. These characters include lack of an external tail, modifications of the shoulder girdle and wrist for greater mobility, and stabilization of the lower back (Begun, 2003). These adaptations allow hominoids to exploit resources in small branches of trees by developing suspensory postures to distribute their body weight. This form of locomotion may have been particularly important in allowing certain species to increase body size. In addition, compared to other primates, hominoids have extended periods of growth and development (Schultz, 1969), an increased complexity of social interactions (Potts, 2004), and larger brains than would be expected for a monkey of the same body size (Rilling and Insel, 1999). The increased encephalization and associated life history elongation of these species suggest that cognitive flexibility and learning were important aspects of the hominoid adaptive complex, which allowed them to deal with locating ephemeral resources from fruiting trees and to negotiate more complicated relationships in fission–fusion societies (Potts, 2004).

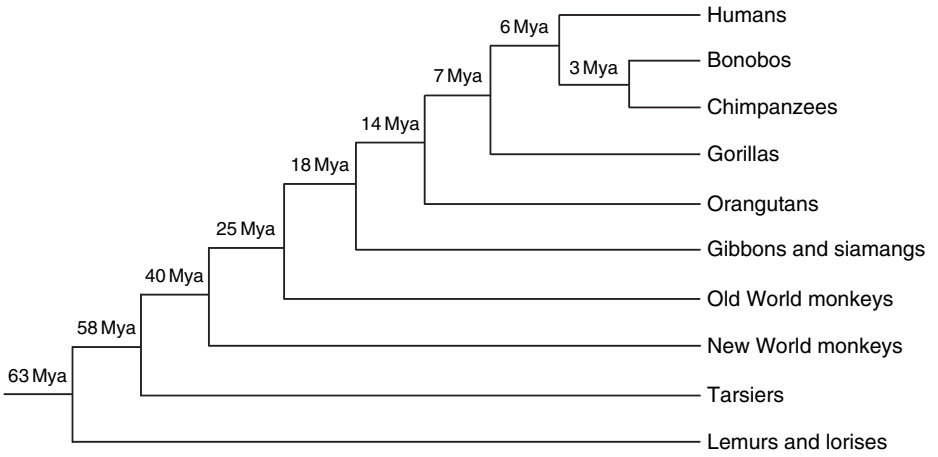

Figure 1 Cladogram showing the phylogenetic relationships of living hominoids and other primates. Estimated divergence dates are taken from Goodman *et al.* (2005).

Although only a small number of hominoid species persist today, the fossil record reveals a diverse array of successive adaptive radiations of hominoids in the past. During the Miocene epoch, global climates were warm and humid, supporting dense forests and lush woodlands extending throughout the tropics and into northern latitudes. These environmental conditions were favorable for the diversification of arboreal specialists, such as the hominoids. In fact, hominoids were the most abundant type of anthropoid primate throughout the Miocene in Africa and Eurasia, occupying a range of different ecological niches (Begun, 2003). The earliest apes in the fossil record are characterized by hominoid-like dental morphology, but monkey-like postcranial anatomy. The best known of these early dental apes is the genus *Proconsul* from the Early Miocene (20–18 Mya) of East Africa. *Proconsul africanus* endocasts show a frontal lobe morphology that is similar to modern hominoids in being gyrified and lacking the simple V-shaped arcuate sulcus that is characteristic of most Old World monkeys (Radinsky, 1974). Furthermore, *P. africanus* had a relatively larger brain than extant monkeys of comparable body size (Walker *et al.*, 1983). Thus, increased encephalization and perhaps a greater degree of frontal lobe gyrification were present early in the evolution of the hominoids.

With the emergence of arid climates in the transition to the Pliocene and the replacement of forests by mosaic habitats, the arboreal specializations of hominoids were less successful. The relatively slow reproductive rates of these taxa, moreover, made it difficult for many to endure habitat loss resulting from climate change and human encroachment in recent times (Jablonski *et al.*, 2000). In the context of these dramatic environmental changes, one lineage adopted a new form of locomotion, upright bipedal walking, which would give rise to modern humans. Other hominoids, however, fared less well and today apes are restricted to a small number of endangered tropical forest species.

4.21.1.2 History of Studies Concerning Hominoid Cortical Histology

At the beginning of the twentieth century, neuroanatomists applied new histological staining techniques to reveal the architecture of the cerebral cortex in numerous species, including apes and humans (Campbell, 1905; Mauss, 1908, 1911; Brodmann, 1909; Beck, 1929; Filimonoff, 1933; Strasburger, 1937a, 1937b). In addition, with the advent of various techniques for tracing neuronal connectivity based on intracellular pathological changes subsequent to ablation, some studies also examined cortical projection systems in apes (Walker, 1938; Lassek and Wheatley, 1945; Kuypers, 1958; Jackson *et al.*, 1969). After the 1950s, however, the amount of research directed toward understanding variation in the hominoid brain declined. There are three main reasons for this. First, the development of molecular biological techniques caused neuroscientists to focus on a small number of model species under the implicit assumption that many aspects of cortical structure are evolutionarily conserved. These ideas were further bolstered by claims of uniformity in the basic columnar architecture of the cerebral cortex (Rockel *et al.*, 1980). Second, findings from the first systematic studies of great ape behavior from the field and laboratory were beginning to be appreciated (e.g., Kortlandt, 1962; Schaller, 1963; Yerkes and Learned, 1925; Yerkes and Yerkes, 1929). These studies contributed to a more sophisticated understanding of cognitive and emotional complexity in great apes and suggested that they deserve special protected status with respect to the ethics of invasive neurobiological experimentation. Third, the book *Evolution of the Brain and Intelligence* (Jerison, 1973) had an enormous influence on the direction of later research in comparative neuroanatomy. This book argued for the predictability of neuroanatomical structure from brain size and encephalization, suggesting that these metrics form the most significant contribution to species diversity in brain organization. Combined with the ready availability of comparative brain region volumetric data in primates and other mammals from the publications of Heinz Stephan, Heiko Frahm, George Baron, and colleagues (e.g., Stephan *et al.*, 1981), a great deal of research effort has been expended in studies of allometric scaling and covariance of large regions of the brain (Finlay and Darlington, 1995; Barton and Harvey, 2000; de Winter and Oxnard, 2001). In contrast, much less attention has been paid to the possibility of phylogenetic variation in cortical histology (Preuss, 2000). Fortunately, advances in quantitative neuroanatomy and immunohistochemical staining techniques have opened new avenues of research to reveal interspecific diversity in the microstructure of hominoid cerebral cortex.

The history of studies of hominoid cortical histology, therefore, has resulted in two eras of research. The early era comprises several qualitative comparative mapping studies of the cerebral cortex based on cyto- and myeloarchitecture, with the occasional comment regarding species differences in the microstructure of homologous cortical areas

(Campbell, 1905; Mauss, 1908, 1911; Brodmann, 1909; Beck, 1929; Bailey *et al.*, 1950). Later studies from this era also contributed quantitative data concerning the surface area of particular cortical areas, as well as cellular sizes and densities in a few nonhuman hominoid species (Mayer, 1912; Tilney and Riley, 1928; von Bonin, 1939; Lassek and Wheatley, 1945; Shariff, 1953; Haug, 1956; Glezer, 1958; Blinkov and Glezer, 1968). These quantitative data, however, were rarely presented in the context of a focused examination of variation among hominoids.

The modern era is characterized by studies that use techniques such as design-based stereology, computerized image analysis, and immunohistochemical and histochemical staining to identify subpopulations of cortical cells. These new approaches are especially appealing for investigations of phylogenetic variation in cortical histology in species that are not common to the laboratory because several enzymatic, cytoskeletal, and other macromolecular constituents that are well preserved in postmortem tissue can be used as reliable markers for subpopulations of distinct neuron types, thereby extending comparative studies of species for which anatomical tracing, electrophysiological mapping, or other experimental procedures would be either unethical or impractical (see The Evolution of Neuron Classes in the Neocortex of Mammals). Subsets of pyramidal neurons, for example, can be distinguished immunohistochemically by staining with an antibody (e.g., SMI-32) to nonphosphorylated epitopes on the medium- and high-molecular-weight subunits of the neurofilament triplet protein. These epitopes are particularly enriched in subpopulations of large neurons of the neocortex that have a specific laminar and regional distribution. Because nonphosphorylated neurofilament protein (NPNFP) is involved in the maintenance and stabilization of the axonal cytoskeleton, its expression is associated with neurons that have thick myelinated axons (Hoffman *et al.*, 1987; Kirkcaldie *et al.*, 2002). In addition, the calcium-binding proteins – calbindin D-28k (CB), calretinin (CR), and parvalbumin (PV) – are useful markers for understanding the cortical interneuron system because each of these molecules is typically co-localized with GABA in morphologically and physiologically distinct nonoverlapping populations (DeFelipe, 1997; Markram *et al.*, 2004).

While the neuroanatomical structure of one hominoid species in particular has been studied most extensively, it is well beyond the scope of this article to provide a comprehensive review of human cortical architecture. Here we focus explicitly on comparative studies of the histology of hominoid cerebral cortex, highlighting evidence concerning shared derived traits of hominoids in comparison to other primates, as well as indicating possible species-specific specializations. Hence, the studies reviewed in this chapter provide the most direct evidence currently available to delimit which aspects of cortical histology are uniquely human, which are derived for all hominoids, and which reflect the specializations of each species.

4.21.2 Comparative Anatomy of the Cerebral Cortex

4.21.2.1 Topology of Cortical Maps

Total brain weight in hominoids ranges from approximately 90 g in Kloss's gibbons (*Hylobates klossii*) to 1400 g in humans (*Homo sapiens*) (Table 1). While there is a large range of variation among hominoids in total brain size, mapping studies of the cortex (Figure 2) generally agree that the location of the primary sensory and motor areas are similar across species (Grünbaum and Sherrington, 1903; Campbell, 1905; Mauss, 1908, 1911; Brodmann, 1909; Leyton and Sherrington, 1917; Beck, 1929; Bailey *et al.*, 1950; Preuss *et al.*, 1999; Hackett *et al.*, 2001; Bush and Allman, 2004a, 2004b; Sherwood *et al.*, 2004b). In particular, the primary visual cortex lies within the banks of the calcarine sulcus. Primary auditory cortex is located on the posterior superior plane of the superior temporal gyrus, usually comprising the transverse gyrus of Heschl in great apes and humans. Primary somatosensory cortex is found within the posterior bank of the central sulcus and extends on to the postcentral gyrus. Primary motor cortex is located mostly on the anterior bank of the central sulcus. One notable difference is the fact that primary visual cortex extends to only a very small portion of the lateral convexity of the occipital lobe in humans, whereas a much larger part of the lateral occipital lobe is comprised of striate cortex in apes (Zilles and Rehkämper, 1988; Holloway *et al.*, 2003). This is because the primary visual cortex in humans is 121% smaller than expected for a primate of the same brain size (Holloway, 1996). Other higher-order areas, particularly within the frontal cortex, have also been shown to occupy similar locations across these species (Strasburger, 1937a, 1937b; Semendeferi *et al.*, 1998, 2001; Sherwood *et al.*, 2003a).

4.21.2.2 Architecture of the Cortex

The general histological architecture of the neocortex in hominoids shares many features in common

Table 1 Endocranial volumes of hominoids (in cc)

Common name	*Species*	*Sex*	*Sample size*	*Mean*	*SD*	*Range*
White-handed gibbon	*Hylobates lar*	M	44	106.3	7.2	92–125
		F	37	104.2	7.0	90–116
Siamang	*Symphalangus syndactylus*	M	8	127.7	8.2	99–140
		F	12	125.9	12.7	102–143
Orangutan	*Pongo pygmaeus*	M	66	415.6	33.6	334–502
		F	63	343.1	33.6	276–431
Gorilla	*Gorilla gorilla*	M	283	535.5	55.3	410–715
		F	199	452.2	41.6	345–553
Chimpanzee	*Pan troglodytes*	M	159	397.2	39.4	322–503
		F	204	365.7	31.9	270–450
Bonobo	*Pan paniscus*	M	28	351.8	30.6	295–440
		F	30	349.0	37.7	265–420
Human	*Homo sapiens*	M	502	1457.2	119.8	1160–1850
		F	165	1317.9	109.8	1040–1615

Endocranial volumes are shown, rather than brain volumes, because larger sample sizes are available for these species. Reproduced from Holloway, R. L. 1996. Evolution of the human brain. In: Handbook of Human Symbolic Evolution (*eds.* A. Lock and C. R. Peters), pp. 74–114. Oxford University Press.

with other primates and mammals in general, such as a fundamental six-layered and columnar organization (Mountcastle, 1998). Compared to other mammals of similar brain size, however, the cerebral cortex of hominoids is reported to have a relatively low density of glial cells and a greater variety of neuron soma sizes (Haug, 1987). Astroglia of the cerebral cortex in great apes, as revealed by immunohistochemistry for glial fibrillary acidic protein (GFAP), resemble other primates in forming long, radially oriented interlaminar processes spanning supragranular cortical layers (Colombo *et al.*, 2004). This configuration may be unique to primates, as GFAP staining in the cortex of other mammals appears distinctly different, comprising a network of stellate astroglial somata with short, branching processes (Colombo, 1996; Colombo *et al.*, 2000; Colombo and Reisin, 2004).

Comparison of mammalian brains indicates that the surface area of the cortical sheet can vary by more than five orders of magnitude, while the thickness of the cortex varies by less than one order of magnitude (Allman, 1990). Accordingly, evolutionary changes in the size of the cerebral cortex have occurred primarily in the tangential dimension, while the vertical dimension of the cortex may be more constrained by the development of columnar units (Rakic, 1988, 1995). Nonetheless, the cortical sheet does tend to display increased thickness in mammals with larger brains (Hofman, 1988). Due to these scaling trends, hominoids have thicker cortices than other smaller-brained primates and homologous cortical areas in humans tend to be thicker than in apes (Figure 3).

With the relative ease of establishing homology among the primary sensory and motor cortical areas on the basis of cytoarchitecture and topology, several studies have compared the microstructure of these areas among different hominoid species (reviewed below). On the whole, the cytoarchitecture of homologous cortical areas shows only subtle differences across hominoid species. Indeed, an early quantitative comparative analysis of the cytoarchitecture of primary cortical areas (areas 3, 4, 17, and 41/42), found marked similarities among species (orangutans, gorillas, chimpanzees, and humans) in terms of the relative thickness of different layers and the proportion of neuropil in each layer (Zilles and Rehkämper, 1988). Only minor differences were noted, such as greater relative thickness of layer III in primary somatosensory cortex (area 3) in humans and gorillas, an increase in the proportion of neuropil in layers V and VI of area 3 in orangutans, and a relatively thicker layer IV of primary auditory cortex (area 41/42) in orangutans. These results were interpreted to corroborate the qualitative observations of Campbell (1905) and Brodmann (1909), indicating that there are not any substantial differences between humans and apes in the cytoarchitecture of these primary cortical areas. The study by Zilles and Rehkämper (1988), however, was based on small samples, which did not permit statistical evaluation of species differences. More recent studies using larger samples, different staining techniques, and more refined quantitative methods have revealed interesting phylogenetic differences among hominoids in cortical histological structure.

4.21.2.3 Primary Visual Cortex

Important modifications of primary visual cortex (Brodmann's area 17) histology, particularly of the

University of Illinois Press. Orangutan (*Pongo pygmaeus*) cortical maps reproduced from (c) Campbell (1905) and (d) Mauss (1908, 1911) compiled in Zilles and Rekämper (1988). c and d, Reproduced from "figure 12-2", *Orang-utan Biology*, edited by Jeffrey H. Schwartz, copyright © 1988 by Oxford University Press, Inc., used by permission of Oxford University Press, Inc.

thalamic recipient layer IV, have taken place at several points in the evolution of hominoids. Distinct parallel ascending fiber systems arising from retinal ganglion cells project to the lateral geniculate nucleus (LGN) of the thalamus. The M-type retinal ganglion cells give rise to the magnocellular channel, which is involved in the analysis of motion and gross spatial properties of stimuli. The P-type ganglion cells process visual

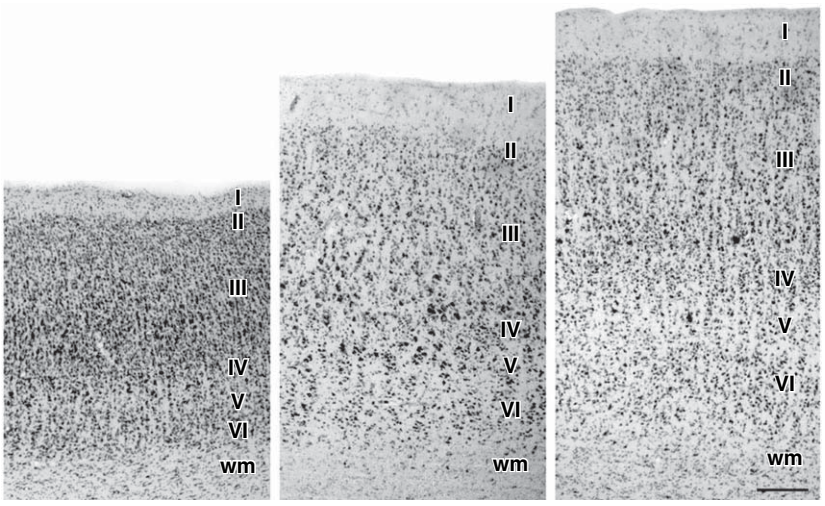

Figure 3 Cytoarchitecture of primary somatosensory cortex (area 3b) in long-tailed macaque (*Macaca fascicularis*), chimpanzee (*Pan troglodytes*), and human (*Homo sapiens*), showing interspecific variation in the thickness of the cortex. Scale bar: 250 μm.

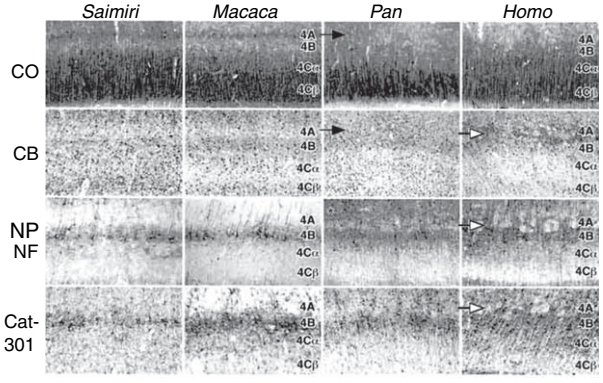

Figure 4 Comparative chemoarchitecture of layer IV in primary visual cortex of squirrel monkeys (*Saimiri*), macaques (*Macaca*), chimpanzees (*Pan*), and humans (*Homo*). Reproduced from Preuss, T. M. and Coleman, G., Human-specific organization of primary visual cortex: Alternating compartments of dense Cat-301 and calbindin immunoreactivity in layer 4A, *Cereb. Cortex*, 2002, 12, 671–691, Oxford University Press.

information with high acuity and color sensitivity, and project to parvocellular layers of the LGN. In the geniculostriate component of these parallel pathways, different systems derive from distinct portions of the LGN and synapse within separate sublayers of layer IV in primary visual cortex. The complexity of segregated geniculostriate projects is reflected in the development of at least three subdivisions of layer IV in primates as demarcated by Brodmann (1909). Two cell-rich layers, IVA and IVC, are separated by a cell-poor layer, IVB, which contains a dense plexus of myelinated axons known as the stria of Gennari. Neurons in the magnocellular layers of the LGN project to the upper half of layer IVC. Neurons in the parvocellular layers of the LGN project to layer IVA.

The chemoarchitecture of layer IVA is markedly different in hominoids compared to other primates (Figure 4). In most monkeys, except the nocturnal owl monkey, there is a dense band of cytochrome oxidase (CO)-rich staining in layer IVA (reviewed in Preuss *et al.*, 1999), reflecting high levels of metabolic activity within this sublayer. However, in the hominoid species examined to date (orangutans, chimpanzees, and humans), intense CO staining in layer IVA is absent, suggesting that the direct parvocellular-geniculate projection to layer IVA was either reduced or more dispersed to include both layers IVA and IVB in the last common ancestor of this phylogenetic group (Preuss *et al.*, 1999; Preuss and Coleman, 2002). Primary visual cortex of great apes and humans is further distinguished from monkeys in having increased staining of CB-immunoreactive (-ir) interneurons and neuropil in layer IVA (Preuss and Coleman, 2002).

Layer IVA of primary visual cortex in humans exhibits additional modifications to the basic hominoid plan described above. In humans, a meshwork pattern is observed in which compartments of neuropil that stain intensively for Cat-301 and nonpyramidal NPNFP-ir cells, and neurites alternate with bands of high densities of CB-ir interneurons (Preuss and Coleman, 2002). These changes in human primary visual cortex have been interpreted to reflect a closer association of this layer to M-pathway inputs than observed in any other primates. The functional implications of

these histological changes are unclear; however, it has been suggested that these alterations are related to specializations in humans for the visual perception of rapid orofacial gestures in speech (Preuss and Coleman, 2002).

Another distinctive feature of primary visual cortex organization in many primates is ocular dominance columns, which correspond to the horizontal segregation of inputs from the two retinas to different compartments in layer IV of primary visual cortex. Ocular dominance columns have been anatomically demonstrated in Old World monkeys, humans, and some other primates, such as the New World spider monkey and the strepsirrhine galago (reviewed in Allman and McGuinness, 1988). A similar pattern of alternating patches of ocular representation within primary visual cortex has been described in a chimpanzee after monocular injection of a transneuronal tritiated tracer substance (Tigges and Tigges, 1979). It is worth noting, however, that this study revealed geniculate projections to layer IVC, but not to layer IVA, as is observed in monkeys.

Large pyramidal neurons, which are found at the boundary between layers V and VI, called Meynert cells, are prominent in the primary visual cortex of primates, and their soma size displays interspecific variation (Figure 5) (Sherwood *et al.*, 2003c). These cells can be distinguished as a unique subtype on the basis of their morphology and connectivity. Their thick axon collaterals project to both area MT/V5 and the superior colliculus, suggesting that these cells are involved in processing visual motion (Fries *et al.*, 1985; Movshon and Newsome, 1996; Livingstone, 1998). In a comparative study, Meynert cell somata were found to be on average 2.8 times lager than other layer V pyramidal neurons across a range of primates (Sherwood *et al.*, 2003c). Because the basal dendrites and axon collaterals of Meynert cells extend horizontally in layers V and VI to integrate information and facilitate responses across widespread areas of visual space, interspecific variation in Meynert cell size appears to be largely constrained by their function in the repetitive stereotyped local circuits that represent the retinal sheet in primary visual cortex. In the context of the general scaling patterns of Meynert cells, it is interesting that soma volumes of these neurons fit closely with predictions among humans (2.84 times larger than neighboring pyramidal cells) and gorillas (2.98 times), whereas they are relatively large in chimpanzees (3.78 times) and relatively small in orangutans (1.94 times). These differences in neural organization for the processing of visual motion may relate to socioecological differences among these apes. Because wild chimpanzees engage in aggressive incursions into the territory of neighboring groups (Watts and Mitani, 2001) and hunt highly mobile prey such as red colobus monkeys (Watts and Mitani, 2002), we speculate that relatively large Meynert cells evolved in this species to enhance detection of visual motion during boundary patrolling and hunting. In contrast, relatively small Meynert cells in orangutans may relate to the fact that these apes are solitary, large-bodied, committed frugivores (van Schaik and van Hooff, 1996), which allows them to maintain low levels of vigilance for motions of predators, competitors, and food items.

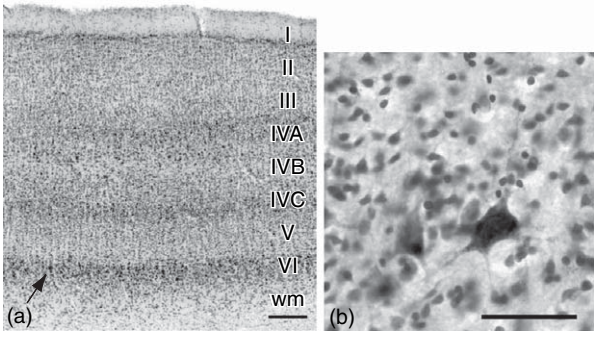

Figure 5 The location and morphology of Meynert cells in an orangutan (*Pongo pygmaeus*). Meynert cells are located at the boundary between layers V and VI, as indicated by the arrow in the Nissl-stained section (a). The morphology of Meynert cells as revealed by immunostaining for NPNFP with Nissl counterstain is shown (b). Scale bar: a, 250 μm; b, 50 μm.

4.21.2.4 Auditory Cortex

There are two parallel thalamocortical projections from the medial geniculate nucleus (MGN) to the superior temporal cortex of primates. Neurons in the ventral division of the MGN supply a tonotopic projection to the core region of auditory cortex (Brodmann's areas 41 and 42). Neurons in the dorsal and medial divisions of the MGN project to areas surrounding the core. The core region of auditory cortex has been identified in macaques, chimpanzees, and humans as a discrete architectural zone as compared to the surrounding belt cortex (Hackett *et al.*, 2001). The core can be recognized by a broad layer IV that receives a dense thalamic projection, heavy myelination, and intense expression of acetylcholinesterase (AChE), CO, and PV in the neuropil of layer IV. In macaques, the relatively high density of cells and fibers makes the auditory cortex core appear structurally homogeneous as compared to the hominoids. In contrast, the medial and lateral domains of the core region of auditory

cortex are more clearly differentiated in humans and chimpanzees because of the lower packing density of structural elements. Additionally, the network of small horizontal and tangential myelinated fibers in layer III appears most complex in humans, intermediate in chimpanzees, and least elaborate in macaques.

The auditory core region is enveloped by several higher-order belt and parabelt fields (Figure 6). The belt areas of auditory cortex, which are less precise in their tonotopic organization, receive major inputs from the core and diffuse input from the dorsal division of the MGN. The belt region is bordered laterally on the superior temporal gyrus by a parabelt region of two or more divisions that are activated by afferents from the belt areas and the dorsal MGN, but not the ventral MGN or the core. Interestingly, AChE-stained pyramidal cells in layer III and V of the belt region are more numerous in chimpanzees and humans compared to macaques (Hackett *et al.*, 2001). Neurons in the belt and parabelt project to auditory-related fields in the temporal, parietal, and frontal cortex. Other types of processing that occur in the other divisions of auditory cortex are not well understood, but they are likely to be important for higher-order processing of natural sounds, including those used in communication. Neurons in the lateral belt cortex areas of rhesus macaques, for example, respond better to species-specific vocalizations than to energy-matched pure tone stimuli (Rauschecker *et al.*, 1995).

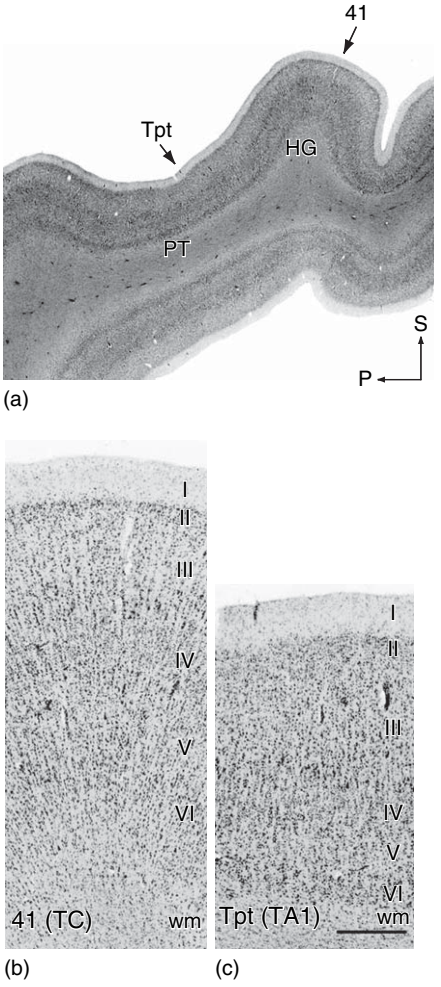

Figure 6 Cytoarchitecture of auditory cortex of an orangutan (*Pongo pygmaeus*). A parasagittal section of the superior temporal gyrus shows the location of regions detailed below (a). Higher-power micrographs show cytoarchitecture in (b) the core of primary auditory cortex (Brodmann's area 41 or von Economo and Koskinas' area TC) and (c) area Tpt (posterior Brodmann's area 22 or von Economo and Koskinas' area TA_1). HG, Heschl's gyrus; PT, planum temporale; S, superior; P, posterior. Scale bar: 500 μm.

The comparative anatomy of one particular region of auditory association cortex has been studied most extensively. In humans, Wernicke's area, a region important for the comprehension of language and speech, is located in the posterior superior temporal cortex. Gross anatomic observations indicate that asymmetries similar to humans are present in the superior temporal lobe of nonhuman primates, such as leftward dominance of the planum temporale in great apes (Gannon *et al.*, 1998; Hopkins *et al.*, 1998) and a longer left sylvian fissure in many anthropoid species (LeMay and Geschwind, 1975; Yeni-Komshian and Benson, 1976; Heilbroner and Holloway, 1988; Hopkins *et al.*, 2000).

Several investigations have examined the microstructure of the cortical area most closely associated with Wernicke's area. Area Tpt (Galaburda *et al.*, 1978) or area TA_1 (von Economo and Koskinas, 1925) comprises a portion of posterior Brodmann's area 22 located on the upper bank of the superior temporal gyrus and sometimes extending to part of the parietal operculum and the convexities of the temporal and parietal lobes (Galaburda *et al.*, 1978). This area represents a transition between auditory association cortex and cortex of the inferior parietal lobule (Shapleske *et al.*, 1999). Cortex with the cytoarchitectural characteristics of area Tpt has been described in galagos, macaques, chimpanzees, and humans (Galaburda and Pandya, 1982; Preuss and Goldman-Rakic, 1991; Buxhoeveden *et al.*, 2001a, 2001b). The microstructure of area Tpt in these primates is distinguished by a eulaminate appearance, with a poorly defined border of layer IV due to the encroachment of pyramidal cells in adjacent layers IIIc and Va, and an indistinct border between layers IV and V due to curvilinear columns of neurons that bridge the two layers (Galaburda and Sanides, 1980).

There are differences among rhesus monkeys, chimpanzees, and humans in the details of minicolumn structure in area Tpt. In the left hemisphere, area Tpt of humans has wider minicolumns as compared to macaques or chimpanzees, whereas the width of minicolumns is similar in the nonhuman species (Buxhoeveden *et al.*, 2001b). These findings suggest that wider minicolumns in human area Tpt may be a species-specific specialization that allows for more extensive neuropil space containing interconnections among neurons.

The microstructure of area Tpt has also been shown to be asymmetric in humans, possibly as a neural substrate of hemispheric dominance in the cerebral representation of language. Long-range intrinsic connections within area Tpt labeled in postmortem brains with lipophilic dyes have revealed greater spacing between interconnected patches in the left hemisphere compared to the right (Galuske *et al.*, 2000). Furthermore, left area Tpt has a greater number of the largest pyramidal cells in layer III, known as magnopyramidal cells, that give rise to long corticocortical association projections (Hutsler, 2003). In addition, AChE-rich pyramidal cells display greater cell soma volumes in the left hemisphere despite lacking asymmetry in number (Hutsler and Gazzaniga, 1996). In humans, left area Tpt has also been shown to contain a greater amount of neuropil and axons with thicker myelin sheaths (Anderson *et al.*, 1999). Of particular significance, a comparative analysis of area Tpt found that only humans, but not rhesus macaques or chimpanzees, exhibit left dominant asymmetry in area Tpt, with wider minicolumns and a greater proportion of neuropil (Buxhoeveden *et al.*, 2001a).

4.21.2.5 Primary Motor Cortex

The primary motor cortex (Brodmann's area 4) has a distinctive cytoarchitectural appearance in primates (Geyer *et al.*, 2000; Sherwood *et al.*, 2004b), containing giant Betz cells in the lower portion of layer V, low cell density, large cellular sizes, an indistinct layer IV, and a diffuse border between layer VI and the subjacent white matter (Figure 7a). In humans, the region of primary motor cortex that corresponds to the representation of the hand exhibits interhemispheric asymmetry in its cytoarchitectural organization. Concomitant with strong population-wide right handedness in humans, most postmortem brains display a greater proportion of neuropil volume in the left hemisphere of this part of primary motor cortex (Amunts *et al.*, 1996). Interestingly, brains of

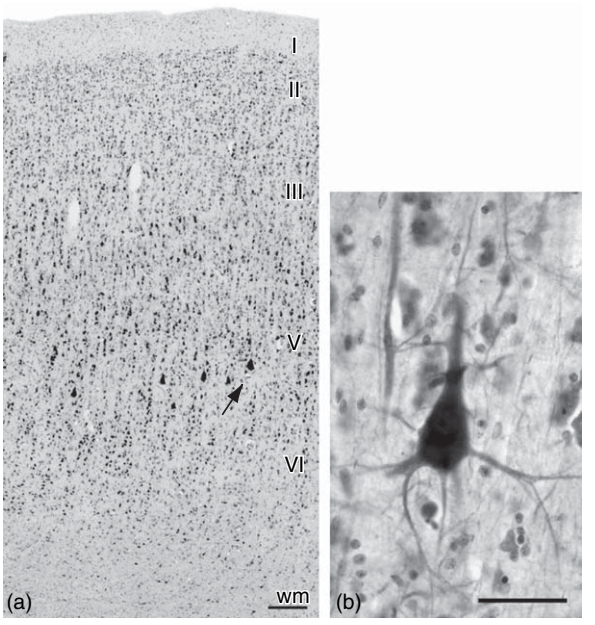

Figure 7 Cytoarchitecture of primary motor cortex and morphology of Betz cells in an orangutan (*Pongo pygmaeus*). Betz cells can be seen in the bottom of layer V, as indicated by the arrow in the Nissl-stained section (a). The morphology of Betz cells as revealed by immunostaining for NPNFP with Nissl counterstain is shown (b). Scale bar: a, 250 μm; b, 50 μm.

captive chimpanzees (Hopkins and Cantalupo, 2004) and capuchin monkeys (Phillips and Sherwood, 2005) show humanlike asymmetries of the hand region of the central sulcus that are correlated with the direction of individual hand preference. However, the histology of primary motor cortex in nonhuman primates has not yet been examined for asymmetry (see The Evolution of Hemispheric Specializations of the Human Brain).

While the cytoarchitectural organization of primary motor cortex is generally similar across species, interspecific differences have been described. The cytoarchitecture of the region corresponding to orofacial representation of primary motor cortex in several catarrhine species (long-tailed macaques, anubis baboon, orangutans, gorillas, chimpanzees, and humans) was analyzed using the gray level index (GLI) method (Sherwood *et al.*, 2004b). Compared to Old World monkeys, great apes and humans displayed an increased relative thickness of layer III and a greater proportion of neuropil space. A stereologic investigation of NPNFP and calcium-binding protein-ir neurons was also conducted in this same comparative sample (Sherwood *et al.*, 2004a). Primary motor cortex in great apes and humans was characterized by a greater percentage of neurons enriched in NPNFP and PV compared to the Old World monkeys

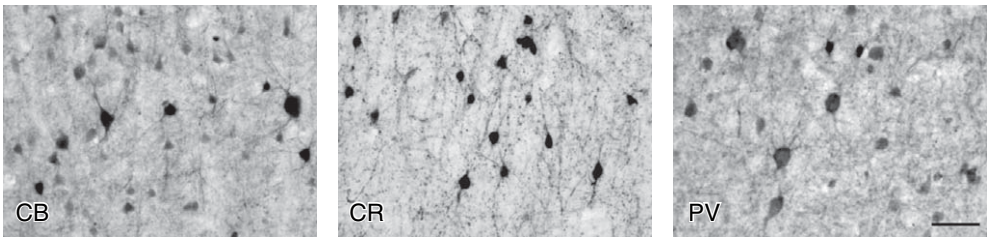

Figure 8 Calcium-binding protein-immunoreactive neurons in layer III of primary motor cortex of a chimpanzee (*Pan troglodytes*). Neurons stained for CB (a), CR (b), and PV (c) are shown. Morphologically, CR-ir interneurons correspond mostly to double-bouquet cells. They are predominantly found in layers II and III, and have narrow vertically oriented axonal arbors that span several layers. CB-ir neurons are morphologically more varied, including double-bouquet and bipolar types, with many showing a predominantly vertical orientation of axons. In contrast, the morphology of PV-ir interneurons includes large multipolar types, such as large basket cells and chandelier cells, which have horizontally spread axonal arbors spanning across cortical columns within the same layer as the parent soma. Scale bar: 50 μm.

(Figure 8). Conversely, the percentage of CB- and CR-ir neuron subtypes did not significantly differ among these species. These modifications of particular subsets of neuron types might contribute to the voluntary dexterous control of orofacial muscles exhibited in the vocal and gestural communication of great apes and humans. Enhancement of PV-ir interneuron-mediated lateral inhibition of cell columns may enhance specificity in the recruitment of different muscle groups for dynamic modulation of fine orofacial movements. Increased proportions of NPNFP-ir pyramidal cells, on the other hand, may be a correlate of greater descending cortical innervation of brainstem cranial motor nuclei by heavily myelinated axons to allow for more voluntary control (Kuypers, 1958).

The giant Betz cells are found in the lower half of layer V of primary motor cortex and possess a large number of primary dendritic shafts that leave the soma at several locations around its surface (Figure 7b) (Braak and Braak, 1976; Scheibel and Scheibel, 1978; Meyer, 1987). They are largest and most numerous in the cortical representation of the leg, where axons project farther along the corticospinal tract to reach large masses of muscles (Lassek, 1948; Rivara *et al.*, 2003). Betz cells are strongly immunoreactive for NPNFP among humans, great apes, and Old World monkeys (Sherwood *et al.*, 2004a). An analysis of scaling of Betz cell somata volumes in the region of hand representation of primates revealed that these cell subtypes become relatively enlarged with increases in brain and body size (Sherwood *et al.*, 2003c). At larger sizes, there is an increase in the distance to the spinal representation of target muscles and a greater number of less densely distributed corticospinal neurons (Nudo *et al.*, 1995). In larger brains and bodies, Betz cell axons need to become thicker to maintain conduction speed to reach more distant targets in the spinal cord. Accordingly, Betz cells are scaled to global connectivity constraints and therefore increase in somatic volume in a manner that is correlated with brain size. Due to these scaling trends, among hominoids Betz cells are relatively largest in humans (10.96 times larger than neighboring pyramidal cells), then gorillas (8.37 times), chimpanzees (7.02 times), and orangutans (6.51 times).

Specializations of biochemical phenotypes are known for certain regionally restricted subsets of pyramidal neurons. Although calcium-binding proteins are expressed transiently during prenatal and early postnatal development (Moon *et al.*, 2002; Ulfig, 2002), their expression in pyramidal neurons of adult mammals is more limited. Neurons expressing the calcium-binding proteins – CB, CR, and PV – are thought to have relatively high metabolic rates associated with fast repolarization for multiple action potentials (Baimbridge *et al.*, 1992). While such calcium buffering mechanisms are most commonly associated with GABAergic interneurons, the presence of calcium-binding proteins in pyramidal cells might reflect a neurochemical specialization for higher rates of activity. In this context, it is interesting that faint CR immunoreactivity is observed in isolated medium- and large-size layer V pyramidal neurons in primary motor cortex of great apes and humans, but not in macaques or baboons (Hof *et al.*, 1999; Sherwood *et al.*, 2004a). PV-ir pyramidal neurons are also very rarely observed in the neocortex of mammals (see The Evolution of Neuron Classes in the Neocortex of Mammals). However, large layer V pyramidal neurons, including Betz cells, have been reported to express PV immunoreactivity in primary motor cortex of humans (Nimchinsky *et al.*, 1997; Sherwood *et al.*, 2004a). Evidence concerning the existence of PV-ir pyramidal neurons in other nonhuman primates is somewhat contradictory. In

one study, PV-ir pyramidal neurons were observed in primary motor and somatosensory cortices of galagos and macaques (Preuss and Kaas, 1996). Another study, however, failed to label PV-ir pyramidal cells in macaques (DeFelipe *et al.*, 1989), probably due to methodological discrepancies among experiments. A comparative study of primary motor cortex using the same immunohistochemical procedures across species found that PV-ir pyramidal neurons were either not present or sparse in Old World monkeys, whereas they were considerably more numerous in great apes and humans (Sherwood *et al.*, 2004a).

4.21.2.6 Inferior Frontal Cortex

The microstructure of the inferior frontal cortex, the region that contains Broca's area in humans, has been described in hominoids on the basis on cyto-, myelo-, and NPNFP-architecture (von Economo, 1929; Bailey and von Bonin, 1951; Braak, 1980; Amunts *et al.*, 1999; Hayes and Lewis, 1995; Sherwood *et al.*, 2003a). Cytoarchitectural studies of chimpanzee and orangutan frontal cortex describe a dysgranular region anterior to the inferior precentral sulcus comprising a part of pars opercularis and designated Brodmann's area 44 (von Bonin, 1949; Sherwood *et al.*, 2003a), FCBm (Bailey *et al.*, 1950), or areas 56 and 57 (Kreht, 1936). In chimpanzees, this region has been shown to receive projections from the mediodorsal nucleus of the thalamus (Walker, 1938). In macaques, a field with similar cytoarchitectural characteristics in the caudal bank of the inferior limb of the arcuate sulcus has been denoted area 44, with area 45 located rostrally (Galaburda and Pandya, 1982; Petrides and Pandya, 1994). The cytoarchitecture of area 44 is characterized by a columnar organization similar to ventral premotor area 6, but it is distinguished by the development of a thin layer IV and clustered magnopyramidal neurons in the deep part of layer III. Layer IV in area 44 has an undulating appearance due to the invasion of pyramidal cells from layer III and layer V. NPNFP staining in area 44 of chimpanzees and humans displays clusters of large pyramidal neurons at the bottom of layer III and a lower band of immunoreactive layer V cells and neuropil (Figure 9) (Hayes and Lewis, 1995; Sherwood *et al.*, 2003a).

The cytoarchitecture of area 45 is distinguished from area 44 by the presence of a more prominent layer IV, a more homogeneous distribution of pyramidal cells in the deep portion of layer III, and the absence of conspicuous cell columns. NPNFP staining in area 45 is characterized by a clearer separation of immunoreactive neurons into upper (layer III) and lower (layer V) populations and by the absence of the intensely stained magnopyramidal clusters, as seen in area 44.

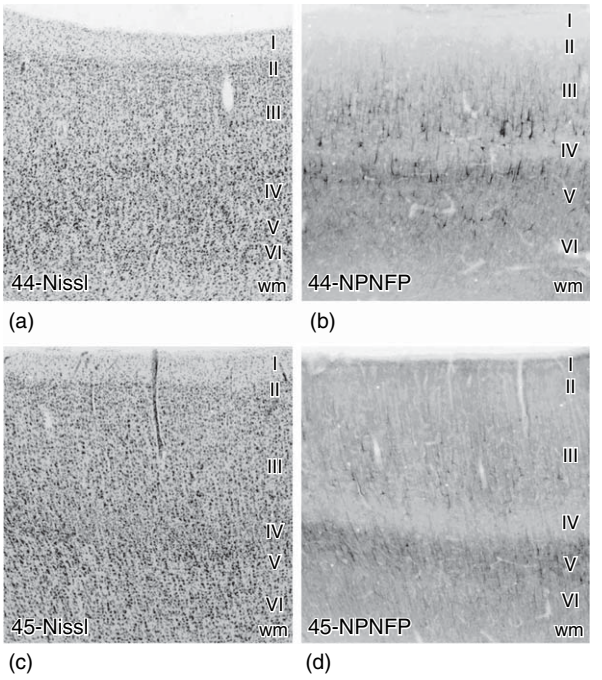

Figure 9 The architecture of areas 44 and 45 in a chimpanzee (*Pan troglodytes*). Area 44 is shown stained for Nissl substance (a) and NPNFP (b). Area 45 is shown stained for Nissl substance (c) and NPNFP (d). Scale bar: 500 μm.

Considering the preponderance of left hemisphere dominant control of language in humans, several studies have examined the cortex of the inferior frontal gyrus in humans for microstructural asymmetries. Using GLI profile analysis methods to quantify regional variation in cytoarchitecture, area 44 has been shown to display left dominance in terms of volume and an increased proportion of neuropil space, whereas area 45 does not show a consistent direction of asymmetry (Amunts *et al.*, 1999). In addition, the total length of pyramidal cell dendrites is longer in the left opercular region of the inferior frontal gyrus due to a selective increase in the length of higher-order segments (Scheibel *et al.*, 1985). Using different methods, another study examined asymmetries in only magnopyramidal cells in layer III of area 45 and found total dendritic length, dendritic complexity (numbers of branches and maximal branch order), and spine densities to be greater in the right (Hayes and Lewis, 1996). In area 45, AChE-positive layer III magnopyramidal cells have larger somata in the left hemisphere, despite lacking asymmetry in their density (Hayes and Lewis, 1995; Garcia *et al.*, 2004).

While asymmetries of the inferior frontal cortex are well established in humans, the condition of nonhuman primates is less clear. Although population-level

leftward asymmetry of the fronto-orbital sulcus, a portion of the inferior frontal gyrus, has been reported in great apes (Cantalupo and Hopkins, 2001), it remains to be known whether humanlike microstructural asymmetries are present in the inferior frontal cortex of these species. In humans and chimpanzees, the borders of areas 44 and 45 have been shown to correspond poorly with external sulcal landmarks (Amunts *et al.*, 1999; Sherwood *et al.*, 2003a). Thus, determination of whether asymmetries are evident in regional volumes and intrinsic circuitry of areas 44 and 45 of great apes will require histological studies.

4.21.2.7 Prefrontal Cortex

While it has been a popular notion that human cognitive abilities are associated with disproportionate enlargement of the frontal or prefrontal cortex, recent data show that the human frontal cortex is no larger than expected for a hominoid of the same brain size (Semendeferi *et al.*, 1997, 2002). Furthermore, progressive increase in the relative size of the frontal cortex accompanies enlarging brain size for primates in general, with hominoids simply continuing this scaling trend (Bush and Allman, 2004a; see Scaling the Brain and Its Connections, Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals, Do All Mammals Have a Prefrontal Cortex?). At present, the comparative quantitative data available concerning the volume of specific prefrontal cortical areas in hominoids are scanty, representing only areas 10 and 13 in one individual per species (Semendeferi *et al.*, 1998, 2001). Taken together, however, it does not seem that these prefrontal areas are disproportionately enlarged in humans beyond what is expected for a hominoid of the same brain size (Holloway, 2002). Nonetheless, quantitative cytoarchitectural analyses have shown that some prefrontal cortical areas differ in their histological organization among hominoid species.

Area 13 is a dysgranular field located in the posterior orbitofrontal cortex (Figure 10). This cortical area is remarkably integrative, receiving inputs from olfactory, gustatory, and visceral centers, as well as premotor, somatosensory, auditory, visual, and parahippocampal cortices (Carmichael and Price, 1995; Cavada *et al.*, 2000). Damage to this region disrupts performance on tasks that require behavioral inhibition and causes impairments in emotional control (Fuster, 1998; Roberts and Wallis, 2000). In a study of the cytoarchitecture of area 13 across macaques and hominoids, several similarities were observed that suggest homology among these species (Semendeferi *et al.*, 1998). This cortical area is distinguished by a poorly defined layer IV, horizontal striations of cells in layers V and VI, large pyramidal cells in layer V, relatively thick infragranular layers as compared with supragranular layers, and greater neuropil space in supragranular layers as compared with deeper layers. Among hominoids, area 13 is located in the posterior portion of the medial orbital and posterior orbital gyri. This concords with the earlier description of an area labeled FF in the posterior orbitofrontal cortex of chimpanzees that seems to correspond to these cytoarchitectural features (Bailey *et al.*, 1950).

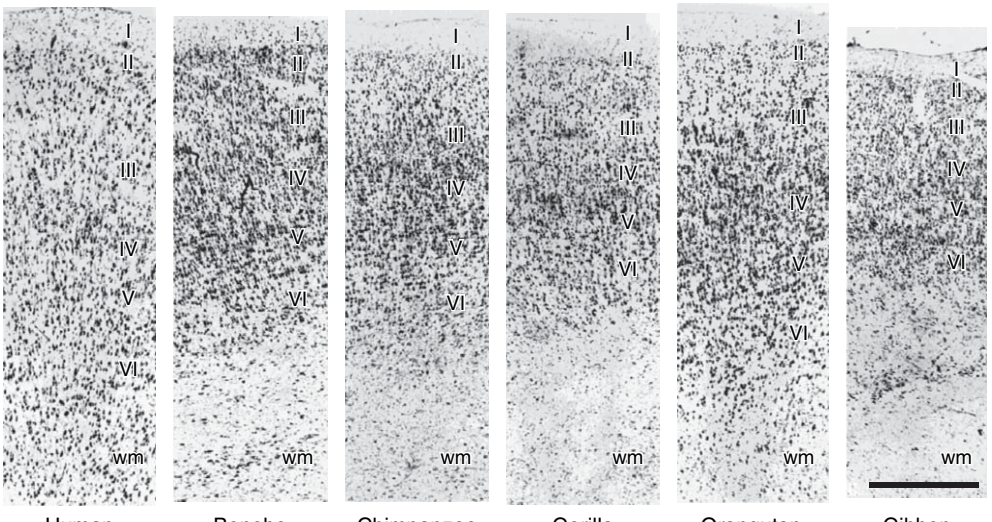

Figure 10 The cytoarchitecture of area 13 in hominoids. Scale bar: 500 μm. Modified from Limbic frontal cortex in hominoids: A comparative study of area 13, *Am. J. Phys. While general similarities are found in the cytoarchitecture of area 13 of hominoids, quantitative analyses have identified some interspecific differences. For example, layer IV in orangutans is relatively wide, making this cortex appear more similar to granular prefrontal cortex. Compared to other hominoids, area 13 in humans and bonobos occupies a small proportion of total brain volume and more cytoarchitectonic subdivisions occupy the orbitofrontal cortex adjacent to area 13. In contrast, area 13 of orangutans is relatively large and thus occupies the majority of the orbitofrontal region.

Area 10 is a granular cortex that forms a part of the frontal pole in most hominoid species, including humans, chimpanzees, bonobos, orangutans, and gibbons (Figure 11) (Semendeferi *et al.*, 2001). This cortical area is involved in planning and decision making (Fuster, 1998). Area 10 receives highly processed sensory afferents from corticocortical connections in addition to inputs from the mediodorsal nucleus of the thalamus, striatum, and many limbic structures (Öngür and Price, 2000). In hominoids, the cytoarchitecture of area 10 is characterized by a distinct layer II, a wide layer III with large pyramidal cells in its deep portion, a clearly differentiated granular layer IV, large pyramidal cells in layer Va, and a sharp boundary between layer VI and the white matter. Quantitative analyses reveal a similar pattern of relative laminar widths among humans, chimpanzees, and bonobos, such that the supragranular layers are relatively thick compared to the infragranular layers (Semendeferi *et al.*, 2001). In contrast, the infragranular layers comprise a greater proportion of cortical thickness in the other hominoids. When GLI profile curves describing laminar variation in neuron volume densities are compared among taxa, apes and macaques follow a similar pattern with roughly equal GLI throughout the cortical depth. The proportion of neuropil space in layers II and III relative to infragranular layers, however, is greater in humans. Notably, Semendeferi *et al.* (2001) raise uncertainty regarding whether a homologue of area 10 is present in gorillas. In particular, the cortex of the frontal pole in gorillas has a prominent layer II and Va, features that are not found in macaques or other hominoids.

4.21.2.8 Anterior Cingulate Cortex

In layer Vb of anterior cingulate cortex (subareas 24a, 24b, and 24c), large spindle-shaped cells are found only in great apes and humans, to the exclusion of hylobatids and other primates (Nimchinsky *et al.*, 1999). These neurons have a very elongate, gradually tapering, large soma that is symmetrical about its vertical and horizontal axes (Figure 12). This distinctive somatic morphology arises from the presence of a large apical dendrite that extends toward the pial surface, as well as a single large basal dendrite that extends toward the underlying white matter, without any other dendrites branching from the basal aspect of the cell. These unique neurons are also substantially larger in size than other neighboring pyramidal cells. Interestingly, spindle neurons increase in soma size, density, and clustering from orangutans to gorillas, chimpanzees, bonobos, and humans. Furthermore, spindle-shaped neurons have been observed in layer Vb of area 24b in a fetal chimpanzee (E 224), indicating that this specialized projection cell type differentiates early in

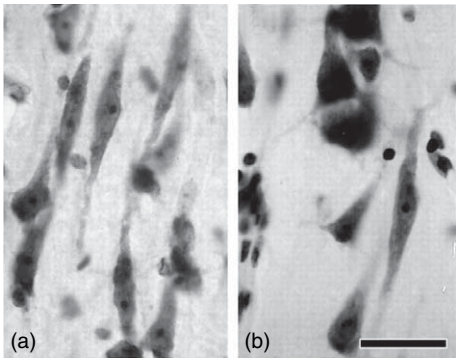

Figure 12 Morphology of spindle-shaped neurons in layer Vb of anterior cingulate cortex in a bonobo (*Pan paniscus*) (a) and gorilla (*Gorilla gorilla*) (b). Scale bar: 80 μm. Modified from Nimchinsky, E. A., Gilissen, E., Allman, J. M., Perl, D. P., Erwin, J. M., and Hof, P. R. 1999. A neuronal morphologic type unique to humans and great apes. *Proc. Natl. Acad. Sci. USA* 96, 5268–5273.

development (Hayashi *et al.*, 2001). Notably, neurons with a spindle phenotype also have a phylogenetically restricted distribution within another region, the frontoinsular cortex. Spindle cells are found in layer V in the frontoinsular cortex only in humans and African great apes (i.e., gorillas, chimpanzees, and bonobos), being far more numerous in humans compared to the apes (see Role of Spindle Cells in the Social Cognition of Apes and Humans; Hakeem *et al.*, 2004).

In addition to spindle-shaped neurons, the anterior cingulate cortex of great apes and humans contains another unique pyramidal cell phenotype. A survey of the anterior cingulate cortex of several primate species revealed a small subpopulation of CR-containing layer V pyramidal neurons that are only found in great apes and humans (Hof *et al.*, 2001). These neurons are located in the superficial part of layer V in areas 24 and 25. In orangutans, they comprise 0.5% of all layer V pyramidal cells in the anterior cingulate, 2% in gorillas, 4.1% in chimpanzees, and 5.3% in humans. The occurrence of these cells decreases sharply at the boundary between anterior and posterior cingulate cortex, suggesting that they are not directly involved in the somatic motor functions associated with the posterior cingulate motor areas.

The restricted phylogenetic distribution of spindle-shaped cells and CR-ir pyramidal neurons in layer V of anterior cingulate cortex may reflect specializations of projection neurons in this region for a role in the control of vocalization, facial expression, attention, the expression and interpretation of emotions, and autonomic functions (Nimchinsky *et al.*, 1999; Allman *et al.*, 2001; Hof *et al.*, 2001). Of particular interest, in humans, CR-immunoreactive layer V pyramidal neurons are also present in the anterior paracingulate cortex (area 32) (Hof *et al.*, 2001). The presence of this distinctive projection cell type in area 32 of humans is intriguing, considering that this cortical area has been found to be recruited in tasks that require theory of mind (Gallagher *et al.*, 2000), which is the capacity to attribute mental states such as attention, intention, and beliefs to others and may be a cognitive capacity that is exclusive to humans (Tomasello *et al.*, 2003).

4.21.3 Patterns of Cortical Organization in Hominoids

4.21.3.1 The Emergence of Cell Types and Their Distribution

Particular cellular subtypes appear to have phylogenetically restricted distributions. It is interesting that among hominoids, the presence of these unique neuron phenotypes accords with the hierarchical nested structure of monophyletic taxa, suggesting that they are indicators of phylogenetic relationships (Table 2). For example, in all great apes and humans, spindle-shaped neurons are found in layer V of anterior cingulate cortex. Also in these taxa, CR-ir pyramidal cells are found in layer V of anterior cingulate cortex and primary motor cortex. In just African great apes and humans, layer V spindle-shaped neurons are found in frontoinsular cortex. And only in humans, CR-ir pyramidal neurons in layer V are found in anterior paracingulate cortex. Thus, novel neuron phenotypes have appeared at several different times in hominoid evolution.

It is tempting to speculate that the evolution of each unique neuron type marks specializations of the cortical areas involved. In particular, the morphomolecular characteristics of these novel neuron types suggest that there have been modifications of specific efferent projections to facilitate high levels of activity or higher conduction velocity for outputs. The possibility that the great ape and human clade is distinguished by such specializations of projection cells is especially intriguing in light of recent hypotheses that intelligence among mammals is correlated with the rate of information processing capacity as represented by axonal conduction speed (Roth and Dicke, 2005). The presence of unique neuron classes in great apes and humans extends this hypothesis to suggest that specific cortical efferents located within behaviorally relevant circuits may be selectively modified. It is also significant that a common feature of these novel projection cells is their localization in layer V. This laminar distribution indicates that evolutionary modifications have

been focused upon descending cortical control over targets in the brainstem and spinal cord.

4.21.3.2 The Evolution of Cortical Asymmetries

A substantial body of evidence shows that the human cerebral cortex expresses lateralization in the control of language and fine motor actions of the hand (Toga and Thompson, 2003). Asymmetries in histological structure have been demonstrated across cortical areas implicated in these processes in humans, including Broca's area (areas 44 and 45), Wernicke's area (area Tpt), and the hand representation of primary motor cortex (area 4). Some authors have hypothesized that these anatomical asymmetries are exclusive adaptations of the human brain that are encoded genetically and comprise the chief evolutionary novelty in the speciation of modern humans (Crow, 2000; Annett, 2002).

An alternative view is that functional and anatomical lateralization may be a byproduct of increases in overall brain size (Ringo *et al.*, 1994; Hopkins and Rilling, 2000). One cost of increasing brain size is that axons must propagate action potentials over a greater distance to communicate between the hemispheres (Harrison *et al.*, 2002). While these delays in conduction can be overcome to some extent by increasing axon cross-sectional area and myelination (Changizi, 2001), the design problems associated with large brains ultimately

may necessitate increased modularity of processing and more of an emphasis on local network connectivity (Kaas, 2000). In particular, as brains grow in size, the efficiency of interhemispheric transfer of information by long connections diminishes because costs, in terms of wiring space, dictate that axons cannot increase cross-sectional area sufficiently to keep pace with demands for processing speed (Aboitiz and Montiel, 2003). Hence, it is expected that cortical processes in large brains, especially those that depend on rapid computations, will come to rely on specialized processing that is dominant in one hemisphere. Indeed, it has been shown that increasing brain size is accompanied by reduced hemispheric interconnectivity via the corpus callosum (Ringo *et al.*, 1994; Olivares *et al.*, 2001) and the development of more pronounced gross cerebral asymmetries among anthropoid primates (Hopkins and Rilling, 2000).

One consequence of lateralized hemispheric specialization of function may be divergence in the histological organization of homotopic cortical areas. Unfortunately, there is a surprising absence of data from nonhumans concerning microstructural asymmetries in the homologues of Broca's area, Wernicke's area, and primary motor cortex. At present, the sole study of such histological asymmetry indicates that lateralization is not present in area Tpt of chimpanzees or macaques, while asymmetry of neuropil space and minicolumn widths are observed in humans (Buxhoeveden *et al.*, 2001a). Although this is an important finding, it should be kept in mind that there are many other aspects of microstructural organization that have been demonstrated to be asymmetric in the human cortex, such as distributions of cell volumes and dendritic geometry, which have yet to be investigated in other species. Thus, at the present time, there are still insufficient data to adequately resolve whether many of the observed microstructural asymmetries of the human cerebral cortex are unique species-specific adaptations that are related to language and handedness.

4.21.3.3 How Much Variation in Cortical Architecture Can be Attributed to Scaling versus Specialization?

Interpretation of interspecific differences in the histological structure of the cortex in hominoids requires parsing the source of this variation. Certainly a portion of it can be attributed to specific alterations of circuitry that generate behavioral differences among species. Another cause, however, may be the effects of allometric scaling. That is, as overall brain size changes, predictable changes occur in cell sizes, cell packing density, dendritic geometries, and other aspects of microstructure (Jerison, 1973; Striedter, 2005). Thus, with variation in brain size among hominoids, some of the observed interspecific differences may simply be the result of scaling to maintain functional equivalence and may not indicate any significant differences in computational capacities. For example, how can we know whether greater densities of AChE-stained neurons in the auditory belt of hominoids (Hackett *et al.*, 2001) is of functional importance until we have developed a clearer understanding of the scaling principles that govern the distribution of AChE-enriched neurons in general? Hence, whenever possible it is best to evaluate phylogenetic variation in cortical histology from the perspective of allometric scaling. Accordingly, the case for declaring that a trait is a phylogenetic specialization is strengthened when it can be demonstrated that individual species depart from allometric expectations or that an entire clade scales along a different trajectory (i.e., grade shift).

It is well established that cortical neuron density varies among mammalian species. Across a large sample of mammals ranging from mouse to elephant, there is a negative correlation between cortical neuron density and brain size that follows a $-1/3$ power law (Tower, 1954; Cragg, 1967; Haug, 1987; Prothero, 1997). Despite this broad trend, however, some evidence suggests that neuron densities may be higher in hominoids (gorilla, chimpanzee, and human) than expected for their brain size (Haug, 1987). It has also been shown that the fraction of the cortex that is comprised by neuropil space versus cell somata increases in a negative allometric fashion with greater brain size (Shariff, 1953; Tower, 1954; Bok, 1959; Tower and Young, 1973; Zilles *et al.*, 1982; Armstrong *et al.*, 1986; Haug, 1987). These empirical findings fit with a model predicting that a constant average percent interconnectedness among neurons cannot feasibly be maintained in the face of increasing gray matter volume, so the reach of processing networks cannot keep pace with brain size variation (Changizi, 2001).

Many of these theories concerning the scaling of network connectedness across brain size, however, were developed to explain variation in mouse-to-elephant comparisons. Are these predicted allometric relationships between neuron density, neuropil space, and brain size maintained when comparisons are restricted to the hominoids? Table 3 shows the results of stereologic estimates of neuron density and GLI from recent comparative studies of areas 4, 10, and 13 in hominoids.

Table 3 Neuron densities (in neurons per mm^3) and gray level index (GLI) values for different cortical areas in hominoids and Old World monkeys

	Area 4[a]		Area 10[b]		Area 13[c]

[b]Semendeferi *et al.* (2001).
[c]Semendeferi *et al.* (1998).
In all studies, neuron densities were estimated by the optical disector method.

In most of these cortical areas, there is not a significant correlation between neuron densities or GLI and brain size. The one exception is prefrontal area 10 neuron density, which scales against brain weight with a reduced major axis slope of −0.42 based on log-transformed data ($p = 0.03$, $n = 6$). Therefore, the mammal-wide relationship between these parameters and brain size may not explain interspecific variance in interconnectedness within all cortical areas of hominoids. This raises the interesting possibility that differences among hominoid species in these variables might instead correspond to functionally significant modifications in the organization of cortical interconnections.

Other aspects of network scaling in the cerebral cortex are less well understood. For example, there does not appear to be a correlation between brain size and the density of glial cells (Tower and Young, 1973; Haug, 1987). However, phylogenetic differences in glial cell densities have not yet been systematically examined using modern immunohistochemical markers to identify astrocytes and oligodendrocytes separately. Furthermore, questions regarding the scaling of subpopulations of interneurons and pyramidal cells have only begun to be addressed. Evidence suggests that the proportion of pyramidal neurons that are enriched in NPNFP may increase with brain size. In the orofacial representation of primary motor cortex, there is a striking increase in the percentage of neurons stained for NPNFP in larger-brained great apes and humans in comparison to smaller-brained Old World monkeys (Sherwood *et al.*, 2004a). Tsang *et al.* (2000) also found increasing NPNFP labeling in primary motor cortex across a sample including rats, marmosets, rhesus macaques, and humans. In addition, Campbell and Morrison (1989) found a larger proportion of NPNFP-ir pyramidal neurons, particularly in supragranular layers, in humans compared to macaque monkeys across several different cortical areas.

Interneuron subtypes, as revealed by labeling for calcium-binding proteins, appear to adhere to different scaling trends in anthropoid primates depending on the cortical area. For example, when regressed on total neuron density, the density of PV-ir neurons scales with negative allometry in the primary motor cortex and thus a greater proportion of PV-ir neurons is observed in hominoids compared to Old World monkeys (Sherwood *et al.*, 2004a). In contrast, CB-ir neurons scale against total neuron density with positive allometry in areas V1 and V2, resulting in a smaller percentage of CB-ir interneurons in apes compared to monkeys in these areas (Sherwood *et al.*, 2005). Further studies using allometric approaches to examine the scaling of different neuron subtypes will be necessary to elucidate phylogenetic specializations of cortical circuitry.

4.21.3.4 Genomic Data Provide Insights into Cortical Specializations

Recent studies of phylogenetic variation in gene sequences and expression provide additional insights into cortical specializations among hominoids. While most of these studies have been directed at determining the genetic basis for human neural uniqueness (Enard *et al.*, 2002a, 2002b; Caceres *et al.*, 2003; Dorus *et al.*, 2004; Uddin *et al.*, 2004), some molecular data point to changes that occurred at earlier times in the hominoid

radiation. For instance, all hominoids have evolved a novel biochemical mechanism to support high levels of glutamate flux in neurotransmission through the retroposition of the gene *GLUD1* (Burki and Kaessmann, 2004). This duplicated gene, *GLUD2*, which is unique to hominoids, encodes an isotype of the enzyme glutamate dehydrogenase that is expressed in astrocytes. All hominoid *GLUD2* sequences contain two key amino acid substitutions that allow the GLUD2 enzyme to be activated in astrocytes during conditions of high glutamatergic neurotransmitter flux. Concordant with this evidence for alterations in the molecular machinery necessary for enhanced neuronal activity in apes, it has been shown that the gene encoding the cytochrome *c* oxidase subunit 4-1 underwent rapid nonsynonymous evolution in the hominoid stem, followed by purifying selection in descendent lineages (Wildman *et al.*, 2002). Because these nucleotide substitutions have functional consequences for the manner and rate at which electrons are transferred from cytochrome *c* to oxygen, it is likely that these modifications were selected to serve the needs of cells with high aerobic energy demands, such as neurons.

Also of significance, an alternative splice variant of neuropsin (type II) has originated in recent hominoid evolution (Li *et al.*, 2004). Neuropsin is expressed in hippocampal pyramidal neurons and is involved in neuronal plasticity. The high incidence of polymorphisms in the coding region of this protein in gibbons and orangutans, however, suggests that it may not be functional in these species. In contrast, the coding region of the type II splice form of neuropsin shows relatively little variation in gorillas, chimpanzees, and humans, signifying that it is maintained by functional constraint and that it might be involved in a molecular pathway important for learning and memory in these hominoids.

With respect to brain size, several genes that are involved in controlling the development of cerebral cortex size have undergone accelerated rates of sequence evolution in the hominoid lineage. The *microcephalin* gene shows an upsurge of nonsynonymous amino acid substitutions in a protein-coding domain of the last common ancestor of great apes and humans (Wang and Su, 2004). Additionally, the *ASPM* gene shows evidence of adaptive sequence evolution in all African hominoids (i.e., gorillas, chimpanzees, bonobos, and humans) (Kouprina *et al.*, 2004).

These data put into phylogenetic context evidence that, in the lineage leading to humans, several genes important in the development, physiology, and function of the cerebral cortex show positive selection (Enard *et al.*, 2002b; Dorus *et al.*, 2004; Evans *et al.*, 2004). Furthermore, findings from studies that have compared human and chimpanzee transcriptomes indicate that the human cerebral cortex is distinguished by elevated expression levels of many genes associated with energy metabolism (Caceres *et al.*, 2003; Uddin *et al.*, 2004), suggesting that levels of neuronal activity might be higher in humans compared to chimpanzees (Preuss *et al.*, 2004). While the phenotypic correlates of many of these genetic changes await characterization by *in situ* hybridization and immunohistochemical studies, it is clear that intensified efforts at analyzing variation in the histological organization of the hominoid cerebral cortex will be necessary if there is any hope of understanding how such molecular differences translate into modifications of the computational capacities of cortical circuits.

4.21.3.5 On the Horizon

There remains an extraordinary amount to learn regarding the microstructure of the cerebral cortex of hominoids. Even the basic cytoarchitecture of many cortical areas, such as the posterior parietal cortex, inferior temporal cortex, posterior cingulate cortex, and premotor cortex, has not yet been explored using the methods of modern quantitative neuroanatomy. Moreover, there is not a single recent study of parcellation for any part of the cerebral cortex using chemoarchitectural staining techniques in apes. It will also be important to examine the scaling patterns that govern the distribution of neurochemically identified subsets of pyramidal neurons, interneurons, and glia across different cortical areas from a broad phylogenetic perspective in order to clearly distinguish network allometric scaling from phylogenetic specialization. Finally, determination of whether humanlike histological asymmetries of cortical areas important in language and control of the hand are present in other apes still requires systematic study. By taking seriously the task of understanding such species-specific neural adaptations, we stand to learn an extraordinary amount about the underlying substrates of the cognitive abilities of humans and our closest relatives.

4.22 The Evolution of Hemispheric Specializations of the Human Brain

M C Corballis, University of Auckland, Auckland, New Zealand

Glossary

allele One of several possible forms of a gene.

antisymmetry Form of bilateral asymmetry in which there are equal numbers of sinistral and dextral forms (e.g., equal numbers of left- and right-handers) in the population.

bilateral asymmetry Condition in which one side of the body is not the mirror image of the other.

bilateral symmetry Condition in which one side of the body is the mirror image of the other.

Bilateria The phylum of ancient origin that includes all organisms (including humans) whose body plan is for the most part bilaterally symmetrical.

bipedalism Standing or walking on two legs rather than four.

Broca's area Region in the left frontal convolution of the brain, usually on the left side, that plays a major role in the organization of speech.

cerebral asymmetry Systematic difference in structure or function between the two sides of the brain.

commissurotomy Section of the commissures connecting the two cerebral hemispheres of the brain, sometimes known as splitting the brain.

directional asymmetry Form of bilateral asymmetry in which the majority of the population exhibit the same direction of asymmetry (e.g., right-handedness in humans).

functional magnetic resonance imaging (fMRI) Technique for measuring blood flow in the intact brain, indicating which parts of the brain are active.

handedness Systematic difference between the two hands, usually favoring the right hand in humans. Can be defined either in terms of preference for one hand over the other or in terms of greater skill or strength on one hand relative to the other.

hemispheric dominance Dominance of one side of the brain over the other.

hemispheric specialization Function performed exclusively or preferentially by one side of the brain rather than the other.

heterozygosity Condition in which an individual carries different alleles on a gene.

homozygosity	Condition in which an individual carries identical alleles at one or more loci in chromosome segments.
human revolution	Emergence of so-called modern behavior in humans, including cave art, more sophisticated tools, and bodily ornamentation, and thought to date from around 40 000 years ago.
right shift	Theory that, in humans, the distribution of differences in function between the two hands is shifted to the right, explaining why most people are right-handed. The right shift is thought to be due to a genetic effect.
temporal planum	Region in the posterior temporal lobe of the brain. This region on the left is part of Wernicke's area, and plays a major role in the comprehension of language.

4.22.1 Introduction

The most obvious mark of hemispheric specialization in the human brain is the near-universal preference for the right hand, implying a left-hemispheric dominance for manual action. This remarkable asymmetry has long been a source of fascination. It seems to apply to all human cultures and has served as a potent source of symbolism (Hertz, 1960). Because the right hand is generally the more skilled, the right is associated with positive values and the left with negative ones, as is evident in the contrast between terms such as 'dexterous', 'adroit', and even 'right' itself, with terms such as 'gauche' and 'sinister'. We speak of a 'right-hand man', but a 'left-handed compliment'. The Bible is said to contain over 100 favorable references to the right hand, and 25 unfavorable references to the left (Barsley, 1970). The negative values associated with the left are often manifest as discrimination against left-handers, even though left-handers often triumph in sports such as tennis or baseball, or even in intellectual ability. The quintessential Renaissance Man, Leonard da Vinci, was a left-hander.

The left cerebral dominance for speech and language, since it was first discovered in the nineteenth century, has been an equally potent source of myth, as is evident in the frequent references in popular culture to left-brain and right-brain values. In this case, though, the differences are not seen as quite so value laden, and if anything there may be more positive associations with the right hemisphere than with the left, even though it is the left hemisphere that controls the characteristically human functions of language and manual manipulation. The right is often portrayed as more creative, artistic, emotionally sensitive, and holistic than the more linear, rule-bound left (Corballis, 1980).

The potency of left and right may be due in part to the fact that both handedness and cerebral asymmetries are functional asymmetries that appear to emerge from symmetrical structures. Our hands look alike, yet function very differently. Similarly, the two sides of the brain are anatomically more or less left–right mirror images, yet one side can produce articulate speech and the other cannot. This discrepancy between function and structure seems to imply some nonmaterial, Cartesian influence, perhaps reinforcing our sense that we humans are unique and superior to other animals, closer to angels than to apes. We are, it has been argued, the lopsided ape (Corballis, 1991). Genetic theories of handedness and cerebral asymmetry are typically based on the premise that a genetic mutation at some point in the hominid lineage gave rise to both handedness and cerebral asymmetry in the majority of humans (e.g., Annett, 1995, 2002; Corballis, 1997; McManus, 1999). It has even been proposed that cerebral asymmetry is the result of a genetic mutation that not only resulted in cerebral asymmetry, but also gave birth to language, theory of mind, a vulnerability to psychosis, and the speciation of *Homo sapiens* (Crow, 2002).

In this article, I propose to challenge this view by summarizing the evidence on cerebral asymmetries in other species and showing that human cerebral asymmetry may in fact have ancient origins. It is almost certainly true that language itself is a uniquely human accomplishment, but its lateralized representation probably derives from asymmetries that go well back in evolution (see Cortical Commissural Connections in Primates). A second aim of this article is to show that bilateral symmetry is as much a property of organisms, including humans, as is lateralization of function. The obsession with handedness and hemispheric specialization has tended to obscure the more obvious fact that our brains and bodies are built on a plan that duplicates the left and right sides in mirror fashion. The main theme of this article, then, is that there is a trade-off between bilateral symmetry and lateral specialization, and this trade-off informs differences both between and within species.

4.22.2 Bilateral Symmetry

We belong to the phylum known as the Bilateria, an ancient lineage that includes over 1.5 million

present-day animal species, including such diverse creatures as soil nematodes, fruit flies, and mammals. The emergence of this lineage is said to mark the transition from stationary or drifting planktonic animals to active swimmers and burrowers. bilaterian fossils have been dated to some 600 Mya, well before the Cambrian (Chen *et al.*, 2004). Bilateral symmetry may even precede the Bilateria, since it is also present in some species of the phylum Cnidaria, which is outside the Bilateria. In the sea anemone *Nematostella vectensis*, for example, bilateral symmetry is dependent on the expression of homologous *Hox* genes much as it is in the Bilateria, suggesting that bilateral symmetry arose even before the evolutionary split between the Cnidaria and Bilateria (Finnerty *et al.*, 2004).

Bilateral symmetry probably evolved in the first instance as an adaptation to directional movement, which effectively defines an anterior–posterior axis in addition to the dorsal–ventral one. These two axes are asymmetrical: the tops of organisms differ from their bottoms, and their fronts differ from their backs. The third axis, orthogonal to these two, is the left–right axis, and organs of movement are then arranged symmetrically to either side of this axis. It seems reasonable to suppose, then, that bilateral symmetry was selected to ensure linear movement, the most efficient way to travel between two points. With very few exceptions, legs, wings, swimming muscles (in fish), and flippers are bilaterally symmetrical. *Nematostella* is a directional swimmer, and the common ancestor we share with this interesting creature presumably lay close in time to the emergence of bilateral symmetry, perhaps as much as 900 Mya (Finnerty *et al.*, 2003).

Given linear movement, there is pressure to ensure bilateral symmetry of the sense organs. To a freely moving organism, it is as well to have the eyes, ears, and skin senses equally placed on either side, since any asymmetry could leave the organism exposed to attack or impervious to prey on the less receptive flank. It follows from the bilateral symmetry of both motor and sensory organs that the neural machinery for both action and perception is also likely to be symmetrical. For most animals, behavior is dominated by sensorimotor activity, involving reactions to an environment that is without overall left–right bias. Symmetry is much less apparent in parts of the body not involved in perception, locomotion, or sensorimotor behavior. The internal organs, including the heart, lungs, stomach, and liver, are arranged asymmetrically, presumably in the interests of more efficient packaging. Even the molecules of living tissue are asymmetrical, a property often taken to be a fundamental property of living matter (e.g., Monod, 1969). In a review of the evolution of bilateral asymmetry, Palmer (2004, p. 828) remarks that "bilateral symmetry is a default state once the anteroposterior and dorsoventral axes are defined." An extra step is therefore required to create bilateral asymmetry. Even the brain, with its origins in the control of sensorimotor activity, remains for the most part built on a bilaterally symmetrical plan.

Besides being largely symmetrical, the brain is also 'double'. In the treatment of intractable epilepsy in humans, surgeons have sometimes resorted to commissurotomy, in which the brain is split through the midsagittal plane, disconnecting the left and right halves. Roger W. Sperry, who pioneered the psychological investigation of the split brain in both humans and animals, wrote that split-brained patients behave as if they had "two separate conscious entities or minds running in parallel in the same cranium, each with its own sensations, perceptions, cognitive processes, learning experiences, memories and so on" (Sperry, 1966–1967, p. 318). Studies have also shown that people can function remarkably well following the removal of an entire cerebral cortex (e.g., Vargha-Khadem *et al.*, 1997; Hertz-Pannier *et al.*, 2002). Although differences between the two halves of the brain have been well documented, and are discussed further below, it is clear that there is considerable overlap.

4.22.2.1 The Trade-Off between Symmetry and Specialization

With respect to basic sensory and motor functions, then, there are clear benefits to bilateral symmetry, given that we live in a world that is for the most part without systematic left–right biases. We humans have nevertheless created left–right asymmetries in the manufactured world, such as the direction of script, traffic conventions, and so forth, and some of these work to the disadvantage of left handers: scissors, golf clubs, corkscrews, the placement of door handles, the sequence of pages in books and magazines. As a general rule, the advantages of symmetry apply more strongly to behaviors that are reactions to the environment than to behaviors that are operations on the environment. There may be advantages to having one hand or its controlling cerebral hemisphere specialized for intricate activities involving tools, as in writing, for example. One advantage of unilateral control is that it is not constrained by the relatively slow conduction time between hemispheres, so that computations can be carried out with greater speed (Ringo *et al.*, 1994), although an alternative solution, of course, would

have been to evolve faster interhemispheric transfer! Another advantage of hemispheric specialization is that it avoids duplication, and this may be especially important in complex functions, like language, that require large amounts of neural circuitry. Duplication may therefore be too wasteful of neural space, and also lead to interhemispheric conflict (Corballis, 1991).

Humans are cognitive specialists, with large brains even by primate standards (Passingham, 1982), and this may well have favored specialization to a greater extent than in other species. That is, the evolution of cognition and the relative independence from stimulus control may well have favored hemispheric specialization at the expense of bilateral symmetry. But it is becoming increasingly clear that cerebral and behavioral asymmetries are widespread in nature, and that at least some of the asymmetries observed in other species seem to operate according to principles similar to those documented in humans. Consequently, any sense that humans are special may derive not from cerebral asymmetry *per se*, but from the nature of the functions that are lateralized.

4.22.3 Hemispheric Specialization in Nonhuman Species

In this section, I review some of the evidence for directional asymmetries in animals, with an emphasis on those that that may provide insight into the nature and origins of our own lopsidedness. First, though, we need to distinguish two different kinds of asymmetry (see Palmer, 2004). One is antisymmetry, in which there are equal numbers of sinistral and dextral forms, as in the claws of male fiddler crabs, which are sometimes larger on the left and sometimes larger on the right. The other is directional asymmetry, in which most of the members of a species are asymmetrical in the same direction, as in the case of the vertebrate heart. In the case of antisymmetry, the direction of asymmetry is almost never inherited, while in the case of directional asymmetry, it typically is. This article is concerned primarily with directional asymmetry, which might arise directly, through some genetic mutation, from symmetry, or it might arise through genetic assimilation from antisymmetry.

4.22.3.1 Handedness

In humans, at least, the most obvious manifestation of cerebral asymmetry is handedness, since the majority of us are right-handed. It seems likely that handedness is one example of a directional asymmetry that arose through genetic assimilation of one form of asymmetry from a character that was previously antisymmetric. Mice are equally divided into left- and right-handers, and selection for left-handedness fails to influence the relative proportions in succeeding generations (Collins, 1969). There does appear to be a genetic component underlying the direction of the handedness component in chimpanzees, however, where the evidence suggests a 65:35 split in favor of right-handedness (Hopkins *et al.*, 2001). In humans, the split is about 90:10 in favor of right-handedness, and there is strong evidence for a genetic component to human handedness (McManus, 1999; Annett, 2002). This progression suggests canalization and genetic assimilation, and may apply more generally to cerebral asymmetry.

Aside from the evidence for weak right-handedness in chimpanzees, and perhaps in other great apes (Hopkins *et al.*, 2001), there is relatively little evidence for comparable asymmetries in other species. One reason for this is that the limbs are generally involved in locomotion, which, as noted earlier, creates a pressure toward bilateral symmetry. The hominids are characterized by bipedalism, which freed the hands from locomotion, allowing for manual specialization to emerge, or at least to become apparent in everyday activities. Nevertheless, there are other isolated examples of consistent handedness in nonhuman species.

Oddly enough, the clearest case of limb asymmetry comes not from primates, but from parrots. Most species of parrot show a strong preference for the left foot in picking up objects, and the proportion of left footers is close to 90%, comparable to the proportion of right-handed humans (Rogers, 1980). Second place may go to the walrus, since there is evidence that 77% of walruses display a preference for the right flipper when feeding, and there is evidence that several bones (scapula, humerus, and ulna) are longer in the right than in the left flipper (Levermann *et al.*, 2003). There have been claims that monkeys show a slight population-level preference for the left hand (MacNeilage *et al.*, 1987). Subsequent evidence has been mixed (see commentaries to the article by MacNeilage *et al.*, 1987), but if true the asymmetry may reflect a right-hemispheric bias for spatial perception. At least one study has shown a slight right-hand advantage for rhesus monkeys, but no bias in capuchins (Westergaard and Suomi, 1996).

McGrew and Marchant (1997) sound a cautionary note. In a comprehensive review, they conclude that among nonhuman primates, "only chimpanzees show signs of a population bias ... to the

right, but only in captivity and only incompletely" (McGrew and Marchant, 1997, p. 201); see also McGrew and Marchant (2001). The evidence for a population-level right-hand preference in chimpanzees comes from Hopkins and his colleagues, but appears to be restricted to certain activities, such as extracting peanut butter from a glass tube (Hopkins, 1996), gestural communication (Hopkins and Leavens, 1998), and throwing (Hopkins *et al.*, 2005), and the ratio of right-to-left-handers is only about 2:1, whereas in humans the ratio is about 8:1. McGrew and Marchant (2001) suggest that the bias in captive chimpanzees is a consequence of contact with right-handed humans, although Hopkins *et al.* (2004) have disputed this, claiming that right-handedness occurs in three distinct populations of captive chimpanzees and is unrelated to the proportion of animals raised by humans, and more recently Lonsdorf and Hopkins (2005) have documented population-level right-handedness for tool use in wild chimpanzees.

4.22.3.2 Vocalization

The left-hemispheric specialization for speech and language in humans may well derive from left-hemispheric control of vocalization. This has been demonstrated even in the frog, suggesting an ancestry that may go back to the very origins of the vocal cords some 170 Mya (Bauer, 1993). In passerine birds, too, vocalization seems to be controlled by the left hemisphere (Nottebohm, 1977), although it has been argued that the mechanisms underlying this asymmetry are not comparable to those in humans (Goller and Suthers, 1995).

Asymmetries for vocalization apply to perception as well as to production. A left-hemispheric advantage for the perception of species-specific vocalizations has been demonstrated in mice (Ehert, 1987), rhesus monkeys (Hauser and Anderson, 1994), and Japanese macaques (Heffner and Heffner, 1984). In chimpanzees, the left temporal planum is larger on the left than on the right (Gannon *et al.*, 1998; Hopkins *et al.*, 1998), an asymmetry that seems not to be present in rhesus monkeys or baboons (Wada *et al.*, 1975) but is well documented in humans (Geschwind and Levitsky, 1968; Jäncke and Steinmetz, 1993; Foundas *et al.*, 1996). This too may reflect an asymmetry in the perception, and perhaps comprehension, of species-specific vocal communication.

4.22.3.3 Facial Asymmetries

The asymmetry for species-specific vocalization may also be manifested in facial movements, but may be reversed for vocalizations and facial movements that are more emotionally based. Hook-Costigan and Rogers (1998) found that marmosets opened the right side of the mouth wider when making social contact calls, implying left cerebral dominance, but the right side of the mouth wider when expressing fear, implying right cerebral dominance for emotion. Curiously, however, Hauser and Akre (2001) found only a bias toward the left side of the mouth in rhesus monkeys, regardless of the nature of the calls, implying uniform right cerebral dominance. Hook-Costigan and Rogers' finding mimics that found in humans, with the right side of the mouth dominant for speech (e.g., Graves and Potter, 1988) and the left for emotional expression. These asymmetries are also evident in 5- to 12-month-old human babies, who open the right side of the mouth wider when babbling, and the left side when smiling (Holowka and Petitto, 2002). In adults, the asymmetry of the mouth when speaking also influences the McGurk effect, in which the perception of spoken syllables depends on movements of the mouth as much as on the actual sounds emitted (McGurk and MacDonald, 1976). This effect depends on movements of the right side of the mouth, not the left (Nicholls *et al.*, 2004).

More generally, there are facial asymmetries associated with emotional expression. For example, human observers see the left side of chimpanzee faces as more emotional than the right side (Fernández-Carriba *et al.*, 2004), implying right-hemispheric dominance. In humans, though, there is controversy as to whether there is a general bias to the left (and thus the right hemisphere) for emotional expression, or whether there is a leftward bias for negative emotions and a rightward bias for positive ones (see Davidson, 1995, for a review of human evidence). The bulk of evidence now seems to support this second view (e.g., Brockmeier and Ulrich, 1993; Jansari *et al.*, 2000).

4.22.3.4 Visual Asymmetries

Lateral asymmetries in the visual system have been widely documented in birds. One striking example comes from the New Caledonian crow, which appears to favor the right eye, and therefore the left hemisphere, when constructing digging tools from Pandanus leaves (Hunt *et al.*, 2001). Not only does this finding parallel the human preference for the right hand (and therefore the left hemisphere) in tool-making and tool use, but it also suggests that manufacture itself, as well as cultural transmission of tool-making techniques, may not be unique to humans (Hunt and Gray, 2003).

Other birds also show visual asymmetries. For example, chicks show a right-eye advantage in fine visual discrimination, suggesting a left-hemispheric advantage. This advantage arises because the right eye is exposed to light in the egg, prior to hatching, whereas the left eye is not (Rogers, 1990). Nevertheless it appears to have adaptive significance. Chicks raised without this prehatching asymmetry do not show the discrimination bias and are at a disadvantage relative to lateralized birds in a situation where they monitor a hovering predator while at the same time discriminating grain from nonedible grit (Rogers, 2002a). This suggests that the lateralized brain is better able to carry out two tasks at once, with the right eye (left hemisphere) picking out the grain and the left eye (right hemisphere) monitoring the hawk. Other evidence shows that the avian right hemisphere is better able to make use of the large-scale geometry of the environment to deal with problems in spatial reorientation (Vallortigara *et al.*, 2004). A left-hemispheric advantage for fine-grained visual analysis and a right-hemisphere advantage for more global vision have also been well documented in humans (Ivry and Robertson, 1998).

The advantage of asymmetry over symmetry is further illustrated in a study with pigeons (Güntürkun *et al.*, 2000). Like chickens, pigeons show a right-eye advantage in discriminating grain from grit. There was a positive correlation between the degree of asymmetry under monocular conditions and the discrimination performance under binocular conditions, suggesting that visual foraging is accomplished more effectively if mediated by a single hemisphere, perhaps because there is less risk of interhemispheric conflict (cf. Corballis, 1991).

4.22.3.5 Behavioral Asymmetries

Many species also show biases in overt behavior, such as turning to escape predators or to attack prey. Faced with a barrier through which a learned predator was visible, some species of fish showed population-level biases to turn left or right, while others did not (Bisazza *et al.*, 2000). This bias was related to the gregariousness of the species, suggesting a social influence: presumably, species that swim together must turn together to avoid collisions. Tadpoles have been shown to have a bias to turn left when escaping a predator, but a bias to turn right when turning to take in air at the surface (Rogers, 2002b), suggesting hemispheric differences. A right-hemisphere bias has also been documented for social responses in a number of species of fish (Sovrano *et al.*, 2001), chicks (Vallortigara and Andrew, 1994), sheep (Peirce *et al.*, 2000), and monkeys (Vermeire, *et al.*, 1998), and may relate to the right-hemispheric involvement in social understanding in humans (e.g., Sperry *et al.*, 1979). There may be a dark side to this, as there is also evidence that the right hemisphere is the more specialized for aggressive behavior in a number of species, including toads (e.g., Rogers, 2002b), lizards (Deckel, 1995), chicks (Howard, *et al.*, 1980), baboons (Casperd and Dunbar, 1996), and humans (Devinsky *et al.*, 1994). Right-handed boxers typically hold a stance in which their opponents are in their left visual fields, perhaps to ratchet up the aggression in their right hemispheres, but also, of course, to give greater momentum to the stronger right hand.

Complementary to the right-hemispheric dominance for attack, there is a left-hemisphere dominance for feeding. Chicks (Deng and Rogers, 1997), pigeons (Güntürkun, 1985), zebra finches (Alonso, 1998), and toads (Vallortigara *et al.*, 1998) respond to prey or to feeding matter preferentially with the right eye. Andrew *et al.* (2000) have suggested that this asymmetry may be related to left-hemispheric control of the mouth structures, an asymmetry that may be widespread in vertebrates and may relate to the left-hemispheric control of vocalization.

4.22.3.6 Summary

The above review is by no means an exhaustive coverage of the now voluminous literature on behavioral and cerebral asymmetries in nonhuman species. It should serve, however, to illustrate that humans are not unique in displaying such asymmetries. Moreover, some of the principles underlying these asymmetries seem to apply to both human and nonhuman species. There appears to be right-hemispheric specialization for emotion (or perhaps for negative emotions), aggression, social behavior, and for the more holistic aspects of perception. The left hemisphere seems to be the more specialized for detailed visual analysis, feeding behavior, and species-specific communication. It is likely that these asymmetries vary between species, perhaps depending on ecological or social factors.

Rarely, if ever, are the asymmetries absolute: each hemisphere, for example, appears to have some capacity to undertake the speciality of the other. Further, not all members of the species show the same directional asymmetry, despite the overall population bias. The percentage of individuals who reverse the asymmetry shown by the majority ranges from 10% to 35% (Ghirlanda and

Vallortigara, 2004). This again suggests that there is a trade-off between symmetry and asymmetry, and one or the other may dominate depending on survival contingencies.

4.22.4 Cerebral and Manual Asymmetries in Humans

As the foregoing review illustrates, the idea that cerebral asymmetry is unique to humans is wrong and may reflect an age-old desire to place humans on a pedestal above other species, closer to angels than to apes. Nevertheless, part of the reason our own lopsidedness seems so salient is that it applies to activities that are themselves characteristically human, if not uniquely so. Handedness is most obvious in tool use, as in writing, hammering, throwing, or, in the present age, texting. Such activities are indeed essentially and in most cases uniquely human, although whether they place us close to angels may be debated. Moreover, it is generally agreed that true language is uniquely human (e.g., Chomsky, 1966; Pinker, 1994). Hence any sense of human uniqueness applies to the activities that are lateralized, rather than to the lateralization itself.

4.22.4.1 Cerebral Asymmetry

The left-cerebral dominance for language nevertheless remains a distinctive feature of the human brain, and may well be more pronounced than asymmetries associated with communication in other species, although this has yet to be established. Patients with damage to the language-mediating areas of the left hemisphere effectively lose the power of speech or of comprehension if the damage occurs in adolescence or adulthood. Since the pioneering discoveries of Broca (1861), speech production has been typically identified with an area in the third frontal convolution of the left hemisphere, known as Broca's area, but more exacting analysis now suggests that the left precentral area of the insula, a cortical structure underling the frontal and temporal lobes, may be more critical (Dronkers, 1996). The important characteristic of language that distinguishes it from other forms of communication is grammar, and although grammar has also been associated with Broca's area, it probably also involves widespread and diffuse regions of the left hemisphere (Dick *et al.*, 2001).

Cerebral asymmetry for language was corroborated by Sperry's work on the split brain, which again revealed that only the left side of the brain was capable of producing articulate speech (Sperry, 1966–1967, 1974, 1982). This work also rather surprisingly showed that the right hemispheres of at least some of these patients were capable of comprehension, albeit at a less sophisticated level than that displayed by the left hemisphere (Zaidel, 1976). Gazzaniga (1983) has maintained, however, that right-hemisphere comprehension is the exception rather than the rule among commissurotomized patients, but Zaidel (1983) has in turn disputed this. This issue remains unresolved.

Brain imaging has further confirmed the dominant role of the left hemisphere in language. Broca's area is typically larger on the left than on the right in most people (Foundas *et al.*, 1995, 1996), as is the temporal planum, as we have seen. We have also seen that the asymmetry of the temporal planum appears to be present in chimpanzees, suggesting that the asymmetry may not be related to language *per se*, but may originate in a left-hemisphere advantage in the processing of species-specific vocalizations. Nevertheless any such asymmetry was no doubt carried over into the processing of language in humans. Functional imaging also shows that that areas of the left hemisphere are activated during both the production (e.g., Huang *et al.*, 2002; Heim and Friederici, 2003) and comprehension (e.g., Springer *et al.*, 1999) of spoken language. Left-hemisphere dominance for speech perception is evident from functional magnetic resonance imaging (fMRI) recordings even in 3-month-old infants (Dehaene-Lambertz *et al.*, 2002).

Although the right hemisphere has some involvement in language processing (e.g., Gernsbacher and Kaschak, 2003), it is clear that in most people language is largely a left-hemispheric enterprise, and indeed occupies widespread circuits in that hemisphere. It is probably the sheer complexity of language, therefore, that makes the asymmetry stand out. It may also explain a striking right-hemisphere dominance for spatial attention. Patients with lesions to the right hemisphere often show a neglect of the left side of space, whereas those with comparable lesions of the left side do not show the reverse asymmetry, or show it only transiently. This follows especially from lesions in the posterior half of the brain, and although the parietal lobe is usually implicated, it has been claimed that the critical area involves the temporal lobe rather than the parietal lobe. According to Karnath *et al.* (2001), this area is homologous to Wernicke's area in the left hemisphere, suggesting that the asymmetry may have been a secondary consequence of language representation in the left hemisphere (cf. Corballis, 1991). There is no evidence for any asymmetry in spatial attention in animals comparable to that

demonstrated by left hemineglect in humans (Driver and Vuilleumier, 2001), although it could be argued that it is related to the right-hemispheric advantage for more global aspects of perception, which has also been documented in birds, as outlined earlier.

4.22.4.2 Handedness

Right-handedness in humans may also be a consequence of cerebral asymmetry for speech. Along with others, I have argued that language itself may derive from manual gestures, rather than from primate calls (Hewes, 1973; Armstrong *et al.*, 1995; Givón, 1995; Rizzolatti and Arbib, 1998; Corballis, 2001a). If this is so, the shift from gestural to vocal language was presumably gradual, so that language for much of our recent evolutionary history was a combination of the two. As we saw earlier, left-hemispheric control of vocalization may go back far in evolution, perhaps to the origins of the vocalization, so the gradual assimilation of vocalization into the language system may have lateralized the neural circuits involved (Corballis, 2003). Indeed, people habitually gesture with their hands while they speak, and in right-handers the right hand predominates (Kimura, 1973). This may have had a spin-off. As vocalization gradually took over, so the hands were released for other activities, such as toolmaking, resulting in the manual specialization that we see in present-day human activities. The release of the hands, and along with it the release also of right-handedness, may also explain what has come to be termed the human revolution that took place some 40 000 years ago in Europe and probably earlier in Africa (Corballis, 2004).

This account explains why the extreme right-handedness observed in the human population is not evident in nonhuman primates. It is likely, though, that right-handedness itself was a species-wide characteristic well before 40 000 years ago. Cornford (1986) analyzed the asymmetries of flakes recovered from La Cotte de St. Brelade in Jersey, dating from 150 000 to 200 000 years ago, and estimated that the incidence of right-handedness among the toolmakers was between 80% and 90%, which is close to present-day estimates. Toth (1985) provides even earlier estimates from asymmetrical flakes found in Lower Pleistocene sites at Koobi Fora in Kenya, dated at 1.4–1.9 Mya. Flakes favoring right-handed action outnumbered those favoring left-handed action in a ratio of about 57:43. Although this bias may seem relatively slight, Toth found that the same ratio was obtained by present-day right-handers given a similar task, which suggested to McManus (1999, 2002) that right-handedness was universal among the early flakers, and that left-handedness was the result of a later mutation. Yet the ratio observed by Toth is not dissimilar to the ratio of right- to left-handers among present-day captive chimpanzees, as reported by Hopkins (1996), and I have suggested that a later mutation may have raised the ratio from 2:1 to about 8:1 (Corballis, 1997). A more conservative conclusion, more aligned with my current thinking, is that right-handedness emerged gradually as vocalization increasingly accompanied manual gesture in the evolution of language. However, the data do not yet permit a clear distinction between big bang and continuity theories of the emergence of handedness.

4.22.5 Genetic Models

Regardless of which of these theories is correct, there seems good reason to suppose that handedness is at least partially under genetic control. Despite the strong human bias toward right-handedness, a minority of the population remains stubbornly left-handed, and a few ambidextrous individuals display no overall preference. Similarly, the right hemisphere controls language in a minority of people, and in some language appears to be represented bilaterally. The asymmetry in language representation, moreover, is loosely correlated with handedness (Knecht *et al.*, 2000). There is at least a weak parental influence on handedness, as revealed in data summarized by McManus and Bryden (1992) and shown in Table 1. Although it is clear that handedness does not 'breed true', single-gene models can accommodate the data reasonably well.

Over 30 years ago, Annett (1972) proposed that the true distinction was not between left- and right-handers, but between those carrying a right shift (RS) factor and those not carrying this factor; in more recent terminology, there is a right-shift allele, RS+, and an allele without directional specification, RS–. To put it simply, right-handedness is inherited but left-handedness is not (Annett, 2002). It should

Table 1 Percentage of left-handed offspring by parental combination, and prediction from McManus' model

	Parental handedness		
	R–R	*R–L*	*L–L*
% Left-handed offspring	9.5	19.5	26.1
Predicted by McManus' model with $p(D) = 0.76$	9.45	20.24	28.87

be emphasized, though, that in Annett's model most of the variation in handedness is random, and the RS+ allele shifts a normal distribution of intermanual differences to the right. For individuals homozygous for the RS+ allele, designated RS++, the shift is about two standard deviations to the right of neutrality; for heterozygotes, designated RS+–, the shift is about one standard deviation to the right; and for those homozygous for the RS– allele, designated RS– –, the distribution is centered on the point of neutrality, that is, the direction of handedness is essentially assigned at random. Annett also makes it clear that the RS gene influences cerebral dominance rather than handedness *per se*. (Since the left hemisphere controls the right hand, it should really be termed a left-shift gene.)

The idea that genes can influence the presence versus the absence of an asymmetry, rather than the direction of the asymmetry, may be a general principle in the genetics of asymmetry (Morgan and Corballis, 1978) and applies for example to the asymmetry of the heart and other visceral organs (Layton, 1976). The same principle is embodied in McManus' (1999) genetic model of handedness. Like Annett, McManus proposes a two-allele gene, with a dextral (D) allele specifying right-handedness and a chance (C) allele, which does not specify the direction of handedness, but leaves it to chance. Unlike Annett, though, McManus argues that handedness is fundamentally dichotomous, so that all DD individuals are right-handed, 75% of CD individuals are right-handed, and CC individuals are equally divided between left- and right-handers. This model makes predictions about the inheritance of handedness that are essentially indistinguishable from those of Annett's model. Table 1 shows how McManus' version fits the data, with the proportion p(D) of D alleles in the population estimated at 0.76.

This estimate might seem high, but perhaps reflects a society in which dextrality, or left cerebral dominance, has greater adaptive fitness than the lack of consistent handedness or cerebral dominance. Variations in this parameter might explain cultural differences in handedness, although the heterozygotic advantage ensures that both alleles are maintained in the population. Figure 1 shows how the asymptotic value of p(D) varies depending on the relative fitness of CC and DD genotypes.

The models can also account for the relations between handedness and cerebral dominance for language. Studies based on the Wada test (Rasmussen and Milner, 1977), electroconvulsive therapy (ECT) (Warrington and Pratt, 1973), and brain imaging (Pujol *et al.*, 1999; Knecht *et al.*, 2000) are reasonably consistent in showing that over 90% of right-handers are left-cerebrally dominant for language, as are some 70% of left-handers. McManus' model, on the assumption that $p(D) = 0.76$ and that handedness and cerebral asymmetry are assigned independently in CD and CC genotypes, predicts that 90.6% of right-handers and 69% of left-handers will be left-cerebrally dominant for language, figures reasonably close to empirically determined values. Annett's model makes similar predictions.

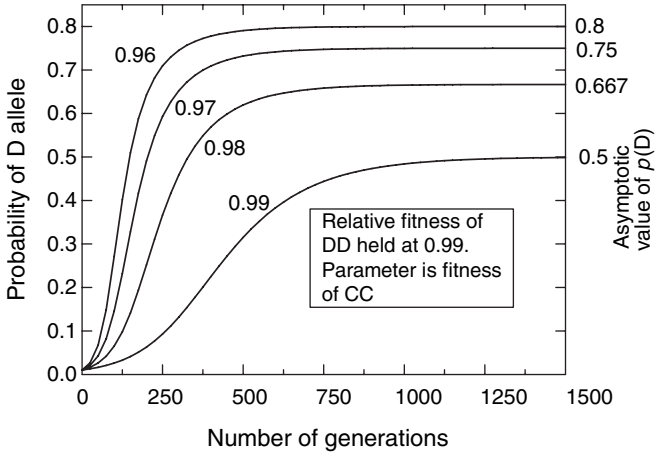

Figure 1 Suppose a mutation occurs creating a dextral allele D in 1% of a population. The figure shows the increase in the probability of the D allele, p(D), over successive generations, given a fitness advantage to the CD genotype. In this example, the relative fitness of the CD genotype is held at 1.0 and that of the DD genotype at 0.99. The rise of the D allele is shown for four different fitnesses: 0.99, 0.98, 0.97, and 0.96, yielding different asymptotic values of p(D). The asymptote would be less than 0.5 if the fitness of the CC genotype were to exceed that of the DD genotype. At asymptote, the ratio of p(D):p(C) is given by $(1–f_{CC}):(1–f_{DD})$, where f_{DD} and f_{CC} are the fitnesses of DD and CC genotypes relative to that of the CD genotype. Reprinted from Corballis, M. C. 1997. The genetics and evolution of handedness. *Psychol. Rev.* 104, 714–727, with permission from APA.

Both Annett and McManus assume that the mutation that gave rise to the RS+ or D allele occurred in hominid evolution. McManus (1999) has speculated that it may have occurred in a copy of one of the genes creating the leftward asymmetry of the heart, perhaps allowing the asymmetry to affect neural tissue as well as the heart rudiment. It seems entirely possible, though, that similar genetic influences may explain the cerebral asymmetries evident in other species. We have seen, in fact, that the proportion of individuals that reverse the population-level bias ranges from approximately 10% to approximately 35% (Ghirlanda and Vallortigara, 2004), and in fact both extremes are evident in humans. Previc (1991) has summarized evidence on what he terms natural forms of auditory and motor asymmetries in humans, and these favor one side over the other in a ratio of 2:1. They include the right-ear advantage in dichotic listening, right-eye dominance, a host of postural asymmetries, and a tendency, especially among newborns, to turn the head to the right. These asymmetries may relate to the fact that about two-thirds of human fetuses are confined to an asymmetrical fetal position, with the right side facing toward the mother's front, during the final trimester. Consequently, approximately 33% of people reverse this asymmetry. The variations between these different asymmetry ratios may reflect the relative fitnesses of homozygotes, under the assumption of an overall heterozygotic advantage, as illustrated in Figure 1.

The gene or genes that create these biases remain hypothetical, although there have been some leads. For example, Crow (2002) has suggested that the laterality gene is located in the *Xq21.3/Yp11.2* region of homology on the X and Y chromosomes, and suggested protocadherin XY as a likely candidate. I have myself argued against this on the grounds that polymorphisms are unstable on the Y chromosome, but suggested, following McKeever (2000), that the gene may be on the X chromosome (Corballis, 2001b). However, a genome-wide search for the handedness gene has since offered little support for X-linkage, and suggests that the region *2p11.2-12* on chromosome 2 may be a better bet (Francks *et al.*, 2002). Although the authors report that this failed to replicate in an independent sample, a further analysis has revealed significant paternal linkage within this site (Francks *et al.*, 2003), suggesting that imprinting may play a role. It is perhaps unlikely that the single-gene models proposed by Annett and McManus will provide the whole answer, but they provide a useful starting point.

4.22.5.1 The Trade-Off between Symmetry and Specialization: A Genetic Perspective

The models proposed by Annett and McManus capture something of the trade-off between symmetry and asymmetry, at least insofar as the D allele stands for asymmetry and the C allele for symmetry. (For simplicity, I use McManus' terminology rather than Annett's, but I do not mean to imply that one model is to be preferred to the other.) Thus DD genotypes are strongly lateralized, with right-handedness and left-cerebral dominance for language, whereas CC genotypes are subject only to random lateralizing influences. The two genes are held in balance by the superior fitness of the CD genotype.

Part of the trade-off may have to do with the relative advantages of language and spatial ability. There is some evidence that left-cerebral dominance for language is achieved through the pruning of the right hemisphere, with some loss of spatial function (Annett, 2002). Thus DD individuals may benefit from having language mechanisms contained within a hemisphere, but while displaying superior skills of oratory may tend to get lost on the way to the Forum. CC individuals may be at risk of divided hemispheric control over speech, with increased risk of stuttering (Foundas *et al.*, 2003) and reading disability (Annett, 2002), but may benefit from greater spatial awareness and more balanced motor skill. Heterozygotic DC individuals may be less prone to either deficiency, and so have the better of both worlds.

A study of 12 770 11-year-olds in the United Kingdom suggests, however, that the academic deficits shown by CC individuals may extend beyond language abilities. Handedness in these children was assessed in a test of skill (checking squares) and ranged from extreme left- to extreme right-handedness. Their scores on tests of verbal ability, nonverbal ability, reading comprehension, and mathematical ability showed a pronounced dip at the point of equality between the hands (Crow *et al.*, 1998). That is, both left- and right-handers scored above those who were ambidextrous. Since CC individuals were more likely to be represented at the point of equality than either DC or DD individuals, this result suggests that they are at greater risk of poor academic performance. This result was not replicated in a German study by Mayringer and Wimmer (2002), who tested a smaller (but still large) sample of 530 boys. Crow *et al.* (1998) refer to ambidexterity as "the point of hemispheric indecision"; the symmetrical brain, so to speak, is unable to make up its mind. The risk of impediment in CC individuals is still relatively small, since many with

this genotype will display asymmetry in one or the other direction by chance.

What, then, are compensatory advantages of a bilaterally symmetrical brain? Many prominent athletes and sportspeople have mixed dominance, and may derive their benefit from an extra degree of perceptual and motor balance. Annett (2002) also claims that surgeons include a disproportionately large number of non-right-handers. It is possible that the benefits of altered handedness derive precisely from being in a minority. Suppose, for example, that members of a group tend to stick together to avoid predation and run off to the left when a predator threatens. By being one of many, each individual is less likely to be singled out by the predator. The predator may nevertheless choose to attack the mob rather than the strays, since the chances of catching at least one victim are maximized. Some individuals may therefore benefit from joining a minority that veers off to the right, a strategy that works only if this group remains a minority. This may have resulted in a subtle selection dynamic that held left- and right-turning in balance (Ghirlanda and Vallortigara, 2004), but with left-turning implying a right-hemisphere dominance for this behavior, maintained for the majority. One might argue similarly that left-handers hold an advantage in fighting, but only so long as they are in the minority (Raymond *et al.*, 1996).

There is also some reason to suppose that the lack of consistent cerebral asymmetry may lead to different styles of thought. In a study of magical ideation and handedness, Barnett and Corballis (2002) reported a relationship that was exactly the reverse of that reported for intellectual achievements by Crow *et al.* (1998). People with mixed-handedness were the most prone to magical ideation, characterized by mild paranoia and superstition, and scores on magical ideation decreased systematically as handedness became more extreme in either direction.

There is also evidence that mixed-handedness – or perhaps hemispheric indecision (Crow *et al.*, 1998) – is associated with a greater sensitivity to sensory illusions (Niebauer *et al.*, 2002) – which was not replicated, however, in a study by Barnett-Cowan and Peters (2004) – and a higher risk of schizophrenia (Claridge *et al.*, 1998; Upadhyay *et al.*, 2004) and strong belief in the paranormal seems to be associated with symmetrical brain activity (Pizzagalli *et al.*, 2000). Another study has shown that people who score relatively low on magical ideation show a left visual field advantage on a lexical-decision task, whereas those who score relatively high show no difference between visual fields, implying a lack of cerebral dominance (Pizzagalli *et al.*, 2001).

Jaynes (1976) speculated that cerebral asymmetry emerged in the second millennium BCE, in response to assorted catastrophes, such as floods, invasions, and the like. Prior to this, people were governed by hallucinations, invoking the gods, but cerebral asymmetry allowed the left hemisphere to create a sense of self, so that people took responsibility for their own actions. Jaynes' theory makes little evolutionary sense, since handedness and cerebral asymmetry almost certainly go back at least 2 My, and perhaps even earlier, in hominid evolution (Corballis, 1997). Nevertheless, there may well be some truth to the idea that cerebral asymmetry underlies rational thought, and that a lack of asymmetry may well lead to more delusional and perhaps hallucinatory thought processes.

At least some of the characteristics associated with the lack of cerebral asymmetry, including paranormal experience, hallucinations, and so on, may be linked to religion. Although religious activities may seem irrational and sometimes counterproductive, it has been argued that religious behaviors has been favored by selection because they promote intergroup alliances (Hayden, 1987). Others have argued that religion is a system used by elites to maintain social control (e.g., Cronk, 1994). While this implies a social rather than an evolutionary origin, there may well have been selection of those predisposed to accept arbitrary leadership. Obedience is a common religious virtue. Religion is undoubtedly a complex phenomenon, but still a universal one, and is in many respects at odds with scientific rationalism. This raises the possibility that the trade-off between symmetry and asymmetry, or the C and D alleles, may have a bearing on the age-old struggle between religion and science, as exemplified in religious opposition to such scientific luminaries as Charles Darwin and Galileo.

Nevertheless, magical thinking may also be related to creativity, with positive implications for science and mathematics. Leonhard and Brugger (1988) note a link between paranormal thought, delusional thought, and creativity, and suggest that these characteristics relate to heightened right-hemispheric activation and relatively coarse semantic activation in that hemisphere. This in turn results in a loosening of associations and enhanced creativity. Although Leonhard and Brugger's account focuses on the right hemisphere, it is possible that the profile has to do with lack of cerebral dominance rather that any specialization of the right hemisphere itself. Despite the evidence of Crow *et al.* (1998) that mixed-handers are deficient in

arithmetic ability, Singh and O'Boyle (2004) report that mathematically gifted adolescents show no hemispheric asymmetry on tasks involving global–local judgments and matching letters, whereas average-ability adolescents and college students show a left-hemispheric advantage, suggesting that the mathematically gifted may lack consistent cerebral asymmetry. Although Singh and O'Boyle selected right-handers for this study, they also characterize the mathematically gifted as "typically male, left-handed, and myopic" (Singh and O'Boyle, 2004, p. 371).

Two individuals who may serve as CC icons are Leonardo da Vinci and Albert Einstein. Leonardo – the prototypical Renaissance Man, artist, scientist, and inventor – is generally regarded as being several centuries before his time. He was left-handed, and habitually wrote backwards, in mirror writing, but was also capable of writing normally. Einstein seems to have been right-handed, but was said to be slow to develop speech and a slow learner, and postmortem analysis of his brain revealed "an unusual symmetry between the hemispheres" (Witelson *et al.*, 1999, p. 2151), especially in the occipital and parietal lobes. He is also reported to have declared "I want to know how God created this world."

4.22.6 Conclusions

The brain and nervous system are built according to a plan that is bilaterally symmetrical. This probably goes back to the first organisms that moved linearly, perhaps even earlier than Bilateria, the lineage that includes nearly all present-day insects and animals, from humans to fruit flies to nematodes. Yet bilateral symmetry is readily broken if there are advantages in lateralization of function. Human handedness and cerebral asymmetry are examples, but there are countless other examples in the animal world, some of which are precursors to our own characteristic lopsidedness. Yet these asymmetries are not absolute. There is considerable overlap of function even in the lateralized human brain, and there is nearly always a minority of individuals within each lateralized species who show the opposite direction of asymmetry, although this may be born of chance fluctuation rather than systematic reversal. This minority appears to range from approximately 10% to some 35%, a range that may also apply to asymmetries that occur within our own species. Again, this suggests phylogenetic continuity rather than human uniqueness.

Genetic theories can explain a number of features of individual differences, at least in humans. The simplest theories are those in which there is a single laterality gene, with two alleles, one specifying a directional asymmetry and the other leaving the direction of asymmetry to chance. Such models remain speculative, since there is no sure evidence as to where the gene might be located in the genome, or even whether such a gene exists. If there is a genetic component to cerebral asymmetry, it may well provide an important basis for individual differences. Despite the widespread belief that right-handedness and left-cerebral dominance for language arose from a genetic mutation that occurred in hominid evolution, the more parsimonious view is that the same mechanisms that underlie these asymmetries also underlie the asymmetries observed in other species. A balance between directional and chance influences is then maintained by a heterozygotic advantage, and the relative costs of the two homozygotic genotypes then determines the relative proportions of lateralized and nonlateralized individuals. This, then, could be the universal mechanism underlying the trade-off between symmetry and specialization.

In any event, the widespread notion that cerebral asymmetry is uniquely human is wrong. Nevertheless, some of the functions that are lateralized in the human brain may well be unique to our species. This applies especially to language, which requires widespread neural circuitry, and if lateralized occupies a good proportion of the hemisphere in which it is housed. This in turn may have created a complementary asymmetry in the other side of the brain for spatial attention. Hand skill is another characteristic that is exceptionally highly developed in humans, and is an asymmetry that is strikingly obvious in everyday human behavior. Yet not all humans show this high degree of asymmetry, and there may be some advantages to an unlateralized brain that offset the advantages of lateralization. Some of these advantages may come about precisely because those who possess them may be in a minority. If nearly all tennis players were left-handed, the advantage of surprise and unorthodoxy would be transferred to the right-handed. If a lack of cerebral dominance were also a characteristic of creative visionaries, the impact of such people would be lessened if we were all like that. The world needs accountants.

Is there a common source for the evolution of lateralization? Perhaps the best candidate is the mouth. MacNeilage (1998) has proposed that speech is based on masticatory movements of the mouth, and Andrew *et al.* (2000) note that left cerebral control of the mouth and its internal structures is widespread in vertebrates. The left-hemispheric control of speech may therefore have

ancient origins. I have proposed that handedness may then have come about because of the association of speech and manual gesture (Corballis, 2003): if language went from hand to mouth, so lateralization went from mouth to hand. But there are perhaps earlier associations between hand and mouth that could have favored the right-hand preference. In some animals, the forelimbs are involved in bringing food to the mouth. We have seen that walruses show a general preference for the right flipper in feeding, and there is controversial evidence that the great apes also show a right-hand preference for a number of activities, including feeding (Hopkins, 1996). Any such preference, however, might be countered by the advantages of bilaterality, allowing an animal to reach with equal facility to either side. The mouth is also a more general manipulative organ, and manipulation also involves the hands, so that right-handedness may have emerged in the context of manipulation, again driven by lateralized control of the mouth. These hand–mouth associations are likely to have been especially decisive in the most manipulative of creatures, *H. sapiens*.

4.23 Neurological Specializations for Manual Gesture and Tool Use in Humans

S H Frey, University of Oregon, Eugene, OR, USA

Glossary

apraxia	A deficit affecting manual skills that cannot be attributed to elementary sensory or motor disturbances. Generally pronounced when pantomiming or imitating transitive actions.
prehension	Manual reaching, grasping, and object manipulation.
transitive actions	Behaviors that involve the use of objects other than one's own body (e.g., using tools or utensils).

4.23.1 Neural Bases of Manual Prehension in Primates

Establishing homologies between brain structures of species whose most recent common ancestor lived 30 Mya is a nontrivial challenge (Kaas and Reiner, 1999). This is made even more difficult when comparisons involve contrasting the response properties of single neurons in macaques with indirect measures of the activity of several million neurons in the human brain recorded with functional magnetic resonance imaging (fMRI) or positron emission tomography (PET) (Orban *et al.*, 2004). With growing evidence for differences between human and macaque cortical architecture (Preuss and Coleman, 2002) including areas of the dorsal visual processing stream that are implicated in manual prehension (Vanduffel *et al.*, 2002; Orban *et al.*, 2004), caution is warranted when evaluating claims of homologies between species. Nevertheless, human research in this area is guided largely by results in macaques, and, as reviewed below, there appear to be marked similarities between species in the gross organization of systems involved in manual actions (see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates, Hand Use and the Evolution of Posterior Parietal Cortex in Primates, Nuclear Schizophrenic Symptoms as the Key to the Evolution of the Human Brain).

4.23.1.1 Ventral and Dorsal Pathways

The extrastriate visual areas of nonhuman primates are grossly organized into two primary pathways with significant reciprocal interconnections (Morel and Bullier, 1990): (1) an occipital temporal (i.e., ventral) stream; and (2) an occipital parietal (i.e., dorsal) stream (Ungerleider and Mishkin, 1982; Mishkin *et al.*, 1983; Felleman and Van Essen, 1991). Areas within these streams are also reciprocally interconnected with regions of prefrontal cortex involved in working memory and planning, and their sensory responses may be modulated via feedback from these higher cognitive centers (Wilson *et al.*, 1993; Goldman-Rakic, 1996). This organization is found in both Old and New World monkeys (Preuss and Goldman-Rakic, 1991), and it is believed to be relatively preserved in human beings (Ungerleider and Haxby, 1994; Ungerleider *et al.*, 1998; Braddick *et al.*, 2000). It is generally agreed that areas within the dorsal stream constitute the major source of input to premotor regions of frontal cortex involved in the organization and control of action (Jeannerod *et al.*, 1995; Johnson *et al.*, 1996; Andersen *et al.*, 1997; Luppino and

Rizzolatti, 2000; Marconi *et al.*, 2001; Rizzolatti and Luppino, 2001).

4.23.1.2 Subdivisions Within the Dorsal Pathway

As illustrated in Figure 1, on the basis of anatomical connectivity with frontal cortex, the macaque's dorsal visual pathway can be subdivided further into dorsal–dorsal (d–d) and ventral–dorsal (v–d) streams (Rizzolatti and Matelli, 2003). Inputs to dorsal (PMd) or ventral premotor cortex (PMv) arise from segregated regions of parietal cortex (Tanne-Gariepy *et al.*, 2002), and these frontal areas are not highly interconnected. In macaques, the primary visual input to the d–d stream is from area V6 along with V6A, parietooccipital (PO), and medial intraparietal (MIP) area in the superior parietal lobule (SPL).

The primary visual input to the v–d pathway is from areas MT/MST (middle temporal/medial superior temporal) along with visual areas of the inferior parietal lobule (IPL: anterior intraparietal area (AIP), PG, PFG, and PF). The v–d pathway projects to PMv cortex and can be further subdivided: neural tracing studies demonstrate that parietal area AIP projects to F5, while the adjacent ventral intraparietal area (VIP) projects selectively to F4 (Luppino *et al.*, 1999). As discussed below, these subdivisions may be involved in constructing representations for grasping objects versus delineating peripersonal space, respectively.

Consensus on the functional significance of the v–d and d–d subdivisions of the dorsal stream is currently

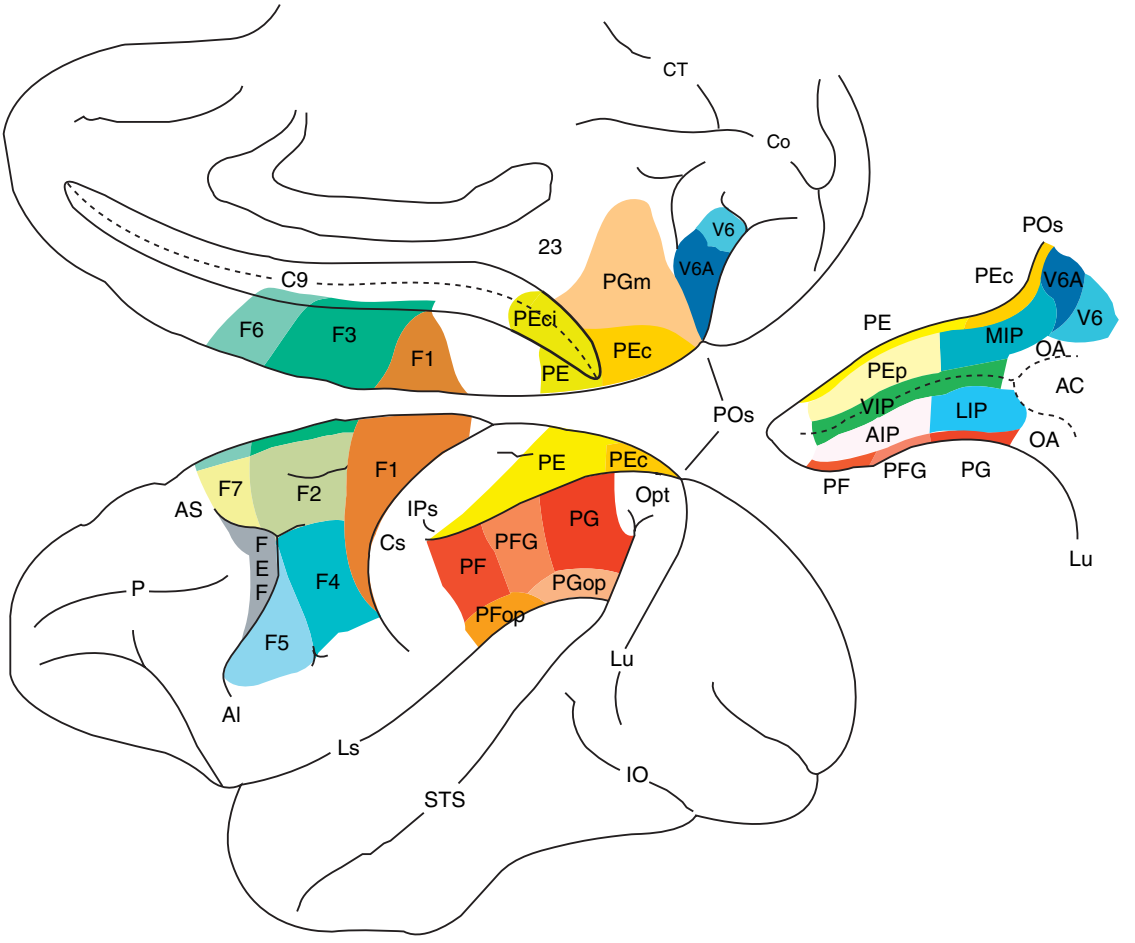

Figure 1 A schematic representation of the parietal and frontal areas of the macaque brain involved in manual prehension. Frontal areas are labeled according to the systems of Matelli and colleagues (Matelli *et al.*, 1985, 1991), and parietal areas use the system of Pandya and Seltzer (Pandya and Seltzer, 1982). Lower: View of the lateral surface of the left cerebral hemisphere. Upper: The medial surface of the left cerebral hemisphere. Inset: The intraparietal sulcus unfolded to reveal areas located within. These include medial (MIP), ventral (VIP), and anterior (AIP) intraparietal areas (from Rizzolatti and Matelli, 2003). AG, annectant gyrus; AI, inferior arcuate sulcus; AS, superior arcuate sulcus; Ca, calcarine sulcus; Cg, cingulated sulcus; Cs, central sulcus; Ls, lateral sulcus; Lu, lunate sulcus; OT, occipitotemporal sulcus; P, principal sulcus; POs, parietooccipital sulcus; STS, superior temporal sulcus. Reproduced from *Exp. Brain Res.*, vol. 153, 2003, pp. 146–157, Two different streams form the dorsal visual system; Anatomy and function, Rizzolatti, G. and Matelli, M. With kind permission of Springer Science and Business Media.

lacking. For the past decade the predominant view has been that reaching and grasping are controlled by parallel dorsal versus ventral visuomotor channels, respectively (Jeannerod *et al.*, 1995). Yet, as articulated by Tanne-Gariepy *et al.* (2002), accruing data suggest that the truth is likely more complex. PMd and PMv both contain representations of distal (F5) and proximal (F4) musculature of the upper limbs involved in grasping versus reaching, respectively. Likewise, both areas contain cells that code movement direction (Kakei *et al.*, 2001). As an alternative, Rizzolatti and Matelli (2003) hypothesize that the d–d pathway is exclusively involved in online motor control while the v–d stream participates in both the execution of prehensile actions as well as premovement organization (Glover, 2004). Another view is that premotor representations are entirely goal-specific and effector-independent (Rijntjes *et al.*, 1999). Consistent with this hypothesis are findings showing that microstimulation of motor and premotor cortex can evoke complex, multijoint movements that appear to be organized on the basis of the final position or action goal (e.g., bringing the grasping hand to the opening mouth regardless of the direction of movement) (Graziano *et al.*, 2002). Regardless of which organizational scheme is ultimately shown best to capture the properties of these systems, the majority of research in this area has been organized around the use of specific functional tasks. In the following sections I will consider evidence regarding those areas contributing to three requisites for dexterous manual prehension in macaques and humans: reaching, grasping, and the representation of peripersonal space.

4.23.1.3 The Dorsal–Dorsal Subdivision

Cells within the medial intraparietal sulcus of the SPL (area MIP), including the so-called parietal reach region (PRR), are involved in the representation of reaching actions (Wise *et al.*, 1997; Snyder *et al.*, 2000; Batista and Andersen, 2001; Andersen and Buneo, 2002). Area PMd also receives visual information via a direct connection with area PO (Caminiti *et al.*, 1996) and proprioceptive input via a circuit interconnecting PEc/PEip-F2 (Lacquaniti *et al.*, 1995; Matelli *et al.*, 1998). Neurons in PMd use this input to compute representations of both the location of visual targets and the direction of forelimb movements needed to acquire them (Johnson and Ferraina, 1996; Johnson *et al.*, 1993, 1996). A subpopulation of PMd neurons responds to specific combinations of sensory cues specifying target location and which limb to use when performing a manual pointing task, suggesting that single PMd units represent plans for specific reaching actions (Hoshi and Tanji, 2000).

Early PET studies identified activation within PMd, intraparietal sulcus (IPS), and SPL during reaching, pointing, and finger-tracking movements in humans (Colebatch *et al.*, 1991; Deiber *et al.*, 1991; Grafton *et al.*, 1992; Kertzman *et al.*, 1997). More recent findings using fMRI are consistent with these earlier results in suggesting the existence of a parietofrontal reach circuit in humans that can be activated by either overt movements (Connolly *et al.*, 2003) or motor imagery (Johnson *et al.*, 2002).

4.23.1.4 The Ventral–Dorsal Subdivision: Grasping

Single-unit electrophysiological recordings indicate that a parietofrontal circuit interconnecting areas AIP and F5 is involved in the transformation of sensory information into motor commands for grasping (Jeannerod *et al.*, 1995; Luppino and Rizzolatti, 2000; Rizzolatti and Luppino, 2001). Reversible inactivation studies with muscimol injections to either AIP (Gallese *et al.*, 1994) or F5 (Fogassi *et al.*, 2001) cause a selective deficit in visually guided grasping without affecting reaching. Electrophysiological recordings in macaques identified cells in the lateral bank of the IPS that are involved in the visual guidance of object-oriented hand movements (Taira *et al.*, 1990). A subpopulation of these cells are highly shape-selective in their responses (Sakata *et al.*, 1995). These object-selective cells can be divided into three categories on the basis of their receptive field (RF) properties. Motor dominant neurons require no visual input and therefore discharge in either the light or dark during manipulation. These cells do not respond to object fixation, and may therefore be coding hand movements necessary to engage objects. Visuomotor neurons respond strongest when objects are manipulated in the light, and less when either the hand or target object is invisible. A subpopulation of the visuomotor neurons also responds when the preferred object is fixated in the absence of manipulation, suggesting that these cells are coding hand movements relative to objects' visual properties. Finally, visual neurons only respond when an object is manipulated in the light, or when it is fixated. These cells are likely coding visual properties of objects that are useful for manipulation (Sakata *et al.*, 1995, 1997).

The object-selective cells within these three classes are distributed in a gradient along the lateral bank of the IPS. Visual neurons are found in higher concentrations in the lateral intraparietal (LIP) areas, known to also be involved in saccades (Colby *et al.*, 1995, 1996; Andersen *et al.*, 1998).

Movement-related motor and visuomotor units are also found in LIP, but are more concentrated immediately posterior to the primary somatosensory area (SI) hand representation in area AIP (Sakata *et al.*, 1995). Injections of a gamma-aminobutyric acid (GABA) agonist (muscimol) into area AIP cause a reversible deficit in preshaping the hand when grasping visual objects while leaving reaching intact (Gallese *et al.*, 1994).

Cells within area F5 of the macaque code the goals of specific prehensile actions rather than the movements of which they are composed. These units can be categorized on the basis of their RF properties into those that represent specific actions such as holding, grasping, or tearing objects. If the same hand movements are made as part of a different action, e.g., grooming instead of feeding, responses are weak or absent (Rizzolatti *et al.*, 1988). This observation has led to the hypothesis that area F5 contains a vocabulary of hand actions (Rizzolatti *et al.*, 1988), in which the goals of hand–object interactions are represented explicitly.

As discussed extensively in Michael Arbib's article (see Premotor Cortex and the Mirror Neuron Hypothesis for the Evolution of the Language), a subclass of neurons in area F5 (Gallese *et al.*, 1996; Rizzolatti *et al.*, 1996) and rostral inferior parietal cortex (PF; Rizzolatti and Craighero, 2004), known as mirror neurons, discharge not only when the monkey produces a specific action but also when it observes the experimenter undertake a comparable behavior (Rizzolatti and Luppino, 2001). This mirror system may be relevant to understanding the acquisition of complex skills through observation (Buccino *et al.*, 2004), as they provide a mechanism for mapping perceived actions on to one's own motor representations. Of potential relevance to the upcoming discussion of tool use, a recent paper reports tool-responding mirror neurons that respond selectively when macaques observe food items being captured with a simple tool and not the hand (Ferrari *et al.*, 2005).

On the basis of cytoarchitectonic similarities, it has been suggested that macaque area F5 is homologous with pars opercularis of the human inferior frontal gyrus (Petrides and Pandya, 1984; Preuss *et al.*, 1996), while F4 may be homologous with human inferior precentral gyrus (Rizzolatti *et al.*, 2002). Several studies report activation of pars opercularis as well as inferior precentral gyrus during visually guided grasping (Ehrsson *et al.*, 2000, 2001), haptic object manipulation (Binkofski *et al.*, 1999), and action observation (Iacoboni *et al.*, 1999; Johnson-Frey *et al.*, 2003). Because the RF characteristics of neurons in AIP and VIP are not strictly segregated, but rather distributed along a gradient (Sakata *et al.*, 1995), it may not be possible to differentiate these regions and adjacent areas of cortex (PF) using current neuroimaging techniques. I will therefore refer to the anterior portion of the human IPS and adjacent cortex as aIPS.

Recent fMRI studies identify activity within aIPS and surrounding cortex in tasks similar to those that evoke responses in cells of macaque AIP and/or VIP. Manipulation of complex versus simple shapes without vision is associated with mean activation in human aIPS (Binkofski *et al.*, 1999). This location is also activated during haptic recognition of shapes (Jancke *et al.*, 2001). Activation within this vicinity is also observed during object discrimination tasks involving both visual-to-tactile and tactile-to-visual transfer (Grefkes *et al.*, 2002). Activity associated with grasping visually presented three-dimensional objects (Binkofski *et al.*, 1998; Johnson-Frey *et al.*, 2005a), or grasping at two-dimensional projected objects (Culham *et al.*, 2003), is centered within a slightly more lateral and anterior site, as is visual discrimination of objects' surface orientations (Shikata *et al.*, 2001). Finally, as reviewed in Johnson-Frey (2004), a number of studies report activation in aIPS and surrounding areas of the IPL when viewing manipulable tools (Chao and Martin, 2000; Kellenbach *et al.*, 2003). Recent work using transcranial magnetic stimulation demonstrates that disruption of aIPS compromises the ability to update plans for visually guided grasping on the basis of rapidly changing visual feedback (Tunik *et al.*, 2005).

4.23.1.5 The Ventral–Dorsal Subdivision: Peripersonal Space

Electrophysiological investigations suggest that visuotactile representations of peripersonal space are constructed in a circuit connecting IPL area VIP with area F4 in PMv (Fogassi *et al.*, 1992, 1996). Area F4 contains a representation of the face, neck, trunk, and limbs and lies caudal to grasp-related area F5 (Figure 1). The majority of units in F4 are bimodal, having tactile RFs that are in register with three-dimensional visual RFs of space immediately adjacent to the animal and are not affected by variations in gaze direction. Similar RF properties can be found in area VIP (Colby *et al.*, 1993; Duhamel *et al.*, 1998), which provide direct afferent input to F4 (Luppino *et al.*, 1999). These observations have prompted the hypothesis that the VIP–F4 circuit constructs representations of peripersonal space in a frame of reference centered on the body part involved in a given visually guided action such as object manipulation (Graziano *et al.*, 1994; Fogassi *et al.*, 1996).

The paucity of neuroimaging studies attempting to identify areas of the human brain involved in the representation of peripersonal space may reflect the technical challenges associated with stimulus delivery and response recording. One successful PET investigation found differential activation in ventral premotor cortex and the IPS in association with bisecting lines located in near versus far space (Weiss *et al.*, 2000). While more work is necessary, these results are consistent with those predicted by the VIP–F4 circuit in macaques.

4.23.2 Primate Tool Use and the Ventral–Dorsal Stream

An interesting possibility to consider is whether tool use in primates might be accounted for by extensions of the sensorimotor mechanisms involved in manual prehension. Similar to using a limb, tool use involves implementing a sensorimotor transformation. However, this transformation must now include parameters that capture the physical and mechanical properties of the tool. Macaques can be trained to use simple tools in the laboratory, and this work suggests that these behaviors may involve acute plasticity within existing neural circuits involved in manual prehension. As noted above, cells in macaque area VIP have visuotactile RF properties similar to those observed in area F4 (Iriki *et al.*, 2001; Obayashi *et al.*, 2000). Interestingly, as illustrated in Figure 2, the RFs of these units appear to increase over time as Japanese macaques learn to use rakes to extend their reach (Iriki *et al.*, 1996). Specifically, visual RFs that are normally in register with tactile RFs of the hand expand to encompass peripersonal space now occupied by the tool. This expansion is only observed when tools are actively used to accomplish a goal-directed action (food retrieval), and not when tools are merely held or when physically similar yet ineffective tools are manipulated. Learning to use tools is associated with increased expression of brain-derived neurotrophic factor within the anterior bank of the IPS, that may reflect neuronal remodeling via axonal sprouting (Ishibashi *et al.*, 2002). Some neurons in PF and AIP also exhibit plasticity with tool use, but the highest density of such cells is

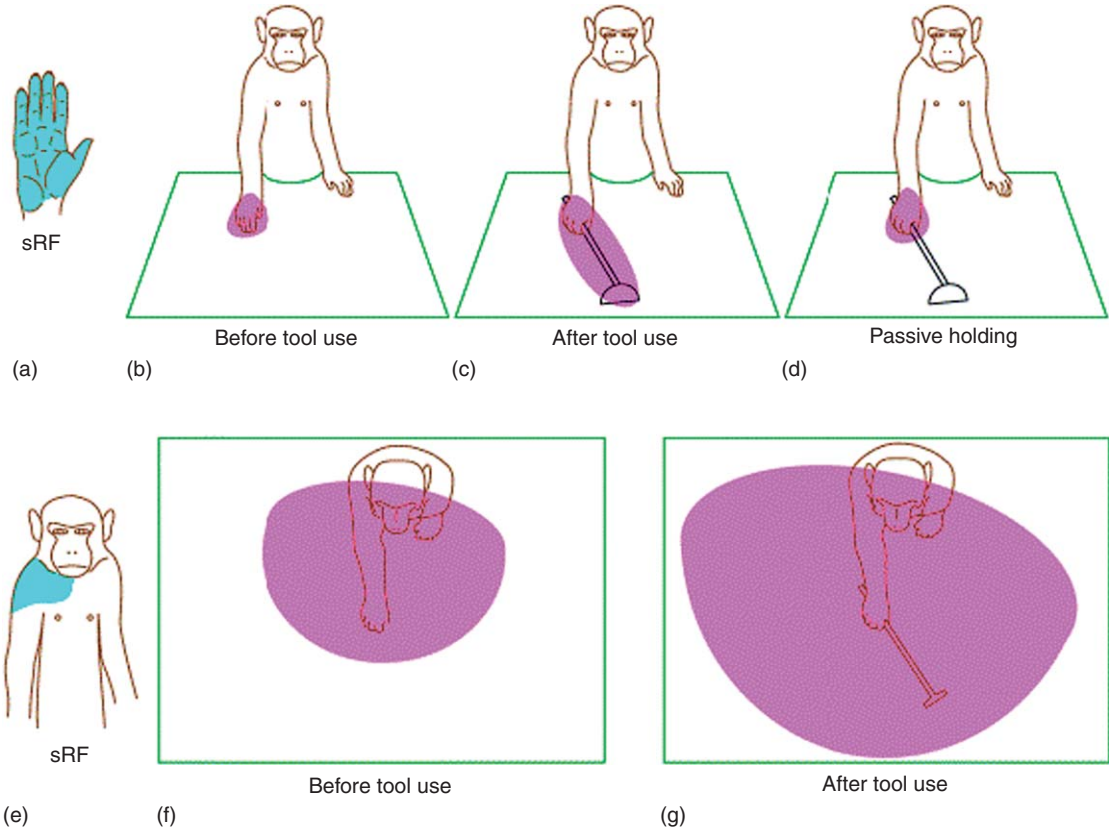

Figure 2 Experience-dependent changes in area VIP neurons with tool use. Distal-type neurons (top): Changes associated with extended tool use in the receptive field of a visuotactile neuron in area VIP that represents the distal forelimb. Proximal-type neurons (bottom): Changes associated with extended tool use in the receptive field of a visuotactile neuron in area VIP that represents the proximal forelimb. Reproduced from Maravita, A. and Iriki, A. 2004. Tools for the body (schema). *Trends Cogn. Sci.* 8, 79–86, Elsevier.

found on the other side of the IPS, i.e., roughly lateral (or anterior) to MIP including VIP and the fundus of the sulcus (Iriki, personal communication). A PET study reveals that performance of these simple tool use behaviors is accompanied by increased activity within a widely distributed network in the macaque brain including regions within v–d pathway (IPS and PMv), as well as basal ganglia, pre-supplementary motor area (pre-SMA), and cerebellum (Obayashi *et al.*, 2001).

Recent studies of humans with parietal lesions reveal behavioral effects that nicely complement the observations of expanded visuotactile hand representations with tool use in macaques (Farne and Ladavas, 2000; Maravita *et al.*, 2001; for a comprehensive review, see Maravita and Iriki, 2004). For instance, some patients suffering right parietal injuries demonstrate left hemineglect when performing a line bisection task positioned within reach. That is, they neglect portions of the line located to the left of fixation, biasing their estimates of center toward the right. However, when bisecting distant lines with a laser pointer they may perform normally. Importantly, when bisecting lines at a distance with a hand-held stick, one such patient again demonstrated neglect (Berti *et al.*, 2001). Similar to changes in the RF properties of IPS neurons in monkeys, use of a stick appears to cause distant space to be remapped as within reach, leading to neglect-related bias in performance. Likewise, there is kinematic evidence in healthy adults suggesting that the same motor representation may be involved in grasping with the fingers and grasping with a tool (Gentilucci *et al.*, 2004).

Results of an fMRI experiment with humans show that employing a set of tongs to extend one's grasp is associated with increased activity centered within the IPS (Inoue *et al.*, 2001). Curiously, these activations are ipsilateral rather than contralateral to the involved limb, as would be expected on the basis of macaque electrophysiology. Reasons for this pattern are uncertain and more work is necessary to determine the source. However, because the control condition involved performing the same grasping actions with the hand without a tool, it is possible that activations within the contralateral sensorimotor regions may have been eliminated during the subtractive comparison.

4.23.3 Human Specializations for Tool Use and Manual Gesture

Whether the explosion of tool use behaviors in hominids reflects the emergence of specialized brain mechanisms is an important and unresolved question. This seems probable for at least two reasons. First, human tool use differs in a variety of ways from that known to occur in nonhumans. Only hominids are known to fashion compound tools by joining together multiple parts and/or materials. Likewise, nonhominids do not appear to make one tool in order to create another (e.g., shaping a rock cutter to manufacture a wooden spear). This latter behavior has been taking place for a relatively long time; the available fossil record indicates that ancestral hominids were using rocks to manufacture stone-cutting implements for at least the past 2.5 million years (Ambrose, 2001). In contrast to other species in which tool use is typically found in specific subpopulations, tool use is a universal characteristic of all human cultures, and highly refined procedures for skillful use have co-evolved with complex tools, and are actively transmitted to successive generations.

Second, it is not possible to understand many complex forms of human tool use exclusively in terms of sensorimotor transformations (Johnson-Frey, 2003a; Johnson-Frey and Grafton, 2003). As is illustrated in Figure 3a, a variety of different postures can be used to achieve a stable grip that will enable an actor to grasp familiar tools stably for

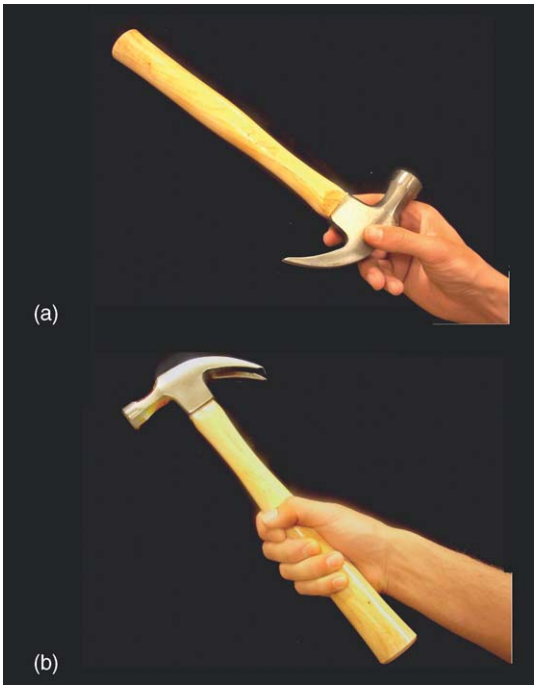

Figure 3 Different ways of grasping a familiar tool. a, The most stable way of gripping a hammer is at its perceived center of mass. b, However, effective use of a hammer requires adopting a less stable grip that is better suited to generating force when pounding. This latter grip depends on both perceived visual properties of the object and access to semantic knowledge.

purposes such as moving them from one location to another, handing them to another individual, or manipulating them. These solutions are clearly not suitable for using familiar tools to perform their ordinary functions, however. As shown in Figure 3b, grips appropriate for tool use frequently differ in nontrivial ways from those chosen solely on the basis of perceived structural information. In addition to mechanisms for online sensorimotor transformations, these actions are influenced by semantic knowledge of the objects' functional properties, the goals it can be used to accomplish, and the user's specific intentions on that occasion. The critical question for understanding these behaviors is how semantic knowledge interacts with and influences sensorimotor representations during the planning and performance of these skills (Johnson-Frey, 2003b). As detailed below, available evidence suggests that the human left cerebral hemisphere may be specialized for constructing representations of these meaningful actions (Johnson-Frey, 2004; Johnson-Frey *et al.*, 2005c; Lewis, 2006; Rumiati *et al.*, 2004).

The majority of what is known about the neural bases of skilled tool use in humans derives primarily from over a century of studies of apraxic patients who have difficulties with praxis skills that cannot be explained in terms of more elementary sensory or motor deficits. A review of this vast literature is well beyond the scope of this article. I will focus instead on findings from recent human neuroimaging studies that have attempted to delineate the neural substrates involved in planning and/or producing familiar tool use actions in the healthy brain.

4.23.3.1 Functional Neuroimaging Investigations of Human Tool Use

As summarized in a review (Johnson-Frey, 2004), the available data from functional neuroimaging studies have two points of convergence with the apraxia literature: First, while systems involved in sensorimotor control are organized in a largely contralateral fashion, the vast majority of evidence shows that mechanisms involved in representing familiar tool use actions are lateralized to the left cerebral hemisphere. Maximal lesion overlap in these patients is found in the left cerebral hemisphere in parietal regions (within and adjacent to the IPs, including angular and supramarginal gyri and ventral SPL) and/or the middle frontal gyrus (GFm) (Haaland *et al.*, 2000).

Second, within this left-lateralized system, mechanisms involved in representing conceptual knowledge about tools and their functions appear to be relatively independent yet interactive with those areas supporting the manual skills involved in their usage.

4.23.3.2 Conceptual-Level Representations

Functional neuroimaging studies show that naming tools selectively activates posterior-left middle temporal gyrus (MTG) (Martin *et al.*, 1996), an area that is also engaged when subjects generate action words (Martin *et al.*, 1995) or answer questions about tools (Chao *et al.*, 1999). Likewise, Damasio and colleagues report activation in this region when subjects identify actions or spatial relations performed with or without a tool (Damasio *et al.*, 2001). On the basis of its proximity to motion-processing centers (putative MT/MST) and its selectivity for manipulable versus nonmanipuable artifacts, it has been suggested that activations in left MTG may be involved in representing nonbiological motions associated with tool use (Heilman *et al.*, 1997; Chao *et al.*, 1999; Beauchamp *et al.*, 2002).

In addition to left posterior temporal cortex, functional neuroimaging studies consistently demonstrate that identification of tools and conceptualization of associated actions activate left frontal and anterior parietal areas. As introduced above, PMv is involved in visuomotor transformations for grasping and manipulating objects in both macaques (Rizzolatti *et al.*, 2002) and humans (Binkofski *et al.*, 1999). In the left hemisphere, this region is also activated when naming (Martin *et al.*, 1996; Chao and Martin, 2000) and viewing (Chao and Martin, 2000) tools, while a larger region including left GFm is activated when identifying the actions with which tools are associated (Grabowski *et al.*, 1998). Activations of left posterior parietal cortex (aIPS/supramarginal gyrus) are also frequently observed in association with these tasks (Martin *et al.*, 1996; Chao and Martin, 2000; Damasio *et al.*, 2001; Kellenbach *et al.*, 2003).

4.23.3.3 Production-Level Representations

In contrast to the sizable literature on conceptual-level action representations, relatively few studies have employed functional neuroimaging techniques to investigate mechanisms involved in organizing and/or producing tool use skills. When activations associated with complex yet meaningless finger and limb movements are removed, pantomiming tool use gestures with either hand activates left posterior parietal cortex in and around the IPS and dorsal lateral premotor cortex (Moll *et al.*, 2000). A similar pattern is also present when tool use pantomimes involving either hand are contrasted with repetitive

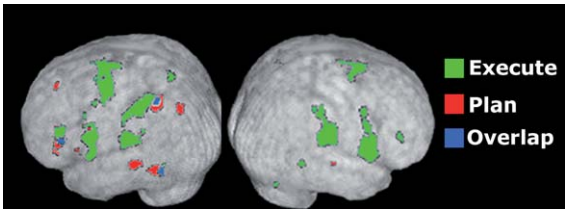

Figure 4 Human cortical regions associated with planning and executing tool use actions. When preparing to pantomime how familiar tools are used, areas of the left frontal, temporal, and parietal cortices are activated, regardless of the hand involved (red). During the execution of tool use pantomimes with either hand, additional regions of frontal and parietal cortex are engaged in both cerebral hemispheres (green). There is modest overlap between regions that are active during both planning and execution (blue). Reproduced from Johnson-Frey, S. H., Newman-Norlund, R., and Grafton, S. T. 2005a. A distributed left hemisphere network active during planning of everyday tool use skills. *Cereb. Cortex* 15, 681–695, by permission of Oxford University Press.

finger movements (Choi *et al.*, 2001), and when gestures are made as though the limb itself is the object (Ohgami *et al.*, 2004). A recent PET study of tool use pantomime found activations of left dorsolateral prefrontal cortex (DLFPC), inferior frontal cortex, and supramarginal gyrus when controlling for effects related to lexical and semantic processing (Rumiati *et al.*, 2004). Interestingly, none of these experiments observed activations in left GFm, as would be expected given the lesion analysis data introduced above. This is also true for results of two recent fMRI studies that used event-related designs to distinguish regions involved in planning (i.e., identifying, retrieving, and preparing actions associated with a familiar tool's usages) versus executing tool use gestures with the dominant right and nondominant left hands (Johnson-Frey *et al.*, 2005b). As illustrated in Figure 4, planning tool use actions for either limb activates a distributed network in the left cerebral hemisphere consisting of areas within the IPL (supramarginal and angular gyri) and frontal cortex (inferior frontal and ventral premotor cortices as well as DLFPC). These studies also detected activation during action planning within the ventral visual pathway (posterior superior temporal sulcus along with proximal regions of the MTG and superior temporal gyri). Involvement of these latter areas likely reflects activation of conceptual-level representations.

An important and unresolved question concerns whether these distributed cortical networks are specific to behaviors involving tools (i.e., transitive skills) or whether they are more generally involved in all manner of familiar skills, including those that do not involve objects (i.e., intransitive skills). In apraxia transitive gestures are often more substantially affected than intransitive gestures (Roy *et al.*, 1991; Rapcsak *et al.*, 1993) and both left and right brain-injured patients may show difficulties pantomiming and/or imitating intransitive actions (Heath *et al.*, 2001). There have been few studies investigating neural bases of familiar intransitive gestures to date, and unfortunately none that has directly contrasted familiar transitive and intransitive skills.

Although the focus has largely been on cortical contributions to skilled actions, both the apraxia (Pramstaller and Marsden, 1996; Hanna-Pladdy *et al.*, 2001) and neuroimaging literatures suggest involvement of subcortical structures. Imamizu and colleagues have demonstrated involvement of the posterior superior cerebellar fissure in learning to control computer mice with novel input–output mappings (Imamizu *et al.*, 2000, 2003).

4.23.4 Conclusions

In summary, results from studies of nonhuman primates indicate the existence of parallel parietofrontal networks involved in the organization and/or execution of prehensile behaviors. Functional neuroimaging studies suggest that aspects of this organization are preserved in the human brain. Findings in macaques demonstrate that use of a tool to extend reach induces an expansion of RFs within parietal visuotactile neurons. Specifically, representations of peripersonal space are remapped to include areas accessible with the tool. Along with complementary results in the human literature, these findings suggest that some forms of tool use may arise from relatively rapid, experience-dependent changes in existing sensorimotor circuits. More complex forms of tool use, that constitute a large potion of the human repertoire, demand input from semantic as well as sensorimotor representations, however. Data from apraxic patients and results of recent functional neuroimaging investigations of healthy adults converge on two points. First, the human left cerebral hemisphere is dominant for the representation of complex tool use actions. Second, although both are necessary for complex tool use behaviors, there appears to be a separation between conceptual and production-level representations.

The story of how complex manual actions are acquired and represented in the primate brain is only now beginning to unfold. Future efforts should be directed at identifying both the similarities in functional organization across primate species, as well as differences that may account for unique, species-specific behaviors.

E Disbrow, University of California, San Francisco, CA, USA and University of California, Davis, CA, USA

Glossary

3b	Brodmann's area 3b, synonymous with S1.
AIP	Anterior intraparietal area.
area 5	Brodmann's area 5.
area 7	Brodmann's area 7.
haptic shape perception	Tactile sampling of a shape.
LIP	Lateral intraparietal area.
MIP	Medial intraparietal area.
multimodal	Neurons that respond to more than one type of sensory stimulus.
PRR	Parietal reach region.
PV	Parietal ventral area.
retinotopy	An ordered representation of the visual field in areas of the visual cortex.
S1	Primary somatosensory area.
S2	Secondary somatosensory area.
saccade	Rapid eye movements resulting in fixation from one point in the visual field to another.
somatotopy	An ordered representation of the skin surface in areas of the somatosensory cortex.
VIP	Ventral intraparietal area.

4.24.1 Introduction

What distinguishes humans from other primates? The most common answer to this question is language. Humans have a unique ability to communicate, and the organization and connectivity of the human brain reflect this specialty (see Primate Brain Evolution in Phylogenetic Context). We would argue that of equal importance is humans' ability to manipulate their environment with their hands. We are unparalleled in our facility to shape and influence our surroundings. As with the special skills associated with language production and comprehension, the human brain has specific features of organization and connectivity underlying their remarkable manual abilities (see Neurological Specializations for Manual Gesture and Tool Use in Humans). One region involved with these abilities is the posterior parietal cortex.

The posterior parietal cortex consists of discrete areas that are proposed to perform different functions (Mountcastle *et al.*, 1975; Andersen *et al.*, 1997; Kalaska *et al.*, 1997; Snyder *et al.*, 1997; Graziano *et al.*, 2000; Gregoriou and Savaki, 2001). In macaque monkeys, the posterior parietal cortex has recently been subdivided into a number of cortical fields, including areas 5, 7 anterior intraparietal area (AIP), lateral intraparietal area (LIP), medial intraparietal area (MIP), ventral intraparietal area (VIP), and parietal reach region (PRR; Anderson *et al.*, 1997; Andersen and Buneo, 2002). Most studies of posterior parietal cortex in human and nonhuman primates examine its visual functions; however, this region also appears to be involved in visuospatial processing, including monitoring limb location during visually guided reaching (Mountcastle *et al.*, 1975; Lacquaniti *et al.*, 1995; Johnson *et al.*, 1996; Gregoriou and Savaki, 2001; Buneo *et al.*, 2002), and grasping (Taira *et al.*, 1990; Sakata *et al.*, 1995, 1998), converting sensory locations into motor coordinates for intentional movement (Andersen *et al.*, 1985; Battaglia-Mayer *et al.*, 2000), and perceiving the movements of the body in extrapersonal space (Andersen *et al.*, 1997; Snyder *et al.*, 1997). Further, the posterior parietal cortex is involved in saccadic eye movements (Colby *et al.*, 1996; Snyder *et al.*, 2000; see The Role of Vision in the Origin and Evolution of Primates), and the processing of visual and tactile shape and orientation information (Murata *et al.*, 2000; Taira *et al.*, 2000; Tsutsui *et al.*, 2001, 2002; see The Evolution of Sensory and

Motor Systems in Primates). There is also evidence that human posterior parietal cortex plays a role in shape perception (Faillenot *et al.*, 1997; Binkofski *et al.*, 1999a, 1999b; Kourtzi and Kanwisher, 2000; Amedi *et al.*, 2001; Bodegard *et al.*, 2001; Grefkes *et al.*, 2002). Thus, it appears that much of the region has evolved in primates as a consequence of, and for the generation of, specialized hand use.

While great strides have been made in understanding the organization and function of the posterior parietal cortex, there are difficulties associated with the study of this region. First, in the macaque monkey the designation of the location of various cortical fields is not consistent across laboratories (Cavada, 2001). Traditionally cortical fields are defined using several criteria. A cortical field is characterized by: (1) architectonic distinctiveness; (2) unique neural response properties; (3) unique connectivity; (4) a complete representation of the receptor surface; and (5) specific deficits after removal (Kaas, 1983). While criteria for defining a cortical field work well for primary fields such as 3b (S1) or S2 and parietal ventral (PV), they are not as useful for defining fields in the posterior parietal cortex. Traditional staining techniques are not adequate for distinguishing architectural boundaries of fields in posterior parietal cortex, and neural response properties are complex and often multimodal. Without clear anatomically defined borders, patterns of connectivity are difficult to determine, and fields appear to lack obvious visuo- or somatotopic organization, or even a complete representation of the receptor array (e.g., Colby and Duhamel, 1991).

These problems are compounded in humans by the striking anatomical differences between macaque monkey and human posterior parietal cortex. In the macaque, the intraparietal sulcus (IPS) is an easily identified relatively shallow sulcus just caudal to the central sulcus that runs in a mediolateral direction (Figure 1). In the human, the sulcal anatomy is quite different, with the bulk of the IPS running in a rostrocaudal direction, often with additional sulci in this region. While attempts have been made to draw parallels between work in macaques and humans (see Culham and Kanwisher, 2001, for review), comparisons are tentative at best. Further, human hand use diverges dramatically from that of macaque monkey hand use. Thus, the second difficulty in determining the organization and function of this region in humans comes from the lack of an animal model.

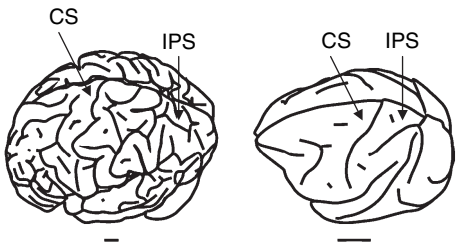

Figure 1 Comparison of human (left) and macaque brains. Note the complexity of the region surrounding the IPS. CS, central sulcus. Scale bars: 1 cm.

4.24.2 Posterior Parietal Area 5

Because of the difficulties associated with identifying particular posterior parietal cortical fields in humans, we began our studies of this region by examining area 5. Several consistent features of area 5 have emerged from the monkey literature regarding its organization and receptive field characteristics. Area 5 is dominated by the representation of the hand and forelimb; neurons in area 5 have contralateral, ipsilateral, and bilateral receptive fields (particularly on the hand and forelimb), and most neurons respond to stimulation of deep receptors of the skin and joints (Mountcastle *et al.*, 1975; Pons *et al.*, 1985; Iwamura *et al.*, 1994, 2002; Taoka *et al.*, 1998, 2000; Iwamura, 2000). Single-unit studies in macaque monkeys indicate that area 5 is involved in intention of movement (Snyder *et al.*, 1997; Debowy *et al.*, 2001), and the generation of body or shoulder rather than eye-centered coordinates for reaching (Ferraina and Bianchi, 1994; Lacquaniti *et al.*, 1995; see Wise *et al.*, 1997, for review). While this field has traditionally been considered a somatosensory area, our work in human (Disbrow *et al.*, 2001) and nonhuman (Padberg *et al.*, 2004, 2005) primates indicates that neurons in area 5 respond to visual stimulation as well.

In our study of titi monkeys we used multiunit electrophysiological recording techniques in an anesthetized preparation to make several interesting observations about area 5 and the surrounding cortex (Padberg *et al.*, 2005). First, the field was dominated by the representation of the hand and forelimb. Second, neurons in area 5 respond to both deep somatic and visual stimulation. Finally, unlike anterior somatosensory fields in which the hand representation is mostly acallosal (Killackey *et al.*, 1983), area 5 receives interhemispheric input in the expected location of the hand representation. Dense label was also observed in area 7, S2/PV, and moderate label was observed in motor, premotor, extrastriate, and cingulate cortex.

Similarly, in preliminary studies of macaque monkeys, we examined responses to somatosensory and visual stimulation in area 5. As in the titi monkey we found that this region was dominated by a somatosensory representation of the hand and forelimb, and

that neurons at several sites within this representation also responded to visual stimulation (Figure 2). Injections placed into the forelimb representation of area 5 revealed connections with anterior parietal and lateral somatosensory areas, additional regions of posterior parietal cortex, as well as M1, supplementary motor area (SMA), and anterior cingulate (Figure 3). These mapping and connectional data indicate that area 5 is involved in integrating visual and somatosensory inputs specifically relating to the hand, and may be generating a motor output for visually guided reaching behaviors.

Based on these findings, we designed a simple functional magnetic resonance imaging (fMRI) experiment to identify area 5 in humans (Disbrow *et al.*, 2001). Stimuli were a moving tactile stimulus applied to the hand, foot, or face, and a visual flow field. Tactile and visual stimuli were presented both individually and simultaneously. When stimuli were presented individually, only primary fields were active; however, simultaneous presentation of visual and tactile stimulation resulted in activation of cortex caudal to anterior parietal somatosensory fields (Figure 4). This field, which we called area 5, was roughly somatotopically organized, and dominated by the hand representation as in the macaque monkey. We used this field as a landmark, and extended our examination of posterior parietal cortex to include more complex stimuli.

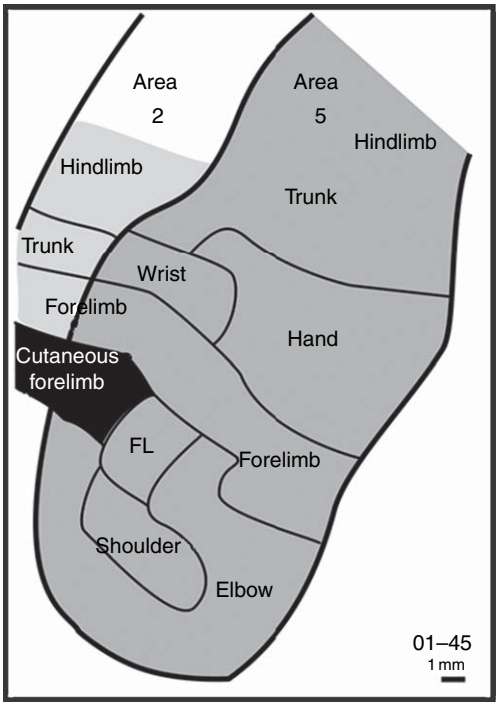

Figure 2 Summary of an electrophysiological map. Area 2 was observed to contain neurons that responded to stimulation of deep receptors, and a zone of cortex containing neurons that responded to cutaneous somatosensory stimulation was observed within both areas 2 and 5. Neurons across a large extent of area 5 were observed to respond to stimulation of deep receptors of the hand and forelimb (FL). Additionally, many of the sites surveyed in area 5 were observed to contain neurons that responded to both deep somatosensory and visual stimulation. Adapted from Disbrow, E. A., Murray, S. O., Roberts, T. P., Litinas, E. D., and Krubitzer, L. A. 2001. Sensory integration in human posterior parietal area 5. *Soc. Neurosci. Abstr.* 511.26.

4.24.3 Effector Specific Network

In posterior parietal cortex cortical field organization based on somatotopy or retinotopy is inadequate. However, there is emerging evidence from studies of the macaque monkey that cortex is organized based on effector – the part of the body performing a movement (for review, see Andersen and Buneo, 2002). In order to identify areas of posterior parietal cortex selective for movements of the eyes, arms, and hands, the same group of subjects also performed a

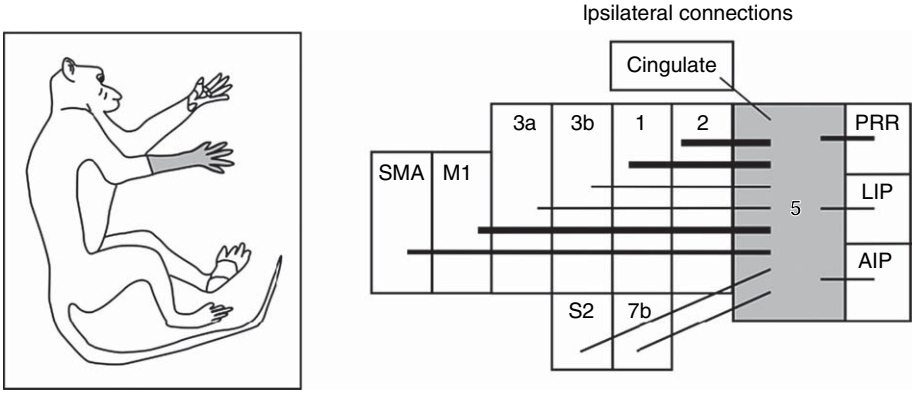

Figure 3 A summary of connections in case 01–45 resulting from injections in the distal forelimb representation in area 5. Labeled cells resulting from injections in area 5 were widespread and were found to be very dense in areas M1, 1, and 2. The PRR and SMA were observed to have dense label. Areas 3a, 3b, anterior cingulate cortex, S2, 7b, and extrastriate cortex, including LIP and AIP, were observed to have moderate label.

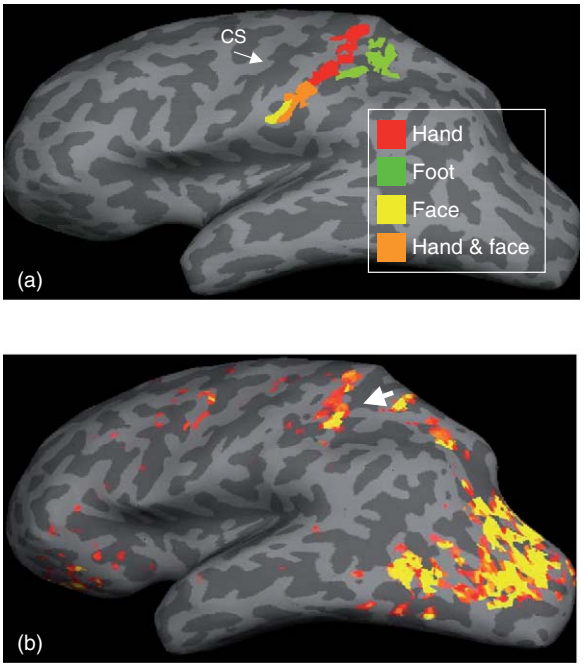

Figure 4 Human area 5. a, Area 5 was only active during a combination of visual and tactile stimulation. Activation from tactile stimulation alone was rostral to area 5 on the central sulcus (CS: arrow) and is not shown in this figure. Area 5 was roughly somatotopically organized, dominated by the representation of the hand (red and orange) as in other primates. b, Activation from a single subject performing a visually guided reaching and grasping task, contrasted with a motor control (eyes closed). Note the late activation in the hand representation of area 5 (arrow), as defined in (a). Visual cortex is active because subjects closed their eyes in the control but not the reaching condition. Adding a visual control reduced the volume of area 5 activation (not shown). Images are displayed on inflated brains (rostral is to the right). Dark gray indicates the location of sulci.

saccade task, a visually guided reaching task, and a haptic shape discrimination task (Disbrow *et al.*, 2001; Hinkley *et al.*, 2004). We hoped to identify a network involved in visually locating an object in space, reaching for and grasping that object, and manually exploring it.

First, we identified a group of cortical fields active during saccadic eye movements. The LIP region is believed to be involved in converting retinotopic visual information to coordinates for oculomotor intention (Mazzoni *et al.*, 1996). Along with LIP, areas of cortex more active during saccades in our subjects also included bilateral regions along the upper bank of the mid-IPS, extending caudally to the parieto-occipital sulcus (Figure 5). We believe that this pattern of activation corresponds to saccade-specific regions identified in monkeys (Duhamel *et al.*, 1992), and its location on a normalized Talairach atlas matches those identified in other human fMRI studies examining the preparation of saccadic eye movements (Connolly *et al.*, 2002; Sereno *et al.*, 2001) in retinotopic space.

Next, we identified fields active during the guidance of a hand toward a visual target. In the macaque monkey the PRR consists of a number of different areas (Snyder *et al.*, 1997), including regions along the MIP portions of area 5 and cortex along the medial wall (7 m, Caminiti *et al.*, 1999). From our human fMRI study, areas more active when subjects are performing a visually-guided reach versus a motor control include cortex within the postcentral sulcus, and cortex along the upper bank of the IPS extending on to the superior parietal lobe at its junction with the parieto-occipital sulcus (Figure 5). Thus we saw unique activation within the PRR region, as well as overlap with activation observed during saccadic eye movements (Table 1).

During conditions where subjects were instructed to manipulate a plastic shape (haptic discrimination task) versus a nonshape (clay), the junction of the postcentral sulcus and lower bank of the IPS were bilaterally active, in a region of cortex other investigators have labeled as human AIP (Binkofski *et al.*, 1998; Culham *et al.*, 2003). In these human fMRI studies, this portion of posterior parietal cortex is more active during object exploration and identification. In macaque monkeys, neurons in the anterior regions of the IPS (AIP) are more active prior to the formation of the hand to interact with the shape of a given object (Sakata *et al.*, 1998) and are found to be selective for the visual and kinesthetic (motor) information from a specific shape (Murata *et al.*, 2000). In addition to AIP, the medial portion of the superior parietal lobe was also active bilaterally. This region of human cortex is also active during the discrimination of the three-dimensional features of an object based on both visual and somatosensory information (Shikata *et al.*, 2003). Similar areas in macaque monkey cortex caudal to AIP (a caudal intraparietal area; Shikata *et al.*, 1996 or posterior intraparietal area; Colby *et al.*, 1988) respond selectively to the orientation of a surface in three dimensions for visual stimuli (Taira *et al.*, 2000). This information is then transferred to anterior intraparietal fields, in order to guide the formation of the hand around an object, a process known as prehension (Gardner, 1998).

4.24.4 The Evolution of Posterior Parietal Cortex

Primates are unique in that they have an expanded posterior parietal cortex compared to other mammals, and our data support the contention that primate brain size and complexity increase in proportion to the ratio of brain to body size, for example, from Old World monkeys to humans (Kaas, 2004). Although the

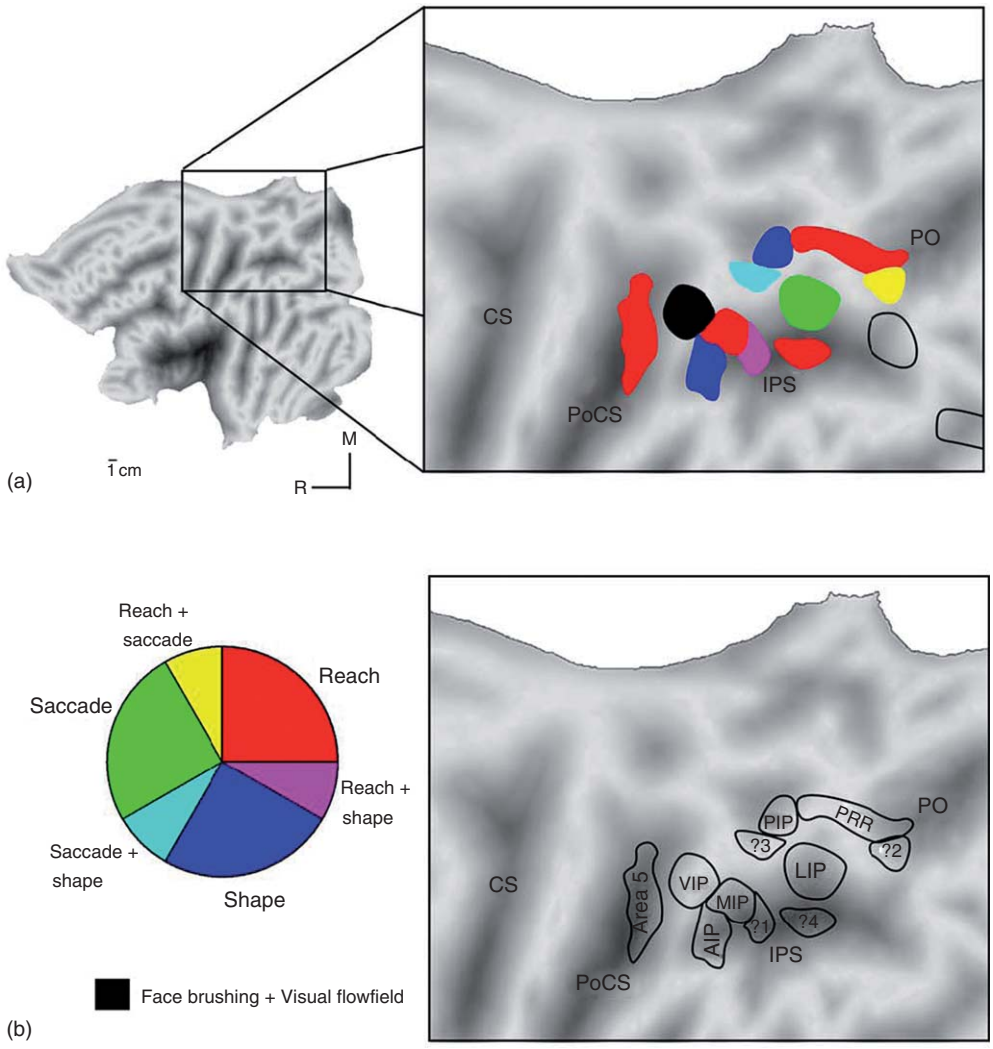

Figure 5 a, Schematic of a group analysis of data from 12 subjects on a flattened brain. Data from three stimulus conditions are overlayed (inset): (1) saccadic eye movements vs. fixation; (2) visually guided reaching and grasping vs. motor control; and (3) haptic exploration of object shape vs. manipulation of clay. b, Location of putative homologues of several cortical fields described in the macaque monkey. Note that there are four areas of activation that do not correspond in location or activation pattern to any field described in the macaque.

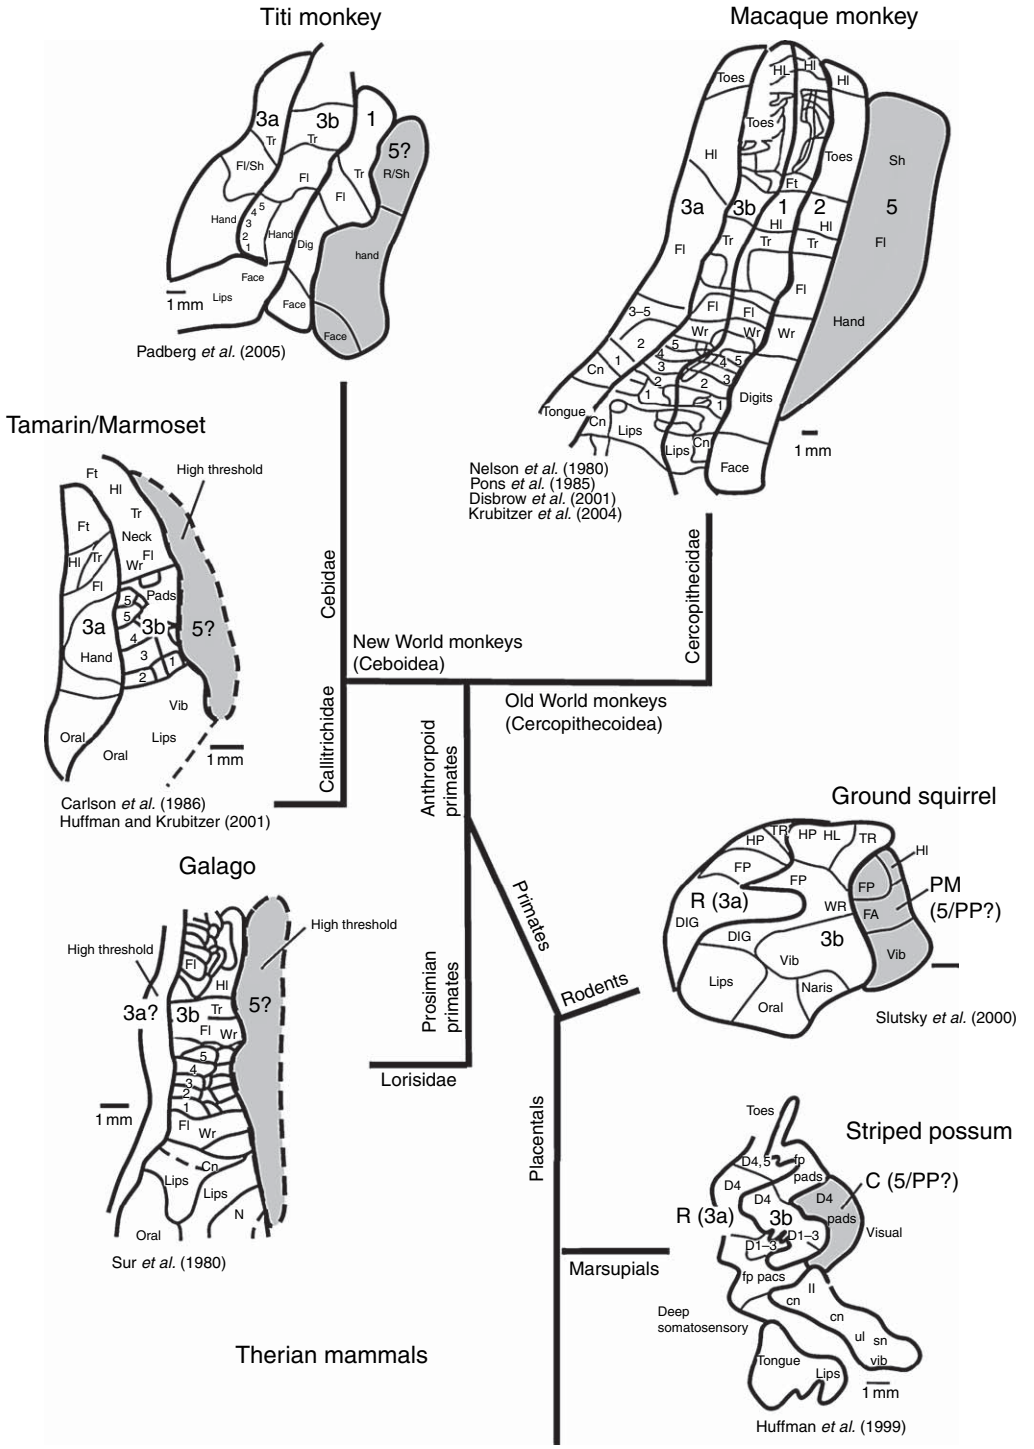

Figure 6 A simplified cladogram depicting the phylogenetic relationship of primates and other mammals, and the organization of anterior and posterior parietal cortex in several species. Comparative data from these and other mammals indicate that early therian mammals possessed a primary somatosensory area (3b or S1), a rostral field (3a or R), and a caudal area (5 or PP, gray). Some species such as simian primates have evolved a low-threshold cutaneous (or deep) representation just caudal to 3b, termed area 1. Since area 1 has not been identified in other mammals, or even in prosimian primates, it is likely that area 1 evolved after the simian and prosimian divergence. Area 2 has only been identified in macaque monkeys. Comparisons across mammals indicate that areas 3a, 3b, and 5 are evolutionarily old fields, and that new, unimodal somatosensory fields such as areas 1 and 2 evolved later in some lineages, and are interspersed between existing fields (i.e., are not added hierarchically). We propose that areas 1 and 2 evolved with the modified morphology of the hand in anthropoid primates, and that older, retained fields, such as area 5, were modified both functionally and connectionally for sophisticated hand use. Phylogenetic relationships come from Murphy *et al.* (2001) and Eisenberg (1981). Cortical organization of different species depicted here is modified from studies listed for each species. Adapted from Padberg, J., Disbrow, E., and Krubitzer, L. 2005. The organization and connections of anterior and posterior parietal cortex in titi monkeys: Do New World monkeys have an area 2? *Cereb. Cortex* 15(12): 1938–1963.

relative locations of the functionally defined areas on the human cortical sheet are similar to the patterns seen in the macaque, additional regions in parietal cortex are active outside our putative homologues and are likely specializations of human neocortex (Figure 5). Unique areas of human posterior parietal cortex have also been described using visual stimuli (Vanduffel *et al.*, 2002).

The relationship to the macaque data can be determined through patterns of overlap of activation as well. For example, at the caudal end of the superior parietal lobe, reach-selective and saccade-selective areas of activation exhibit a degree of overlap similar to the border between PRR and LIP in the macaque monkey (Calton *et al.*, 2002). Conversely, unique patterns of overlap in our data set which do not fit existing macaque literature might represent regions of cortex independently derived in humans. For example, a region of the lateral portion of the superior parietal lobe was active during both saccadic eye movements and haptic shape exploration – a pattern which has not been described in macaques. While we leave open the possibility that such an area selective for both complex movements of the hands and eyes has yet to be identified in nonhuman primates, such novel regions might provide the neural substrate for higher-order functions that would require fast sensorimotor transforms, such as eye–hand coordination.

In contrast, a region resembling area 5, in which neurons respond to deep somatic stimulation and often visual stimulation, has been identified in a variety of mammals (Figure 6), such as squirrels (Slutsky *et al.*, 2000), insectivores (Krubitzer *et al.*, 1997), and marsupials such as the striped possum (Huffman *et al.*, 1999) and the flying fox (Krubitzer and Calford, 1992), as well as New and Old World monkeys and humans. Thus, area 5 appears to be part of a common plan of organization in all primates, and in all mammals, and were interleaved between area 5 and V3a in the human. These new areas may be related to the evolution of the hand and complex cortical processing networks associated with hand use.

While area 5 may be a retained or homologous field in mammals, the addition of new areas and new connections likely promotes new functions of retained cortical fields. Our work in the macaque and titi monkey indicates that area 5 has a unique pattern of connections providing the anatomical substrate for its role in the motor aspects of visually guided reaching, the motivational state of reaching, as well as its role in intermanual transfer of information across hemispheres necessary for bilateral coordination of the hands (Padberg *et al.*, 2004, 2005). Thus, area 5 in squirrels and flying foxes may be homologous to area 5 in primates, but not strictly analogous. Indeed, much like the magnification of behaviorally relevant body parts in area 3b, in area 5 these representations and associated functions appear to magnify to the extreme in particular lineages. In primates, the hand representation dominates area 5 and much of posterior parietal cortex appears to be specialized for hand use.

4.25 Premotor Cortex and the Mirror Neuron Hypothesis for the Evolution of Language

M A Arbib, University of Southern California, Los Angeles, CA, USA

Glossary

language-ready brain	A species (only humans, as far as we know) has a language-ready brain if it equips infants of the species to learn languages akin to that of modern humans; it is controversial whether such a brain includes an innate specification of general structures of syntax.
mirror neuron	A neuron active during both the execution of an action and the observation of a similar action.
mirror system	A neural region active during both the execution of a class of actions and the observation of actions from that class. Note that a mirror system need not contain mirror neurons, though it is generally assumed that it will.
parity property of communication	The meaning of a message intended by the sender is approximately the meaning extracted from the message by the receiver.
protolanguage	A hypothetical form of communication employed by hominids before they had language in its modern sense; unlike the vocalizations of nonhuman primates, it supported the open-ended creation of new symbols but did not employ the syntax and compositional semantics of full human languages.

4.25.1 Parity and the Language-Ready Brain

Any normal human child reared in a modern human society will acquire language. In this sense, the human brain and body is language-ready in a way in which the brains of other species are not. Some would argue that the basic structures of language must be innate, forming a universal grammar encoded in the human genome, so that the child need simply hear a few sentences to set the parameter for each key feature of the grammar of his first language. Against this, others have argued that the modern child has both a rich set of language stimuli linked to action and perception and powerful learning mechanisms, so that the child can learn these key features of the grammar from its social interactions. Of course, this is consistent with the view that the different experiences of a modern human and early *Homo sapiens* means that developmental self-organization will yield adult brains of somewhat different structure.

The parity requirement for language in humans – that what counts for the speaker must count approximately the same for the hearer – roots language (and communication more generally) in a social context in which speaker and hearer are motivated to communicate with each other. Since normal face-to-face speech involves manual and facial as well as vocal gestures, and because signed languages are fully developed human languages, the speaker and hearer may use hand and face gestures rather than vocal gestures. This motivates a study of the evolution of the language-ready brain not restricted to speech mechanisms (see The Evolution of Language Systems in the Human Brain).

4.25.2 The Original Mirror System Hypothesis

The system of the macaque brain for visuomotor control of grasping has its premotor outpost in an area called F5 (see Figure 1, left), which contains a

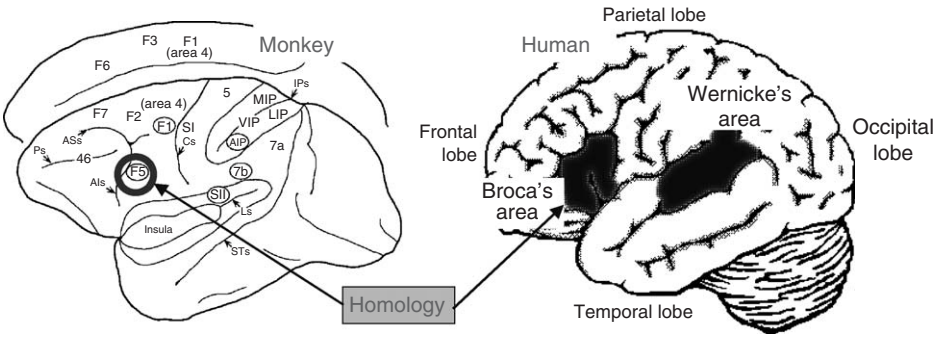

Figure 1 A comparative side view of the monkey brain (left) and human brain (right), not to scale. The left view emphasizes premotor area F5; the right view emphasizes Broca's area and Wernicke's area, considered crucial for language processing. F5 and Broca's area are considered homologous.

set of neurons, called mirror neurons, such that each mirror neuron is active not only when the monkey executes a specific grasp, but also when the monkey observes a human or other monkey execute a more or less similar grasp (Rizzolatti *et al.*, 1996). Thus, macaque F5 contains a mirror system for grasping that employs a common neural code for executed and observed manual actions. The homologous region of the human brain is in or near Broca's area (the posterior part of the inferior frontal gyrus; Figure 1), traditionally thought of as a speech area, but which has been shown by brain imaging studies to be active when humans both execute and observe grasps. It is posited that the mirror system for grasping was also present in the common ancestor of humans and monkeys (perhaps 20 Mya) and that of humans and chimpanzees (perhaps 5 Mya). These findings ground the mirror system hypothesis (MSH; Rizzolatti and Arbib, 1998): the parity requirement for language in humans is met because Broca's area evolved atop the mirror system for grasping which provides the capacity to generate and recognize a set of actions.

Rizzolatti and Arbib posited three stages in the evolutionary progression:

- *R&A1*. Use of the mirror system for recognizing praxic grasping actions of others.
- *R&A2*. Extension of the mirror system to allow the generation and recognition of manual gestures to serve an open system of communication, yielding a proto-Broca's area.
- *R&A3*. Collateralization to allow the system to incorporate vocal as well as manual gestures, yielding a true Broca's area.

Barrett *et al.* (2005) summarize functional and structural evidence supporting differential localization of mechanisms for limb praxis, speech and language, and emotional communication, showing further that in most humans, the left hemisphere may be dominant in the control of vocalization associated with propositional speech, but the right hemisphere often controls vocalization associated with emotional prosody. Such data must be taken into account in refining the MSH, but in no way contradict it. As general principles of cortical evolution, one may state that increasing complexity of behavior is paralleled by increases in the overall size and number of functional subdivisions of neocortex and the complexity of internal organization of the subdivisions, and reduplication of circuitry may form the basis for differential evolution of copies of a given system, with differing connectivities to serve a variety of functions (Kaas, 1993; Striedter, 2004).

Recent work (see Arbib, 2005, for a review and commentaries on current controversies) has elaborated the MSH in two main ways: by refining the above three stages and by extending the anatomy of the mirror system. We consider these in turn.

4.25.3 Elaborating the Stages for the MSH

Arbib (2005) extended the evolutionary progression from three to seven stages:

- *S1*. Cortical control of hand movements.
- *S2*. A mirror system for grasping shared with the common ancestor of human and monkey.
- *S3*. A simple imitation system for grasping shared with common ancestor of human and chimpanzee.
- *S4*. A complex imitation system for grasping.
- *S5*. Protosign, a manual-based communication system, breaking through the fixed repertoire of primate vocalizations to yield an open repertoire.
- *S6*. Protospeech, resulting as protosign mechanisms evolved to control a vocal apparatus of increasing flexibility.
- *S7*. Language – the development of syntax and compositional semantics.

The argument for the transitions from S2 to S3 and on to S4, and their suggested timing, is given by:

1. The claim (Visalberghi and Fragaszy, 2002) that imitation plays a major role in learning by human children and a very limited role, if any (the topic is open to debate), in social learning in monkeys.
2. The observation (Myowa-Yamakoshi and Matsuzawa, 1999) that in a laboratory setting, chimpanzees typically took 12 trials to learn to 'imitate' a behavior, and in doing so paid more attention to where the manipulated object was being directed, rather than the actual movements of the demonstrator.
3. Humans, however, are capable of complex imitation. This has two parts: the ability to perceive that a novel action may be approximated by a composite of known actions associated with appropriate subgoals and the ability to employ this perception to perform an approximation to the observed action, which may then be refined through practice.

The transition from S4 to S5 is argued to involve two components:

1. The transition from the use of hand movements for praxis to their use for pantomime, with communication being the primary and intended effect of an action rather than a side effect. A grasping movement that is not directed toward a suitable object will not elicit mirror neuron firing in macaque (Umiltá *et al.*, 2001). By contrast, in pantomime, the observer sees the movement in isolation and infers what nonhand movement is being mimicked by the hand movement, and thus the goal of the action. The transition to pantomime does seem to involve a genuine neurological change.
2. The use of conventional gestures to disambiguate pantomime. This may also require further neurological change.

The power of pantomime is that it provides open-ended communication that works without prior instruction or convention (Stokoe, 2001). However, even signs of modern signed language that resemble pantomimes are conventionalized and are thus distinct from pantomimes. Pantomime *per se* is not a form of protolanguage; rather, it provides a rich scaffolding for the emergence of protosign, a manual-based communication system that broke through the fixed repertoire of primate vocalizations to yield an open repertoire of communicative gestures.

It is not claimed that S5 (protosign) was completed before S6 (protospeech) or that protosign attained the status of a full language prior to the emergence of early forms of protospeech. Rather, once hominids had come to employ pantomime and discovered how to use conventional gestures to increasingly augment, ritualize, and in some part replace the use of pantomime, then S6 followed naturally as vocal gestures entered the mix.

MSH implies that the role of F5 in grounding the evolution of a protolanguage system would work just as well if our ancestors had been deaf. However, primates do have a rich auditory system (Ghazanfar and Santos, 2004). The protolanguage perception system could thus build upon the existing auditory mechanisms in the move to derive protospeech. However, it appears that considerable evolution was needed to yield a vocal-motor system able to accommodate an ever-expanding protospeech vocabulary.

The final stage, S7 – the transition from protolanguage to language – is claimed to involve little if any biological evolution, but instead to result from cultural evolution (historical change) in *H. sapiens*. Pinker and Bloom (1990) espouse the view that universal grammar is innate, and argue for its possible evolution through multiple stages, but their definition of universal grammar is incomplete, and some of their stages seem as amenable to cultural as to biological evolution. Nonetheless, the debate over the nature of protolanguage and thus of what constituted the transition to language remains hotly contested.

4.25.4 Extending the Anatomy of the Mirror System

4.25.4.1 Multimodal Mirror Neurons

A particularly controversial aspect of MSH is that it sees protosign, based on the recognition of hand actions, as providing crucial scaffolding for speech. Many would argue that the vocalization system of nonhuman primates provided the complete basis for the evolution of the language-ready brain. The debate is still very much open, but here are some relevant data.

It has been found that macaque F5 mirror neurons are not limited to visual recognition of hand movements. Kohler *et al.* (2002) studied mirror neurons for actions that are accompanied by characteristic sounds (e.g., breaking a peanut in half), and found that a subset of these are activated by the sound of the action as well as sight of the action. However, monkeys do not use their vocal apparatus to mimic the sounds they have heard, thus weakening any case that these neurons might serve vocal

communication but demonstrating that mirror neurons do receive auditory input that could be relevant to the protosign–protospeech transition.

Ferrari *et al.* (2003) studied orofacial motor neurons in F5 and showed that about one-third of them also discharge when the monkey observes another individual performing mouth actions. The majority of these mouth mirror neurons become active during the execution and observation of ingestive actions. However, there are other neurons active during the execution of ingestive actions for which the most effective visual stimuli in triggering them are communicative mouth gestures – one action becomes associated with a whole performance of which one part involves similar movements. The observed communicative actions for such neurons include lip-smacking, lip protrusion, tongue protrusion, teeth-chatter and lips and tongue protrusion – all a long way from the sort of vocalizations that occur in speech.

Of course, these observations do not address the issue of whether the changes that molded F5 for the language-ready brain were driven by a multimodal system for coordinated control of manual and orofacial movements or by changes focused on the vocalization system itself, perhaps even by interactions between the two. Further analysis must address data on comparative analysis of neural pathways underlying vocal control (Jürgens, 2002). Human speech needs input from the ventral premotor and prefrontal cortex, including Broca's area, for motor planning of longer purposeful utterances, as well as input from the supplementary motor area (SMA) and pre-SMA, which give rise to the motor commands executed by the motor cortex. The crucial fact for evolutionary analysis is that SMA has been found to produce vocalization only in humans, not in other mammals. The anterior cingulate gyrus (ACG), in contrast, produces vocalization in non-human mammals, such as the rhesus monkey, squirrel monkey, cat, and bat, but not in humans. Jürgens (2002) argues that this difference in cortical representation might reflect the far greater role that motor learning plays in the vocal behavior of humans as compared to other mammals.

In humans, lesions that invade ACG as well as SMA and/or pre-SMA usually yield initial akinetic mutism followed eventually by transcortical motor aphasia – the patient can again produce well-articulated, grammatically correct sentences but makes very few spontaneous utterances, and cannot provide emotional intonations (Jürgens and von Cramon, 1982). This reminds us that MSH addresses the parity problem – how meaning may be shared between speaker and hearer – but not the problem of what motivates the speaker to say something, and the hearer to listen. It would seem that the anterior cingulate cortex (ACC) plays here the crucial motivational role. Paus (2001) makes it clear that ACC involves many areas and that these have differential involvement in motor, cognitive, and affective functions. In any case, the roles of ACC appears to be complementary to that of the F5–SMA–pre-SMA system and its parietal extension, to which we now turn.

4.25.4.2 Bringing in the Parietal and Temporal Lobes

4.25.4.2.1 A broader view of the macaque mirror system We now look at data implicating parietal areas in the mirror system of macaque. We distinguish the mirror neurons of macaque F5 from the canonical neurons of F5, which are active when the monkey itself performs a grasp but not when the monkey observes that grasp performed by another. The populations of canonical and mirror neurons appear to be spatially segregated in F5 (Rizzolatti and Luppino, 2001). Both sectors receive a strong input from the secondary somatosensory area (SII) and parietal area PF (Brodmann area 7b). In addition, canonical neurons are the selective target of the anterior intraparietal sulcus (AIP). Perrett *et al.* (1990) and Carey *et al.* (1997) found that STSa, in the rostral part of the superior temporal sulcus (STS), has neurons that discharge when the monkey observes such biological actions as walking, turning the head, bending the torso, and moving the arms. Moreover, some of these neurons discharged when the monkey observed goal-directed hand movements, such as grasping objects (Perrett *et al.*, 1990) – though STSa neurons do not seem to discharge during movement execution as distinct from observation. STSa and F5 may be indirectly connected via the inferior parietal area PF (Matelli *et al.*, 1986). About 40% of the visually responsive neurons in PF are active for observation of actions such as holding, placing, reaching, grasping, and bimanual interaction. Moreover, most of these action observation neurons were also active during the execution of actions similar to those for which they were observers, and were thus called PF mirror neurons (Fogassi *et al.*, 1998).

Computational modeling has explored some interactions observed experimentally and hypothesized others to make the system work. The FARS model (Fagg and Arbib, 1998) shows how prefrontal cortex may modulate AIP–F5 interactions in action selection through task-related analysis of object identity by the 'what' path of inferotemporal (IT) cortex, through

working memory, and through selection cues in conditional tasks. The MNS model (Oztop and Arbib, 2002) shows how STS and PF inputs may be associated with activity in F5 canonical neurons to train F5 mirror neurons so that they can respond to data on the actions of others and not just during action execution. These models challenge us to further anatomical and neurophysiological analysis of the macaque, to 'lift' these models to the human brain, to extend the resulting models to models of language performance, and then test the result in part through more rigorous analysis of macaque–human homologies (Arbib and Bota, 2003).

4.25.4.2.2 Imaging the language-performing brain Jürgens (2002) reviewed human imaging studies, showing that spoken utterance of a single word involves activation of the sensorimotor cortex, SMA, insula, and temporal cortex, but that utterance of a longer sequence of syllables or words involves the additional activation of the inferior parietal cortex and Broca's area. However, lesions of Broca's area alone do not cause Broca's aphasia for more than a few days (Levine and Sweet, 1982) but do cause a persistent reduction in verbal fluency. Imaging studies have demonstrated that Broca's area has the mirrorish property of being active not only during production of speech, but also during listening to speech (Price *et al.*, 1996).

Lesions in the inferior parietal cortex also affect speech, yielding phonemic substitutions (paraphasia) and neologisms (Cappa *et al.*, 1981). Electrical stimulation of the inferior parietal cortex during ongoing speech interrupts speech or causes phonemic errors. On this basis, Jürgens (2002) suggests that inferior parietal cortex employs proprioceptive feedback information from the articulatory organs to transform word representations stored in Wernicke's area into commands that can be used by the motor cortex to control verbal articulation.

4.25.4.2.3 The riddle of Wernicke's area Given that the F5 mirror neurons are part of a larger network that includes parietal and temporal cortex, one must consider the extension to MSH to include the hypothesis that the evolutionary changes that lifted the ancestral F5 homologue to yield human Broca's area also lifted other regions to yield Wernicke's area and other areas that support language in the human brain. Arbib and Bota (2003) sought to integrate MSH with the account of Aboitiz and García (1997) in expanding the account of relevant macaque–human homologies. Aboitiz and García (1997) hypothesize that multimodal concepts in Wernicke's area are mapped into phonological sequences as follows: the system of long temporoparietal–prefrontal connections serves to integrate sensory and mnemonic information from the temporoparietal lobes with the organization of behavior, both short and long term, by the frontal systems. They further hypothesize that selective pressure to learn complex vocalizations through imitation and repeated practice was a key aspect in establishing a phonological working memory system. On this view, a prefrontal system in which information from other sensory modalities was integrated and coordinated with the representation of complex vocalizations was developed concomitantly.

Since frontal projections from macaque area Tpt (≈human Wernicke's region) do not terminate massively in macaque areas 44–45 (≈human Broca's area), Aboitiz and García (1997) propose that in human evolution, area Tpt may have become increasingly connected with inferoparietal regions such as the supramarginal gyrus (area 40), thus feeding the latter with auditory information to be used in the phonological loop. Some neurons in area 40 may then project to Broca's region, thus establishing a neuronal circuit for the phonological-rehearsal system. However, macaque data suggest the importance of an alternative route for auditory input from temporal cortex to Broca's area. The anterior superior temporal (aST) region, just caudal to Tpt, projects to the inferior frontal gyrus (IFG) and other parts of the ventrolateral prefrontal cortex (VLPFC). Together, aST and IFG seem to form a 'what' stream for the recognition of auditory objects (Rauschecker, 1998; Romanski *et al.*, 1999), perhaps related to the role of IT cortex in visual object identification mentioned earlier for the FARS model. Moreover, neurons in macaque aST are quite selective for species-specific vocalizations. Rauschecker (2005) argues that aST in nonhuman primates is a precursor of the same region in humans and that nonhuman primate vocalizations are an evolutionary precursor to human speech sounds. However, recognizing speech sounds is just one small component of being language-ready. It is quite consistent with MSH that as protospeech spirally evolves with protosign, it would co-opt available resources rather than invent a new periphery. Following Rauschecker (2005), one might view the projection from aST to IFG via the uncinate fascicle as serving a similar role for auditory objects to that served by IT cortex for the visual system. Wernicke's area might then be seen as providing an input stage to parietal cortex in an auditory dorsal pathway – but further empirical data are needed to test these hypotheses.

4.25.5 Prospects

In conclusion, we see that the MSH appears to provide rich insights into certain of the distinctive characters of the human brain that make it language-ready, with special attention to the parity property of language and the fact that language performance is multimodal, integrating the use of hand, face, and voice. However, it is not a standalone hypothesis, and future research will increasingly move beyond the mirror to meld it with analysis of the evolution of articulation and working memory, to explicate the linkage between neural mechanisms for scene perception and action planning with those for the perception and production of language, as well as to integrate the symbolic and emotional meanings of utterances.

4.26 Visual Cortex: Evolution of Maps and Mapping

R B H Tootell, Y Sasaki, and T Knutsen, MGH
NMR Center, Charlestown, MA, USA

Published by Elsevier Inc.

Glossary

cortical magnification factor (CMF) The distortion in the size of a given representation in cortex, relative to the geometry of corresponding points in the visual field. In primates and some other animals, the largest cortical representation is devoted to the center (fovea) of the visual field, with progressively less cortex devoted to regions increasingly further (more preipheral) in the visual field.

functional magnetic resonance imaging (fMRI) Magnetic resonance imaging is a noninvasive technique in which the subject is placed in a steady magnetic field, that field is systematically perturbed, and images of the brain (or other target) are obtained by systematic analysis of the induced magnetic field changes. 'Functional' MRIs are obtained when analysis is focused on the hemodynamic changes accompanying changes in neural activity.

hemodynamics Generally, circulatory changes. As applied to neuroimaging, this normally includes changes in blood flow, blood volume, oxygenation, or related parameters which accompany local changes in neural activity.

lissencephalic Roughly, smooth-shaped, when applied to the external shape of the cerebral cortex. The term is generally opposed to 'gyrencephalic', referring to a cortical surface which included multiple folds (gyri and sulci).

retinotopy The topographical projection of the retina onto the cortical surface. Because the projection of tretina reflects the geometry of the visual field, the cortical retinotopy is often related directly to the geometry of the visual field.

4.26.1 Introduction

The goal of understanding the evolution of primate visual cortex is by necessity an imaginative extrapolation from extant species, because decomposing brains leave no fossil record (unless one counts endocasts of the skull). Complicating this, any information about visual cortical maps is available from less than 10 of the ~230 living primate species. Among that 10, comprehensive information is limited mostly to macaques, humans, and a few New World species. Even more problematic, the techniques used to map visual cortex differ across different species. Thus, it has been difficult to define a common map of 'primate visual cortex'.

Vision is the primary sense in most primates, and visual cortex is correspondingly enlarged (occupying more than 50% of the cortical surface in some species) and elaborated (into 10–32 distinct areas). Visual cortical areas are typically distinguished from each other based on four main criteria: (1) retinotopy, (2) function, (3) histology, and (4) connections. In well-accepted, lower-tier visual areas such as V1, V2, and MT, unambiguous information is available from most or all of these criteria, and the area borders defined by all criteria agree perfectly with each other. However, in higher-tier (hypothetical) areas, information about area location and function is often based on only one or

two criteria, and this information can be frustratingly subtle and/or incomplete. In the latter cortical regions, uncertainty about the number and location of areas is rife, and controversies abound accordingly. Areas V3 and V3A represent intermediate levels (of information and consensus), in which recent discussions of area boundaries and differentiation appear to be converging on a common primate model.

Retinotopic criteria are rich in quantitative detail, often conserved across different species, and retinotopy can be measured using multiple techniques. Hence, retinotopic criteria tend to be most credible for distinguishing cortical visual areas. Functional differences between areas are also used as a criterion, and the prime example of this is the motion- and direction-selective area 'MT', also known as 'V5'. However, even though this area appears to be present in all primates tested, some functional differences in 'MT' appear to exist across the primate order. Moreover, the degree of motion- and direction selectivity in other visual areas (e.g., V3 relative to V3A) appears to vary across primate species.

Recent studies have begun to clarify the development of different cortical visual areas, and the nature of connections between them. Thus, despite the overwhelming difficulties of studying a dynamic property (evolution) from a limited endpoint perspective, progress continues to be made, and the broad pattern of organizational principles is starting to emerge.

Among primates, evolutionary differences have been documented at many levels of the visual system, from retina through the lateral geniculate nucleus through the visual cortex (for reviews see Kaas, 1997a; Tootell *et al*., 2003; Orban *et al*., 2004; Preuss, 2004a, 2004b; Sereno and Tootell, 2005). However, much of the variation (and similarity) across species is simply unknown. There are ~230 known species of primate (Fleagle, 1999), but most 'primate' visual research has been conducted on just a few of those species, principally humans and macaques. Thus, any conclusions about the evolution of the visual system require enormous extrapolations between the few species mapped, plus assumptions about genetic predecessors who are completely unknown (and currently unknowable).

Another thorny problem in this analysis is that many of the techniques used to study humans are different from those used to study monkeys. Thus, it has been difficult to directly compare data across those two primates. In response to this problem, it has been increasingly common to use a common technique (e.g., histology or fMRI) to directly compare the visual system in humans and nonhuman primates. This can eliminate the need to worry about technical differences; although in practice some minor technical differences can remain in both the functional magnetic resonance (fMRI) approaches (e.g., Tootell *et al*., 2003; Orban *et al*., 2004) and the histology of humans versus macaques (Tootell and Taylor, 1995; Preuss, 2004a, 2004b).

As such evidence has accumulated, it has become correspondingly more challenging to 'keep a blind eye' to the evolutionary diversity between humans, macaques, and other primates. Some studies embrace this evolutionary diversity, presuming that it will help reveal underlying mechanisms of neural development – and progress in this realm has been made (see below). Other studies have focused on visual processing *per se*, in which it is optimal to show that a given feature is 'fundamental' (i.e., evolutionarily conserved, present and unchanged across multiple species). As eloquently emphasized by Preuss (2004a, 2004b) and others, in such cases there are strong pressures to 'emphasize the similarities and downplay the differences' between humans and the monkey 'model'.

Only one conclusion is certain. As more information accumulates, both differences and similarities will be increasingly found in comparisons of the visual system of humans and other primates. This 'glass half empty/full' situation may be frustrating to both 'splitters' and 'lumpers', but it may be the logical expectation from comparisons of primates separated by ~50 million years of independent evolutionary divergence.

4.26.1.1 Cortical Maps

There are many excellent reviews of cortical visual areas, describing how the areas have apparently evolved among different primates, and how scientific data about them have evolved in different laboratories during the past several decades. The reader is referred to those reviews (Felleman and Van Essen, 1991; Kaas, 1997b; Rosa, 1997; Preuss, 2000, 2004a, 2004b; Kaas and Lyon, 2001; Krubitzer and Kahn, 2003a, 2003b; Orban *et al*., 2004; Gattass *et al*., 2005; Rosa and Tweedale, 2005; Sereno and Tootell, 2005) for detail beyond the scope of this review. One way in which such maps have changed during the last decade is that fMRI is increasingly used to reveal the maps in human and nonhuman primates, to supplement data based on classical, invasive mapping methods. That data are incorporated in the present review.

Cortical maps offer a well-constrained system in which to study evolutionary diversity. Basically,

cerebral cortex is a two-dimensional 'sheet' of enormously variable extent (in hominid primates, ranging from ~7 cm^2 in the marmoset to ~275 cm^2 in humans) but relatively constant thickness (1.5–4 mm), including numerous topographical features which can be 'tracked' (assuming homology) across different species. In some cases, these topographic features can even be directly manipulated to test ideas about cortical architecture and development (for reviews see Grove and Fukuchi-Shimogori, 2003; Krubitzer and Kahn, 2003a, 2003b). To more easily visualize and measure topographic variations in the cortical sheet, it has become increasingly customary to study cortex in 'flattened' format, after physical (Tootell *et al.*, 1981; Olavarria and Van Sluyters, 1985; Tootell and Silverman, 1985; Strominger and Woolsey, 1987; Krubitzer and Kaas, 1993; Sincich *et al.*, 2003) or computational (Van Essen *et al.*, 2001; Sereno *et al.*, 1995; Engel *et al.*, 1997; Dale *et al.*, 1999; Fischl *et al.*, 1999) unfolding of the gyri and sulci. Without such flattening transformations, it is difficult to make sense of the cortical maps, except in species with lissencephalic brains.

Vision is the primary sense in primates, and primate visual cortex has been elaborated accordingly. In macaques, visually driven regions occupy more than half the surface area of cortex. Some authors have distinguished as many as 32 distinct visual cortical areas (Felleman and Van Essen, 1991), although other investigators (e.g., Kaas, 1997a; Rosa and Tweedale, 2005) suggest a smaller number (e.g., 12–15). Moreover, the number of distinct visual cortical areas may well vary across primate species.

Human visual cortex is 'physically' larger than macaque visual cortex. However, visual cortex occupies a 'proportionately' smaller part of cortex (~30%) – presumably reflecting the even greater expansion of nonvisual regions in human cortex (reviewed in Kaas, 1997a; Preuss, 2000; Van Essen, 2004; Rosa and Tweedale, 2005). Relative to macaque, the increase in the absolute size of human visual cortex partly reflects increases in the size of each comparable area, for those areas that can be safely assumed to be homologous (e.g., V1, V2, V3, and MT) (see The Evolution of Visual Cortex and Visual Systems, Evolution of Color Vision and Visual Pigments in Invertebrates).

Some areas vary in proportionate size more than others. For instance, visual cortical area V3 is much thinner in macaque than in human, and area V2 is significantly smaller in the nocturnal aotus monkey, compared to the diurnal monkey species which have been tested so far. Though such variations have prompted some teleological speculation, the reasons for those disproportionate increases are ultimately unknown. Part of the absolute increase in human cortical size (relative to macaque cortical size) is due to co-variation with body size (e.g., Preuss, 2000, 2004a, 2004b; Sereno and Tootell, 2005). However, even in primates that are of equal body size (e.g., chimpanzees and humans), cortex is much larger in humans.

Because human cortex has expanded so much relative to cortex in other primates, it has been suggested that additional areas may exist in human cortex (including visual cortex) which have no counterpart in macaques or other monkeys. However, no such human-specific visual cortical area has yet been identified with certainty (but see Denys *et al.*, 2004).

Before proceeding, it may be helpful to discuss one possible source of confusion in these comparative studies, which arises from evolutionary changes in body posture (see Figure 1). The terms 'dorsal' and 'ventral' are coordinates related to the spine, referring to the back and belly, respectively. In macaques and other quadripeds, these axes coincide with 'superior' and 'inferior' axes in brain, respectively – and they have been used interchangeably (and accurately) in that context. However, humans walk upright while facing forward, so brain axes are rotated accordingly, by 90°. In humans, 'dorsal' and 'ventral' axes coincide instead with the caudal/posterior and rostral/anterior brain axes, respectively.

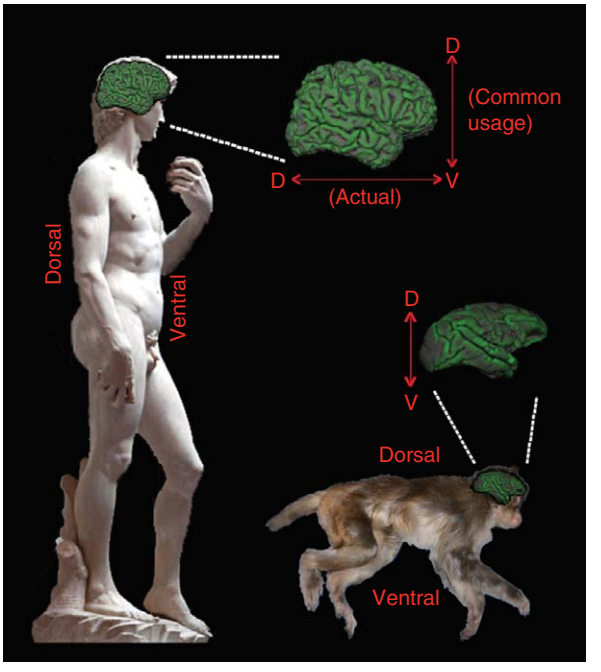

Figure 1 'Dorsal' and 'ventral' axes are rotated in human brain, relative to corresponding axes in macaque brain. D, dorsal; V, ventral.

This discrepancy can lead to confusion if the terms 'dorsal' and 'ventral' are taken literally. For instance, the well-known 'dorsal stream' and the 'ventral stream' (Ungerleider and Mishkin, 1982) are dorsal and ventral to each other in macaque brain, but not in human brain (in which they should be called the 'superior stream' and 'inferior stream'). For the same reason, the names given to some inferiorly located human brain areas are technically incorrect. For example, 'VO' (Liu and Wandell, 2005) is not really located in 'ventral occipital' cortex. In response to this, the neuroimaging field has apparently generalized the terms 'dorsal' and 'ventral' to indicate equivalent brain axes in both humans and quadripeds.

4.26.2 Retinotopy

It is often said that visual cortical areas can be defined based on four different criteria: (1) retinotopy, (2) histological properties, (3) cortical connections, and (4) functional differences (e.g., Felleman and Van Essen, 1991; Kaas, 1997a). Areas that are most certainly defined (e.g., V1, MT, and V2) are based on all four of these criteria, and all the data converge to a common area definition. For instance, area V1 (primary visual cortex) includes one (and only one) complete map of the visual field, thus satisfying the first criterion. V1 is also distinguished from surrounding cortex by a prominent band of higher myelination running throughout layer 4B (the stria of Gennari), which ends abruptly at the border of V1 (i.e., the representation of the vertical meridian based on retinotopy); this satisfies the second criterion. Retinotopically corresponding regions of V1 all project in a point-to-point fashion to V2 and other areas; this satisfies the third criterion. Throughout V1, there are consistent variations in function, some of which are in turn related to laminar and topographic (i.e., cytochrome oxidase blobs) variations within V1; this satisfies the fourth criterion.

However, most cortical areas are based on data from only one or two of these criteria, so that the borders (and even the existence) of these areas are much less certain (e.g., Felleman and Van Essen, 1991). For many areas, histological measures of cortex are indistinguishable, based on current markers. Higher-tier areas often lack retinotopy, and global functional differences between areas can be frustratingly subtle. Studies of cortical connections sometimes lead to ambiguous conclusions because it can be difficult to distinguish between cortical areas and columnar subdivisions within areas. Additional complications of tracer studies are reviewed in Salin and Bullier (1995).

If only one criterion could be picked, many researchers would have most confidence in retinotopic data, because such retinotopic information includes so many informative subdimensions. These retinotopic subdimensions include cortical representations of visual field eccentricity, polar angle, field sign, magnification factor, receptive field size, half- versus quarter-field representations, ipsilateral versus contralateral distinctions – in addition to area size and shape, which are deterministically linked to the global retinotopy in each area.

Retinotopic criteria are also an attractive criterion because the corresponding data are relatively straightforward to interpret across both fMRI and single unit data, in humans and monkeys, respectively. This is not the case for the other criteria. For instance, it is well known that hemodynamic (fMRI) and electrophysiological (single unit) data do not correlate completely, because their biological sources are so dissimilar (e.g., Logothetis *et al.*, 2001; Toth *et al.*, 2001). It is easy to imagine that data based on other criteria (e.g., 'functional' or 'functional connection' data) might not coincide when compared across fMRI versus single unit realms, for a given cortical area. However, because retinotopy is based on multiple, locally systematic representations of spatial location (each of which can be independently verified with reference to the visual field, and with respect to neighboring points in the map), retinotopic maps should be essentially identical, whether based on fMRI or electrophysiology. This conclusion has been generally confirmed (Brewer *et al.*, 2002; Fize *et al.*, 2003; Tootell *et al.*, 2003; Orban *et al.*, 2004).

4.26.2.1 Improbable Retinotopy

By the same token, the many different subdimensions in the retinotopic realm give rise to their own set of expectations, and some of these expectations are made explicit only rarely. What happens when those expectations are not met? Many of the current controversies in the retinotopic realm are of this type.

For instance, it is expected that each retinotopic area will include a complete representation of the contralateral visual field. Proposed areas which do not meet this expectation have been called 'improbable' (e.g., Kaas, 1993) or 'faith-based' visual cortical areas. Though nearly everyone would agree that this whole-visual-field representation is the most parsimonious expectation, often the

empirical data drive investigators to propose such areas at least as a temporary measure: the list of proposed partial representations is not small. One of the most well known of these controversies is whether macaque area 'V3' is comprised of two physically separated representations of the upper and lower contralateral visual fields ('V3d' plus 'V3v': Ungerleider and Desimone, 1986; Boussaoud *et al*., 1990), or whether the upper field representation is really an entirely different visual field ('VP' instead of 'V3v'), based on differences in connectional and functional criteria (e.g., Maunsell and Van Essen, 1983; Felleman and Van Essen, 1991; Burkhalter and Van Essen, 1986; Felleman *et al*., 1997). Increasingly, investigators have adopted the former assumption because it is simpler and it is most similar to the more recently described human fMRI data. However, many of the originally reported differences in macaque VP versus V3 have not been refuted. An analogous controversy has arisen with respect to the human homologue of macaque area 'V4', based largely on fMRI comparison of functional and retinotopic criteria (McKeefry and Zeki, 1997; Hadjikhani *et al*., 1998; Tootell and Hadjikhani, 2001; Wade *et al*., 2002).

Based largely on electrophysiology, other authors (reviewed in Gattass *et al*., 2005) have reported that many extrastriate areas in macaque represent only the central portion of the visual field – for example, from 0 through 30–50°, not the full visible portion of the contralateral visual field (0 through ~80°). By this model, some visual information from the peripheral visual fields would be processed only by areas V1 and V2. A related (but less radical) model suggests that the cortical magnification factor (and thus, the relative emphasis on central versus peripheral visual fields) varies systematically in extrastriate visual cortex. According to this model (Buffalo *et al*., 2005), visual cortical areas in the 'ventral stream' have a relatively larger central representation, whereas the peripheral visual field is represented more prominently in areas of the dorsal stream. This model is supported by earlier tracer results, reporting a projection from foveal V1 to foveal V4, without a corresponding projection from peripheral V1 to V4 (Zeki, 1971; Ungerleider *et al*., submitted).

Another assumption in studies of retinotopy is that visual areas are subdivided along the representation of either vertical or horizontal meridian(s). Reported counterexamples include subdivision between macaque V4v and V4d, which is reported to lie along a polar angle within the lower visual field (Gattass *et al*., 1988). Though unexpected, such an arrangement would rationalize the larger surface area of V4d in comparison to V4v. A similar situation has been suggested in one exceptional report from the V1–V2 border of owl monkey (Blasdel and Campbell, 2001).

Recently, the relative value of the four mapping criteria has become a more pressing issue, following the demonstration that one pair of adjacent cortical visual areas (V3 and V3A, based on retinotopy) has 'switched' functional properties, in comparisons between macaques and humans. In macaques, area V3 is moderately motion selective (Felleman and Van Essen, 1987; Vanduffel *et al*., 2001), whereas adjacent V3A is not; in humans this functional relationship is reversed (Tootell *et al*., 1997; Orban *et al*., 2003). Except for a change in the relative size of V3, the retinotopy of areas V3d and V3A appears to be relatively unchanged in macaques and humans – although the retinotopic definitions of areas V3 and V3A are themselves subject to a new debate (e.g., Rosa and Tweedale, 2005; see below).

4.26.2.1.1 Additional caveats Among the primates, detailed retinotopic maps of visual cortex have been acquired in macaques, humans, owl (Aotus) monkeys, marmosets, and Cebus monkeys. Such maps have been acquired on a variety of techniques, including single unit recording, neural tracers, optical recording, deoxyglucose mapping, and/or fMRI. With all this information, one might hope for a clear consensus about visual cortical maps, and how they evolved. Unfortunately, this goal has proven elusive, although progress has been made.

One major problem is that measurement noise and/or technical differences can significantly obscure the (presumably real) features in maps in each species. Even in macaque, the most thoroughly mapped monkey, different investigators come to quite different conclusions about the cortical maps (cf. Boussaoud *et al*., 1990; Felleman and Van Essen, 1991; Stepniewska and Kaas, 1996), at least in some cortical regions. The situation is similar in humans and other primate species. It is fair to say that complete agreement on cortical mapping features is the exception rather than the rule, except in areas V1, V2, and MT (also known as V5).

4.26.2.1.1.(i) Common areas: V1, V2, and MT Generally, investigators agree on the location and retinotopy of lower-tier visual areas, but disagree more with respect to higher-tier (extrastriate) areas. This generality arose for multiple reasons. First, lower-tier areas have smaller receptive fields, so the retinotopy is easier to define in those areas. Also,

some lower-tier areas can be defined unambiguously based on histological features, as well as the presence of subcortical inputs. In conventional hierarchies of macaque cortex, areas V1 and V2 are the sole first- and second-tier areas, respectively. Area MT is considered to be fifth tier, based on laminar terminations (e.g., Felleman and Van Essen, 1991), but in some respects its hierarchical position is instead 'lower tier' because it also receives direct input from V1 (Maunsell and Van Essen, 1983), and from subcortical nuclei (O'Brien *et al*., 2001). Like V1 and V2, MT is histologically distinctive, and apparently present in all primates tested.

It has been suggested that V1 and MT serve as stable 'molecular anchors' that develop before other cortical visual areas (Rosa and Tweedale, 2005). According to this idea, higher-tier areas are intrinsically more variable because they develop later, from the borders of previously developed areas, based on more diffuse molecular gradients. However, as described above, uncertainties persist in the cortical visual maps reported in different species, using different techniques, from different investigators, and even in different studies from the same laboratory. Thus, it is difficult to know whether additional higher-tier cortical visual areas are fundamentally more variable, or whether they are biologically stable but difficult to map accurately.

It has been suggested that visual cortical areas develop in a manner that minimizes the mean length of axonal connections (e.g., Kaas, 1997a; Van Essen, 1997). A striking example of this can be seen in the topographical relationship of areas V1 and V2, in several species of monkey. In these monkeys, the ubiquitous 'point-to-point' connections between retinotopically corresponding points in V1 and V2 (comprising perhaps the most prominent intracortical connections in both V1 and V2) are demonstrably as short as possible, or nearly so. This produces to a unique folding pattern in the gyri and sulci of these areas, such that most of the border between areas V1 and V2 lies on or very near the crown of the gyral edges of the cortical operculum (see Figure 2). This distinctive folding pattern is found in some species of both New and Old World

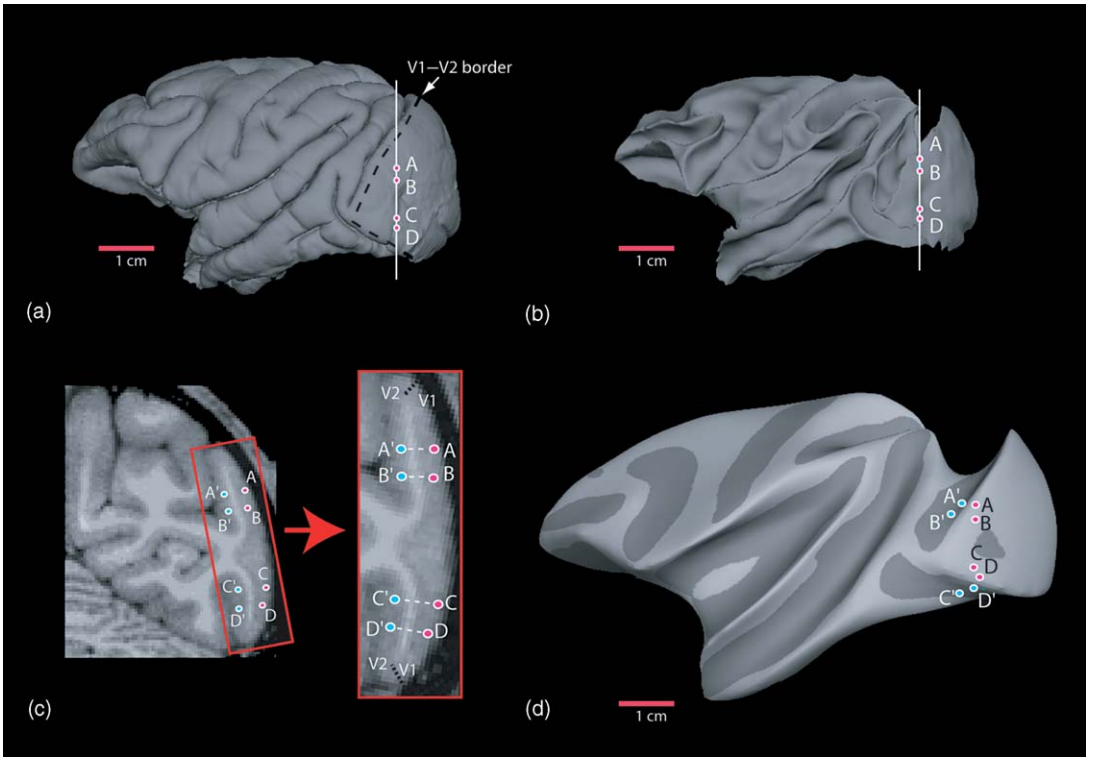

Figure 2 a, A lateral view of the left visual hemisphere, as seen in a normal dissection. An arbitrarily positioned coronal slice plane is indicated in white. Along that slice, two points in the upper primary visual cortex (V1) (A and B) and two points in the lower primary visual cortex (C and D) are indicated on the surface. b, A lateral view of the white matter surface, underlying the view shown in panel (a). The position of these four points are projected onto the white matter surface. c, Now these four points are projected onto the coronal slice. Their retinotopically corresponding projections (A′–D′) on V2 can be seen. d, All of eight points from V1 and V2 are presented on the inflated format of cortex. This figure shows how the retinotopically corresponding points in V2 are found almost immediately underlying their counterparts in V1. Without this particular form of cortical fold, the axons connecting these cortical points would be much longer. This folding pattern connects points within the central half of V1 and V2.

primates (e.g., macaque, *Cercopithecus*, and *Cebus*), spanning ~70 million years of independent cortical evolution. On the other hand, other species with more (e.g., humans) or less (e.g., *Aotus, Saimiri*, and *Galago*) cortical folding do not show this distinctive 'fold' along the V1–V2 border.

4.26.2.1.1.(i).(a) V3 and V3A In the next-most anterior area (V3 or its namesakes), the history of mapping conclusions has been surprisingly convoluted – though recently it has been converging (reviewed in Kaas and Lyon, 2001; Rosa and Tweedale, 2005). In macaque, this 'third' retinotopic map is typically subdivided into dorsal and a ventral halves (as in adjacent area V2), representing ventral and dorsal quadrants of the visual field, respectively (Zeki, 1978; Maunsell and Van Essen, 1983; Ungerleider and Desimone, 1986; Boussaoud *et al.*, 1990; Felleman and Van Essen, 1991). However, unlike the organization in V2, the two halves of V3 were reported to be shorter than their counterparts in V2, separated by many millimeters at the foveal representation, and they do not extend as far into the periphery. Thus, V3 was assumed to be roughly but not truly mirror symmetric to its neighbor V2, located immediately posterior (see Figure 3). If true, these failures to match the mirror symmetry of V2 are not consistent with the 'shortest possible connection' model described above.

Anterior to macaque V3, an additional retinotopic area was subsequently described. Though it is a completely independent area, it was given a misleadingly diminutive name (V3A), because it was discovered after V3 and V4, but located between them on the cortical sheet (Zeki, 1978; Gattass *et al.*, 1988). V3A is considered to include a contiguous map of the entire contralateral visual field.

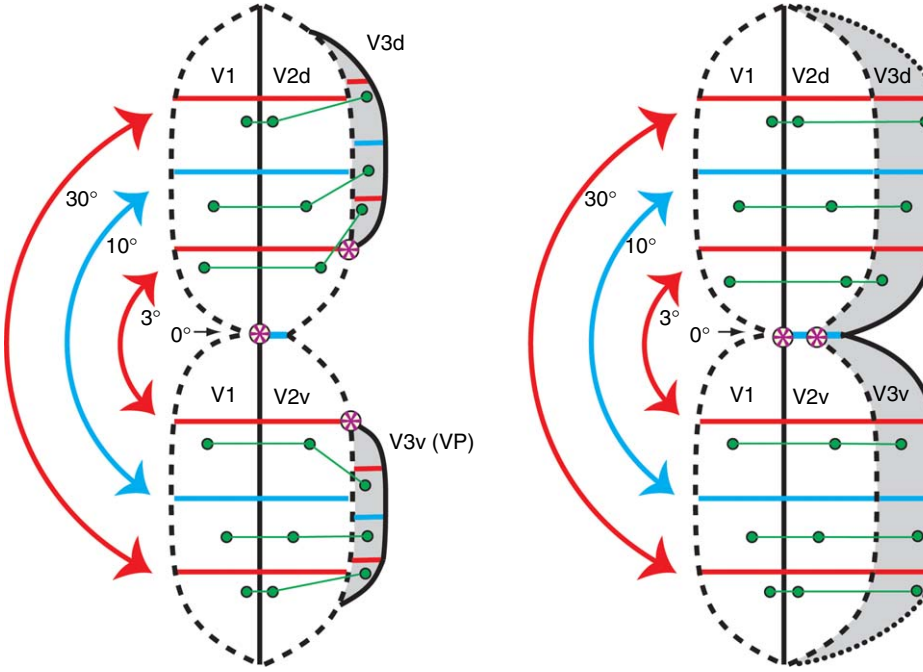

Figure 3 The model of retinotopic organization for human 'V3' is simpler than that for macaque V3. a, Current model for macaque visual areas (V1–V3). The foveal representation is marked as a star, the vertical meridian representation is indicated with solid lines, and the horizontal meridian is represented with dashed lines. The horizontal meridian representation in V1 has been artificially 'split' in this diagram (indicated with double-headed arrows). In all areas, the representation of 3°, 10°, and 30° eccentricities is indicated with red, blue, and red lines, respectively. Retinotopically corresponding points in V1, V2, and V3 are indicated in green. In macaque, the representation of corresponding eccentricities in V3 (V3d, VP/V3v) is shifted, relative to that in V1 and V2. b, Current model for human visual areas (V1–V3). Diagram format as in panel (a), except that short-dashed lines indicate the presumptive (unknown) peripheral representation of V3. The representation of eccentricity in human V3 (V3d and V3v) is topographically aligned relative to that in V1 and V2, unlike that in macaque. This creates shorter connections to/from V3, relative to inputs and feedback connections with V2 and V1.

In human fMRI, the apparent homologue of area V3 is much larger than it is in macaque, both objectively and proportionately (see Figure 3). This has made it much easier to measure V3 in humans, despite the spatial resolution limits of the fMRI (Sereno *et al*., 1995; De Yoe *et al*., 1996; Engel *et al*., 1997; Tootell *et al*., 1997). Topographically, human V3 appears to be essentially a mirror-symmetric replica of V2, continuous through the foveal representation, with contiguous representation of eccentricity throughout its length. Thus, in human V3, the representation of retinotopic eccentricity does satisfy the 'shortest possible connection' rule (Kaas, 1997a; Van Essen, 1997), with respect to the topography of its prominent inputs from V2 (and from V1, for that matter) (see Figure 3). Anterior to human V3, an apparent human homologue of macaque V3A has also been described (Tootell *et al*., 1997).

Because V3 is easiest to measure in humans, and because the topography of V3 is simplest in that primate species (i.e., a simple mirror-symmetric duplication of the previous area, V2), it brings up the question whether the simpler V3 topography also applies to other primates. For instance, recent fMRI maps from macaque (Brewer *et al*., 2002; Fize *et al*., 2003) allow for the possibility that macaque V3 is instead continuous through the foveal representation, as in human V3. However, this cannot yet be confirmed: macaque V3 is very thin (~2–4 mm), and near the limits of spatial resolution of the fMRI technique.

In the New World Aotus (owl) monkey, an analogous, strip-shaped third visual area ('V3') was not found initially (Allman and Kaas, 1975; Kaas, 1997a). Instead, as many as five different visual areas were reported to lie immediately adjacent (and anterior) to V2. One of these anterior areas was a contiguous representation of the contralateral field ('DM'), which was superficially similar to V3A. However, the most recent accounts now do describe a V3 analogue between V2 and DM in this species (Kaas and Lyon, 2001). Thus, current maps of owl monkey are more similar to macaque and human maps – due partly to technical improvements in mapping of New World monkeys (e.g., Lyon and Kaas, 2002).

Recently, it was proposed that a quite different model of the V3/V3A retinotopy is common to all primates (including Cebus monkeys, macaques, and humans). This new 'unified V3' model is generalized from maps of marmoset (Rosa and Tweedale, 2005), including a 'V3' which extends through the foveal representation. However, this new model also eliminates V3A entirely from all primate species; in that sense it is a radical departure from previous models. However, because this retinotopic model is proposed to extend across all primates, it would be unifying if confirmed. Retinotopic mapping based on macaque fMRI can be construed to support this new model (e.g., Brewer *et al*., 2002; Fize *et al*., 2003) – although (as stated above) the 2–4 mm width of macaque area V3 makes it difficult to resolve the underlying retinotopy using fMRI.

4.26.3 Functionally Defined Areas

Here we consider a second criterion for defining cortical areas: functional properties. To the extent that functional properties are distinctive in different cortical visual areas, those properties can be used to 'track' whether that area is present, and/or functionally unchanged, across evolution. Classically, area MT (also known as V5 in macaques and humans) is the visual area considered functionally most distinctive, compared to other visual areas. Single units in MT/V5 respond best to visual stimuli which are moving in a specific direction, in all primates tested (e.g., macaques, Aotus monkeys, and humans, based on fMRI). However, even in MT, there is some evidence for evolutionary variation in function across species. For instance, optical recordings suggest that stimulus orientation is three times as significant as stimulus direction in area MT of owl monkeys (Malonek *et al*., 1994). This contrasts with the profound selectivity for stimulus direction, based on single units from macaque MT (e.g., Dubner and Zeki, 1971; Maunsell and Van Essen, 1983).

A more direct example of evolutionary differences in MT is shown in Figure 4. The left-most panels show fMRI activity acquired from human MT(+) during viewing of a motion aftereffect, along with that produced during control stimuli which do not produce such an aftereffect (Tootell *et al*., 1995; He *et al*., 1998; Culham *et al*., 1999; Huk *et al*., 2001). Such stimuli produce a clear increase in fMRI amplitude with a time course essentially identical to the psychophysical effect (squares in panel (c)), and a 'memory' effect also similar to the psychophysical effect (Culham *et al*., 1999). Subsequent fMRI studies (Huk *et al*., 2001; Nishida *et al*., 2003) suggested that this 'fMRI motion aftereffect' is strongly gated by attention, but those studies do not affect the interpretation of the (passive viewing) results we discuss here.

Subsequent studies initially showed very little correlate of the positive-going fMRI motion aftereffect (in humans) in single units from macaque area MT

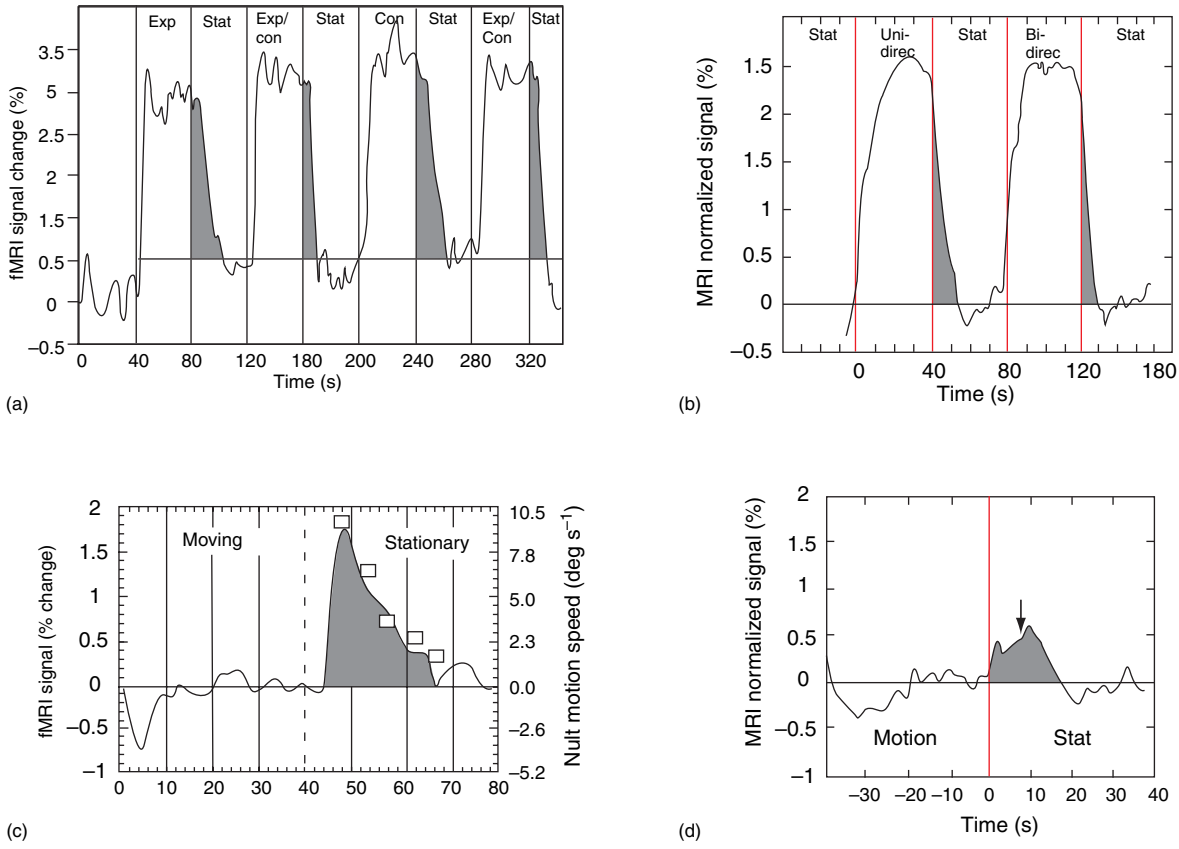

Figure 4 fMRI-based 'motion aftereffect' in both human and monkey. Time course of fMRI activity from area MT (or MT+) from human (a) and monkey (c) subjects, when both were awake and passively viewing, during blocks of unidirectionally moving, bidirectionally moving, and static stimuli. Analogous elevated response to static stimuli are found after seeing unidirectionally moving stimuli (i.e., during perceptual motion after effect) are observed in both humans (b) and monkeys (d). However, this fMRI-based 'motion aftereffect' is smaller in macaques compared to humans.

(Van Wezel and Britten, 2002), but more comprehensive single unit studies did show something analogous (Kohn and Movshon, 2003). In these macaque single unit results, attention was uncontrolled, as in the initial fMRI studies in humans. Also, both single unit studies implicitly assumed that macaques perceived a motion aftereffect like that seen by humans. This is a classic example of using macaque monkeys as a 'model' for human vision.

To test some of the assumptions underlying this across-species comparison, we tested whether an 'fMRI motion aftereffect' is present in macaques as well as humans. The fMRI data were acquired from awake fixating monkeys, with the same stimuli presented earlier to human subjects, using the same MRI scanner and analysis. Surprisingly, these stimuli produced only a very small fMRI-based 'motion aftereffect' in macaques – though it was of the same polarity as that seen in the human experiments (see Figure 4). Although further controls would be useful to assess the effect of attention (in both the macaque single units and the fMRI), the direct comparison in Figure 4 demonstrates that similar processes operate in both humans and macaques in the processing of such stimuli – though differences in the amplitude of this effect are also significant. Other fMRI data (Vanduffel *et al.*, 2002; Denys *et al.*, 2004; Sasaki *et al.*, 2005) also reveal clear differences in functional emphasis between presumably homologous cortical areas and processes in humans compared to macaques.

Other functionally defined regions appear to be amazingly stable evolutionarily. Following many fMRI reports for an apparently face-selective region in human visual cortex ('FFA'; Kanwisher *et al.*, 1997, 1998; Tong *et al.*, 1998; Haxby *et al.*, 2000; Heekeren *et al.*, 2004), a presumably homologous set of face-selective patches was revealed by fMRI in the corresponding location of macaque visual cortex (Tsao *et al.*, 2003; Pinsk and Kaster, 2005). Analysis in flattened cortex, at high spatial resolution, revealed that these macaque 'modules' take the form of small isolated patches (akin to sparsely

distributed cortical columns) rather than a contiguous classical cortical 'area' (Tsao *et al.*, 2003). Prompted by this insight in macaque, reanalysis of fMRI suggests that human FFA can also be described as a set of functionally similar patches rather than a classical cortical 'area'. Presumably, any patchiness in previous fMRI results from humans was less obvious because most of those scans used voxels which were much larger (~25–50 times the volume), compared to those used in the macaque fMRI. This is a nice example of how insight from macaque can 'feed back' to clarify results in human cortex.

This is also a nice counterexample for the generality that higher-tier cortical features are evolutionarily more variable than lower-tier features. The fMRI-defined face-selective patches appear essentially identical in both humans and macaques, though they are distributed widely throughout the higher-tier cortex.

The near-columnar size and irregular topography of the face-selective patches also supports the speculation of Rosa and Tweedale (2005) that classical cortical 'areas' are not really present in higher-tier visual areas such as inferotemporal (IT) cortex. These investigators suggested instead that IT cortex may be divided into column-like modules, separated by gradual rather than abrupt functional transitions. This generality may be simply another example in which area borders are considered to be gradual when they are merely invisible using the techniques available at the time. This is historically common: recall how the extent of 'associative cortex' shrank as more reliably defined cortical areas were revealed within it. On the other hand, the model of Rosa and Tweedale (2005) could rationalize why there is so little consensus in published maps of cortical areas in IT cortex drawn by different investigators (cf. Boussaoud *et al.*, 1990; Felleman and Van Essen, 1991; Stepniewska and Kaas, 1996). Irrespective of whether area borders are exact or gradual in IT cortex, there is increasing evidence for column-sized functional patches in this region (Vanduffel *et al.*, 2000; Tanaka, 1997; Tootell *et al.*, 2004).

4.26.4 Additional Criteria

The final two criteria for defining cortical areas in human and nonhuman primates (cortical connections and histology) are reviewed in detail elsewhere (Kaas, 1997a; Tootell *et al.*, 2003; Preuss, 2004a, 2004b). It remains impossible to definitively trace connections in human visual cortex, though diffusion imaging (Conturo *et al.*, 1999; Le Bihan *et al.*, 2001; Tuch *et al.*, 2001) and other techniques (Paus *et al.*, 1997; McIntosh, 1999; Brandt *et al.*, 2001) may eventually provide supplementary information. Some progress has been made documenting histological differences between human visual cortical areas in postmortem tissue (e.g., Galuske *et al.*, 2000; Eickhoff *et al.*, 2005), though histological differences between cortical areas are usually subtle and probabilistic rather than definitive, outside of a few areas such as V1 and MT.

4.26.5 Development of Visual Cortical Areas

The rich array of architectural features in primate visual cortex, and the intriguing balance of similarities and variation across species in the cortical maps, naturally raises the issue of how these features develop (for reviews, see Grove and Fukuchi-Shimogori, 2003; Krubitzer and Kahn, 2003b). Changes in the size of the cortical sheet could arise relatively simply via changes in the cell-cycle kinetics, via upregulation of genes such as beta-catenin. In retinotopic areas, one possibility is that neurons and local connections are organized based on the local correlation of electrical activity, arising from spontaneous and/or driven activity in the retina. Another idea is that chemical factors such as Wnt, Shh, Fgf8, and BMP govern gross cortical gradients. Another intriguing and plausible idea is that new cortical areas could arise evolutionarily from modular subdivisions within existing areas (Krubitzer, 1995).

4.26.6 Conclusions

After more than half a century of detailed retinotopic mapping in primate visual cortex, it is somewhat sobering to realize how little agreement there is on specific details of the maps in different species. However, some current evidence suggests a more common plan for the organization of areas in different primates; if confirmed, this will simplify the subsequent analysis of area topography. At the very least, there is an increased awareness that systems research needs to take into account differences and similarities in the cortical maps in different species.

4.27 Evolutionary Specializations for Processing Faces and Objects

K L Hoffman, Max Planck Institute for Biological Cybernetics, Tuebingen, Germany
I Gauthier, Vanderbilt University, Nashville, TN, USA

Glossary

amygdala An almond-shaped structure buried in the temporal lobe in the primate brain, consisting of three sets of nuclei of diverse origin. Of the cortical nuclei, the basolateral complex, and the centromedial nuclei, the latter two are implicated in emotional learning.

anterior medial temporal sulcus (AMTS) Sulcus lying in the ventral aspect of the temporal lobe, running in an anterior–posterior direction.

configural processing Visual object recognition strategy that makes use of precise metric information in the stimulus, including the spatial relationships between different parts.

critical period A period of time during which the brain must receive appropriate stimulation from the environment in order to be capable of acquiring a specific ability. A more stringent type of sensitive period.

face-inversion effect Poorer performance in identification of faces that are presented upside-down compared to upright; typically a larger cost is found with inversion of faces than that of other objects.

featural processing Visual object recognition strategy that codes information for individual parts, such as their shape and color. Eyes, nose, and mouth are considered features of the face.

fusiform gyrus Gyrus in the ventral aspect of the human temporal lobe, which contains a smaller face-selective region referred to as the 'fusiform face area'.

homologue Feature that is similar in two species because it is inherited from a common ancestor.

homoplasy As opposed to homology. Any characteristic found in two species whose similarity is not due to common descent.

inferotemporal (IT) cortex Temporal cortex running from the fundus of STS to the bank of the rhinal sulcus, and from the temporal pole in the posterior direction to the OTS marking the occipital lobe.

innate releasing mechanism The process by which only certain innately specified stimuli come to elicit or 'release' appropriate behaviors with exposure.

MT (V5) Motion-sensitive area in the posterior portion of the superior temporal sulcus of the primate brain.

other race effect	Poorer performance in identification of faces from an unfamiliar race compared to faces of a familiar race.
pulvinar	Part of the thalamus, receiving visual inputs from other thalamic nuclei and projecting to the cortex.
sensitive period	A restricted temporal window in development during which experience or learning has a much stronger effect than learning outside the window.
superior colliculus	Subcortical relay station for visual information arriving from the retina, involved in head and eye orienting.
superior temporal sulcus (STS)	Large sulcus running along the anterior–posterior length of the lateral aspect of the temporal lobe. Contains MT/MST/FST in the posterior section, TE on the anterior part of the lower bank, and TPO along the length of the upper bank.
temporal area TE	Lying in the gyrus and banks between the AMTS and the STS.

4.27.1 Introduction

The title of this article illustrates a common misphrase, 'faces and objects', since faces are one type of object. Yet faces are considered as a special case of objects on numerous grounds. Here, we will use faces as an example object class, one that we consider a good candidate for receiving evolutionary specializations in neural circuits.

4.27.1.1 Why Faces?

Across human cultures, social dominance hierarchies exist, making the identification of an individual advantageous for appropriate behaviors. Moreover, common facial expressions and vocalizations indicate the current social climate, again facilitating appropriate responses. Several brain regions respond more vigorously to the presentation of faces than to that of most other objects. The fusiform gyrus, posterior superior temporal sulcus (STS), and amygdala are among the most consistently implicated regions in face processing. Moreover, both acute brain damage as well as congenital and developmental disorders are associated with deficits in processing faces despite relatively spared object recognition abilities (Behrmann and Avidan, 2005; Farah, 1990; Schultz, 2005). Cross-cultural similarities in face processing, together with consistent and discrete neural regions of activation, suggest that this object class may be the target of evolutionary specialization (see Evolution of the Neural Circuitry Underlying Laughter and Crying, Evolution of the Amygdala in Vertebrates).

4.27.1.2 How to Differentiate Innate Mechanisms from Common Developmental Paths (Nature vs. Nurture)

One possibility is that face processing is the product of mostly innate mechanisms. Processing abilities that are unique to faces compared to other objects and present at birth would be the most unambiguous evidence for innate face-processing skills; however, numerous traits that are genetically specified do not appear until later in development. Thus, another marker of innate face mechanisms would involve normal face processing following deprivation during development. An alternative possibility is that face processing develops as the result of an interaction between environmental and innate paths. An innate releasing mechanism or sensitive period in which the right stimulus (or the right stimulus at the right time) must be present for full processing capabilities is exemplified by some types of birdsong learning. Correct song production does not occur in isolation, thus the song is not completely prespecified; yet the wrong tutor call, or the right tutor call presented in the wrong time window, will not lead to correct song productions either, suggesting an innate sensitivity for a particular song during a particular developmental window (Gardner *et al.*, 2005; Marler, 1997). Considering that song learning and production is a fairly complex neural process, it nicely illustrates the ways in which face processing may contain evolutionary and developmental components. Along these lines, one current model of face processing (Nelson, 2001) suggests that specialization for faces is due to experience-expectant processes, whereby early experience with faces drives the development of this neural system. If true, inspection of face processing in infants may provide one means of separating evolutionary from developmental components.

A different approach to studying the evolutionary nature of a skill is comparative: homologous structures in extant primate species would signify a common evolutionary history. Unfortunately, among the social primates, only a few have been studied with respect to face-processing abilities, and even fewer have been examined for possible neural homologues of face processing. As such, it is difficult to separate homology (common evolutionary source) from homoplasy (convergent or parallel evolution) in putative common brain structures. Nevertheless, common neural structures in primates with similar

face-processing abilities would suggest an evolutionary neural specialization.

4.27.2 Evidence from Human Development

4.27.2.1 Newborns

Speculation that face processing is innate dates back to at least the 1930s (Bowlby, 1969; Bühler, 1933). Testing for recognition of faces versus other patterned objects has produced a myriad of results over the last five decades, but the more recent experiments, with more refined controls, reveal some surprising face-processing abilities beyond a mere face preference (Johnson and Morton, 1991; Morton and Johnson, 1991; Nelson and Ludemann, 1989). Newborns can recognize a mother's face from that of strangers (Pascalis and de Schonen, 1994), and preference for gaze towards versus away (Farroni *et al*., 2002). The face preferences in newborns, however, can be subtle, and the state of the infant and exact measurement parameters can make or break an effect, leading to a diversity of results. Newborns can only be tested with a small number of stimuli in any one experiment, and the nature of the control stimuli is crucial. Schematized face-like stimuli are often used (dark spots for eyes and mouth in a tapered simplified head shape on a contrasting background) in efforts to cater to the limited sensitivity of the visual system at that age. Control stimuli have typically been the same pattern upside-down, and no other 'object' control class is generally used. In fact, increasing evidence from studies using more nonface categories suggests that, in days-old newborns, the 'face' preference is captured by any stimuli with top-heavy asymmetry, even when parts are arranged in an otherwise 'non-face-like' configuration (Turati *et al*., 2002). More robust face preferences are obtained in infants older than 2 months, perhaps owing to increased visual acuity and contrast sensitivity (de Schonen and Mathivet, 1989; Simion *et al*., 1998), or to different processing mechanisms, or both. A recent study measured preferences of newborns and 3-month-olds by pitting a natural face stimuli against a top-heavy scrambled face pattern (Simion *et al*., 2006). While newborns preferred the top-heavy nonface stimulus, the opposite preference emerged by 3 months of age. Unfortunately, 3 months of visual experience is quite a bit; thus, one cannot make claims of innate mechanisms. Nevertheless, understanding what aspects of face processing are normally functioning at different stages of development can help narrow down the underlying neural processes, including those aspects that may be innate from those that require experience.

4.27.2.2 The Young Infant – 6 Months of Experience

Within the first 6 months of life, face-inversion effects can be seen (Fagan, 1972), gender can be discriminated (Cohen and Strauss, 1979), and, at 7 months, facial expressions are also distinguished. The other race effect, better discrimination of faces of a familiar race, can be observed as early as 3 months of age (Sangrigoli and De Schonen, 2004), but can still be reversed in adulthood (ethnic Koreans who moved to France as children 3–9 years old show an other race effect for Koreans (Sangrigoli *et al*., 2005)). So it appears that much of a fully developed face-processing system occurs in the course of a few months' development, with some features remaining modifiable well into childhood.

4.27.2.3 Early Deprivation

The inconclusive newborn data, as well as complex developmental changes taking place early in life, leave open the issue of the extent to which developmental processes are required for normal face processing. Are these abilities innately specified, or do they instead result from visual experience? Individuals with congenital cataracts were not exposed to normal visual input in the first few months of life. They represent an interesting test for whether the first few months of development reflect a critical period for face processing. Although able to discriminate faces based on features and contours (Le Grand *et al*., 2001), and to match facial expression and gaze direction (Geldart *et al*., 2002), these patients show deficits in their 'expert' processing of faces, specifically in holistic processing of faces (Le Grand *et al*., 2004) and discriminating faces based on configural changes, leading to an absent face-inversion effect for configurally modified faces (Le Grand *et al*., 2001). Moreover, visual stimulation to the right hemisphere in the first months after birth appears to be necessary for normal development of configural face processing (Le Grand *et al*., 2003). Thus, early visual experience is not required for most face-processing skills to develop, but it appears to be necessary for configural face-processing skills that are useful to individuate faces. This argues against an extreme innate account postulating that the entire face recognition system is hard-wired before birth, but also suggests that certain aspects of face processing exhibit sensitive periods early in life, after which the system will not develop normally.

In sum, it appears as though there are some innate preferences in newborns that lead them to look preferentially at faces, or at least at stimuli sharing some geometrical properties with faces such as a top-heavy part configuration. Whatever the initial preferences, the time from birth to 2–6 months of age appears to be important in the normal development of the full spectrum of face-processing skills, with at least two aspects of face processing, configural and holistic sensitivity, requiring normal visual inputs to the right hemisphere during this time period.

4.27.3 Evidence from Nonhuman Primates

4.27.3.1 Face Recognition in Monkeys

The biological advantages that might be conferred from an evolutionary specialization for face processing in humans also apply to many nonhuman primate species that share social features such as dominance hierarchies, vocal communication, and communication through facial expressions. Thus, neural specialization for face processing may have been present in common ancestors that can be viewed in homologous structures in extant primates. One of the best tests for this would examine the social demands of various primate species, their phylogenetic differences, and the corresponding neural substrates mediating face processing. Unfortunately, very little is known about potential neural substrates for face recognition across primate species. As a consequence, our discussion is limited to macaques, the genus for which we have the greatest collective knowledge about behaviors and neural structures related to face processing (see Preuss, 2000, for a discussion of phyletic analysis and cortical specializations).

Like humans, monkeys are able to identify conspecifics based on their faces (Rosenfeld and Van Hoesen, 1979); they recognize kin relationships, discriminate facial expressions (Haude and Detwiler, 1976; Kenney *et al*., 1979; Redican *et al*., 1971; Rosenblum and Alpert, 1974) and gender (Kenney *et al*., 1979; Rosenblum and Alpert, 1974), and are sensitive to changes in gaze direction, while maintaining an ability to generalize across viewpoints when recognizing an individual (Heywood and Cowey, 1992). They show signs of face 'expertise', as measured by their subordinate-level classification of monkeys but not other animals at the individual, or subordinate, level (Humphrey, 1974), and by the presence of a face-inversion effect (Bruce, 1982; Parr *et al*., 1999; Perrett *et al*., 1988; but see Rosenfeld and Van Hoesen, 1979; Swartz, 1983; Vermeire and Hamilton, 1998).

Although the onset and development of these abilities is largely untested, viewing patterns show gaze sensitivity in 1-week-old monkeys, the youngest age tested (Mendelson *et al*., 1982). Face preferences have been seen at the earliest time points tested, in 2.5–10-week-old macaques (Lutz *et al*., 1998), and species discrimination is possible in 2–3 month-olds (Swartz, 1983). More compelling is evidence coming from the sole study of the effects of complete social isolation on responsivity to faces. Isolated monkeys with no prior exposure to faces, yet not subject to sensory deprivation, responded differentially to the presentation of threatening monkey pictures, but not to fearful, sexual, or neutral images of monkeys, nor to other objects (Sackett, 1966). Changes were observed both in natural behaviors and in lever-pressing to view images. This unambiguously innate behavior was detected at 2.5 months of age. So, at least for macaques, there is an innately specified component to some aspect of face processing, namely, the recognition of threatening emotional expressions, though its interaction with normal developmental processes is still not understood.

4.27.3.2 Face-Processing Regions in the Macaque Brain

In the macaque, neural responses to faces have been commonly observed throughout a large territory of temporal lobe, including the upper and lower banks of the STS, extending along the lateral convexity of the inferotemporal (IT) cortex to the anterior medial temporal sulcus (AMTS), including areas TPO, TEa, TEm, TE1, TE2, and TE3 (Bruce *et al*., 1981; Desimone *et al*., 1984; Gross *et al*., 1972; Perrett *et al*., 1982, 1992). In addition, face-selective cells have been reported in orbitofrontal cortex and the amygdala (Leonard *et al*., 1985; Nakamura *et al*., 1992; Rolls, 1996; Thorpe *et al*., 1983). Face responses are almost exclusively excitatory, and tend to be selective to facial expressions and gaze/head direction changes in STS, and identity in TE (Eifuku *et al*., 2004; Hasselmo *et al*., 1989; Perrett *et al*., 1985). Face cells appear to cluster together, as reported from electrophysiological investigations, and suggested from optical and functional magnetic resonance imaging (Logothetis *et al*., 1999; Pinsk *et al*., 2005; Tsao *et al*., 2003; Wang *et al*., 1998). Temporal lobe regions implicated by these fMRI studies are consistent across monkeys and macaque species (long tailed and rhesus). Subcortical regions such as the amygdala, thalamus, superior colliculus (SC), and ventral occipito-temporal regions have also

shown activation in a subset of studies (Hoffman *et al.*, 2005; Logothetis *et al.*, 1999), perhaps owing to the nature of the stimulus set, the gradient of signal intensity of the coil (i.e., use of surface rather than volume coils), or degree of susceptibility artifact near the structures mentioned.

In contrast to deficits associated with prosopagnosia in humans, selective face-processing deficits in the monkey have remained elusive. Damage to the STS region produced deficits in discriminating gaze direction, but not view or identity (Heywood and Cowey, 1992). Cooling of the STS, or the gyrus above or below it, produced face discrimination deficits, without affecting stripe orientation discrimination (Horel *et al.*, 1987). Interestingly, there was no difference in the face discrimination deficits induced by cooling anterior or posterior parts of STS/TE, suggesting a distribution of critical regions in the anterior and posterior portions of the temporal lobe (Horel, 1993). Facial expression recognition was not tested in either experiment, and though experimental manipulations produced significant deficits, animals showed some preserved face-processing ability, with performances above chance. More extensive lesions in IT that disrupt face processing are nonselective, producing deficits with other objects as well (Gross, 1978). In addition, deficits in socioemotional behavior in 2- and 6-month-old infants follow from TE or amygdalo-hippocampal lesions that are made by 3 weeks of age, but only the amygdalo-hippocampal damage leads to deficits that persist into adulthood (Bachevalier *et al.*, 2001; Malkova *et al.*, 1997). The face-processing abilities in these monkeys has not been tested, thus STS/TE lesions are the only lesions known to affect face processing, and, even there, only gaze perception and configuration deficits are observed. These results could reflect a less modular, less discrete face representation in macaques compared to humans, or that the STS region in monkeys is not a homologue to the human fusiform gyrus but rather to the posterior STS in human.

4.27.3.3 Visual System Development in the Macaque

How are the above-mentioned structures interconnected, and how do such connections develop? Some striking patterns of visual system development occur with no prior visual experience, such as the striation of ocular inputs in the lateral geniculate nucleus (LGN) (Shatz, 1990, 1996). Clearly, then, some components of visual system anatomy are innate. Yet, primates stand out in their delayed neural maturation, specifically for postnatal cortical development.

As in human infants, visual acuity in the monkey at birth is limited: only low spatial frequencies are perceived. Visual acuity in infancy is not limited by retinal receptors or optics, nor by behavioral response deficits, but instead appears to be a more central limitation, perhaps due to delayed development of the visual neocortex, particularly the parvocellular system (Boothe, 1982; Teller, 1983). Indeed, many neocortical areas show very different distributions of projections prenatally and in infancy than those seen in the adult. One striking feature of this development is the change in the relative distribution of supra- and infragranular projections among cortical areas. In general, there is a reduction in the relative proportion of supragranular 'feedback' projections among occipital and temporal regions from embryonic days 112–140 that can continue after birth (Batardiere *et al.*, 2002). The STS, unlike other visual areas tested, has a prominent supragranular projection to V1 in infancy that disappears by adulthood (Kennedy *et al.*, 1989). Moreover, this transient supragranular projection pattern is not seen in the cat, whose cortical associational projections appear to develop and stabilize much sooner (Bullier *et al.*, 1984; Luskin and Shatz, 1985; Price and Blakemore, 1985). Other transient projections are seen between the amygdala/surrounding rhinal cortices, and visual areas TE and TEO (Webster *et al.*, 1991a), projections which can be maintained if area TE is damaged early in development (Webster *et al.*, 1991b). Thus, cortico–cortico projections between striate cortex and other regions of visual cortex appear to be in flux both pre- and postnatally. Consistent with this postnatal plasticity, lesions to striate cortex made early in development have more modest effects than lesions made in adulthood, suggesting striate cortex is part of a developmental visual process, but that other visual areas are somehow able to compensate.

One candidate circuit that could process visual information in the absence of striate cortex is comprised of the SC, which receive retinal input, and which project to the amygdala and cortical visual areas via the pulvinar. This superior colliculus route has two features important for early visual processing: it is already developed in newborn monkeys (Wallace *et al.*, 1997) and is biased towards low-spatial frequency stimuli. Evidence for a compensatory role of this circuit includes virtually unaltered responses in middle temporal (MT) and superior temporal polysensory area (STP) as a result of striate or SC lesions alone, but an elimination of visual processing in MT for combined lesions (Bruce *et al.*, 1986; Girard *et al.*, 1992; Rodman *et al.*, 1990). In contrast, striate

lesions alone are sufficient to eliminate V2, V4, and IT visual responses (Girard and Bullier, 1989; Girard *et al*., 1991; Rocha-Miranda *et al*., 1975; Schiller and Malpeli, 1977). In light of these findings, the most likely route through which cortical activity can be maintained when striate cortex is damaged is from the SC–pulvinar pathway.

What might an SC–pulvinar route to the amygdala or STS have to do with face processing? Aside from the general responsivity to faces in these areas, which could be entirely due to input via LGN-striate cortex, there is evidence from human fMRI and lesion data suggesting that the SC, pulvinar, and amygdala are active in processing emotional or dangerous stimuli (Liddell *et al*., 2005; Morris *et al*., 1999). In particular, all three regions prefer the low-spatial frequency band for emotional face stimuli (Vuilleumier *et al*., 2003). Studies from blindsight patients suggest this subcortical route is active for processing threatening faces (Morris *et al*., 2001). Finally, one recent study of a patient with unilateral pulvinar damage suggests that the pulvinar is required for the rapid processing of visual information about threatening stimuli (Ward *et al*., 2005). Taken together, key attributes of this system across studies seem to include sensitivity to threatening stimuli, low-spatial frequency sensitivity, and fast perception/transmission of stimulus information. Recall that there was maintained neural activity in STS (but not in IT) following striate lesions that suggests some, but not all, regions of neocortex would be responsive to this alternate route (Bruce *et al*., 1986; de Gelder *et al*., 1999). Previous studies have suggested that the STS, compared to adjacent areas of IT, is particularly responsive to facial expressions (Eifuku *et al*., 2004; Hasselmo *et al*., 1989). The face-selective responses in STP also commonly occur at very short latencies, peaking in the range of 50–80ms, though the source of visual input is unknown (Hoffman, unpublished observation). The above observations hint at a role of the SC–pulvinar pathway in face processing in the adult monkey. But consider that infant monkeys, who only process low spatial frequency information, had an innate response to threatening monkey faces. These coincidences aside, there is no hard evidence that processing of emotional face stimuli occurs in the STS through a SC–pulvinar route at the time of birth.

4.27.4 Models of Face-Processing Acquisition

One popular conceptual model of newborn face preferences postulates two separate mechanisms, one of which corresponds to a subcortical pathway, such as the one described above. This mechanism, termed CONSPEC, would be in effect for the first months of infancy, and would only be responsible for the preference for a basic face configuration observed in newborns. At around 6 weeks, it would be replaced by CONLERN, a more flexible cortical system taking over the charge of learning what distinguishes individual faces (Johnson and Morton, 1991). Other models propose even more systems to explain further changes taking place during infancy (de Schonen and Mathivet, 1989). Whereas the CONSPEC/CONLERN model incorporates some of the developmental features of the brain, the distinction between the two systems may be somewhat artificially imposed. A subcortical system need not be completely inflexible nor supplanted by a cortical system.

A complementary view, requiring only one system, attempts to explain not only the postnatal effects, but, importantly, how some aspect of sensitivity to faces could begin earlier, in the absence of visual experience (Bednar and Miikkulainen, 2003). Internally generated activity appears to play a role in the development of other neural systems such as LGN segregation, auditory cortex, and retinal organization; likewise, the visual cortex might receive spontaneous activity waves to form connections in the absence of external input, specifically through ponto-geniculo-occipital (PGO) waves occurring during rapid-eye-movement (REM) sleep. A formal model is proposed to demonstrate how a simple input pattern could propagate via the PGO wave through the LGN and visual cortex, to provide a face-detection response consistent with the schematic face-like stimuli used in several newborn studies (Johnson *et al*., 1991). Though interesting and simple in design, there is little independent evidence to support this theory. The role of PGO waves must be explored, and the layers themselves (labeled retina, LGN, V1, and face-selective area) may actually be implemented through other structures. Further research should test the behavioral and functional predictions of their model.

Finally, a more general model extending from faces to other objects incorporates externally generated activity as inputs to two competing modules (Dailey and Cottrell, 1999). The mere addition of low-spatial frequency information to one of the modules and high-spatial frequency information the other is sufficient to bias the former toward individuating faces and the latter toward classification of objects at the superordinate level. Although not explicitly a developmental model, it is interesting that LSF information leads to face individuation,

since LSF processing is more commonly associated with threatening stimuli including faces. Furthermore, this model provides an explanation of how other (dissimilar) objects may come to be represented in separate circuits from those involved in face processing.

4.27.5 Conclusions

Supposing that face recognition develops in a similar fashion in humans and macaques, there is some evidence for the existence of a neural system that contains both innate and sensitive-period elements. It appears that such a system:

1. supports recognition of threatening facial expressions with no prior experience;
2. requires normal visual experience in the first postnatal months to support configural and holistic processing; and
3. under normal circumstances, acquires many of the adult face-processing abilities within the first few months after birth, beginning with a preference toward low-spatial frequency images with a top-heavy bias.

The term 'neural system' is meant to include any brain region or structure that contributes to any of the numerous aspects of face processing, including recognition of the individual, threatening expressions, or gaze sensitivity. There is evidence that these processes occur at different points in development, and may involve largely independent regions in the brain. We nonetheless consider these as components of a larger system. The CONSPEC/CONLERN model proposes independent components that are useful at different stages of development. In contrast, the pattern-generating wave model proposes largely interacting components. By way of illustration, consider the amygdalar modulation of the fusiform gyrus activation for fearful faces (Vuilleumier *et al*., 2004) . The amygdala is not currently thought to help in the individuation of faces, but the fusiform region is. Yet, amygdalar activity can modulate face responses in the fusiform gyrus. These two areas may have separate developmental histories and primary functions, and nevertheless interact under the appropriate conditions of face processing. It is in this sense that they may be better conceived as parts of a larger neural system for face processing.

Understanding which neural components subserving face processing are most closely linked in function and development will require further research. Studying the specialization of structures before birth, and the mechanisms underlying the rapid changes in ability after birth, could benefit from the intersection of two lines of research: (1) cross-primate comparisons of face-processing abilities and the corresponding neural specializations, and (2) neural development occurring around the time of birth. Hopefully, such future research will clarify the function behind our innate, early, and protracted face-processing abilities.

4.28 The Evolution of Human Emotion

L A Parr, Emory University, Atlanta, GA, USA
B Waller, University of Portsmouth, Portsmouth, UK

Glossary

homology	A trait or behavior in two related species that is attributable to a common ancestry.
social emotions	Emotions such as shame, embarrassment, guilt, and pride that require self-consciousness and an understanding of social rules and their transgressions.
theory of mind	The ability to understand the mental states of others.

4.28.1 Introduction: Emotion Is Necessary for Survival

> Human emotions, rooted though they are in our animal nature, are nevertheless run through, as mere animal emotions are not, with thought and belief, wish and want, fantasy and imagination, as should be expected of language-using, concept-exercising creatures (Bennett and Hacker, 2005, p. 31).

Emotion has long been viewed as an important phenomenon underlying animal behavior. Emotion helps individuals attend to and extract relevant information from the environment and organize physiological, motivational, and cognitive action patterns that facilitate adaptive responses to aid the survival of the organism. As such, emotion can be thought of as a process that facilitates appropriate responses to a wide range of both internal and environmental situations. Emotional reactions are critical in avoiding predation, finding mates, nurturing young, caring for the elderly, and engaging in behavior that is consistent with social and cultural rules. Some researchers refer to these as drives, innate reflexes, or unconditioned responses. No matter the term, each of these phenomena involves emotion.

Emotion is not only an elusive concept by definition, but the investigation of emotion is fraught with difficulty. One of the main reasons is that emotion influences, and is influenced by, so many facets of the mind and biology. Emotions involve cellular and hormonal processes that in turn affect physiological and neural systems. These collectively affect behavior, the interactions between individuals and other species, and ultimately the integration of the individual within its society. In part because of its interdisciplinary nature, it is becoming a more common practice for researchers to examine emotion as a multidimensional construct, incorporating multiple levels of analysis that cross basic evolutionary, biological, behavioral, social, and cultural boundaries (Cacioppo and Gardner, 1999; Frijda, 1986; Kappas, 2002; Keltner and Haidt, 1999). Whereas this componential approach has a progressive structure, ranging from basic biological to social processes, it has been argued clearly by others that this progression is anything but linear or hierarchical (Cacioppo and Berntson, 1992). In fact, social factors can influence biological factors and vice versa, with no one level of analysis having any greater role than another for understanding emotion. Many have argued that the only way to fully understand emotion is to examine each level, not restricting the analyses to any single component (Kappas, 2002; Leventhal, 1991). Only through the collective integration of ideas and findings across disciplines will researchers begin to identify the quantitative and qualitative features leading to the expression of emotion in animals

and ultimately to identify and understand what is unique about human emotion.

4.28.1.1 Directions for Understanding the Evolution of Emotion

This article will focus on three broad developments in the emotional behavior of animals with reference to human behavior. The first is that emotion involves innate, reflexive, and adaptive behavior that shares commonalities in its underlying mechanisms of production in all animals. Studies from both nonhuman primates and human neonates suggest, for example, that some facial expressions are produced from birth with little or no social experience. Additionally, the underlying mechanisms for these behaviors have a common signature in animals due to the role of various brain structures, particularly the limbic system, and the recruitment of physiological processes that serve to increase the survival of the organism (Panksepp, 1982). These survival responses are aided by the nervous system's bias for processing negative information at high levels of arousal (Cacioppo *et al.*, 1999). These reflexive and adaptive behaviors are arguably the building blocks from which more complex and flexible forms of emotional responses evolved and, even in advanced species such as humans, they are ever vigilant.

The second development is that socially living species have means to communicate with one another about emotion, through visual, auditory, tactile, or chemosensory signals. The communication system and the signals therein need not be specific or referential, or even self-conscious, for that matter. There need not be a specific association, for example, between the signal, e.g., a facial expression, and its emotional meaning, e.g., fear, although this has been suggested in humans (Ekman, 1992). Rather, these signals are predictive of the general motivation and/or tendency of the organism to engage in a series of actions given a set of social and environment conditions (van Hooff, 1973). The signals, however, must be easy to recognize and discriminate from other signals and/or noise in the environment, or their information content and predictive value will be lost. Thus, in addition to the signal being discrete and distinctive, the receivers of the signal must be tuned to its detection. Because of the strong relationship between facial expressions and emotion in humans, much of this section will focus on evidence for homologous facial expressions in humans and related species and introduce the development of a behavioral coding system, similar to that used for humans, that will prove extremely influential in identifying the underlying meaning of these signals.

Finally, greater flexibility in communication systems, more complex social environments, and individual social relationships fueled by an expanding neocortex contributed to the evolution of socially derived emotions, or self-conscious emotions, such as guilt, shame, pride, and embarrassment. These emotions are rooted in a basic awareness of the self and the unobservable mental states of others, a concept known as theory of mind. The absence of these socially derived emotions is, in many cases, associated with various forms of psychopathy and neurodevelopmental disorders such as autism (Heerey *et al.*, 2003; Hillier and Allinson, 2002; Levenston *et al.*, 2000). Though there is little conclusive evidence for theory of mind in species apart from humans, it will be argued that a precursor to theory of mind must have been an awareness of others' emotions, a basic form of empathy, which appears to be present in rudimentary forms in mammals, including our closest-living primate cousins (Parr, 2001; Preston and de Waal, 2002; Povinelli and Preuss, 1995).

4.28.1.2 Emotion Underlies Adaptive Behavior

4.28.1.2.1 Subconscious evaluative processes
Emotion involves behavioral reflexes that represent adaptive responses by an organism to environmental challenges. These basic reflexes can be deconstructed to include approaching things judged to be positive, or appetitive responses, and avoiding things judged to be negative, or aversive responses. This basic bivalent system was derived from research on unconditioned reflexes in animals, with appetitive motivational systems including behaviors such as ingestion, copulation, and nurturing young and aversive motivational systems including behaviors such as withdrawal and the rejection of noxious stimuli. Furthermore, there is evidence that these basic evaluative systems are implicitly associated with motor responses that aid in the adaptive responding of the organism. Studies have found, for example, that muscle extension is more often associated with negative affective responses, such as withdrawal and avoidance, than with muscle flexion, which is associated more with positive responses, or approach (Cacioppo *et al.*, 1993). In this experiment, stimuli were judged more pleasant when individuals flexed their arms as if pulling an item toward them than when their arms were extended, as if pushing the item away (Cacioppo *et al.*, 1993). These stimuli consisted of neutral Chinese ideographs, ruling out the possibility that subjects had preconceived affective attitudes toward these stimuli that subconsciously affected their evaluations. Additionally, these effects were not found when subjects simply observed someone engaging in

muscle flexion and extension, indicating that the motor action itself was necessary for differential evaluative responses. Similarly, response latencies to either push or pull a lever when presented with affective words were faster when the flexion action of pull was paired with a positive emotional word-stimulus and when the extension action of push was paired with a negative emotional word-stimulus than when push and pull were incongruently paired with positive and negative stimuli, respectively (Chen and Bargh, 1999). These associations were not the result of any conscious processes, in that subjects did not report any awareness of the association between their behavior and their affective evaluations. In addition, when asked to form intentional, conscious judgments about certain stimuli, such as semantic characteristics compared to evaluative characteristics, these responses weakened (Bargh *et al.*, 1996). Finally, these processes were found for novel, abstract stimuli that were rated as being either positively or negatively valenced (Duckworth *et al.*, 2002). This provides further support for the influence of unconscious, affective evaluative processes on the automaticity of adaptive behavioral responses (Murphy and Zajonc, 1993).

At this primitive level, appetitive and aversive behavioral responses are modulated by specific neural circuits in the brain that share a common neuroarchitecture among mammals. These brain systems are genetically hard-wired to enable animals to respond unconditionally to threatening, or appetitive, stimuli using specific response patterns that are most adaptive to the particular species and environmental condition (Berridge, 1996; Panksepp, 1982). When aversive stimuli are detected, for example, receptors in the sensory cortex and thalamus are activated. These sensory afferents activate the amygdala directly, leading to a cascade of responses that enable the organism to escape or reject the current situation (LeDoux, 2000). The same information travels via a slower route to the cortex and then back to the amygdala, providing the organism with an opportunity for postcognitive emotional evaluation. Appetitive systems, on the other hand, have a rich history in studies of the nucleus accumbens and mesolimbic dopamine system that are involved in regulating the body's response to reward and pleasure (see Berridge, 2003). Although it is still common for the neural control of emotional behavior to reside solely on the shoulders of the limbic system (MacLean, 1949; Panksepp, 1982), studies have implicated a variety of brain structures in both cortical and subcortical regions including the amygdala, cingulate cortex, hypothalamus, insular cortex, orbitofrontal and prefrontal cortices, and even brainstem sites and cerebellum (Allman *et al.*, 2001; Berridge, 2003; Lane *et al.*, 1998; Parvizi *et al.*, 2001). Studies in both humans and animals using a variety of techniques are now showing that a single brain area subserving emotion is drastically simplistic, in fact, just plain wrong. Rather, the brain appears to have distributed connectivity among regions that individually play key roles in the experience of emotion, but only collectively provide the color for emotional experience (for excellent reviews, see Berridge, 2003; Buck, 1999).

4.28.1.2.2 Emotions are negatively biased The evaluations described above are, however, not without influence and/or interindividual variability. Stimuli are evaluated not only with respect to environmental change but are weighted in relation to the individual's current motivation within that environment. To determine which response is most adaptive given a set of internal and environmental conditions, animals, like humans, rely on a basic system of appraisals that evaluate environmental events according to their self-relevance. Appraisals refer to implicit, rapidly occurring evaluations made about the significance of an object or event and are likely to differ depending on the individual, his or her previous history, and his or her current condition (Scherer, 2000). In terms of emotion, similar patterns of appraisals may emerge across individuals, resulting in similar emotional experiences. When objects and events are appraised as being conducive to achieving an important personal goal, happiness may result, whereas events that are appraised as occurring suddenly, with uncertain and potentially threatening consequences, are likely to result in emotions such as fear (Scherer, 2000). Whereas appraisals are considered a form of cognition, they are not necessarily conscious, although conscious awareness and control of behavior may occur later in the processing stage in some species.

From an evolutionary perspective, species should arguably be more invested in aversive, defensive response systems in some situations than appetitive, positive response systems. If an individual does not safely avoid the dangers of predation, he or she will not be able to seek out mates and reproduce, and thus contribute his or her genetic investment to future generations. Thus, individuals might be in a constant state of vigilance, with defensive systems ready to respond if dangers are detected. Moreover, positive and negative motivational systems may be co-activated, having nonreciprocal associations rather than occur along a single bivalent dimension. Thus, an animal may choose to approach a food source in the presence of a potential predator if its feeding motivation is high, co-activating appetitive and defensive systems. Similarly, a human may refrain from eating his or her favorite dessert when on a diet. Thus, an

improvement in the traditional bivalent system, where positive and negative motivations lie at opposite ends of a continuum, Cacioppo and Berntson (1994) have proposed that attitudes and emotions are better viewed according to a model of evaluative space. Evaluative processes refer to the neural circuitry and subsequent behavioral adaptations involved in processing the affective significance of a stimulus. This is opposed to nonevaluative processes that refer to the discrimination and categorization of such stimuli (Cacioppo *et al.*, 1999). According to the evaluative space model, positive and negative responses are under the regulation of separable motivational substrates that can act independently of one another (Cacioppo and Berntson, 1994). Therefore, dimensions of positivity and negativity can be activated reciprocally or individually or they can be uncoupled with each dimension either co-activating or co-inhibiting the other.

According to the evaluative space model, the positive motivational system is characterized by greater activation when the arousal level of the system is low. So, at low levels of arousal, individuals tend to respond with greater positive responses than negative responses. This also makes sense from an evolutionary perspective. Positive emotional behaviors, such as copulation, maternal care, and grooming, are all highly social interactions that are best served when individuals are calm and not likely to be easily driven into a heightened state of defensive arousal. In contrast, the negativity bias, as it has been termed, is defined as greater output in the negative motivational system than in the positive motivational system, given the same degree of activation, or level of evaluative input. Evidence for these two dimensions has been found in a number of studies. Negative stimuli, for example, elicited larger event-related potential responses in humans than positive pictures, even when subjects were not required to make any affective evaluations of the stimuli, evidence of the negativity bias (Ito and Cacioppo, 2000). In addition, Ito *et al.* (1998) used regression analyses to assess people's arousal ratings for a variety of emotional stimuli. As predicted by the regression parameters, a shallower slope and higher value at low levels of arousal were found for positive arousal ratings (higher intercept value), whereas a steeper regression slope with greater ratings of negativity at higher levels of arousal was found for negative arousal ratings (negativity bias). Thus, the model helps to explain the evolution of distinguishable motivational systems in animals that allow for the co-occurrence of exploration and self-preservation (Cacioppo *et al.*, 1999). These models are particularly useful for developing theories about the evolution of human emotion because they lay a framework for understanding the behavior of animals in an ever-changing and increasingly complex social and ecological environment. Basic drive systems are constantly present, but control over these basic reflexes creates a myriad of potential outcomes that have helped to shape the evolution of animal behavior and emotion. These concepts will become important for the discussions in the final section of this article.

4.28.1.3 The Innate Expression of Internal Arousal Systems

4.28.1.3.1 Hedonic facial reactions to taste One of the earliest and most conspicuous behavioral manifestations of these arousal systems is the production of facial expressions. Although numerous studies have examined both the perception and production of facial expressions in human infants (Izard, 1971; Nelson, 1987), fewer studies have focused on these distinctions in nonhuman primates. However, evidence to date suggests that some facial expressions may have strong innate components, occurring in primates soon after birth, with little or no prior social experience with conspecifics.

One set of evidence for the innate production of facial expressions comes from a series of elegant studies in humans and nonhuman species on the faciogustatory response to various tastes and smells. Sweet, sour, and bitter stimuli, for example, produced highly similar patterns of spontaneous facial displays in both adult humans and neonatal infants; i.e., neonates were less than 16 h old and were tested before their first feeding experience (Steiner and Glaser, 1995). These authors found very stereotypical facial reactions in all subjects in response to these gustatory and olfactory stimuli that could be divided according to basic hedonic valence. Sweet stimuli produced facial relaxation, retraction of the mouth corners into a basic smile, and licking and sucking movements (see The Evolution of the Sweetness Receptor in Primates). Bitter tastes produced depression of the mouth corners and elevation of the upper lip, whereas sour tastes produced pursing of the lips (Steiner, 1974). Based on these facial response patterns, stimuli could be divided into two broad hedonic or motivational categories: one of acceptance, consummation, and pleasure, and the other suggestive of rejection, repulsion, and aversion (Steiner and Glaser, 1984).

To determine the evolutionary commonality of these innate facial reactions, Steiner and colleagues examined facial responses to tastes in numerous

species of nonhuman primates including prosimians, New World monkeys, Old World monkeys, and hominoids (Steiner and Glaser, 1984, 1995; Steiner *et al.*, 2001). Facial reactions were coded using detailed ethograms of facial movements, including components of the facial action coding system (FACS) developed by Ekman and Friesen (1978) to characterize human facial movements according to their underlying facial musculature (see Section 4.28.2.2.2.1) and for ethological descriptions of primate facial expressions (Andrew, 1963). Also important to these studies is the concept of homology described in the second section of this article (see Section 4.28.2.1). In brief, it is important to show that the pattern of facial reactions and accompanying behavior is homologous across the species tested, thus enabling researchers to conclude that the behavior is the result of similar affective evaluations mediated by similar neural substrates. Results found that facial reactions and behaviors in nonhuman primates could be grouped according to positive and negative hedonic dimensions and that these affective behavioral reactions were similar across species and taste categories (Steiner *et al.*, 2001). Reactions observed in all species shared universal components, including a rhythmic pattern of tongue protrusions in response to the sweet stimuli and an open-mouth gape with head shake in response to the bitter stimuli. Furthermore, across taxonomic groups, taste-elicited affective reactions were more similar among closely related species. Hominoid-specific expressions, for example, included actions involving the lips and middle part of the face. A smile in response to sweet stimuli, for example, was observed only in apes and humans. Old World monkeys showed characteristic brow elevation in response to the sweet stimuli, a pattern not observed in the other species. Reactions specific to New World species included a tongue protrusion pattern that categorized bitter versus sweet stimuli. Therefore, these gustofacial responses are innate, stimulus-dependent communication signals common among related primate species that reflect the organisms' ability to differentiate afferent sensory stimuli along basic hedonic dimensions (Steiner, 1974; Steiner *et al.*, 2001). As such, these facial patterns can be used to measure and compare emotional responses across species and provide evidence for an innate and phylogenetic relationship between facial expressions and emotional experience.

4.28.1.3.2 The role of social experience One of the first psychologists to speculate about the relationship between emotion and social behavior was Harry Harlow at the Wisconsin Regional Primate Research Center in Madison, Wisconsin. His research focused on the emotional needs of young rhesus monkeys (*Macaca mulatta*) during their early stages of development. Although these studies did not explicitly emphasize the importance of facial expressions or emotional communication, this research was pivotal in documenting the severe emotional and behavioral consequences that result when young rhesus monkeys are deprived of social contact with their mother from birth and are raised in social isolation (Harlow *et al.*, 1971). The attachment of an infant to its mother was not simply based on the need for food, but on the even more fundamental need for what Harlow termed love and affection. These studies also provided an experimental format for examining nature versus nurture issues, such as which behaviors are expressed innately and which require social experience. Regardless of the specific application, these studies raised a critical awareness within the primatological community, and far beyond, as to the importance of early social experience for normal social and emotional development (Harlow and Mears, 1983).

During this period, Gene Sackett, a student of Harlow, demonstrated that socially naïve monkeys produced appropriate facial expressions and behavioral responses when shown photographs of threatening conspecifics compared to photographs of conspecifics with playful or fearful expressions, monkeys engaged in sex, or control photographs depicting nonsocial stimuli (Sackett, 1966). The key conclusion from these studies was that social experience was not necessary for the production of species-typical facial expressions; rather, these expressions were the product of an innate releasing mechanism and could be elicited in a morphologically intact form in the complete absence of social experience (Sackett, 1965). When these isolated monkeys were later introduced to a social group, however, they were unable to respond appropriately to the range of facial displays and complex emotional messages produced by their new group mates. It seemed that although the appropriate production of facial expressions may be the result of innate mechanisms, the comprehension of facial displays made by other individuals in a dynamic social context required a period of normal social and emotional development.

Sackett's studies suggest that the subtle context-dependent meaning of facial expressions can be learned only from direct social experience. A direct gaze, for example, is interpreted by rhesus monkeys as being threatening; hence an important component of a threat face is to stare directly at the opponent (Hinde and Rowell, 1962; van Hooff, 1962). But do monkeys really understand these

cues from birth or must they see others engage in these interactions before they understand their meaning? To study the development of how infant rhesus monkeys respond to a direct open-mouth threat, 1-, 3-, and 7-week old rhesus infants were tested on their responses to the faces of conspecifics with direct or averted gaze (Mendelson *et al.*, 1982). These faces were presented using projection slides. No differences in viewing were detected in the 1-week-old infants. By 3 weeks of age, however, infant monkeys looked for a longer time at the faces with the direct gaze than at those with the averted gaze. This increased viewing was accompanied by negative emotional behaviors; i.e., the individuals showed submissive squealing, grinned, and lip-smacked at the direct-gaze faces. By 7 weeks of age, the infants avoided looking at the direct-gaze faces altogether. Instead, these infants preferred to look at the faces with the averted gaze and no longer produced emotional responses in their presence. These results suggest that by 3 weeks of age, rhesus monkey infants understand the social implications of the direct stare and respond submissively to this threatening stimulus. These infants, however, do not as yet have the social competence or knowledge to avoid looking at these faces. By 7 weeks of age, the infants' behavior changed dramatically. They now learned to respond to this socially threatening stimulus by looking away, a response that is critically important for integration into a rhesus macaque social group.

Further evidence for the specific role of facial expressions in social communication was provided in a series of studies by Izard, one of the founders of facial expression research in humans and infants (Izard, 1971). In a series of studies, Izard and colleagues transected the facial nerve (cranial nerve VII) of 3-year-old monkeys and examined the behavioral and emotional consequences when these individuals were physically unable to make facial expressions. How would individuals get by when the primary tool for social and emotional communication was not at their disposal? Although these studies were never published in a peer-reviewed format, preliminary results suggest a number of important findings. (The preliminary report was published in Izard's seminal book *The Face of Emotion*, 1971, pp. 385–391.) First, the animals that received facial nerve transections displayed more aggression, mounting, and general activity than their cage mates. Second, when returned to their social group, experimental subjects showed greater displacement activities, threats, and attacks than group mates and eventually dropped in rank. Third, the relationship between the operated females and their infants was compromised. Infants appeared not as strongly attached to their mothers and spent more time apart from her interacting with other, unoperated group members. Results suggest that communicating through facial means is an important, and perhaps necessary, ability for social integration and the expression of typical social behavior.

A series of intriguing studies was performed by Robert Miller and his colleagues. They demonstrated that rhesus monkeys could communicate affective information to one another using facial expressions. Specifically, Miller *et al.* (1959) exposed monkeys to a photograph of a familiar group mate with a neutral face. The presentation of this conditioned stimulus (CS) was paired with a shock that subjects could avoid only by pressing a lever in their test cage. Subjects quickly learned to press the lever when this face appeared, thereby avoiding the shock, i.e., standard operant conditioning. Next, subjects were shown another photograph of the same CS individual, but this time making a fearful facial expression. When subjects were shown this new stimulus, they produced spontaneously significantly more avoidance responses than during the acquisition of the conditioned response when the CS was the same monkey with a neutral face. This suggests that a negative facial expression is much more effective in communicating an upcoming aversive event, i.e., the shock, than a neutral face, illustrating that at some level the monkeys understood its inherent negative emotional meaning. Similar findings have been reported in humans using implicit priming studies. Winkielman *et al.* (1997) demonstrated that when humans were presented with photographs of smiling faces for 10 ms, too quick for conscious perception, they rated neutral stimuli as being more pleasant than if primed with frowning faces or blank slides.

In a second study, Miller *et al.* (1963) tested whether a stimulus monkey and a responder monkey could cooperate in producing an avoidance response. In this paradigm, only the stimulus individual could see the CS that signaled the upcoming shock, but unlike the previous situation, this individual had no access to the avoidance lever. In another room, the responder monkey could access the lever, but it could not see the projection screen that displayed the CS. The responder monkey could see only a live video feedback of the face of the stimulus monkey in the other room. The idea was that changes in the facial expression of the stimulus individual as it viewed the CS would be sufficient to communicate the upcoming danger to the responder monkey, who in turn would press the lever so that

they both would avoid the shock. The result of this cooperative avoidance paradigm was that the responder monkey produced more lever presses during the period when the CS was visible to the stimulus monkey, indicating that the stimulus monkey's facial expression was sufficient in communicating the appropriate affective information to the responder monkey.

These studies serve to demonstrate several important characteristics of affective facial expressions in nonhuman primates. First, these expressions have an innate component. This includes both the production of specific facial expressions and the type of information they communicate. Threatening facial expressions are better for communicating negative events, congruent with their emotional quality, than neutral faces. Interestingly, this was not found for positive facial expressions, supporting the concept of a negativity bias in the evolution of affective communication (Ito *et al.*, 1998) and perhaps the fact that these monkeys were in a heightened state of arousal in this aversive conditioning paradigm. Second, they provide an excellent reminder of the importance of normal social development and social experience for learning the appropriate meaning of facial expressions and how to use them with sufficient skill when interacting with conspecifics.

4.28.2 Assessing Emotion through Facial Movement

Emotion, to this point, has been described primarily as an automatic, adaptive process with a strong innate component. Its social expression and utility in maintaining social cohesion, however, require experience and learning. Emotion is also an experiential process that includes a strong subjective component unique to each individual. Because this process may never be fully understood or achieve direct comparison both within and between species, emotion must be studied at a more concrete, observable level. The human literature has provided a rich history for the study of observable emotion through facial actions and expressions. From the early empirical work of French neurologist Duchenne de Boulogne, who was the first to electrically stimulate facial muscles to create emotional expressions, to more contemporary studies by Paul Ekman and others, the association between facial movement and emotion provides a means for identifying and measuring emotions in naturalistic and experimental contexts (Duchenne de Boulogne, 1862; Ekman and Friesen, 1975; Izard, 1971; Tomkins and McCarter, 1964).

Additionally, facial expressions provide a robust level of comparison for understanding the evolution of emotion for several reasons. First, the facial expression repertoires of related species, despite highly varied patterns of social organization, are very similar. Common facial expressions have been described in many different species of nonhuman primates, suggesting that they were important behaviors in our evolutionary history (see The Evolution of Parallel Visual Pathways in the Brains of Primates). Furthermore, some of these expressions are elicited in similar social contexts, which is suggestive of, although not evidence for, a common function or meaning. Second, the mimetic facial musculature that forms the structure of facial expressions is highly conserved across primate species. This indicates that, with few exceptions, the facial behavior of related species can be compared directly in a manner that reinforces evolutionary continuity in the form of expressive behavior. Third, a large body of multidisciplinary research, as has already been discussed, strongly supports the association between facial expressions and emotion in primates. Humans in many diverse cultures are able to identify basic facial expressions using emotion labels, leading to the claim that facial emotions are biological universals, not culturally derived behavior patterns. Finally, this cross-cultural research has been aided considerably by the development of an objective, highly detailed coding system for analyzing facial movements according to their units of production, the mimetic facial musculature. Therefore, facial expressions represent a highly salient and empirically robust unit of measurement for understanding the evolution of emotion in primates. These different points are discussed below.

4.28.2.1 Are Primate Facial Expressions Homologous?

4.28.2.1.1 Facial expression repertoires are similar among closely related species Although the order of Primates can be characterized by striking differences in social organization and behavior across species, the appearance of facial expressions has remained remarkably similar. Contemporary research over the past half-century has considerably advanced our understanding of the communicative repertoire of nonhuman primates. This includes detailed descriptive reports of facial expressions in a variety of primate species including chimpanzees, bonobos, macaques, and capuchin monkeys (de Waal, 1988; Hinde and Rowell, 1962; van Hooff, 1962; Andrew, 1963;

Goodall, 1968; Parr *et al.*, 2005; Weigel, 1979). The two main goals of this research have been to document the range of communication systems present in our closest ancestral lineage and examine whether these facial expressions are similar, both morphologically and functionally, to our own.

This similarity in the appearance of facial displays is due, in part, to a general conservation of the facial muscles that underlie these expressions (discussed below), which show a similar basic plan across mammals (Huber, 1931), and to ritualization, a process by which a formerly adaptive, unspecialized behavior becomes divorced from its originally adaptive context to take on a different and typically more communicative meaning. The result of this ritualization process has been that signals become easily recognizable, highly conspicuous, and often stereotypical in their movement, helping to ensure that they are easily detected and understood by members of the same species.

Due to the association in humans between facial expressions and emotion, comparing the characteristics of facial expressions between related species would be insightful for making general assumptions about the emotional quality of nonhuman primates' facial behavior. That said, determining homology in behavior is a particularly daunting task because there are many levels on which to draw such comparisons. Behavior can be homologous due to its genetic basis, ontogenetic development, morphological structure, nervous innervation, and/or behavioral function (Lauder, 1994; Redican, 1982). Indeed, a character may be continuous throughout evolution on one of these levels, but shift from the ancestral character on another level. This can make the identification of homologous traits both difficult and controversial (Cartmill, 1994). In determining the most optimal unit of analysis, researchers are often self-serving; i.e., primatologists might use behavioral appearance, whereas molecular biologists might use protein structure. In addition, a behavior might be strikingly similar between species at one level of analysis, i.e., such as the appearance of facial expressions, but closer examination of other levels including the ontogeny, underlying musculature, and social function, could reveal dissimilarity. This raises an important point with regard to understanding the homology of primate facial displays: visual appearance alone is insufficient to make assumptions about the homologous nature of facial displays because different species have different facial shapes that may influence the appearance of facial actions made by the same muscle, or the facial actions may look similar but the muscular basis for these movements might be different. Thus, for the comparison between human and nonhuman primate facial expressions, appearance and musculature together provide a better and more evolutionarily stable unit of analysis for understanding the evolution of emotion than appearance or social function alone.

Several expressions have been addressed in terms of human and nonhuman primate homology, particularly the silent bared-teeth (sbt) display, often called the fear grin, and the relaxed open-mouth face, or play face. These have been compared to the smile and laughter displays of humans, respectively (Preuschoft and Van Hooff, 1995; Waller and Dunbar, 2005). The sbt consists of a retraction of the mouth corners, pulling the lips away from the teeth while the mouth remains closed. The evolutionary origin of this movement is suggested to be a protective response in drawing the lips away from noxious stimuli (Andrew, 1963). Through ritualization, this movement has come to signal social submission and/or appeasement, although its use is quite varied. In the chimpanzee, for example, the sbt has been observed in aggressive contexts and more positive emotional contexts, such as affinitive behavior and play, and thus seems to have diverged considerably from its association with fear (Parr *et al.*, 2005). Van Hooff (1973) recognized this important deviation and suggested that in some highly developed taxa, the sbt might have a reassuring function associated with attachment tendencies. The muscle action that accomplishes this movement in both humans and chimpanzees is contraction of the zygomaticus major, although there has been debate about whether the same visual appearance can be achieved through the contraction of the risorius, which pulls the mouth corners laterally, or the platysma, which pulls the mouth corners downward on the jaw (Redican, 1982). These phylogenetic comparisons are important to fully understand the homologous relationship between underlying structure and observable function and how these have been shaped by evolution to fit the specific needs of each species.

4.28.2.1.2 Primate facial expressions share structural elements The mimetic muscles involved in the production of facial expressions have changed little over the course of primate evolution. It has even been argued that they have been shaped by evolution specifically to aid visual communication (Huber, 1931). The facial muscles in all primates are formed from two basic sheets – the sphincter colli superficialis and the sphincter colli profundus (Huber, 1931). The latter provides the material for the majority of the facial muscles, particularly

those that are involved in expressive movements, and the former develops into the platysma, a broad sheath of muscle fibers in the neck region. In general, the complexity and subtlety of the facial musculature as a whole are features that are unique to the order of Primates, but the relative size and differentiation of these two muscle sheets do vary between primate species. There is greater differentiation observed in the sphincter colli superficialis and, moreover, this differentiation is attributed to the more highly expressive species (Huber, 1931). Another interesting feature of this muscle sheet is that the individual muscles that arise from it often attach directly to the skin, which is in contrast to other skeletal muscles that attach to bone and connective tissue. This provides confirmatory evidence that the primary function of the muscles derived from the sphincter colli superficialis is to produce movement of the facial landmarks, i.e., skin, providing the basis for visual communication. There is also evidence linking the evolution of facial expressions and elaboration of the facial musculature to brain function. Sherwood *et al.* (2004) reported phylogenetic differences in the organization of neurons enriched with neurofilament protein in the primary motor cortex among nonhuman primates. Species with more elaboration in the mimetic facial muscles and greater repertoire of facial expressions, such as great apes and humans, showed a greater density of neurons that might contribute to greater dexterity and more voluntary control of the facial region. In addition, the volume of the facial nucleus in the pons of the brainstem was larger than would be predicted based on standard phylogenetic regression in great apes and humans, again suggesting greater spontaneous control of the facial musculature in hominoids than in other nonhuman primate species (Sherwood *et al.*, 2004). Thus, there appears to be a phylogenetic relationship between facial expression repertoire and neural control of the facial musculature.

An understanding of the phylogenetic nature of the facial muscles can inform us about interesting species differences in facial movements by tracing the origin of these movements back to their muscular basis. Prosimians, for example, an evolutionarily older group of primates, having split from the ancestors of anthropoids 40–45 Mya, have very fine control of their ear movements through action of the postauricular muscles. Contraction of this muscle retracts the posterior portion of the scalp and results in the action of ear flattening. This muscle is also present in the cercopithecine primates; however, it has less influence over ear movement and instead serves primarily to retract the scalp in collaboration with frontalis. Thus, in one species, contraction of this muscle produces noticeable differences in ear movements, but in other species, it acts mostly to change the appearance of the scalp. In humans and some species of great apes, further differentiation between the actions of the postauricular and frontalis muscles has resulted in a separation between the actions of the ears and scalp. As a result, ear movement is not associated with brow or scalp movement (Burrows *et al.*, 2006; Waller *et al.*, 2006). Some have suggested that because of the previous connection between the actions of the postauricular and frontalis muscles, the brow movements of humans are vestiges of ear perking movements in lower mammals, for example, when orienting attention (Andrew, 1963). It has been suggested that brow movements can act as conversational signals of emphasis and attention, invoking the phylogenetic origin of these muscle actions (Ekman, 1977).

An examination of the buccinator muscle provides an illustration of how muscles can be released from their original adaptive function and through ritualization can come to play important roles in social communication. The buccinator is a muscle that lines the buccal pouch in many primates and aids primarily in the manipulation of food in the mouth. In humans, the buccinator is used during mastication and when contracted it also dimples the cheek fat, an expressive movement associated with contempt and, in contrast to other emotional expressions, does not appear to be present in primate species other than humans (Matsumoto and Ekman, 2004). Thus, although some interesting differences between species can be discussed, primates appear to share displays that are similar in appearance (expressions), in their structural elements (underlying musculature), in their use in particular social contexts (function), and in their ability to communicate information to conspecifics (meaning). Thus, facial expressions provide a robust unit of behavior for comparing emotional communication across related species.

4.28.2.2 Assessing Similarity in Human Facial Expressions

4.28.2.2.1 Facial expressions as biological universals

Numerous reviews have been written regarding the ability of humans to recognize emotion from facial expressions (Ekman, 1992; Izard, 1994; Russell, 1995). The two main claims from this work have been that facial expressions of emotion are described by people in similar ways and are displayed in response to similar emotional

experiences regardless of culture. Considerable debate still surrounds these premises, largely due to the presence of well-known display rules and various methodological issues that arise when conducting cross-cultural research (Russell, 1995). Display rules represent culturally specific social norms that dictate when and when not to express certain emotions and/or behaviors in social contexts. One of the most well-cited studies is that of Ekman and colleagues (1972). They showed stress-inducing films to college students in the United States and Japan when the subject was either alone or in the presence of an experimenter from the same cultural group. When alone, the students in both groups made facial expressions that differed only minimally; however, in the presence of an experimenter, the Japanese students inhibited their negative facial expressions more often and showed more smiling than the American students (Ekman and Friesen, 1971, cited in Fridlund, 1994). This is presumed to be the result of the collectivistic Japanese culture to control negative emotional expression in public as a way of facilitating a harmonious community (Shioiri *et al.*, 1999).

Since this study, display rules have become an accepted mechanism for the regulation of emotion, although these studies have largely viewed regulation of emotion as occurring through the inhibitory control of facial expressions. Matsumoto *et al.* (2005) have developed a new approach that goes beyond simple measures of inhibition or suppression. According to the display rule assessment inventory (DRAI), individuals may express emotion with no inhibitions, amplify or deamplify the intensity of the expression, mask the true expressions with either a neutral face or another expression type, or qualify their expression, which involves showing the true expression together with a smile. In another study, these authors requested American, Russian, and Japanese subjects to try and feel a set of basic emotions in four hypothetical social settings: interactions with family members, with close friends, with colleagues, or with strangers. Americans were found to have the greatest amplification scores, whereas Japanese had higher deamplification and qualification scores (Matsumoto *et al.*, 2005). Thus, the DRAI provides a more sensitive and detailed tool for the measurement of cultural variation in the use of different display rules.

Cultural differences are also present in the ratings of facial emotions. Izard (1971), for example, tested the ability of American, European, Japanese, and African individuals to identify basic facial emotions from photographs of Americans and found some cultural variation in emotion recognition accuracy. American and European subjects showed the best overall recognition, whereas Japanese and African subjects showed quite poor recognition. Indeed, some expressions, i.e., anger, seem to be poorly recognized across cultures, whereas other expressions, i.e., happiness, are almost universally recognized. Several studies have attributed such discrepancies to in-group expertise effects. In other words, individuals are best at identifying facial emotion when posed by members of their own race, or at least of races for which they have considerable experience; i.e., Japanese-Americans would be good at discriminating Caucasian facial expressions, but Japanese students who have lived only in Japan would not. This phenomenon is very similar to the other-race effect described for general face processing and cannot be accounted for by simple motivational differences at judging faces of another ethnic group (Tanaka *et al.*, 2004). Elfenbein and Ambady (2003), for example, found that recognition rates for six basic emotions, happiness, fear, anger, disgust, sadness, and surprise, were significantly better when the judges were of the same ethnic origin as the posers of the facial expressions. Similar results were found when the ethnicities of the rater and the poser were different, but the rater had had considerable experience within the culture of the poser's country, i.e., Tibetan raters living in China or African raters living in the United States (Elfenbein and Ambady, 2003). Thus, emotion recognition judgments were influenced by the degree of exposure individuals had with the ethnicity in question. No such investigation has been made into potential cultural or regional differences in expressive behavior in nonhuman primates. That primates might show cultural variation in their use of communicative facial behaviors has not been suggested up to this point, despite evidence showing cultural variation in other types of behavior. Such an investigation, however, would be extremely interesting and informative.

4.28.2.2.2 An objective coding system links expressive movement to muscle action

4.28.2.2.2.(i) The FACS In one review, Paul *et al.* (2005) suggested that the activity of the facial muscles would provide a useful endpoint for comparing emotion in animals and humans if related facial expressions in animals could actually be identified. Due in part to the issues mentioned above, such as problems in identifying the homologous characters of facial behavior, very few studies have attempted to directly compare particular facial expressions in human and nonhuman primates. Darwin's (1872) seminal book *The Expression of the Emotions in Man and Animals* remains one of the most detailed

comparisons of facial expressions across species and it claims that, to understand human emotional expressions, one must first understand emotional expressions in animals. Even with renewed interest in this question, contemporary studies suffer from many of the same problems that Darwin encountered, namely, what unit of measurement to use and how to directly compare behavior across species without relying on anthropomorphic interpretations.

In humans, the development of an objective and extremely detailed coding system for measuring facial movements has virtually eliminated potential emotional biases that can arise when interpreting facial expressions. The FACS, developed by Ekman and colleagues, identifies a series of action units (AUs) that represent the movements of underlying facial muscles (Ekman and Friesen, 1978). This enables researchers trained in this technique to describe faces in terms of visible action units rather than emotions. When a person is happy, for example, he or she typically smiles. However, smiles can be posed, insincere, and even deceptive (Ekman and Friesen, 1982; Ekman *et al.*, 1988). Using the FACS system, however, smiles associated with genuine enjoyment, or so-called felt smiles, were found to be associated with contraction of the zygomaticus major, which retracts the lips over the teeth (AU12), and contraction of the obicularis oculi (AU6), which produces slight wrinkles around the eyes, sometimes called crow's feet (Frank *et al.*, 1993; Krumhuber and Kappas, 2005). The AU6 smile is often referred to as the Duchenne smile, after the seminal work on facial expression measurement by the neurologist Duchenne de Bologne (1862), which predated Darwin's book. Subjects rated smiles associated with genuine enjoyment, compared to those associated with false enjoyment, more accurately when those smiles contained contraction of the obicularis oculi and these individuals were viewed as being more positive. Researchers also found that there was less variability in smiles that contained AU6, suggesting that the presence of an AU6 is a reliable indicator that the smile is associated with genuine enjoyment (Frank *et al.*, 1993).

Various studies have validated the usefulness of the FACS system for identifying universal facial emotions and the unique involvement of individual AUs in their categorization. Kohler *et al.* (2004) used certified FACS coders to rate human facial expressions using action unit codes and then analyzed whether each facial emotion was associated with unique action unit identifiers. These FACS ratings revealed different patterns of action units for expressions of posed and elicited happy, sad, angry, and fearful expressions. Though there was some overlap in action units recorded for each facial expression category, both the presence and absence of unique units, or unit combinations, enabled an identifying pattern to be found for each emotion type – happiness: unique AU6 (cheek raiser) and AU12 (lip corner puller), absent AU4 (brow lower), and AU20 (lip stretcher); sadness: unique AU17 (chin raiser), absent AU26 (jaw drop); anger: unique AU9 (nose wrinkler) and AU16 (lower lip depressor), absent AU1 (inner brow raiser); fear: unique AU5 (upper lid raiser) and AU2 (outer brow raiser), absent AU7 (lid tightener) and AU10 (upper lip raiser) (Kohler *et al.*, 2004).

4.28.2.2.2.(ii) The chimpanzee FACS Our understanding of the evolution of emotion would be considerably advanced if such a rigorous and objective system could be applied to comparisons of human and nonhuman primate facial expressions. An FACS system for identifying chimpanzee facial movements based on the underlying facial musculature has been developed (Vick *et al.*, 2003). This involved cataloguing thousands of videos and still photographs of naturally occurring chimpanzee behavior and identifying recurring facial movements. The muscular basis for these movements has also been verified through an extensive review of the comparative anatomy literature and through direct intramuscular stimulation of both humans and chimpanzees to verify the appearance of facial movement when muscles are stimulated (Waller *et al.*, 2006). Additionally, facial dissections have been performed to identify the presence or absence and precise location of facial muscles in the chimpanzee to help in validating the behavioral and physiological approaches described above (Burrows *et al.*, 2006). These studies confirm the homologous nature of chimpanzee mimetic facial muscles and the action they produce when contracted. These studies are critical for comparing emotional expressions in chimpanzees and humans.

The development of a chimpanzee facial coding system will be extremely valuable for understanding similarities and differences in the facial movements of chimpanzees and humans. The use of such a system could, for example, provide a direct assessment of whether sbt displays differ among species where this expression has an appeasing, reassuring function versus a fearful, submissive function. One might assume that the emotional differences would also be associated with different muscle action patterns. The chimp FACS has already validated the subjective categorization of nine chimpanzee facial expressions: the bared-teeth display (bt), play face (pf), hoot face (ho), relaxed-lip face (rl), neutral (n), scream (sc),

Table 1 Predicted classification of nine chimpanzee facial expressions using chimp FACS by discriminant functions analysis

alert face (al), pout (po), and whimper (wh). One hundred and seventy-eight individual chimpanzee expressions from 63 different individual chimpanzees were FACS coded using 10 action units in the chimp FACS (by two trained chimp FACS coders), AU6, AU9, AU10, AU12, AU16, AU17, AU22, AU25, AU26, and AU27. These were then subject to a discriminant functions analysis, similar to the approach used by Kohler *et al.* (2004). According to this analysis, over 74% of the expressions were categorized correctly after cross-validation using chimpanzee FACS action units. The classification matrix can be seen in Table 1. Expression types that were not accurately classified included the relaxed-lip face, the alert face, and the pout. Based on this kind of analysis, prototypical action units that best characterize each expression type can be identified, a tool that will be extremely useful when comparing directly the homologies between emotion expressions in chimpanzees and humans.

Table 2 provides a comparison of prototypical facial expressions in chimpanzees and humans and gives their collectively coded action units according to the human FACS and the newly developed chimp FACS. These are matched not only according to their morphological similarity and involvement of similar muscle movements, but according to their functional similarity as well. It is not possible to provide a detailed assessment of the proposed function of chimpanzee facial displays in this article. Readers are referred to numerous excellent reviews and ethograms for detailed descriptions (Goodall, 1968; van Hooff, 1967, 1973; Marler, 1965; Parr *et al.*, 2005). In brief, the bulging-lip face is typically displayed by males after a dominance display, suggesting its association with displaying status and superiority. The bared-teeth display can be silent or can be accompanied by a scream, squeak, or bark vocalization. It is used in many different situations including times of uncertainty, to signal appeasement and/or friendly contact, when fearful, and during times of extreme excitement, such as feeding time. No study to date has attempted to determine whether the bared-teeth displays used in each of these contexts can be distinguished morphologically, as in the case of the Duchenne smile. Chimpanzees scream in many contexts, including during aggressive/assertive situations, after receiving aggression, and in protest of another's actions. The pant–hoot is used to signal excitement over long distances and most often precedes a dominance display, or bluff display, and is often accompanied by piloerection. The pout is given when individuals are denied access to something and are most typically seen in weaning infants and during times of distress. The relaxed open-mouth display, or play face, is used almost exclusively during playful interactions with other individuals.

4.28.3 The Evolution of Social Emotions

4.28.3.1 Building Blocks for Complex Emotions

Group living offers many advantages to the individual, including access to resources (mates, food, and shelter), predator defense, and the ability to defend resources from intergroup encounters. Yet, group living also incurs costs, for although animals in groups are able to access and defend a greater number of resources, they also experience increased intragroup competition for these valuable resources. Many animal species have evolved strategies for dealing with these cost–benefit conflicts, but many primates have mastered a particular quality of behavior that allows complex, interactive groups to form and remain stable for long periods of time. We refer to this as sociality. Sociality reduces the

Table 2 Chimpanzee and human facial expressions characterized by the chimpanzee and human FACS systems

Chimpanzee display		*Prototype AUs*	*Equivalent human facial expression?*

costs associated with group living by facilitating the formation of flexible dominance hierarchies and assisting in the formation of long-lasting relationships, including alliances, coalitions, and cooperative behaviors (Boesch, 2002; de Waal, 1989).

Arguably, the difference between groups of animals that exist with sociality and those that exist without sociality is the presence of a complex, yet flexible system of communication. It is in this capacity that the relationship between distinctive, observable facial movements and underlying emotional states might be more central for understanding sociality than previously considered. Once emotional states are expressed, interpreted by group members, and responded to in socially appropriate ways, requiring a prolonged period of social learning during early development, they become part of a dynamic, interactive social network, or society. In addition, the cognitive processes necessary for both the effective production and efficient processing of signals within such a communicative system are also likely to have undergone selection and may have even co-evolved within this system (i.e., see social brain hypothesis in Dunbar, 1998). The end result is that animal relationships and societies are hinged on emotional communication and the more complex the society/relationship, the greater the need for the expression, perception, and perhaps most importantly, the experience of emotion. The presence of nonlinear hierarchies, intragroup and intergroup encounters, and complex social organizations replete with dynamic and reciprocal social relationships have contributed to the advancement of social emotion/motivation systems beyond the innate, reflexive survival mechanisms described above. Here we will describe several unique qualities of the social organization of chimpanzees and how this may have placed demands on their communication system leading to the evolution of social emotions.

4.28.3.1.1 Complex social environments and social relationships The ability to recognize and monitor not only one's own relationships, but also the relationships among other individuals, though striking in chimpanzees, is not a skill unique among anthropoid primates. Many other primate species show complex forms of social knowledge (e.g., Cheney and Seyfarth, 1990). Social knowledge is critical for navigating a social environment in which knowing who is your friend and, perhaps more importantly, who is your aggressor's friend is crucial to avoiding conflict and maintaining access to resources. Valuable social and physical resources (e.g., grooming bouts, food sharing, and alliances) are traded between individuals in a 'biological marketplace' where traders must not only keep up with their own trading partners and transactions, but also keep track of commodity flow among others (Henzi and Barrett, 2002; Noe and Hammerstein, 1995). Primates, and chimpanzees in particular, are known to share food in exchange for grooming bouts (de Waal, 1997), engage in cooperative hunting (Boesch, 2002), and form coalitions (Watts, 1998). Such mental record keeping in complex societies typically involves triadic interactions, where individuals monitor and manipulate the behavior of others, not only in reference to themselves, but with reference to others. Triadic reconciliations have been reported in a number of species, where the former aggressor in a conflict will engage in affiliative interactions with kin members of the victim and not the victims themselves (Aureli *et al.*, 1992; Call *et al.*, 1996). Moreover, individuals who witness conflicts have been found to increase affiliative behavior with each other, despite having played no direct role in the conflict itself (Judge and Mullen, 2005).

The result of these complex interactions is that many societies have developed rules for social behavior that function to maintain order within the group. Some rules are basic and are likely to be present in many animals (i.e., do not bite the alpha male, do not kill infants), but others are more complex (i.e., the tit-for-tat reciprocity described among chimpanzees; de Waal, 1997). These require that group members recognize one another at the individual level, remember interaction partners, keep track of the details of the interaction, including the type of commodity involved, remember these events for some duration of time, make the decision to respond or not respond at some point in the future, and subsequently adjust their knowledge about the interaction partners for future reference. These details are specifically challenging for individuals that live in dispersed social systems in which individuals are not always in visual proximity and can travel individually or in small subgroups for periods of time (see Section 4.28.3.1.2). The basic assumption underlying social emotions, described below, is that they require individuals to understand that social rules and norms apply to their behavior and that violating these rules and norms will have social consequences. Among nonhuman primates, social transgressions are typically addressed by the alpha male of a group, who may physically punish those individuals who break social rules, but other group members, including females, may also play pivotal roles. De Waal (1982; 1989) has elegantly provided numerous descriptions of such interventions. Among

captive animals, humans may become entangled in such triadic interactions involving transgressions of behavioral norms that we have come to impose on our simian colleagues. The following anecdote was observed by the lead technician in L.P.'s laboratory:

> I had positioned the computer cart in front of the animal's cage for testing and loaded the software program. While holding the joystick panel up to the cage, Patrick (the only male in the group) was messing around with me while I tried to secure the top hook. Julie was sitting calmly and awaiting her turn, but then I noticed she began to fiddle with something below the panel. She used her two index fingers to fish the cord that ran from the back of the joystick to the computer through the caging. When I realized what she was doing, I tried to pull the cord from her, but she grabbed it and bit it at the same time. So this severed the cord from the joystick and she ran off with it. I proceeded to remove the joystick panel and the cage mates were all screaming. I looked into the cage and the older females were screaming at Julie. Lulu (47 years old) was above her on a perch and Wenka (52 years) was positioned at her side. Julie was on the floor below them against the wall. She was screaming with bared teeth and reaching out to Lulu with an open palm, a typical gesture used by chimpanzees when requesting reconciliation or reassurance. A few moments later Julie returned to the front of the cage and handed the cord to me, unsolicited, through the mesh. She then turned back to the older females and continued to gesture for reconciliation. Patrick, the only male in the group, was in the back doorway displaying. Later that afternoon, I went out to their group and Julie presented for me to groom her and allowed this for almost an hour! She was sweet and nonaggressive, quite different from her typical behavior toward me (May 2005).

All behavioral interpretation can follow a high or low cognitive road. The high-level interpretation of this scenario is that the older females in the group, who often take initiative in helping to resolve group disputes, recognized that Julie had done something inappropriate, i.e., grab and break the joystick. This action led the researcher to remove the joystick panel, which, despite the individual who is working on a task, is often associated with everyone getting some kind of food treat. They responded by berating Julie for her actions. Julie's only response was to use her communication skills to request forgiveness, by extending her open hand and baring her teeth, signaling her need for reassurance and for the screaming to end. Some time later, she allowed the researcher to groom her, perhaps in an attempt to re-establish a good social bond with the researcher after her bad behavior. A low-level interpretation might be that the old females were somehow disturbed by the broken joystick and responded with an egoistic bout of screaming, which would reveal that they were each affected in the same manner by the incident as they collectively targeted Julie. As in the high-level interpretation, Julie responded with social cues that she has learned will sometimes terminate conflict. Her grooming tolerance later might have been an attempt to receive some treats she missed earlier.

4.28.3.1.2 Nonlinear hierarchies and fission–fusion societies Many species of primates maintain stable groups through a linear and despotic dominance hierarchy (e.g., rhesus macaques, *Macaca mulatta*; de Waal and Luttrell, 1985). According to such a system, dominance relationships between two individuals are unambiguous and stable: the dominant animal will always win the resource through force and intimidation, and this is not likely to change during the lifetime of the individuals. However, some species have more flexible, egalitarian styles of dominance, in which power relationships can be more fluid and complex (e.g., chimpanzees, *Pan troglodytes*; de Waal, 1982). Contests are won through cooperation and alliances rather than aggression and specific dominance relationships are dependent on the presence or absence of other individuals – alliance partners – and can change often throughout one's lifetime.

Preuschoft and van Hooff (1995) have proposed that the use and function of communicative signals among primates vary in accordance with dominance style, reflecting the specific demands placed on the communication systems of species with different social hierarchies. A full description of this hypothesis (the power asymmetry hypothesis of motivational emancipation) is outside the scope of this article (Preuschoft and van Hooff, 1995, 1997). Briefly, species with strict dominance hierarchies show clear signals of affiliation, appeasement, and submission that can be easily distinguished from one another in both their morphological form and context of use, or social function. The sbt display in rhesus macaques, for example, is a highly ritualized facial expression of submission that is unidirectionally performed by a subordinate individual toward a dominant (de Waal and Luttrell, 1985). In contrast, species with a more relaxed, nonlinear dominance style will show less predictability between display types and their associated social function. The homologous sbt display in Tonkean macaques, for example, might be performed by the dominant individual in some contexts, and its form has become blended with that of an appeasement display, changing its social function in this species (Preuschoft, 1992). The same is true of the chimpanzee sbt display, which is often used during sexual contacts, during play, and during uncertainty (Parr *et al.*, 2005; Waller and Dunbar, 2005). In sum, the architecture of a flexible social environment requires signals to have

meanings that are transferable across different situations and, as a consequence, the demands placed on cognitive flexibility are increased as species must develop strategies for dealing with increasingly flexible communication systems (Parr *et al.*, 2005). If communicative signaling is additionally influenced by emotional state, it follows that species living in complex social groups must also possess well-developed emotional processing skills, as they must be able to interpret the different meanings associated with similar facial displays used in different emotional contexts.

An addition to the cognitive complexity placed on species living in relaxed dominance hierarchies, such as the chimpanzee, is the nature of their society itself. Chimpanzees, as is characteristic of most ape societies, live in a dispersed social system, what is referred to as a fission–fusion society. (Spider monkeys (*Ateles* spp.) are perhaps unique among monkeys in that they have fission–fusion structure.) In contrast to other primate group structures, fission–fusion societies are not characterized by constant, gregarious, group living, where all individuals travel and sleep together, but instead each chimpanzee community is composed of small foraging groups that unite after varying periods of time (Nishida, 1979). The large complete group is, nonetheless, bonded interindividually, and complex, long-term relationships exist among group members (Goodall, 1986). This presents a taxing cognitive challenge for these species as they must be able to keep track of and remember not only their own social relationships, but the relationships among other individuals who they may not see together for long periods of time. During that time, new relationships may have formed and these social changes must be processed in the absence of direct experience, i.e., by directly observing and interpreting behavior with reference to previous knowledge.

A hypothesis to explain the relationship between complex societies, advanced cognitive abilities, and unusually large brain size compared to body size among hominoids has been postulated. The 'social brain hypothesis' proposes that large neocortex volume and superior sociocognitive skills coevolved to deal effectively with the increasing demands stemming from large and complex social groups and more specifically the increased number of individual relationships that one can sustain (Dunbar, 1998). Large brains, such as those present in chimpanzees and humans, equaled better cognitive processing speed and the ability to keep track of many individuals at once, including interindividual relationships, and remember social events over longer periods of time. In fact, the part of the brain that shows the strongest relationship with group complexity is the newer region of the neocortex, not phylogenetically older regions, such as the amygdala or areas of visual cortex (Joffe and Dunbar, 1997). Moreover, Barrett *et al.* (2003) have suggested that maintaining group cohesion in light of such temporal and geographical distance is far more demanding in terms of computational and cognitive load than a group that preserves a constant grouping structure, such as that found among most cercopithecines. Therefore, there is compelling evidence that social cognition and brain evolution are mutually interactive.

In sum, facial cues may provide information about the consequences of social interactions even when group mates do not directly witness all the details of those events. Thus, facial expressions can be used not only to reason about the immediate motivation of the signaler, i.e., they are upset, hurt, or angry, but also to understand something about an event that was not observable, i.e., a change in social status. This distinction is similar to what has been described as knowledge by acquaintance versus knowledge by description. Knowledge by acquaintance is an innate understanding based on direct immediate perceptual experience, has been selected for throughout evolution, and is commonly found in most animals. In contrast, knowledge by description is a more general process whereby experience, conditioning, and cognition collectively provide the means to reconstruct raw data into an internal representation of reality (see Buck, 1999). Thus, this latter skill gives one the ability to reason about events in which the details of the events are not all immediately present. Although this does not indicate that nonhuman primates, such as chimpanzees, are able to attribute or reason about the mental states of other individuals, an ability referred to as theory of mind, this emotional reasoning ability, or emotional awareness, allows them to infer something about the quality of unobserved interactions among group mates. In sum, emotional communication and emotional awareness facilitate social cohesion and increases the quality of social relationships.

4.28.3.2 Social Emotions

Although researchers have described basic or biological emotions for several decades, some theorists have begun describing a new generation of emotions that appear to be specifically involved in social regulatory processes. These are considered secondary emotions, or social emotions, given their function in evaluating social interaction (Buck, 1999;

Keltner, 2003). Moreover, some of these social emotions have been viewed as moral, self-conscious emotions as they occur in response to the violation of social rules and moral behavior (Eisenberg, 2000), require an understanding of the consequences of one's actions and the expectations of others, and function to promote reconciliation and apology (Keltner and Buswell, 1997). These emotions are considered unique to humans and, to date, there is little justification to argue for their existence in other animals (Harris, 2003).

Although there is no general agreement as to the number of discrete social emotions, most theorists agree that they require some degree of self-assessment, or self-consciousness, and an evaluation of others compared to basic, or biological, emotions. Bennett and Hacker (2005) have identified these as pride, shame, humiliation, regret, remorse, and guilt. Others have limited the self-conscious emotions to include embarrassment, pride, guilt, and shame (Keltner and Buswell, 1997; Tangney *et al.*, 1996). Social emotions have also been regarded in terms of their reciprocal contingencies, i.e., whether the goal was achieved or not. These include pride/guilt, envy/pity, joy/sorrow, arrogance/shame, and jealousy/trust (Buck, 1999). Regardless of the number and/or psychological arrangement of these emotions, they share in common a degree of self-consciousness that is not typically invoked when referring to basic emotions such as fear, anger, happiness, sadness, surprise, or disgust. That said, social emotions are not always independent of biological emotions and are often extensions of basic emotions or include emotion blends.

4.28.3.2.1 Facial displays of pride, embarrassment, guilt, and shame Distinct displays have been associated with pride, embarrassment, and shame. Pride, for example, is associated with an upward head turn (AU53) and slight Duchenne smile (AU6 + AU12) with pressed lips (AU24) (Shiota *et al.*, 2003). Pride may be unique among the self-conscious emotions in that it is associated with positive affect, like happiness, whereas most self-conscious emotions are negative. Displays of pride may function to draw social attention to the individual, signal success at a socially valued endeavor, or highlight one's important status within the group (Shiota *et al.*, 2003). Unlike the basic emotion of happiness, however, pride does not appear to be recognizable from the face alone, with greatest recognition rates found in forced-choice tasks involving entire body postures (Tracy and Robins, 2003).

Embarrassment is described by a sequence of gaze aversion and gazing downward, smiling and smile control, a downward head turn to expose the neck, and face touching (Keltner, 1995; Keltner and Buswell, 1997). When these expressive components occur together, embarrassment is recognized up to 92% of the time from its facial expression alone (Keltner, 1995). This is comparable to, if not greater than, recognition rates of basic emotions from their expressive displays (see review by Fridlund, 1994). According to several theories, embarrassment is associated with an acute sense of how others evaluate their behavior and social identity (Tangney *et al.*, 1996). Thus, it can often occur when an individual fails to act in accordance with these socially defined conventions. These conventions must be known by others; for example, one might not experience embarrassment after tripping in a private situation compared to tripping in public (Keltner and Buswell, 1997). Moreover, the experience of embarrassment is less intense in the presence of family and close friends, individuals who would be very forgiving when social norms are violated, than in the presence of strangers (Lewis *et al.*, 1991). Finally, theorists have speculated that embarrassment has evolutionary origins in the appeasement behavior of animals. Appeasement, including bowing the head, gaze aversion, and face touching in nonhuman primates, restores social harmony, decreases the likelihood of future negative interactions and aggression, and reduces the interindividual distance among group members. Furthermore, these displays may have an earlier ontogenetic onset than previously considered, with reports of coy smiles appearing in human infants at approximately 2–3 months of age (Reddy, 2000). Thus, it functions to restore relationships after social transgressions (Keltner and Buswell, 1997).

Shame is typically displayed as a coordinated sequence of downward gaze and head movements and lowered posture. Shame typically occurs when one's actions fail to live up to the expectations of others, when one's personal standards are not met, or when one fears criticism or disapproval from others (Harris, 2003). Thus, shame necessitates an understanding of the expectations of others, the expectations of one's self, and the ability to weigh one's own actions against them. Shame can, for example, occur in the absence of onlookers and appears to be most associated with failure to fulfill obligations either to the self or to others (Tangney *et al.*, 1996). Guilt is similar to shame, but is different in that the transgression involves deviation from a moral rule or norm (Harris, 2003; Tangney, 1992). Therefore, in general, guilt is more society-focused, or focused on the specific behavior involved, whereas shame is more self-focused. Although distinctions

can be drawn between shame and guilt, both of these emotions correlate with feelings of empathy, suggesting a strong relationship between these emotions and perspective taking (Harris, 2003). Although Tangney (1991) found that when controlling for level of shame, guilt was more associated with empathic responsiveness than shame. There is no associated facial expression or postural expressive pattern described for guilt and it often results from the self-appraisal that one has put a low level of effort toward a situation.

These last three emotions do not have known correlates in nonhuman primates. Most of their behavioral elements are similar to those described for appeasement displays (Keltner and Buswell, 1997). Behavioral responses similar to shame, for example, have been observed by the author in the context of cognitive research on captive chimpanzees at the Yerkes Primate Center. Subjects are typically tested in pairs, with one going first while the other waits, and then their roles switch. This sequence has been reinforced for over 10 years of studies and very rarely does the subject waiting misbehave. If such misbehavior occurs, subjects might grab at the experimenter, or attempt to distract the testing subject by grabbing his/her hands away from the joystick, soliciting play, etc. When this behavior is discouraged by the experimenter, the chimpanzee will often lower its face, rubbing it with its hands, close its eyes tightly, and retreat to a corner of the enclosure. Although these are anecdotes and do not occur frequently, they suggest that the subjects understand the rules of the game and when their attempts to disrupt these conventions cause them to be scolded by the experimenter, they express behavior roughly consistent with the shame/guilt descriptions provided above.

4.28.3.2.2 Asymmetrical versus symmetrical facial expressions Another aspect of social emotions that makes them distinctive from basic emotions is that they often involve more exaggerated forms of expression and are often more asymmetrical. These exaggerations, or embellishments, can include winks or brow raises that are typically unilateral in their execution. The wink, for example, involves the eye closing (action unit LAU46), which can refer to a private message, be suggestive, or teasing. A unilateral outer eyebrow lift (LAU2) can be questioning, doubtful, or an expression of interest. The unilateral upper lip raise (LAU10) and the unilateral nose wrinkle (LAU9) are typically involved in expressions of contempt or disgust. More specifically, contempt has been shown to involve a unilateral lip corner raise and tighten (LAU12 + LAU14; Matsumoto and Ekman, 2004). Although contempt is often referred to as a basic emotion, this is debated in the literature (Izard and Haynes, 1988) and studies have shown that scenarios involving contempt can indicate an assessment of another's low social status or one's own demonstration of moral superiority (Keltner and Haidt, 1999). It is unclear, although doubtful, that such embellishments or patterns of asymmetry are present in nonhuman primates despite findings that many of their basic expressions involve asymmetrical components (Fernandez-Carriba *et al.*, 2002). These asymmetries reflect a greater intensity of the displays associated with one side of the face or the other and do not involve the inclusion of unilateral embellishments.

4.28.3.3 Brain Systems Involved in Social Emotions

In a review of neuroimaging studies of emotion, Phan *et al.* (2002) conducted a meta-analysis of emotion studies using both positron emission tomography and functional magnetic resonance imaging (fMRI). This included 55 studies using only healthy human subjects published through the year 2000. They further categorized studies according to whether the task involved a distinct cognitive component, such as emotion naming, emotion identification or ratings, and recall/encoding or recognition, or noncognitive tasks involving the passive presentation of emotional stimuli. The results revealed the most commonly activated region, regardless of the type of task or emotion employed in the study, to be the medial prefrontal cortex (MPFC). Researchers have, for example, consistently reported activation of the MPFC during the processing of photographs designed to elicit either pleasant or unpleasant emotion, compared to neutral photographs (George *et al.*, 1993; Kesler-West *et al.*, 2001; Lane *et al.*, 1997). Specifically, the rostral–ventral area of the MPFC has been shown to respond to individual emotions (BA9 + BA10). This region extends into the anterior, emotion-processing region of the cingulate cortex, which will be discussed below. Moreover, this region is separable from the orbitofrontal region (BA11 + BA12), which, although associated with processing positive and negative emotional images, is thought to play a predominant role in the monitoring and evaluation of the quality of social versus nonsocial information (Damasio *et al.*, 2000; Northoff *et al.*, 2000).

The emotion of fear was found to be strongly associated with activity in the amygdala (Phan *et al.*, 2002). This finding supports data from

numerous areas of psychology and neuroscience that have shown the amygdala to involve a direct, fast-acting pathway for the precognitive and emotional aspects of stimulus processing. The amygdala has been implicated in the processing of fearful facial expressions, whether processed implicitly or explicitly (see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates; Adolphs, 1999; Morris *et al.*, 1998; Whalen *et al.*, 1998), during fear conditioning (Davis, 2000; LeDoux, 2000), and in phobias (Lang *et al.*, 2000). Because of the primacy of fear processing in the amygdala, and its association with implicit autonomic arousal, some researchers have speculated that the amygdala is not so much tied to the processing of basic fearful stimuli, but rather is tuned to detect salient stimuli in the environment, even at subconscious levels (LeDoux, 2000). Therefore, the amygdala is critically involved in aiding the allocation of necessary biological resources to aid the organism's response to potentially threatening environmental stimuli.

The region of the cingulate cortex is interesting for the processing of emotion because it bridges the numerous brain areas including the amygdala and orbitofrontal cortex (OFC). Numerous studies have identified activity in the anterior cingulate in response to emotion processing (Damasio *et al.*, 2000; George *et al.*, 1993; Keightley *et al.*, 2003; Lane *et al.*, 1998). Additionally, the cingulate gyrus can be divided into a rostral–ventral region (BA25, BA33, and the rostral portion of BA24) that is involved in emotional awareness, and a more dorsal region that is involved in cognition and attention (Drevets and Raichle, 1998). Researchers have demonstrated selective activation of both the MPFC and the anterior cingulate when subjects were required to make an emotional appraisal of photographs, but activations were restricted to the amygdala and insular regions when the task involved only passive viewing, suggesting the specific involvement of these regions in more attentive, self-conscious emotion processing (Taylor *et al.*, 2000).

Interestingly, researchers have identified the presence of specialized projection neurons in layer V-b of the anterior cingulate cortex in great apes and humans, but not in gibbons or monkeys (Nimchinsky *et al.*, 1999). These cells, referred to as spindle cells because of their shape, might play a key role in the integration of sensory inputs related to emotion, vocal production, and the recognition of emotional faces, as described above. They lie in a region of the cingulate just superior to the genu of the corpus callosum (BA24), a region shown to be active during the recall of guilt emotions by Shin *et al.* (2000), described below. Thus, the anterior cingulate appears to play an important role in the processing of emotion, particularly when the emotion is explicitly evaluated, or processed with specific reference to the self, and these specializations may be unique to hominoids.

Although numerous studies have examined the neural responses to basic emotions, some of which are described above, fewer studies have examined self-conscious emotions or those that may involve perspective-taking skills (Phan *et al.*, 2002). Takahashi *et al.* (2004), for example, measured brain activity using fMRI as subjects were asked to rate the emotional content of short sentences describing situations of guilt or embarrassment. They revealed greater activation in the MPFC, left posterior superior temporal sulcus (STS), and visual cortex. Embarrassment was also associated with greater activation in the left OFC, anterior temporal cortex, and the anterior right temporal cortex. Distinguishing the two categories of emotion, however, was the finding of greater activation of the right temporal cortex, bilateral hippocampus, and visual cortex for embarrassment and greater activation of the MPFC for guilt (Takahashi *et al.*, 2004). Shin *et al.* (2000) found greater activation of the anterior temporal poles, anterior cingulate gyrus, and left anterior insular cortex during a relived-emotions task involving guilt than during a task involving neutral emotion. Thus, it appears from the associated brain regions that guilt involves more self-conscious emotion processing than does embarrassment.

When comparing responses to self-conscious emotions that involved either intentional or unintentional (embarrassing) violations of social norms using fMRI, Berthoz *et al.* (2002) found greater activity in the left medial and superior prefrontal cortex, anterior cingulate gyrus, left inferior parietal cortex, and left superior occipital gyrus. Specific judgments involving moral issues activated anterior prefrontal cortex (BA9 + BA10), posterior cingulate (BA31), and angular gyrus (BA39) (Greene *et al.*, 2001). Moll and colleagues reported activation in similar regions: the MPFC, anterior temporal cortex, angular gyrus, and globus pallidus; however, in another study, they included an important control for the neural systems activated by emotion judgments by presenting moral and nonmoral emotional stimuli (Moll *et al.*, 2002). Regions activated during the nonmoral condition included the amygdala, lateral OFC, and some areas of visual cortex. Moral judgments, however, activated the medial OFC, left temporal pole, and STS in a region near the angular gyrus. Comparing the two regions revealed selective activation of the medial OFC and STS in the moral compared to the

nonmoral condition. Thus, moral emotion judgments appear to exclusively activate OFC and STS and can be distinguished from self-conscious emotions that additionally activated the medial prefrontal cortex, portions of temporal cortex, and anterior cingulate cortex (Moll *et al.*, 2002).

Self-conscious emotions are, thus far, uniquely human traits and appear to be integrally associated with brain structures that also subserve theory of mind skills, including the medial prefrontal cortex, the anterior cingulate cortex, and the orbitofrontal cortex, as described above. Studies have examined the recognition of self-conscious emotions and their association with theory of mind skills in autistic children. Autism is a pervasive developmental disorder characterized by impaired language function, decreased social responsiveness, deficits in communication and emotional expressiveness, and repetitive or stereotypical behavior before the age of 3 years. Individuals diagnosed with autism spectrum disorder also have poorly developed perspective-taking skills (Dawson *et al.*, 2002) and lack of empathy and theory of mind (Baron-Cohen *et al.*, 2001; Joseph and Tager-Flusberg, 2004; Mundy, 2003). Impairments in joint attention skills in autistic individuals, for example, are more strongly correlated with impairments in tasks that rely on the ventromedial prefrontal cortex, an area that is associated with general affective, motivational, and social behavior (Dawson *et al.*, 2002). Heerey *et al.* (2003) examined the ability of autistic children to identify from photographs both self-conscious emotions, such as embarrassment and shame, and non-self-conscious emotions, such as contempt, anger, disgust, fear, happiness, sadness, and surprise. They found that the children with autism showed no differences in their ability to identify the non-self-conscious emotions compared to the control children, and these scores were uncorrelated with theory of mind skills, but the autistic children were significantly impaired in recognizing the self-conscious emotions. In addition, for both groups of children, their performance on self-conscious emotions was significantly correlated with their theory of mind skills (Heerey *et al.*, 2003). Hillier and Allinson (2002) examined the responses of children with and without autism to several levels of embarrassment: one in which the individual's behavior is conspicuous to others, one in which the individual takes into consideration how the audience evaluates his or her behavior, and one in which the embarrassing event happens to a friend. As opposed to other studies, children with autism showed deficits only when interpreting scenes of empathic embarrassment – the last scenario, in which the embarrassing event happens to the friend of the story's protagonist and the subject was asked to rate how the protagonist felt (Hillier and Allinson, 2002). Thus, their deficits in embarrassment occurred only in the context of empathic awareness.

Self-conscious social emotions, such as those described above, do not take the place of more primitive, basic emotions that are primarily under the control of subcortical structures and their interconnections. As Berridge (2003) has stated, subcortical systems do not lose their basic function in higher organisms, but they may give up some of their autonomy in terms of the degree to which higher cortical systems can modulate their functions or regulate the emotional experience. Emotion regulation is a growing area of research that will reveal important new insights into the role of specific brain regions involved in the cognitive control of emotion. These areas are, not surprisingly, similar to the brain areas involved in self-conscious emotions, most specifically the medial and lateral prefrontal cortices and anterior cingulate cortex (Beauregard *et al.*, 2001). What may fundamentally differ between humans and other animals, despite the evolutionary similarity in the organization of basic emotive brain circuits and connectivity (LeDoux, 2000), is the likelihood that these circuits have more elaborate, reciprocal connections to higher cortical areas involved in both the self-regulation of emotion and the experience of self-conscious emotions. These reciprocal interconnections provide the individual with information as to the nature and meaning of their emotional experiences (Panksepp, 1982).

4.28.3.4 Precursors in the Evolution of Human Emotion: A Final Word

This article has drawn a rough trajectory through various aspects of emotion and its impact on communication and the organization of primate societies, from reflexive, biologically adaptive behaviors to complex social interactions. The important theme therein is that in primates, both human and nonhuman, the ability to understand emotion in others is critical for maintaining social interactions. One way in which individuals are able to learn about the emotional states of others is through the process of emotional contagion. Primitive emotional contagion has been referred to as "... the tendency to automatically mimic and synchronize expressions, vocalizations, postures and movements with those of another person and, consequently, to converge emotionally" (Hatfield *et al.*, 1994, p. 153). Although this definition might be somewhat

limited, it does present a basis for comparative studies on the evolution of emotion across multiple modalities, e.g., face, voice, and posture, in which the presence, absence, or intensity of mimetic convergence across individuals can be empirically measured. Emotional contagion also describes a mechanism for the interpersonal sharing of emotion, or empathy, which features a matching of internal states between individuals, in that individuals will converge emotionally through the mimetic synchrony of behavioral expression. This emotional synchrony can be more specifically referred to as a kind of resonance of physiological arousal between the individuals. Similar changes in arousal between individuals can, under some conditions, result in similar subjective feelings that can significantly affect the subsequent behavior and emotional experience of the observer in the absence of conscious awareness (Dimberg, 1987; Vaughan and Lanzetta, 1980). This type of emotional awareness, or low-level empathy, functions to coordinate activity among group members, facilitate social cohesion, and motivate conciliatory tendencies and is likely to play a key role in coordinating social behaviors in large-brained social primates, such as hominoids.

Evidence for behavioral synchrony is widely reported among numerous animal species from schooling fish to the synchronized flying behavior of birds. Researchers have reported evidence of contagious yawning in adult chimpanzees in response to a video showing a conspecific's yawning compared to conspecifics with open mouths (Anderson *et al.*, 2004). Thus, only the actual behavior and not relevant aspects of the perceptual features of the behavior were important to elicit this behavior, similar to the data on reflexive crying in human neonates, in which only the cries of age-matched infants could elicit crying in subjects (Sagi and Hoffman, 1976). Among primates, behavioral synchrony also takes the form of basic imitation. Infant chimpanzees, like human neonates, have been shown to imitate facial expressions shortly after birth (Bard, 1998). Specifically, Myowa-Yamakoshi (1996) demonstrated facial imitation in an infant chimpanzee between 5 and 11 weeks of age, including mouth opening, tongue protrusion, and lip protrusion, in response to posed expressions by an experimenter. Notably, after 12 weeks, the infant chimpanzee showed a marked decrease in imitative performance (Myowa-Yamakoshi, 1996). A similar study reported facial imitation in two infant chimpanzees reared by their mothers within their first week of life (Myowa-Yamakoshi *et al.*, 2004). These infants imitated a human who demonstrated mouth opening and tongue protrusion, but this ability declined after 9 weeks of age, suggesting that this innate ability seen in neonates might be replaced by more socially communicative behaviors early in development, similar to what is reported in human infants (see Neurological Specializations for Manual Gesture and Tool Use in Humans; Meltzoff and Moore, 1977; Myowa-Yamakoshi *et al.*, 2004).

According to these examples, neonatal imitation is an innate/contagious process that provides not only valuable sensorimotor feedback for matching the behavioral state of another, but also provides an avenue for proprioceptive feedback that may facilitate an understanding of the relationship between facial expression and emotional responses. The importance of this relationship for emotional communication was reviewed in Section 4.28.2. Proprioceptive feedback, or affective resonance, in the form of physiological changes can easily become conditioned to specific internal or external events facilitating the likelihood that an individual, whether human or nonhuman, will show a similar emotional response in a future context. Therefore, one individual's emotional reactions may be considered a conditioned stimulus for unconditioned emotional responses in an observer (Vaughan and Lanzetta, 1980). Through these basic contagion processes, individuals come to learn about their own emotional states and the relationship between these and other's emotions during early ontogeny. As a consequence, emotional contagion and its affective resonance is one of the most powerful mechanisms for transmitting emotional information and facilitating coordinated actions and feelings among social animals.

From an evolutionary perspective, it is not surprising that one of the primary modalities for the transmission of emotional information is through the face. This article has highlighted some of the important issues in understanding the evolution of human emotion. Section 4.28.1 described the adaptive function of emotion in aiding the survival of living organisms. These innate biological reflexes include facial expressions and body postures that appear more tuned to processing negative information rapidly at high levels of arousal. Section 4.28.2 described the need for social animals to communicate about emotion and the importance of the face in affective communication. This section revealed that one of the primary modes for expressing emotion and reading emotional signals from others shares homologous mechanisms in humans and some nonhuman primates. Finally, Section 4.28.3 introduced the presence of self-conscious or social emotions and their relationship to specific brain regions that not only differ from regions involved in basic emotions

but also appear to overlap with brain regions subserving moral problem-solving and theory of mind. These emotions may be unique to humans. Although some have suggested that chimpanzees might share mental reasoning abilities, such as theory of mind, with humans (Hare *et al*., 2001; Tomasello *et al*., 2003), the data are scarce and limited to situations in which individuals compete for food. Thus, though clearly one role of emotion is to help an organism respond rapidly and unconditionally to life-threatening situations with adaptive behavior that increases survival, these emotion systems and the behaviors they produce are also highly dependent on an individual's life history, early experience, and cognitive perceptions in a complex social environment. Thus, one of the key roles of emotions is to free the individual from responding unconditionally. This provides humans, and perhaps related species, with a greater ability to speculate about emotion, engage in emotionally complex relationships, and attribute emotional states to others.

4.29 Evolution of the Neural Circuitry Underlying Laughter and Crying

M J Berkowitz and J-A Bachorowski, Vanderbilt University, Nashville, TN, USA

Glossary

affect induction	The process by which call acoustics elicit emotion-related responses in conspecific receivers.
crying	A distress signal produced by humans; characterized by repetitive, unarticulated vocalizations produced in conjunction with spasmodic breathing patterns and interruptions of vocalization, typically upon inhalation.
laughter	An affiliative signal produced by humans; characterized by repetitive, unarticulated vocalizations produced in conjunction with spasmodic breathing patterns and interruptions of vocalization, typically upon exhalation.
nonreferentiality	A quality of a signal that characterizes its dependence upon arousal, stimuli, and/or context in order to convey meaning.

4.29.1 Introduction

Humans are noisy organisms, persistently communicating with one another by vocalizing. Although speech is the most prominent means of communication among humans, it is not the only type of vocal signal on which we rely. Humans also chuckle, snort, gasp, weep, sigh, and use a variety of other vocal signals. Laughter and crying are two vocal signals that are often described as being uniquely human. Indeed, a number of aspects of these expressions differentiate them from other species' vocalizations. In the functions they putatively serve, however, these signals are not exclusive to humans. Other species produce both homologous and analogous signals, and while these are not acoustic equivalents of laughter and crying, their functional similarities suggest that similar neural substrates might underlie their production across species. Emphasizing comparisons between humans and nonhuman primates (hereafter primates), this article will describe the purpose of laughter and crying from an evolutionary perspective, and use studies of human and primate neural structures to describe the salient circuitry involved in the production of these dynamic signals.

4.29.2 Homologues and Analogues of Laughter and Crying

As is the case with most primate calls, human laughter and crying are species-specific. That is, homologous and analogous calls found in other species are not acoustically comparable to human versions. Laughter has been argued to have emerged during the course of hominid evolution to facilitate the occurrence of cooperative relationships, including those among unrelated conspecifics (Owren and Bachorowski, 2001). Some primates also exhibit such affiliative signals, with the laugh-like vocalizations produced by juvenile chimpanzees seemingly the clearest homologue to human laughter. Human crying, in contrast, is akin to the distress signals that have been documented to occur in a large number of primate species.

According to an affect-induction account of vocal signaling, the function of calling is to utilize the acoustics of vocalizations to influence the behavior of conspecific receivers (Owren and Rendall, 1997; Owren *et al.*, 2003). In the case of affiliative signals such as human laughter, calling serves to strengthen social bonds by forging associations between individually distinctive vocalizations and positive affect on the part of the receivers. Many species of

primates display a play face, an unequivocally positive facial expression that is considered to be a homologue to smiling in humans (Van Hooff, 1972). Only a few species of primates produce an accompanying pant-like vocalization that is most likely to be produced during roughhousing among younger animals in some primate species. This play panting, hypothesized to be the phylogenetic precursor of human laughter (Van Hooff, 1972), is exhibited in common chimpanzees and pygmy chimpanzees, although similar pants are produced during social play in both bonobos and Barbary macaques (de Waal, 1988; Kipper and Todt, 2002).

Species-specific distress calls are ubiquitous and have been shaped by the need to protect oneself against predators and aggressive conspecifics (Edmunds, 1974). Crying is functionally similar to these calls in that it is meant to influence conspecifics by encouraging them to aid the vocalizer. The noxious acoustic features of crying and other distress signals can readily induce negative affect in conspecific receivers (Owren *et al.*, 2003). Receivers typically seek to alleviate the induced discomfort, for instance, by aiding the vocalizer or ceasing an attack on the vocalizer.

Aside from primates, a few other mammalian species exhibit apparent analogues to both laughter and crying. For example, juvenile rats produce both a 50 kHz call that has been interpreted as an affiliative signal (Knutson *et al.*, 1998; Panksepp and Burgdorf, 2003) and a 22 kHz distress call (Anderson, 1954; Brudzynski, 2001). Although studied less frequently, vocal repertoires of the common cat have also been characterized as including both affiliative and distress signals (Zhang *et al.*, 1994; Nicastro and Owren, 2003).

4.29.3 Laughter and Crying Are Distinct from Speech

There are a number of aspects associated with both laughter and crying that indicate they are similar to particular forms of species-specific primate vocalizations, but dissimilar to speech. These features include, but are not limited to, production mode, repetition, innateness, and lack of referentiality.

Laughter and crying are both readily recognized by their distinctive acoustic features. Both are essentially repetitive, unarticulated vocalizations produced in conjunction with spasmodic breathing patterns (Deacon, 1989, 1997; Bachorowski *et al.*, 2001; Ruch and Ekman, 2001). Laughter typically involves interruptions of vocalization upon exhalation, whereas crying involves interruptions of vocalization upon inhalation. Many of the vocalizations produced by various species of primates also consist of this sort of repetitive call structure, spasmodic breathing pattern, and call interruption on inhalation, exhalation, or both. In contrast, a hallmark characteristic of speech is the communication of novel information. It is therefore rarely repeated in quick succession (Deacon, 1997).

Behavioral evidence also supports the homology of laughter and crying to primate calls, and distinguishes both from human speech. For instance, laughter, crying, and arguably most primate calls, with the possible exception of vervet monkey alarm calls, are innate (Seyfarth *et al.*, 1980). Primates reared without hearing their own species-specific calls can still produce those calls (Owren *et al.*, 1993), and humans who are born both deaf and blind still laugh and cry (Eibl-Eibesfeldt, 1989). Language acquisition, on the other hand, involves a critical period during which exposure to language is necessary for its ultimate emergence.

Laughter and crying, as well as the affiliative and distress calls used by primates, lack the referentiality of human speech. Speech is often used to reference objects, events, internal states, and organisms in a way that is not necessarily bound by arousal, stimuli, or context (Deacon, 1989; Hauser, 1996). In contrast, nonreferential signals such as laughter and crying depend on arousal, stimulus, and context. Rather than to communicate information, these nonreferential signals seem to function largely by eliciting affect-related responses in others (Owren and Rendall, 1997).

4.29.4 Neural Correlates in Primates

Two main brain regions have been consistently associated with the mediation of species-specific calls, including homologues and analogues of laughter and crying, in primates: the periaqueductal gray (PAG) and the anterior cingulate gyrus. We also note that many primate species also have a number of other brainstem and limbic areas that have been implicated in vocal production, including the internal capsule, cerebral peduncle, tegmentum, medial lemniscus, substantia nigra, inferior colliculus, pontine nuclei, amygdala, thalamus, ventral hypothalamus, and hippocampus (Deacon, 1989). Most of this neurophysiological research has focused on squirrel monkeys.

The short latency between stimulation of the PAG and a vocal response is one reason this area was first considered important to vocal behavior. Jürgens and Pratt (1979) found that vocalizations elicited from PAG stimulation not only show the shortest

response latency compared to all other vocalization-elicitation loci, but also show the greatest variety of calls produced. The caudal, rostral, medial, lateral, and dorsal sections of the PAG have all been implicated in species-specific call elicitation (Jürgens, 1994). The PAG and adjacent parabrachial and dorsal tegmentum are probably the phylogenetically oldest vocalization centers, and are argued to be the final common pathway for species-specific vocalizations (Deacon, 1989). That is, these areas receive convergent projections from almost all other loci implicated in vocalization as well as from the motor nuclei of the brainstem, which control vocal and respiratory musculature.

Ablation of the PAG results in mutism in monkeys and eliminates the capacity of any other loci to elicit vocalization (Deacon, 1989). Additionally, lesions to the areas of the parabrachial and dorsal tegmentum adjacent to the PAG have been shown to alter various qualities of species-specific vocalizations in many different species (e.g., Jürgens and Ploog, 1970). Lesions to the lateral tegmentum bordering the PAG have been shown to cause very specific deficits in primates. For example, in squirrel monkeys, it is possible (through partial lesioning) to abolish the vocal alarm call while leaving intact the vocal startle-response to being grabbed (Newman and MacLean, 1982; Jürgens, 1994). Jürgens and Pratt (1979) identified efferent projections from the PAG terminating in the parabrachial nuclei, the reticular formation of the lateral pons, the motor nucleus of the trigeminal nerve, and the area surrounding the motor nucleus of the facial nerve and the nucleus ambiguus. These areas are all highly involved in species-specific vocalizations. The motor nucleus of the trigeminal tract controls the mandible, the facial nucleus controls the facial musculature, the nucleus ambiguus innervates the laryngeal musculature, and the rostral nucleus ambiguus controls oral manipulation (Deacon, 1989).

The PAG does not project efferents to the hypoglossal nucleus, the motor nucleus that innervates the tongue. This absence of projections supports the contention that primate vocalizations are largely unarticulated. As noted earlier, this lack of articulation is also characteristic of both laughter and crying. The tongue does, however, play a crucial role in the articulatory gestures involved in speech production. There is thus evidence for a clear dichotomy between the neural pathways involved in species-specific primate calls and human speech, largely stemming from differences in the circuitry at the midbrain-pontine level (Deacon, 1989; see Evolutionary Specializations for Processing Faces and Objects and Premotor Cortex and the Mirror Neuron Hypothesis for the Evolution of Language).

It should also be noted that the areas implicated in primate species-specific vocalizations do not overlap those areas most commonly implicated in human speech, such as the left frontal neocortex. While damaging neocortical motor areas in humans can cause mutism via paralysis of the vocal musculature, lesions in the same areas in nonhuman primates do not appear to significantly disturb the structure of species-specific calls (Sutton *et al.*, 1974; Jürgens *et al.*, 1982; Deacon, 1989).

Early mapping studies of monkey brains (*Macaca mulatta*) demonstrated that species-specific vocalizations could be elicited by electrical stimulation of the anterior cingulate gyrus (e.g., Smith, 1945). Subsequent research revealed that many primate species, such as macaques, squirrel monkeys, rhesus monkeys, gibbons, and marmosets, also have so-called vocalization centers in or near the anterior cingulate cortex. Although the anterior cingulate gyrus has often been held to be a primary locus for species-specific call production, this view is incomplete. Lesions to the cingulate cortex do not abolish all, or even most vocalizations. Lesions to this area do, however, cause serious detriment in the conditioning of call production in macaques, possibly because of interference with volitional vocal production (e.g., Sutton *et al.*, 1972; Aitken, 1981). Furthermore, latency between stimulation and calling can be very long (up to 2.2 s) when the cingulate cortex is stimulated (Jürgens and Ploog, 1970; Jürgens, 1979). These latency data indicate that production of a vocalization might be secondary to other processes in the anterior cingulate gyrus. One hypothesis is that the anterior cingulate gyrus plays a mediating role in the production of affect-related vocalizations.

The research on neural correlates of species-specific calls in primates does not seem to distinguish between areas responsible for affiliative signals, distress signals, and other calls. For instance, different areas of the PAG have been shown to elicit various species-specific calls, but the exact loci vary among individual primates within a species (Jürgens, 1994).

4.29.5 Neural Correlates in Humans

Directly studying human neural circuitry is always difficult, but perhaps even more so with respect to laughter and crying. Aside from the difficulty of obtaining lesion-related data, the neural correlates of laughter and crying must be teased apart from those of the emotions that often elicit these behaviors. Some of the most informative research in this area comes from case studies involving exploratory stimulation and lesions due to pathology.

The neural correlates of pathological laughter and crying are studied far more frequently than those of typical laughter and crying. It is accepted that pathological laughter and crying are usually caused by disinhibition of regulatory circuitry, but the specific nature of this circuitry is still debated. For example, it has been asserted that lesions of cerebro-ponto-cerebellar pathways are responsible for the disinhibition of these behaviors (Parvizi *et al.*, 2001), but lesions that affect prefrontal regulation of limbic circuitry have also been implicated (Tateno *et al.*, 2004).

Still, case studies of pathological laughter and crying are germane to understanding the neural correlates of these vocalizations. A problem in sorting through these studies is that the pervasive neurological deficits that often result from stroke or other brain damage also often result in pathological laughter or crying. Because of the co-occurrence of pathological laughter and crying with other neuropathologies, the research on the neurology of pathological laughter and crying has probably invoked too many areas as being vital to their production. Patients suffering from pathological laughter and crying often self-report that their affective state is not appropriately matched by their vocalizations (although it should be noted that some patients do exhibit mood elevations or depressions that are respectively associated with pathological laughter or crying; Mendez *et al.*, 1999; Okun *et al.*, 2003; Wild *et al.*, 2003). Below are just a few of the case studies that examine the neural correlates of laughter and crying.

In their review of a case involving a 67-year-old man who had laughed unremittingly for 20 years, Mendez *et al.* (1999) proposed that the anterior cingulate gyrus is responsible for "endowing experiences with emotional consciousness." The authors also implicated a feedback loop involving the temporal lobes and amygdala, which both send emotional content back to the anterior cingulate. Lastly, they described a pontomedullary circuit that coordinates the cognitive, emotional, and muscular circuitry involved in laughter. These neural substrates are very similar to those discussed earlier in regard to primate vocalizations.

During exploratory intracranial stimulation of a 16-year-old girl, Fried *et al.* (1998) identified a 4 cm^2 area on the left superior frontal gyrus that was found to induce both laughter and mirth. When asked why she was laughing, the patient attributed humor to various objects or people in the room. Although the stimulated area was spatially close to the anterior cingulate, the results are difficult to interpret as humor and laughter were entangled. Still, this outcome is interesting insofar as it illustrates a top-down influence on laugh production.

Okun *et al.* (2003) described a case study of a 46-year-old woman with Parkinson's disease who demonstrated pathological crying when her subthalamic nucleus was stimulated; her crying was not associated with actual changes in mood. Although limbic cortices are highly involved in emotional processes, this finding supports the idea that these cortices play a role in the elicitation of crying that is separable from their role in the elicitation of negative affect.

Parvizi *et al.* (2001) reviewed the case of a 51-year-old, otherwise healthy, man who showed both pathological laughter and crying after a stroke. MRIs revealed three brainstem and two cerebellar lesions. The authors noted that the descending pathways to the cerebellum originate in areas that include motor and limbic cortices. These pathways then continue through the internal capsule and cerebral peduncle to the nuclei of the basis pontis. The authors thereby concluded that the observed pathological laughter and crying were a direct result of the partial deafferentation of the cerebellum, which caused deficits in the cerebro-ponto-cerebellar pathways responsible for mediating such vocalizations. While the cerebellum does not appear to be directly implicated in the production of such vocalizations in other research, it is possible that it inhibits their production. The other nuclei that Parvizi and colleagues identified as being important in both laughter and crying were all brainstem and limbic centers; these data are congruent with those obtained from studies on species-specific vocalizations in macaques.

Taken together, although very little research has been conducted directly on the human neurophysiology of laughter and crying, the available findings indicate that the neural substrates underlying these vocal behaviors include the same structures that appear to be involved in the production of species-specific calls in other primates. One notable exception is the PAG, which has not yet been directly implicated in the production of either human laughter or crying. There are two likely reasons for this exception. First, case studies involving neural stimulation (usually involving patients with intractable epilepsy) would most likely not probe the PAG. Second, lesions to the PAG would most likely cause widespread vocal deficits and therefore not directly link this area to laughter and crying.

4.29.6 Conclusions

Laughter and crying are examples of species-specific calls that are similar to the affiliative and distress, respectively, signals produced by other primates. The production and function of these vocalizations differentiates them from human speech, but supports the

idea that they are homologous or analogous to similar primate behaviors. Data from primate studies consistently show two main areas as being highly involved in the production of species-specific vocal signaling: the PAG and anterior cingulate gyrus. Along with involvement from other limbic and brainstem regions, these areas are thought to be responsible for coordinating the cognitive, emotional, and neuromuscular aspects of species-specific calls. The available data from case studies suggests that similar neural circuitry is involved in human laugh and cry production.

4.30 Role of Spindle Cells in the Social Cognition of Apes and Humans

K K Watson and J M Allman, California Institute of Technology, Pasadena, CA, USA

Glossary

von Economo cells — Large bipolar neurons described by the anatomists Constantin von Economo and Georg Koskinas, in 1925. They are restricted to anterior cingulate cortex and frontoinsula cortex, and present in great apes and humans, but not other primates.

immunohistochemistry — The use of antibodies to recognize and label specific molecules in a tissue specimen.

Nissl stain — A classic cell-body stain used for nervous tissue. Cresyl violet, a typical Nissl stain, stains the somas of neurons and the nuclei of glia purple.

Golgi stain — A metal impregnation technique used to label neurons, glia, or nerve fibers. It is used in some applications to randomly stain the cell bodies and processes of a small percentage of cells in nervous tissue, allowing the dendritic arborization of a few individual neurons to be distinguished from the surrounding cells.

dopamine — A neurotransmitter derived from tyrosine. Dopaminergic cells are located in discrete nuclei in the midbrain, which project heavily to the frontal cortex and the basal ganglia. Dopamine is implicated in motor processes and reward processing, and is also the precursor to epinephrine and norepinephrine.

serotonin — A molecule derived from tryptophan. Serotonin is found widely throughout the central nervous system, where it acts as a neurotransmitter, and in the periphery. In the gastrointestinal system, serotonin causes the peristaltic action of the smooth muscles.

4.30.1 Morphology

4.30.1.1 Background and History

One way to divide neurons into distinct classes is to base the categories on shape, as is evident in the names of the pyramidal and stellate cells (see The Evolution of Neuron Types and Cortical Histology in Apes and Humans). Similarly, when Nimchinsky *et al.* (1999) identified a type of cell that was unique to great apes and humans, its identity was based on its distinctive morphology. At the time, they termed this population the spindle cells, but to avoid potential confusion with other uses of this name we now refer to them as von Economo (VE) cells.

This name is chosen in honor of the neuroanatomist Constantin von Economo, who, with Georg Koskinas, first described this distinctive class of neurons in 1925 (von Economo and Koskinas, 1925). Upon inspection of his Golgi preparations of human cortex, he noted that these large cells were located in layer 5 and restricted to two regions of the human brain: the anterior cingulate cortex (ACC) and in posterior orbitofrontal cortex adjacent to the insula, a region that he termed frontoinsular cortex (FI, Figure 1). Both of these regions lack a granular layer 4; as in motor cortex, this agranularity may reflect a functional specialization.

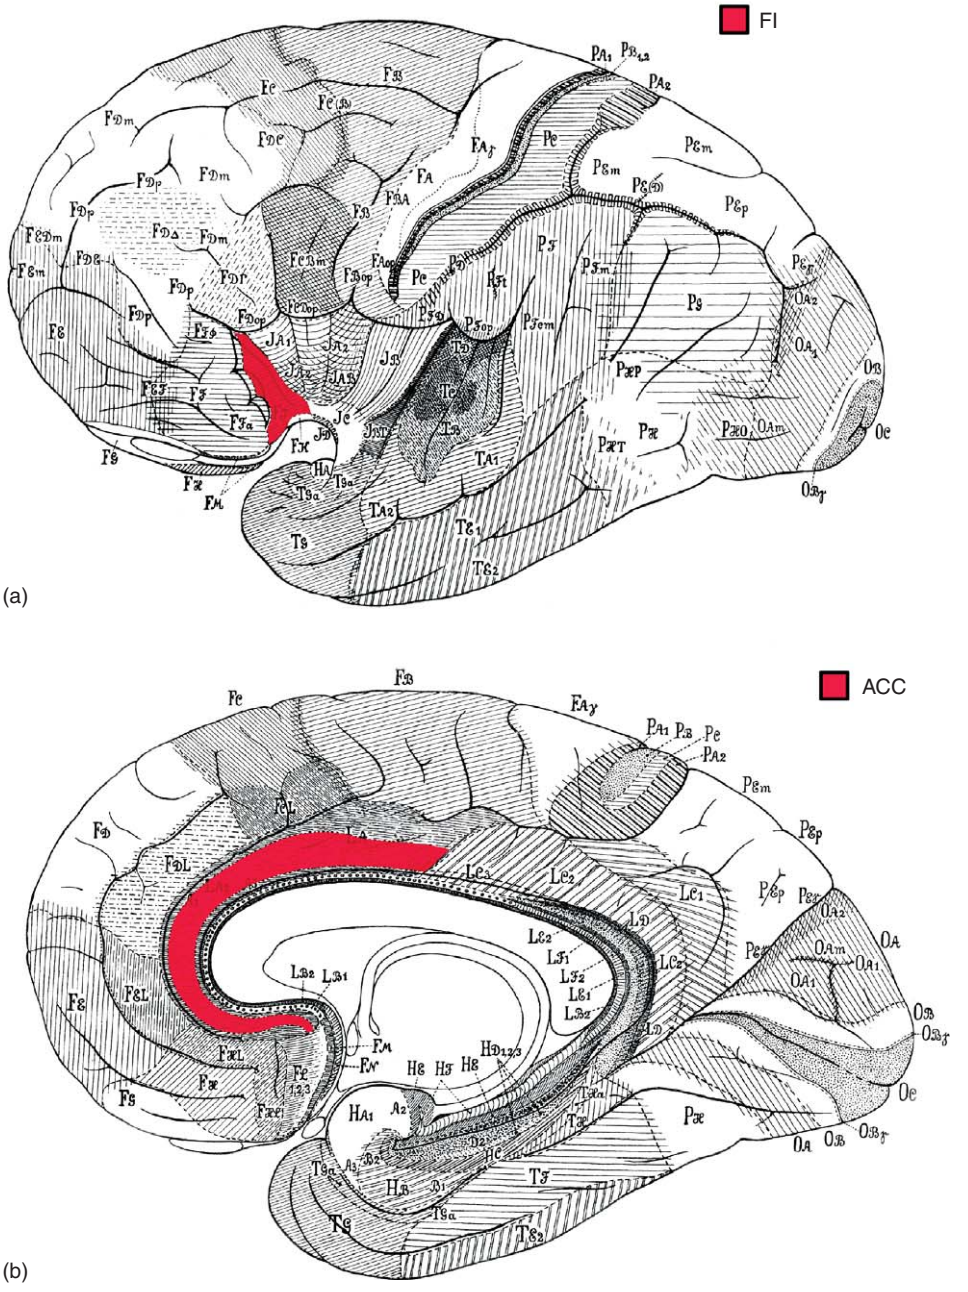

Figure 1 Cytoarchitechtonic divisions of the adult human brain as drawn by von Economo. Lateral view of the brain is shown in (a), with FI indicated in orange. In the medial view (b), ACC is visible and indicated in orange. Drawing modified from von Economo, C. and Koskinas, G. 1925. Die Cytoarchitectonik der Hirnrinde erwachsenen Menschen. Springer, by Atiya Hakeem.

In a cresyl violet-stained sample of human or great ape cortex, these cells may be easily distinguished from the neurons around them due to their symmetric, bipolar soma shape and their large size (Figure 2). Years later, it was discovered that these distinctive-looking cells were only present in the great apes and the humans, which implies that they evolved within the last 15 My (Figure 3). In the case of the VE cells in the FI, they are present only in the great African apes and not the orangutan. This pushes the likely emergence of VE cells in that region to 9 Mya, which in turn predates the rapid expansion of the hominid brain by 3–6 My (Kumar and Hedges, 1998; Wood and Collard, 1999).

Using the Golgi technique, we found that the apical dendrites of the VE neurons are quantitatively very similar to the apical dendrites of the neighboring pyramidal neurons; however, the branching pattern of the basal dendritic trees is much simpler on VE cells compared to the pyramids (Figure 4) (Watson *et al.*,

2006). The somatic symmetry that is apparent in Nissl stains is retained for some distance along the dendritic tree for VE cells. The Golgi technique also revealed spines on the VE neurons of the frontoinsula, which implies that these large cells are excitatory.

Figure 2 Nissl-stained brain section from a 7-month-old human infant. The somas of two VE cells are stained purple in the center of the image, with the apical dendrite oriented upwards. Note the elongated shape and presence of a single large basal dendrite.

In order to determine the projection targets of neurons, typical tract-tracing methods require invasive applications of the tracing material and the subsequent sacrifice of the animal. This technique would obviously be difficult or unethical in hominoids. However, there are several pieces of evidence to indicate that the VE cells are projection cells. First, they are located in layer V, a classical output later. Second, they are immunohistochemically labeled with SMI-32, a selective antibody for nonphosphorylated neurofilament (NPN) (Nimchinsky *et al.*, 1995). Upon phosphorylation, these molecules are translocated from the soma to the axon, where they increase the diameter of the axon and, consequently, transmission speed. Third, the volume of the VE cell somas is correlated with encephalization, with the largest VE neurons occurring in the largest brains of the primates. This is true also of the Betz cells of the motor cortex, which are known to project long distances (Sherwood *et al.*, 2003).

4.30.1.2 Sterology and Development

VE cells appear in the 35th week after conception in very small numbers. Unlike typical pyramidal cells, the VE cells are still very sparse at birth, suggesting that they differentiate from pyramidal cells or migrate in after birth (Allman *et al.*, 2005). Although we do not at this time know the exact age of proliferation, the population size is very

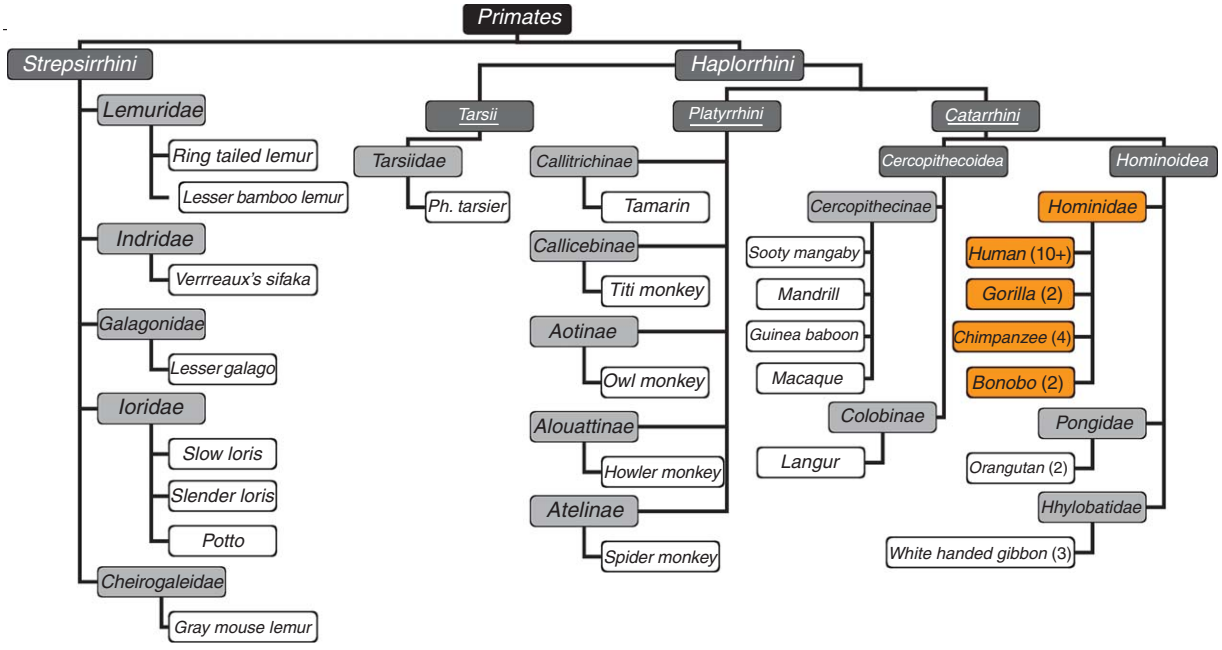

Figure 3 Primate phylogenetic tree. Species that have VE neurons in frontoinsula are indicated in orange. The number of brains that have been inspected is indicated. Based on the Semendeferi, Welker, Yakovlev, and Allman Brain Collections; analyzed by Atiya Hakeem, Nicole Teteault and John Allman. Figure by Atiya Hakeem based on Rowe, D. 1996. The Pictorial Guide to the Living Primates. Pogonias Press.

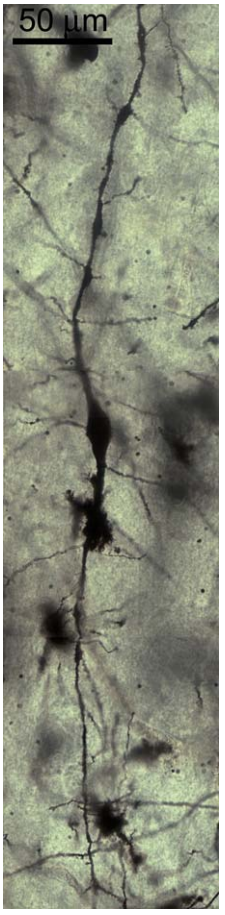

Figure 4 Neurolucida models of Golgi-stained neurons from the FI of a 23-year-old male human. Note the relative absence of dendritic complexity (i.e., sparse branching) on the VE neuron (left) in comparison to the FI pyramidal neuron (right). Neurolucia tracings by Tiffianie Jones.

near the adult level in the single 4-year-old human specimen that we have analyzed.

Humans have far more VE neurons than the great ape species. All species, however, show a consistent asymmetry, with about 30% more VE neurons in the right hemisphere compared to the left.

4.30.2 Immunohistochemistry and Functional Insights

What is the function of the VE cells? The fMRI literature reveals that two major types of paradigms activate the VE cell regions: decision-making in the context of high uncertainty and social paradigms. This in turn allows us to make educated guesses about what sort of molecules, particularly surface receptors, might be expressed by the VE cells, which we could then probe using immunohistochemistry on postmortem human specimens.

4.30.2.1 Uncertainty, Dopamine, and Serotonin

The VE cell regions appear to be strongly activated during periods of high uncertainty. In an fMRI study during which subjects were engaged in a simple gambling task, activation in both FI and ACC got increasingly stronger as the uncertainty in the task increased (Critchley *et al.*, 2001). In a similar vein, both regions were activated during a reversal task, in which a subject attempts to maximize reward during a task that changes contingencies when the subject's behavior stabilizes (O'Doherty *et al.*, 2003). A series of incorrect answers will prompt the subject to switch strategies, at which point both ACC and FI show increased activity.

Recordings from individual dopaminergic neurons in the macaque monkey ventral tegmentum reveals a similar pattern of activation. During trials with high uncertainty of reward, dopamine neurons exhibit a gradual increase in firing rate across the duration of the trial (Fiorillo *et al.*, 2003). Dopaminergic neurons project heavily to frontal cortex and limbic regions, including the VE cell regions. Using D3-specific antibodies on human brain tissue, we found that the VE cells are labeled strongly for this high-affinity dopamine receptor on the somas and apical dendrites (Figure 5). VE cells are labeled in this manner more often than the neighboring pyramidal cells, with 85% of VE cells

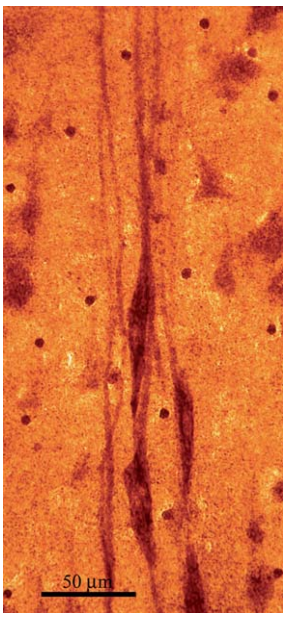

Figure 5 Dopamine D3 receptor labeling on two VE neurons (right) and a pyramidal neuron (lower left) in human ACC. Brown diaminobenzidine (DAB) deposits indicate the presence of the receptor on the soma and the apical dendrites.

being labeled compared to only 50% of the layer V pyramidals.

Taken together, this evidence implies that the VE cells take part in a circuit that is involved in processing uncertainty. Dopaminergic input is known to be associated with learning, signaling the extent to which a reward is unexpected.

Serotonin has been proposed to mediate the aversive component of learning, signaling the presence or absence of punishment in a manner similar to relationship between dopamine and reward (Daw *et al.*, 2002). Immunohistochemistry reveals that the VE neurons express at least two serotonin receptors, including 5HT-1b and 5HT-2b (Figure 6). 5HT-1b is associated with the inhibition of aggression; applying a 5HT-1b antagonist or knocking out the receptor in mice increases aggressive behavior, while applying a 5HT-1b agonist decreases aggression (Bouwknecht *et al.*, 2001; de Almeida *et al.*, 2001). The 5HT-2b receptor, while heavily prevalent in the human gut, is rare in the human central nervous system (Borman *et al.*, 2002). We found that, in the VE cell regions, the 5HT-2b receptor was specific to layer V and present on VE cell somas, pyramidal somas, and short segments of apical trunks in the absence of somatic labeling. In the human gastrointestinal system, this receptor causes peristalsis through the induction of smooth muscle contraction. Interestingly, insular cortex has recently been shown to be involved in interoception, that is, the representation and monitoring of one's internal states (Craig, 2004). The presence of 5HT-2b on both the VE neurons and in the viscera may indicate a functional connection between the two, perhaps a collateral projection that allows the CNS to rapidly process information relevant to the body. The presence of such a connection would be highly relevant to Damasio's (1994) theory of somatic states, which hypothesizes that many decisions are made on the basis of signals arising from regulatory processes that occur in the periphery.

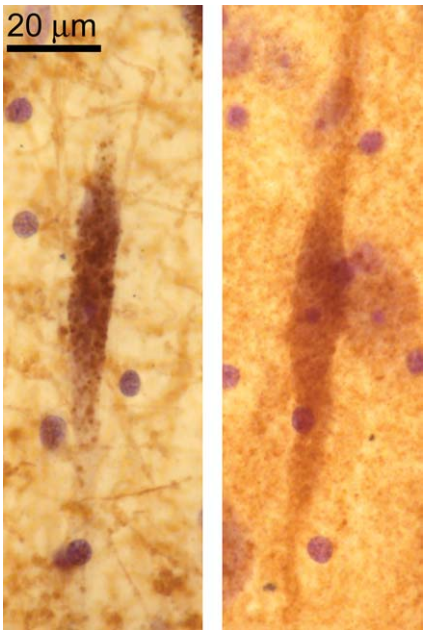

Figure 6 Immunohistochemical (DAB) labeling of the serotonin 1b (a) and 2b (b) receptors on VE neurons in the ACC. Both samples are Nissl counterstained to reveal unlabeled cells. Scale bar applies to both images.

4.30.2.2 Social Behavior and Vasopressin

Functional imaging paradigms associated with social behavior also reliably activate both VE cell regions. For example, both ACC and FI are active during the act of lying (telling untruths), and they are both active when a subject receives an unfair offer while playing the ultimatum game (Sanfey *et al.*, 2003; Spence *et al.*, 2004). Studies by Bartels and Zeki (2000, 2004) show both regions are active when subjects view the face of their love partner or child. Singer *et al.* (2004b) showed that both VE cell regions are active when a person feels empathy for pain, that is, when they know that their loved one, outside of the scanner, is being delivered an electric shock. Interestingly, the extent of activation an individual shows under these conditions is directly correlated to that individuals score on a trait measurement for empathy. Finally, in a separate study, Singer *et al.* (2004a) demonstrated that left FI is specifically active when subjects view faces of individuals who are reported to behave in a trustworthy fashion.

Fortunately, there is an excellent molecular model that allows us to specifically implicate the VE neurons in these various social behaviors. A body of work by Insel and Young indicates that the oxytocin and vasopressin V1a receptors mediate social bonding (Insel *et al.*, 1998; Young *et al.*, 2001; Lim *et al.*, 2004). Insel *et al.* (1998) also suggest that these molecules may interact with dopamine to impart the rewarding aspects of social bonding. Our immunohistochemical results show that the antibodies specific for the V1a receptor label a subpopulation of VE cells, as well as pyramidal neurons in layers 2/3 and 5 of ACC and FI.

4.30.3 The Social Cognition Hypothesis

In light of the above evidence, we hypothesize that the recently evolved VE neurons are a functional specialization of a circuit involved in making appropriate responses during quickly changing, ambiguous circumstances (Allman *et al.*, 2005). Links between the VE cells and interoception – including, literally, gut feelings – could provide the basis for their role in fast decision-making in the absence of explicit reasoning. In apes and humans, complex social interactions between conspecifics provide a forum in which this cognitive capacity would prove to be particularly useful (see Human Cognitive Specializations). This is because participants must rapidly synthesize an enormous number of relevant but often ephemeral informational cues in order to act appropriately. We thus propose that VE cells mediate the rapid assessments and behavioral modifications required for the successful navigation of social interactions.

4.31 Evolution of the Sexually Dimorphic Brain

J Bachevalier, Emory University, Atlanta, GA, USA

Glossary

androgen Class of hormones that primarily influence the growth and development of the male reproductive system. The main and most active androgen is testosterone, produced by cells in the testes. Androgens produced in smaller quantities, mainly by the adrenal gland but also by the testes, support the functions of testosterone. Females produce trace quantities of androgens, mostly in the adrenal glands, as well as in the ovaries.

concurrent discrimination task Subjects are presented with a list of 20 pairs of objects. In each pair, one of the objects is rewarded and subjects must learn the correct object within each pair. In this particular version of the task, the 20 pairs are presented to the subjects only once a day.

delayed-matching task Subjects are first shown a stimulus and, after a short delay, the subjects are required to make a choice between the familiar stimulus and a new one. In this version of the task, subjects must select the familiar stimulus (match) to be correct.

delayed-response task Subjects are shown a reward being placed in one of two locations on a testing tray. The two locations are then covered with identical plaques and, after a delay that prevents the subject's view of the tray, the subject is required to retrieve the reward.

estrogen Class of hormones that primarily influence the female reproductive system's development, maturation, and function. The three major estrogens – estradiol, estrone, and estriol – are mainly produced by the ovaries and placenta; the adrenal glands and the testes secrete smaller amounts.

object discrimination reversal task Subjects are presented with two stimuli (one rewarded and the other not) and learn to select the rewarded stimulus on each trial. After acquisition of the discrimination problem and, without warning, the reward is now shifted to the previous unrewarded stimulus. Subjects must inhibit a learned response and select a correct strategy. Several reversals are generally given.

spatial span memory task A small circle appears on a particular location of a computer screen and subjects are required to touch the circle to receive a reward. On the second trial, the first circle in the same location and an identical circle in a new location appear and subjects need to displace the circle covering the new location. On each trial, circles are added one at a time over a new location of the screen. Spatial span is the number of circles displaced before the subjects make an error (i.e., displace a circle in a location that had already been selected in the previous trials).

4.31.1 Introduction

Evolutionary forces together with numerous molecular events create individual organisms with great genotypic and phenotypic similarity. Yet, within the common genetic boundaries that define a species, there is wide diversity of individual phenotypes. One of the most striking differences in phenotypes is between males and females of the same species. A large number of studies in birds and rodents have indicated that gonadal hormones act during development to establish permanent sex differences in the anatomy and function of the vertebrate brain. While it is generally agreed that most brain sexual differences are determined by the central action of androgens during development, the relative contribution of ovarian secretions to the full development of female brain organization and function is still a matter of debate (Pilgrim and Hutchison, 1994; Fitch and Denenberg, 1998).

Gonadal steroid hormones are implicated in the development of sex differences in reproductive behaviors at two critical periods (Phoenix *et al.*, 1959; Harris and Levine, 1962; Young *et al.*, 1964; Goy, 1968; Phoenix, 1974). First, the release of testicular (androgens) and ovarian (estrogens) hormones during critical periods of brain development (organizational period) exerts a profound effect on the genesis and survival of neurons in specific brain areas related to reproductive behaviors. They also act during adolescence and adulthood (activational period) to activate and modulate existing neural system pathways in a reversible manner.

Increasing experimental evidence indicates that, as with reproductive behaviors, sex differences in cognitive abilities could similarly be determined by genetic and hormonal factors acting at specific critical periods, i.e., early in development during the organization period to regulate neural events in neural structures mediating cognitive abilities, and later in adolescence and adulthood to activate and modulate the same neural structures. The critical periods of hormone influence vary among species and among the different behaviors. For example, in rhesus monkeys, the critical period for hormonal influences on maternal grooming by the offspring occurs earlier than the critical period of hormonal influences on juvenile play (Goy *et al.*, 1988).

Converging findings from different research areas are supporting this view. First, sex differences have been reported in various cognitive abilities that depend on neural structures other than those involved in reproductive functions. Second, there are sex differences in the morphology of neural structures mediating cognitive abilities. Third, biochemical studies of gonadal hormone binding and metabolism have revealed that androgen- and estrogen-binding sites and metabolizing enzymes are present in neural structures that are known to mediate cognitive functions. Fourth, lesions of neural structures underlying specific cognitive functions can affect males and females differently. Finally, sex differences in cognitive abilities, brain morphology, and/or in the effects of brain lesions can be reversed by manipulations of gonadal steroid hormones in animals. Although most data pertaining to the effects of gonadal steroid hormones on cognitive abilities has been gathered in rodents (for review, see Beatty, 1979; Meaney, 1988), there is a growing corpus of data suggesting that the same may hold true from nonhuman primates and humans. The present article first presents evidence for cognitive sex differences in nonhuman primates and then provides comparisons with recent data in humans. The final section offers tentative speculations on how differences in brain functions could have evolved (see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates, Primate Brain Evolution in Phylogenetic Context, The Evolution of Parallel Visual Pathways in the Brains of Primates, Brain Size in Primates as a Function of Behavioral Innovation, The Evolution of Language Systems in the Human Brain, The Evolution of Hemispheric Specializations of the Human Brain, The Evolution of Human Brain and Body Growth Patterns, Constraints on Brain Size: The Radiator Hypothesis, Evolutionary Specializations for Processing Faces and Objects, Evolution of the Neural Circuitry Underlying Laughter and Crying).

4.31.2 Distribution of Gonadal Hormone Receptors in the Brain

The distribution of androgen- and estrogen-binding sites in the monkey brain is widespread and includes not only brain structures known to mediate reproductive behaviors, but also those that support nonreproductive behaviors and cognitive abilities. Estrogen receptors are found in many regions of fetal and adult brains, such as the medial basal hypothalamus, amygdala, cerebral cortex, and cerebellum. However, no definitive sex differences in the distribution of estrogen receptors were found in any neural structures examined, suggesting that both sexes are potentially susceptible to estrogen influence (Pfaff *et al.*, 1976; MacLusky *et al.*, 1986; Sholl and Kim, 1989). Similarly, androgen receptors are widely distributed in the primate

brain, including the hypothalamus, amygdala, dorsolateral prefrontal cortex, orbital frontal cortex, visual and somatosensory cortex, as well as corpus callosum of the fetus and adult rhesus monkeys (Pomerantz *et al.*, 1985; Roselli and Resko, 1986; Sholl and Pomerantz, 1986; Clark *et al.*, 1988). In addition, Sholl and Kim (1990) noted that, in the medial basal hypothalamus and amygdala, androgen aromatase activity (the enzyme responsible for the transformation of testosterone to estradiol) was higher in male than in female monkeys, whereas the levels of 5α-reductase (the enzyme responsible for the transformation of testosterone to dihydrotestosterone (DHT)) and androgen receptors did not differ between sexes. They proposed that, at an early stage of development, differentiation of the hypothalamus and amygdala of male fetuses may be more susceptible to androgen modification, by way of aromatization to estrogens, than corresponding areas in female fetuses. Furthermore, androgen receptors are differentially distributed between the right and left cerebral hemispheres of the male fetal rhesus monkeys (Sholl and Kim, 1990). Thus, androgen receptor levels were higher in the right than in the left frontal lobe in males but not in females. By contrast, androgen receptor levels were consistently higher in the left than in the right temporal lobe in males only. Together these data suggest a role for gonadal hormones in the modulation and maturation of brain regions mediating functions other than those related to sexual behaviors. Furthermore, the differential cortical distribution of androgen receptors in fetal male versus female monkeys supports the view that prenatal androgens from the fetal testes may affect the differentiation of sexually dimorphic, site-specific, cortical activity and functions.

4.31.3 Sex Differences in Cognitive Functions

Although sex differences in cognitive functions in nonhuman primates have not been extensively studied, there exists growing evidence to suggest significant differences between males and females in several cognitive processes that have been observed throughout the life span.

4.31.3.1 Juvenile Social Behaviors

Early social experience in monkeys emerges from playful interactions between peers. Several sex differences have been noted in the behavior of juvenile monkeys and appear to result from the prenatal androgen environment of the developing fetus (for review, see Meaney, 1988; Wallen, 1996). During play behaviors, juvenile females tend to use social vocalizations more than males, whereas juvenile males engage in mounting behaviors and rough-and-tumble play more than females. Manipulation of steroid gonadal environment during gestation can in fact alter these sexual traits. For example, experimentally increasing the prenatal androgen environment of female fetuses increases the expression of the male-typical sexually dimorphic behaviors (mounting and rough-and-tumble plays) when these female monkeys are juvenile, and these effects varied depending on when in gestation the androgen manipulation occurred (Goy *et al.*, 1988; Eaton *et al.*, 1990; Wallen, 1996). Thus, androgen exposure started at day 40 of gestation and maintained for 25 days results in extensive masculinized female genitalia and increases mounting behaviors, but not play behaviors. By contrast, androgen treatment started at 110 days of gestation yields no apparent genital masculinization, but masculinizes both mounting and play behaviors. These results indicate that the effects of prenatal androgen exposure on behavior were independent of its effects on genital masculinization, and that the developing nervous system in nonhuman primates is sensitive to the organizational actions of androgens throughout a large portion of gestation. Finally, they demonstrate that the critical periods for the development of specific sexually dimorphic behavior can occur at different gestational times, whereas a single critical period seems to be present for genital masculinization. Although the possible neural locus for these hormonal effects in monkeys remains unknown, studies in rodents have indicated that the amygdala could be a potential neural substrate (Meaney, 1988). Amygdaloid lesions made on days 21 or 22 in rats reduce the levels of play-fighting in male pups to those of normal females. The same lesions have no effect on the play-fighting of females. This finding suggests that a sex difference in some portions of the amygdaloid complex might, at least in part, mediate the sex difference observed in the play-fighting of juvenile rats. Because the amygdala is a principal target of gonadal hormones in rodents as well as in monkeys (Pfaff, 1976; Pfaff *et al.*, 1976; Clark *et al.*, 1988), it is possible that androgens might act directly on this limbic structure to masculinize play-fighting in monkeys as it does in rodents (Meaney, 1988).

4.31.3.2 Sex-Typed Toy Preference

Recent findings have also documented that nonhuman primates show preferences for sex-typed toys

similar to those seen in human children (Alexander and Hines, 2002). In this particular study, colonies of vervet monkeys were provided with toys typically preferred by boys (a toy police car and a ball), toys typically preferred by girls (a rag doll and a cooking pot), and toys preferred equally by boys and girls (a picture book and a stuffed dog). Videotapes were made of the animals interacting with the toys, and researchers unaware of the sex of the animals recorded the amount of time that male and female vervet monkeys spent in contact with each type of toys. Male monkeys spent more time than females in contact with toys usually preferred by boys, female monkeys spent more time than males in contact with toys usually preferred by girls, and male and female monkeys spent similar amount of time in contact with toys that both girls and boys enjoy. Since vervet monkeys had no prior experience with any of the toys and had no cultural expectations about which toys were for males or females, it was concluded that the differences between male and female vervets in toy preferences cannot be attributed simply to social/cognitive mechanisms. The authors suggested that a differential influence of androgens on the development of cortical visual areas related to either object features (ventral visual pathway) or object movements (dorsal visual pathway) (Ungerleider and Mishkin, 1982) may influence perception of object characteristics that have different adaptive significance for males and females, and promote the formation of children's sex-typed object categories.

4.31.3.3 Learning and Memory Abilities in Infancy

Two separate lines of evidence strongly support the role of androgens in the development of sex differences in learning and memory abilities in nonhuman primate infants.

Acquisition of an object discrimination reversal task, known to depend on the integrity of the orbital frontal cortex in the adult monkey, is significantly more rapid in male infant monkeys than in females (Clark and Goldman-Rakic, 1989). Postnatal injections of testosterone propionate (TP) in the females enhance their performance to the level of normal infant males. When orbital prefrontal cortex is removed in infancy, intact male monkeys and androgenized female monkeys are as impaired as adult monkeys with the same lesions, whereas treated infant females do not differ from untreated age-matched females. The data suggest that the orbital frontal cortex matures earlier in male than in female monkeys.

Conversely, acquisition of a concurrent visual discrimination learning task (Figure 1), known to depend on the integrity of the inferior temporal cortex, is significantly more rapid in female infant monkeys than in males (Bachevalier and Hagger, 1991), and this sex difference is positively correlated in 3-month-old male animals with circulating levels of testosterone (the higher the level of testosterone, the poorer the score on the task), but not with estradiol levels. Neonatal orchiectomy, which reduced plasma testosterone levels, hastens performance on visual discrimination learning in male infant monkeys, whereas treatment of androgens (DHT) in neonatally ovariectomized female infant monkeys delays their performance. Finally, early postnatal inferior temporal cortex lesions affect performance of female but not of male infant monkeys, though male and female adults with the same lesions are equally impaired. The data suggest that this temporal cortical area is functionally more mature in female infant monkeys than in males.

The two sets of findings lead to intriguing conclusions. On the one hand, they suggest that sex differences in the development of learning and memory abilities are due to the influence of gonadal steroid hormones on the maturation of the

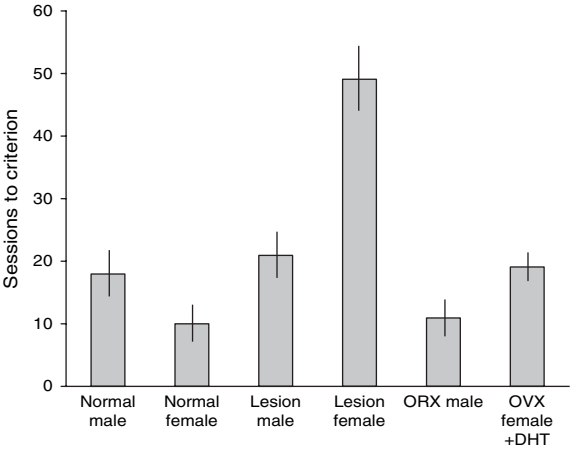

Figure 1 Summary of rate of acquisition of 20 concurrent discrimination problems in 3-month-old monkeys (*Macaca mulatta*). Normal females learned at a faster rate, and required fewer trials than normal males to reach the learning criterion. Young female monkeys were impaired after lesions to the temporal cortical area TE (lesion female), requiring more trials than did females that did not have surgery (normal female). By contrast, males with the same lesions (lesion male) and normal males learned at the same rate. Newborn males that were orchiectomized (ORX male) learned faster than normal males and at the same rate as normal females. By contrast, newborn females (OVX female + DHT) that were ovariectomized and treated with DHT (2 mg kg^{-1} three times a week) learned at a slower rate than normal females.

specific cortical regions underlying these abilities. On the other hand, they also indicate that the directionality of such hormonal influences on structure and function varies from one cortical area to the other. Specifically, whereas the orbital frontal cortex appears to mature earlier in males than in females, inferior temporal cortical area TE appears to mature earlier in females than in males. Although the specific biological mechanisms for such cortical effects of androgens are still unknown, it has been hypothesized (Bachevalier and Hagger, 1991) that the actions of TP and DHT might be mediated by different receptors in the cortex. It has been shown in nonhuman primates that TP, which is aromatized into estrogens at a neural level, has a high affinity for estrogen receptors, whereas DHT, an androgen not significantly aromatized in the primate brain, has higher affinity than TP for the androgen receptors (Michael *et al.*, 1986). Since both estrogen- and androgen-binding systems have been located in all cortical areas of the primate brain, there might be local cerebral metabolic differences (estrogenic vs. androgenic action) that underlie some of the different behavioral effects of gonadal steroids in primates. Such regional metabolic differences were underscored by the work of Michael *et al.* (1989).

4.31.3.4 Learning and Memory Abilities during Adulthood and Aging

In adult rhesus monkeys, females outperform males in spatial working memory as measured by the delayed-response task, and, in adult chimpanzees, females exhibit superior short-term stimulus memory, as measured by the delayed matching-to-sample task (for review, see Mitchell, 1977). A more recent investigation showed that, although male and female rhesus monkeys perform similarly on tasks of object memory and executive function, young males outperform young females on a spatial memory task (Lacreuse *et al.*, 1999). This superior level of spatial ability in young males declined sharply with age, and, at older ages, performance on this task is similar for both sexes. These findings have now been replicated with a large group of 90 rhesus monkeys (Lacreuse *et al.*, 2005a) and thus suggest that biological rather than sociocultural factors underlie the sex differences in cognition.

Further studies have also shown that gonadal hormone levels in male and female rhesus monkeys are associated with differential levels of spatial memory performance. In a recent study (Lacreuse *et al.*, 2001), young adult female rhesus monkeys were tested in an object recognition memory task (with two different delays) and spatial span memory task during the entire menstrual cycle. Spatial memory scores varied consistently during the menstrual cycle, with better performance during the follicular and lutheal phases (when estradiol levels are low) than during the periovulatory phase of the cycle, indicating that spatial memory performance in female rhesus monkeys is affected by cyclic estradiol variations. Furthermore, estrogen replacement therapy in ovariectomized female rhesus monkeys decreased performance on the recognition of conspecifics' faces but had no effects on spatial memory or object recognition memory (Lacreuse and Herndon, 2003). Nevertheless, another study demonstrated substantial improvement in spatial working memory performance mediated by the prefrontal cortex and modest improvement in an object recognition memory task mediated by the medial temporal lobe following estrogen replacement therapy (Rapp *et al.*, 2003). These findings clearly need to be replicated and extended to other memory tasks to further our understanding of the role of estrogen in cognitive functioning.

Finally, cognitive sex differences were also found with aging in monkeys. Thus, a progressive deterioration of motor functions was demonstrated in aged male rhesus monkeys, but not in aged females (Lacreuse *et al.*, 2005b). The authors also showed no volumetric differences in the size of the caudate nucleus and putamen in aged male and female monkeys, even though dysfunction of the nigrostriatal dopaminergic system has been associated with the decline of motor abilities in male monkeys. Together the results indicate that ovarian hormone status seems to broadly modulate neural systems and influence normal cognitive functions in monkeys across the life span.

4.31.4 Sex Differences in Brain Areas Related to Cognitive Abilities

Although no direct correlation has been established between sex differences in cognitive abilities and morphology of brain areas, there exist sex differences in numerous neural structures related to cognitive abilities. The majority of this work has been carried out in rodents (for reviews, see Beatty, 1979; Juraska, 1991; Kawata, 1995). In the limbic system (bed nucleus of the stria terminalis and hippocampus), the number and volume of neurons differ in male and female rats. These morphological differences are reversed after postnatal treatment with gonadal steroid hormones. In the cortex, the rate of cell proliferation has been shown to be

slower in male than in female rats, indicating a delayed maturation of the neocortex in males compared with that of females. Finally, recent findings indicated that the rat's corpus callosum is sexually dimorphic; the males' corpus callosum and more specifically the splenium of the corpus callosum are larger than the females (Fitch *et al.*, 1990; Nunez and Juraska, 1998). Manipulations of testosterone levels in males (castration) and females (injection of TP) had a significant impact on females but not males, in that injection of testosterone in female rats masculinized the corpus callosum.

Sex differences in brain structures have not been well documented in nonhuman primates. However, the advent of magnetic resonance imaging (MRI), which provides excellent anatomical resolution, gives a compelling new tool to investigate sex differences in the size and volume of different brain regions, not only in the adults but also across the life span and across different nonhuman primate species. Earlier anatomical studies in monkey postmortem brains (Cupp and Uemura 1981), showed that males' brains (90.57 g) weighed 11% more than females' brains (81.50 g). A similar sexual dimorphism in total brain volume has also been found using MR images in rhesus monkeys (Franklin *et al.*, 2000). However, sexual dimorphism in corpus callosum measurements in nonhuman primates is still controversial. Holloway and Heilbroner (1992) measured the volume of the corpus callosum in four different species of primate (*Macaca mulatta, M. fascicularis, Callithrix jacchus,* and *Saguinus oedipus*) and found no evidence for a sexual dimorphism of this brain structure, although they noted that in *M. mulatta* the splenium of the corpus callosum in the males was larger than in the females. More recently, Franklin *et al.* (2000) reported that, while the total brain volume and total callosal volume are smaller in young female rhesus monkeys than in the males, the area of the splenium of the corpus callosum was larger in the female monkeys than in the males. No sex difference was found in the volume of the amygdala. Using MRI volumetric measures to follow the maturation of the total brain, hippocampus, and amygdala volumes in male and female rhesus monkeys (*M. mulatta*) ranging from 1 week to 2 years of age, Machado *et al.* (2002) indicated that male macaques have slightly larger total brain volume (10%) than females in infancy, but this difference was absent in adulthood. In addition, while the initial volume of the hippocampal formation did not differ between the left and right hemispheres for males and females, the right amygdala displayed a significantly larger initial volume than the left in males but not in females. These data suggest the presence of sexually dimorphic differences in specific limbic regions in the macaque brains that could vary during maturation. Furthermore, a recent report in chimpanzees (*Pan troglodytes*) indicated a right hemispheric asymmetry for the hippocampus but not the amygdala, with a tendency for males to be more lateralized than females (Freeman *et al.*, 2004). While interesting sex differences in brain structures are starting to emerge in the literature, additional data in this area will greatly inform on the neural bases of sex differences in cognitive functions across the life span.

4.31.5 Sex Differences in Cognitive Abilities in Humans

There is also accumulating evidence that gonadal steroid hormones in humans do influence brain and behavior in a manner similar to that documented in other species (for reviews, see Witelson, 1991; Collaer and Hines, 1995; Wisniewski, 1998). During the developmental period, both behavioral and cognitive development is protracted postnatally in boys compared to girls (Maccoby and Jacklin, 1974). Girls generally learn to sit, crawl, and walk earlier than boys. This precocious behavioral ability in girls is accompanied by precocious abilities in stimulus processing (Tighe and Powlison, 1978; Clifton *et al.*, 1984; Creighton, 1984; Held *et al.*, 1984; Bauer *et al.*, 1986) and in certain learning and memory functions (Diamond, 1985). Girls also acquire language earlier than boys (McGuiness, 1976), and are superior in most forms of visual and verbal recall (Duggan, 1950; Mittler and Ward, 1970), although the superiority of boys in spatial tasks is well documented (Tyler, 1965; Guilford, 1967; Garai and Scheinfeld, 1968; Hutt, 1972; Kerns and Berenbaum, 1991). Childhood play behaviors, such as toy choices and activity and playmate preferences, also show differences between boys and girls. These sex differences can be reversed by modulation of androgen levels in the case of genetic disorders, such as congenital adrenal hyperplasia, as well as in the case of normal variability of androgen levels in the prenatal period (for review, see Hines, 2003).

Interestingly, the double dissociation found in infant monkeys with the object discrimination reversal and concurrent discrimination tasks (see above) has been replicated in very young children using almost identical cognitive tasks and nonverbal procedures (Overman, 2004; Overman *et al.*, 1997). Boys under the age of 29 months significantly outperform girls on the object reversal task, but girls

outperform boys on the concurrent discrimination task. Given the close parallel in learning behavior in human infants and infant monkeys, it is reasonable to propose that the gender differences are mediated by similar biological mechanisms in both species. Therefore, in children, as in infant monkeys, there may be a more rapid maturation of orbital prefrontal circuits in boys and a more rapid maturation of inferior temporal circuits in girls. The sex differences found on tasks measuring orbital frontal functioning appear to persist in adolescents and adults (Overman, 2004).

Sex differences in cognitive functions have also been reported during adulthood. Many studies showed that women excel in verbal abilities, perceptual speed, articulation, and fine motor skills, whereas men generally excel in tasks measuring visuospatial abilities, particularly those requiring mental rotation of objects and imagining what an object would look like from a different vantage point (Hyde and Linn, 1988). Numerous studies also report sex differences in perceiving, interpreting, and reacting to social cues that signify the potential presence of threat. Thus, females tend to perform more accurately than males when labeling others' feelings, such as anger and hostility, based on facial expressions (Hall, 1978; McClure, 2000), but they also show greater increases in skin conductance and a tendency toward stronger startle potentiation to threatening scenes (Bradley *et al.*, 1999; McManis *et al.*, 2001). These sex differences appear to be largest after the transition from adolescence to adulthood (Hall, 1978; McClure, 2000; Nelson *et al.*, 2002).

While direct manipulation of gonadal hormones is not possible in humans, the organizational and activational effects of the hormones on cognitive functions have usually been inferred from studies of different populations of individuals (for review, see Sanders *et al.*, 2002). They include boys and girls suffering from long-standing prenatal hormonal anomalies or who have been exposed to exogenous hormones *in utero*, women during regular fluctuations of estrogen and progesterone throughout the menstrual cycle or postmenopausal women receiving hormone replacement therapy, and elderly individuals showing a decline in cognitive functions. Thus, girls with congenital adrenal hyperplasia, who are genitally masculinized and prenatally exposed to excessive androgens, show significant enhancement of visuospatial ability as compared to unaffected females. Also, boys exposed with diethylstilbestrol (a synthetic estrogen) in the perinatal period show poorer performance on several spatial tasks than males who suffer from low testosterone due to postpuberty pathology (for review, see Reinisch *et al.*, 1991). In addition, when performance on several visuospatial tasks is compared at different phases of the menstrual cycle, women perform significantly more poorly during the estrogen surge just prior to ovulation than at other points in the cycle. Conversely, higher levels of estrogen during the menstrual cycle are associated with better performance on many tasks in which women typically excel. When postmenopausal women are tested either when receiving estrogen therapy or when they are off medication for at least 4 days, performance on fine motor and spatial tasks tends to be faster and more accurate during the treatment compared with the off-treatment phase (for review, see Hampson and Kimura, 1992). Finally, estrogen deficiency in menopausal women is associated with memory impairments that are reversible by estrogen replacement therapy, whereas testosterone replacement therapy in elderly men enhances spatial performance (Janowsky *et al.*, 1994).

The advances of neuroimaging techniques in the last 10 years have tremendously increased the number of studies in humans devoted to sexual dimorphism in brain structures. Both structural and functional MRI techniques are providing mounting evidence of small but robust sex differences in brain morphology, metabolism, weight, volume, and neocortical neuron number (Gur *et al.*, 1995; Pakkenberg and Gundersen, 1997; de Courten-Myers, 1999; for review, see Hampson and Kimura, 1992). These differences seem to be evenly distributed among the four lobes, although regional tissue composition show sex differences only within the parietal lobes, with females having proportionally more gray matter on the right side (Nopoulos *et al.*, 2000). Finally, sex differences are found in hemispheric and cortical asymmetry (for review, see Voyer, 1996; Witelson, 1991; Wisniewski, 1998). In general, males tend to exhibit more accentuated asymmetries and stronger right-hemisphere dominance compared with females, while females typically exhibit more diffuse lateralization patterns and greater left-hemisphere bias compared with males.

Sex dimorphism in human brain anatomy appears also to be present during development (Giedd *et al.*, 1997; De Bellis *et al.*, 2001). Males show a 9% larger cerebral volume. When corrected for cerebral volume, the caudate nucleus is relatively larger in females and the globus pallidus larger in males. Furthermore, the amygdala and hippocampal volumes increase for both sexes, but with the amygdala volume increasing significantly more in males than females, and hippocampal volume increasing

more in females. Similarly, women with gonadal hypoplasia have smaller hippocampi than controls (Murphy *et al.*, 1993).

More recently, the use of functional MRI has provided a way perhaps to understand better the relationship between sex differences in brain structures and functions. Thus, Killgore *et al.* (2001) reported a sex difference in the functional maturation of the affect-related prefrontal-amygdala circuits during adolescents. Females show a progressive increase in prefrontal relative to amygdala activation in the left hemisphere, whereas males fail to show a significant age-related difference. Interestingly, as shown with the sex dimorphism found in the orbital frontal cortex in monkeys (see above), a recent study indicated larger orbital frontal cortex in women than in men (Gur *et al.*, 2002), supporting mounting behavioral evidence for sex differences in emotion processing (Canli *et al.*, 2002; McClure *et al.*, 2004; Schirmer *et al.*, 2004).

4.31.6 Conclusions

This article provides a brief survey of sex dimorphism in behaviors and cognitive abilities not related to sexual behaviors, its expression across primate species and across the life span, and its relation to brain anatomy and function. Although sex differences in cognitive and learning abilities are presently widely acknowledged, the basis for these differences remains controversial. The data reviewed here suggest that androgens organize the brain pre- and perinatally for all sexually dimorphic behaviors, including problem-solving behaviors, and this appears to be true in mammals, nonhuman primates, and humans. Moreover, the pattern of variation in learning abilities documented recently over the menstrual cycle and during aging raises the possibility that sex differences in cognitive abilities in nonhumans and humans may also be due at least partly to an activational influence of gonadal hormones, both androgens and estrogens, on the brain throughout life. Thus, it is becoming clear that sex differences in structure and function are likely to be a pervasive characteristic of brain organization mediated by gonadal steroid hormones. Nevertheless, the challenge is to specify precisely the biological mechanisms by which these differences occur and to take into consideration the circular interactions between biological factors and socioenvironmental factors. Ultimately, the understanding of cognitive sex differences will necessarily depend upon converging evidence from many different disciplines, including anthropology, evolution, endocrinology, animal and human behavior, neurobiology, electrophysiology, and brain imaging.

Although the causes and functions of sex differences in cognitive processes are largely unknown and remain puzzling, sex differences in cognitive functions are likely to result from selective pressures on both male and female traits, as already proposed for sex differences in reproductive behaviors (Plavcan, 2001). In addition, sex differences result from different developmental pathways, all of which can be affected by different selective pressures throughout an animal's entire life history. This article provided few examples that seem to support the idea that sex-related differences in cognitive functions appeared early in human evolution, prior to the emergence of a distinct hominid lineage. Many have proposed that the diverse requirements based on tasks conducted more by males or females may have promoted differential selection pressures on diverse cognitive functions.

For example, sex differences in preferences for sex-typed toys have been demonstrated in both children and nonhuman primates (for review, see Hines, 2003). Alexander and Hines (2002) have proposed that these sex differences by males and females may be associated to sex differences in visual perceptual categories (color, shape, and movement) that are in turn mediated by sex differences in cortical visual areas, such as the ventral visual pathway involved in the processing of object features and the dorsal visual pathway involved in the processing of object movements (Ungerleider and Mishkin, 1982). They argued that, like chromatic color vision in primates, which appears to have evolved to facilitate foraging for fruit and edible leaves, sex-typed toy preferences may have evolved from the formation of perceptual categories of objects with differential adaptive significance for males and females. Similarly, the sex differences in spatial abilities observed in nonhuman species and humans may be related to sex differences in hippocampal volume, a brain structure critical for the processing of spatial information. While the significance of sex dimorphism in brain structure and function related to spatial abilities is unknown, it could also be based on different task requirements for males and females. Greater spatial abilities in males could have evolved for a role in males in gathering food and hunting, both abilities requiring good spatial skills. Conversely, greater use of communication and language in females could have evolved from a task requirement for females in regulating cohesion in the social group. Although we can offer only broad speculations at this time due to the large gaps in our understanding of the evolution of sexual dimorphism in general and, more

particularly, of the evolution of sex differences in cognitive functions, the growing interest in this field of research together with the great advances in technology to investigate genetic and molecular factors as well as brain/behavior relationships are likely to augment our understanding of this controversial topic.

4.32 Evolutionary Psychology

S J C Gaulin, University of California, Santa Barbara, CA, USA

Glossary

altruism A social interaction in which the actor derives a net fitness cost and the recipient derives a net fitness benefit.

cognitive module A psychological mechanism, instantiated as neural architecture, that accomplishes a specific function by handling a certain class of inputs and generating a certain class of outputs, for example, a face-recognition module.

Natural selection (Darwin, 1859) is the inexorable engine of adaptive evolution. It results from the differential success of alternative genetic variants in creating phenotypes that usefully address the challenges of surviving and reproducing in actual environments (Williams, 1966). In each generation new genotypes assemble new phenotypes. Because they better meet the demands of the local environment, some of those phenotypes reproduce more than others. In the course of doing so, they differentially transmit the genes that built them to the next generation. Seen in this way, the process is inevitable, ubiquitous, and unending.

As selection sorts variation, it produces what can logically be regarded as designs for reproduction (Dawkins, 1976). Designs for reproduction are not limited to the sex organs. The heart, lungs, and liver are designs for reproduction to the extent that the sex organs perish without them. The same is true for countless other aspects of anatomy and physiology. Organisms are richly integrated bundles of such designs. Each design tends to do one job. The heart, lungs, and liver are functionally integrated, but each is specialized for a specific task. The reason for this is that hearts that both pumped and aerated blood were worse pumps. An improvement in a system with respect to one function will usually decrease its ability to perform others. Because selection favors improvements, it tends to build specialized systems.

Evolutionary psychology, like the rest of academic psychology, is materialistic. In other words, it assumes that, at base, psychology reduces to anatomy and physiology. If this approach is accepted, it means that natural selection will have designed psychological systems and mechanisms in precisely the same way it builds other bodily systems – by the spread of genetic variants that favorably influence the growth, organization, and functioning of the underlying architectures. Selection refines any function (be it circulation of the blood or parental care) by improving the various organs that accomplish it. By the same logic developed above, the output of such selection is expected to be an integrated bundle of specialized psychological mechanisms.

There are two related conclusions that follow from this line of thinking: the brain is not one organ but many; and the brain is not a general-purpose computer (Tooby and Cosmides, 1990, 1992). These concepts are related because they both follow from the principle of specialization. Psychological systems should have been designed by natural selection to produce adaptive (i.e., reproduction enhancing) behavior. That ultimate function would be served by many different and specific kinds of behaviors – effective communication, distinguishing reliable from unreliable associates, recognizing other's emotional states, and predicting their behavior, parsing speech, avoiding dangerous situations, recognizing nutritious foods, assessing the needs of offspring; the list is long. There is no evidence, nor theoretical reason, suggesting that the psychological mechanisms involved in, say, phoneme discrimination might serve other functions, such as the ability to read facial expressions or know when your child is in danger. The brain is many specialized organs precisely because there are many distinct tasks that must be accomplished along the road to reproduction.

The opposite side of the same coin is that the brain is not a generalized computational device primarily because it was not shaped by the demands of any 'general-purpose problem'. Selection sorts genes with reference to real-world situations. Since the barriers to reproductive success were specific, our psychologies comprise many specific mechanisms. The computer provides a useful analogy. Imagine an immensely powerful general-purpose computer with lots of computational resources in the form of vast amounts of hardware, but without any

task-specific software. It will be useless, just like a general-purpose brain would be.

A lot of controversy has swirled around the concept of psychological modularity (Fodor, 1983; Pinker, 1997). An evolutionary view of the mind predicts functional modularity in the sense that there will be different mental 'organs' specialized for different tasks. This stance is agnostic as regards anatomical modularity; functions may or may not be spatially localized. This localization debate is not relevant to the argument for cognitive modularity.

What kind of modules should we expect the mind to comprise? From the foregoing, the answer is obvious: modules that solved the problems recurrently faced by our ancestors (Tooby and DeVore, 1987). Understanding the full import of this conclusion goes a long way towards clarifying the approach of evolutionary psychology. The assumption is not, for example, that humans go about calculating the relative impact of fixed versus variable-rate mortgages on the expected number of their surviving grandchildren. For 99.9% of the 7 million years since our lineage diverged from the one leading to chimpanzees, fixed abodes, never mind compound interest rates, did not exist. Why should our minds be in any way prepared for this problem?

Consider two pictures: a sleek coiled snake and a shiny new Porsche. Which is more frightening; which more attractive? Fine, but how about a reality check? How many people die or are seriously injured each year by snakes versus cars? Obviously, the statistics tell us that cars are presently more much dangerous than snakes. Perhaps we are, as some economists might assert, irrational; but that conclusion has no temporal perspective. We are not irrational in relation to the world where our minds were designed, a world without motorized transport of any kind, but a world brimming with many natural dangers such as poisonous snakes (Gaulin and McBurney, 2004).

These examples raise two issues. The first is the one just discussed. Selection cannot design for the future, so our psychological adaptations will be the ones that functioned over the long haul of human evolution, not necessarily the ones that would be useful in the novel world of the twenty-first century (see Human Cognitive Specializations). The second is that psychological adaptations do not necessarily and automatically put fitness maximization in the spotlight of consciousness. In fact, they are often cognitively impenetrable (Pylyshyn, 1999). Let us return to the snake. The rapid, 'gut-level' emotional and behavioral response to the snake does not involve a conscious chain of reasoning: snakelike objects are often poisonous; poison may harm or kill me, thus probabilistically reducing my genetic contribution to future generations. The response is much quicker, more automatic, 'unreasoned' and inaccessible in the sense that no amount of introspection will allow us to say what happened between the glimpse of the snake and our response. The benefits of automaticity are obvious: no opportunities to make reasoning or inference errors, quick and reliable output.

In large part, evolutionary psychology consists in trying to map the environmental pressures that would have operated over the big sweep of human evolution, and testing whether the psychological mechanisms necessary to meet these challenges are present (Tooby and DeVore, 1987; Tooby and Cosmides, 1992). Critics will argue that they could be present by chance, or as incidental side effects of other mechanisms. Thus, the best way to proceed is to examine whether structurally (cognitively, emotionally) similar mechanisms that would not have served the same function are absent. This approach is applicable to all of psychology. A great deal of attention has been focused on psychological adaptations to the challenges of mating and parenting (e.g., Buss and Schmitt, 1993), and this focus is reasonable because these mechanisms are closely linked to evolutionary fitness. But any of the traditional domains of psychology – cognition, emotion, development, perception, and learning to name a few – are amenable to evolutionary analysis (e.g., Gigerenzer and Todd, 1999; Damasio, 1994; Bugental, 2000; McBurney *et al*., 1997; Gallistel, 1990).

This short list may raise a flag for some. What about learning? Aren't learned behaviors complementary to evolved ones? Absolutely not; and this insight is one of the most powerful that evolutionary psychology can offer. To say that a behavior is learned sweeps away all the interesting questions with a mere label. When learning occurs, behavior is modified by experience: but which behaviors and which experiences? The older Pavlovian and Skinnerian (e.g., Skinner, 1956) views would assert that it does not matter; any combination is possible. But this formulation was being undermined even as it was being articulated.

Consider food-deprived versus water-deprived rats, each rewarded with the withheld substance in a T-maze. Which group will learn the task more quickly? The answer depends on reward placement. In the 'fixed' design, each rat is always rewarded in the same arm. In this case thirsty rats learn where water is more quickly than hungry rats learn where food is. Perhaps thirst is more 'motivating' than hunger. Possible, but consider the next experiment. In the 'reversal' design, reward placement alternates – right,

left, right, left – in successive trials. This is a harder task, to be sure, but rats can learn it, if the reward is food. However, they never learn the task if the reward is water (e.g., Petrinovich and Bolles, 1954). So much for open-ended learning, but can we make sense of these results?

Remember that all adaptations are formed by natural selection operating in real-world environments. In the real world, food often moves around but water typically does not. Rat brains are apparently set up to handle information about food and water locations differently, such that the former is easily updated while the latter is not. This is a nice example of a fine-grained cognitive specialization. I am not aware that anyone has tested this hypothesis in humans but, because the selection pressures in these domains would have been similar in the two species (stable water sources, mobile food sources), the result could be expected to generalize.

The topical focus of evolutionary psychology is – like all of psychology – mind, brain, and behavior. But its explanatory stance unites it methodologically with evolutionary biology. Thus, one studies psychological adaptations with the same two tools used to analyze any adaptation: cross-species comparison and reverse engineering. I will explain each method and then, for each, give two examples of their use by evolutionary psychologists.

Cross-species comparison can be used to work forward from a given selection pressure to ask what kind of adaptation it would cause, or to work backwards asking what adaptive function a given trait might have been designed to serve. This method assumes that closely related species will tend to be similar because of their shared inheritance from a recent common ancestor. But if closely related species are subject to different selection pressures, their adaptations should diverge. And if distantly related species are subject to similar selection pressures, their adaptations should converge. By examining such cases of divergence and convergence, one can evaluate whether particular adaptations are systematically associated with particular environments. For example, the notion that eyes are an adaptation for forming images from reflected light gains support from the finding that, in a variety of taxa (fish, shrimp, crayfish), closely related species differ in the possession of eyes: those that live in environments where light penetrates have eyes, whereas those that live in deep caves lack them.

An early example of this approach in evolutionary psychology involves questions about the possible adaptive basis of sex differences in spatial ability. Men – and male laboratory rodents – make fewer errors on spatial tests such as navigating a maze or visualizing objects from multiple perspectives. Such a pattern should only occur where male reproductive success is more heavily dependent on such abilities than is female reproductive success. This would be the case under some types of polygynous mating systems, where individual females forage for food in a limited area, but individual males travel much more widely attempting to maximize their exposure to sexually receptive females. Such mating systems are not universal however; for example, in monogamous systems opposite-sex pairs travel together and thus exploit quite similar ranges. From these ecological facts one can predict that sex differences in spatial ability should be limited to the polygynous species. Based on experiments and observations with wild microtine rodents (voles), this prediction is supported both for spatial performance and for the relative size of the hippocampus, the brain structure most heavily involved in spatial processing (Gaulin and FitzGerald, 1986, 1989; Jacobs *et al*., 1990). Independent confirmation comes from comparisons among and wild icterids ('blackbirds'; Sherry *et al*., 1993).

Quite a different example concerns the function (and malfunction) of parental love. Here again an initial hypothesis is easy: parental love primes solicitous behavior and thus promotes the survival of the parental genes. Obvious test cases would be situations where parents and nonparents find their reproductive interests in conflict. More specifically, in some species male tenure in breeding groups is relatively brief (as a result of strong competition among males) and this turnover regularly brings adult males into close proximity with dependent young they could not have sired. Lactating females generally do not ovulate in wild populations, thus producing a conflict of interest: females are better off nursing their current offspring to independence, but new males can profit by terminating investment in the offspring of their predecessors. This pattern of infanticide has evolved repeatedly in species where new males frequently displace fathers from breeding units and not in species without such displacements. In their studies of humans, Daly and Wilson (1988) have shown that the replacement of the father by a new breeding male is a common correlate of infanticide in the ethnographic record. Likewise, living with a step-parent is the single most predisposing factor for both child abuse and infanticide in industrialized societies (Daly and Wilson, 1988, 1996, 1999). Those investing in bearers of their own genes are decidedly more solicitous than those who are not.

Reverse engineering provides another method for testing adaptive hypotheses. If a trait is to serve function x, it must have the components that allow

it to accomplish this function. Returning to the eye, we can predict that an organ designed to form sharp images from reflected light would have to possess an appropriately adjustable aperture, a lens, a focal plane at an appropriate distance from the lens, light-sensitive elements that capture the image on the focal plane, etc. If eyes do not have these features, they are probably not adaptations for forming images from reflected light.

To illustrate the reverse-engineering method, let us choose the problem of altruism. Why is altruism a problem? It seems unlikely to evolve by the differential replication of altruistic (as opposed to selfish) alleles because the former would be at a competitive disadvantage. There are (at least) two ways around this problem only one of which – reciprocity – will be treated in this brief article. If: (1) actors were in a position to provide relatively large benefits to others at small costs to themselves and (2) actor and recipient regularly exchanged roles, then both would derive net long-term benefits from such reciprocity (Trivers, 1971). This works as long as actors are not drawn into too many relationships with cheaters (=nonreciprocators); if they fall prey to such exploitation, they do not get enough benefits to offset their costs and selection will eliminate altruism. This means that selection for reciprocity can only evolve in the context of the simultaneous evolution of adaptations for withholding benefits to cheaters.

Reverse engineering requires us to ask the question: what features would an evolved system like this have to have? One basic element is the ability to recognize when cheating has occurred. Leda Cosmides and John Tooby have used the study of logical abilities as a platform for investigating cheater detection. In general, people are not very good at solving logical problems and require significant training to perform well. What Cosmides and Tooby have done is to construct a wide array of logical problems, all of which have the same logical structure. Each problem describes some social situation and each requires the same logical response, but some describe a situation where an actor may have cheated and some contain no such possibility. The striking result is that performance on these two classes of problems is very different: some 70–90% of subjects solve the problems where cheating may have occurred but only 20–40% do so where there is no such possibility (Cosmides, 1989; Cosmides and Tooby, 1992; Gigerenzer and Hug, 1992). The conclusion: there is no general logic-solving module (the brain is not a general-purpose computer), but there is a specialized cheater-detection module.

Holding to the example of reciprocity, one can suggest other plausible engineering features of system. It would be adaptive, for example, to remember who had cheated in the past. Linda Mealey and her associates (Mealey *et al*., 1996) tested the idea that facial memory is primed by the assignment of a 'cheater' label. They first obtained a sample of facial photographs and created a sample of positive, neutral, and negative statements about individuals; the negative statements emphasized cheating. Then they combined these statements and photographs (using an appropriately counterbalanced design) and showed these captioned photographs to people without explaining their purpose. One week later, the participants returned and were shown another set of faces without statements; one-half of this second set was new and one-half had been paired with statements the week before. The participants' task was simply to say which faces were new, a task that obviously required them to remember which faces they had seen. In this experiment faces previously assigned a 'cheater' label were more likely to be recalled (see Evolutionary Specializations for Processing Faces and Objects).

The power of this approach is that it usefully guides our search for psychological mechanisms. It should be clear from these examples that one can generate explicit and testable predictions about specific psychological features from a consideration of evolutionary theory and the context of human evolution. George Williams wrote nearly 40 years ago: "Is it not reasonable to anticipate that our understanding of the human mind would be greatly aided by knowing the purpose for which it was designed?" (Williams, 1966, p. 16). Evolutionary psychology is beginning to answer that question in the affirmative.

4.33 The Interpreter in Human Psychology

M E Roser, University of Plymouth, Plymouth, UK
M S Gazzaniga, University of California, Santa Barbara, CA, USA

Glossary

corpus callosum	A large myelinated axonal tract that connects the two cerebral hemispheres, allowing interhemispheric interaction at the cortical level. Interhemispheric tracts are known as commissures.
split brain	Patients in whom the corpus callosum has been severed, for the relief of intractable epilepsy, in an operation known as a callosotomy. Occasionally other, smaller, commissures are also severed in a procedure known as a commissurotomy.
left-hemisphere interpreter	The term used to describe the tendency for the isolated left hemisphere in split-brain patients to generate hypotheses about information with which it is presented, including explanations of the patient's actions that were initiated by the right hemisphere.
confabulation	The production of fictitious explanations for past or present events and behavior occurring as a result of brain damage. Confabulations, which can diverge sharply from reality, are usually accompanied by an appearance of conviction on the part of the patient.

4.33.1 The Interpretive Nature of Consciousness

Although writers may disagree on the degree to which the brain exhibits modularity of function (Pinker, 1997; Fodor, 2000), there is growing evidence that the brain is not a generalized computing device exhibiting equipotentiality between regions (Lashley, 1950). Rather, the brain is a collection of functionally specialized areas that carry out domain-specific processing, such as for object or face identity, spatial location, or emotional content. This evidence has motivated the view that consciousness, although experienced as a unitary and coherent whole, is instead a composite of fractionated and disparate processes that are drawn together in a dynamic network or workspace (Baars, 1989; Dehane and Naccache, 2001). According to this hypothesis, consciousness, at any one time, comprises only those distributed processes that have been integrated into a large-scale system of cortical activity, and which receive attentional amplification. Consequently, much processing occurs outside of awareness (Zeki, 2003).

The most striking demonstration of the disunity of consciousness comes from studies of patients who deny that they have a severe cognitive deficit. For example, patients who exhibit hemispatial neglect, commonly as a result of right parietal damage, are often aware that they have been diagnosed with a deficit, but sometimes refuse to accept the diagnosis. To the patient, the notion that they neglect a side of space can seem nonsensical since their conscious experience has been reduced to encompass only a subset of perceptual and memory processes. As one patient put it "I knew the word 'neglect' was a sort of medical term for whatever was wrong but the word bothered me because you only neglect something that is actually there, don't you? If it's not there, how can you neglect it?" (Halligan and Marshall 1998).

Similarly, in anosognosia for hemiplegia, the paralysis of a limb is denied, even when the patient is confronted with their paralyzed hand (Ramachandran and Rogers-Ramachandran, 1996). This usually results from damage to the right hemisphere (Bisiach *et al.*, 1986; Gainotti, 1989). According to the workspace view of consciousness, this happens because any remaining processing in the damaged domain is unavailable for integration into a widespread cortical system and cannot therefore contribute to awareness. Thus, a lesion in a specific location may wipe out not only processing of an attribute, such as input from a side of space or

the body, but also the awareness that the attribute exists. For the patient, therefore, denying a deficit is congruent with their conscious experience.

These patients often exhibit a tendency to interpret experiences in a way that rationalizes conflicting information and involves considerable confabulation, or storytelling, that may diverge markedly from reality (Gazzaniga, 2000; Cooney and Gazzaniga, 2003). These confabulations are attempts to produce logical explanations for evidence of the patient's impairments, which fit with their conscious experience. Bizarre confabulations that seem untenable to most people, because of conscious access to information that contradicts them, probably seem completely normal to patients to whom only a subset of the elements of consciousness are available for integration.

Confabulations reveal the piecemeal and interpretive nature of conscious experience. To construct a coherent narrative from the various elements of experience, a system for resolving ambiguities is needed. This system must take the information available from other brain processes – perceptual, motoric, mnemonic, and emotive – and integrate them into a stable description of reality that can be used for ongoing behavioral maintenance.

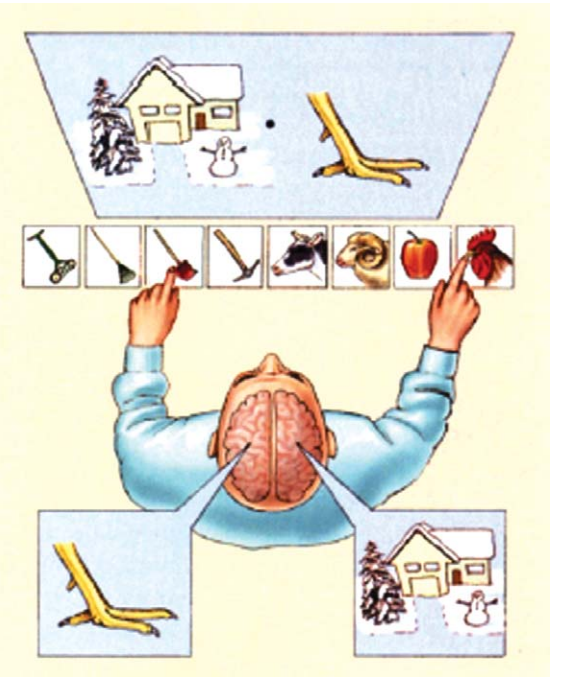

Figure 1 The method for testing each hemisphere of a split-brain patient. Each hemisphere receives only the visual input presented contralateral to fixation. Each hemisphere then chooses an item congruent with the scene presented. Reproduced from Cooney J. W. and Gazzaniga, M. 2003. Neurological disorders and the structure of human consciousness. *Trends Cogn. Sci.* 7, 161–165, with permission from Elsevier.

4.33.2 Interpretive Processes in the Two Hemispheres

A number of experimental findings suggest that the left hemisphere is particularly involved in incorporating available information into a stable representation of reality. Cutting the corpus callosum, the large band of axons that joins the two hemispheres, divides consciousness between the two hemispheres (Sperry, 1969). Lateralized presentation of visual stimuli can allow one hemisphere to be conscious of some event while the other hemisphere remains unaware of the exact nature of the stimulus (see Cortical Commissural Connections in Primates, The Evolution of Hemispheric Specializations of the Human Brain). These split-brain patients typically profess to feel completely normal.

Dividing the hemispheres can, however, reveal the interpretive nature of consciousness in the left hemisphere. In fact, the left hemisphere seems driven to generate hypotheses about information with which it is presented. Gazzaniga (2000) has termed this the left-hemisphere interpreter. In one experiment (Gazzaniga, 2000), the patient is presented with two different scenes simultaneously, one to each hemisphere (Figure 1). The patient is then asked to use his or her left hand (controlled primarily by the right hemisphere) to choose an appropriate item from an array of pictures of objects that may or may not be typically found within the presented scenes. The left hemisphere, which has no knowledge of what was presented to the right hemisphere, can observe the actions of the right hemisphere. When the patient is asked to describe why they chose a particular item, the left hemisphere, which houses the main centers essential for language production in most people, will often reply with an explanation for the action that is congruent with the scene presented to the left hemisphere. These rationalizations can be elaborate, including experiences from outside the experimental setting, and resemble the confabulatory explanations made by patients. Similarly, if a verb such as 'laugh' is presented to the isolated right hemisphere, the represented action may be carried out. When the patient is asked what he is doing, the left hemisphere usually replies with a reasonable explanation for his action, while the patient remains unperturbed by the discord between the explanation and the true stimulus for the action (Figure 2).

Memory tasks also reveal the predilection of the left hemisphere for generating hypotheses about recent experiences, even when this is detrimental to performance. Studies in which each hemisphere of a split-brain patient is required to determine whether a

Figure 2 Lateralized presentation of a command to the right hemisphere can lead to left-hemispheric interpretation of the actions initiated by the isolated right hemisphere. Reproduced from Cooney J. W. and Gazzaniga, M. 2003. Neurological disorders and the structure of human consciousness. *Trends Cogn. Sci.* 7, 161–165, with permission from Elsevier.

picture was drawn from a previously viewed set of scenes suggest that recognition–memory performance by the left hemisphere is more affected by expectations based on the meaning of the scenes than is performance by the right hemisphere (Phelps and Gazzaniga, 1992; Metcalf *et al.*, 1995). For instance, the left hemisphere often falsely recognizes pictures as having been presented in an earlier session if they are congruent with one of the previously viewed scenes. It is thought that this is because the left hemisphere elaborates on the scenario presented and consequently confuses these internal elaborations with novel semantically related distractor stimuli. The isolated right hemisphere does not exhibit this tendency, but instead seems to maintain a more veridical representation in memory of recent events. Thus, a left-hemispheric interpretive system that elaborates on the information it receives may be primarily responsible for the distortions of memory that have been well documented in normal subjects and for the apparent lack of memory deficit in some patients who have suffered insult to right-frontal cortex (Miller and Gazzaniga, 2000).

Another finding that hinted at the tendency for the left hemisphere to generate hypotheses about input it receives involved a task in which subjects had to predict the location (high or low on a screen) of a target stimulus. Neurologically normal subjects usually distribute their responses according to the probability that each stimulus will appear, a strategy known as frequency matching, even though this is suboptimal. This tendency reflects a search for sequences in the stream of stimuli (Yellott, 1969, cited in Wolford *et al.*, 2004). Wolford *et al.* (2000) found that this response strategy was also displayed by the isolated left hemisphere of two split-brain patients, but that the right hemisphere maximized the number of correct responses by consistently choosing the location at which the target was most often displayed. The mode of responding adopted by the right hemisphere is also exhibited by animals. Essentially the same finding was obtained by testing patients who had sustained damage to either the left or the right frontal lobe. Thus the left hemisphere based its responses on a hypothesized pattern in the stimuli, but the right hemisphere did not. More recent tests have revealed that the right hemisphere does, in fact, frequency-match when presented with stimuli for which it is specialized for processing, such as faces, while the left hemisphere responds randomly (Miller and Valsangkar-Smyth, 2005). These results were interpreted as suggesting that one hemisphere cedes control of the task to the other hemisphere, essentially giving up on the task, if the processing required is outside of its domain of expertise (Wolford *et al.*, 2004).

Another area of relative expertise in which the right hemisphere seems to interpret available evidence is visuospatial perception. Split-brain testing suggests that both hemispheres are capable of a range of visual perceptual tasks, such as determining whether objects are of the same size or luminance. The right hemisphere, however, outperforms the left in tests of spatial ability, such as determining alignment and orientation (Corballis *et al.*, 1999b, 2002), and some, more sophisticated visuospatial processes are only able to be performed by the right hemisphere in split-brain patients. Amodal completion, for example, in which occluded contours are perceived, and which requires the visual system to group stimuli and infer the contours, cannot be performed by the left hemisphere (Corballis *et al.*, 1999a). Similarly, only the right hemisphere is able to extract the causal structure from the spatial and temporal properties of the movements of colliding stimuli (Roser *et al.*, 2005), and functional imaging of normal subjects has also suggested right-hemispheric involvement in this task (Fugelsang *et al.*, 2005). Thus the right hemisphere

might also be said to engage in interpretation of a kind that extracts structure from a fragmented sensory representation. Corballis (2003) has referred to this construction of higher-level representations of the visual environment as a right-hemispheric visual interpreter and speculated that the poor performance of the left hemisphere on tasks requiring complex visual analysis may be due to its having lost visuospatial abilities it once possessed as lateralization of function evolved (Corballis *et al.*, 2000).

The interpretive abilities of the isolated right hemisphere are, however, limited. The extraction of causal structure from collision events undertaken by the right hemisphere was evident in the absence of the ability to perform another task that required logical reasoning about causal contingencies at a level that is achieved by 2-year-old children (Roser *et al.*, 2005). For this task, the left hemisphere was necessary. Earlier testing of two split-brain patients also found that only the left hemisphere could perform above chance on inferential tasks, such as choosing the picture representing the correct consequence of combining objects represented by two other pictures and carrying out simple mathematical operations, despite these two patients possessing some language comprehension in the right hemisphere (Gazzaniga *et al.*, 1984).

Recent functional imaging studies suggest that logical reasoning, such as deducing a conclusion from a set of premises, seems to involve mostly left-hemispheric regions, including the left prefrontal cortex (PFC) (Goel and Dolan, 2003; Noveck *et al.*, 2004). Reasoning about abstract problems with no semantic content, the so-called content-independent reasoning, has been found to elicit activity in a left-hemispheric frontal-parietal system. Content-dependent reasoning, in which tasks involve stimuli relevant to an individual's beliefs, values, and goals, involves a left-hemispheric frontal-temporal system. These left-hemispheric regions overlap with, but extend beyond, areas involved in language.

Right-hemispheric activity is also apparent in some imaging studies of reasoning (Houdé *et al.*, 2000, 2001), although sometimes at levels of significance much lower than those seen in the left hemisphere (Goel and Dolan, 2003; Noveck *et al.*, 2004). Heterogeneity of experimental tasks may account for some differences in observed areas of activation, but results suggest that emotional factors, and conflicts between logical conclusions and beliefs, engage right ventral-medial PFC. This area was activated by the inclusion of an emotive component in a task in which subjects had to learn to inhibit a commonly made logical error (Houdé *et al.*, 2000, 2001). This activation was in the same location as the damage sustained by Phineas Gage and by patients assessed by Damasio (1999), who exhibit logical reasoning problems thought to be due to the destruction of a crucial emotional component in reasoning (Houdé and Tzourio-Mazoyer, 2003). This same region was also found to be active when a syllogism's logically valid conclusion was not believable and is thought to be involved in inhibiting the response associated with a belief bias (Goel and Dolan, 2003). The involvement of additional regions outside the left hemisphere may underlie the behavioral observation that content-dependent (nonabstract) reasoning is performed better than abstract reasoning even if the logical structure is the same. The developing picture, however, is that processing of logical rules is primarily undertaken by networks of regions within the left hemisphere.

That the left hemisphere solves syllogisms by abstracted reasoning is also suggested by the observation that the suppression of the right hemisphere by electroconvulsive therapy (ECT) leaves patients inclined to accept conclusions that are absurd but based on strictly true logic. After left-hemispheric ECT, the same absurd conclusions are indignantly rejected (Deglin and Kinsbourne, 1996). Thus, if the right hemisphere is suppressed by ECT or damaged, as in hemispatial neglect, the left hemisphere seems to persist in applying logical rules to its reduced subset of consciously experienced inputs, with little heed paid to their common sense likelihood. The resulting confabulatory explanations for life events may serve to resolve conflicts between potentially contrary information and may make perfect sense within the limited sphere of the left hemisphere's consciousness, but they can often diverge sharply from reality. Disconnection of the right hemisphere from the left by callosotomy also results in interpretation from a reduced range of available input although, in split-brain patients, the intact right hemisphere may prevent confabulations from becoming too outlandish.

4.33.3 An Evolutionary Perspective

Maintaining a stable representation of reality over time must involve the incorporation of input from multiple distributed brain processes, but for the resulting construct to bear a resemblance to reality this process must occur in an orderly, logical fashion. Evidence suggests that interpretation of perceptual and cognitive processes, and the construction of a personal narrative, depends on the left hemisphere, as, to a large degree, do language and logical reasoning. The common functional requirement between

these domains is the need to manipulate units of information in a syntactic manner, that is, according to formal rules sometimes involving several levels of recursion. For instance, in constructing an explanation for one's response to a stimulus, such as the actions of another, the interpretive system must take account of the rule that causes must always precede effects. Taking multiple perceptual, mnemonic, and cognitive processes and combining them in a rule-based manner in order to generate a novel description of current experience is likely subserved by brain systems in the left hemisphere, including, but not limited to, the areas classically associated with language. Although verbally expressing a confabulatory story to explain one's experiences obviously depends on language, it is probably not the case that nothing more than language mechanisms are involved in interpretation. The observation that a number of extralinguistic areas are recruited in logical inference, and the placid acceptance of circumscribed conscious experience as representative of reality by many brain-injured patients, suggest that interpretation is not merely storytelling, but is instead an essential component of consciousness involving many brain areas.

The close association between language, logic, and interpretation suggests a similar evolutionary history (see Evolutionary Psychology). PFC in humans does not seem particularly large when compared to other primates (Roth, 2001), suggesting that human interpretive abilities cannot be accounted for simply by appealing to absolute or relative PFC size. Instead, changes to structural and functional organization and the relative size of regions within the PFC may be more promising avenues for investigation (Fuster, 1997).

Important differences between human and nonhuman brains do, however, exist in this area. For instance, Broca's area in the left frontal lobe, which is involved in syntactic processing in language, is asymmetric in humans. Modern apes do not exhibit the same hemispheric asymmetry in the homologue of this area (Sherwood *et al.*, 2003). The earliest date for the emergence of Broca's area is around 2 Mya, with the genus *Homo*, as suggested by its appearance in skull endocasts (Falk, 1983; Tobias, 1987). If syntactic combinatorial abilities in tool production (Ambrose, 2001), and in either manual or vocal communication (Corballis, 2002), first emerged with this genus, then interpretive abilities, drawing on the same mechanisms for rule-based operation, may have emerged alongside.

In fact, interpretation of one's own behavior, and the behavior of others, in mental terms may only have become necessary once behavioral complexity and flexibility evolved to a point at which it became impossible to represent the range of possible behaviors as simple abstractions based on statistical co-occurrence. The uniqueness to humans of a mentalistic representation of the self and of others is suggested by research that delineates the limitations of chimpanzee cognition (Premack, 2004), and which points out that behavioral abstraction can account for many findings that have been taken as evidence for mentalistic representation in chimpanzees (Povinelli and Giambrone, 2000; Povinelli and Vonk, 2003).

Interpreting one's conscious experience in a coherent manner underlies a conception of oneself as a mental entity, with continuity through time, and with control over one's actions. This capacity stems from the systems that make humans unique, the left hemisphere's ability for generative, recursive thought.

Glossary

emulation	A type of social learning characterized by copying a rule pertaining to environmental effects (causes), results, or goals using idiosyncratic movements. Emulation is often contrasted with imitation, which is typically defined as copying specific actions and their respective goals.
episodic memory	Memories about one's personal past; autobiographical recollections.
percept	A representation of something perceived by the senses, regarded as the basic component in the formation of concepts.
proprioception	The perception of bodily movement and the spatial position of limbs relative to the rest of the body arising from internal (bodily) stimuli.
retroduction	A general process of logical inference that generates possible causes (theories) for available facts. Competing (causal) theories are evaluated based on their relative predictive abilities. Also known as hypotheticodeduction.
theory of mind	The ability to reason about unobservable psychological states such as seeing and knowing.

4.34.1 Introduction

What makes the human mind 'human'? Arguably, Charles Darwin articulated the most influential answer to this question. In *The Descent of Man*, Darwin (1871) challenged orthodoxy and many of his champions, including the co-discoverer of the theory of natural selection Alfred Russell Wallace, and argued in favor of the view that the likeness between humans and other primates was not simply skin deep:

> . . .man and the higher animals, especially the primates, have some few instincts in common. All have the same senses, intuitions, and sensations. . .they practice deceit and. . .possess the same faculties of imitation, attention, deliberation, choice, memory, imagination, the association of ideas and reason, though in very different degrees. . .Nevertheless, the difference in mind between man and the higher animals, great as it is, certainly is one of degree and not of kind (Darwin, 1871, p. 82).

This theory, known as the theory of the continuity of mind, made two radical assertions: (1) the mind is like every other morphological feature – subject to selection and change over time and (2) having directly descended from other living organisms, human and nonhuman animal minds evidenced only quantitative but not qualitative differences.

However, from the outset, such an idea was fraught with problems. Principally, the second point articulated by the theory of continuity of mind was more consistent with pre-Darwinian ideas that espoused a Great Chain of Being – the notion that organisms are ranked from the lowest forms, such as bacteria, to the highest forms, such as humans, angels, and God (Mayr, 1985). According to Hodos and Campbell (1969, 1991), the notion of the Great Chain of Being exists today in the form of the phylogenetic scale. That is, the notion that species may be ranked on a single ladder of ascending complexity. In spite of the obvious limitations and

contradictions with neo-Darwinian theory, the idea of psychological continuity continues to influence how scientists think about the evolution of mind and the broader question of human cognitive specialization. As a result, whereas the modern biologist has thrived on understanding the genetic and morphological diversity that exists both within and among populations of species, those interested in the evolution of mind and behavior have largely shunned an exploration of diversity. Perhaps, when compared to the evolution of physiological features, the evolution of mind has significant social and political ramifications. This was true in Darwin's time (Mayr, 1985) and it is certainly true today, as, for example, the academic resistance to sociobiology (Rose *et al.*, 1984; Wilson, 1975/2000; Lewontin *et al.*, 1985; Alcock, 2001). Therefore, we should not be surprised that those scientists who study the minds of both humans and animals – comparative psychologists – have been the most resistant to elucidating phylogenetic psychological differences. Indeed, the resistance to the idea of a significant and qualitative difference between the minds of human and nonhuman animals has been noted by many (e.g., Hodos and Campbell, 1969; Lockard, 1971; Wasserman, 1981; Boakes, 1984; Kamil, 1984; Macphail, 1987).

But why are so many scientists inclined to believe that the mind has escaped evolution? One possibility is that the domains in which comparative psychologists have traditionally searched for qualitative phyletic differences are precisely those in which we should least expect to find them. In this sense, the statement of Macphail (1987) that "causality is a constraint common to all ecological niches" exposes a more general claim that there are no differences in intelligence among vertebrates. Given that causality is a universal feature of biological environments, the types of general-purpose learning mechanisms that early behaviorists championed should be expected to be present in all animals. This approach has come to be known as general process learning theory (Seligman, 1970). This learning theory attempted to account for all learning with the same set of principles (Shettleworth, 1997).

The general process learning theory turned out to be too simplistic and, eventually, untenable. In a series of now classic papers that were adamantly resisted by establishment psychologists, Garcia and Kimeldorf (1957), Garcia *et al.* (1968, 1976) reported that, when rats are made ill from X-rays at the time they ate food pellets, they form associations about the flavor but not the size of the pellets. However, if, while eating, they are treated with a painful electric shock (rather than X-rays), they form an association with the size but not with the flavor of the pellet. In subsequent tests, rats were systematically treated to electric shock whenever they drank flavored juice. In this condition, rats never learned to avoid the flavored drink. This result perplexed behaviorists but delighted evolutionary thinkers. From an evolutionary perspective it made perfect sense that the consumption of liquids and food does not result in pain in your skin; however, ingesting toxic substances can have damaging internal effects. It follows that animals capable of detecting internal damage and linking these sensory cues with foods or fluids that were recently consumed would have been able to modify their diet adaptively. No such benefit comes from circuitry that enables rats to associate specific foods or fluids with skin pain since ingested substances have no way of acting on external sensors (Alcock, 2001). Refocusing research efforts on ecologically relevant domains in this way might lead to the detection of psychological differences.

Although psychological innovations are rare, rarity should not imply a lack of importance. For instance, in the case of morphological evolution, there have been very few radical transformations in basic animal body plans, yet these core innovations constitute the basis for the classification of distinct phyla (Mayr, 1985, 2001). So, too, radical alterations in psychological forms might occur relatively infrequently. But this is not to state that they never occur. Indeed, comparative psychologists might have already detected the evolution of several such innovations (see Bitterman, 1960, 1975; Gallup, 1982; Rumbaugh, 1990; Itakura, 1996). Thus, in addition to the detection of differing finely scaled psychological dispositions among species, large-scale transformations might also be detectable.

4.34.2 The Reinterpretation Hypothesis

Evidence that has accumulated over the past years suggests that one possible discontinuity between human and nonhuman minds is the ability to interpret observable phenomena, such as an individual's gaze or the propensity for unsupported objects to fall, in terms of unobservable psychological concepts such as desires or physical concepts such as gravity (Povinelli and Preuss, 1995; Povinelli, 2000; Povinelli and Vonk, 2003). For example, when reasoning about behaviors prior to the evolution of a theory of mind system (TOM) in the genus *Homo*, social animals possessed complex nervous systems equipped to detect the various statistical regularities

in the behaviors of others (Heyes, 1997; Povinelli, 2000). The very first social systems were probably quite simple and the information that individual organisms needed to keep track of was relatively limited. However, as some lineages evolved increasingly complicated social interactions, brain systems dedicated to processing information about the regularities of the behaviors of others became increasingly sophisticated as well. The general point is that, for hundreds of millions of years, vertebrates and other taxa have been under steady and unending selection pressures to detect, filter, and process information about the regularities in both their social and physical environments. The hypothesis presented here makes one simple claim: about 3 Mya, one peculiar lineage – the human one – began to evolve the additional ability to interpret these statistical regularities in terms of unobservable causal states. Naturally, this reinterpretation of physical and behavioral events in terms of unseen causal forces was integrated with a pre-existing mechanism for interpreting the observable features of these events.

If this hypothesis (or something like it) is correct, what causal role does the representation of unobservable states play in generating behavior? After all, if complex social behaviors such as self-awareness, gaze-following, social learning, and so forth evolved prior to a TOM and complex technological behaviors such as tool selection, construction, and use evolved prior to an understanding of physical forces, this implies that other psychological systems are independently capable of controlling their execution. Does this mean that the representation of causal forces plays no role in one's actions? We do not think so. Rather, the initial evolutionary advantages of this new psychological system that reinterprets observable phenomenon in terms of imperceptible concepts was that it allowed already existing behaviors (such as social learning or tool use) to be employed in more flexible and proactive ways, without discarding the ancestral psychological systems. As a result, we contend that, for any given behavior, humans will have multiple causal pathways of executing it.

So what evidence exists that phylogenetically ancient behaviors coexist with the uniquely derived ability to interpret these ancient behaviors in terms of invisible causes such as belief and force? A number of laboratories, including our own, have pursued various lines of research in various domains in an effort to answer this and related questions.

Below, we review the results from three general domains: (1) self-awareness, (2) social cognition, and (3) physical cognition. We conclude with an overarching view of human cognitive uniqueness.

4.34.3 The Self

4.34.3.1 Mirror Self-Recognition

In 1970, Gordon Gallup reported that chimpanzees used their mirror reflections to explore body parts difficult to see without the aid of a mirror such as their under arms, teeth, and anogenital region (Gallup, 1970; Figure 1). Gallup also reported that, after lengthy exposures to mirrors, monkeys continued to display social behaviors toward their mirror image, which suggested that they failed to see their reflections as representations of their selves (Gallup, 1970). Following this study, additional research has reported mirror self-recognition in bonobos (Hyatt and Hopkins, 1994; Walraven *et al.*, 1995) and orangutans (Lethmate and Dücker, 1973; Suarez and Gallup, 1981). Gorillas, however, have failed to recognize their mirror image (Suarez and Gallup, 1981; Ledbetter and Basen, 1982; Shillito *et al.*, 1999) with one exception (Patterson and Cohn, 1994; Patterson and Linden, 1981). Subsequent studies with monkeys confirmed Gallup's initial negative findings (e.g., Suarez and Gallup, 1981; Hauser *et al.*, 2001).

Among human infants, evidence of mirror self-recognition first appears around 18 months of age (Amsterdam, 1972; Bertenthal and Fischer, 1978; Johnson, 1982; Anderson, 1994). At this age, infants begin to use their reflection to investigate marks on body parts such as their nose and head much as nonhuman apes do (Figure 1a). The distribution and development of mirror self-recognition within the primate order suggests that the ability to recognize one's self-image represents an example of a phylogenetic cognitive specialization (see Evolutionary Specializations for Processing Faces and Objects).

The pattern of performance reported for apes in front of mirrors raises an important question: do apes and young human children equally depend upon representing psychological and temporal dimensions of the self? One view of self-recognition has emphasized the role of the kinesthetic dimension

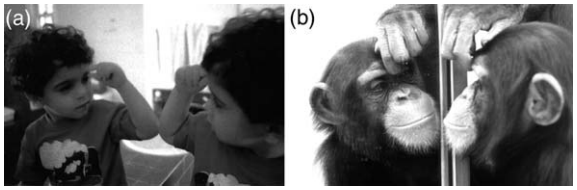

Figure 1 Mirror self-recognition. Examples of a child (a) and of a chimpanzee (b) using a mirror to explore marks on their faces.

of the self (e.g., Povinelli, 1995; Povinelli and Cant, 1995; Barth *et al.*, 2004). In this view, once an organism can hold in mind a kinesthetic representation of the current state of its body, it is able to match this information with the one seen in the mirror. Accordingly, self-exploratory behaviors arise from an association between proprioception and contingent visual cues provided by the mirror's reflection. This kinesthetic–visual matching can be contrasted with a psychological interpretation of the mirror's reflection (e.g., That's me!). In this case, subjects must reinterpret the association between proprioception and visual perception as an abstract self that guides actions independently of both proprioception and visual perception.

To address important aspects of this question, Povinelli and colleagues used live video feeds to explore the role of temporal contingency in supporting mirror self-recognition in 2- to 5-year-old children (Povinelli *et al.*, 1996; Povinelli and Simon, 1997; Povinelli *et al.*, 1999a, 1999b). In those studies, an experimenter played a game with the children in which the subjects were regularly praised. On some occasions the experimenters used this opportunity to secretly put a sticker on the child's head. One group of children saw a live video feed (i.e., they saw the experimenter placing a sticker on their head), the other group saw a 3 min delayed video showing the placement of the sticker. Most of the children that saw the live images retrieved the sticker, whereas few of the younger children who saw the delayed video retrieved the sticker. However, it is important to note that the younger children did not fail to retrieve the sticker on their head because they failed to recognize themselves in the delayed images. In fact, they would accurately state that they saw themselves in the video, but would refer to him/her (i.e., speaking in the third person) as having a sticker on their head. This suggests that for children younger than 4 years of age it is difficult to link the present self to a past self. This is a remarkable fact when one considers how early in development mirror self-recognition appears (see Amsterdam, 1972).

As has been noted by various scientists, the ability to recognize one's image has a number of implications. Gallup (1977) repeatedly proposed that the evidence of mirror self-recognition may be used as an index of self-consciousness or, as he phrased it, the ability to become the object of one's own attention. This interpretation of the results was premised on the notion that, to recognize an image in a mirror as one's own, one had to have an abstract (unobservable) concept of self. Later, Gallup (1982) speculated further, arguing that, if chimpanzees, bonobos, and orangutans (and by extension, 18-month-olds) were self-aware in this sense, they might also have the capacity to reflect upon their own experiences and, by inference, the experiences of others; this topic we discuss below at length.

4.34.3.2 Episodic Memory: The Self in Time

Tulving (1983; Tulving and Markowitsch, 1998) named the ability to reflect upon one's experiences as episodic memory. Tulving and Markowitsch (1998, p. 202) defined episodic memory as having to do with "the conscious recollection of previous experiences of events, happenings, and situations." In short, episodic memory concerns events experienced in one's personal past. Such autobiographical memories are, presumably, defined by a concept of self that is not anchored to facts about our lives in the here-and-now, but is free to move seamlessly backward and forward in time while reflecting on its history.

Schwartz and Evans (1994, 2001) have argued that episodic memory is characterized by three critical features: (1) it refers to a specific event in one's personal past; (2) retrieval involves re-experiencing a past event; and (3) it is accompanied by a strong sense of confidence in the veracity of the memory. Clayton and Dickinson (1998) developed criteria to examine features of episodic memory in nonlinguistic animals. In their view, the critical components of episodic memory is the binding of information about the what, where, and when of a given event. Others have included who, as well (Schwartz *et al.*, 2002). These researchers have resorted to the term episodic-like in recognition of the fact that with nonlinguistic animals it is impossible to ascertain whether they are reflecting on or re-experiencing their past.

To date, the strongest evidence of episodic-like memory has been reported in food-storing birds (scrub jays) and in apes (Clayton and Dickinson, 1998; Schwartz and Evans, 2001; Schwartz, 2005). Scrub jays are particularly interesting because in the wild these birds cache extra food. When food is in short supply, they return to the cache sites. In a series of laboratory studies, Clayton and Dickinson measured whether scrub jays remembered the location of cached food on a single and unique trial of learning. In these studies, jays had to encode information about the type of food (what), it's freshness (when) and its location (where). In a typical experiment, crickets were stored on one side of an ice tray and peanuts were stored on the other side. Jays naturally prefer to eat crickets, but, whereas peanuts remain edible for long periods of time, crickets do

not. To respond adaptively, jays had to encode when a given food was cached, switching from crickets to peanuts after long delays. This is, in fact, how jays responded. Clayton *et al.* (2001) argued that this is evidence that jays bind information about the what, the where, and the when of events.

There is only a single published account of a nonhuman primate encoding multiple types of information in a single event. Schwartz and his colleagues have reported that a gorilla named King made what and who judgments in some cases after a 24h delay (Schwartz *et al.*, 2002, 2004, 2005). In one study, King had to select different cards that contained information about a type of food (e.g., banana) or an individual trainer. During training, King learned to respond appropriately to the commands "what did you eat?" and "who gave you the food?" During testing, King was asked both what and who questions. King responded correctly to what and who questions on 43% of the trials (chance was 10%).

While intriguing, the presence of this type of memory binding in species that do not typically evidence spontaneous mirror self-recognition, such as birds and gorillas, suggests that encoding multiple components of an event as described by Clayton and Dickinson and Schwartz and colleagues is independent of a concept of self (kinesthetic or otherwise) free to move forward and backward in time (Tulving, 1983). In this regard, we expect that future studies will show that many animal species are able to bind different facts about an event. Yet, we are doubtful that this paradigm, by itself, will answer whether nonhuman animals are able to re-experience their past in the same way humans do.

4.34.4 Social Cognition

4.34.4.1 Gaze-Following

One of the features that characterize the primate order is its gregariousness. For example, our closest living relative, the chimpanzee, resides in medium-sized groups that consist of males and females (Goodall, 1986). Males patrol the borders of their territories and cooperate when hunting small monkeys (Mitani, 2006). They also engage in complex social struggles for control over valuable resources such as food, mates, and allies. De Waal (1982) has aptly referred to this feature of chimpanzee societies as chimpanzee politics. In order to navigate their social worlds, chimpanzees, like humans, probably form representations of the behavior of others, predict future actions and adjust their own conduct accordingly (see Relevance of Understanding Brain Evolution). For example, when a chimpanzee sees a conspecific pursing his lips with hair bristling, he need not represent each of these behaviors separately. Rather, a concept of threat display can be formed. In like fashion, primates are likely to form all sorts of concepts based on observable behaviors.

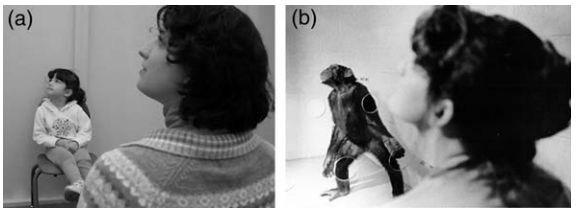

Figure 2 Gaze-following. Examples of a child (a) and of a chimpanzee (b) following the gaze of an experimenter.

Consider the behavior of gaze-following and joint-attention. Primates in general and apes in particular are acutely sensitive to the direction of gaze (Figure 2). Determining the precise direction of another's attention is an important ability because it provides salient information about the location of objects such as food and predators. In social settings, a great deal of information is communicated by means of following other individuals' gaze to specific individuals or to call attention to specific events.

Several field studies suggest that primates can follow the gaze of conspecifics (e.g., Chance, 1967; Menzel and Halperin, 1975; Whiten and Byrne, 1988). However, in field studies, it is difficult to identify which object, individual, or event is the focus of two individuals' attention and whether they arrived at the focal point by following one another's gaze. For instance, individuals may come to fixate on the same object because the object is inherently interesting even if they do not follow gaze. Such interpretational confounds can be effectively excluded in laboratory studies. In fact, various studies have demonstrated that many primate species follow the gaze of others to objects (e.g., chimpanzees, mangabeys, and macaques) (Call *et al.*, 2000; Emery *et al.*, 1997; Tomasello *et al.*, 1998; Tomonaga, 1999). They do this even when the target is located above and/or behind them (Itakura, 1996; Povinelli and Eddy, 1996b, 1997). Itakura (1996) studied the ability of various species of prosimians, monkeys, and apes to follow a human experimenter's gaze. Only chimpanzees and one orangutan responded above chance levels. Neither Old nor New World monkeys (i.e., brown lemur, black lemur, squirrel monkey, brown capuchin, whiteface capuchin, stump-tailed macaque, rhesus macaque, pig-tailed macaque, and Tonkean macaque) responded above chance levels.

The clearest evidence for the ability to follow gaze in nonhuman primates comes from laboratory work

on great apes, in particular chimpanzees (Figure 2). For instance, Povinelli and Eddy (1996a), in order to investigate how chimpanzees follow another individual's gaze, installed an opaque barrier in a testing room, obstructing subjects' line of sight. In cases where the experimenter looked to an object next to the barrier (outside the immediate line of sight of the subject), chimpanzees followed the experimenter's line of sight around the barrier to the unseen object. These results have been replicated and extended to all four great ape species (Bräuer *et al.*, 2005) and human children (Moll and Tomasello, 2004). This ability might be important when trying to extrapolate information from other's attention, specifically when the focus of attention is out of sight (rhesus monkeys: Emery *et al.*, 1997; chimpanzees: Tomasello *et al.*, 1999). These findings suggest that primates do not reflexively follow gaze to the first available object within their view, but actively track the gaze of others geometrically to locations or objects that are the focus of others' attention.

One method commonly used to investigate nonhuman primates' ability to use gaze cues, is the object-choice task. In this task, subjects must choose one of two containers, only one of which is baited (Figures 3 and 4). In a series of studies, Anderson and his colleagues used this task to investigate whether capuchin monkeys (Anderson *et al.*, 1995) and rhesus macaques (Anderson *et al.*, 1996) use human gaze to locate hidden food rewards. Subjects were tested in various conditions: pointing only, gaze only (head orientation and eyes cues), and gaze and pointing. None of the capuchin monkeys or rhesus macaques could be trained to use the gaze-only cue to retrieve a concealed reward. However, some subjects eventually learned to use either the pointing only or the gaze and pointing cue. However, it is likely that local enhancement (Thorpe, 1956) may explain these subjects' success in the gaze and pointing situation (e.g., responses may be guided by the hand's proximity to the container).

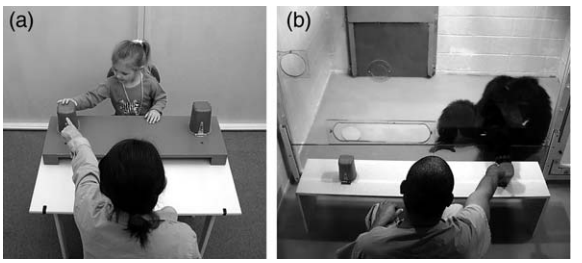

Figure 3 Using proximate pointing cues. A child (a) and a chimpanzee (b) using an experimenter's proximate pointing cue to locate hidden rewards.

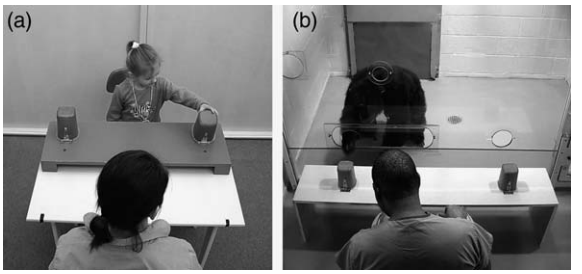

Figure 4 Using distant gaze cues. A child (a) and a chimpanzee (b) using an experimenter's distant gaze cue to locate hidden rewards.

Using a similar paradigm, Itakura and Tanaka (1998) found that chimpanzees, an enculturated orangutan, and human infants (18–27 months old) used an experimenter's gaze, including pointing and glancing (without head turning), to choose a baited container. These responses appeared to be spontaneous and independent of training. Povinelli *et al.* (1999), however, found that chimpanzees failed to use the eyes only (glancing) cue when responding in a similar task. These differences may be due to the age, experimental experience, testing design, and developmental history of the different groups of chimpanzees. Nevertheless, the available research suggests that there is a qualitative difference between monkeys' and apes' understanding of gaze cues in the object-choice task (see also Itakura and Anderson, 1996).

Povinelli and Eddy (1996a, 1996b) have offered an explanation for the differences between monkeys and apes in this task. They theorized that following another individual's gaze might be an automatic response and form part of a primitive orienting reflex triggered by a reward. This reflex does not require the attribution of a mental state. The use of an operant task to test gaze-following would fail to test for the presence of a primitive orienting reflex compared to a more complex social cognition mechanism (e.g., a theory of mind). Monkeys, for example, might follow the gaze of conspecifics yet fail to use the same cue in operant tasks.

The development of this ability in chimpanzees and humans closely parallel one another. For instance, Okamoto *et al.* (2002) demonstrated that, starting at 9 months of age, a chimpanzee infant began using various social cues such as tapping or pointing and head turning to direct the attention to an object. By 13 months of age the infant reliably followed eye gaze. Starting at 21 months of age, the infant looked back to targets located behind him, even when there was a distracter in front of him (Okamoto *et al.*, 2004). Research

with human infants has produced similar results. From 3 months of age, human infants are able to discriminate changes in an adult's eye direction (Hains and Muir, 1996). The development of gaze-following in human infants has been widely studied (e.g., Scaife and Bruner, 1975; Butterworth and Cochran, 1980; Butterworth and Jarrett, 1991; Corkum and Moore, 1995; D'Entremont *et al.*, 1997). By 12 months of age, human infants begin to follow their mother's gaze toward particular objects in their visual field, and at around 18 months they can direct their attention to objects outside of their visual field. Although there are some developmental differences in the onset of gaze-following, on the surface the development of gaze-following in human and chimpanzee infants appears to be remarkably conserved.

But alongside these similarities in the gaze-following behavior of humans and nonhuman primates important differences exist. For example, Okamoto *et al.* (2002, 2004) reported that an infant chimpanzee failed to look back at the experimenter after following her gaze to an object located behind him. This triadic interaction between mother, child, and object of interest has been widely reported in the human developmental literature but is largely absent in the animal literature. Researchers have offered various explanations for these differences. Among humans, a number of changes in social communication occur at around 6 to 9 months of age (Carpenter *et al.*, 1998a). By 6 months, human infants interact dyadically with objects or with a person in a turn-taking (or reciprocally exchanging) sequence. However, they do not interact with the person who is manipulating objects (Tomasello, 1999). From 9 months on, infants start to engage in triadic exchanges with others. Their interactions involve both objects and persons, resulting in the formation of a referential triangle of infant, adult, and object to which they share attention (Rochat, 2001; Tomasello, 1999). That is to say, shared attention is an important component of social cognitive skills in human infants 12 months of age and older. These theories suggest that the chimpanzee infant described in Okamoto *et al.* (2004) and the human experimenter jointly attended to the object behind the infant without engaging in shared attention.

Nevertheless, results from our own laboratory (Povinelli and Eddy, 1996c; Povinelli, 2000) have revealed that chimpanzees and humans share many aspects of gaze-following behavior exhibited by 18-month-olds, including: (1) the ability to extract specific information about the direction of gaze from others; (2) the ability to display the gaze-following response whether it is instantiated by movements of the hand and eyes in concert or the eyes alone; (3) the ability to use another's gaze to visually search into spaces outside their immediate visual field in response to eye plus head/upper torso movement, eye plus head movement, or eye movement alone; (4) no requirement to witness the shifts in another's gaze direction in order to follow it into a space outside their immediate visual field; and (5) the possession of at least a tacit understanding of how another's gaze is interrupted by solid, opaque surfaces.

4.34.4.2 Understanding Seeing

There are two broadly different ways of interpreting the level of social understanding associated with chimpanzees' gaze-following abilities. First, chimpanzees and other nonhuman primate species (and even human infants) may understand gaze not as a projection of attention, but as a direction cue. It is possible that the ancestors of the modern primates evolved an ability to use the head/eye orientation of others to direct their own visual system along a particular trajectory. Once their visual system encountered something novel, the orientation reflex would ensure that two chimpanzees, for example, would end up attending to the same object or event, without attributing an internal (psychological) state to each other. This kind of gaze-following system may have evolved because it provided useful information about predators or social exchanges at little or no cost to individuals involved. A second account is that apes follow gaze because they appreciate its connection to internal attentional states. We will refer to these two accounts as the low-level and the high-level account of gaze-following.

In an effort to distinguish between the low- and the high-level account of gaze-following, Povinelli and colleagues executed a series of studies that measured chimpanzees' and human children's understanding of 'seeing' as a psychological (unobservable) function of eyes. To address this question, they used the chimpanzee's natural begging gesture (Figure 5), a gesture that this species uses in a number of different communicative contexts, including soliciting allies, requesting food, or reconciliation with others after hostile encounters. The apes were trained to use this gesture in a standardized routine: the apes entered a test unit in which they were separated from human experimenters by a Plexiglas partition, and they quickly learned to gesture through a hole directly in front of a single, familiar experimenter who was either standing or sitting to their left or to their right. On each trial that

they gestured through the hole to the experimenter, this person praised them and handed them a food reward. This training set the stage for examining the animals' reactions to two experimenters, one whose eyes were visible and therefore could respond to their gestures, and another whose eyes were covered or closed and therefore could not respond to their gestures. Several treatments recreated this problem (Figure 6).

When first confronted with two experimenters during one of these treatments, the animals' first reaction was to pause. But after noticing the novelty of the conditions, the apes in these studies were as likely to gesture to the person whose eyes were covered/closed as to the person whose eyes were visible/open. In other words, the chimpanzees displayed no preference for gesturing toward the experimenter who could see them. Yet, on trials when subjects were presented with a single experimenter, the apes gestured through the hole directly in front of them on virtually every trial. Thus, despite their general interest and motivation in the test, when it came to the seeing/not seeing treatments, the animals responded indiscriminately seemingly, oblivious to the psychological state of seeing. These same chimpanzees were tested in a number of other experiments, which further manipulated the presence of eyes and/or the orientation of the experimenter's posture (Figure 6). Nevertheless, in all instances, chimpanzees ignored the eyes as cues and relied almost exclusively on global cues such as the back/front posture of the experimenter. These results have now been independently replicated by other comparative psychologists working with captive chimpanzees (Kamisky *et al.*, 2004).

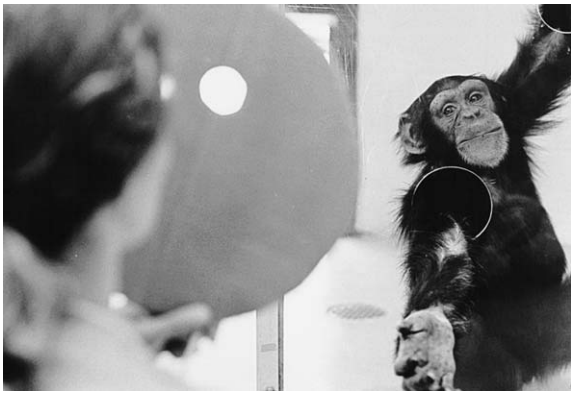

Figure 5 Chimpanzee begging gesture. Example of a captive chimpanzee gesturing to an experimenter.

This pattern of performance contrasted sharply with the performance of human children. Children, like the chimpanzees, were trained to gesture to an experimenter for brightly colored stickers. They were tested on several of the conditions used with the apes and it was found that the youngest children (2-year-olds) were correct in most or all of the conditions from their very first trial forward (Povinelli and Eddy, 1996a).

Hare and associates have challenged these results (Hare, 2001; Hare *et al.*, 2000, 2001, in press). They used a competitive paradigm (individuals must compete with conspecifics or human experimenters for food) because they argue that this paradigm is more ecologically valid than the cooperative paradigm (in which subjects gesture to an experimenter) used by Povinelli and Eddy (Hare, 2001; Hare and Tomasello, 2004). In the paradigm of Hare *et al.*, a dominant and a subordinate chimpanzee were

Figure 6 See/not see paradigm. Different experimental manipulations used by Povinelli and Eddy (1996c).

placed in opposite sides of a large enclosure. In certain trials, both the subordinate and the dominant animal were in view of one another and food was placed in a position that was visible to both the subordinate and the dominant animal. In other trials, food was strategically placed in a position that was only visible to the subordinate. Hare and colleagues reported that subordinate animals avoided the food that was visible to the dominant animal but not the food that had been strategically positioned so that only the subordinate animal could see. These results were interpreted as evidence that chimpanzees infer some aspects of mental states such as seeing (Hare, 2001; Hare *et al.*, 2000, 2001, in press). Povinelli and colleagues have offered alternative interpretations for these results (see Karin-D'Arcy and Povinelli, 2002; Povinelli and Vonk, 2003, 2004).

However, the see/not-see paradigm (whether competitive or cooperative) poses at least three distinct problems. The first problem involves whether or not the cooperative paradigm of Povinelli and Eddy (1996b, 1996c) or the competitive paradigm of Hare *et al.* (2000, 2001, in press) can adequately isolate nonhuman primates' understanding of unobservable psychological states such as seeing from their understanding and/or use of nonpsychological, observable cues associated with the psychological interpretation of seeing, such as the visibility of the face and the eyes. The main concern is that neither of these particular competitive or cooperative paradigms is adequate to answer the question of whether or not chimpanzees understand seeing as a psychological state. In either paradigm, subjects can develop behavioral rules based on observable cues such as the visibility of the competitor's face, or they may develop rules premised on psychological interpretations of these observable (nonpsychological) cues. However, because the psychological inference depends on the availability of observable cues, and the use of either rule would lead to the same behavioral consequence, it is impossible to discern which rule – psychological or behavioral – subjects are using.

The second problem concerns whether competitive paradigms are better than cooperative paradigms in terms of eliciting psychological interpretations of others' behavior(s). If, in fact, the performance of subjects in Hare and colleagues' studies is dependent upon a specific setting or paradigm, it further suggests that observable cues (unique to the setting), rather than unobservable (psychological) inferences, are guiding the subjects' behavior. This possibility is reinforced by the assertions of the senior authors who have stressed that competitive paradigms mimic the type of situations that might elicit such psychological inferences in the wild (Hare and Tomasello, 2004). But rather than eliciting psychological inferences, such settings can activate arousal/motivational mechanisms that make subjects more sensitive to a competitor's behavior. Regardless, as noted above, because reasoning about what competitors can and cannot see necessarily involves the ability to reason about observable (nonpsychological) variables such as the visibility of the face and eyes, the argument that competitive paradigms are more ecologically valid does not resolve the problem that chimpanzees can use either a behavioristic or mentalistic rule when making a response.

The third problem involves the interpretation of the results and its implication for chimpanzee and human cognition. Despite our skepticism of the studies described above, we do not believe that chimpanzees are mindless automatons. The results reported here and elsewhere speak to the contrary. Chimpanzees use information in a flexible and adaptive manner. In particular, chimpanzees' performance on social (e.g., Hare *et al.*, in press) and physical tasks (e.g., Visalberghi *et al.*, 1995; Povinelli, 2000) speaks volumes about this species' problem-solving abilities as well as their unique perception of the world. We should be neither discouraged nor insulted by the suggestion that chimpanzees may reason about the world in a way that's unique and different from our own. Rather, we should celebrate it.

4.34.4.3 Intentional Communication

In the middle of the twentieth century, a number of studies sought to inculcate into nonhuman primates a uniquely human behavior: language (e.g., Hayes, 1951; Kellogg and Kellogg, 1967; Gardner and Gardner, 1969; Terrace, 1979; Terrace *et al.*, 1979). At best, this tradition highlighted what apes might be capable of learning were they trained under ideal circumstances; at worst, it demonstrated that language is a uniquely human trait and of little use to nonhuman primates (Chomsky, 1964; Terrace, 1979; Pinker, 1994). A different tradition has sought to explore how apes naturally communicate with each other. This vein of research explores parallels in the intentional desire to express goals, desires, and intentions through a means other than language.

But what separates intentional communication from other forms of communication? Tomasello and Call (1997) argue that, in order for a signal (or gesture) to be an intentional form of communication, it must involve a goal and some flexibility for attaining it. This entails using the behavior in

different contexts and with different communicative functions, or, conversely, using different signals in the same communicative context. For these authors, this entails learning. But the learning is not of the signal itself – rather, learning the appropriate social contexts in which to use such signals. Another important feature of identifying intentional communication is that the intentional cue has to be directed to a specific individual rather than to a general (i.e., nonspecific) audience. This appears to be the case with the vervet alarm call system. Vervet monkeys have three general calls for three different predators: eagles, leopards, and snakes. Each call is associated with a specific behavioral response: eagles – run to the center of trees and look up; leopards – run to the limbs of trees; snakes – stand up and look at surroundings (Cheney and Seyfarth, 1990).

Tomasello *et al.* (1985, 1989) recorded a number of gestures used by juveniles in a group to solicit food, play, grooming, nursing, etc. Although they collected no systematic data, these investigators reported that the behaviors were flexibly used in different contexts. Tomasello and Call (1997, p. 244) cite two examples of gestures being used to initiate play:

> . . . the initiation of play often takes place in chimpanzees by one juvenile raising its arm above its head and then descending on another, play-hitting in the process. This then becomes ritualized ontogenetically into an 'arm-raise' gesture in which the initiator simply raises its arm and, rather than actually following through with the hitting, stays back and waits for the other to initiate the play . . . In other situations a juvenile was observed to actually alternate its gaze between the recipient of the gestural signal and one of its own body parts . . . (an invitation to grab it and so initiate a game of chase) . . .

This view of chimpanzee communication has found support among a number of field researchers. For example, Whiten and a number of other renowned primatologists reported 39 behavioral patterns, including a number of behavioral patterns that the authors described as "patterns customary or habitual at some sites yet absent at others, with no ecological explanation" (Whiten *et al.*, 1999, p. 683). Of those, five are described as having communicative functions: rain dance (display), branch slap (attention-getting), branch din (warn/threat), knuckle-knock (attract attention), leaf-strip (threat). There were two other actions with possible communicative/affiliative functions: stem pull-through (which makes a loud sound like leaf-strip and might be used as a threat), and handclasp (where two individuals clap hands above their heads while grooming as a specific affiliative gesture).

A number of controlled studies, however, suggest that apes have difficulty reasoning about (and hence communicating) beliefs and desires (Premack and Premack, 1994; Tomasello and Call, 1997). This apparent inability to reason about the beliefs of others may handicap nonhuman primates' ability to use communicative signals in a meaningful and intentional fashion. Although some studies suggest that chimpanzees might be able to use pointing gestures to located occluded rewards (Menzel, 1971, 1974; Povinelli *et al.*, 1992; Call and Tomasello, 1994; Itakura and Tanaka, 1998), other work has demonstrated that, when humans use pointing gestures to inform chimpanzees about the location of hidden food, chimpanzees appear to rely more on the proximity of the finger or pointing hand than on the referential aspect of the pointing hand/finger (Povinelli *et al.*, 1997; Barth *et al.*, 2005; but see Itakura and Tanaka, 1998).

Chimpanzees may have a more difficult time understanding the referential cues of humans than a conspecific. While no long-term field study on chimpanzee social behavior has ever documented an instance in which a member of this species pointed to something in a referential manner (Nishida, 1970; Goodall, 1986), chimpanzees do use a gesture that topographically resembles pointing: holding out a hand (Bygott, 1979; Figure 5). This gesture does not appear to be used in a referential fashion, rather it appears to be used to solicit food, bodily contact, or as a means to recruit allies during conflicts (De Waal, 1982; Goodall, 1986). In captivity, however, chimpanzees exhibit a number of gestures that look like pointing, but these seem to be restricted to their interactions with humans (Woodruff and Premack, 1979; Savage-Rumbaugh, 1986; Gomez, 1991; Call and Tomasello, 1994; Leavens *et al.*, 1996; Krause and Fouts, 1997). How might we explain such gestures in captivity? One possible explanation is that chimpanzees construct pointing-like gestures from their existing behavioral repertoire because humans consistently respond to their actions (such as reaching) in a manner that the chimpanzees themselves do not understand or intend (Povinelli *et al.*, 2003). A number of people have argued that this is also the case in infancy (Vygotsky, 1962). But whereas human infants begin to redescribe their gestures in an intentional manner between the ages of 18 and 24 months (Karmiloff-Smith, 1992), a similar redescription process might never occur in the development of nonhuman primates.

4.34.4.4 Imitation Learning

As with the attribution of mental states, there has been a long-standing controversy over whether or

not humans are unique in the ability to learn from others. In fact, Aristotle argued in the *Poetics* that humans are "the most imitative creatures in the world and learn first by imitation." In the past 30 years, interest in imitation has experienced a renaissance, particularly as scientists have found that, from birth, neonates copy the facial expressions of adults (Meltzoff and Moore, 1977), and primatologists have documented various instances of tool traditions in populations of wild chimpanzees (McGrew, 1992, 1994, 2001; Whiten *et al.*, 1999) and orangutans (van Schaik *et al.*, 2003).

To date, seven studies have directly compared imitation learning in human and nonhuman (adult) apes using analogous procedures (Nagell *et al.*, 1993; Tomasello *et al.*, 1993; Call and Tomasello, 1995; Whiten *et al.*, 1996; Horner and Whiten, 2005; Horowitz, 2003; Call *et al.*, 2005). Four of these studies reported that, on an operational task for which a tool had to be manipulated in a certain manner to retrieve a reward, humans reproduce the demonstrator's actions with greater fidelity (i.e., imitation) than mother-reared apes (Nagel *et al.*, 1993; Tomasello *et al.*, 1993; Call and Tomasello, 1995; Call *et al.*, 2005). The other two studies reported both similarities and differences between humans and peer-reared chimpanzees when executing specific actions on an object following a demonstration (Whiten *et al.*, 1996; Horner and Whiten, 2005); and one found no differences between the performance of adult humans and chimpanzees (Horowitz, 2003).

However, the notion that humans are unique when learning by imitation has been challanged by Subiaul and colleagues. Subiaul *et al.* (2004) have distinguished between motor imitation (the imitation of a motor rule) and cognitive imitation (the imitation of a cognitive rule). In a series of studies, they reported that rhesus macaques – primates that typically do poorly in motor imitation tasks (Chamove, 1974; Thorndike, 1898; Whiten and Ham, 1992; Tomasello and Call, 1997) – excelled in a cognitive imitation task in which the execution of specific motor rules was independent of the execution of specific serial (cognitive) rules. These researchers suggested that human and nonhuman primates may differ fundamentally in the manner in which they plan, coordinate, and represent the actions of others. This conclusion is buttressed by a number of studies showing a dissociation between action and perception (monkeys: Hauser, 2003; Fitch and Hauser, 2004; human infants: Diamond, 1990; Spelke, 1994, 1997; apes: Myowa-Yamakoshi and Matsuzawa, 1999).

Researchers from a number of disciplines have reported that human and nonhuman primates share

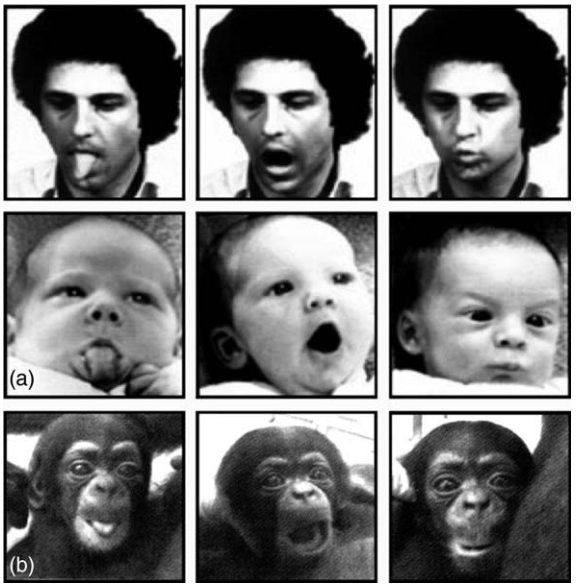

Figure 7 Oral facial imitation. a, Human infants (Meltzoff and Moore, 1977) and b, neonatal chimpanzees (Myowa-Yamakoshi *et al.*, 2004) copying three distinct orofacial movements. Reprinted from Meltzoff, A. N. and Moore, K. W. 1977. Imitation of manual and facial gestures by human neonates. *Science* 198, 75–78. Copyright 1977 AAAS.

a number of homologous mechanisms mediating behavior-matching. For example, Iacoboni *et al.* (1999) and Rizzolatti *et al.* (1988) reported that neurons in the inferior frontal lobe of humans (BA44) and macaques (area F5) are active both when subjects execute a specific action and when they observe a demonstrator execute the same action. Investigators have concluded that BA44 and F5 are evolutionarily homologous (Rizzolatti *et al.*, 2002).

Behavioral research by comparative developmental psychologists has found no significant differences between a human and a chimpanzee infant's ability to copy the orofacial expressions of a model. Chimpanzees, like human infants (e.g., Meltzoff and Moore, 1977), reproduce tongue protrusions, lip protrusions, and mouth openings in response to a model displaying the same expression (Myowa-Yamakoshi *et al.*, 2004). Figure 7 illustrates the similarities of responses between human infants (e.g., Meltzoff and Moore, 1977) and those of neonatal chimpanzee (Myowa-Yamakoshi *et al.*, 2004).

There are also parallels in the developmental trajectory of orofacial imitation in both of these species. Myowa-Yamakoshi *et al.* (2004) report that, after 9 weeks of age, the incidence of orofacial imitation in chimpanzees slowly disappears. A similar phenomenon has been reported for human infants (Abravanel and Sigafoos, 1984). In short, this study found no qualitative differences between humans infants and infant chimpanzees in orofacial imitation.

Nevertheless, there is considerable evidence suggesting that, when learning from others, humans differ from other primates in significant ways. This has become evident in various imitation experiments with young children who evidence reasoning about unobservable mental concepts such as a model's goals and intentions. For example, in one study, Carpenter *et al.* (1995, 1998a, 1998b) exposed children to a model which, while executing a target action, made superfluous movements that were not necessary to achieve the goal. Children only copied the actions that were necessary to achieve the objective, omitting movements that were unnecessary. Gergeley *et al.* (2002) has reported a similar phenomenon. No comparable results have been reported for nonhuman primates.

The performance of human subjects also differs from that of nonhuman primates in a ghost control; that is, a treatment in social learning experiments in which target actions are executed in the absence of a demonstrator. A number of studies have employed this control to isolate imitation from emulation learning (Heyes *et al.*, 1992; Fawcett *et al.*, 2002; Klein and Zentall, 2003; Subiaul, 2004; Subiaul *et al.*, 2004; Thompson and Russell, 2004; Huang and Charman, 2005). However, whereas a number of investigators have reported that human subjects benefit from the standard social learning condition as well as the ghost condition (Subiaul, 2004; Thompson and Russell, 2004; Huang and Charman, 2005), comparative psychologists have reported that animals that copy a rule executed by a conspecific do not copy a similar rule in the ghost control (Heyes *et al.*, 1992; Atkins *et al.*, 2002; Subiaul *et al.*, 2004). This difference between the performance of humans and animals suggests that the ghost treatment is a measure of something other than emulation because, at least among primates, emulation appears to be the default social learning strategy (Horner and Whiten, 2005; Call *et al.*, 2005). Although increasing the salience of the target actions in this control treatment might be sufficient for learning in certain paradigms (Klein and Zentall, 2003), we suspect that learning novel rules in the ghost condition might involve grappling with unobservable concepts. Depending on the experimental context and the task employed, learning in this control condition may require inferring (implicitly or explicitly) actions, intentions, or agency.

The research we have summarized above leads to a number of interesting questions and, potentially, new avenues of research. Some possible questions for future research in social cognition include:

1. Do human and nonhuman primates differ in their sensitivity to behavioral cues and/or the statistical regularities of behaviors?
2. Does the propensity of a human to reinterpret behavioral regularities in terms of unobservable concepts lead to predictable errors that nonhuman primates do not make?
3. Is there a nonverbal experimental paradigm that can distinguish between the use of a behavioral rule and a psychological rule without confounding the two?

4.34.5 Physical Cognition

We live in a world governed by invisible forces such as gravity, strength, weight, and temperature. Although they are invisible, we reason about these forces constantly. A long-lasting question in the comparative sciences has been: do nonhuman primates similarly reason about these forces that cannot be directly perceived but must be inferred?

From a very young age, humans are predisposed to make these kinds of inferences about the physical world. So, when young children see a ball, hit a stationary ball, and then see this second ball darting away, they insist that the first ball caused the second ball to move. Indeed, as the classic experiments of Michotte (1962) revealed, this seems to be an automatic mental process in humans. But what is it, exactly, that humans believe causes the movement of the second ball? As Hume (1739–1740/1911) noted long ago, this belief goes beyond the mere observation that the balls touched. Rather, humans redescribe this observation in terms of the first ball transmitting something to the second ball. That 'something' is, of course, a theoretical force that is ubiquitous, yet unseen.

At the very least, the earliest comparative studies on physical cognition date back to Köhler (1925). In the past decade, there has been a resurgence of interest in nonhuman primates' folk physics. Empirical attention has focused both on tools and on the conceptual systems that govern their use (Köhler, 1925; Boesch and Boesch, 1990; Matsuzawa, 1996, 2001; Hauser, 1997; Visalberghi and Tomasello, 1998; Santos *et al.*, 1999, 2003; Munakata *et al.*, 2001; Santos and Hauser, 2002; Fujita *et al.*, 2003). A significant number of studies have investigated how monkeys understand the relationships between means and ends (e.g., Hauser, 1997; Hauser *et al.*, 1999, 2002b). Of these, some have focused on the

question of whether or not the ability to reason about invisible causal forces mediating the behavior and properties of objects represents a human cognitive specialization (see Visalberghi and Trinca, 1989; Visalberghi and Limongelli, 1994, 1996; Visalberghi, 1997; Limongelli *et al.*, 1995; Visalberghi and Tomasello, 1998; Povinelli, 2000; Kralik and Hauser, 2002; Santos and Hauser, 2002).

In a series of studies, Hauser and his colleagues repeatedly demonstrated that a New World monkey – the cotton-top tamarin – once trained how to use a tool, will readily transfer what it has learned to novel tools that differ in terms of shape and color (Hauser, 1997; Hauser *et al.*, 1999, 2002a, 2002b). A more recent study with capuchin monkeys replicated this result, but, in addition, showed that these monkeys, while not being distracted by the irrelevant features of the tools, nevertheless failed to attend to relevant variables of the task. For instance, they did not learn to pull in the appropriate tool to procure a reward when obstacles or traps impeded performance (Fujita *et al.*, 2003).

In another study, Hood *et al.* (1999) adapted a paradigm used to test gravity rules in human children (Hood, 1995) for use by cotton-top tamarins. The task involved dropping a food reward down a chimney which was at times clear and at other times opaque. The chimney was connected to various solid containers. Whereas children eventually learned to search in the container connected to the chimney, tamarins always searched in the container where the food was dropped on the first trial, ignoring whether the chimney was connected to that container or not. This result suggests that tamarins do not understand general principles of gravity (or connectedness).

However, some authors have suggested that, whereas the same representational abilities characterize the tool-using capacity of monkeys and apes (Westergaard and Fragaszy, 1987), others have implied that chimpanzees use tools in a more complex and sophisticated fashion than monkeys (Westergaard, 1999). In particular, these researchers have hypothesized that the apes succeed where the capuchin monkeys fail because of apes' ability to represent the abstract causal forces underlying tool use (Visalberghi, 1990; Limongelli *et al.*, 1995; Visalberghi *et al.*, 1995).

In an effort to test this and other hypotheses, Povinelli and colleagues in the mid-1990s systematically explored what they termed chimpanzee folk physics (Figure 8). Specifically, they focused the apes' attention on simple tool-using problems such as those used by Köhler, Hauser, and Visalberghi (Povinelli, 2000). Given chimpanzees' natural proclivity with tools (e.g., Whiten *et al.*, 1999), the goal was to teach them how to solve simple problems. All the tasks involved pulling, pushing, poking, etc. Carefully designed transfer tests assessed chimpanzees' understanding of why the tools produced the observed effects. In this way, Povinelli and his associates attempted to determine if their subjects reasoned about things such as gravity, transfer of force, weight, and physical connection, or whether they only reasoned about spatiotemporal regularities. Throughout, these researchers contrasted such concepts with their perceptual properties (see Table 1).

For instance, a series of experiments explored in detail the chimpanzees' understanding of physical connection – the idea that two objects are bound together through some unseen interaction such as the force transmitted by the mass of one object resting on another, or the frictional forces of one object against another. Or, conversely, the idea that

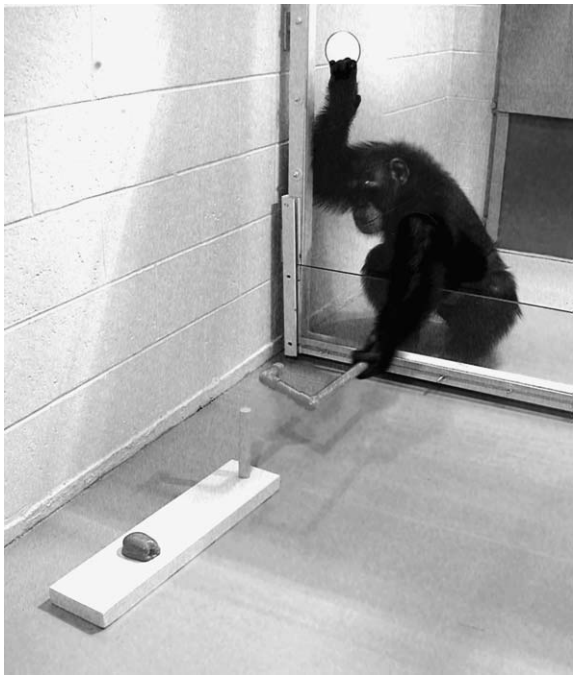

Figure 8 Chimpanzee tool use. One example of a tool task employed by Povinelli (2000) to assess captive chimpanzees' understanding of connectedness, shown here.

Table 1 Theoretical concepts and their observable properties

Theoretical concept	*Paired observable properties*
Gravity	Downward object trajectories
Transfer of force	Motion–contact–motion sequences
Strength	Propensity for deformation
Shape	Perceptual form
Physical connection	Degree of contact
Weight	Muscle/tendon stretch sensations

simply because two objects are touching each other does not mean there is any real form of connection. To answer this question, Povinelli and colleagues presented the chimpanzees with numerous problems. In one set of studies chimpanzees were first taught to use a hooked tool to pull a food tray within reach. Chimpanzees quickly mastered this task. In order to address exactly what the chimpanzees had learned, they were presented with two choices: one was consistent with a theory of intrinsic connection (transfer of force); the other choice was consistent with a theory of superficial contact. In all cases, perceptual and/or superficial contact seemed to be chimpanzees' operating concept. In fact, any type of contact was generally sufficient for chimpanzees to think that a tool could move another object.

Bates and colleagues presented 10-month-old children with a battery of tests similar to those Povinelli (2000) presented to chimpanzees. In each case, a fuzzy toy could be attained only with the aid of a tool. The conditions varied in the amount of contact between the tool and the toy, from a toy resting on a cloth, to a toy positioned next to a stick. Children as young as 10 months old successfully retrieved the toy when it was making contact with the tool, but not in instances where the toy did not make direct contact with the tool or in cases where the contact was implied (Bates *et al.*, 1980).

In another group of studies, Brown (1990) trained 1.5-, 2-, and 3-year-old human subjects to use a tool to retrieve a reward. Once they had mastered the task using a training tool, she presented these same subjects with a choice between two tools differing in their functional properties. One of these tools retained the correct functional characteristics; for example, the tool was sufficiently long, rigid, or it had an effective pulling end. The second tool was perceptually more similar to the training tool; that is, it was the same color or shape, but it was functionally ineffective, being too short, made of a flimsy material, or did not have an effective end. Brown reported that children as young as 24 months virtually ignored surface features such as color or the shape of the effective end of the tool. Instead, young children's choices, unlike the choices of chimpanzees, were guided by abstract physical properties such as rigidity, length, and an effective end; that is, the tool properties that were related to the causal structure of the task.

In spite of the fact that chimpanzees attend to statistical regularities associated with objects and events – using these regularities to execute behaviors that are coherent and rule-governed – they fail to reason about these same regularities in terms of invisible causal forces. Indeed, we have speculated that, for every unseen causal concept that humans may form, chimpanzees will rely exclusively on an analogous concept, constructed from the perceptual invariants that are readily detectable by the sensory systems (see Table 1). Of course, like chimpanzees, humans rely on these same spatiotemporal regularities most of the time, perhaps relying on systems that are homologues of those found in chimpanzees and other primates. But, unlike apes, we believe that humans evolved the unique capacity to form additional, far more abstract concepts that reinterpret observable phenomenon in unobservable terms (such as force, belief, etc.). If this interpretation of the data is correct, future research should address the following:

1. Can animals ever be taught to explicitly reason about unobservable physical forces such as gravity or connectedness?
2. For any given unobservable learned through explicit training, is it stable and generalizable across tasks and domains or restricted to a limited set of problems?
3. Do human and nonhuman primates form different percepts when confronted with identical sensory stimuli? If so, how might these differences affect nonhuman primates' conceptualization of physical unobservables?

4.34.6 Conclusions

The evidence reviewed above demonstrates that various features of the human and nonhuman mind are remarkably conserved. As a result, human and nonhuman primates are remarkably similar in each of the cognitive domains reviewed (see Figures 1–7). However, this same evidence also suggests that the ability to wield abstract theoretical concepts is the basis for much of what is deemed higher-order cognition in humans. We speculate that primate minds come in two forms: minds that are capable of generating predictions about regularities (physical and/or behavioral) alone and minds that are capable of generating predictions about regularities in addition to generating predictions about abstract (theoretical) concepts. For instance, the ability to interpret a given behavior, such as reaching for an object, as intentional depends on the ability to infer from observable behavior an unobservable intervening variable, and to use this intervening variable to describe the behavior in psychological terms. But note that describing a behavior as reaching (for an object) need not be additionally redescribed as wanting (an object). In fact, the same observable behavior – reaching – may lead to predictions

understood in behavioral terms alone (reaching=consumption or possession) or in terms of mental states (reaching=wanting or needing). Note that both types of minds describe the behavior and may respond to an individual reaching for a desirable object such as food in the same way.

Importantly, the system that describes observable phenomena in terms of mental states or physical forces did not replace the older system that only analyzed observable features. Instead, this newer integrated system co-evolved with the existing psychological systems of primates. Because the ability to reason about unobservable concepts such as minds co-evolved with a phylogenetically older behavioral system, we found ourselves in the position of being able to represent ancient behavioral patterns in explicitly psychological terms, and of using these new representations to modulate an existing behavioral repertoire in order to cope with the newly uncovered mental world in addition to the directly observable aspects of the social and physical world with which our ancestors had been coping for millions of years. If this view of human cognitive specializations is correct, the most crucial differences between humans and apes are defined by cognitive, not behavioral, innovations. This view contrasts with a number of hypotheses about the evolution of primate intelligence. First, unlike the social intelligence hypothesis, our theory does not assume that the ability to predict behaviors based on unobservable psychological states produced an entirely new class of behaviors. To the contrary, we believe that the nonlinguistic behaviors of organisms with minds that can generate unobservable concepts and use these concepts to redescribe certain behaviors do not qualitatively differ from the behaviors of organisms with minds that can generate only observable concepts. Second, the ecological (e.g., Parker and Gibson, 1977, 1979) and technical intelligence hypothesis (Byrne, 1997; Parker and Gibson, 1977, 1979), which argues that challenges in the physical environment favor unique behavioral and cognitive traits, has the same limitations. As in the social domain, selection likely favored the ability to successfully and accurately interpret the observable statistical regularities that characterize objects in the environment (e.g., flowering plants or tools). We agree with the assessment of Byrne (1997, p. 293) that, "Rapid learning and efficient memory, having evolved because of social [and physical] profits, evidently also allow benefits in quite different, nonsocial tasks." But we do not agree that apes' unique technical abilities requires the evolution of an additional system that reinterpret spatiotemporal regularities in terms of unobservable forces. The sophisticated behaviors that characterize apes in general requires, "efficient learning and large memory capacity...and possession of theory of mind [or a system for representing unseen forces] is not necessary for the case" (Byrne, 1997, p. 292).

The ability to reinterpret observable phenomena in terms of unobservable concepts may depend on a specific type of inference which the philosopher Charles Sanders Pierce called retroductive inferences. For Pierce, "Retroduction comes first and is the least certain and...the most important kind of reasoning...because it is the only kind of reasoning that opens up new ground" (as cited by Kehler, 1911). Pierce viewed retroduction as fundamental to the scientific enterprise because it depended upon the development of hypotheses about observable phenomena. Elsewhere (e.g., Povinelli and Dunphy-Lelii, 2001; Povinelli and Vonk, 2003; Povinelli, 2004), it has been argued that there is a difference between a mind that predicts events and one that seeks to explain them. But, of course, there is nothing trivial about predictions. Note that predictions come in two varieties: forward (e.g., classic conditioning), and backward (e.g., descriptive). If the reinterpretation hypothesis is correct, we can imagine, on the one hand, a mind that responds in a predictive manner to events and cues, and, on the other, a mind that generates rules that makes predictions (from hypotheses) across domains. In other words, a mind that engages in retroductive reasoning.

Thus far we have focused on the aspects of the conceptual systems of humans that may be unique in the primate order. But the human conceptual system may be distinct because fundamental features of the human peripheral nervous system are unique. As noted in the introduction of this article, it has been assumed since time immemorial that the differences between humans and other primates is not only skin deep; as a result, physiologists and psychologists have assumed that basic features of the nervous system (e.g., receptors and effectors) of primates do not meaningfully differ. Yet, differences in the sensory systems of primates will result in the generation of different percepts. If two organisms form different percepts from the same sensory experience, they will develop different concepts of the same event. Imagine the different visual percepts formed by the eyes of prosimians (who are largely nocturnal) versus the eyes of catarrhines (who are diurnal). If these differences at this basic level are real, we can be certain that the percepts that develop from these differences are similarly real.

In short, we should expect that humans and other primates differ in ways large and small. These

differences may be instantiated at the conceptual level as well as in more basic levels. We should not be surprised if differences at more basic levels of information processing (i.e., sensory system) have an effect on cognition. In fact, it is entirely possible that quantitative differences in the sensory systems may result in qualitative differences in the conceptual systems of primates. Only through a systematic exploration of these various problems will we ultimately come to understand human and nonhuman cognitive specializations.

4.35 The Evolution of Language Systems in the Human Brain

T W Deacon, University of California, Berkeley, CA, USA

Glossary

acheulean The stone tool technology associated with the hominid species *Homo erectus*.

akinetic mutism Immobility and nonresponsiveness due to dorsal frontal midline cortical damage involving the anterior cingulated cortex, that includes verbal nonresponsiveness.

allometry The nonisometric scaling of anatomical structures with growth and comparative size.

arcuate fasciculus The fiber tract extending from the temporal and inferior parietal lobes to the inferior frontal lobes on the human brain passing beneath the supramarginal gyrus somatic and motor areas just dorsal to the Sylvian fissure.

Baldwin effect A theoretical evolutionary mechanism proposed independently by James Mark Baldwin, Conwy Lloyd Morgan, and Henry Osborne in 1896 arguing that physiological and behavioral plasticity could shield a lineage from elimination by natural selection long enough for new variations to accumulate (e.g., by chance mutation) that could supplement or replace the plastically acquired adaptatation.

Broca's aphasia (area) The language disorder first described by Paul Broca in 1861 and elaborated in 1865 that was produced by damage involving the posterior part of the inferior third frontal convolution on the left side of the brain (commonly referred to as Broca's speech area). This aphasia syndrome is typically associated with nonfluent, telegraphic speech and often agrammatism (a difficulty constructing or assessing syntactic structures).

co-evolution An evolutionary dynamic that is a consequence of two interacting selection processes, typically occurring between species whose survival is linked or between organizational levels of the biological hierarchy. In this context, it is

	used to describe the complex interactions that have likely characterized the evolution of the human brain and the evolution-like processes of language transmission and change which may have imposed novel selection pressures on human brain evolution as an artificial niche (see 'niche construction').
diffusion tensor weighted MRI	A structural MRI technique that uses oriented diffusion processes (constrained by fiber tract orientation) to visualize three-dimensional organization of major axonal pathways.
FOXP2	A highly conserved transcription factor gene of the fork-head family of genes that is associated with an inherited disorder of speech articulation and syntactic regularization.
generativity (generative grammar)	The capacity for indefinite novelty of combinatorial uses of words provided by the grammatical and syntactic apparatus of a language. Generative grammars are theoretical rule-governed grammars that by recursive application of these rules enable generativity of sentential forms.
genetic drift	The random mixing, accumulation of genetic variants, and elimination of alleles due to the relaxation of the effects of natural selection or the greater effect of probabilistic factors in small breeding populations.
Homo erectus	A long-persisting fossil precursor species to modern humans (from approximately 1.6 Mya to 350 kya, depending on which specimens are included) with roughly modern stature and postcranial skeletal structure, and a brain size average in the range of 950 cm^3 (at the very low end of the modern range). *H. erectus* is found in Africa and also throughout Eurasia, extending into Europe, central Asia, China, and Indonesia.
Homo habilis	One of the two earliest identified fossil members of our genus *Homo* dating to approximately 1.8 Mya in northeast Africa and associated with early stone tools. This species is characterized by reduced dentition and a slightly larger brain case in comparison to earlier australopithecine hominids.
Homo rudolfensis	One of the two earliest identified fossil members of our genus *Homo* dating to approximately 1.8 Mya in northeast Africa and associated with early stone tools. This species is characterized by a significantly larger brain case but minimally reduced dendition in comparison to earlier australopithecine hominids.
hopeful monster	A hypothetical significantly deviant member of a species produced by a mutation that radically alters some phenotypic character which just happens to be better suited to the current environment and thereby manages to outreproduce and eventually replace the more typical phenotypes of the population. This theory was championed by Goldschmidt in the early 1900s and is often tacitly assumed by proponents of a saltational origin of language abilities.
index (and indexicality)	The mode of reference that works by virtue of correlational relationships, as in pointings, symptoms, samples, and simple learned associations.
Lamarckian inheritance	The mode of trait inheritance proposed by Jean Baptiste de Lamarck in the early 1800s in which physical and behavioral traits acquired by effort, exercise, or exposure to demanding conditions were presumed to be passed directly to offspring during reproduction.
Mousterian	The stone tool industry associated with Neanderthals and early modern humans prior to the upper Paleolithic period beginning somewhere between about 60 and 75 kya.
niche construction	The effect that a species has in altering its immediate environment so that the influences of natural selection are significantly affected by this modification, as in the way that beaver dam construction has played a significant role in providing selection favoring the evolution of aquatic adaptations.
symbol (symbolic)	The mode of reference that picks out objects of reference by virtue of a system of sign–sign relationships (correlational relationships, as in pointings, symptoms,

	samples, and simple learned associations).
universal grammar (UG)	The hypothetical common core of grammatical rules that all human languages share. The theory was championed by the linguist Noam Chomsky and is argued by many linguists to be the innate endowment of all humans from which the specific grammars of existing languages are derived.
upper Paleolithic	An archeologically delineated period of human prehistory beginning roughly between 60 and 75 kya (most notably in Europe, but with more ancient precursors appearing in Africa) in which stone tool technologies begin to exhibit significant regional varieties and the first unambiguous representational forms (i.e., carvings and cave paintings) appear.
Wernicke's aphasia (area)	The language disorder first described by Wernicke (1874) that is produced by damage involving the posterior part of the superior temporal lobe on the left side of the brain (commonly referred to as Wernicke's speech area). This aphasia syndrome is typically associated with fluent speech that includes inappropriate, phonologically deviant, and/or semantically deviant word choice, and typically a deficit in comprehending sentence meaning and in naming objects.

4.35.1 Introduction: Human Neural Language Adaptations

4.35.1.1 Language Uniqueness and Nonhuman Communication

The comparative uniqueness of language is probably its most important and troubling feature. Besides being vastly more complex, language is substantially different in referential function, behavioral organization, and neural control than any other known animal communication system. Although a number of features are shared in common with the communication systems of some species, for example, vocal–auditory medium, social transmission, its most distinguishing characteristics – symbolic reference, grammar, open-ended generativity, and combinatorial patterning – are unprecedented. The lack of clear behavioral homologies in other species renders the comparative method problematic. There are no other species with various grades of language to provide clues about the contexts that support language evolution (though there are species that exhibit the ability to acquire aspects of language; see below), or the range of brain systems that can be involved. There is only one exemplar, *Homo sapiens*, and if there were intermediate levels of these abilities in our ancestry they have all been eliminated. This noncomparability is made all the more enigmatic when we consider the apparent absence of neurological dishomologies with respect to major neuroanatomical structures that might be expected to correlate with such a significant cognitive-behavioral discontinuity. Generations of comparative neuroanatomists have failed to identify even one major novel brain structure in humans. This suggests that our special adaptations for language are the result of using previously evolved primate brain structures in new ways and in new combinations.

4.35.1.2 Linguistic Context of Language Adaptation

Because of this unusual status of language, it has long been regarded as one of the defining features of human distinctiveness. Historical efforts to explain its origins have consequently been confounded with efforts to define the essence of humanness. This tendency is well exemplified by linguistic debates about the origin and basis for language. Under the influence of persuasive arguments by the linguist Chomsky (1972) and the psychologist Lenneberg (1967), it became popular to argue that language depended on elaborate innate capabilities unique to humans. Chomsky has been particularly influential in articulating what this might entail. At the center of this theory is the claim that all humans have inherited a common innate universal grammar (UG). This innate faculty is presumed to make the acquisition of language possible even at a stage in the life when other forms of learning are undeveloped, and makes effortless the unconscious deployment of a vast set of syntactic rules. These rules are thought to underlie the real-time capacity to interpret or generate a nearly infinite number of grammatical sentences (generativity). Despite the fact that Chomsky, and other colleagues, locate this language capacity in the brain, he maintains the view that it cannot be explained as an adaptation, whereas other linguists (e.g., Jackendoff, 1994; Pinker, 1994) argue that it is an evolved adaptation (see Section 4.35.5). The formal tools developed by generative linguists over the past four decades have

provided unparalleled rigor for the analysis of morphology and sentence structure; however, despite their theoretical commitment to an inherited biological substrate for linguistic capacities, these methods have yielded relatively little in the way of verified neurological predictions, and it is also not clear that they could be substantiated or falsified by brain research. More than a generation has elapsed since this view achieved ascendancy; neither a discrete neural locus for grammatical processes or a neurological lesion that selectively disrupts core features of UG nor a genetic defect that produces systematically divergent forms of grammar have been identified (though neural and genetic impairments of certain features of morphological or syntactic processing have been identified; see below). One major reason for this may be the difficulty of translating highly abstract linguistic formalisms into concrete anatomical predictions. At least superficially, language appears to be generated according to symbolic principles that are very different from the phylogenetic and epigenetic principles that determine functional organization within brains. Nevertheless, linguistic lists of the necessary and sufficient capacities for language remain highly influential, and linguists have been the staunchest proponents of a radical discontinuity between humans and other animals with respect to language.

4.35.1.3 Animal Exceptions and the Significance of Animal Language Experiments

Efforts to identify analogues to human language features in nonhuman species' naturalistic communication have demonstrated only limited behavioral and functional overlap. The most influential examples include the vocal learning of parrots and songbirds, the socially transmitted songs of humpback whales, and the referential alarm calls of numerous species, but most notably vervet monkeys (see Section 4.35.3). Vocal learning is deemed significant because the vast majority of terrestrial mammals to not exhibit any significant capability to learn or mimic noninnate species-typical vocalizations. The examples of complex socially transmitted vocalizations in many bird lineages and in humpback whale pods thus exhibit a deviation from the norm that parallels a key characteristic of language. The referential function of alarm calls to pick out distinctive classes of predators has been demonstrated in primates, birds, and even rodents. Classic theories of animal calls had caricatured them as merely extrinsic symptoms of emotional states, so demonstrations of specific extrinsic reference linked to specific innate calls also suggested parallels with the ubiquitous referential function of words and sentences. However, these superficial similarities are to be contrasted with many unprecedented language features.

Despite a failure to demonstrate any naturally occurring language-like systems outside of humans, partially successful efforts to train nonhuman species to perform certain limited language tasks have helped focus attention on the specific cognitive differences that separate them from humans. Studies of ape, dolphin, and parrot abilities to acquire language-like systems tailored for their different propensities and sensory-motor capacities have variously demonstrated the simple use of symbolic reference and a very basic understanding of syntactic operations, even if not anywhere near the level of interpretive and generative competence observed in a 3-year-old human child. Significantly, these three animal groups represent considerably different brain structures, since dolphin and especially bird brains (see below; and see Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?, The Evolution of Vocal Learning Systems in Birds, The Evolution of Vocal Learning Systems in Birds and Humans, Forebrain Size and Social Intelligence in Birds, The Hippocampal Formation in Food-Storing Birds, Cetacean Brain Evolution) are organized quite differently than are human brains. One possible implication is that at least rudimentary language-like capacities are not dependent on primate (or even mammalian) brain architecture, and so may be achievable in diverse ways.

4.35.1.4 Gestural Language: Neural Correlates and Evolutionary Scenarios

A counterpart to this diversity of potential neural substrates for language-like behaviors is demonstrated by the modality independence of language in humans. The manual languages that have developed in numerous deaf communities throughout the world show that fully complex languages can be acquired independent of the aural–vocal modality. However, despite this significant modality difference, there is also considerable overlap in neural representation with spoken language (Neville *et al.*, 1997). This may indicate that the critical neural adaptations supporting language are not, as is often suggested, merely specializations in motor or auditory processing, though these are also likely. Many scenarios for language origins have suggested that manual or gestural language preceded spoken

language in evolution (see, e.g., Hewes, 1973; Corballis, 2002). Neurological support for this view comes from the absence of voluntary articulate control of laryngeal musculature in most terrestrial mammals that have been studied, including all great apes (anatomy discussed below). Humans are the sole exception. It is therefore likely that the common ancestor of humans and chimpanzees lacked this control and that articulate vocal control is a derived trait that arose at some point in hominid evolution, possibly after the emergence of the genus *Homo*. Although most face-to-face speech is accompanied by gesture for emphasis and indexicality, language develops almost exclusively in the vocal channel, not manually, if speech and hearing are possible. Also, the locations of the major cortical systems critical for language processing are similar in both speakers and deaf signers. So support for a separate prior specialization of the brain for gestural language is weak. More likely, spoken and gestured symbolic communication were employed in linked fashion for a significant part of the evolution of language, with vocal capacities lagging behind but eventually becoming the more prominent modality.

4.35.2 Human Neuronatomical Features Associated with Language

4.35.2.1 Gross Neuroanatomical Homologies

Generations of comparative neuroanatomists have explored the possibility that human brains contain species-unique large-scale structures (e.g., distinct nuclei, cortical areas, fiber tracts) that might correlate with our species-unique form of communication. However, since the famous nineteenth century debate between Thomas Huxley and Richard Owen in which Huxley disproved the existence of a uniquely human hippocampal structure, there has been widespread confirmation of the extensive homologies linking human and great ape brains and no verified claims of any phyletically unprecedented macroscopic structure in the human brain. Nevertheless, claims of the evolutional functional divergence of brain structures are widespread in the literature. Two cortical regions have been consistently implicated in these claims: Broca's region in the inferior frontal lobes and the angular gyrus region at the temporal-parietal–occipital junction. The uniqueness of speech has led to hypotheses that Broca's region is uniquely developed in human brains, and the supramodal nature of semantic associations has led to hypotheses that a cross-modal association area is uniquely developed in the region of the angular gyrus. The hypothesis that Broca's region was uniquely developed in the hominid lineage led to investigations of fossil skull endocasts (see critical discussion below) and reports that the distinguishing sulci of this region could first be detected on an endocast of a *Homo rudolfensis* specimen, KMNER 1470 (then identified as *Homo habilis*) (Falk, 1983; Tobias, 1987). Phyletic novelty of this structure has since been cast in doubt by the evidence of both cytoarchitectonic and connectional homologies of this region with corresponding regions in ape and even monkey brains (Deacon, 1992b; see Section 4.35.2.3). The hypothesis that the human angular gyrus region is an unprecedented cross-modal association area critical for language was first articulated by the neurologist Geschwind (1964). Early claims of poor cross-modal transfer of information in monkeys were subsequently disproven (Wegener, 1965; Blakeslee and Gunter, 1966), and subsequent studies have since identified polymodal function in homologous cortical regions as well as other inferior parietal and middle temporal areas (e.g., Ettlinger and Wilson, 1990). In response to this failure to find unprecedented brain structures relevant to human language facility, most attention has turned to quantitative, connectional, and peripheral dishomologies that may be relevant.

4.35.2.2 Allometric Deviations Potentially Associated with Language Adaptation

That the human brain has been subject to quantitative deviation from ape brain proportions is indisputable. Human brains are both absolutely and comparatively larger than expected for an anthropoid primate or even a great ape. For this reason, much attention has been focused on the plausible link between this deviation in brain proportions and the deviant features of human language. Both brain/body proportions and the internal scaling of brain structures with respect to each other and the gross brain size are highly correlated (Sacher, 1970; Gould, 1975; Finlay and Darlington, 1995), but most brain structures do not scale up or down isometrically with respect to total brain size across species. Allometric scaling patterns are also exhibited at every level of brain structure. For example, larger brains tend to have higher proportions of telencephalon to diencephalon, more neocortex to limbic cortex, more eulaminate cortex to specialized agranular and sensory koniocortex, more white matter to gray matter, more glia per neurons, and so on.

Generally, it is argued (on theoretical, not empirical grounds) that structural proportions that are predictable from allometric scaling (e.g., with respect

to the trend exhibited by large interspecific sample as a background) indicate nondeviant function as well. Consequently, interest has mostly focused on quantitative findings of allometric deviation of human brain structures with respect to apes or to anthropoid primates in general (e.g., Stephan, 1969; Stephan *et al.*, 1981). These investigations are complicated by disparities of results obtained using different statistical approaches, different methods of structural measurement, and disagreements about the significance of deviations that these analyses suggest. At present, there is no agreed upon theoretical basis (and limited empirical data) for predicting the functional correlates of either the allometric or deviant changes in relative proportions of brain regions. Comparative studies showing quantitative structural correlations with peripheral specialization offer the most useful comparisons. Examples of regional enlargements with respect to manipulative forelimbs (e.g., large forelimb tactile representation in primates and raccoons), elaborated or degenerate sensory organs (e.g., specialized tactile representation in the star-nose mole or elimination of visual cortical responses in the blind mole rat, respectively), or highly modified and hypertrophied organs (e.g., cerebellum in electric fish) offer support to the phrenological null hypothesis that increase in relative size equals functional augmentation as well. Perhaps those most relevant to the cognitive-behavioral specialization of language are the size correlations between song complexity in songbirds and the relative sizes of forebrain nuclei involved in singing (e.g., DeVoogd *et al.*, 1993). It is likely, however, that there are other possible correlates of allometric deviation that have yet to be explored (other alternative possibilities are explored in Deacon, 1990b).

Despite this uncertainty about the significance of allometric scaling and deviations in brain structure proportion, there has long been an interest in searching for possible correlations between allometric deviations of human brain structure and language. Different studies have, for example, provided analyses that suggest that human brains have divergent enlargement of cerebral and cerebellar cortices, prefrontal cortex, and certain thalamic nuclei, and divergent reductions of primary visual cortex, primary motor cortex, and olfactory bulbs. Similarly, quantitative studies have found hemispheric asymmetries in language-related areas of cortex, though such asymmetries have also been reported for nonhuman apes. Many of these findings must be considered preliminary, however, since most have been contradicted by studies using different methods that have come to different conclusions. There is also a considerable variation in the size of cytoarchitectonically identified language areas to contend with (e.g., Amunts *et al.*, 1999). One illustrative example of a quantitative dispute with implications for language concerns the allometric predicatability or deviation of the human prefrontal cortex. Studies based on histological analyses of the cytoarchitectonic distinction between granular prefrontal and agranular premotor cortex have reported that human prefrontal cortex is allometrically larger than predicted with respect to other anthropoids (e.g., Deacon, 1997). In contrast, MRI-based studies using major sulci and fissures as morphological markers to discern frontal from parietal and temporal cortex suggest no deviation (Semendeferi *et al.*, 1997). Claims of disconfirmation of one or the other result are, however, clouded by the use of these different anatomical methods, different definitions of frontal and prefrontal cortex, comparison of nonhomologous structures, including different primate species as a comparison set, and employing different statistical tests for deviance (Deacon, 1997, 2004).

Despite these unresolved methodological issues, most studies have concluded that human brains deviate from allometric predictions in a number of internal relationships that might be relevant for language. Probably the most consistently reported finding is that human cerebral cortex is larger than allometrically expected with respect to the two major forebrain nuclear complexes that are most intimately related to it: the thalamus and the basal ganglia (Deacon, 1988, 1990a; Dunbar, 1993; Rilling and Insel, 1999). Additionally, there is evidence for allometric deviation of kiniocortex and agranular cortex to eulaminate cortex (Deacon, 1990a), visual cortex (e.g., Holloway, 1979), temporal lobe morphology (Rilling and Seligman, 2002), and prefrontal cortex (Deacon, 1988, 1997; Rilling and Insel, 1999). It is hard to believe that significant deviations in these major forebrain relationships would not have an impact on language. For example, Deacon (1997) argues that this disproportion may have aided invasion of cortical efferents into brainstem vocalization nuclei (see below), as well as biasing developmental competition among cortical afferents affecting parcelation of functional cortical areas. Finally, difficulties of discerning comparable boundaries of cortical areas across species of widely differing sizes have made more fine-grained allometric studies of the scaling of individual cortical areas even more problematic.

Efforts to link allometric deviations of some of these structures with language adaptation have mostly focused on two findings, the expansion of

prefrontal cortex (e.g., Aboitiz and Garcia, 1997; Deacon, 1997) and quantitative deviations and asymmetries of Broca's and Wernicke's language areas compared to their homologues in chimpazees (e.g., Gannon *et al*., 1998). For example, prefrontal expansion may provide working memory support for symbol learning, visual cortex reduction may reflect parietal cortex expansion and an augmentation of cross-modal cognition, and asymmetries of language cortex may provide the substrate for hemispheric specialization for language.

4.35.2.3 Connectional Homologies and Dishomologies Relevant to Language

Neither the lack of novel human brain structures nor the uncertainties about the existence or relevance of allometric deviations precludes the possibility of evolutionary changes in neural circuitry. Unfortunately, methods used to accurately trace axonal connections between brain structures require lethal experiments and so are only available for study of nonhuman species, and indeed are not even applicable to apes because of their endangered status and the ethical issues involved. Thus, information concerning human neural connections is mostly lacking and must be extrapolated from nonhuman data. However, indirect evidence from human functional differences, clinical studies, and *in vivo* imaging can be compared to connectional data derived from nonhuman primates to support a handful of fairly robust connectional claims.

Probably the most robust behavioral distinction between the vocal abilities of humans and other primates (and in general with respect to all terrestrial mammals) is the ability for humans to produce a wide range of vocal sounds that can be freely organized into diverse combinations. In addition, we also have an unprecedented ability (for a terrestrial mammal) to mimic vocal sound combinations that we hear others produce. In contrast, the vast majority of terrestrial mammals, including primates, has relatively fixed vocal repertoires, for which sound mimicry learning plays almost no role. Associated with our lack of constraint on productive sound combination, we experience a relative freedom from specific correlations between vocalizations, emotional states, and stereotypic referential contexts, unlike what is characteristic of the other primates (Deacon, 1997). This is a critical requirement for language, as it allows socially transmitted patterns of sound production (e.g., words) to be learned in association with any given reference. Though humans still exhibit a small repertoire of innate stereotypic species-specific vocal 'calls' such as laughter and sobbing, which do have fixed structure and are associated with highly constrained emotional contexts, this call repertoire is both small compared to that in chimpanzees and atypical in form and context (Deacon, 1997; Provine, 2000).

These differences are probably in part attributable to a change in the central innervation of the laryngeal control nucleus of the brainstem, the nucleus ambiguus. Tracer studies in nonhuman primates have demonstrated that this nucleus is almost entirely innervated by subcortical structures from midbrain and adjacent brainstem regions (Jürgens *et al*., 1982). This is an expected pattern given that the nucleus ambiguus is a visceral motor nucleus that is segregated from significant influence from volitional systems in order to provide reliable automatic responses for a system that is associated with life-and-death consequences. Though electrical stimulation of ventral motor cortex regions in the macaque monkey brain can result in vocal muscle movement, there is little evidence that this is mediated by a direct projection. In addition, bilateral ventral frontal motor cortex damage in monkeys does not appear to block their ability to vocalize. In contrast, unilateral damage to left inferior motor cortex in humans (even just in the left hemisphere) can produce significantly impaired vocal ability, and even mutism. This clinical evidence is supported by experimental studies that also suggest that the human nucleus ambiguus is directly innervated from motor cortex (Jürgens *et al*., 1982). Taken together, this makes it likely that this connection constitutes a uniquely human feature, by virtue of which precise control of pitch and vocal timing is achieved in speech and song. This would also explain the remarkable coordination of vocalization with the other cortically controlled tongue, jaw, and facial muscles that are necessary for articulate speech. In this regard, humans have dual control of vocalization, as is exhibited in the tendency for speech to be interrupted with impulses to laugh or sob in response to intense emotional states (Provine 2000; see Figure 1).

The left inferior frontal cortical region that likely includes Broca's speech area has been subject to conflicting claims concerning (1) which components of this region are responsible for the deficits associated with Broca's aphasia, (2) how they are functionally connected with other cortical and subcortical regions also associated with language processing, (3) whether the cortical area itself or its connections with other areas are more important for its language role, and (4) whether or not its

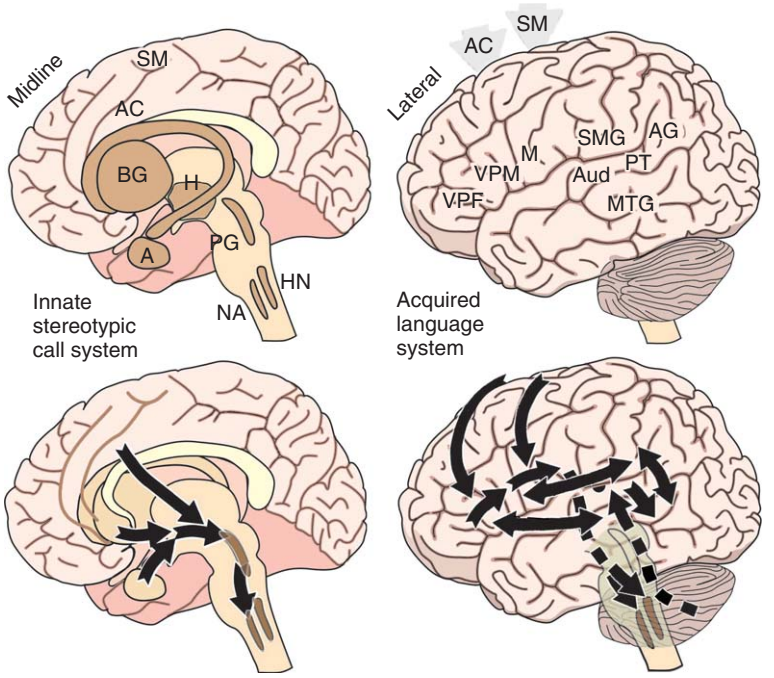

Figure 1 Highly simplified schematic comparison of brain structures (above) and major connections (below) comprising the mammalian innate call production system and the human spoken language system. Many connections and relevant structures are not shown, including notably the involvement of a cortical–basal ganglia–thalamic–cortical loop and the cerebellum in language production. The forebrain structures of the innate call system are almost exclusively associated with arousal control, whereas those supporting language are almost exclusively sensorimotor and 'association' cortical structures. So these two vocal communication systems of the brain are largely nonoverlapping in terms of structures and connections, with the exception of final brainstem output systems controlling oral, vocal, and respiratory muscles, and the anterior cingulate cortex. Projections from motor cortex extend directly to brainstem vocal motor nuclei, whereas forebrain output controlling innate calls is mediated by the periaqueductal gray area of the midbrain. In humans, both systems operate in parallel, and may compete for the control of vocal output. The differential involvement of numerous interconnected forebrain systems in language as compared to the few involved in innate vocalizations is superficially similar to the neural differences between birds that learn complex variable songs and those with innate stereotypic songs (see Figure 2). A, amygdala; AC, anterior cingulate cortex; AG, angular gyrus; Aud, auditory area; BG, basal ganglia; H, hypothalamus; HN, hypoglossal nucleus; M, motor cortex; MTG, middle temporal gyrus; NA, nucleus ambiguus; PG, periaqueductal gray; PT, planum temporale; SM, supplementary motor area; SMG, supramarginal gyrus; VPM, ventral premotor; VPF, ventral prefrontal.

connectivity with other structures is typical of other primate brains. The clinical literature is even still split on what Brodmann's areas (Brodmann, 1909) are the substrates for Broca's area language functions (Dronkers *et al*., 1992), whether multiple frontal cortical areas subsume component language functions (Paulesu *et al*., 1997; Deacon, 2004), and whether these cortical areas are the primary locus, rather than the underlying white matter and striatal structures (D'Esposito and Alexander, 1995; Lieberman, 2002). Nevertheless, claims that this area is in some way uniquely organized in humans are reinforced by the common incidence of agrammatism in Broca's aphasics and by the belief that it is grammar that sets humans apart from the other species.

One of the long-standing assumptions about Broca's area is that it is a convergence zone where auditory input contributes to the formulation of speech. Could this connection pattern be a unique feature of human brains supporting speech? Combining connection data from primates with new *in vivo* functional image data on language processing, it is possible to settle some of these long-standing questions. Tracer studies of connections of the macaque inferior frontal cortex demonstrate linkages with other cortical and subcortical sites that include both parietal and temporal cortical areas. But these tracer results delineate at least three quite different connection patterns associated with different subregions of the monkey ventral frontal cortex (Deacon, 1992b). Motor and premotor cortical areas are primarily interconnected with inferior parietal and superior insular regions of cortex, and premotor cortex is connected with dorsal midline supplementary motor cortex. In comparison, the rostrally adjacent ventral prefrontal area is primarily interconnected with superior temporal and middle temporal gyrus areas, as well as with

dorsal prefrontal areas and anterior cingulate cortex, but lacks connections with motor areas. So primate connection data do not support a simple convergence of auditory and tactile motor functions in their anatomical homologue to Broca's region, and instead exhibit a tier-like organization with caudal–rostral segregation of parietal from temporal input zones. Physiological confirmation of an auditory projection zone in this macaque ventral prefrontal region has been provided by single cell recording (Romanski *et al*., 1999). But is this segregation of auditory and motor functions in the primate homologue to Broca's area evidence that monkeys and humans differ in this respect? The corresponding connection patterns in the human brain have recently been traced using diffusion tensor weighted MRI techniques, which enable the visualization of fiber tracks (Catani *et al*., 2005). This study mapped the course of the components of the fiber bundle known as the arcuate fasciculus, which in humans carries fibers presumed to interconnect Wernicke's area with Broca's area. The findings are consistent with the monkey brain connection pattern, not with a simple convergence zone logic. Inferior parietal projections terminate in ventral motor and premotor areas and superior and middle temporal gyrus projections terminate more rostrally in ventral prefrontal areas. Inferior parietal areas and superior temporal areas are also interconnected, but not superior temporal areas and ventral motor or premotor areas. As in the macaque brain, auditory information is relayed to the frontal areas by way of a prefrontal cortical area in front of and separate from the premotor–motor areas involved in speech production.

This evidence for fractionation of the contributions to language processing in ventral frontal cortex is also consistent with the accumulation of *in vivo* imaging data that show slightly different localizations in this region for heightened activity during language tasks that differentially involve auditory and motor processing. For example, word association and linguistically mediated mnemonic tasks preferentially activate the ventral prefrontal component, while tasks involving motor analysis preferentially activate premotor and motor areas located more caudally. The implications are first that Broca's area is not a single functional unit, but comprises two or more adjacent regions, second that only the prefrontal component utilizes temporal auditory input, and third that the language specialization of this region did not depend on any major restructuring of connectivity. In addition, if as in macaques this same auditory recipient ventral prefrontal area is linked to the anterior cingulate cortex, it would also represent a bridge between a language-specialized area and the one cortical area known to be involved in primate call production.

4.35.3 Comparative Functional Analyses

4.35.3.1 Functional Dissociation of Call and Speech Motor Control

The discovery of predator-specific alarm calls in vervet monkeys (Seyfarth *et al*., 1980) suggested that the functional dichotomy between language and primate call systems might not be so great as once believed. The existence of distinct calls given to leopards, eagles, and snakes suggested that the origins of language might be envisioned as a gradual elaboration of a larger and larger specific repertoire eventually requiring more complex production and combination mechanisms. However, evolutionary continuity is difficult to support when the difference in neural substrates between calls and language is considered. Electrical stimulation and lesion experiments established that primate calls could be elicited by stimulation of midbrain and limbic forebrain structures, including basal forebrain, ventral striatum, amygdala, hypothalamic, and anterior cingulate cortex, but not by cerebral cortical areas (e.g., Jürgens, 1979). Correspondingly, damage to monkey's cerebral cortical areas homologous to those involved in language processing in humans do not interfere with call production. Conversely, damage to limbic and telencephalic structures homologous to structures supporting primate calls do not produce language deficits in humans. There are some exceptions that prove this rule. One is the anterior cingulate cortex, which if bilaterally damaged in humans, may result in akinetic mutism (immobility that includes vocalization). But this is arguably an impairment of the arousal to speak and move rather than a disturbance of language processing. There have also been reports that stimulation of the amygdala in human subjects can sometimes produce spontaneous curses as well as emotional cries. And in patients with global aphasia, cursing is sometimes spared or even facilitated. Expletives are, however, an interesting intermediate; an acquired vocalization that has become relatively automatic and stereotypically associated with specific intense emotional experience. Taken together, these data demonstrate that the neural substrates for language functions and

innate calls derive from almost completely dissociated brain systems. Along with evidence that speech depends on direct cortical projection to oral–vocal motor nuclei, independent of the older limbic-midbrain–brainstem pathway, and the fact that speech and human innate calls exist side by side in our vocal repertoires, we can confidently conclude that the language system is not an elaboration of the call production system. The only significant overlap of these two systems is a final common output pathway.

4.35.3.2 Songbird Comparisons

Despite the fact that telencephalic organization in birds and mammals is radically different, there are useful analogies that can be drawn from comparison to birdsong control and its differences in different species (Jarvis, 2004). Research into the organization of song acquisition and control in different bird species demonstrates a consistent pattern that distinguishes song learners able to produce complex songs from nonlearners with simple songs. Comparisons between songbirds, parrots, and hummingbirds also demonstrate that complex singing abilities have evolved independently at least three times in the course of bird evolution and that in each of these lineages motor control of song output is mediated by slightly different forebrain systems. Species with highly stereotypical innate songs utilize only one or two forebrain motor nuclei for song production. In both songbirds and birds with stereotypic songs, a primary motor output nucleus in the caudal telencephalon (RA in songbirds) projects to the common vocal output pathway in central midbrain, and from there to brainstem motor nuclei. In addition, species that learn significant aspects of their songs and produce complex variable songs may require the coordinated contributions from as many as a dozen forebrain structures. In this regard, the difference between birds that sing complex sounds and those that sing stereotypic songs is crudely analogous to the human/nonhuman primate difference. So understanding the differences between the alternative complex song control strategies in different bird lineages and the difference between complex singers and stereotypic singers may provide useful comparisons (see Figure 2).

Two major classes of forebrain systems are integrated with the forebrain motor output nuclei to enable song learning and song complexity: auditory and striatal motor systems. These are necessary for learning from auditory experience. In addition, a higher-order premotor nucleus (high vocal center (HVC) in songbirds) is also critical for song complexity and flexibility. The differences between different lineages where vocal learning evolved are also interesting as a comparison. Some of the most sophisticated learners, such as parrots, have a different motor output pathway from the forebrain than do oscine songbirds. Although it is not clear from current research whether these differences are more than variations on a theme, differences in the midbrain/brainstem output targets of these nuclei are suggestive. For example, in songbirds, a midbrain region (probably homologous to the mammalian periaqueductal gray area which mediates call production) mediates between forebrain and brainstem motor control nuclei, but in parrots and possibly hummingbirds there is also a direct projection from forebrain motor nuclei (not homologous to RA) to brainstem motor systems. It is tempting to speculate that this latter pattern is analogous to the direct forebrain (cortical) projections to the vocal motor centers that distinguishes humans. Whether these differences account for the remarkable vocal mimicry of parrots and their kin is unknown.

So, although a good deal is still to be learned about the evolution of vocal learning and vocal skill in birds, exploring this more experimentally accessible parallel to the human case may provide important clues about how vocal flexibility evolves. An intriguing example is discussed below.

4.35.3.3 Lateralization of Language Functions

One of the more enigmatic features of language representation in the brain is the fact that the two hemispheres play very different and unequal roles in controlling speech and comprehension. This is not because there are different cortical areas on the two sides. Ever since the French surgeon Paul Broca first catalogued cases of speech impairment associated with localized brain lesions (Broca, 1865), it has been known that the left-hemisphere damage is far more debilitating for language functions than the right-hemisphere damage. The brain regions in the inferior frontal gyrus and superior temporal gyrus that are the loci most likely damaged in Broca's and Wernicke's aphasia, respectively, are identified for the left hemisphere, but their right-hemisphere counterparts can often suffer damage with no obvious speech impairment. This left 'dominance' for language, as it is often described, is not universal, with just a few percent of people exhibiting complete right-sided language bias. The exceptions also correlate strongly with left handedness, suggesting a link between the asymmetrical biases. Beginning in the 1960s, a series of surgical

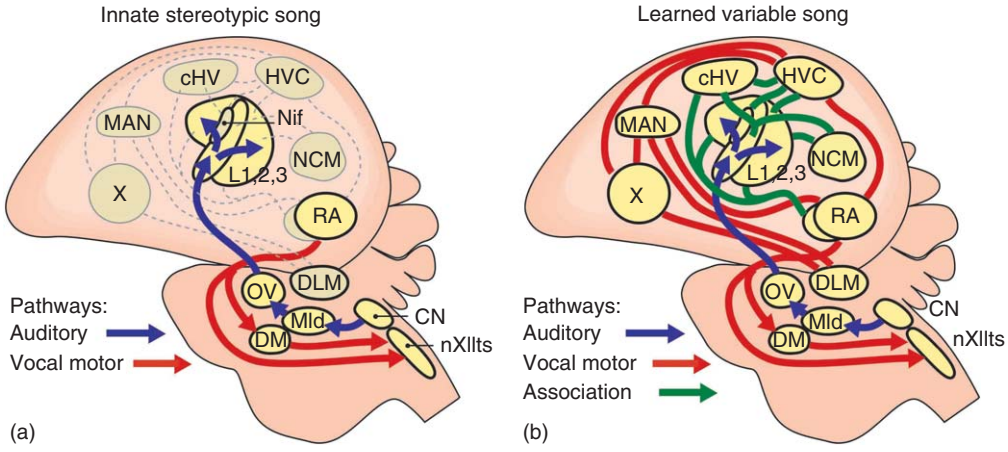

Figure 2 Comparison of major structures and connections in brains of (a) songbirds that do not learn their song and (b) those that do. Dashed connections and structures not connected by heavy lines are minimally involved in song (many structures and connections are not shown for simplicity). Innate stereotypic birdsong is relatively insensitive to damage to most forebrain structures (a) excepting a primary motor nucleus (RA) which projects to the central midbrain and to vocal motor nuclei, such as the hypoglossal nucleus (nXIIts). In contrast, striatal structures (e.g., areas X and MAN), auditory centers (e.g., L1, L2, and L3), and numerous pathways linking these with premotor (e.g., HVC) and motor (RA) nuclei are all involved in various aspects of learning a song 'dialect' from adult singers in early life. In these birds damage to any of these structures or their interconnections can disturb learning, complexity, or flexibility of song. Other bird orders exhibiting learned vocalizations, such as parrots and hummingbirds, are distinguished by differences in final motor output pathways (not shown). The distribution of song control to a diverse system of forebrain structures in song learners is loosely analogous to the shift in control from limbic structures to the diverse system of interconnected sensory, motor, and association cortical areas and striatal nuclei that evolved to control language (see Figure 1). In both systems the involvement of a diverse constellation of interconnected forebrain structures appears to be correlated with complex, flexible, context-sensitive, socially transmitted, learned vocal skills. For a more detailed account of the comparative neurology of bird vocalizations and human language see Jarvis (2004). cHV, caudal region of the hyperstriatum ventrale; CN, cochlear nucleus; DM, dorsal medial nucleus of the midbrain; DLM, medial nucleus of the dorsolateral thalamus; MAN, magnocellular nucleus of the nidopallium; HVC, high vocal center; L1–3, primary auditory fields; Mld, mesencephalic lateral dorsal nucleus; NCM, caudal medial nidopallium; Nif, interfacial nucleus of the nidopallium; nXIIts, hypoglossal nucleus (nucleus XIIth cranial nerve, tracheal syringeal division); OV, nucleus ovoidalis; RA, robust nucleus of the arcopallium; X, area X of the striatum.

interventions to limit the spread of epilepsy susceptibility from one hemisphere to the other cut the corpus callosum, and other forebrain commissures, severing the two hemispheres so that they could not exchange signals. The results were startling. If information was carefully provided to only one of the isolated hemispheres, patients could use language to describe the stimulus only if presented to the left hemisphere (input from the right side). This suggested that the right hemisphere was essentially mute.

There are a few clues to how and why this functional asymmetry evolved to be so robustly associated with language functions. The first clue comes from understanding what language-related functions, if any, are contributed by the contralateral counterparts to Broca's and Wernicke's areas in the right hemisphere. Two lines of evidence suggest that, contrary to earlier views, the right hemisphere does indeed contribute to language processes. Both kinds of evidence come from cases of right-hemisphere brain damage. First, there is a higher incidence of aprosodia with right-hemisphere damage (Ross, 1981). Aprosodia is an impairment of the ability to produce or accurately comprehend the changes in tonality and rhythmicity that is used to convey emotional tone, emphasis, or differential focus in speech. This suggests that the right hemisphere is involved in regulating the nonreferential social–emotional context of spoken conversation in parallel with the left-hemisphere production and comprehension of the syntactical and semantic content of speech. Second, right-hemisphere damage appears to impair the ability to keep track of the larger semantic and pragmatic frames of speech. Right-hemisphere-damaged patients have difficulty understanding what makes one joke funny and another lame, and also have difficulty following the theme of a story, often failing to recognize the insertion of incongruous elements (Gardner *et al.*, 1983). So although the right hemisphere appears to be minimally, if at all, involved in immediate semantic and syntactic processing of

words and sentences, it appears to be carrying out important supportive background tasks in parallel.

This parallelism may help to explain another curious feature of language lateralization: its development in childhood. Studies of very young children who have had their left hemispheres surgically removed show a remarkable sparing of language abilities, with minimal obvious impairment in adulthood (see review in Kolb, 1995; and recently Boatman *et al*., 1999). So, although left lateralization of the semantic, syntactic, and phonological processing of language is highly predictable and probably reflects an innate bias, it is only a bias and not a fixed and inflexible adaptation.

Why should there be laterally asymmetric distributions of language functions in an otherwise bilaterally symmetric brain? Although there is no certain answer to this question, considering the functional characteristics that are lateralized, the fact of their progressive differentiation during maturation, and other correlates of lateralization (e.g., handedness) some plausible hypotheses can be formulated. First, there are consistent structural asymmetries in human brains (discussed already). The relative sizes of cortical areas and morphological structures associated with Broca's and Wernicke's language areas indicate that the right side counterparts are on average smaller. This could be a source of developmental bias or also a consequence of developmental differentiation, but other left–right asymmetries in neonatal brains support the possibility that anatomical bias contributes. Second, the language functions that appear to segregate to opposite hemispheres seem to divide according to both rate of processing (rapid processing on the left) and extent of conscious online monitoring required (also left). This can probably be understood in terms of segregating functions that need to run in parallel but would likely interfere with one another because of their very different processing parameters (Deacon, 1997). Third, the correlation with asymmetric manual skill suggests a possible linkage, perhaps with tool use (Kimura, 1993). Finally, the unilateral representation (also to the left) of vocal skill learning is also characteristic of songbirds (Nottebohm and Nottebohm, 1976). Since vocalization involves muscle systems that are aligned along the midline of the body and are bilaterally controlled, it may be necessary to strongly bias control to one hemisphere in order to avoid functional conflict. In summary, lateralization may not be a requirement for the evolution of language, but it is likely a bias built in to aid functional segregation of processes that are best run in parallel systems and thus avoiding mutual interference.

4.35.3.4 The Mirror System

Although the class of cells called 'mirror neurons' are discussed elsewhere in this volume (see Premotor Cortex and the Mirror Neuron Hypothesis for the Evolution of the Language), including their possible roles in language processing, this class of neural responses has also been implicated in many language origins theories (Rizzolatti and Arbib, 1998) Recording from single neurons in a ventral premotor subregion (designated F5) of the macaque monkey brain, Rizzolati and colleagues identified a subset of neurons that preferentially spiked when the subject observed himself picking up an object and also when observing an experimenter picking up the same object in the same way. This responsiveness to the general form of the action, irrespective of the role of agency and perspective, suggested the name 'mirror neuron'. The relevance to the evolution of the language capacity is twofold: first it suggests the possibility that this kind of neural responsiveness could play a role in the ability to mimic others, and second the location of these cells in the macaque brain is in a region generally considered adjacent to the monkey brain region deemed homologous to the premotor division of Broca's area (see Section 4.35.2.1), and possibly overlapping. *In vivo* imaging data have further suggested that there is a similarly responsive premotor region in the human brain. Although it can be debated whether this response characteristic is specifically found in the same premotor region in human brains as the one that plays a critical role in language, these coincidences make it reasonable to entertain the hypothesis that this might help support the vocal mimicry necessary for word learning in language. If so, what might be the implications for language evolution? First, it must be noted that the presence of mirror neurons in macaque brains is sufficient to exclude these cells or their connections from being the difference in human brains that makes language possible; however, it could be argued that their presence predisposed this premotor zone for a later role in language processing. Second, speech mimicry demands that a parallel class of auditory–vocal mirror neurons be identified (visual–manual mirror neurons might be more important for mimicry in gestural language), though some of these neurons exhibit responses to the sound of

an object being manipulated as well. In the monkey brain, mirror neurons receive input from neurons in inferior parietal cortex that are also responsive to visuomanual stimuli, but if there are corresponding auditory–vocal mirror neurons we might rather expect them to receive input from superior or middle temporal sources. Until such a parallel class of neurons is identified it is probably premature to assume that mirror neurons are critical to language functions, but looking for them is thus a relevant enterprise. One plausible scenario – assuming that mirror neurons are indeed critical for mimicry – is that they played a role in an early, more gestural phase of language evolution, and possibly paved the way for the evolution of these hypothetical auditory counterparts.

4.35.4 Genetic Correlates of Language Adaptation

4.35.4.1 Hopeful Monsters and Megamutation Scenarios

Probably the most popularly accepted scenario for language evolution is what has sometimes derisively and sometimes seriously been referred to as the 'big bang' scenario. On the analogy to the birth of the universe, this scenario suggests that language was made possible as a result of one or just a few major mutation events that resulted in the significant reorganization of brain functions. This resonates well with assumptions about an innate UG (see Section 4.35.1.2) or a 'language acquisition device' constituting the difference between human and nonhuman brains. It also resonates with paleoarcheological theories for explaining the sudden burst of cultural artifacts (such as diverse tools types, representational cave paintings, and carvings) that arose within the last 50 000 years. Since *H. sapiens* has been around for greater than 100 000 years, and hominids with comparably large brains and complex stone tools have been around for roughly half a million years, this transition appears quite recently in human evolution. But the idea that what distinguishes speaking humans from other species and from our recent ancestors can be explained by a couple of very lucky genetic accidents seems both counterintuitive in terms of what is known about the genetics of the developing brain and what is known about the complexity of language control. But more generally, it also leaves almost the entire explanation of this adaptation to an incredibly lucky accident. This kind of evolutionary scenario is often described as a hopeful monster story, because it imagines that a mutation producing a major phenotypic distortion becomes so enormously successful that it replaces all alternatives. Though one cannot argue that it is impossible, it is a claim about evolution that is little better than invoking a miracle. Nevertheless, there is at least one serious proposal for just such a critical genetic change.

4.35.4.2 Genes Affecting Language Processing

In the mid-1980s, when excitement about the plausibility of innate UG was at its peak, a surprisingly specific inherited language disorder was described. Called specific language impairment (SLI) by researchers, it was expressed in a family (identified as the KE family) in which many members exhibited specific difficulty with regularized aspects of English syntax (Gopnik, 1990; Gopnik and Crago, 1991). Most notably, this was manifested in a problem learning to use the regular past tense ending '-ed'. Subsequent study of this deficit showed it to also be accompanied by significant oral motor apraxia (pronunciation and fluency problems) and neurological reduction of motor areas and basal ganglia (Vargha-Khadem *et al.*, 1998). Chromosomal damage to a common locus was subsequently correlated with expression of this trait, and in 2002 a transcription factor gene, FOXP2, was identified as the critical damaged gene in this disorder (Enard *et al.*, 2002), expressed in structures affected in the KE family (Lai *et al.*, 2003). It is the first single gene to be correlated with a known neurological disturbance of language function. It is not a 'new' gene unique to the human lineage, since it is present and plays a critical role in development of the brain in all mammals (a homologue is also found in birds and fruit flies), and it is a highly conserved gene in terms of sequence variations across species, and the KE family variant is damaged at a site conserved in all known species (and so likely critical).

Important with respect to its plausible role in the evolution of language are two point mutations in the human variant that distinguish it from the chimpanzee version (and basically from all other mammals in which it is highly conserved). Linkage information even suggests that these human deviations are relatively recent – possibly within the last 100 000 years – and are likely universal or nearly so in living humans. This does not prove, however, that these human-specific differences contribute to a crucial change in function (though the evidence is highly suggestive), and the alterations do not correspond to the damaged locus in the KE family. At the present

time, we cannot even say for certain that having the chimpanzee gene would result in diminished language function, or whether a chimp with a human version of the gene would have improved oral motor capacity. But damage to a regulatory gene that is critical for early brain development (as it is in all mammals) will almost certainly result in significant disruption of function, since it likely controls the expression of many other genes. So although the gene did not evolve for language, the neural features it controls during development have clearly been recruited by language, and it seems likely that the mutations that occurred in it in human evolution played some role in the evolution of speech.

Assuming that the point mutations of FOXP2 that are unique to the human lineage do play a role in our language adaptation, we next need to ask what kind of effect. And this requires considering its contribution to development of specific brain structures. Comparative and clinical data suggest that it plays a role in the development of the basal telencephalon, which will become ventral basal ganglia and basal forebrain in the adult. Though these basal ganglia structures are not classically identified as language structures *per se*, there are many reasons to think that basal ganglia structures could be important contributors to language learning and use (Lieberman, 2002), particularly of those processes that become relatively automatic. This is consistent with the critical role played by basal ganglia in skill learning, the automatization of many routine behavioral functions, and the establishment of procedural memories. Since there is an extensive interdependence between the anterior cortical areas and basal ganglia, via a recurrent circuit through the pallidum and thalamus, it should be no surprise that functions associated with frontal language cortex might also be affected by basal ganglia disturbances, especially motor functions. As a comparison, disruption of fluency, pronunciation, and syntactic processing have all been shown in Parkinson's disease patients, who also have reduced basal ganglia function (Lieberman, 2002). So if recent human-specific point mutations in the gene FOXP2 do reflect an adaptation for language processing, it is most likely with respect to aiding speech automatization. This role in learned vocalization is also supported by two additional comparative findings. First, the bird homologue to FOXP2 is found to be expressed in striatal nuclei associated with song learning (particularly in area X), and is more extensively expressed in species that learn their songs (Haesler *et al.*, 2004). Second, damaging one copy of FOXP2 in mice produces an impairment of their ultrasonic vocalization, and damaging both causes severe motor impairments, elimination of ultrasonic vocalizations, and premature death (Shua *et al.*, 2005). So although it is not specifically a gene for language, nor did it evolve only in humans, it has clearly been critical for neural systems underlying vocal motor functions in terrestrial vertebrates for a very long time, and it may have been tweaked in recent human evolution.

4.35.5 Evolutionary Processes and Brain–Language Co-Evolution

4.35.5.1 Evolutionary Scenarios

Estimates of the age of language date from as little as 50 000 years to more than 2 million years. Some of this difference reflects different definitions of language, some reflects different notions about the tempo of evolution (i.e., whether the change was sudden or gradual), and some takes different views about the number of mutational changes that were necessary. In general, those who argue that the language faculty is a highly specialized modular capacity tend to favor a recent date of origin and a saltational transition, whereas those who favor a more generalized conception of the language faculty supported by a constellation of adaptations tend to favor more ancient dates.

Exactly how the processes of natural and sexual selection might have contributed to the evolution of the human language adaptation is also contentious. Darwin (1871) argued that language might have evolved from something like courtship song under the influence of sexual selection. Modern theories that appeal to sexual selection have also focused on the use of language for social manipulation. The most common scenarios, however, focus on the role of language as a tool for social coordination and maintenance of social groups.

Two extreme language selection scenarios are commonly opposed in the literature to predict what changes in brain structure might be relevant: scenarios assuming that language is a consequence (or late-stage tweak) of a more prolonged trend toward increasing general intelligence (exemplified by a 2-million-year expansion of brain size) and scenarios assuming that language is the consequence of domain-specific neural modifications and is independent of general intelligence. These are not mutually exclusive options, but they do make different predictions with respect to neural structural and functional consequences, as well as

evolutionary timing. These functional implications can be used retroductively to probe the plausibility of each. If language has an ancient origin, it would follow that it is likely supported by a significant and extended natural selection history, including the contributions of many genetic changes affecting the brain. If, on the other hand, language is of recent origin and largely without precedent, it would follow that little time has elapsed for significant effects of natural selection to accumulate. As a result, ancient origin hypotheses predict that language functions will be more thoroughly integrated into other cognitive functions, will likely have distributed representation in the brain, and should be highly plastic with respect to both minor brain disorders and genetic variation. Recent origin hypotheses, on the other hand, are more consistent with language processes being highly modular and domain specific, localized to one or a very few neural systems, fragile with respect to brain damage and genetic variation, and possibly radically altered in grammatical organization by genetic abnormalities. With the exception of claims for domain specificity, which are controversial, the neuropsychological evidence argues against a recent rapid transition to language capacity. But archeological evidence is also brought to bear on this question. The paleoarcheological record is surprisingly stable from about 1.6 Mya to roughly 350 kya, with the transition from Acheulean to Mousterian tool culture, but does not begin to show signs of regional tool styles, decorative artifacts, and representational forms (e.g., carvings and cave paintings) until roughly 60 kya, with the dawn of what is called the Upper Paleolithic culture. This recent transition to technological diversity and representational artifacts has been attributed to a major change in cognitive abilities, which many archeologists speculate reflects the appearance of language. Fossil crania, however, provide no hint of a major neuroanatomical reorganization, and the genetic diversity of modern human populations indicates that there are some modern human lineages who have been reproductively separated from one another for at least twice this period and yet all have roughly equivalent language abilities. These considerations weigh in favor of a protracted evolution of language abilities and for the convergence of many diverse neural adaptations to support language (Johansson, 2005).

An adaptive convergence logic also helps to resolve some of the mysteries concerning the absence of direct neuroanatomical or functional homologies between language and nonhuman communication adaptations. The novelty of language can be understood in terms of the combined effects of systems which individually may have served quite different functions in ancestral species but which collectively interact in novel ways to produce emergent consequences. If the human language adaptation reflects the combined contribution of many diverse systems whose parallel evolutionary paths have come together to provide an unprecedented functional synergy, we should not expect to find highly divergent local changes in brain structure, but rather global reorganization in which most structures participate in some respect or other. But considering language functions to be emergent adaptations, in this sense, poses new questions about the evolutionary process. Specifically, we must explain how such functional synergies among diverse systems can be explored and recruited by the process of natural selection. In general, this reflects a common challenge posed to evolutionary theory since the time of Darwin, and can be generally answered the way he explained the probable evolution of the eye. He argued that even quite minimal non-image-forming light-sensitive proto-eyes would, none the less, provide an adaptive advantage over the absence of any light sensitivity, and that any minor modifications to adjacent structures that improved on this in any way would likewise be advantageous and selectively retained. As more comparative anatomical and genetic information has come to light concerning the evolution of eyes, in the century and a half since Darwin's time, his speculation has found ample justification. However, language differs from this sort of complex adaptation in one important respect: much of the detail of a language's functional architecture is transmitted socially.

4.35.5.2 Co-Evolutionary Scenarios

In contemporary behavioral biology, the concept of instinct no longer comes with the connotation of learning playing no role. Many species-typical behaviors from the social learning of birdsongs to the hunting behavior of wolf packs involve the interaction of behavioral and learning biases with socially transmitted habits and variable environmental contexts. Darwin recognized the relevance of this environmental conditionality when he described the language adaptation as "an instinct to acquire an art." Language is, of course, special with regards to the relatively massive contribution of extrinsic factors, and also with respect to the likely combinatorial and emergent character of its supporting neurology. So its emergent character is unusually dependent on interactions between diverse neural

and social mechanisms producing specific outcomes. This combinatorial co-dependence provides a challenge to simple caricatures of language evolution on the analogy of other physiological adaptations.

Recognition of this co-dependency has given rise to evolutionary scenarios that incorporate this interactional logic. Most develop from an evolutionary logic that has come to be called the Baldwin effect, after Baldwin (1896) who described how behavioral plasticity enabling the production of acquired adaptations might serve as an evolutionary precursor to a more innately produced analogue of this adaptation. The general logic of this evolutionary mechanism involves two phases: (1) the production of phenotypic plasticity (e.g., learned behaviors) making it possible for acquired adaptations to be conditionally produced that enable a lineage to persist despite a suboptimal match to the environment and (2) the appearance of new variants in that lineage that are selectively retained because they take over some fraction of the load of acquisition. This, presumably, described a Darwinian mechanism that would produce the evolutionary equivalent of Lamarckian inheritance of previously acquired traits. Proponents of innate UG invoked versions of this logic to argue that language-like behavior in our ancestors could have become progressively internalized as an innate faculty that is presently only minimally dependent on learning in the standard sense (e.g., Pinker, 1994). But the same logic could equally support the evolution of biases and aids to learning, without invoking a replacement of learned with innate knowledge of language (e.g., Deacon, 1992a, 1997). More recently, these arguments have been revisited in the context of the concept of niche construction (Odling-Smee *et al*., 2003; Deacon, 2003), in which persistent socially maintained language use can be understood as a human-constructed niche that exerts significant selection pressures on the organism to adapt to its functional requirements. This approach is compatible with the claim that language function is supported by many modest distributed evolutionary modifications of brain anatomy and chemistry. It also assumes that language-like communication was present in some form for an extensive period of human prehistory.

4.35.5.3 Degenerative Processes as Possible Contributors to Language Evolution

A co-evolutionary scenario for the evolution of language still does not account for the generation of the novel functional synergy between neural systems that language processing requires. The discontinuities between call control systems and speech and language control systems of the brain suggest that a co-evolutionary logic alone is insufficient to explain the shift in substrate. Recent investigation of a parallel shift in both complexity and neural substrate in birdsong may be able to shed some light on this.

In a comparative study of a long-domesticated bird, the Bengalese finch, and its feral cousin, the white-rump munia, it was discovered that the domesticated lineage was a far more facile song learner with a much more complex and flexible song than its wild cousin. This was despite the fact that the Bengalese Finch was bred in captivity for coloration, not singing (Okanoya, 2004). The domestic/feral difference of song complexity and song learning in these close finch breeds parallels what is found on comparisons between species that are song learners and nonlearners. This difference also correlates with a much more extensive neural control of song in birds that learn a complex and variable song. The fact that this behavioral and neural complexity can arise spontaneously without specific breeding for singing is a surprising finding since it is generally assumed that song complexity evolves under the influence of intense sexual selection. This was, however, blocked by domestication. One intriguing interpretation is that the relaxation of natural and sexual selection on singing paradoxically was responsible for its elaboration in this example. In brief, with the song becoming irrelevant to territorial defense, mate attraction, predator avoidance, and so on, degrading mutations and existing deleterious alleles affecting the specification of the stereotypic song would not have been weeded out. The result appears to have been the reduction of innate biases controlling song production. The domestic song could thus be described as both less constrained and more variable because it is subject to more kinds of perturbations. But with the specification of song structure no longer strictly controlled by the primary forebrain motor center (RA) (see Section 4.35.3.2), other linked brain systems can begin to play a biasing role. With the innate motor biases weakened, auditory experience, social context, learning biases, and attentional factors could all begin to influence singing. The result is that the domestic song became more variable, more complicated, and more influenced by social experience. The usual consequence of relaxed selection is genetic drift, increasing the genetic and phenotypic variety of a population by allowing random reassortment of alleles, but neurologically, drift in the genetic control of neural functions should cause

constraints to become less specific, generating increased behavioral flexibility and greater conditional sensitivity to other neurological and contextual factors.

This is relevant to the human case, because a number of features of the human language adaptation also appear to involve a relaxation of innate constraints allowing multiple other influences besides fixed links to emotion and immediate context to affect vocalization. Probably the clearest evidence for this is infant babbling. This unprecedented tendency to freely play with vocal sound production occurs with minimal innate constraint on what sound can follow what (except for physical constraints on vocal sound generation). Babbling occurs also in contexts of comparatively low arousal state, whereas laughter, crying, or shrieking are each produced in comparatively specific high arousal states and with specific contextual associations. This reduction of innate arousal and contextual constraint on sound production opens the door for numerous other influences to begin to play a role. Like the domesticated bird, this allows many more brain systems to influence vocal behavior, including socially acquired auditory experience. In fact, this freedom from constraint is an essential precondition for being able to correlate learned vocal behaviors with the wide diversity of objects, events, properties, and relationships language is capable of referring to. It is also a plausible answer to the combinatorial synergy problem (discussed above) because it demonstrates an evolutionary mechanism that would spontaneously result in the emergence of multisystem coordination of neural control over vocal behavior.

But although an evolutionary dedifferentiation process may be a part of the story for human language adaptation, it is clearly not the whole story. This increased flexibility and conditionality likely exposed many previously irrelevant interrelationships between brain systems to selection for the new functional associations that have emerged. Most of these adaptations remain to be identified. However, if such a dedifferentiation effect has been involved in our evolution, then scenarios hypothesizing selection for increased innateness or extrapolation from innate referential calls to words become less plausible.

4.35.6 Conclusions

Despite decades of research to identify the distinctive neuroanatomical substrates that provide humans with an unprecedented faculty for language, no definitive core of uniquely human anatomical correlates has been demonstrated. Only a few distinctive anatomical differences can be directly associated with the human language adaptation. These are associated with the special motor adaptations for speech. There is an unprecedented direct projection from motor cortex to the laryngeal motor nucleus of the brainstem (nucleus ambiguus) allowing direct control of vocalization independent of arousal state or innate vocal motor pattern. There is also one known genetic correlate with language competence, the gene FOXP2. Although it is clearly not specifically a language gene, nor can we be sure that its few human sequence differences represent adaptive modifications with respect to language, it is clear that it plays a necessary supportive role in the development of brain systems involved in speech production. Damage to gene in humans results in both generalized vocal disarthria and disruption of the ability to automate certain highly regular syntactic operations, and is associated with reduction of anterior basal ganglia structures. Besides these specific effects, however, it also appears likely that the neural changes associated with language adaptations involve more generalized allometric deviations from the ape pattern. Correlated with the increase in brain size in hominid evolution, there appears to have been quantitative remodeling of relationships between brain structures that is likely to have produced quantitative connectivity changes as well. If, as now appears likely, human brain adaptations for language involve many systems' coordinated interactions, it is likely that some or all of the quantitative alterations of brain organization reflect language adaptations. Although there is still considerable controversy concerning the proper assessment of the allometry human brain structures, candidates include overall cortical expansion, disproportion between cerebral cortex and basal ganglia, disproportionate increase in eulaminate cortical areas with respect to specialized sensory and motor areas, prefrontal expansion, increases in proportions of corticocortical and corticocerebellar connections, among others. However, the relevance of any of these cannot be discerned until there is a better understanding of the contributions of these systems to language acquisition, comprehension, and production. But a definitive assessment of the significant allometric deviations of human brain structure from typical primate trends could likewise provide hints of major differences in cognitive processing relevant to language.

The highly robust and developmentally canalized nature of language acquisition suggests that this capacity does not depend on only a few subtle neurological changes from the ape pattern but instead

likely reflects a prolonged process of selection involving many systems, and perhaps extending over a million years. The nature of this selection process appears to have involved early protolanguage use as a kind of niche construction, providing selective pressure to better support the unusual demands imposed by language. If this is an accurate assessment, it means that the neurological adaptations supporting language can at least in part be understood as adaptations for language, rather than merely accidentally giving rise to language. Some aspects of this ability may also be the result of evolutionary degradation of other functional specializations, which has allowed more diverse and distributed neural systems to directly or indirectly influence vocalization.

Though human brains unquestionably include numerous species-unique innate adaptations supporting the acquisition and use of language, there is to date little evidence for a specific neuroanatomical substrate for an UG. So, progress in understanding the language-related evolutionary changes of human brain structure can mostly be marked by what we now know is not the case, and just a few clear correlates of language adaptation. But this imposes considerable constraint on the scenarios we can consistently entertain and focuses neural research on a few notable problem areas.

4.36 Nuclear Schizophrenic Symptoms as the Key to the Evolution of the Human Brain

T J Crow, University of Oxford, Oxford, UK

Glossary

Broca's area	A region of the frontal lobe of the left cerebral hemisphere associated with articulate language.
cerebral asymmetry	The concept that the two cerebral hemispheres differ in function. This is reflected in differences in the anatomical organization of the two hemispheres.
schizophrenia	A psychopathological disorder characterized by delusions, hallucinations, disorganized thought, and a poverty of emotion, speech, and intention.
sexual selection	The process where some individuals have greater reproductive success than others because of competitive advantages in mating.

4.36.1 The Nuclear Symptoms of Schizophrenia and the Central Paradox

The core nuclear symptoms of schizophrenia according to Kurt Schneider, as defined by the glossary of the Present State Examination (Wing *et al.*, 1974), are:

1. Thought echo or commentary: the subject experiences his own thought as repeated or echoed with very little interval between the original and the echo.
2. Voices commenting: a voice or voices heard by the subject speaking about him and therefore referring to him in the third person.
3. Passivity (delusions of control): the subject experiences his will as replaced by that of some other force or agency.
4. Thought insertion: the subject experiences thoughts *which are not his own* intruding into his mind. In the most typical case, the alien thoughts are said to have been inserted into the mind from outside, by means of radar or telepathy or some other means.
5. Thought withdrawal: the subject says that his thoughts have been removed from his head so that he has no thoughts.
6. Thought broadcast: the subject experiences his thoughts actually being shared with others.
7. Primary delusions: based upon sensory experiences (delusional perceptions) the patient suddenly becomes convinced that a particular set of events has a special meaning.

Why do the core symptoms have this form? What primary function is disturbed? What neural structure is the focus of the disturbance?

Through the presence of these features the authors of the WHO Ten Country Study of the Incidence and Manifestations of Schizophrenia (Jablensky *et al.*, 1992) reached their conclusion that:

> schizophrenic illnesses are ubiquitous, appear with similar incidence in different cultures, and have clinical features that are more remarkable by their similarity across cultures than by their difference.

Thus, schizophrenia is constant across populations that differ widely in geographic, climatic, industrial, and social environment; it seems it is a characteristic of human populations. It is a disease (perhaps the disease) of humanity.

If the core syndrome is a characteristic of populations it must somehow be intrinsic, i.e., genetic in origin. This raises the central paradox: why if the disease is associated with a biological disadvantage is this genetic variation not selected out? About the existence of the fecundity deficit there is little doubt: it is of the order of 70% in males and 30% in females (Essen-Moller, 1959; MacSorley, 1964; Vogel, 1979; Haverkamp *et al.*, 1982; Penrose 1991). To balance such a disadvantage, a substantial and universal advantage must be invoked. But what could such an advantage be, and by whom might it be carried? These questions were first clearly formulated in a paper (Huxley *et al.*, 1964) notable by an authorship that includes J. S. Huxley and E. Mayr, two progenitors of the modern evolutionary synthesis of Mendelian genetics and Darwinian theory. The first paragraph identifies these two as the originators of the notion. Yet the theory they proposed – that the balance lay in resistance to wound shock and stress – was clearly mistaken, as Kuttner *et al.* (1967) pointed out soon after. It makes no sense to suppose that the advantage of a particular genetic variation lies in a field that is unrelated to the disadvantage. Kuttner *et al.* considered three advantages – intelligence, language, and complex social ability – and favored the last. But these three are clearly related and one – language – is both of more obvious adaptive significance and is more readily defined in terms of neural function than the other two.

What is striking about the nuclear symptoms is that they can hardly be conceived except within the framework of language. Auditory hallucinations (items 1 and 2 above) are self-evidently an anomaly of the perception of the spoken word. Thought insertion, withdrawal, and broadcast (items 4, 5, and 6) are disturbances of the experience of thought and of the transition from thought to speech production. Primary delusions (item 7) represent a deviation in the attachment of meaning to symbolic representations, that is to say, they are a disturbance of semantics. Only delusions of control (item 3) are not immediately recognizable as a disturbance of speech, but these cannot be described except with the use of language. They can perhaps be understood as anomalies of identification of the self in relation to the rest of the universe of symbols.

4.36.2 The Problem of Language for Evolutionary Theory

The concept of language as the defining characteristic of humanity has an ancient origin:

> In most of our abilities we differ not at all from the animals; we are in fact behind many in swiftness and strength and other resources. But because there is born in us the power to persuade each other and to show ourselves whatever we wish, we not only have escaped from living as brutes, but also by coming together have founded cities and set up laws and invented arts, and speech has helped us attain practically all of the things we have devised (Isocrates, 436–338 BC, quoted in Harris and Talbot, 1997, p. xiii).

Darwin can be quoted in agreement with this view. On p. 53 of *The Descent of Man*, he writes that language "has justly been considered as one of the chief distinctions between man and the lower animals" and he seems not to have regarded this as a particular difficulty. But in 1873, within 2 years of the publication of *The Descent of Man*, Mueller (1873), who held the chair of Philology in the University of Oxford, delivered a series of three lectures at the Royal Institution in which he drew attention to the problems that language raises for Darwin's theory:

> My object is simply to point out a strange omission, and to call attention to one kind of evidence – I mean the evidence of language – which has been most unaccountably neglected, both in studying the development of the human intellect, and determining the position which man holds in the system of the world.

In the second lecture Mueller addresses the problem:

> There is one difficulty which Mr Darwin has not sufficiently appreciated ... There is between the whole animal kingdom on the one side, and man, even in his lowest state, on the other, a barrier which no animal has ever crossed, and that barrier is – *Language* ... If anything has a right to the name of specific difference, it is language, as we find it in man, and in man only ... If we removed the name of *specific difference* from our philosophic dictionaries, I should still hold that nothing deserves the name of man except what is able to speak ... a speaking elephant or an elephantine speaker could never be called an elephant. Professor Schleicher, though an enthusiastic admirer of Darwin, observed once jokingly, but not without a deep meaning, "If a pig were ever to say to me, 'I am a pig' it would *ipso facto* cease to be a pig."

Mueller thus raised for Darwin the problem for evolutionary theory raised 86 years later by Chomsky (1959) in his critique of Skinner's claim to have an explanation of language in operant principles derived form studies in the rat. The strong implication was that there were principles underlying language that were human-specific. The concept of universal

grammar as a defining human characteristic and of its generativity have implications for speciation theory. The question raised by Chomsky, as by Mueller, is: what is the nature of a species?

In the last chapter entitled 'Recapitulation and Conclusion' of *The Origin of Species by Means of Natural Selection*, Darwin had written:

> In the distant future I see open fields for far more important researches. Psychology will be based on a new foundation, that of the necessary acquirement of each mental power and capacity by gradation. Light will be thrown on the origin of man and his history.

The form of words – "that of the necessary acquirement of each mental power and capacity by gradation" – is of note because it clearly expresses Darwin's predilection for a gradualist account of the origin of human faculties along with other evolutionary innovations. The paradoxical point has been made that an issue on which *The Origin of Species* is weak is the origin of species. One figure appears in the book (chapter 4) to show how within one genus different varieties and species emerge over eons of time. The implication of the figure is that variation within species is qualitatively the same as variation between species, hence the absence of a clear differentiation of varieties and species.

In the same chapter Darwin wrote:

> Hereafter we shall be compelled to acknowledge that the only distinction between species and well-marked varieties is, that the latter are known, or believed, to be connected by intermediate gradations, whereas species were formerly thus connected.

His aim was to establish that species have a common origin, they are not the subjects of independent creations. Species can arise, subject to favorable environmental circumstance, out of the variation that is present in the natural world at any point in time. It is a gradualist theory. That gradualism was preserved into the evolutionary synthesis of the Darwinian theory of natural selection with Mendel's laws of genetic inheritance in the 1940s (Mayr and Provine, 1998).

The test comes in the application of the theory to actual speciation events. Such events are not generally observed, but somewhere in the figure, if it were to be applied to the case of humans, we must suppose there is a separation that leads on the one hand to the chimpanzee and bonobo and on the other to *Australopithecus*, *Homo erectus*, and modern *Homo sapiens*. The branch point and its sequelae is of theoretical and specific interest.

In 1863, T. H. Huxley addressed the question in *Man's Place in Nature*. He mounted a powerful case that on a series of anatomical comparisons the distance between humans and any one of the great apes was no greater than that between any pair of the great apes compared on their own. Huxley (1863) thus fit humans into the framework of the Darwinian theory of natural selection of which he was so powerful an advocate. But on the issue of speciation, he did not see eye to eye with his mentor. After the publication of *The Origin*, he wrote to Darwin that he was ready to go to the stake for the theory but added that he thought that Darwin had loaded himself with "an unnecessary difficulty in adopting *Natura non facit saltum* so unreservedly." Huxley was thus the first in a line of evolutionists including Bateson (1894), De Vries (1901), Goldschmidt (1940), and most recently Gould (2002), who have held that species transitions were more discontinuous, and the characteristics of species more stable, than appeared to follow from Darwin's formulation (see The Evolution of Language Systems in the Human Brain, The Interpreter in Human Psychology).

4.36.3 Darwin's Intuition on Sexual Selection

When Darwin (1871) addressed himself to the problem of human origins in *The Descent of Man* – this publication linked in a single volume *The Descent of Man and Selection in Relation to Sex* – the anatomical and paleontological case with Darwin's theory of sexual selection. In his introduction, Darwin writes that:

> During many years it has seemed to me highly probable that sexual selection has played an important part in differentiating the races of man; but in my *Origin of Species* I contented myself by merely alluding to this belief. When I came to apply this belief to man, I found it indispensable to treat the whole subject in full detail (Darwin, 1871, *The Descent of Man*, pp. 4–5).

Some passages in the second part of the book indicate that Darwin considered the two arguments to be related in a more fundamental way. Thus:

> . . .Sexual selection has apparently acted on both the male and the female side, causing the two sexes of man to differ in body and mind . . . [and] has indirectly influenced the progressive development of various bodily structures and of certain mental qualities. Courage, pugnacity, perseverance, strength and size of body . . . have all been indirectly gained by one sex or the other, through the influence of love or jealousy, through the appreciation of the beautiful in sound, color and form, and through the exertion of choice. . . (Darwin, 1871, *Selection in Relation to Sex*, p. 402).

Although Darwin believed that sexual selection and the descent of man are related, he nowhere specifies exactly how this is the case and the fact remains that these are separate books. Thus, on the one hand we have Charles Darwin committed to the

view that humans are descended from the great apes by the process of natural selection with a strong intuition that the ancillary process of sexual selection also has something to do with it but unable to integrate these processes. On the other hand, we have Friedrich Max Mueller complaining that language has characteristics that are present in the communicative abilities of no animal other than humans and that Darwin has given no account of its origins. The solution to this dispute that I have offered (Crow, 1998a, 1998b, 2000a, 2002a, 2002b, 2002c) is that the Darwinian gradualist account indeed has to give ground to a saltational version, as argued strongly for example by Goldschmidt and Gould. Speciation events have a reality that is obscured in *The Origin of Species*. But that there is a relationship between speciation and sexual selection, as Kaneshiro (1980) and Carson (1997), among others, have argued; species are distinguished by characteristics that are often sexually dimorphic. The possibility is that the first change in the process of speciation occurs in one sex, generally the male, and that this change is then subject to mate choice to define what Paterson has called a specific mate recognition system. My proposal is that changes on the sex chromosomes, including chromosomal rearrangements and subsequent epigenetic modifications of gene control, play a critical role in these transitions. This concept of the nature of speciation comes from a consideration of the problem that vexed Max Mueller – the origins of language and its relationship to the origin of humans – and its relevance to the central paradox of psychosis – the universal persistence in human populations of a genetic predisposition in the face of a biological disadvantage (Crow, 2000b).

4.36.4 Paul Broca and Cerebral Asymmetry

The key to the solution lies in the asymmetry or torque that appears to be characteristic of the human brain. After he had convinced himself (Broca, 1861) of the reality of the earlier observations of Marc Dax that language in the frontal lobes is localized on the left side, Broca (1877) came to the conclusion that:

> Man is, of all the animals, the one whose brain in the normal state is the most asymmetrical. He is also the one who possesses the most acquired faculties. Among these faculties ... the faculty of articulate language holds pride of place. It is this that distinguishes us most clearly from the animals.

While it is clear that there are directional asymmetries (e.g., of the habenular nucleus) that are ancient in vertebrate phylogeny, these are presumably unrelated to those expressed in the cortex that are associated with language. Such species specificity would have been no surprise to Broca (see Harrington, 1987, pp. 49–51, for his views on the essence of human nature), but the assumption that directional asymmetry on a population level is present in other primates, perhaps based upon Darwinian gradualist principles, has been widespread in the literature. Annett introduced a discussion of the issue in her earlier volume (Annett, 1985, pp. 169–173) with reference to the work of Finch (1941), who found no evidence of directional handedness in a group of 30 chimpanzees. Subsequent studies, for example, Annett and Annett (1991), of 31 lowland gorillas in European zoos and Byrne and Byrne (1991), of 38 mountain gorillas in Rwanda, have reinforced this conclusion. Recently, Marchant and McGrew (1996) systematically studied 42 chimpanzees in the Gombe National Park and reviewed the primate literature to conclude that "non-human primate hand function has not been shown to be lateralized at the species level – it is not the norm for any species, task, or setting, and so offers no easy model for the evolution of human handedness" (McGrew and Marchant, 1997; see also Holder, 1999 for congruent conclusions from a field survey of primates in Africa). Thus, we have evidence that a putative correlate of the capacity for language that Mueller and Chomsky identify as the defining characteristic of *H. sapiens* demonstrates a discontinuity in the primate phylogenetic tree (Figure 1).

Thus, at some point in the course of hominin evolution, the dimension of asymmetry was introduced in the sequence of brain development, and this dimension, or some modification of it, is the obvious correlate of language.

	Number of Individuals	Activities
Chimpanzee	38	46
Human	1960	75

Figure 1 Hand preference for everyday activities in chimpanzees and *H. sapiens* compared. Data for chimpanzees referred to a community of 38 animals (*Pan troglodytes schweinfurthii*) observed by Marchant and McGrew (1996). Data for *H. sapiens* were collected by questionnaire by populations of undergraduates by Provins *et al.* (1982). Medians and boundary values for 95% have been extracted from graphs in the original publications.

But why should the capacity for language be variable between individuals? Perhaps only when we understand the nature of the genetic mechanism will we have a clear answer (Crow, 2002c). The important point is that Broca's hypothesis – that language is lateralized in the brain – provides an indication of the neurophysiological basis and an approach to its pathophysiology.

Buxhoeveden *et al.* (2001) have recently documented the anatomical correlate of population bias to right-handedness. Through a statistical analysis of the minicolumn structure of the cerebral cortex, they have demonstrated asymmetries, for example, of minicolumn width and separation that are present in the planum temporale of human but absent in those of the chimpanzee and rhesus monkey.

4.36.5 The Torque and Related Asymmetries in Psychosis

The form of the asymmetry – from right frontal to left occipital, described as cerebral torque – has implications for function, as the anatomy has for pathophysiology. Aspects of anatomical asymmetry are deviant in individuals who suffer from psychosis (see Crow, 1990b, 1997; Petty, 1999; Esiri and Crow, 2002) and there is evidence from a study of handedness in childhood that they are lateralizing less, or more slowly (Crow *et al.*, 1996; Leask and Crow, 2005) than the population as a whole. In postmortem studies, the anatomical changes appear to be more posterior in the brain; losses or reversals of asymmetry have been detected in fusiform, parahippocampal (McDonald *et al.*, 2000), and superior temporal (Highley *et al.*, 1999b) gyri. A curious feature of these findings is that although the loss or reversal was present in both sexes, the relationship to age of onset was different: greater anomaly related to earlier age of onset in females but to later age of onset in males.

Other sex differences have been detected in postmortem brain. Density of fibers in the corpus callosum was greater in females than in males, consistent with the generalization that connectivity is inversely related to degree of asymmetry (Highley *et al.*, 1999a). In patients with psychosis, fiber density was reduced relative to female controls, while in males it was increased relative to male controls. Consistent with these findings in an magnetic resonance imaging (MRI) study (Highley *et al.*, 2003), white matter in the occipitotemporo-occipital regions was greater in females than in males, while in female patients it was reduced and in male patients increased relative to same sex controls.

Thus, there are morphological changes in the brain in psychosis that are sex-dependent and may relate to the sex difference in age of onset: onsets are earlier in males, and earlier onsets are generally associated with a poorer outcome and a preponderance of negative symptoms (affective flattening and poverty of speech). Conversely, with increasing age of onset the proportion of females increases and the form of the illness is more likely to be paranoid, i.e., delusional. This sex difference has been identified by two evolutionary theorists (Gould and Gould, 1989) as evidence that sexual selection operates in humans. This attractive argument encounters the difficulty that on a simple developmental interpretation, the sex difference is in the wrong direction: brain size (Kretschmann *et al.*, 1979) and verbal ability (Crow *et al.*, 1998) develop faster in females than in males, yet onset of psychosis is earlier in males (Figure 2).

A solution to this problem may unravel the evolution of the human brain. Some recent data are relevant. In a postmortem study (Chance *et al.*, 2006), planum temporale asymmetry of surface area to the left was found to be greater in males than females, consistent with the sex difference in the torque. But there was also an asymmetry of Heschl's gyrus (primary auditory cortex) and this, as has been found with the asymmetry of the paracingulate sulcus in the frontal lobes (Clark *et al.*, 2006) was greater in females. A possible generalization therefore is that the brain growth is faster and the plateau is earlier in females and that asymmetries, for example of primary sensory cortex, that are formed earlier are greater in females, whereas those, for example of posterior heteromodal association cortex that have the opportunity of developing longer, are greater in males.

The principle that interhemispheric connections are inversely related to degree of asymmetry together with the hypothesis that there is a relative loss of fibers in one direction (Witelson and Nowakowski, 1991) provides a possible solution to the age of onset paradox. Myelination continues into the third and fourth decades of life in the corpus callosum and apparently continues longer in females than males (Cowell *et al.*, 1992; Pujol *et al.*, 1993). This sex difference may reflect the longer time required in females to myelinate the larger body of interhemispheric axons. If we assume that the first symptoms of psychosis emerge as a consequence of some limit imposed on interhemispheric transmission by these late myelinations (for example, that those predisposed to psychosis fail to differentiate connections in the two directions), then owing to the faster myelinization, this may be apparent earlier in males. In

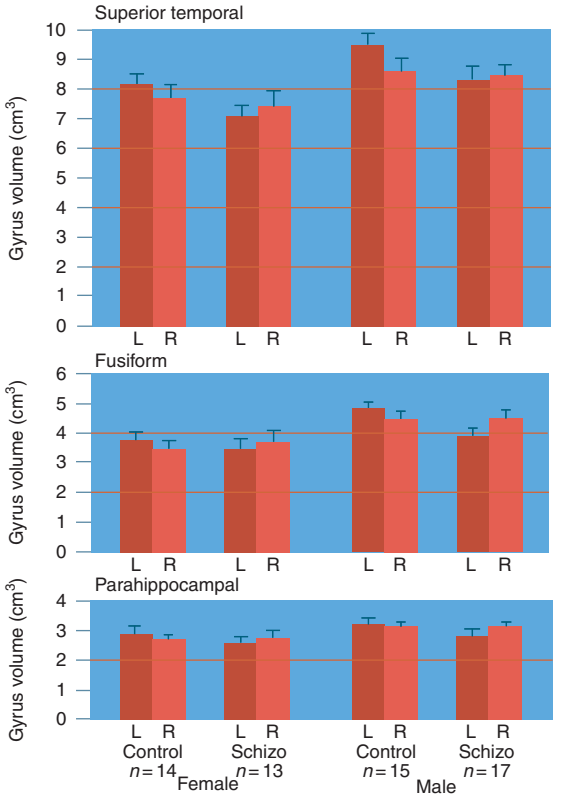

Figure 2 Volumes of cortical gyri (superior temporal, fusiform, parahippocampal) in patients with schizophrenia and controls assessed by stereology on postmortem brain. There are subtle asymmetries to the left in controls, and to the right in patients in each case. Reproduced from Esiri, M. M. and Crow, T. J. 2002. The neuropathology of psychiatric disorder. In: Greenfield's Neuropathology (*eds.* D. I. Graham and P. L. Lantos), 7th edn., vol. II, pp. 431–470. Arnold.

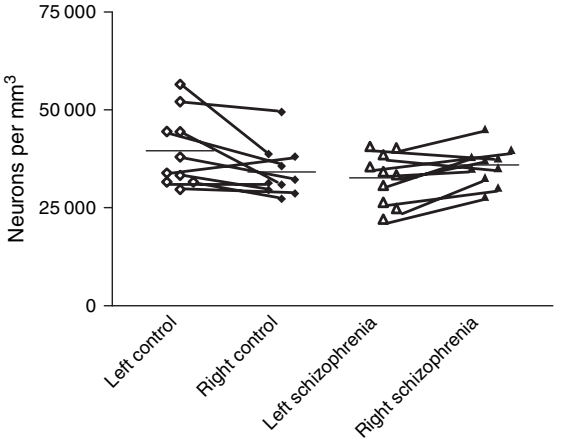

Figure 3 Pyramidal cell density in layer 3 of the left and right hemispheres of schizophrenic and control brains. An asymmetry to the left is present in controls and to the right in patients. Reproduced from Cullen, T. J., Walker, M. A., Eastwood, S. L., Esiri, M. M., Harrison, P. J., and Crow, T. J. 2006. Anomalies of asymmetry of pyramidal cell density and structure in dorsolateral prefrontal cortex in schizophrenia. *Br. J. Psychiatry* 188, 26–31, Elsevier.

this way, age of onset of psychosis may reveal to us the operation of sexual selection in humans in determining the limits of species-specific phenotypic variation (Crow, 1993, 1998a, 2002c) (Figure 3).

In frontal regions, no gross asymmetry and no change in gyral volume was detected in schizophrenia (Highley *et al.*, 2001), but in the density of cells in the cortex (in area 9) there was an asymmetry (greater cell density) to the left in controls and loss or reversal of this asymmetry in patients (Cullen *et al.*, 2006).

4.36.6 The Structure of Language and Its Decomposition in Psychosis

How are the symptoms to be explained? On the basis that the anatomical changes reflect an alteration in connectivity and that the asymmetry of the human brain (the torque) is the foundation of the faculty of language, one can construct a theory of nuclear symptoms – that these are primary disorders of the structure of language, and that they reveal its constituent elements and the way in which the elements are segregated within and relate to each other between the four quadrants of heteromodal association cortex.

4.36.6.1 The Linguistic Sign Is Bihemispheric

de Saussure (1916) maintained that the linguistic sign (the word) was characteristically bipartite,

comprising a signal (the sound pattern or phonological engram) and a signaled (the associated concept or meanings). The association between the sound pattern and its meanings, according to de Saussure, is arbitrary – any sound pattern can be associated with any concept or meaning (the first principle). This is what is distinctive about the human use of words and what makes language so flexible.

There is a two-way relationship between the components, with movement from the sound pattern to the meanings in speech reception, and from the concepts to sound patterns in speech production. One can ask, what is the neural basis of the separation of the two components? If asymmetry is what is characteristic of the human brain, it seems that there must be a relationship between specialization of function of the hemispheres and the feature that de Saussure identifies as the key to language. The most parsimonious hypothesis is that the components are (at least in part) segregated to the two hemispheres.

From Broca's observations, it is clear that what is localized in the hemisphere that is labeled as dominant is the phonological engram. It follows that some part of the signifieds must be assumed to be located in the nondominant hemisphere. For each phonological engram, there must be a corresponding engram – a mirror image – in the nondominant hemisphere, but one that is systematically transformed by the differing terminations of the interhemispheric connections in that hemisphere.

de Saussure's second principle is that speech is linear, 'just a ribbon of sound'. Allied to this is the notion that there must be a speaker and a hearer – speech is necessarily communicative – and the ribbon of sound is what travels between them (Figure 4).

One envisages therefore that speech is encoded, and this is a bihemispheric process, by the speaker from his concepts or thoughts into phonological engrams that are then transformed into the ribbon of sound, and that this is received by the hearer, and decoded into his own meanings or concepts, and that this decodification takes place partly by interhemispheric interactions. Communication depends upon the hearer sharing at least some of the speaker's signifier–signified associations, in other words, that they speak the same language.

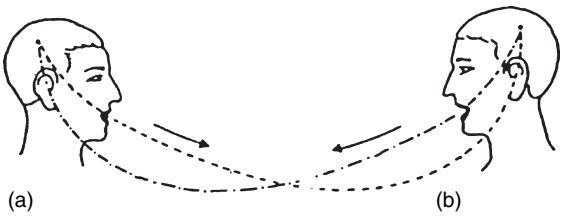

Figure 4 The relationship between the speaker and the hearer according to de Saussure (1916).

4.36.6.2 Deixis and the Significance of the Indexical

The system works well so long as the speaker refers to the world outside himself and the hearer. But a complication arises when he refers to himself. As Hurford (1992) points out, such a referral necessitates further decoding on the part of the hearer – that the 'I' that the speaker refers to, relates not to the 'I' of the hearer but to the 'you' (to him) of the speaker. This class of symbols – the indexicals – referring to the speaker or hearer belongs to the wider class of deictic symbols that include reference to the here of the present place and the now of the present moment in time.

The interest is that deixis – the necessity to define this class of symbols by pointing – has a special status in philosophy and in the structure of language. According to Buehler (1934), this triad of terms defining the present moment and the location and identity of the speaker is the coordinate origin around which language is structured – this place, at the present moment in time, defined by the 'I' of the speaker. Without this, language has no point of reference and loses its capacity to convey meaning.

The concept of the indexical also relates to the nature of psychotic symptoms. While it is true that there is no general misuse of the first person pronoun in individuals with psychosis, those with early-onset developmental disorders such as autism and Asperger's syndrome sometimes have difficulty in acquiring the distinction between the use of 'I' and 'you'. The more general significance arises in relation to Hurford's point that these symbols relate to what is self-generated in speech and what is other-generated – that there is a fundamental dichotomy between speech production and speech perception – and that this dichotomy can be understood in terms of the brain torque (Figure 5).

4.36.6.3 The Human Brain as a Four-Chambered Organ

It is often overlooked that the asymmetry of the human brain is not a simple left–right difference but a deviation across the fronto-occipital axis that transforms the human brain from the standard primate and vertebrate pattern of two-chambers (anterior and posterior corresponding to motor and sensory compartments) into a four-chambered organ in which motor and sensory compartments are distinguished on the left and the right sides. The torque has the effect of differentiating the two

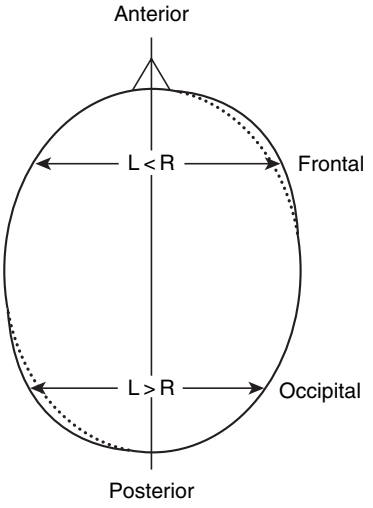

Figure 5 The Yakovlevian torque from right frontal to left occipital.

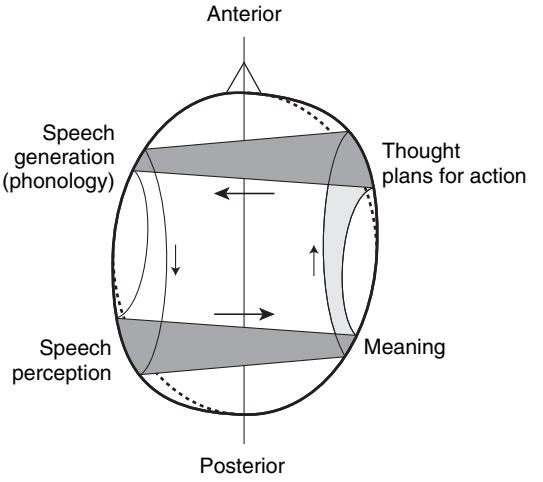

Figure 6 The implications of the torque for the relationship between the four areas of association cortex. Interhemispheric fibers can merge from right to left anteriorly and from left to right posteriorly. The figure also illustrates the segregation of function that has allowed the separation of thoughts from speech production and meaning from speech perception.

sides of the brain by influencing the relative surface area of the cerebral cortex, but it does so in different directions in the anterior (motor) and posterior (sensory) halves. It is a remarkable fact that the volumes of the two hemispheres are closely similar. What has changed relative to other primates is either the distribution of tissue between the two sides along the anteroposterior axis or perhaps even more subtly the sulcogyral folding of the cortical surface. The effect must be assumed to be that the distribution of interhemispheric connections differs on the two sides and it is this that allows the spread of neural activity to be systematically different on one side compared to the other. But the direction of the difference is opposite in the motor and sensory halves of the brain – converging from right to left anteriorly and from left to right posteriorly (Figure 6).

If the torque is what is characteristic of the human brain, these changes, and no others, are critical to the evolution of language. The interconnections between areas of heteromodal cortex have changed and these changes alone must account for what is characteristic of the capacity for language. Two features are suggested – the arbitrariness of the association between the signifier and the signifieds, the phonological engram and its meanings (de Saussure, 1916), and universal grammar, a mechanism that generates the structure of the sentence (Chomsky, 1988). But the striking fact about the evolution of language is that it occurred relatively abruptly, in the transition to modern *H. sapiens*, and all of a piece (Bickerton, 1990, 1995) along with the capacity for symbolic representation (Mellars, 2002). It does not make sense to suppose that there were two sequential innovations, each contributing a revolution to brain function. These two features must reflect different aspects of the same change and that change must be either the introduction of the torque or some modification of a torque that was introduced earlier in hominin evolution.

The key change is the separation of a phonological engram from its associations. The human cortex is not qualitatively different from that of the chimpanzee or any other primate. It must presumably have the same capacity to receive inputs and to transform them into outputs. What is different about the human brain is the interaction between areas of (particularly heteromodal) cortex on the two sides. Thus, if we assume that what is segregated in the dominant hemisphere is the phonological engram – a collection of simple but heavily interconnected motor sequences – this leaves open the possibility that each of these motor patterns has connections with engrams that are systematically different (either more diffuse or more restricted) in the nondominant hemisphere.

But here is the key consequence of the torque – whether the connections are more diffuse or more restricted depends upon whether they are in the motor or sensory halves of the brain. The convergences are in different directions in the anterior and posterior heteromodal association cortices, and this has an obvious implication for the organization of the capacity for language. Whatever transformation takes place from right to left in dorsolateral prefrontal cortex is reversed in sense in the transition from

left to right in occipitoparietotemporal cortex. This can be regarded as the first principle in the neural organization of language.

The second principle is that the sensory phonological engram is distinct from the motor engram. This must obviously be the case and these engrams are presumably located in Wernicke's and Broca's areas, respectively. But it is not so obvious that the form of the engram must be different – the motor engram can be relatively directly associated with motor neurones and with the output, but the sensory engram is one step removed from the acoustic input – word traces need to be filtered out from the totality of incoming sensory information.

Nonetheless, there is a relationship between the two. Words that are heard are recognized as related if not identical to those that are spoken. The form of the relationship presumably is what is established in the course of language acquisition. Conversely, some aspect of the distinction between the two is what is lost in the case of auditory hallucinations; what is clearly intrinsically generated (whether in the process of thought or in motor planning) has activated engrams that are normally accessible only to incoming acoustic stimuli. In this distinction, and in the association of the signifier and the signifieds, lies a solution to the conundrum of psychosis.

The four chambers of the human brain are the framework within which the problem can be solved, in the separation of the motor from the sensory by the central sulcus, and in the segregation of the signifier (the phonological engram) in its two forms in the dominant hemisphere from its primary associations in the nondominant, by the bias of the torque. The key to the solution is to specify the nature of the difference between what is motor and what is sensory and to identify what is intrinsic to the signifier and what is arbitrarily associated with it, on the one hand in its sensory form, and on the other in its motor configuration.

Speech is versatile – what has to be accounted for is the infinity of sentences that can be generated and the diversity of meanings that can be extracted, and the fact that these two processes are integrated with each other and yet separated in the brain.

The simplest approach is to assume that contiguous functions are dealt with in anatomically related areas. Thus, if the phonological engrams of the output are assembled in the association areas of cortex that are focused on Broca's area in the left hemisphere, one must assume that the processes that are related to this assembly, but differ from it in the crucial respect that they confer upon it its arbitrariness and flexibility, are located in the homologous regions in the right hemisphere. In functional terms, these engrams can be loosely referred to as 'thought', the precursor of, or the plans for, speech. It has a relationship to speech in that each element has an associated phonological engram in the left hemisphere, but it is not speech in that without the linear sequence that forms the output on the left, the association between elements is, to a certain degree, random and arbitrary. This presumably is related to the fact that each phonological engram on the left is associated with a number of less well-structured engrams on the right. The relationship from right to left is many-to-one.

In the parietotemporo-occipital junction association areas, the convergence is in the opposite direction. From the phonological engrams that have been extracted from the primary acoustic signal in the auditory association areas on the left, there is a convergence to a smaller area of homologous cortex on the right. Thus, the many-to-one transition in this case is from left to right, and the process of simplification may be identified as the distillation of 'meaning' from the linear sequence of phonology on the left.

According to this concept, the transition from thought to speech takes place from right to left in dorsolateral prefrontal cortex, and from perceived speech to meaning from left to right in parietotemporo-occipital association cortex. But what is the relationship between perceived 'meaning' and the 'thought' that is the plan for speech? Both are concepts or associations (signifieds) removed from the phonological engram, but one is sensory and one is motor. There is a connection between them and that connection is mediated by the uncinate and arcuate bundles in the right hemisphere. The patterns of activity in the right parietotemporo-occipital cortex is thus accessible to the thought processes in right dorsolateral prefrontal cortex, but the activities are distinct, and the distinction differs from that between the activity in the association cortices around Broca's and Wernicke's areas.

4.36.6.4 The Deictic Origin and the Performative Hypothesis

The key here is syntax – the ability to relate the self to the outside world – and to use words to do it. According to Buehler, as noted above, language is built around a coordinate framework with an origin in the self, the present location and the present moment in time defined by the deictic symbols 'I', 'here', and 'now'. Without this, language loses its structure. Language mediates the individual's relationship with the outside world and other individuals. In every linguistic interaction, there is

a speaker and a hearer, and sentences are the substance of the negotiation between them. The distinction between what is self- and what is other-generated and the meanings of these two classes of symbol is critical. This distinction clearly relates to the division between the motor and sensory association cortices in the right hemisphere.

The nuclear symptoms of schizophrenia tell us what happens when the distinction breaks down. Thought, the precursor of speech, loses its characteristic of independence from the outside world – thoughts are inserted into or removed from the individual's mind – while retaining the features of thought, they have lost the relationship to self-generated acts, which is a defining feature of thought as a precursor of speech. The obvious interpretation is that they are influenced by activity in posterior association cortex in a way that differs from the normal exchange between posterior and anterior regions. Conversely, auditory hallucinations such as thoughts spoken aloud or running commentary presumably represent self-generated neural activity (thoughts or plans for action) that activates phonological engrams (perhaps in the superior temporal cortex on the left side) that are normally activated by speech from another individual. In each case, there is a loss of the boundary in symbolic representation (words) between what is self- and what is other-generated. In each case, we can see that the boundary has something to do with what is anterior and what is posterior in association cortex. But we cannot suppose that what is abnormal is simply that some neural activity crosses this boundary. Activity must normally be transmitted between posterior and anterior along, for example, the arcuate and uncinate bundles. The problem is to specify what is normal and what is abnormal. The nature of nuclear symptoms is the clue that we have (Figure 7).

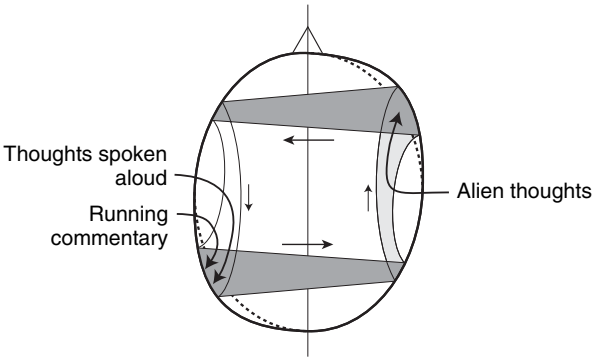

Figure 7 The origin of nuclear symptoms forging the concept of the compartmentation of language. According to this concept, symptoms arise because leakage occurs of neural activity normally segregated within one or more of the chambers.

The possibility must be considered that Buehler's formulation – that language is intrinsically organized around a deictic core – and the distinction between what is self- and what is other-generated that is illustrated by the nature of the nuclear symptoms are both necessary to a solution of the problem of syntax. In his thesis of *How to Do Things with Words*, Austin (1962) made the case that many uses of language are not simply to convey information but to have an effect, that is to say to bring about a state of affairs according to the speaker's intention. Such utterances Austin referred to as performatives to distinguish them from the constatives, the utterances, more usually the subject of linguistic and philosophic analyses, that convey information, generally about the external world. Later he generalized the concept of the performative into the notion that all utterances have an illocutionary force in the sense that they are formulated toward some objective of the speaker.

An interesting parallel to Austin's concept in the performative hypothesis has been formulated in different forms by a small number of theoretical linguists to account for certain features of the use of indexicals (symbols that refer to the speaker or hearer). Ross (1970) defines the theory as that declarative sentences (constatives) "must also be analysed as being implicit performatives, and must be derived from deep structures containing an explicitly represented performative main verb." Performative sentences, he says:

> . . . must have first person subjects and usually have second person direct or indirect objects in deep structure. They must be affirmative and non-negative, they must be in the present tense, and . . . their main verb must belong to the class that includes verbs such as advise, answer, ask, beg, command, declare, implore, inform, pronounce, say, write, in other words the class that designates the transmission of information, instructions, orders etc. The implication of the performative hypothesis is that the declarative sentence has an implicit (unstated) superordinate clause of the form "I say unto you . . ." in the first person and the present tense.

Austin's concept and the performative hypothesis bear a relationship to Buehler's notion of a deictic origin to the coordinate frame of language, and to de Saussure's insistence that language can only be understood in terms of the relationship between the speaker and the hearer. Without the deictic frame, Buehler insists the structure of language dissolves. This may be what happens in the case of thought disorder – the determining focus is lost. What the nuclear symptoms of schizophrenia are telling us is what happens when the distinction between the indexicals 'I' of the speaker and 'you' of the hearer begins to dissolve. If the performative hypothesis is

right, thus conceived they are disorders of the foundations of syntax. They tell us that the phonological engram for the perception of speech is quite separate from the phonological engram for speech production. They tell us that thoughts as the precursor to speech are distinct from the meanings that are extracted from perceived speech in the nondominant hemisphere. They draw attention to the obscure process of the motor and sensory elements of the associations (the signifieds) that takes place in the nondominant hemisphere (Mitchell and Crow, 2005). In each case, the phenomena of psychosis provide evidence on the neural organization of language through what happens when the mechanism goes wrong. We begin to understand this through the structure of the torque.

4.36.7 XY Homology and the Xq21.3/Yp Translocation

The most fundamental prediction of the asymmetry hypothesis is that the genetics of psychosis is the genetics of the speciation of *H. sapiens* (Crow, 2004); in other words, the genetics of asymmetry is conceived as the species-defining characteristic. To approach such predictions, it is necessary that the cerebral dominance gene or right shift factor be identified.

An important clue comes from sex chromosome aneuploidies. Individuals who lack an X chromosome (XO, Turner's syndrome) have nondominant hemisphere (spatial) deficits on cognitive testing. Individuals with an extra X (XXY, Klinefelter's and XXX syndromes) have verbal or dominant hemisphere deficits (Table 1). A possible explanation is that an asymmetry determinant is present on the X chromosome. But then the question arises of why males, who only have one X chromosome do not have spatial deficits such as are seen in Turner's syndrome. The answer must be that the copy of the gene on the X chromosome is complemented by a copy on the Y, i.e., that the gene is in the X–Y homologous class (Crow, 1993). A hormonal explanation will not account for the similarity of the changes in XXY individuals, who are male, and XXX individuals, who are female. The case that the gene is present also on the Y chromosome is strongly reinforced by the verbal deficits/delays that are observed in XYY individuals (Geerts *et al.*, 2003).

The hypothesis is further strengthened by evidence that Turner's and Klinefelter's syndrome individuals have corresponding deviations in anatomical asymmetry (Rezaie *et al.*, 2004) and by the demonstration of a same sex concordance effect – the tendency for handedness and sex to be associated above chance expectation – the hallmark of X–Y linkage (Corballis *et al.*, 1996). A role for an X–Y homologous gene is consistent with the presence of a sex difference – brain growth is faster (Kretschmann *et al.*, 1979) and lateralization is stronger (Crow et al., 1998) in females.

When we come to consider where such a gene might be located, there is an important lead. A major chromosomal rearrangement took place in the course of hominin evolution. Two regions on the human Y chromosome short arm share homology with a single region on the human X chromosome long arm (Xq21.3) (Page *et al.*, 1984; Lambson *et al.*, 1992; Sargent *et al.*, 1996). These homologies were created by the translocation of a 3.5 Mb contiguous block of sequences from a chimpanzee hominin precursor X chromosome to the Y chromosome short arm that was subsequently split by a paracentric inversion (by a recombination, presently undated, of LINE-1 elements (Schwartz *et al.*, 1998; Skaletsky *et al.*, 2003) to give two blocks of homology in Yp11.2 (Figure 8). Genes within this region are therefore present on both the X and Y chromosomes in *H. sapiens* but on the X alone in other great apes and primates, and an explanation for the retention of the sequences on Yp presumably lies in the gene content of this block.

Three genes are known to be expressed within this region; *PABPC5*, a poly (A) -binding protein whose Y gametologue has been lost during hominin evolution; *TGIF2LX* and *Y*, (homeobox-containing genes with testis-specific expression), and *ProtocadherinX* (*PCDH11X*) and *ProtocadherinY* (*PCDH11Y*). *PCDH11X* and *Y* (each comprising seven extracellular cadherin motifs, a short transmembrane region, and an intracellular cytoplasmic tail) that code for cell surface adhesion molecules of the cadherin

Table 1 Neuropsychological impairments associated with sex chromosome aneuploidies

	XX	*XY*	*XO*	*XXY*		
	Normal female	*Normal male*	*Turner's syndrome*	*Klinefelter's syndrome*	*XXX*	*XYY*
No. of sex chromosomes	2	2	1	3	3	3
Verbal ability	Normal	Normal	Normal	Delayed	Delayed	Delayed
Spatial ability	Normal	Normal	Decreased	Normal	Normal	Normal

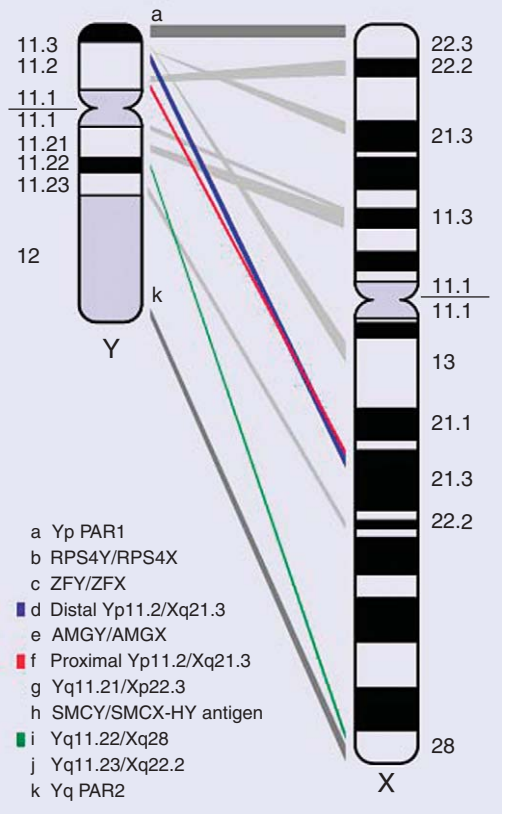

Figure 8 The regions of homology between the X and the Y chromosomes including PAR1 at the telomeres of the short arms and PAR2 at the telomeres of the long arms. Blocks of homology are labeled from a to k on the Y chromosome. Some blocks are identified by their gene content, e.g., RPS4Y/RSP4X, AMGY/AMGX, SMCY/SMCX. Reproduced from Affara, N., Bishop, C., Brown, W., *et al.* 1996. Report on the second international workshop on Y chromosome mapping 1995. *Cytogenet. Cell Genet.* 73, 33–76, Elsevier.

superfamily are of note because both forms of the gene have been retained and are highly expressed both in fetal and adult brain (Yoshida and Sugano 1999; Blanco *et al.*, 2000), including the germinal layer of the cortex (T. H. Priddle, personal communication). The protein products of this gene pair are thus expected to play a role in intercellular communication, perhaps acting as axonal guidance factors and influencing the connectivity of the cerebral cortex. These genes may thus have been subject to selective pressure relating to one or more brain characteristics during hominin evolution.

4.36.8 Implications for Evolutionary Theory

4.36.8.1 The Case for Saltation

To take seriously a structural discontinuity as an explanation for a species difference, it is necessary to consider concepts of evolutionary change other than Darwinian gradualism and the biological or isolation species concept.

The theory of punctuated equilibria (Eldredge and Gould, 1972) was preceded by a long history of challenges to the gradualist version (Bateson, 1894; De Vries, 1901; Goldschmidt, 1940), and some of these have had an explicit genetic basis. Thus, White (1978) and King (1993) have argued strongly for a role for chromosomal change in speciation, but their arguments have not overwhelmed the established view. Against chromosomal change, it is argued (e.g., Coyne and Orr, 1998) that radical rearrangements, for example chromosomal fusions, may apparently have few phenotypic effects, and in some cases alternative chromosomal configurations persist, as it were, as a polymorphism within a species.

The case for saltation in species transitions has been argued at a macroevolutionary level (Stanley, 1998), stating that the amounts of change seen within species and other taxa are simply insufficient to account for the overall pattern of evolutionary change that is seen over time, and at the level of morphology (Mellars, 1998), claiming that the intermediate states in the transition between species that are required by the gradualist theory are absent. But all such general arguments come up against the difficulty that Goldschmidt's (1940) hopeful monster ran into: the greater the magnitude of the saltational change, the less likely it is to have survival value, and the greater the difficulty the hopeful monster will have in identifying a mate. The difficulty is particularly great if the change has the reproductive consequence of reducing fertility in the hybrid state. The possibility that the monster can identify an individual with the same mutation is clearly dependent on reproduction already having taken place, and even then the new mutation is at a severe statistical disadvantage with respect to the existing population.

4.36.8.2 Sexual Selection and the Mate Recognition Principle

However, here Darwin's (1871) juxtaposition of *The Descent of Man* and the theory of sexual selection offers a way out. If sexual selection and speciation were in some way interdependent this might solve the problem of discontinuity and that of mate selection. The case of cerebral lateralization in modern *H. sapiens* illustrates the possibility. All authorities on the genetics of lateralization (Annett, 1985, 2002; McManus, 1985; Corballis, 1997; Crow, 1998a, 1998b; Mckeever, 2000) agree that there is a sex difference: females are more

right-handed than males (although the adult male brain is more asymmetrical than that of the female; Bear *et al.*, 1986; Barrick *et al.*, 2001). The female brain grows faster than that of the male (Kretschmann *et al.*, 1979) and females have greater mean verbal fluency and acquire words earlier (Maccoby and Jacklin, 1975; McGlone, 1980; Halpern, 2000) than males. If language is the species-defining characteristic and lateralization is the process by which it evolved, these facts are related, and they tell us about the nature of the genetic mechanism. Only two explanations of the sex difference in lateralization are conceivable, that it is hormonal in origin (Geschwind and Galaburda, 1985) or that it reflects a sex chromosomal locus (Crow, 1993, 1994), and the facts of sex chromosomal aneuploidies (XXY and XXX individuals who differ in hormonal status have similar hemispheric deviations in development) speak decisively in favor of the latter interpretation. The hypothesis that the asymmetry factor is present on both X and Y chromosomes (Crow, 1993; Corballis *et al.*, 1996) can explain the transmission of handedness within families and apparent dosage effects in the aneuploidies. That there are problems (Corballis, 1997) in accounting for persisting variation in males and females in terms of conventional polymorphisms and heterozygote advantage explanations should not dissuade us from pursuing the line of thought. The genetic principles involved may not be those on which we have hitherto relied.

The paradigm of *H. sapiens* therefore suggests a new version of saltational speciation – that it is not chromosomal changes in general that play a role in speciation but changes on the sex chromosomes, and perhaps particularly changes in regions of X–Y homology that are involved. These regions have a special status because they can account (as in the case of lateralization in humans) for quantitative differences in a characteristic in males and females, and such quantitative differences are a potential substrate for sexual selection. The Y chromosome itself has a unique role, because it is not necessary for survival. There are interindividual differences on the Y (reviewed by Tyler-Smith, 2002), but there are also large interspecific differences. While the X is the most stable chromosome across species, the Y is by far the most variable.

The mammalian Y therefore can be seen as a testbed of evolutionary change. One possibility is that the primary change in speciation takes place on the Y, and when it is located in a region of homology with the X, there is the possibility of correlated but independent change in the two sexes. Such correlated but quantitatively differing ranges of variation have the potential to explain the type of runaway sexual selection envisaged by Fisher (1930), and this may be what occurred with respect to cerebral asymmetry at some point in hominin evolution (Crow, 1998a, 1998b); the introduction of the dimension of symmetry–asymmetry allowed brain growth to equilibrate at a new point of plateau, and this equilibration took place around successive modifications of genes on the Y and then on the X chromosome. There is thus a potential three-way relationship between sexual selection, sex linkage, and speciation, and the pattern suggested by hominin evolution is backed up in the recent literature relating to other species.

A role for sexual selection in modifying a primary change in a sexually dimorphic feature to establish a new species boundary has been argued in relation to Hawaiian Drosophilid species by Kaneshiro (1980) and Carson (1997). Similar arguments apply in the case of the prolific speciation of cichlid fishes in the lakes of East Africa (Dominey, 1984; McKaye, 1991) and may also apply in birds (Price, 1998). Some putative speciation loci, for example, the Odysseus homoeobox (Ting *et al.*, 1998) and the *per* gene (Ritchie and Kyriacou, 1994) that have been identified in *Drosophila* species, are X-linked. In discussing the relationship between the X chromosome and speciation that she finds in Lepidoptera, Prowell (1998) offers three explanations: (1) that X-linked traits evolve more quickly, (2) that traits related to speciation tend to be sex-limited, and that sex-limited traits tend to be on the sex chromosomes, and (3) that female-limited X-linked traits undergo faster rates of evolution when, as in the case of Lepidoptera, the female is heterogametic. These explanations are not mutually exclusive. Prowell asks whether the X chromosome bias is unique to Lepidoptera and concludes that this is unlikely. Haldane's rule is that when, in a species hybrid, one sex is sterile or inviable it is the heterogametic sex. Coyne and Orr (1998) consider various explanations, including faster evolution and recessivity of genes on the X chromosome. While each of these observations and hypotheses is consistent with a relationship between speciation and the sex chromosomes, none of the authors considers the more restrictive formulation suggested by the sequence of events (Sargent *et al.*, 1996, 2001, 2002) on the mammalian Y chromosome, that it is the interaction between the sex chromosomes, particularly the possibility of transfer of material between them, that is critical in speciation.

4.36.8.3 Species-Specific Variation Is Epigenetic

Reinhold considers the case that sexual selection acts selectively on sexual dimorphisms that relate

to sex-linked genes, as suggested by Rice (1984). The sequence of events, including a translocation and a paracentric inversion, suggested by the work summarized by Sargent *et al.* (2002) and by the X–Y hypothesis as relevant to the course of hominin evolution, carries the further implication that epigenetic modification is involved in the process of sexual selection and speciation. In mammals, genes on one X chromosome are subject to the process of X inactivation, but gene sequences that are also represented on the Y chromosome are protected from this influence. Such genes are expressed from both X and Y in males and from both Xs in females, a similar dosage thus being maintained in each sex. The mechanism by which this protection is achieved is unknown (Burgoyne and McLaren, 1985; Crow, 1991). Gene sequences that have been transferred from the X to the Y are in a new situation; whatever the mechanism, a phase of epigenetic equilibration must be assumed (Jegalian and Page, 1998). If X–Y pairing in male meiosis plays a role, the orientation of the sequence on the Y is also relevant. The paracentric inversion on the Y short arm could be critical.

An MRI investigation in monozygotic twins of handedness and asymmetry of the planum temporale (Steinmetz *et al.*, 1995) indicates that there is room for an epigenetic influence on cerebral asymmetry, and this may account for the stochastic element incorporated in genetic theories (Annett, 1985, 2002; McManus, 1985). There is a possibility, therefore, that the genetic mechanisms underlying the development of cerebral asymmetry in humans are a paradigm for a more general interaction between genetic and epigenetic mechanisms in sexual selection and speciation. Perhaps sexual selection and natural selection are mediated by distinct but complementary genetic processes: natural selection ensures the organism's survival through response of any part of the genome to environmental change, whereas sexual selection reflects the sequential response of the female genome (for example, the mammalian XX complement) to change on the Y chromosome, and that this process involves particularly the epigenetic modulation of genes on the X. According to this concept, speciation follows the history of the nonrecombining sex chromosome, in mammals the Y.

4.36.8.4 Speciation Events Occur on the Heterogametic Chromosome

Birdsong has relevance to the genetics of species-specific characteristics (see The Evolution of Vocal Learning Systems in Birds, The Evolution of Vocal Learning Systems in Birds and Humans). The neural capacity is lateralized, season-dependent, and strongly sexually dimorphic, being generally confined to males. The lateralization is a parallel and independent evolutionary development to the cerebral torque of the human brain, such lateralization being absent in intervening vertebrate families such as rodents and primates, and the neural mechanisms are quite distinct. But the individual songs of birds, like the capacity for human language, are species-specific. In that they are a component of mating behavior, they can be regarded as specific mate recognition systems as described by Paterson. Whereas there are elements, for example the season-dependence that is hormone-sensitive, there are also components that are determined by genes and these are located on the Z and W chromosomes (Arnold, 2004). The hormone-sensitive elements are generally those that cross species, whereas the components that are species-specific are mostly genetically determined. Thus, there is the possibility that the species-defining characteristic in song birds, which can reasonably be described as the mate recognition system, is dependent upon genes present on both Z and W chromosomes. Moreover, it appears that the differences between species in this salient characteristic must be determined by genetic differences at the relevant loci on the sex chromosomes.

This theory attributes general significance to X–Y (or W–Z) homologous genes in relation to a mate recognition system in Paterson's sense, and thereby accommodates the role for an X–Y homologous determinant of cerebral asymmetry and language in humans, as suggested above. Perhaps one can propose that it is events on the heterogametic chromosome (the Y in mammals) that have particular significance in relation to speciation, and that it is the interaction between those sequences on the Y that have changed and the pre-existing sequences on the X that is of particular interest. For while the X is remarkably stable in structure across species (the gross structure of the mouse X closely resembling that of the chromosome in humans) the structure of the Y is highly variable even between quite closely related species.

Thus, one can postulate that the primary change in speciation takes place on the Y (more generally the heterogametic chromosome), and the subsequent changes on the X establish the stable sexual dimorphisms that distinguish species.

Ellegren has pointed to a possible molecular correlate of such a sequence. Considered in relation to the rest of the genome and when relative population size in terms of the two sexes is taken into account, the genetic variation on the heterogametic chromosome (the Y in mammals, the W in birds) is

considerably less than would be expected. The reduction in polymorphic loci may reflect a selective sweep at the origin of the species.

The hypothesis emerges that the primary event that leads to a new species is a change (maybe a duplicative translocation as in the hominin lineage, but deletions or insertions are also possible) that occurs on the heterogametic chromosome. The change occurs in one individual (a male in mammals, a female in birds) that represents the rare case in which such a chromosomal change is associated with a reproductive advantage in that such individuals are preferentially selected as mates. Thus, the new chromosome increases in frequency in the population along with its associated phenotypic innovation, but in the first generation is confined to the heterogametic sex. But in the next generation there is the possibility that there will be an impact on the homogametic chromosome because the altered structure of the Y (or the W) has the potential to influence the epigenetic status of the X (or the Z) because regions of the sex chromosomes that are paired are protected from the process of inactivation (meiotic suppression of unpaired DNA) that otherwise leads to the inactivation of one of the two Xs or Zs in the daughters or sons, respectively, of the founder individual and his or her immediate same sex progeny.

Such epigenetic change will be particularly relevant if the primary change occurs in or generates a region of X/Y (or Z/W) homology. Thus, homologies may perhaps be preferentially selected by the speciation process. If the primary event occurs within the nonrecombining region of the heterogametic chromosome (the mammalian Y or the avian W), this allows genes relating to the speciation characteristic 'and its homogametic homologue and related genes' to undergo sequence variation that is independent in the two sexes. The variability in this genetic process could account for the diversity of sexual dimorphisms across species.

These proposals deriving from the case of hominin evolution bear a relationship to concepts of speciation in *Drosophila* developed by R. S. Singh and colleagues as well as to the literature on sexual selection and speciation referred to above. Civetta and Singh (1999) distinguished between sex-related and non-sex-related genes and found a higher rate of Ka/Ks ratios among the former. They suggested that directional sexual selection had shaped the evolution of sex-related genes (defined in a broad sense to include all components of sexuality not confined to courtship and mating) and that these changes were more likely to have occurred in the early stages of speciation. Developing these ideas, Singh and Kulathinal (2005) emphasize the rapid evolution of sex-related traits in a wide variety of taxa, the faster rate of DNA sequence divergence in genes affecting sexual function and fertility, and the evidence for involvement of novel traits and genes in sexual function.

4.36.9 Conclusions

1. Language and the paradox of psychosis:
   - The faculty of language as a defining feature of *H. sapiens* with characteristics absent in the communicative systems of the great apes challenges Darwinian gradualism. It is more readily assimilated to a saltational account of speciation as suggested by T. H. Huxley and developed by R. Goldschmidt.
   - The paradox is that interindividual variation apparently genetic in origin persists at approximately the same frequency in all populations in the face of a fecundity disadvantage.
   - This variation represents a component of variation associated with the capacity for language; it is argued that the phenomena of psychosis are the key to an understanding of the neural organization of language. Thus, psychosis and language have a common evolutionary origin in the speciation event.
2. The cerebral torque and its implications:
   - Broca's hypothesis that cerebral asymmetry is the characteristic that defines *H. sapiens* is supported by recent cross-species comparisons for directional handedness and anatomical asymmetry.
   - The cerebral torque (the bias from right frontal to left occipital across the anteroposterior axis) defines the human brain as a four-chambered organ by comparison with the two chambers (anterior motor and posterior sensory) of the brains of other primates, and dictates a reversal of sign of the convergence of interhemispheric connections (from left to right posteriorly and from right to left anteriorly).
3. The quadripartite structure of language:
   - These transitions are critical to the separation of the sensory and motor phonological engrams in the dominant left hemisphere from some of their associated signifiers (the sensory meanings and the motor thoughts) in the nondominant hemisphere.
   - Critical to the distinction between the speaker and the hearer and to what is motor and what is sensory in the neural representation of speech is the notion (Buehler's) of a deictic origin ('I',

'here', 'now') to the coordinate system of language.
- The nuclear symptoms of schizophrenia (e.g., thoughts spoken aloud, running commentary, thought insertion) are seen as the ectopic presence (leakage) of one or more of the components of language outside the relevant compartment of association cortex.
- The deictic origin is located in Broca's area and defined by its interaction through the uncinate and arcuate bundles with Wernicke's area.

4. The genetic basis of the speciation event:
   - There is a strong case from the phenomena of sex chromosome aneuploidies and a family study of handedness that the cerebral dominance gene is in a region of homology between X and Y chromosomes.
   - A duplicative translocation 6 Mya created a *sapiens*-specific region of homology between Xq21.3 and Yp11, within which there have been subsequent rearrangements including a paracentric inversion.
   - Within the region of homology, the *ProtocadherinXY* gene pair coding for cell surface adhesion proteins has been subject to accelerated evolution.
5. Implications for evolutionary theory:
   - The sequence of events in the speciation of *H. sapiens* was saltational in form. It suggests the general theory of speciation that rearrangements on the heterogametic chromosome play a role by initiating a phase of sexual selection that, on account of sequences shared between the sex chromosomes, involves related characteristics in the two sexes. The interaction establishes a mate recognition system (in Paterson's sense) that defines the new species.
