I have seen lower respiratory tract complications develop in three children receiving steroid treatment for croup. In one case, an adenoviral pneumonia worsened, and in the other cases, bacterial tracheitis with pneumonia occurred. In these three cases, they all received corticosteroid treatment over the course of several days and not single-dose treatment. In the study of Super and colleagues,[207] two steroid-treated patients developed pneumonia during therapy; none of the control subjects developed pneumonia. In a more recent trial in which 28 children received nebulized dexamethasone, two children with neutropenia developed bacterial tracheitis.[108] Burton and associates[23] reported the occurrence of *Candida* laryngotracheitis as a complication of corticosteroid and antibiotic treatment in a child with croup, and Myers and colleagues[159] reported an infant who developed multiple pulmonary abscesses caused by *Legionella pneumophila* after receiving prolonged corticosteroid treatment of severe croup.

Today, the standard of care for the initial treatment of laryngotracheitis and spasmodic croup is the use of corticosteroids administered orally, intramuscularly, or by nebulization.[3,14,70] Recommended therapy is a single dose of intramuscular or oral dexamethasone. The limited use of nebulized budesonide also is effective. In the most definitive study, the treatment dose was dexamethasone (0.6 mg/kg) given orally once.[13] In a subsequent review, Bjornson and Johnson[14] noted that the standard dose of dexamethasone is 0.6 mg/kg (oral or intramuscular); they suggested that oral is preferable because absorption is excellent, and peak serum concentrations are achieved as rapidly as with intramuscular administration.

As noted earlier, I and others have observed bacterial and fungal infections as complications in children who have received multiple doses of steroids in croup. It is disturbing to me to note that in pediatric practice many children are receiving 3- to 5-day treatment courses rather than the recommended single-dose schedule. The data from the cotton rat model of human parainfluenza virus type 3 laryngotracheitis provides strong evidence supporting the limited use of steroids in croup.[168] In this model, topical steroid therapy significantly reduced the degree of inflammatory infiltrates and cell damage. The steroid therapy increased the virus load but did not prolong virus shedding.

I believe the most dramatic evidence supporting the use of steroid therapy in laryngotracheitis and spasmodic croup is the marked decrease in the number of hospitalizations for croup in Ontario, which coincided with the 1992 recommendation by the Canadian Pediatrics Society to use dexamethasone for treatment.[103,194] Steroids should not be used in laryngotracheobronchitis, laryngotracheobronchopneumonitis, or epiglottitis.

Because laryngotracheitis is a disease of viral etiology, what seems apparent is that antibiotic therapy would not be indicated and consequently not employed. In our analysis of more than 200 hospitalized children with laryngotracheitis, we noted that antibiotics had been administered to 85 percent.[75] A review of the records in many instances revealed that the physician had given antibiotic therapy because the possibility of epiglottitis had not been ruled out adequately. In several instances, the epiglottis had been observed and thought to be reddened or questionably enlarged.

A second consideration with regard to antibiotic therapy in croup is that the most dramatic reduction in mortality rates coincides with the introduction and widespread use of antibiotics. In my opinion, many of the deaths attributed to croup in the preantibiotic era were caused by secondary bacterial infections. Although use of antibiotics contributed to the reduction in the number of deaths caused by croup, other factors may be important. At about the same time that antibiotics were introduced, disease caused by *S. pyogenes* decreased in incidence and severity. Reasons for the decreased frequency of streptococcal disease were not clear.

Most patients with laryngotracheitis today do not need antibiotic therapy. In severe cases in which bacterial sepsis cannot be ruled out, however, antibiotic therapy should be employed. The pathogens to consider include pneumococci, group A streptococci, *S. aureus*, and *H. influenzae*. In patients with laryngotracheitis in whom fever persists or signs change, secondary infection should be considered. In these instances, appropriate culture specimens should be obtained before therapy is initiated (see the section on laryngotracheobronchitis for specific antibiotic therapy).

The use of nebulized racemic epinephrine, which was introduced by Jordan[112] in 1966 and popularized by Jordan and other members of the Utah group,[1,113] has been adopted widely throughout the United States and elsewhere.[118,131,138,152,189,196] The usual method of nebulization of racemic epinephrine is by intermittent positive-pressure breathing. This form of therapy was associated with a marked reduction in tracheostomies in several series.

In 1973, Gardner and associates[76] performed the first double-blind, controlled study in which racemic epinephrine was nebulized by a compressor without intermittent positive-pressure breathing. They found that saline-treated patients responded as well to therapy as did the racemic epinephrine recipients. In retrospect, this study can be criticized because the investigators failed to differentiate spasmodic croup from laryngotracheitis. In 1975, Taussig and associates[214] reported a small but carefully conducted study with intermittent positive-pressure breathing and racemic epinephrine in which they noted acute improvement in all cases, recurrence of symptoms in 2 hours, and no change in partial pressure of oxygen with clinical improvement; 24 to 36 hours after therapy, treated and untreated children were clinically similar. In another significant study that involved children hospitalized with severe croup without improvement after admission to a high-humidity mist room, Westley and colleagues[233] showed that racemic epinephrine therapy caused definite short-term improvement in children compared with saline treatment. This study is particularly important because a parainfluenza viral etiology was documented in more than 65 percent of the study's subjects, and all cases were clearly laryngotracheitis and not spasmodic croup.

The following points can be made about the use of racemic epinephrine in the treatment of croup: (1) Many children with croup respond to moist air alone; (2) significant rebound occurs after racemic epinephrine therapy, so it frequently needs to be repeated many times; (3) in a hospitalized child with severe acute

*See references 14, 26, 37, 57, 70, 71, 79, 121, 142, 186, 216.
†See references 3, 13, 14, 44, 51, 52, 70, 71, 84, 86, 103, 106, 107, 121-123, 125, 186, 187, 216.

laryngotracheitis, racemic epinephrine should be used. Tracheotomy or endotracheal intubation can be prevented in some cases. The most important issue today regarding the use of racemic epinephrine is whether it can be used safely for outpatient therapy.[40,117,178] In the past, most experts advised against the use of racemic epinephrine in the outpatient setting because of the known rebound that occurs. Some data suggest that with careful observation for a sufficient period (at least 2 hours) after administration, patients can be managed safely, and the number of hospitalizations can be decreased.[40,117,178] In a small study, investigators found that the administration of a helium-oxygen mixture (heliox) resulted in improvement in children with croup similar to that with racemic epinephrine treatment.[228]

The establishment of a mechanical airway seldom is necessary today in patients with laryngotracheitis. The planned procedure has a better outcome than does the procedure performed under emergency conditions. Traditionally, tracheostomy was the preferred method when a mechanical airway was needed.[7,74,240] When careful attention is given to tube size and other aspects of placement and maintenance, however, nasotracheal intubation compares favorably with tracheostomy.[7,240] The management of a child with a mechanical airway requires trained pediatric intensive care physicians and the facilities of an adequately staffed intensive care unit.

Five antiviral drugs have activity against viruses that cause laryngotracheitis.[88,105,146,212,234] Amantadine and rimantadine are approved for use in treating influenza A viral infections, and ribavirin is active against parainfluenza viruses, influenza A and B viruses, and respiratory syncytial virus (see Chapters 251 and 190). The neuraminidase inhibitors, zanamivir and oseltamivir, are active against influenza A and B types.[25,41] At present, consideration of therapy for severe croup that occurs during documented epidemics caused by influenza A or B viruses would seem reasonable. Because of high levels of resistance of influenza A strains to amantadine and rimantadine, treatment with the neuraminidase inhibitors is recommended.[25]

LARYNGOTRACHEOBRONCHITIS AND LARYNGOTRACHEOBRONCHOPNEUMONITIS (BACTERIAL TRACHEITIS)

Generally, all the treatment considerations discussed for laryngotracheitis except corticosteroids and racemic epinephrine by aerosol apply to laryngotracheobronchitis and laryngotracheobronchopneumonitis. Most important, however, because most patients have bacterial disease, antibiotics should be administered to all patients after appropriate culture specimens are obtained. Empiric therapy should be directed against *S. aureus*, *S. pyogenes*, *S. pneumoniae*, and *H. influenzae*. At present, initial treatment with vancomycin (40 mg/kg/day intravenously every 6 hours) and a third-generation cephalosporin, such as cefotaxime (150 mg/kg/day every 6 hours intravenously), is reasonable. If methacillin-sensitive *S. aureus* is isolated, treatment should be changed to oxacillin (150 mg/kg/day every 6 hours intravenously) or a similar agent.

Most children with advanced laryngotracheobronchitis or laryngotracheobronchopneumonitis need the placement of a mechanical airway. Whenever possible, this procedure should be done electively rather than as an emergency.

LARYNGITIS

Patients with laryngitis should rest their voices as much as possible. Increased fluid intake and perhaps the use of a vaporizer may help liquefy secretions and might provide symptomatic relief. Because group A streptococcal infection is a cause of laryngitis, culture should be performed. If it is positive, penicillin or a suitable alternative antimicrobial agent should be administered. In children and adolescents with prolonged hoarseness, sinusitis should be considered. Radiographs of the sinuses and a quantitative culture from the nose should be performed in search of a predominant abnormal bacterial flora. If either is positive, therapy with appropriate antibiotics is indicated. If laryngeal symptoms are persistent, the child should undergo laryngoscopic examination and other appropriate studies to exclude tumor, foreign body, and other chronic diseases.

PROGNOSIS

The prognosis of acute laryngotracheitis has improved markedly during the last 50 years. Today, a child with croup only rarely requires a mechanical airway, and virtually all deaths should be preventable. The child should be observed for the following complications: hypoxemia and cardiorespiratory failure, pulmonary edema, pneumothorax and pneumomediastinum, mechanical problems caused by tracheotomies and nasotracheal tubes, and secondary bacterial infections. Children with a history of croup have a higher prevalence of increased bronchial reactivity than children without such history.[87,141,229]

PREVENTION

At present, acute laryngotracheitis is not preventable. The widespread use of influenza vaccines could reduce the incidence of croup caused by influenza A and B viruses.

Lower Respiratory Tract Infections

CHAPTER 23

Acute Bronchitis

James D. Cherry

Bronchitis is a common diagnosis in pediatric practice, although little unanimity exists among physicians regarding its exact clinical constellation, and in the true pathologic sense, it probably never occurs as an isolated entity. Acute bronchitis is a febrile illness with cough, rhonchi, and referred breath sounds.[15] Asthmatic bronchitis (infectious asthma), similar to acute bronchitis, but with associated wheezing and expiratory distress, is discussed in Chapter 25. On pathologic examination, the clinical illness of acute bronchitis reflects acute inflammatory disease of the larger air passages, including the trachea and the large and medium-sized bronchi.[25]

ETIOLOGY

Table 23–1 lists various infectious agents associated with acute bronchitis. Infections with adenoviruses, influenza viruses, parainfluenza viruses, respiratory syncytial virus, and *Mycoplasma pneumoniae* account for most cases of acute bronchitis in children. These agents, plus many rhinoviruses, a few enteroviruses, and perhaps human metapneumovirus, human bocavirus, and the newer human coronaviruses, account for virtually all cases in the United States today.

Of the adenoviruses, type 7 has been associated most commonly with acute bronchitis in children. In military recruits, including adolescents, adenovirus types 4 and 7 cause epidemic acute respiratory disease, in which bronchitis is a usual occurrence.[22,64]

Influenza A virus infection is a common cause of severe acute bronchitis, particularly at the time of antigenic shift of influenza A virus subtype and pandemic disease. Acute bronchitis caused by influenza A virus also is a regular occurrence between pandemics in new susceptible individuals (young children) in the population. Influenza B virus also is an important cause of bronchitis, and it was a more common causative agent than was influenza A virus in one large longitudinal study.[13]

All cases of measles involve the bronchi, but measles has been an uncommon occurrence since the advent of widespread use of vaccines. Of the parainfluenza viruses, type 3 is associated most commonly with acute bronchitis. Respiratory syncytial virus is a common cause of acute bronchitis, particularly in very young children. The more recently identified human metapneumovirus is another cause of acute bronchitis.[57]

Of the bacterial agents listed in Table 23–1, only *Haemophilus influenzae* clearly can be incriminated. *Bordetella pertussis* infection involves the trachea and bronchi, but fever is an uncommon event, and the illness is outside the definition of acute bronchitis. When sought, *M. pneumoniae* is a common cause of bronchitis. *Chlamydia pneumoniae* has been found to be the cause of bronchitis in adolescents and young adults.[32]

EPIDEMIOLOGY

The epidemiology of the common viruses that are associated with bronchitis is presented in Section XVII. Chapman and associates[13] published the results of a study of acute bronchitis in a single private group pediatric practice in Chapel Hill, North Carolina. The study occurred during a 104-month period, during which 5489 episodes of lower respiratory illness occurred. Of these illnesses, 40.1 percent were acute bronchitis. The bronchitis attack rate was highest in children in the second year of life (6.71%), and then it decreased gradually to approximately 2 percent in teenagers. In contrast to the age-specific attack rates, the ratio of bronchitis cases to all lower respiratory illness cases increased with age. In the first year of life, the ratio was 0.29; in children 12 years old or older, it was 0.69.

During the first 6 years of life, respiratory syncytial virus and parainfluenza virus type 3 were the most common etiologic agents noted in the Chapel Hill study. During the first 2 years of life, adenoviruses also commonly were associated with bronchitis. In patients older than 6 years, *M. pneumoniae* and influenza A and B viruses were the most common etiologic agents. In a study of cough illnesses of 6 days' duration or longer in university students, investigators found that 15 of 31 students with laboratory evidence of *Bordetella* spp. infection were considered by their primary care providers to have bronchitis.[46]

The incidence of acute bronchitis peaks in the winter months, declines to midsummer, and increases again through the fall. Attack rates generally are higher in boys than in girls.[13,39,65] A sex difference is most pronounced during the first 6 years of life.

PATHOPHYSIOLOGY AND PATHOLOGY

Because acute bronchitis is an illness characterized by clinical features and one not usually associated with death, knowledge of its pathophysiology and pathology is meager. The general pathophysiology of human infections with viruses and *M. pneumoniae* that cause acute bronchitis is presented more completely in the sections of this book related to the individual infectious agents.

In virtually all cases of acute bronchitis, evidence of upper respiratory viral infection (pharyngitis, rhinitis) also is present. Tracheal and bronchial infection apparently is the result of distal spread. In bronchitis, the clinical features result from damage to the ciliated epithelium of the lower trachea and the large and medium-sized bronchi.[25] Although the cytopathologies of the various infectious agents is different,[71] the resulting obstruction of the air passages leads to similar symptoms. The duration of symptoms depends to some extent on the specific initial infectious agent and, in cases of prolonged illness, on secondary bacterial infection.

TABLE 23–1 Infectious Agents Associated with Acute Bronchitis

Agent	Importance in Causation*	References
Viruses		
Adenovirus types 1-7, 12	+++	1, 2, 5, 10-12, 14, 23, 27, 28, 35, 36, 42, 54, 59, 62, 65, 66, 70

*+++, *very common;* ++, *common;* +, *rare;* –, *of questionable etiologic significance.*

In acute bronchitis, the larynx and subglottic trachea are not involved prominently. Conversely, today, bronchial involvement is seen only occasionally in croup.

CLINICAL PRESENTATION

Initial manifestations of acute bronchitis are upper respiratory in nature and, depending on the etiologic agent, are predominantly nasal, as in the common cold, or show additional objective evidence of pharyngitis, as in nasopharyngitis. Fever usually is present, and temperatures vary from 37.8° C to 39° C (100° F to 103° F) on most occasions. Cough always is present, and its onset can be insidious or abrupt. Initially, the cough is dry and harsh and often brassy in younger children. As the illness progresses, the cough becomes looser. In older children, purulent sputum is raised and expectorated. In younger children, the swallowing of often tenacious sputum frequently leads to gagging and vomiting. Older children may complain of chest pain resulting from coughing.

On initial physical examination, a variable degree of rhinitis usually is present; many patients have diffuse pharyngeal erythema. As the disease progresses, these upper respiratory signs generally decrease. Examination of the chest reveals rhonchi and referred breath sounds. Coarse, changing rales are noted frequently.

In the usual case of acute bronchitis, the illness can be separated into three phases: (1) a 1- to 2-day prodromal period when fever and upper respiratory symptoms predominate, (2) a 4- to 6-day period of marked tracheobronchial symptoms with some fever and general discomfort, and (3) a recovery period that may last 1 or 2 weeks and is characterized by cough and expectoration. Occasionally, the recovery period is particularly distressing and is associated with a low-grade fever, suggesting secondary bacterial infection. Bronchitis caused by *C. pneumoniae* often is insidious in onset and frequently associated with or preceded by pharyngitis.[32,40] Illness persists for several weeks but responds to appropriate antibiotic therapy.

Laboratory study in acute bronchitis is of limited use. Children in whom throat cultures reveal pathogenic bacteria in predominant growth tend to have more severe illness than do children with only viral infections.[16,47] The white blood cell count usually is greater than 10,000 cells/mm^3, and approximately one third of the cases have a predominance of neutrophils.[47] The chest radiograph is normal unless associated pulmonary involvement is present.

DIFFERENTIAL DIAGNOSIS AND SPECIFIC DIAGNOSIS

Because acute bronchitis is a clinical entity caused by multiple etiologic agents, the most difficult differential aspect of diagnosis is the selection of the specific infectious cause. Also important is the separation of acute, self-limited bronchitis from chronic,

more serious problems, such as cystic fibrosis, allergic respiratory disease, and sinusitis.

An epidemiologic history frequently can help in assigning a particular virus, *M. pneumoniae*, *C. pneumoniae*, or *B. pertussis*, as the presumptive etiologic agent. If epidemic bronchiolitis is occurring in the community, respiratory syncytial virus would be a likely cause. Similarly, predictions of causation by influenza virus, parainfluenza virus, adenoviruses, *M. pneumoniae*, *C. pneumoniae*, or *B. pertussis* can be made through clinical epidemiologic observations. Specific etiologic diagnosis can be established through the isolation of an organism or its identification by a direct antigen test from the nasopharyngeal secretions. Serologic study on paired sera may be useful for the diagnosis of *M. pneumoniae*, *C. pneumoniae*, and *B. pertussis*.

Children with protracted illnesses or febrile exacerbations should be examined by culture, radiograph, and perhaps further imaging studies for secondary bacterial infection of the tracheobronchial tree or the lungs or both. Children with chronic recurrent illnesses should be tested for cystic fibrosis, allergic conditions, and anatomic problems, such as gastroesophageal reflux and tracheoesophageal fistula.

TREATMENT

Treatment of acute bronchitis is distinguished more by what *not* to do than by specific modalities. In most mild cases, no specific therapy is indicated.

For children who feel miserable during the initial phases of acute bronchitis, analgesic therapy may be useful. Formerly, aspirin was the recommended analgesic. Because aspirin is an etiologic factor in influenza-associated Reye syndrome and because differentiating influenza viral infections from other respiratory viral infections is difficult, it is prudent to use acetaminophen rather than aspirin. The dose per single administration of acetaminophen by year of age is as follows: younger than 1 year, 60 mg; 1 to 3 years, 60 to 120 mg; 3 to 6 years, 120 mg; 6 to 12 years, 150 to 300 mg; older than 12 years, 325 to 650 mg. Administration may be repeated three or four times daily in young children and every 4 hours in older children. Acetaminophen rarely should be given to infants younger than 6 months of age.

As a result of widespread advertising, a common practice of individuals with acute bronchitis is to use an array of cold remedies, which contain various combinations of antihistamines, decongestants, and antitussives. None has been shown to be useful in acute bronchitis, and in certain stages of illness, they may aggravate the recovery process. Repeated bouts of coughing occasionally result in emesis, exhaustion, or insomnia, and the careful use of antitussive agents (codeine or dextromethorphan) can be helpful.[19] Cough suppressants should be used with caution when a cough is productive.

Intake of fluids should be encouraged to prevent overall dehydration and to decrease the viscosity of new secretions. Use of mist therapy also may help in thinning the exudate-containing respiratory secretions.[24,49]

In severe cases of acute bronchitis, treatment with specific antiviral agents should be considered. When influenza A virus is the likely etiologic agent, amantadine, rimantadine, zanamivir, or oseltamivir therapy may be beneficial.[9]

As noted in Table 23–1, most cases of acute bronchitis are caused by viruses, so antibiotic therapy would not be indicated.[48,69] In cases in which fever returns or no trend toward recovery is seen by the seventh day of illness, the possibility of a secondary bacterial infection should be considered. The association of sinusitis or a throat culture with a predominant growth of a respiratory pathogen (*Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Moraxella catarrhalis*, *H. influenzae*) is an indication for therapy. Infection with *M. pneumoniae* also should be treated, but in contrast to treatment of pneumonia, the therapy usually does not show an impressive response. Bronchitis caused by *C. pneumoniae* should be treated with erythromycin (50 mg/kg/day divided every 6 hours) for 10 to 14 days.[32]

PROGNOSIS

The prognosis in acute bronchitis usually is excellent. Although the duration of cough can be disturbing to the parent and the child, full recovery is the rule. Several studies suggest that lower respiratory illness in the first few years of life may be associated with persistent respiratory symptoms and with abnormalities in lung function in later life.[7,18,43,44] Although none of these studies has followed children with acute bronchitis specifically, the findings in other illnesses (bronchiolitis and croup) indicate a need to observe children with episodes of acute bronchitis carefully as well.

PREVENTION

At present, no practical method of prevention of acute bronchitis in children exists. Because most cases result from infections with common respiratory viruses, the development of vaccines could be expected to be helpful.

CHAPTER 24

Chronic Bronchitis

I. Celine Hanson ❂ William T. Shearer

Chronic bronchitis is a serious and costly health problem in adults.[17] In a U.S. review of the epidemiology of chronic bronchitis, affected adult morbidity estimates were greater than 900,000 hospitalizations and 10 to 14 million physician visits each year.[24] The World Health Organization estimates 23.6 million adults have chronic obstructive pulmonary disease, representing more than 15 percent of the adult population, and many of these cases meet the definition for chronic bronchitis.[5] In the adult literature, the accepted definition of chronic bronchitis includes daily excessive production of sputum with manifestation of cough

present on most days for 3 months in a year for not less than 2 successive years.[46]

For most pediatricians, the clinical entity of chronic bronchitis is ill-defined. Chronic cough complex can be associated with other, more common respiratory or cardiac diseases that must be excluded before a diagnosis of chronic bronchitis is considered.[11] Chronic bronchitis usually is described in the literature as chronic productive cough and is synonymous with asthmatic bronchitis.[8,43] The lack of uniform or standardized definitions of pediatric chronic bronchitis leads to wide discrepancies in reported childhood prevalence (Table 24–1). In affected patients, causal relationships and acute exacerbations have been linked to exposure to a noxious inhaled agent (e.g., environmental/industrial pollution, cigarette smoke), specific host factors (e.g., genetic predisposition), and infectious respiratory pathogens. The pathology of the disease entity is unclear. Bronchoscopy of pediatric patients with chronic bronchitis has revealed findings similar to those noted in children with asthma, which reflects the inclusion of asthma in the spectrum of the chronic bronchitis complex.[27] Pediatric bronchoscopic evaluation yields heterogeneous histologic findings (granulocyte and mononuclear cell predominance at lavage and biopsy) that are distinct from findings in adults with chronic bronchitis.[43]

DIFFERENTIAL DIAGNOSIS

Because chronic bronchitis is accepted by most physicians as being a complex of symptoms characterized by persistent cough with or without wheezing, it is imperative that the physician evaluate the patient for diseases that include chronic bronchitis within their spectrum of signs and symptoms. Figure 24–1 includes disorders that have clinical manifestations of chronic cough for longer than 3 months and provides guidelines for diagnostic evaluation of children with chronic cough.[26]

Heading the differential list is asthma,[10] defined as reversible obstructive airways disease with a significant inflammatory component leading to increased edema and production of mucus.

TABLE 24–1 Prevalence of Childhood Bronchitis

Author	Year	Study Subjects	Prevalence (%)	Acute/Chronic Bronchitis
Bland et al.	1974	Kent schoolchildren	5.5	Acute/chronic
Burrows and Lebowitz	1975	Arizona children	7.1	Chronic
Burrows et al.	1977	Arizona retrospective	46.4	Chronic
Kubo et al.	1978	Japanese children	1.4	Chronic
Peat et al.	1980	Sydney schoolchildren	20	Acute/chronic

Modified from Morgan, W. T., and Taussig, L. M.: The chronic bronchitis complex in childhood. Pediatr. Clin. North Am. 31:*851-864, 1984.)*

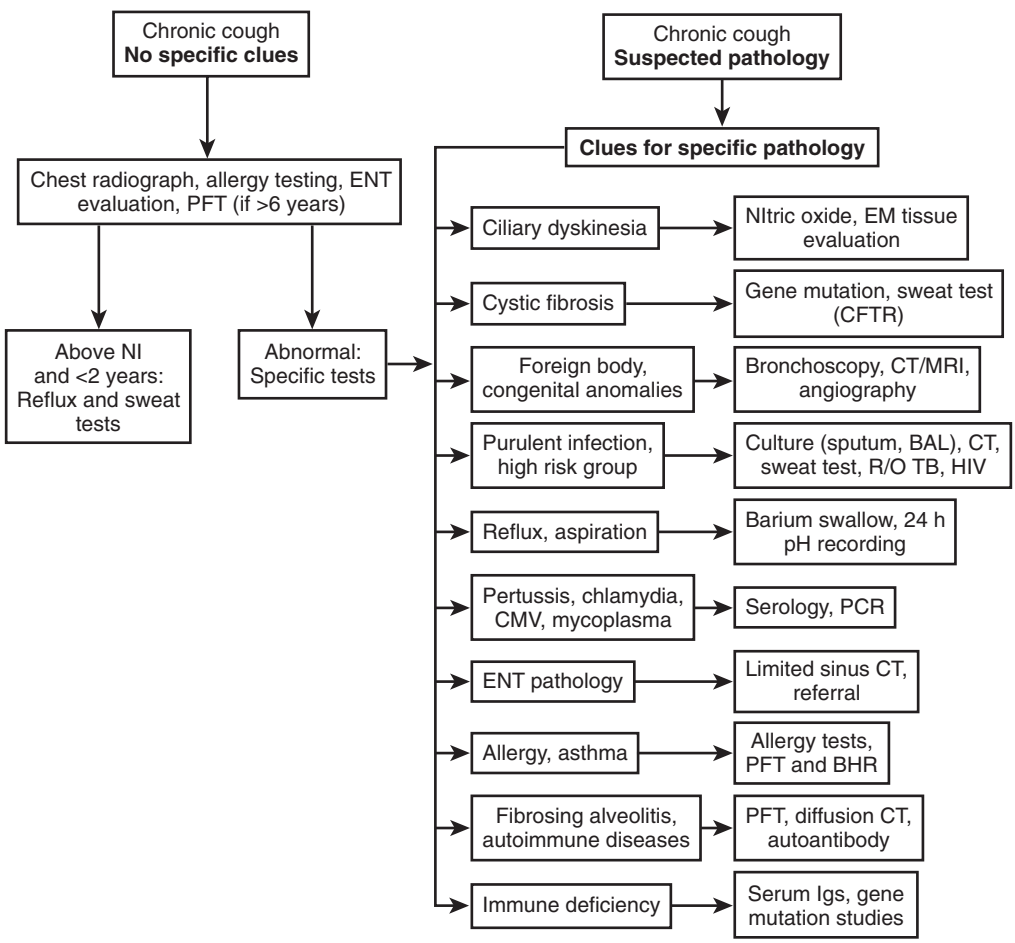

Figure 24–1 Diagnostic evaluation of children with chronic cough. BAL, bronchoalveolar lavage; BHR, bronchial hyperreactivity; CFTR, cystic fibrosis transmembrane conductance regulator; CMV, cytomegalovirus; CT, computed tomography; EM, electron microscopy; ENT, ear, nose, throat; HIV, human immunodeficiency virus; MRI, magnetic resonance imaging; NI, no information; PCR, polymerase chain reaction; PFT, pulmonary function test; TB, tuberculosis. (*Modified from Morice, A. J., Fontana, G. A., Sovijarvi, A. R., et al.: Diagnoses and management of chronic cough. Eur. Respir. J.* 24:*487, 2004.*)

Asthma is a common pediatric lower respiratory disease, affecting more than 6.3 million children younger than 18 years old in the United States.[1] Asthma can be distinguished from chronic bronchitis by pulmonary function evaluation documenting reversal of airway obstruction after delivery of pulmonary bronchodilators. Recurrent episodes of acute bronchitis often can be interpreted as chronic bronchitis, although the intermittent nature of these episodes and absence of a persistent cough usually distinguish this group of patients clinically.[4]

Specific viral infections (e.g., rhinovirus, parainfluenza virus) in children with or without allergic rhinitis may provoke airway hyperreactivity and late asthmatic reactions, which may be confused symptomatically with chronic bronchitis.[6,20] Persistent lower respiratory tract infections (i.e., *Chlamydia* spp., pertussis, *Mycoplasma* spp., and *Mycobacterium* spp.) frequently manifest with the complex of symptoms described and are evaluated best with chest radiographs in a search for enlarged hilar nodes or interstitial lung infiltrates. Respiratory tract secretions for appropriate bacterial and viral culture and serum for determinations of antibacterial antibodies should be obtained. In the case of tuberculosis, a delayed hypersensitivity skin test for *Mycobacterium tuberculosis* antigen should be applied.

Cystic fibrosis is a recessively inherited illness occurring in approximately 1 in 3700 live births, with clinical manifestations of failure to thrive, steatorrhea, nasal polyps, and recurrent lower respiratory tract symptoms. The disorder is associated with mutation of the cystic fibrosis transmembrane conductance regulator (CFTR) gene.[38] Cystic fibrosis can be diagnosed by newborn screening methodologies including identifying typical CFTR gene mutation patterns in DNA extracted from dot blots or other collected blood specimens at or after birth or by detecting abnormally elevated chloride levels (>60 mEq/L) as measured by the sweat iontophoresis test.[40] In clinical practice, one or both modalities may be used for establishing the diagnosis, especially for patients with genetic variations of the CFTR gene not typical of the classic cystic fibrosis phenotype or for patients with uninterpretable sweat test outcomes.

Primary ciliary dyskinesia encompasses the immotile cilia disorders and Kartagener syndrome (rhinosinusitis, bronchitis or bronchiectasis, and situs inversus) and affects 1 in 15,000 white births. Primary ciliary dyskinesia typically is inherited as an autosomal recessive disorder and is associated with defects in mucociliary transport in the respiratory tree. The symptom complex also has been associated with polycystic kidneys, hepatic disease, and central nervous system symptoms. Screening tests for primary ciliary dyskinesia include nasal nitric oxide and in vivo tests of ciliary motility, but these tests are not universally available, and standardization is problematic.[31] More recently, physicians have used tissue biopsy specimens to identify structural defects by electron microscopy, high-speed analysis of cilia beat patterns, and cell culture when establishing the diagnosis has been difficult.[29]

The primary immune disorders associated most frequently with recurrent sinopulmonary infections include selective IgA deficiency, functional antibody deficiencies, hypogammaglobulinemia, and ataxia telangiectasia.[3] Selective IgA deficiency is the primary immune disorder encountered most commonly, with an incidence of 1 in 500. It may be asymptomatic or accompanied by a propensity for atopy and an increase in associated autoimmune disease (most often rheumatoid arthritis and systemic lupus erythematosus). The diagnosis is made readily by evaluation of quantitative serum immunoglobulins defining IgA levels of less than 10 mg/dL. IgA deficiency may be associated with IgG subclass deficiencies (IgG2 deficiency was identified in 85 percent in a series of >150) with or without clinical symptoms. Functional antibody deficiencies have been detected and include inability to respond serologically to vaccination with polysaccharide antigens such as *Streptococcus pneumoniae* or *Haemophilus influenzae*.[13]

Patients with hypogammaglobulinemia represent a diverse group having primary immune disorders that include X-linked agammaglobulinemia, common variable immune deficiency (CVID), and hyper-IgM syndrome. X-linked agammaglobulinemia typically affects boys, with recurrent sinopulmonary infections with onset occurring postnatally as maternal antibody wanes. X-linked agammaglobulinemia is associated with deficiency of a B-cell maturation enzyme, Bruton tyrosine kinase, and is characterized by the absence of circulating mature B lymphocytes. CVID is a disorder of young adults, with immune findings of agammaglobulinemia and variable T-cell defects. Clinical presentation includes lower respiratory and sinus disease. Inherited CVID disorders have been described and include defects in inducible T-cell costimulator gene and transmembrane activator and calcium-modulator and cyclophilin ligand interactor (TACI).[3] Patients with TACI defect and CVID may lack circulating mature B lymphocytes. More often, patients with CVID normally express B-cell markers on circulating lymphocytes. Hyper-IgM syndrome is a rare disorder associated with elevated IgM and low IgG and IgA and recurrent infections including sinopulmonary and hepatic infections. Different gene defects have been identified in patients with hyper-IgM syndrome; patients with defects in nucleotide-modifying enzymes located only in B cells have no associated T-cell defect.

Patients with ataxia telangiectasia have depressed serum IgA concentrations and marked dysfunction of the swallowing mechanism, leading to recurrent lower respiratory tract infections probably secondary to recurrent aspiration. These patients are identified by telangiectasias of the skin and conjunctivae in association with aberrant and progressively deteriorating neurologic symptoms and immunodeficiency (depressed IgA and IgE and aberrant T-cell–mediated immunity). Some patients have depressed IgG subclasses (IgG2, IgG4) as well. The gene mutation in ataxia telangiectasia has been identified as disruption of the ataxia telangiectasia molecules responsible for detection and implementation of DNA repair dependent on phosphatidylinositol-3-kinase signal transduction pathways.

Primary immune disorders with hypogammaglobulinemia can be diagnosed through evaluation of serum immunoglobulin levels. Further characterization includes assessment of antibody production after vaccine or neoantigen challenge, evaluation of circulating lymphocyte cell surface markers, and in vitro proliferative responses to plant lectins or specific antigens. Evaluation of associated gene defects is important for determining corrective interventions (e.g., transplantation, gene therapy) and genetic counseling.

Graft-versus-host disease affecting the lungs has been described in immunocompromised patients after they have undergone bone marrow transplantation. The lesion is caused by chronic pulmonary lymphocytic infiltrates and pulmonary fibrosis mimicking the symptom complex of chronic bronchitis and often is indistinguishable radiographically or clinically from infections that characteristically are pathogenic (i.e., *Pneumocystis jiroveci*, *Candida albicans*, *Aspergillus* spp.).

Secondary immune disorders (prematurity and pediatric human immunodeficiency virus [HIV] infection) also may be associated with significant sinopulmonary infections. Premature infants with attendant severe respiratory distress syndrome requiring positive-pressure ventilation may develop bronchopulmonary dysplasia. Diagnostic criteria include hypoxia requiring oxygen supplementation, characteristic diffuse interstitial markings on chest radiograph, and clinical signs of pulmonary disease (i.e., tachypnea, intercostal retractions). In one series, more than 60 percent of surviving children with bronchopulmonary dysplasia were documented to have significant pulmonary disease and associated morbidity (i.e., increased hospitalizations).[33] Continued improved care for premature infants and resultant decreased

incidence of mortality may increase the population of infants with bronchopulmonary dysplasia.

Pediatric HIV infection is estimated to affect approximately 1.5 percent of infants born to HIV-infected mothers in the United States.[28] This reduced infection rate can be attributed to (1) availability and use of highly active antiretroviral therapy (HAART) to pregnant women and their newborn infants, (2) U.S. practices that minimize exposure to breast milk, and (3) obstetric practices that minimize exposure to infected blood products (cesarean delivery and practices that decrease time from membrane rupture to delivery). For infants in the United States who continue to be infected, with noncompliance to treatment or lack of treatment, HIV is associated with serious lower respiratory tract illness.

In previous years, lymphoid interstitial pneumonitis/hyperplasia, reported in 25 percent of all children with acquired immunodeficiency syndrome, was associated with chronic cough, but this HIV-associated outcome rarely is reported with the advent of improved antiviral medications to suppress replication of HIV. Despite restoration of immunocompetence with HAART, lower respiratory tract infections (viral, bacterial, fungal) are still common occurrences in children infected with HIV.[23] In the face of improved survival for HIV-infected children, the incidence of chronic radiographic lung changes (parenchymal consolidations and nodular disease for >3 months) has been described in 33 percent of children by the time they are 4 years of age.[30] An unexpected consequence of HAART therapy in HIV-infected children may lead to increased risk of developing asthma through an immune reconstitution mechanism.[14] The diagnosis of HIV infection is established by viral diagnostic assays (polymerase chain reaction, p24 antigen) for perinatally exposed infants younger than 18 months of age and by serology (enzyme-linked immunosorbent assay and confirmational assays [Western blot analysis, indirect fluorescent antibody assay]) for perinatally exposed infants 18 months or older.[35]

Anatomic lesions that lead to pulmonary obstructive airway disease can simulate the complex of chronic bronchitis. An infant with chronic cough, poor feeding habits, and failure to thrive should undergo evaluation for gastroesophageal reflux and tracheoesophageal fistula, which are identified most easily by barium swallow or pH probe monitoring. Mediastinal tumors can produce extrinsic obstruction, leading to recurrent cough and wheezing. Congenital heart disease should be considered in this patient group and can be evaluated with chest radiography, electrocardiography, and echocardiography.

Respiratory tract irritants have been implicated as a cause of chronic cough, as documented in adult populations of industrial European nations.[44] An assessment of the public health impact of pollution in Austria, France, and Switzerland concluded that air pollution caused 6 percent of all mortality, or 40,000 attributable cases per year.[19] Nonindustrial, rural communities, such as the forest zone of Nigeria, report virtually no chronic bronchitis, whereas metropolitan New York reports an increased risk for development of upper and lower respiratory tract infections in adults and children who reside in parts of the city with the highest ambient air levels of sulfur dioxide and particulate air pollution.[22] After exposure to urban air particulate matter, animal models with induced chronic bronchitis (exposure to 200 ppm of sulfur dioxide for 6 weeks) have shown pathologic changes consistent with exacerbation of chronic bronchitis—changes in ventilatory capacity and marked pulmonary inflammation.[9]

A correlation between tobacco smoking and reduced ventilatory capacity in adults has been reported by many investigators. Peat and associates[34] described teenagers in Sydney, Australia, with recurrent episodes of bronchitis with worsened lung function when coupled with tobacco smoking. A meta-analysis of 21 relevant publications on relationships between exposure to environmental tobacco smoke and lower respiratory tract infection in infancy and early childhood concluded that exposure to environmental smoke resulted in adverse childhood respiratory outcomes.[21] The outcomes included an increased number of lower respiratory tract infections and an increased number of hospitalizations for these infections. These data suggest that it is imperative for physicians to obtain a smoking history not only for the patient but also for other household members.

Other noxious agents associated with outdoor pollution have been associated with poor control of chronic cough complex diseases such as asthma. In Los Angeles, adults with asthma were more poorly controlled if they resided near areas of heavy traffic.[25] Similar findings of poorly controlled lung disease associated with traffic pollution have been documented in adult and pediatric patients in Lima, Peru.[7] Occupational exposures long have been cited for exacerbating pulmonary diseases. Blanc and colleagues[2] evaluated the risk for developing chronic lung disease from occupational exposure and identified the population attributable risk at 15 percent for chronic bronchitis and chronic obstructive pulmonary disease. Classic examples of occupational exposure to dust leading to increased risk of developing chronic cough are described in coal miners in Great Britain, foundry workers in the Rhine-Ruhr area of Germany, potters in West Virginia, and farmers in Croatia.[47] After the disaster of September 11, 2001, in New York City, firefighters with existing sarcoidosis (reported at higher frequency in firefighters before the disaster) reported increased incidence of bronchial hyperreactivity measured by pulmonary challenge testing.[16]

EPIDEMIOLOGY AND ETIOLOGY

Differentiating the impact of clinical, social, and environmental factors on lower respiratory tract disease, including chronic bronchitis, has been problematic and has led to conflicting outcomes in epidemiologic assessments.[12,42] In addition, the lack of a standardized definition of chronic bronchitis in the pediatric literature leads to confusing interpretation of data when attempting to appreciate the prevalence or etiology of the disease complex.[43] In Table 24–1, the data from Kubo and associates[18] separate acute recurrent bronchitis, asthmatic bronchitis, and chronic bronchitis, leading to a decrease in the prevalence from a proposed 46.4 percent (in the Arizona questionnaire) to 1.4 percent.[27]

Considerable overlap also exists in evaluating etiologic agents for chronic bronchitis. The same viral agents proposed as the exacerbating factors of asthmatic bronchitis (see Chapter 25) are implicated in exacerbations of chronic bronchitis,[1,15] including rhinoviruses, parainfluenza viruses, respiratory syncytial virus, influenza A and B viruses, adenoviruses, and enteroviruses. Persistent adenovirus infection has been implicated as a cause of childhood chronic bronchitis. In a study of 11 children with chronic bronchitis, transbronchial biopsy specimens revealed no evidence of persistent adenovirus infection (culture or polymerase chain reaction),[36] suggesting that viral infections may precipitate cough, but their roles in the pathologic findings associated with chronic bronchitis should be questioned.

Table 24–2 lists predominant bacterial pathogens isolated from washed sputum for a group of 40 pediatric patients with chronic bronchitis and exacerbations of cough and fever; these pathogens include *H. influenzae*, *S. pneumoniae*, and *Staphylococcus aureus*.[18] These bacteria also are implicated as etiologic agents in the triggering of asthmatic bronchitis. Neither *Mycoplasma* nor human metapneumovirus was included in this listing, but this simply may reflect the time-frame (late 1970s) when the Kubo study was conducted.[32,45] Treatment of exacerbations of chronic bronchitis with antibiotic therapy usually is effective in reducing the volume of sputum and purulence during the acute infection but shows no parallel elimination of the cultured microorganisms.

TABLE 24–2 Predominant Pathogens in Washed Sputum of Chronic Bronchitis (40 Cases)

Pathogen	No. Cases
Haemophilus influenzae and *Streptococcus pneumoniae*	21 (52.5%)
H. influenzae	17 (42.5%)
Staphylococcus aureus	2 (5%)
Superinfection with gram-negative rods	
Pseudomonas aeruginosa	4
Klebsiella pneumoniae	2
Escherichia coli	1
Enterobacter cloacae	1

From Kubo, S., Funabashi, S., Uehara, S., et al.: Clinical aspects of "asthmatic bronchitis" and chronic bronchitis in infants and children. J. Asthma Res. 15*:99-132, 1978.*

TREATMENT

When a specific diagnosis is found in association with chronic cough or wheezing, therapy is directed toward the primary disease entity and the clinical presentation of cough. Bronchodilators (beta-adrenergic agents, cromolyn sodium, corticosteroids) and anticholinergic agents are used, when appropriate, for the treatment of chronic cough associated with asthma or acute exacerbations of chronic obstructive pulmonary disease.[41] Appropriate positioning techniques (prone 30 degrees), feeding schedules, and medications (e.g., prokinetics or cholinergics) are indicated in the approach to infants with gastroesophageal reflux. Patients with hypogammaglobulinemia can be helped with supplemental intravenous immunoglobulin preparations currently available commercially (400 to 600 mg/kg per dose every 3 to 4 weeks) in an attempt to decrease the incidence of infections.

It is imperative that patients with chronic pulmonary diseases such as cystic fibrosis, asthma, or ciliary dyskinesias understand the pulmonary irritant effect of tobacco smoking, dust exposure, and air pollution. A change of occupation may be essential for their well-being. It also is imperative to stress the irritant effect of parental smoking on the already compromised pulmonary function of the child.

Antibiotic therapy for chronic bronchitis usually is reserved for patients with severe illness in whom the likelihood of developing a secondary bacterial infection is great. In these instances, antibiotic therapy can be considered and usually consists of amoxicillin (45 to 90 mg/kg per 24 hours), erythromycin (40 mg/kg per 24 hours), or, in adolescents and adults, tetracycline (25 to 50 mg/kg per 24 hours) or quinolones for 5 to 10 days. There do not seem to be significant differences in short-term effectiveness in adults with these outlined treatment regimens.[39] Methylxanthine therapy is used less frequently in chronic bronchitis care. When it is used, certain antibiotics, such as erythromycin, lead to elevated serum concentrations of theophylline, which renders toxicity more likely to occur. Treatment with mucolytic agents in chronic pulmonary disease has not proven to have a significant impact except in adults with already advanced disease with multiple hospitalizations, and no evidence suggests that they are beneficial in children.[37]

As with patients with obstructive lung disease, attention must be aimed at careful and sequential monitoring of pulmonary function. The prognosis for chronic bronchitis varies and is dependent on the specific etiology of this syndrome.

CHAPTER 25

Bronchiolitis and Infectious Asthma

Robert C. Welliver

Bronchiolitis and infectious asthma, which also is called *asthmatic bronchitis*, *wheezy bronchitis*, or *virus-induced asthma*, are common illnesses of children, characterized by symptoms of upper respiratory tract infection and signs of obstructive airway disease, particularly wheezing. Bronchiolitis and infectious asthma often are considered to be distinct entities, and not all infants who develop bronchiolitis have infectious asthma in later life. Although the two illnesses are similar in terms of clinical presentation and have some mediators in common, the pathologic findings may contrast in some cases. Differences in terms of etiologic agents that precipitate episodes of illness or in terms of response to therapy are more a function of the patient's age (particularly older or younger than 3 years) than of any underlying disease process. *Infectious asthma* is considered as a term defining the occurrence of repeated episodes of bronchiolitis, and the two conditions are discussed together.

DEFINITIONS

Bronchiolitis is an acute communicable disease predominantly manifesting in infancy and characterized by cough, coryza, fever, grunting, tachypnea, retractions, inspiratory crackles, expiratory wheezing, and air trapping. The first (and the most severe) episodes occur most frequently in infants aged 2 to 6 months. *Infectious asthma* is a term that generally refers to infection-induced wheezing occurring beyond infancy. Nonetheless, a patient may experience bronchiolitis during the first months of life and a recurrent episode caused by the same virus in the second year, suggesting an identical underlying nature of the two illnesses. Certain viruses (e.g., respiratory syncytial virus [RSV] and influenza viruses) seem capable of causing bronchiolitis in all children; in contrast, other agents (rhinovirus in particular) seem to induce wheezing only in atopic children.

HISTORY

Although all practicing pediatricians today are familiar with the term *bronchiolitis* and associate it with an acute clinical illness with the signs and symptoms of obstructive emphysema, it has been recognized in the medical literature for only a relatively brief period. In the early years of the 20th century, the term *capillary bronchitis* was used to describe an inflammatory illness of the smallest alveoli.[56] The condition could not be distinguished clinically from pneumonia, however, and whether the pathologic entity (i.e., bronchiolitis) ever occurred separately from pneumonia was doubted. In the 11th edition of *Holt's Diseases of Infancy and Childhood*,[73] published in 1940, capillary bronchitis is discussed only briefly and is considered under pneumococcal pneumonia. Acute bronchiolitis finally was listed as a heading in the sixth edition of the *Textbook of Pediatrics*,[118] published in 1954; even at that time, bronchiolitis was associated with interstitial pneumonitis.

In contrast to the delayed textbook recognition of bronchiolitis, good clinical descriptions were presented in journals. In 1941, Hubble and Osborn[76] published "Acute Bronchiolitis in Children," in which they described an epidemic of bronchiolitis involving 50 hospitalized children. Pratt[131] in 1944 and Nelson and Smith[119] in 1945 published excellent clinical articles. Studies in the late 1950s and early 1960s established the etiologic association of RSV and other viruses with acute bronchiolitis.[6,21,22,24,25,145]

ETIOLOGIC AGENTS

RSV is the major cause of bronchiolitis in infancy and virtually the only important etiologic consideration when major epidemics are occurring. Other agents cause smaller annual outbreaks. Table 25–1 presents the frequency of infectious agents in the overall cause of bronchiolitis. These data were compiled from 12 reports in which respiratory illness in children was observed over an extended period, and in most instances, numerous clinical illness categories were being studied. During major epidemics in the colder months in temperate climates, virologic and serologic studies indicate RSV as the cause in 80 percent or more of the cases, especially in the more severe ones. In nonepidemic situations, more than 50 percent of the isolates or instances of serologic evidence of infection are infectious agents other than RSV.

Sporadic disease rarely is associated with more than a 50 percent association of infectious agent and illness, despite the fact that infections undoubtedly are the cause of sporadic and epidemic bronchiolitis.[107]

Children surviving infantile bronchiolitis often have recurrent episodes of wheezing that, on clinical grounds, seem to be precipitated by upper respiratory infections. Studies designed to determine the infectious agents responsible for these repeated wheezing episodes have yielded variable results, presumably because they involve patients of different ages followed during different seasons of the year.[8,55,98,108-111]

A comprehensive study based on more than a decade of observation of children from birth through 15 years of age[68] revealed that viruses and *Mycoplasma pneumoniae* are the most common etiologic agents (Table 25–2). RSV is the most common cause of recurrent, wheezing-associated respiratory illness occurring in young children, including children who previously experienced bronchiolitis, which strongly suggests the identical nature of infection-related wheezing episodes occurring in children of different ages. With increasing patient age, rhinoviruses and *M. pneumoniae* account for most infection-induced wheezing episodes. The parainfluenza viruses and influenza viruses are important causes of such wheezing episodes throughout childhood, whereas coronaviruses and adenoviruses are less common causes in infancy. Human metapneumovirus and bocaviruses are more recently identified causes of bronchiolitis, and their relative importance as etiologic agents is being determined. RSV remains an important cause of wheezing in adolescents[68] and can cause airway obstruction in middle-aged and elderly individuals.[175]

The role of bacteria as primary agents, synergistically active participants, or secondary invaders in bronchiolitis has interested investigators for many years. No evidence has been found of a primary role for bacteria in bronchiolitis of infants.[6,94] The data on synergistic viral-bacterial infections also are unconvincing. Wood and colleagues[189] in 1954 and Sell[149] in 1960 reported results of studies in which bacteriologic and serologic evidence tended to associate *Haemophilus influenzae* infections with bronchiolitis. Some of the children from these studies later were shown serologically to have had RSV infection.[26] Later studies showed evidence of mixed viral-bacterial infections in bronchiolitis[99,121] and other lower respiratory illnesses.[121]

These serologically defined mixed infections were found no more commonly among patients with bronchiolitis than among patients with mild upper respiratory tract disease, whereas RSV was recovered 10 times as often from patients with lower respiratory tract disease as from patients with upper respiratory tract disease alone.[99] A significant role for mixed viral-bacterial infection in bronchiolitis of infancy is unlikely to exist. Bacterial superinfection is an uncommon occurrence in bronchiolitis (at least in developed countries), as is discussed later in the section on complications and prognosis.

The association of asthma and infectious illnesses was appreciated throughout the 20th century. Initial reports tended to relate bacterial agents to wheezing; in 1909, Carmalt-Jones[19] reported improvement of patients with asthma in association with injections of a bacterial vaccine. Throughout the first half of the 20th century, "bacterial allergy" was the main consideration in infection-related wheezing, and controversy raged about the therapeutic merits of bacterial vaccines. Despite widespread use of bacterial vaccines in the treatment of infectious asthma, no evidence exists that bacterial organisms of the normal flora precipitate asthmatic attacks.[64,74,112,113,173] More recent, large retrospective reviews have shown the rarity with which bacterial infection complicates bronchiolitis, even in severe cases.[133,134] Generally, after a diagnosis of RSV or parainfluenza virus infection has been established, antibiotic courses started empirically can be safely stopped.

TABLE 25–1 Infectious Agents Associated with Acute Bronchiolitis

Infectious Agent	Relative Frequency (%)
Respiratory syncytial virus	50
Parainfluenza viruses	25
Type 1	8
Type 2	2
Type 3	15
Adenoviruses	5
Mycoplasma pneumoniae	5
Rhinoviruses	5
Influenza viruses	5
Type A	3
Type B	2
Metapneumovirus	5-10
Enteroviruses	2
Herpes simplex virus	2
Mumps virus	<1

EPIDEMIOLOGY

Bronchiolitis predominantly is a disease of infancy, although an identical disease occurring in older children arbitrarily may be referred to as another diagnostic entity. In a study involving 1148 children, the peak age of incidence was 2 to 6 months, with more than 80 percent of the cases occurring during the first year of life.[126] In a study of families in or near Houston, Texas, rates of RSV infection were 68.8 per 100 children in the first year of life and 82.6 per 100 children in the second year, including many reinfections. Lower respiratory illness was caused by RSV in 22.4 of 100 children in the first year of life. Of all RSV infections

TABLE 25–2 Principal Agents Recovered from Children of Different Ages with Wheezing Precipitated by Infection

	Frequency of Isolation of Each Age Group†			
Agent*	*0-2 years*	*2-5 years*	*5-9 years*	*9-15 years*

TABLE 25–3 Attack Rates of Respiratory Syncytial Virus

Age in months [per Welliver] (*n*)	Infections per 100 Child-Years	LRI per 100 Child-Years	LRI per 100 Infections
0-12 (125)	68.8	22.4	32.6
13-24 (92)	82.6	13	15.8
25-36 (65)	46.2	10.8	23.3
37-48 (39)	33.3	7.7	23.1

LRI, lower respiratory tract infections.
From Glezen, W. P., Taber, L.H., Frank, A. L., et al.: Risk of primary infection and reinfection with respiratory syncytial virus. Am. J. Dis. Child. 140:543-546, 1986.

occurring in children younger than 12 months of age, one third were accompanied by lower respiratory illness. Although the attack rate of RSV decreased with age, the frequency with which lower respiratory disease occurred among individuals infected remained constant (Table 25–3), at least until they reached 4 years of age.[53] In Tucson, Arizona, a study of 1179 children enrolled in a health maintenance organization found that the rate of lower respiratory illness in the first year of life was 32.9 episodes per 100 children; 60 percent of these episodes were diagnosed as bronchiolitis.[192]

Studies in the Washington, D.C., area[84] and in North Carolina[68] estimated the risk of hospitalization for bronchiolitis among infants 0 to 12 months old to be 10 per 1000. A combined study involving 10 centers in Great Britain[28] concluded that the frequency of hospitalization for lower respiratory tract disease (predominantly wheezing) caused by RSV was 1 per 114 infants younger than 1 year of age and 1 per 476 children younger than 5 years. Peak rates of hospitalization were observed for children 1 to 3 months old (1 in 56).

More recent studies suggest that the rate of hospitalization for bronchiolitis may be higher currently than in the above-mentioned older studies. A study of the Tennessee Medicaid population found that the frequency of hospitalization for bronchiolitis was 4.4 and 1.5 per 100 child-years of observation for infants infected in the first and second 6 months of life, respectively.[10] Approximately 123,000 infants younger than 1 year of age are hospitalized annually with bronchiolitis, with RSV infection accounting for 51,000 to 82,000 of these hospitalizations. Including cases diagnosed as pneumonia, RSV infection results in 70,000 to 120,000 hospitalizations.[150]

Between 1979 and 1997, an average of 95 bronchiolitis-associated deaths occurred annually, with 77 percent occurring during the RSV epidemic season. Including fatal cases of bronchiolitis or pneumonia, RSV infection might have resulted in 171 to 510 deaths annually.[151] The yearly incidence of hospitalization for bronchiolitis increased from 12.9 per 1000 infants in 1980 to 31.2 per 1000 in 1996, suggesting an increased severity of illness developing during this interval.[150]

Epidemic bronchiolitis caused by RSV is markedly seasonal in temperate climates, with peak activity occurring from January to April and virtually no activity seen from August to October.[84] Sporadic bronchiolitis cases caused by other agents are seen throughout the year. In their study of 1179 cases, Kim and associates[84] found that 77 percent of the cases of RSV infection occurred between December and June. The lowest incidence occurred in August (2%). Regional differences can be striking. In Miami, RSV activity is year-round, with the maximum number of cases occurring in September and October. Epidemics usually begin in October in other southern states, although still earlier than in the Northeast. Further north (Winnipeg, Canada, and Alaska), the duration of the RSV season again becomes longer, and cases occur essentially year-round. Near the equator, temperature and humidity are positively associated with the number of bronchiolitis cases. In contrast, further from the equator (in either direction), temperature and humidity are inversely associated with bronchiolitis cases. Ultraviolet radiation is negatively associated with bronchiolitis in several regions.[194]

Bronchiolitis occurs more frequently in boys; the male-to-female ratio is approximately 1.5 : 1.[45] In older children, wheezing attributable to viral and mycoplasmal infections also occurs more frequently in boys (male-to-female ratio 1.35 : 1) until they reach 9 years of age, when the incidence becomes equal for the sexes.[68] Crowding may be a major determinant of hospitalization rates for lower respiratory illness caused by RSV, with the incidence of hospitalization for infants 1 to 3 months old residing in rural, urban, and heavily industrialized areas of Great Britain being 1 in 80, 1 in 60, and 1 in 40, respectively. The figures for all children younger than 5 years of age were 1 in 714, 1 in 588, and 1 in 227, respectively.[28] Studies from Tucson, Arizona, indicate that many socioeconomic factors, including absence of breast-feeding, low level of maternal education, and exposure to cigarette smoke, are associated with an increased risk of developing lower respiratory infection at the time of infection with RSV. The greatest risk was conferred by sharing sleeping quarters with two or more individuals.[192]

CLINICAL PRESENTATION

Acute bronchiolitis occurs most commonly in infants 1 to 12 months of age. In most instances, the patient's history reveals exposure to an adult or older child with a common cold or other trivial respiratory infection. Occasionally, as in the daycare setting, the child is exposed to other children with more marked respiratory illness. After exposure, the incubation period is approximately 5 to 7 days. The initial signs include copious nasal discharge (often serous in the early stage), cough, irritability, poor feeding, and vomiting in some cases. Slightly more than 50 percent of infants have fever, with rectal temperatures ranging from normal to 40.6° C (105.4° F) (mean, 39° C [102° F]).[137] Nasal congestion with tenacious secretions and progressive cough and dyspnea dominate the clinical picture.

Symptoms of upper respiratory infection persist for several days, and the onset of lower respiratory infection usually is precipitous, with the time of the onset of wheezing often being recognizable from the caretaker's description of the illness. The maximum severity of illness generally is attained within 24 to 36 hours of the first signs of lower respiratory illness. Apnea may occur and may be sufficiently severe to require mechanical ventilation.[12]

At the time of hospital admission, all patients have cough and evidence of respiratory distress. The pulse is rapid, and the respiratory rate usually is 40 to 80 breaths/min. The breathing is labored, with flaring of the alae nasae; grunting; abdominal breathing; and supraclavicular, subcostal, and intercostal retractions. The degree of retraction of the lower chest wall may be an accurate indicator of the severity of the illness. Wheezing often is audible without the use of a stethoscope, and the chest is full. Hyperresonance may be detected on percussion, and auscultation generally reveals harsh rhonchi, high-pitched or low-pitched expiratory wheezes, or fine inspiratory rales. Occasionally, wheezing is not audible despite other evidence of airway obstruction. A prolonged expiratory phase of breathing may occur, suggesting the presence of a more severe degree of illness. Cyanosis also occurs in severe cases.

Other findings include a mild conjunctivitis in one third of cases, pharyngitis of varied severity in approximately half of affected infants, and otitis media in 5 to 15 percent of cases. The abdomen frequently appears distended, and the liver and spleen usually are palpable; the organs are not enlarged but are pushed down because of emphysema and the flattened diaphragm.

The duration of the hospital course of bronchiolitis varies. Significant improvement occurred in half of the cases within 2 days in one large study.[1] In the same study, approximately one third of the cases had a gradual course without evidence of clear-cut improvement at any one time; 71 percent of the patients were afebrile by the third hospital day. In another study done more than 25 years later,[54] the average duration of hospitalization was 3.4 days. Longer stays were required for infants with initial oxygen saturations of less than 90 percent and infants younger than 6 weeks at the onset of illness. Reasonable criteria for admission in otherwise healthy infants seem to include hypoxia (i.e., oxygen saturation of <90-92%), age younger than 6 weeks, and a degree of respiratory distress sufficient to reduce fluid intake to inadequate levels. Other criteria include apnea, immunodeficiency, premature birth, and the presence of significant underlying heart or lung disease. Most patients can be discharged from the hospital within 2 to 3 days after admission, although mild wheezing still may be present.

In 121 hospitalized patients, the total white blood cell count was less than 12,500/mm^3 in 74 percent, and in 15 determinations had more than 60 percent neutrophils.[1] In another study, a mean leukocyte count of 16,000/mm^3 was determined for children with lower respiratory tract disease, including bronchiolitis, as was an increased percentage of band form neutrophils compared with that of a control group.[137] As in most infections, eosinophil counts in peripheral blood are reduced at the time of acute RSV infection.[48] Nonetheless, some patients maintain detectable eosinophilia in peripheral blood; these infants may be more likely to develop childhood asthma.[37]

Abnormalities of oxygenation frequently are present. Cyanosis may not be evident, even in the presence of markedly reduced oxygenation.[31,152] The respiratory rate is related inversely to the degree of oxygenation except when respiratory failure is imminent. In mild to moderate cases, carbon dioxide retention does not occur because the alveoli that are functioning can compensate for alveoli that are not ventilated. In severe disease, the blood pH is low, and the $Paco_2$ is elevated.[31,152] The technique of pulse oximetry has obviated the need for arterial blood gas sampling except perhaps in severe cases in which hypercarbia is a concern.

In certain patients, clinical findings (e.g., degree of chest wall retractions, wheezing) often are out of proportion to the degree of hypoxia as measured by pulse oximetry.[116,178] Infants with marked dyspnea must be evaluated carefully because respiratory failure may occur precipitously, despite their reassuring oximetry readings. A more meaningful scoring system to assess severity of illness has been developed.[57]

The radiographic appearance of the chest in bronchiolitis varies considerably.[88] Anteroposterior x-rays may be normal in mild cases. In moderate to severe illness, radiographs often appear exceptionally clear because of hyperinflation. The diaphragms often are flattened or depressed. The costophrenic angle is less acute, and the hilar vascular shadows are stretched. Frequently, areas of atelectasis give the appearance of pneumonitis, although true consolidation is a rare occurrence. The heart usually appears small. On the lateral radiograph, the diaphragm is depressed markedly, and reversal of the normal convexity frequently may be seen. The anteroposterior diameter of the chest is increased.

With recurrent wheezing episodes, the prodrome may be considerably shorter in duration with little or no fever and minimal coryza. In these children, differentiation of infection-induced wheezing from more conventional asthma becomes essentially impossible clinically.[186]

PATHOPHYSIOLOGY

The pathophysiology of bronchiolitis deservedly has been the focus of numerous investigations. Several original theories can be discounted reliably, whereas others warrant further study. Pathologic examinations of the lung in bronchiolitis or human airways in organ culture[70] reveal necrosis of the respiratory epithelium with destruction of the ciliated layer; mononuclear cell invasion of the peribronchial tissues; edema of the submucosa and adventitia; and obstruction of small airways with dense plugs consisting of dying epithelial cells, fibrin, and inflammatory cells. In contrast to asthma, mucin (periodic acid-Schiff positive material) usually is absent in fatal bronchiolitis.[184] An associated interstitial pneumonitis often is present, and patchy areas of atelectasis frequently are noted.[188]

The predominant cell types present in the lung of fatal cases are macrophages and neutrophils. Lymphocytes bearing CD4 (helper cells), CD8 (cytotoxic cells), and CD56 (natural killer cells) antigens are almost absent.[184] Even in surviving infants, CD8 lymphocyte counts are less than 1 percent of the total cells in bronchoalveolar lavage fluids,[41] and cytokines characteristically released by CD4 and CD8 cells (interleukin-2 [IL-2], IL-4, IL-5, IL-13, and interferon-γ) are present in low concentrations in nasopharyngeal and tracheal secretions.[184] Adaptive immune responses seem to be poorly developed in infants with severe forms of bronchiolitis. In contrast, staining for markers of apoptosis (caspase 3 and Fas) is positive in infected epithelial cells,[184] suggesting that recovery from primary infection depends on the antiviral activity of phagocytic cells, induction of apoptosis, and perhaps the activity of other innate immune mechanisms.

Recovery from bronchiolitis apparently is complete histologically,[117,187] although plugging of the airway still was prominent in an infant 5 weeks after having an acute episode of bronchiolitis. This infant had experienced an apparent full clinical recovery before eventually dying of acute pneumococcal pneumonia.[117]

Infants may be particularly prone to the development of severe illness as a result of infection of the small airways for many reasons, including the small diameters of their airways. The infant lung is deficient in collateral alveolar ventilation through the pores of Kohn, which develop only in later life.[100] Atelectatic areas cannot be re-expanded readily. Other studies have shown that the small airways in children younger than age 5 years contribute fivefold to sevenfold more to total airway resistance than do small airways of adults.[72] Viral infections involving small airways in young children are more likely to manifest as serious clinical illnesses than are similar infections in adults. Nonetheless, these abnormalities exist in all infants. In contrast, most infants infected with RSV do not develop lower respiratory illness, which suggests that host or environmental factors may be involved in determining the pathogenesis of RSV infection. Table 25–4 lists environmental factors, and potentially important host factors are described later.

TABLE 25–4 Factors Associated with an Increased Risk and Severity of Bronchiolitis and of Postbronchiolitic Morbidity

Factor	Increase in Frequency	Increase in Severity	Increase in Later Morbidity
Crowding	+++	+++	?
Passive smoking	+++	+++	++
Male gender	+	++	++
Absence of breast-feeding	+	+	?
Family history of asthma	±	±	±
Personal atopy	–	–	+++
Congenitally small airways	++	?	–
Airway hyperreactivity	–	+	++
RSV-specific IgE responses	++	++	++

+++, implies strong relationship; ++, implies moderate relationship; +, implies weak relationship; ±, implies controversial relationship; –, implies no relationship; ?, implies unknown relationship.

RSV, respiratory syncytial virus.

Data from references 16, 28, 52, 60, 68, 89, 97, 102-104, 154, 163, 179, 180, 183, 185, 191-193, 195.

One factor that may predispose to the development of lower respiratory illness on RSV infection is the infecting dose of virus. Infants with greater quantities of RSV in their nasopharyngeal secretions are more likely to exhibit severe illness.[15] In fatal cases, abundant virus is evident in epithelial cells plugging the airway lumen by immunohistochemical staining.[184] The fact that crowding is associated with greater risk of developing lower respiratory infection also suggests the importance of the initial inoculum.[187]

Another risk factor for the development of lower respiratory infection may be the relative diameter (or degree of intrinsic constriction) of the airway. When pulmonary function testing is completed on healthy infants before lower respiratory infection occurs, certain infants have lower air flows in smaller airways (and presumably more narrow airways) than do other infants. When followed prospectively, these infants are more likely to develop wheezing early in life than are infants with better air flow.[102] These abnormalities of lung function no longer are associated with an increased risk of wheezing after the child reaches 3 years of age. Instead, evidence of atopy becomes the principal risk factor for recurrent wheezing.[104]

Studies of adolescents reveal reversibility of their airway narrowing after receiving bronchodilator treatment, indicating the airways were constricted, but not stenotic, in early life.[160] Several studies have shown that the airways of infants are intrinsically more reactive to bronchospastic stimuli than are airways of older children,[92,169] particularly children from families with asthma.[193] How long this increased reactivity persists is unknown, and no study has shown that infants with greater degrees of hereditary airway hyperreactivity are more likely to develop bronchiolitis or recurrent virus-induced wheezing. In later childhood, repeated occurrences of viral infections are necessary to sustain this increased reactivity.[177]

In addition to the hereditary airway hyperreactivity, viruses themselves may induce increases in reactivity. Viral infections that clinically appear to be restricted to the upper respiratory tract in adults and children nonetheless result in transient, increased constrictive responses of the airway to a variety of stimuli, including histamine, irritants, and other agents, and small airway dysfunction.[2,3,9,30,39,93] Whether these minor changes contribute to the airway obstruction observed in bronchiolitis is doubtful, in that they are of much lesser magnitude than is the markedly increased reactivity that is observed in asthmatic individuals after exposure to allergens. These virus-induced changes were observed in all infected individuals, including subjects who did not experience wheezing at the time of the virus infection. If airways already are hyperreactive in infants, on a hereditary basis or as a result of a preceding viral infection, the subsequent stimulus of RSV infection may be sufficient to cause airway obstruction.

Immunologic deficits may be expected to lead to more severe forms of virus-induced respiratory illness. Studies of the antibody response to RSV infection in serum and in respiratory secretions show, however, that the nature of responses generally is similar among patients with bronchiolitis or simple upper respiratory illness alone caused by this agent.[82,181] Antibody-directed cellular cytotoxicity expressed against tissue culture cells infected with RSV also is similar in patients with all forms of illness caused by this agent.[80,147] Although investigators have shown that cells infected with RSV can activate complement through classic and alternative pathways,[159] studies suggest that in vivo activation of the complement cascade occurs with equal frequency among patients with all forms of illness caused by the virus.[81]

The concept that serum IgG antibody to RSV, acquired by vaccination or transplacentally, might sensitize the host has been dispelled by results of studies showing that severe bronchiolitis may occur in the absence of circulating antibody[126] and that titers of maternal antibody correlate with protection against infection caused by the virus.[52,123]

Lymphocyte hypersensitivity has been suggested to play a role in the development of severe bronchiolitis. Original field trials showed that a formalin-inactivated RSV (FI-RSV) vaccine induced humoral and cell-mediated immune responses to the virus. Nonetheless, vaccinated subjects manifested more severe forms of illness than did unvaccinated controls when subjects in each group subsequently were infected naturally.[85] Cell-mediated immune responses to viral antigen were greater among recipients of this FI-RSV vaccine compared with control subjects who previously had experienced natural infection.[86] The resulting disease in vaccine recipients was similar in form to bronchiolitis, and the idea that natural RSV bronchiolitis is a consequence of lymphocyte hypersensitivity to the virus has persisted.

Nonetheless, reasons to doubt that the illness that followed FI-RSV vaccination is the same as that following natural bronchiolitis exist. The two FI-RSV vaccine recipients who died after having subsequent natural infection had numerous lymphocytes and eosinophils present in the lung, which is not the case after natural RSV infection.[85,184] Infants surviving RSV infection after receiving the FI-RSV vaccine had high eosinophil counts in peripheral blood, which also is unusual in natural RSV infection.[48] In addition, cytotoxic T-lymphocyte activity is not detected easily in infants after they have had bronchiolitis,[4] and more recent autopsy studies have shown the virtual absence of CD4 and CD8 antigen-positive cells in the lung.[184] Although the development of cell-mediated cytotoxic antiviral responses may be protecting individuals with milder disease, little reason exists to contend that lymphocyte hyperresponsiveness contributes to severe bronchiolitis.

Immediate hypersensitivity to viral antigens has received much consideration as a potential contributing factor in bronchiolitis. The association of a family history of asthma with the development of bronchiolitis in infancy remains controversial.[89,154,161,195] Production of virus-specific IgE and subsequent release of mediators of bronchoconstriction have been documented, however, in infants hospitalized with bronchiolitis caused by RSV and the parainfluenza viruses.[16,179,182,183] In bronchiolitis caused by RSV, the quantities of virus-specific IgE produced and histamine present in respiratory secretions correlate with the severity of illness, as measured by degree of arterial oxygen tension.[183] Leukotriene C_4 is a product of mast cells and eosinophils primarily, but also epithelial cells and macrophages, and is a potent stimulant of airway smooth muscle constriction and mucus secretion. This mediator is released into the airway in acute bronchiolitis,[176] as is histamine,[183] and histamine is found in increased concentrations in plasma of patients with bronchiolitis.[156] In addition, prostaglandins and metabolites can be detected in secretions and blood after bronchiolitis.[156]

A possible role for eosinophils in the pathogenesis of bronchiolitis is supported by the finding of increased concentrations of eosinophil cationic protein in secretions of infants with bronchiolitis and (among high responders) an overall correlation of concentrations of this protein with the degree of hypoxia.[48,49] Peripheral blood eosinophil counts are depressed during the acute phase of most infectious diseases, including RSV infection. Nonetheless, eosinophil counts in peripheral blood are higher in infants with bronchiolitis than in infants with upper respiratory illness only, particularly in boys.[48] This finding is notable because boys generally have more severe forms of bronchiolitis. A contrasting viewpoint is that eosinophils contribute to the clearance of viruses after infection. This view is supported by the fact that eosinophils contain enzymes with ribonuclease activity, which inactivates RSV.[34,35] IgE-dependent and eosinophil-dependent mechanisms may be important in recovery from viral infections, much as they are in parasitic infections.

The airways of asthmatic individuals are infiltrated by T lymphocytes (predominantly T-helper lymphocytes) and eosinophils. T-helper cells can be classified as type 1 (T_H1), which produce primarily interferon-γ and IL-2, or type 2 (T_H2), which produce IL-4, IL-5, IL-13, and others. This finding is important because IL-4, IL-5, and IL-13 are important factors in promoting IgE synthesis and eosinophil migration. Asthma is thought by some researchers to be a result of a T_H2 bias in the airway. An attractive hypothesis is that RSV infection induces airway obstruction and wheezing by inciting the same type of T_H2 responses as observed in asthma. Interferon-γ and IL-4 are found in respiratory secretions of infants with RSV bronchiolitis, but IL-5 and IL-13 rarely are detectable in serum or secretions,[50,174] suggesting that bronchiolitis is not characterized by a T_H2 lymphocyte bias.

Chemokines are proteins released by airway epithelial cells, inflammatory cells, fibroblasts, and other cell types that are chemotactic for leukocytes. Certain chemokines (e.g., IL-8) are active on a broad variety of leukocytes. Others, such as macrophage inflammatory protein 1-alpha (MIP-1α); monocyte chemotactic protein, types 1 through 4; eotaxin; and regulated on activation, normal T-cell expressed and secreted (RANTES), are more selective for eosinophils, basophils, mast cells, and T lymphocytes. These chemokines represent an alternative to T_H2 lymphocytes in terms of initiating the inflammatory response in asthma and bronchiolitis. Studies suggest that MIP-1α, eotaxin, and monocyte chemotactic protein may be particularly important in the pathogenesis of bronchiolitis because they correlate with the degree of hypoxia observed during acute illness.[50] Abnormalities of chemokine responses, rather than T-helper cell responses, may underlie the pathogenesis of bronchiolitis and represent therapeutic targets.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

A tendency exists to attribute all infantile respiratory distress occurring after the immediate newborn period to bronchiolitis. The list of causes of infantile dyspnea consists of conditions that are associated with upper and lower airway obstruction, however. Recognition of upper airway obstructive disease should cause little difficulty because the problem is one of distress with inspiration, rather than air trapping. Illnesses that cause lower airway obstructive disease and diseases that suggest this problem are listed in Table 25–5.

The differential diagnosis of allergic disease causes the most difficulty. Generally, the first episode of allergic respiratory disease, when associated with infection, cannot be separated from bronchiolitis by any objective measures. Anatomic defects such as vascular rings can cause obstruction of the airway at many locations; inspiratory or expiratory distress, or a combination, can occur. Frequently, a child with an anatomic defect does not have any detectable difficulty until a trivial respiratory infection occurs, which complicates the diagnostic picture.

Foreign bodies should be considered even in very young infants. Gastroesophageal reflux disease has become recognized as a frequent cause of wheezing in young infants. Because of its obvious therapeutic implications, bacterial pneumonia is the most important differential consideration, although wheezing occurs rarely in association with bacterial pneumonia.[98,99]

TABLE 25–5 Differential Diagnostic Considerations in Acute Bronchiolitis and Infectious Asthma

Allergy
Asthma
Allergic pneumonias (e.g., allergic aspergillosis)
Anatomic cause
Vascular ring, lung cysts, lobar emphysema
Pneumothorax, hydrothorax, chylothorax
Foreign body
Circulatory failure
Congenital and acquired heart disease
Anemia
Nephritis
Infections
Viral, chlamydial, rickettsial, mycoplasmal, bacterial, and fungal pneumonias
Migrating parasites
Irritants
Inhalation of toxic substances (e.g., chlorine gas)
Aspiration pneumonia
Gastroesophageal reflux
Metabolic cause
Poisons (e.g., salicylate)
Acidosis

SPECIFIC DIAGNOSIS

Because bronchiolitis and infectious asthma are clinical diseases with arbitrary boundaries and multiple etiologic agents, outlining a method for establishing specific diagnosis is difficult. When illness is epidemic, RSV usually is the cause. In nonepidemic situations, a careful history and appropriate laboratory studies and radiographs should be considered to exclude the other differential diagnostic possibilities that are listed in Table 25–5.

A specific etiologic diagnosis can be made by the isolation of virus from the nasopharynx. The diagnostic virologic facilities of many medical centers enable the isolation in tissue culture of RSV, parainfluenza viruses, influenza viruses, adenoviruses, rhinoviruses, enteroviruses, and herpesviruses. The use of the shell vial technique has been applied to RSV infection with success.[158] The polymerase chain reaction technique also shows promise in amplification of small quantities of RSV RNA from clinical specimens, although its having superiority to other methods for testing of infants does not seem likely.[128] Rapid detection of viral antigen of RSV directly in nasopharyngeal secretions by commercially available (e.g., enzyme-linked immunosorbent assay) or fluorescent antibody techniques is the method of choice in most laboratories for several reasons.

The accuracy of these techniques often is superior to that of standard cell culture (at least in infants) because antigens remain stable under transport conditions that inactivate live virus. Results also are available several days earlier than by cell culture. Infections with influenza viruses, parainfluenza viruses, and adenoviruses also can be identified by rapid detection techniques, and reliable commercial kits permitting simultaneous testing for each of these agents are the standard in most laboratories.

TREATMENT

The cornerstone of therapy for bronchiolitis is the administration of oxygen because sicker patients usually are hypoxemic.[36,152] Oxygen saturation should be maintained at 92 percent or higher. Usually, an oxygen concentration of 30 percent or 40 percent can achieve this goal, and the patient's respiratory status can be monitored by pulse oximetry; however, blood gas determinations should be obtained when indicated by clinical findings (e.g., cyanosis, agitation). A common practice is to place children with bronchiolitis in tents and administer mist vigorously. Although oxygen should be humidified, the use of mists and aerosols except to deliver specific antiviral therapy is discouraged; mist can act as

an irritant, causing reflex bronchoconstriction, and the water usually does not reach the lower airways.[5]

Although dehydration is a potential problem in children with bronchiolitis because of vomiting and lack of intake, care must be taken not to overhydrate such patients. Because edema is an important part of the pathology of bronchiolitis, excess water may contribute to obstruction of the airway.

Beta-adrenergic bronchodilators have been used frequently in bronchiolitis. Slight improvements in air flow, in oxygenation, and in clinical illness scores have been reported,[63,87,91,143,144] but these effects are not likely to be meaningful clinically; hospitalization is not prevented, and hospital stays are not shortened.[33,43] Improvements observed after the administration of the first dose of these compounds usually are not observed after administration of subsequent doses. In one study, oral and aerosolized beta-adrenergic agents were compared with inactive substances given by the corresponding route. The degree of improvement was the same in all four groups.[47] Combinations of salbutamol and dexamethasone also have no objective effect.[167]

In the past, epinephrine often was administered subcutaneously to older infants in an attempt to differentiate allergic disease from true bronchiolitis. This approach rarely was successful in differentiating one illness from the other or in improving the condition of the patient. Studies have suggested, however, that use of aerosolized, racemic epinephrine produced greater improvement than the use of beta-adrenergic aerosols alone.[144] Other studies of alpha-adrenergic agents have resulted in the same conclusion. Generally, the minor improvements in pulmonary function obtained using alpha-adrenergic agents or racemic epinephrine are not clinically meaningful; the mortality rate is not improved, and the duration of stay in the intensive care unit or in the hospital is not reduced.

Aerosolized sympathomimetic drugs are used frequently in older children with wheezing presumed to be caused by viral infections, with better results than those in infants.[77,91,129,143] Nonetheless, no evidence exists that this form of therapy reduces the need for hospitalization of these patients. Aerosols of ipratropium also have been administered in bronchiolitis without observable benefit.[148] Possible explanations for poor responses to bronchodilators include a paucity of beta-adrenergic receptors in infancy[139]; decreased amounts of smooth muscle capable of responding to bronchodilators surrounding the terminal airways[136]; the nature of the airway obstruction itself (intense plugging with cellular debris)[184,188]; and, presumably, persistence of virus in the airway, stimulating continued inflammation or release of bronchoconstrictive mediators, or both.

Trials of alpha-adrenergic or beta-adrenergic aerosols may be attempted in seriously ill patients,[13,36] although persistence with either of these approaches in the absence of an initial response may prove harmful.[77,124] Most infants hospitalized with bronchiolitis recover quickly with no other intervention than supplemental oxygen and fluid replacement as necessary. A child treated for croup with multiple doses of racemic epinephrine developed ventricular tachycardia and a small myocardial infarction,[18] emphasizing the need to avoid the careless use of these compounds in viral respiratory infections.

Corticosteroids have been employed repeatedly in treating bronchiolitis. Controlled studies have failed to reveal any benefit in terms of prevention of hospitalization, reduced duration of hospitalization, reduced need for intubation, or reduced frequency of recurrent wheezing episodes after bronchiolitis.[8,14,31,32,44,90,138] In a child with nonrespiratory indications for the administration of corticosteroids, these drugs need not be withheld because of fear of complications, although the duration of viral shedding may be extended in individuals treated with steroids.

Early experience with the antiviral substance ribavirin in bronchiolitis suggested that mild subjective benefits and improvement in oxygenation occurred after near-continuous aerosol administration of this compound.[60,61,141,165] The degree of improvement in patients treated with ribavirin was not marked. No study has shown whether the administration of ribavirin could prevent deaths, avoid the need for mechanical ventilation, or shorten the duration of hospital stays.[105,112,157] A meta-analysis of studies using ribavirin showed slight benefits in morbidity and mortality rates that were not statistically significant.[135]

Ribavirin is quite expensive and is difficult to use because of the need for prolonged aerosol administration. Although the drug may precipitate in ventilatory circuits of mechanical ventilators, it can be administered safely if filters are used to prevent plugging of the circuits.[124,125] Because ribavirin is teratogenic in rodents, concern has arisen regarding the safety of health care workers exposed to aerosols of the drug.[65,140] Although absorption may occur in hospital workers, the amount absorbed is negligible.

Other approaches to therapy of RSV infection include the use of interferon-α,[27] vitamin A,[120] DNase,[106] and nitric oxide.[127] The results of these studies were negative. Surfactant[83,171] and leukotriene receptor antagonists[155] have been used in very small studies of bronchiolitis or virus-induced wheezing, with positive effects that require confirmation. Preparations containing a very high titer of neutralizing antibody against RSV have been tested in the prevention and treatment of RSV infection in high-risk populations.[57,66,170] The results of the prophylaxis studies were positive, as discussed later. A significant therapeutic effect of these compounds could not be identified after RSV infection was established, however.[101]

Because bronchiolitis is a viral disease, antibiotics are not useful or necessary. In many instances, the radiographic picture suggests pneumonia, and the blood leukocyte count is elevated; the physician feels compelled to administer antibiotics. Most authorities do not use antibiotics in bronchiolitis or discontinue their use after RSV infection is confirmed because bacterial infection of the lung is rare in bronchiolitis even when infiltrates are identified on chest radiographs. In one large study, secondary bacterial infection occurred in no more than 7 (1.2%) of 565 children with RSV infection.[62] Institution of antibiotics should be considered during the course of therapy when a change in illness suggests the possibility of secondary bacterial infection.

A child with bronchiolitis generally is more comfortable in the supine position with the head end of the crib slightly elevated. Infant seats are used frequently, but are not optimal because the child's head tends to fall to the side or forward, which constricts the upper airway. The sitting position also causes a possibly deleterious upward pressure on the diaphragm. If respiratory failure occurs (virtually absent inspiratory breath sounds, severe inspiratory retractions, inability to maintain an oxygen saturation of >90% in 40% ambient oxygen, cyanosis in 40% oxygen, decreased or absent response to painful stimuli, and a $Paco_2$ of ≥65 mm Hg), ventilatory assistance, such as nasotracheal intubation, neuromuscular blockade, and positive-pressure ventilation,[36,124] is indicated.

PREVENTION

The development of a method to prevent RSV infection is a high priority. The initial adverse experience with formalin-inactivated vaccine (described earlier) has nearly prevented further investigation of inactivated vaccines.[85,172] Later, a live, temperature-sensitive vaccine was developed by adapting RSV to grow at low temperatures in cell culture. This attenuated vaccine was designed to grow at the lower temperatures of the upper respiratory tract but be inactive at the higher temperatures in the lung. In initial field trials, the vaccine strain caused febrile respiratory illnesses in seronegative vaccinees but did not replicate adequately in

seropositive subjects.[23] Further trials of temperature-sensitive mutant RSV strains as vaccines showed improved immunogenicity and some protection, at least against rechallenge with the vaccine strain. Nasal congestion that could cause apnea was common in recipients, however.[78] Numerous other vaccine candidates, including RSV nucleic acid vaccines, bovine RSV strains, parainfluenza virus strains bearing RSV antigens, and human RSV strains with gene deletions or given with immunologically active adjuvants, have been developed. Many of them are in early clinical trials, but development of a successful vaccine is not imminent.

In contrast to the largely negative experience with vaccine development, protection against serious illness caused by RSV infection was achieved using a pooled preparation of human serum obtained from donors with very high titers of neutralizing antibody against RSV.[57] This compound, when administered during the RSV season on a monthly basis to infants and young children with a history of birth at less than 32 weeks' gestation or with bronchopulmonary dysplasia, caused a marked reduction in the severity of illness and rate of hospitalization after RSV infection.

These trials have been repeated successfully using a mouse monoclonal antibody against the RSV fusion protein.[170] The antibody is reconstructed so that it has more than 95 percent of the protein structure of a human antibody. This compound is approximately 50 percent effective in preventing RSV-related hospitalization when administered to high-risk infants, and it has received approval for use in infants born prematurely with or without lung disease of premature birth. Separate trials in infants with hemodynamically significant congenital heart disease have shown a similar reduction in the rate of hospitalization for RSV-related illness, and the compound is now approved for use in these infants as well.[42]

COMPLICATIONS AND PROGNOSIS

Virtually all cases of bronchiolitis in healthy children resolve without acute complications. Secondary bacterial infection in bronchiolitis now is a rare occurrence, at least in developed countries. Scott and colleagues[146] identified minor electrocardiographic abnormalities in 2 percent of 188 children with bronchiolitis. Involvement of other organs apparently does not occur.

The overall mortality rate in bronchiolitis is low. Before the modern era of improved ventilatory support, mortality rates ranged from 2 to 5.5 percent.[36,67,71] A multicenter study in Great Britain published in 1978[28] estimated the mortality rate owing to RSV infection in infancy at 0.5 percent. Deaths should occur rarely except among infants with severe underlying cardiac or pulmonary disease; even in these cases, mortality rate should not exceed 1 percent of cases.[42] Between 1979 and 1997, an average of 95 bronchiolitis-associated deaths occurred annually in the United States, with 20 percent occurring in infants with underlying heart disease, lung disease, or premature birth.[151]

The association of bronchiolitis with the subsequent development of asthma has long been controversial. Fifty percent of patients with bronchiolitis have recurrent episodes of wheezing, although this figure decreases to approximately 10 percent by adolescence and may not be above that of the general population by this time.[96,97,160] Whether this recurrent wheezing is caused by RSV infection or, alternatively, suggests that RSV infection in early life is an indicator of a tendency toward airway obstruction is still being investigated. Recurrent wheezing after having a case of bronchiolitis could reflect an inherited asthmatic trait. Some studies find a strong correlation between atopic family history and postbronchiolitic wheezing,[38,46,142,186,195] whereas others, particularly studies from Great Britain,[132,153,154] do not. Titers of total serum IgE[130,161] and peripheral blood eosinophil counts[37,103,195] have some predictive value for the development of recurrent wheezing after having bronchiolitis. Two studies showed that peripheral blood eosinophilia during viral infections, particularly RSV bronchiolitis, predicts the development of recurrent wheezing in school-aged children.[37,103] Atopy seems to explain a great deal of the recurrent wheezing that occurs after bronchiolitis.

RSV infection in early infancy could damage the developing airway, rendering the airway more prone to obstruction in later life. Pulmonary function tests performed in former patients with bronchiolitis 12 years after an episode of bronchiolitis reveal an increased frequency of airway hyperreactivity in response to challenge with exercise or chemical agents, increased ratios of residual volume to total lung capacity, and reduced expiratory air flow at low lung volumes.[58,79,132,153,162,163,169,190] Although these abnormalities are observed commonly in individuals with asthma, they could not be explained in several of the previous studies simply by the presence of a personal or family history of atopy.[59,132,154] Some of these retrospective studies showed, however, that a single episode of RSV bronchiolitis was not associated with long-term lung dysfunction; abnormal lung function was observed only if at least two episodes of lower respiratory illness had occurred before the patient had reached age 2 years.[69,177]

Prospective studies show that recurrent wheezing in children through age 3 years after bronchiolitis (but not beyond) is related to abnormalities of lung function that existed before RSV infection occurred.[102] Wheezing persisting beyond age 3 years was related, at least partially, to the atopic status of the host.[103,104] No study has shown a relationship between the severity of the initial bronchiolitis episode and the degree of abnormality of long-term lung function.[58,59,132,153] Personal atopy is responsible for many of the long-term manifestations proposed to be sequelae of bronchiolitis. Some factor other than atopy may determine in part the apparent lung abnormalities seen after a case of bronchiolitis,[96,179,191,192] but no direct evidence indicates that this other factor is the initial episode of RSV infection itself.

RSV infection could induce persistent airway hyperreactivity. Retrospective studies have shown that airway reactivity is greater in individuals 1 decade after having an episode of infantile bronchiolitis than in control populations without a history of bronchiolitis.[58,132] Airway reactivity in all children (even children never experiencing bronchiolitis) is greater than that in adults, however, and it is greatest in children of atopic families and in children exposed to cigarette smoke.[193] Airway hyperreactivity occurring after bronchiolitis is not a reflection of the RSV infection itself. One prospective study found no relationship between RSV bronchiolitis and the degree of airway reactivity at age 2 years.[2]

RSV infection possibly can promote sensitization to allergens. In animal models, critically timed RSV infection can enhance temporarily the degree of airway reactivity induced after sensitization to an allergen. Whether this phenomenon occurs in humans is unknown. The absence of T_H2-like cytokine responses at the time of having RSV bronchiolitis[50] suggests, however, that RSV infection in infancy likely does not promote a persistent atopic state in the host.

RSV infection more likely results in the release of mediators of airway obstruction, such as histamine and leukotrienes, through a mechanism other than T_H2 cytokine responses. Chemokines such as MIP-1α, which cause mast cell and basophil degranulation, are possible candidates. Release of these mediators at the time of having RSV infection may result in wheezing in susceptible individuals. These same individuals may develop wheezing again at the time of having allergen exposure in childhood (particularly if they are atopic), but the relationship of bronchiolitis in infancy and such subsequent childhood wheezing would not be causal, but rather would be based on the underlying susceptibility of the airway to obstruction.

The overall outlook for infantile bronchiolitis generally is excellent. In a follow-up study conducted at the author's institution,[179] severe lung disease was not observed in former bronchiolitis patients. All oxygen saturation levels were greater than 95 percent, and at least some of the air flow obstruction present in patients aged 7 to 9 years was reversible with a single bronchodilator treatment, as was confirmed later.[160] Single episodes of infantile bronchiolitis (in the absence of passive smoke exposure and without recurrent wheezing episodes) have not been associated with abnormalities of lung function or airway hyperreactivity in later childhood.[79,163,177]

The natural history of postbronchiolitic wheezing in childhood is for episodes of wheezing to become progressively milder,[58,97,132,153] and the frequency of postbronchiolitic wheezing eventually decreases to essentially the same rate as that of children who did not experience bronchiolitis in infancy.[69,97,160] Nonetheless, the overall prognosis is not entirely benign, and exposure to noxious environmental elements may result in an accelerated deterioration of lung function in later life.[27,186,190] The combination of respiratory tract illness in early life and subsequent cigarette smoking especially may be harmful.[166] Individuals who develop bronchiolitis in infancy should avoid smoking in later life and occupations that are associated with exposure to respiratory irritants.

CHAPTER 26

Nonbacterial Pneumonia

Kenneth M. Boyer

Nonbacterial pneumonias remain the most frequent pulmonary infections encountered in pediatrics. In recent years, conjugate vaccines against invasive *Haemophilus influenzae* type b (Hib) and *Streptococcus pneumoniae* infections have decreased significantly the importance of these bacterial pathogens.[33,34] Relatively less progress has been made in creating effective vaccines against the most common nonbacterial pathogens that cause pneumonia. Work is progressing on several attenuated viral vaccines,[128] however, and the recommendations for annual influenza vaccination of children have been broadened considerably.[208]

Numerous terms, based on causes, clinical manifestations, or histologic features, are used for these pulmonary infections. Although the connotations differ, viral pneumonia, viral lower respiratory tract infection, atypical pneumonia, infant pneumonitis, and interstitial pneumonia are encountered frequently. The varied causes, excluding bacteria and fungi, cover a broad taxonomic spectrum. With improvements in microbiologic techniques, the number of known causative agents continues to increase. Defining the origin of these infections once was the province of the epidemiologist and virologist, but a sufficient body of knowledge has accumulated to permit informed diagnostic judgment to be made by practicing physicians and rapid specific diagnosis to be confirmed by clinical microbiology laboratories. Although most nonbacterial pneumonias have a good prognosis, occasionally they are life-threatening. Therapy directed against the causative agent may shorten the duration of the course of illness or may avert serious complications. At times, it is lifesaving. This chapter provides an overview of pneumonia syndromes caused by viruses, mycoplasmas, and chlamydiae, as well as by *Coxiella burnetii* (a rickettsia) and *Pneumocystis jiroveci* (an apicomplexan parasite).

HISTORICAL ASPECTS

The development of systematic bacteriology in the late 19th century led to the widespread consensus that pneumonias were bacterial infections with differences in manifestations (bronchial, lobular, lobar) that primarily were the result of differences in anatomic localization. During the 1918 influenza pandemic, most postmortem examinations of patients with pneumonia revealed numerous bacteria in the lungs. Various different species were identified, not exclusively *H. influenzae*, the organism at that time regarded as the cause of influenza. However, in a few cases in

which no bacteria were found, Goodpasture[89] and Winternitz and colleagues[253] found distinctive histopathologic lesions in the lung that they concluded were induced by a nonbacterial agent. Isolation of influenza A virus by Smith and associates[234] in 1933 confirmed their observations, altered the prevailing bacteriologic and anatomic concepts of pneumonia, and ushered in a new era of etiologic diagnosis of respiratory syndromes.

The first isolation of influenza virus and subsequent isolation of *Chlamydia psittaci* (psittacosis) and *C. burnetii* (Q fever) involved transmission of infection to experimental animals such as ferrets and chick embryos. The development of tissue culture techniques in the 1950s enabled researchers to identify numerous other common respiratory viruses: adenoviruses, parainfluenza viruses, respiratory syncytial virus (RSV), enteroviruses, and rhinoviruses. The major etiologic agent of primary atypical pneumonia had been passed to experimental animals in the 1940s, but it was not identified as a mycoplasma definitively until 1962.[42]

In the 1960s and 1970s, the most valuable studies of nonbacterial respiratory infection in pediatrics were comprehensive longitudinal investigations in which epidemiologic and clinical patterns of illness were defined. These studies established that most lower respiratory tract infections in infants and young children are caused by nonbacterial agents, principally respiratory viruses and *Mycoplasma pneumoniae*.

The attention of current investigators is being directed increasingly at developing methods for rapid diagnosis, chemotherapy, and prevention. However, more refined tissue culture and nucleic acid amplification techniques have enabled researchers to identify numerous new agents, including Sin Nombre hantavirus,[111,245] human metapneumovirus,[247] human bocavirus (HBoV),[3] and several strains of coronavirus, including the virus that caused the global epidemic of severe acute respiratory syndrome (SARS).[56,139,247,256]

ETIOLOGY

Three *Mycoplasma* spp., a single *Rickettsia* sp., 3 *Chlamydia* spp., 1 protozoan parasite, and at least 16 different virus groups have been associated with pneumonia syndromes in children. The overall importance of these agents is not measured simply by their incidence. Some agents, although quite common, generally give rise to mild illness; others, less frequently encountered, characteristically cause serious disease. In Table 26–1, the major agents in various age groups are presented by their overall frequency, their typical degree of severity, and their mode of access to the lung. Although the incidence data are representative of numerous major epidemiologic studies,* one should recall that the proportion of pneumonias of unproven cause in most such studies has been approximately 50 percent. Possible explanations for the high percentage of such cases include the following: a bacterial origin[175]; partial treatment with antimicrobial agents[127]; late collection of viral cultures and sera[71]; suboptimal storage, transport, or cultivation of specimens[83,218]; and as yet unidentified agents. The use of antigen tests for bacterial pathogens and of immunoassays and polymerase chain reaction (PCR) assays for viruses accounts for the higher rates of diagnosis in some studies.[110,127,258]

RSV generally is accepted as the agent found most frequently in pediatric pneumonias, particularly those associated with bronchiolitis.† Although infection with this virus is quite common in all age groups, lower respiratory tract involvement is especially prominent in infancy.

The three parainfluenza viruses (types 1, 2, and 3) are second only to RSV as causes of lower respiratory tract disease in infants and younger children. Parainfluenza virus type 3 is the agent most frequently found in pneumonia[85,86,117,198]; infection with parainfluenza virus types 1 and 2 generally produces laryngotracheitis.

Human metapneumovirus, described in children with upper and lower respiratory tract infection in the Netherlands,[246] is thought to account for 10 percent of otherwise unexplained respiratory infections. The clinical symptoms in infected children resemble those caused by RSV.[188,246]

Influenza A and B viruses are not as prevalent overall as are RSV and parainfluenza viruses, but during periods of epidemic spread, they may become predominant isolates in hospitalized children with lower respiratory tract disease[15,26,81,134,193,197,226] The threat of a pandemic of influenza A, secondary to a recombination event resulting in a "humanized" avian virus, keeps influenza in the forefront of concern for global public health agencies.[81,204]

Adenoviruses commonly are isolated in children with pneumonia* and pertussis syndrome.[25,48,186,190] The overall impact of these viruses in the origin of nonbacterial pneumonia in children probably is somewhat less than that of the aforementioned agents; however, many fatal illnesses have been reported. Their common asymptomatic carriage and potential for endogenous activation by unrelated illnesses can render causation difficult to prove.[68,186] Of the 51 known adenoviruses, types 1, 2, 3, 4, 5, 7, 14, 21, and 35 clearly have been associated with pneumonia.[25,135] In certain aboriginal populations such as the Maori, Native Americans, and Inuit, adenoviruses commonly produce severe infection.[114,140] In military recruits, adenoviruses are second to *M. pneumoniae* as a cause of atypical pneumonia.[54]

Rhinoviruses[15,79,199,215,240] have been associated less frequently with pneumonia, although upper respiratory infection with the multiple serotypes of these organisms is common. Some degree of lower respiratory involvement by rhinoviruses also is indicated by the documented role of these viruses in exacerbations of asthma[176] and bronchitis.[171] Among the enteroviruses, primary viral pneumonia has been documented best with coxsackieviruses A9[146] and B1,[58] although coxsackieviruses A16, B4, and B5 and echoviruses 9, 11, 19, 20, and 22 also have been reported.[42,97,230]

Coronaviruses HCo-OC43 and HCo-229E have been implicated as causes of pneumonia since the 1960s, but until recently, this family of viruses was considered a rare cause of human disease.[132,168] The worldwide epidemic of SARS that occurred in 2002 to 2004 focused new interest on these pathogens and led to a new appreciation of their reservoirs in domestic animals and their potential to cause severe pneumonia and respiratory failure.[56,139] Fortunately, the SARS-CoV, no longer circulating, appears to be unique in its pathogenic potential. Two other strains of coronavirus, HCo-NL63[247] and HCo-HKU1,[256] have been discovered more recently. They appear to be among the less common causes of lower respiratory infections, but their clinical manifestations are similar to those caused by the other common respiratory viruses.[61,212]

The respiratory virus most recently described that can cause pneumonia is HBoV.[3] It is a parvovirus closely related to bovine parvovirus and canine parvovirus. (The "bo" in "bocavirus" derives from "bovine," the "ca" from canine.) It was identified using a novel technique based on amplification of nonspecific viral nucleotide sequences, a method that holds promise for identification of other previously uncultivated human viral pathogens. Because only a few population-based studies have been per-

formed, the contribution of HBoV to the overall epidemiology of pediatric pneumonia remains uncertain. It has been identified in serum and feces, as well as in respiratory specimens[73] and was found to be a relatively common (19%) finding in a Finnish study of children with asthma exacerbations.[2]

Pneumonia is the most frequent serious complication of measles. Kohn and Koiransky[137] demonstrated, by careful radiographic study, that 55 percent of patients with routine measles cases had pulmonary infiltrates early in the illness, a finding suggesting a viral rather than a bacterial cause. Secondary bacterial pneumonia in measles is caused by common respiratory pathogens: *S. pneumoniae*, *H. influenzae*, *Streptococcus pyogenes*, and *Staphylococcus aureus.* Progressive, fatal, primary measles pneumonia (Hecht giant-cell pneumonia) occurs in immunocompromised patients, particularly those with hematologic malignancy or infection with human immunodeficiency virus type 1 (HIV-1).[138,159,228,229] The typical measles rash often is absent. In some persons immunized with killed measles virus vaccine during the 1960s, unusual nodular pneumonia, along with vasculitis of the distal extremities, developed after infection with wild measles virus. Although no longer seen, atypical measles remains important because its pathogenetic mechanism has implications for the development of new vaccines.[74]

Viruses that may attack the lungs by hematogenous spread include varicella-zoster virus (VZV), Epstein-Barr virus (EBV), rubella virus, cytomegalovirus (CMV), herpes simplex virus (HSV), and HIV. Rubella virus, CMV, and HSV may cause interstitial pneumonia in congenitally or perinatally infected infants.[10,106,255,261] CMV and VZV are causes of life-threatening pneumonia in immunocompromised hosts[120,203,252] Pneumonia has been noted in association with primary EBV infections.[8,62] Pulmonary infiltration also is a component of the fatal X-linked lymphoproliferative syndrome caused by EBV.[211] One of the characteristic features of HIV infection in children is lympho-

cytic interstitial pneumonitis, an indolent but progressive process that occurs in approximately one fourth of children in whom acquired immunodeficiency syndrome (AIDS) develops.[221] Both HIV RNA and EBV DNA have been demonstrated in the lung tissue of affected children.[6] The relative contributions of the two agents to the pathogenesis of lymphocytic interstitial pneumonitis are not understood clearly, although EBV is suspected to be the trigger.[131]

Of the 15 known *Mycoplasma* spp. that infect humans, only *M. pneumoniae* is a well-established cause of pneumonia. In children younger than 2 years of age, infection is a common occurrence, but pneumonia is unusual. In children older than 5 years of age, *M. pneumoniae* is the most common cause of nonbacterial pneumonia.[44,71] Studies have associated genital mycoplasmas, in particular *Ureaplasma urealyticum* and *Mycoplasma hominis*, with congenitally and perinatally acquired pneumonia.[32,107]

Three *Chlamydia* spp. have been associated with pneumonia. *C. psittaci* is the well-recognized cause of psittacosis (ornithosis). *Chlamydia trachomatis*, the established agent of inclusion blennorrhea in neonates, causes a characteristic afebrile pneumonitis syndrome in infants aged 4 to 14 weeks.[17] In urban areas in the United States where the condition first was studied carefully (Chicago, Seattle, San Francisco, and Birmingham, Alabama), it was the most frequent cause of pneumonia in that age group.[57,109] With widespread screening and treatment of pregnant women for *Chlamydia*, the incidence of this condition appears to be decreasing. *Chlamydia pneumoniae* was isolated first in 1965 and was recognized as a cause of pneumonia in 1986.[91] It now is considered to be the second most frequent cause of pneumonia in older children and young adults.[92,223]

Of the rickettsiae, only *C. burnetii* is associated with pneumonia, in the form of Q fever. This infection may be severe, but because of its restricted zoonotic niche in domestic farm animals, it is a rare occurrence in children.

P. jiroveci, a protozoan parasite, is an important cause of pneumonia in compromised hosts,[120,203,252] although its incidence in children receiving chemotherapeutic regimens for malignancy has been reduced dramatically with the use of trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis.[119] *P. jiroveci* is an established cause of pneumonia in premature and debilitated infants,[77] and, with *C. trachomatis*, CMV, and genital mycoplasmas, it has been associated with the afebrile pneumonitis syndrome of infancy.[57,201,237,238] *P. jiroveci* is the most frequent cause of death in infants with HIV infection, although the incidence is reduced markedly in U.S. populations as a result of early diagnosis and treatment of perinatal HIV infection and by the institution of chemoprophylaxis with TMP-SMX.[216,231]

EPIDEMIOLOGY

The major contributors to the overall epidemiology of nonbacterial pneumonia in children are RSV, parainfluenza viruses, *M. pneumoniae*, and, to a lesser extent, influenza viruses A and B.[53] Because of their brief incubation periods and high degree of communicability, these agents often spread through communities in well-defined waves[83,85] (Fig. 26–1). During intervals between epidemics, RSV, parainfluenza viruses types 1 and 2, and influenza viruses A and B rarely are isolated. Between peaks, *M. pneumoniae* and parainfluenza virus type 3 tend to persist endemically. During seasons of respiratory disease in the colder months, an interference phenomenon has been noted whereby peaks of infection by particular agents seldom occur simultaneously[83] (Fig. 26–2).

Annual incidence rates of childhood pneumonia show a rough inverse correlation with age. These rates range from

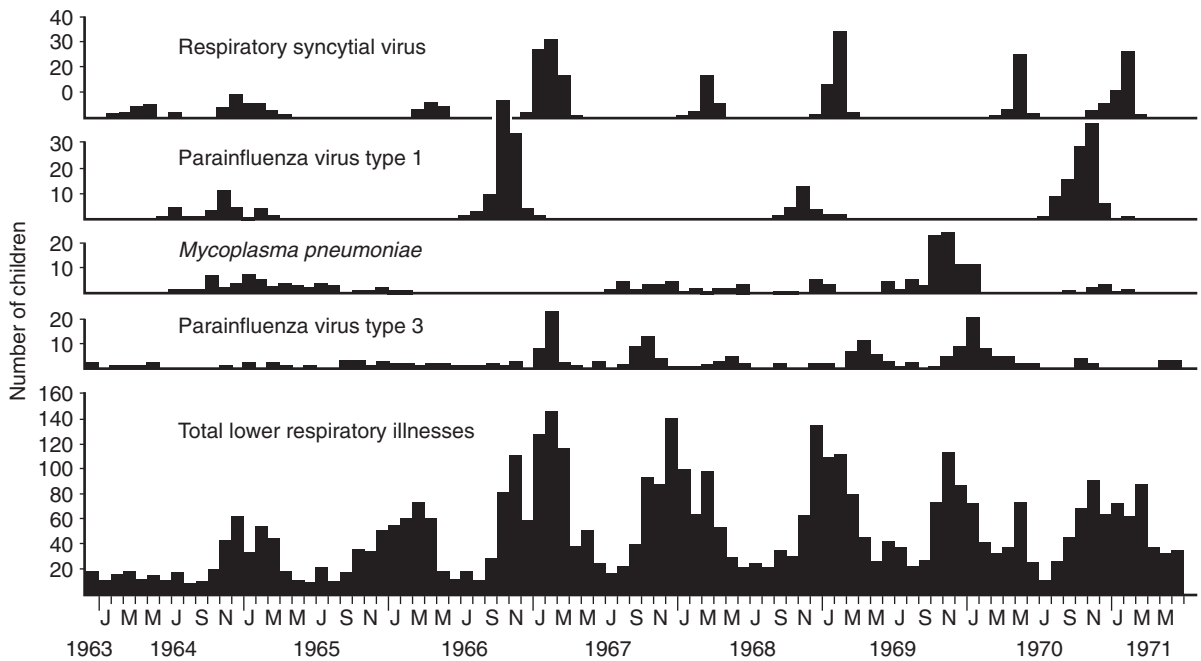

Figure 26-1 Number of isolations, according to month, of four major respiratory pathogens from children with lower respiratory illnesses in Chapel Hill, North Carolina. (*From Glezen, W. P., and Denny, F. W.: Epidemiology of acute lower respiratory disease in children. N. Engl. J. Med.* 288:*500, 1973. Reprinted with permission from the New England Journal of Medicine.*)

W.: Epidemiology of acute lower respiratory disease in children. N. Engl. J. Med. 288:500, 1973. Reprinted with permission from the New England Journal of Medicine.)*

40 per 1000 in children younger than 5 years of age to 7 per 1000 in adolescents aged 12 to 15 years.[71,183] RSV is the most common etiologic agent in children younger than 5 years of age; in those older than 5 years, *M. pneumoniae* is the most common.[71] Most studies have shown a male preponderance in pediatric lower respiratory infections on the order of 1.25:1. The increased rates of lower respiratory infection in lower socioeconomic groups correlate best with family size, a reflection of environmental crowding.[83]

Pregnancy, chronic lung disease, valvular heart disease, and neuromuscular conditions in adults predispose them to experiencing greater severity of viral, particularly influenzal, pneumonia.[154] In children, congenital heart disease and bronchopulmonary dysplasia are associated with greater severity of viral pneumonia, especially with RSV.[156] Pulmonary deterioration in patients with cystic fibrosis has been shown to be accelerated by respiratory viral infection.[249] In treated hematologic malignancy, marrow transplantation, and immunosuppressed states, common respiratory viruses have been recognized increasingly as causes of severe pneumonia and respiratory failure.[104,108] Children with these underlying conditions also are prone to developing serious pulmonary infection with such agents as measles virus, VZV, and CMV, which have the capacity for hematogenous dissemination and viral latency. Pediatric HIV infection has added a new category of immunocompromised children susceptible to these pathogens, as well as to the common bacterial agents of pneumonia. Profoundly immunocompromised patients, such as those with severe combined immunodeficiency disease, are prone to acquiring progressive and prolonged pulmonary disease caused by common respiratory viruses.[125]

Transmission of the more common agents of lower respiratory tract disease most often occurs by means of droplet spread from relatively close contact with a source case. Direct inoculation at the alveolar level probably does not occur in most cases because of the extremely small size of aerosolized particles necessary for such transmission to be accomplished. Studies of nosocomially transmitted RSV infection have shown the importance of adults with relatively trivial upper respiratory tract infection as intermediates in transmission to susceptible young infants.[100] School-aged children often introduce respiratory viral agents into households and thus are the source of secondary infections in parents and younger siblings.[83] The increasing use of group daycare by working parents has been associated with enhanced transmission of numerous respiratory pathogens,[151,210] and it certainly has extended the definition of "school age" to increasingly younger children.

PATHOGENESIS AND PATHOLOGY

After the upper respiratory tract has been inoculated, viral agents that cause pneumonia proliferate and spread by contiguity to involve the lower and more distal portions of the respiratory tract. Infected epithelium loses its ciliary appendages, rounds up, and sloughs into the air passages, with subsequent stasis of mucus and accumulation of cellular debris.[1,31,262] When infection extends to the terminal airways, the alveolar lining cells lose their structural integrity. As a result, surfactant production is lost, hyaline membranes form, and pulmonary edema develops. The inflammatory response at the site of tissue damage results in mononuclear infiltration of submucosal and interstitial structures, which further contributes to narrowing of air passages and alveolocapillary block of gas exchange. Relative expiratory obstruction gives rise to hyperinflation and air trapping. Complete obstruction or

stop-valve mechanisms result in atelectasis. Ventilation-perfusion mismatch further exacerbates the hypoxia.

The relative rarity of fatal outcomes in patients with the common causes of nonbacterial pneumonia has resulted in a narrow view of the characteristic pathologic features, limited largely to autopsy studies of overwhelming illness in infants and military recruits. The pathology associated with infection by RSV, adenoviruses, and influenza virus A has been studied most extensively in humans. Studies of the pathology of RSV, parainfluenza virus, and *Mycoplasma* infection have been aided by animal model systems such as mice,[90] the Syrian hamster,[84] and the cotton rat.[95]

Five major pathologic findings have been described in fatal human infections, any or all of which may be present in a given case: acute bronchiolitis, necrotizing bronchiolitis, interstitial pneumonia, alveolar pneumonia, and diffuse alveolar damage. Acute bronchiolitis is characterized by relatively superficial and reversible destruction of ciliated respiratory epithelium, along with accompanying mononuclear infiltration. Necrotizing bronchiolitis extends to the deeper submucosal layers lining the respiratory tract and may not be as readily reversible. It is associated particularly with adenoviral pneumonia.[16] Interstitial pneumonia is a diffuse process in which the inflammatory mononuclear response predominantly involves the peribronchial alveolar septa. In alveolar pneumonia, the alveoli are filled with degenerating lining cells and mononuclear or polymorphonuclear inflammatory cells with or without hyaline membranes. Hyaline membranes consist of fibrin deposits triggered by local release of tissue factor–factor VII complexes, as well as inhibitors of fibrinolysis.[21] When hyaline membranes are present, the process is described as *diffuse alveolar damage*. It is the histopathologic hallmark of the acute phase of the adult respiratory distress syndrome.[219,220] Acute bronchiolitis and interstitial pneumonia are observed in most cases of fatal nonbacterial pneumonia, regardless of cause.[1] Alveolar pneumonia may reflect bacterial superinfection, adult respiratory distress syndrome, or agonal changes associated with intensive ventilator support and oxygen toxicity.

Three important factors that influence the pathologic expression of nonbacterial pneumonia in children are anatomy, preexisting pulmonary disease, and immunity. In young infants, the small caliber of the terminal airways and the absence of interconnections between alveolar spaces (pores of Kohn) contribute to the development of wheezing and lobular atelectasis.[182,254] Preexisting pulmonary disease (e.g., bronchopulmonary dysplasia) is characterized by emphysema, squamous metaplasia of the tracheobronchial tree, hypertrophied goblet cells, and enhanced airway smooth muscle reactivity. An inability to clear the excessive secretions triggered by infection in patients with bronchopulmonary dysplasia often leads to bronchospasm, atelectasis, and respiratory failure.

Immunopathologic mechanisms have been invoked to explain the disparity between infants and older children in the clinical expression of infection by RSV and *M. pneumoniae*.[36,169] Investigators have widely accepted that both viral replication and inappropriately enhanced immune responses contribute to the severity of RSV disease in infants. In a recent study, however, quantities of lymphocyte-derived cytokines were unexpectedly minimal in respiratory secretions, and CD8-positive lymphocytes and natural killer cells were nearly absent in autopsy lung tissue. Thus, it now appears that the severity of RSV in infants relates to inadequate (rather than excessive) adaptive immune responses to robust viral replication and apoptosis of respiratory epithelium.[250] In contrast, cumulative immunity that develops after repeated natural infections with *M. pneumoniae* may account for the more impressive clinical expression of illness in older children and adults.[66] Specific cell-mediated immunity, detectable at low levels in young children but increased in adults, probably contributes to the pathogenesis.

Opportunistic nonbacterial pathogens generally take advantage of the defects in cell-mediated immunity induced by immunosuppressive therapy or HIV infection. Various unique pathologic manifestations of viral pneumonia, including giant-cell pneumonia (leukemia or HIV infection with superimposed measles),[159,228,229] lymphoid interstitial pneumonitis or pulmonary lymphoid hyperplasia (HIV with associated EBV infection),[6,221] and graft-versus-host disease (bone marrow allograft with associated CMV infection), may ensue in these circumstances.[60,241,252]

CLINICAL MANIFESTATIONS

Acute nonbacterial pneumonia in infants and young children generally occurs after 1 or 2 days of coryza, decreased appetite, and low-grade fever. The onset usually is gradual, with increasing fretfulness, respiratory congestion, vomiting, cough, and fever. In very young infants, fever may be minimal, and apneic spells may be the most prominent (and frightening) initial complaint.[29] The most reliable physical findings are those of respiratory distress: tachypnea (respiratory rate =50/min[41]), tachycardia, nasal flaring, and retractions, but without the stridor characteristic of upper airway obstruction. In patients with atelectasis or air trapping, grunting may be present. Cyanosis generally accompanies the apneic spells or coughing attacks, but it may be present at rest in patients with advanced disease or in those with underlying chronic cardiopulmonary conditions.

Other physical findings are quite variable and, in fact, may be normal. Wheezing occurs in infants with associated bronchiolitis or bronchospasm. Hyperresonance may be noted if air trapping is present. Diminished local percussion or breath sounds may indicate lobar consolidation or atelectasis. In interstitial pneumonia, fine crackling rales may be present diffusely or locally. Also important in initial assessment is an evaluation of the young child's state of hydration because increased insensible loss from fever and hyperventilation, coupled with anorexia, can result in significant deficits in fluid.

The afebrile pneumonitis syndrome of young infants, in contrast to the usual acute viral pneumonias affecting this age group, is subacute to chronic in its development and is nonseasonal. Characteristic features include the absence of fever, a "staccato" cough pattern (individual coughs separated by inspirations), and diffuse rales on auscultation.[17] Radiographic findings usually consist of interstitial infiltrates with subsegmental atelectasis. Hypergammaglobulinemia and mild eosinophilia are abnormalities frequently detected in the laboratory.

Most infants with HIV/AIDS and *P. jiroveci* pneumonia have a progressive febrile course leading to respiratory failure over the course of 1 to 3 weeks. Typical upper respiratory symptoms may be absent, and these infants fail to respond to conventional antibiotic therapy. When pneumonia actually is detected by chest radiography, the severity of involvement may not be appreciated because abnormalities often are subtle early in the course. However, even with mild radiographic abnormalities, hypoxia may be obvious and severe. Frequently, the discovery of HIV seropositivity first raises this diagnostic possibility. An important observation is that *P. jiroveci* pneumonia may develop in infants with HIV/AIDS who have CD4 lymphocyte counts in the "normal" range.[231]

Nonbacterial pneumonia in older children and adolescents clinically is more nearly like the pattern seen in adults. Premonitory complaints generally include such systemic symptoms as malaise, myalgia, and anorexia, in addition to upper respiratory symptoms. "Chilliness" may occur, but rigors generally are absent. Cough usually is irritative and nonproductive. A temperature higher than 39° C (102.2° F) is unusual. Although tachypnea, flaring, and retractions typically are present, they may be less apparent than in an infant or young child. Findings on examina-

tion of the chest are more reliable than in infancy and may include local percussion dullness or diminished breath sounds and local or diffuse fine rales. Because apnea rarely occurs in older patients, cyanosis is an ominous sign of advanced disease and respiratory failure. Progression to acute respiratory failure occurred in a disturbingly high proportion of patients with SARS.[143,207]Although mild dehydration often is present, generally it is not evident on examination. Nonspecific rash suggests a viral or mycoplasmal cause.[43]

Radiologic findings in nonbacterial pneumonia are variable and depend on the child's age and the infecting agent.[49,50,160,163,192,217,232] In infants and young children, bilateral air trapping and perihilar infiltrates are the most frequent findings. Patchy areas of consolidation may represent lobular atelectasis or alveolar pneumonia. In older children and adolescents, lobar involvement more frequently is definable, but typically the affected areas are not consolidated completely. Although lobar consolidation may occur in nonbacterial pneumonia, this finding should be distinguished from atelectasis and is more consistent with a bacterial origin. Similarly, although small pleural effusions may be detected on decubitus films in patients with nonbacterial pneumonia,[67] effusions are much more suggestive of a bacterial cause.

Peripheral leukocyte counts are quite variable in nonbacterial pneumonia.[71,187,206] Leukocytosis occurs most frequently in children with influenza and parainfluenza pneumonia,[71] but high counts are more consistent with a bacterial origin.[71,164] Gram staining of sputum or tracheal secretions from patients with nonbacterial pneumonia tends to show epithelial cells as the predominant cell type, with a mixed bacterial population representing the patient's pharyngeal flora. A predominance of neutrophils may be seen, but this finding generally reflects bacterial superinfection or preexisting chronic pulmonary disease.

DIFFERENTIAL DIAGNOSIS

In the differential diagnosis of nonbacterial pneumonia, the following factors need to be considered: status of the host, whether normal or compromised; the environment, whether animate (human and other animal exposure) or inanimate; the age of the patient; and, finally, the season. In certain epidemiologic settings, the diagnosis of nonbacterial pneumonia may be made with relative certainty. Often, however, this category of pulmonary infection is a diagnosis of exclusion. The major conditions to be differentiated include the following: noninfectious pulmonary disease; bacterial pneumonia amenable to conventional antibiotics; and the more unusual bacterial, fungal, or parasitic infections that may require specialized forms of therapy.

Noninfectious conditions that may simulate nonbacterial pneumonia are summarized in Table 26–2. These conditions are particularly relevant to consider in a child with persistent or recurrent pulmonary disease. The line of demarcation between infectious and noninfectious conditions may be blurred. In a child with sickle-cell anemia, for example, pulmonary vascular occlusive crisis is manifested as fever, leukocytosis, and patchy pulmonary infiltrates (the acute chest syndrome).[13,205] Differentiating it from pneumococcal, *Haemophilus*, or mycoplasmal pneumonia, to which a child with sickle-cell anemia has increased susceptibility, may be difficult or impossible. Early recognition of noninfectious conditions either mimicking or underlying pneumonia may prevent recurrence or improve the prognosis. Aspiration resulting from gastroesophageal reflux, for example, is a relatively common correctable cause of recurrent diffuse pneumonia.[45] Early recognition of and initiation of treatment for cystic fibrosis as an underlying condition have clear beneficial effects in reducing irreversible pulmonary damage.[191]

Pneumonias caused by pyogenic bacteria are classically lobar in distribution and exhibit consolidation on radiographs. Atelectasis, conversely, is a common event in viral pneumonia and must be distinguished from true consolidation. Pleural effusions, circular infiltrates, consolidations with convex margins, and pneumatoceles all favor a bacterial cause. In a young child, high fever with significant leukocytosis also suggests a bacterial origin.[166] In contrast to patients with lower counts, children with pneumonia who had leukocyte counts greater than 15,000/mm^3 were found to have a high probability of rapid defervescence with antimicrobial therapy in one emergency department study, presumably on the basis of a bacterial origin.[164]

Other laboratory investigations, such as erythrocyte sedimentation rate, C-reactive protein, and reduction of nitroblue tetrazolium by leukocytes, frequently are positive in children with bacterial respiratory infection.[63,162,189] However, these tests add little to careful initial clinical examination, roentgenographic findings, a differential white count, and, if accessible, Gram stain and culture of tracheal secretions in excluding a bacterial cause.[164] Specific detection techniques for bacterial antigens, used with urine or respiratory secretions, occasionally are helpful. However,

TABLE 26–2 Noninfectious Conditions That May Simulate Nonbacterial Pneumonia in Children

Technical	Damage by Physical Agents	Collagen Disease (SLE, JRA)
Poor inspiratory film	Lipoid pneumonia	Sarcoidosis
Underpenetrated film	Kerosene pneumonia	Neoplasm
Physiologic	Near drowning	Histiocytosis X
Prominent thymus	Smoke inhalation	Bronchogenic cyst
Breast shadows	Iatrogenic pulmonary damage	Vascular ring
Chronic pulmonary disease	Drugs (bleomycin, nitrofurantoin)	Pulmonary sequestration
Asthma	Radiation pneumonitis	Cystic adenomatoid malformation
Bronchiectasis	Graft-versus-host disease	Congenital lobar emphysema
Bronchopulmonary dysplasia	Atelectasis	$Alpha_1$-antitrypsin deficiency
Pulmonary fibrosis	Mucus plug	Allergic alveolitis
Cystic fibrosis	Foreign body	Dust (farmer's lung)
Recurrent aspiration	Congestive heart failure	Mold (allergic aspergillosis)
Gastroesophageal reflux	Pulmonary infarction	Excreta (pigeon breeder's lung)
Tracheoesophageal fistula	Sickle vaso-occlusive crisis	Pulmonary hemosiderosis
Cleft palate	Fat embolism	Desquamative interstitial pneumonitis
Neuromuscular disorders	Pleural effusion	Adult respiratory distress syndrome
Familial dysautonomia	Pleural reaction	

JRA, juvenile rheumatoid arthritis; SLE, systemic lupus erythematosus.

false-negative results occur frequently. Because a bacterial cause cannot be excluded with certainty, these tests seldom are used in clinical laboratories.[122,222]

Positive cultures of blood, pleural fluid, or lung aspirates provide definite evidence of the origin of bacterial pneumonia. Because of the common asymptomatic carriage of potential pulmonary pathogens in children, however, the diagnostic value of upper respiratory tract and tracheal bacterial cultures is debated.[14,86,150] In a child with a suspected nonbacterial pneumonia, the finding of "normal flora" in endotracheal secretions generally is reassuring but may reflect aspiration. In a child who is not doing well, a predominant pathogen in such cultures can be helpful in selecting or altering antimicrobial therapy.[22,42]

Among the less common causes of pneumonia, tuberculosis should never be forgotten. Tuberculin testing should be considered in the initial evaluation and is especially important in children residing in urban areas, in recent immigrants, and in Native Americans. Fungal pneumonia, particularly coccidioidomycosis, histoplasmosis, and blastomycosis, should be considered in children residing in or visiting endemic areas. Often a suggestive history, such as exposure to excavations (backyard swimming pools, geologic or archaeologic "digs"), clean-up chores in old sheds and barns, and exposure to dust storms, may be elicited. Erythema nodosum and eosinophilia are common clinical clues to these entities. Immunodiffusion serologic testing, urine antigen detection, biopsy of skin lesions, and bronchoscopy often are required for establishing the diagnosis. Other fungal pneumonias, such as aspergillosis and cryptococcosis, occur in the setting of immunosuppression. These conditions, coupled with the possibility of *Pneumocystis*, fungal, resistant bacterial, and CMV pneumonia, warrant the use of bronchoalveolar lavage or open lung biopsy as a definitive approach to diagnosis in compromised hosts.[72,255] In an appropriate epidemiologic setting, progressive or recurrent pneumonia should prompt obtaining serologic testing for HIV. At present, pulmonary disease is the most common defining condition in pediatric AIDS.[221] Pulmonary paragonimiasis caused by the lung fluke *Paragonimus westermani* has been recognized as a cause of chronic pneumonia in Indochinese immigrants in the United States.[30]

SPECIFIC DIAGNOSIS

Isolation of virus can be performed in most major medical centers and public health laboratories. With the possible exception of HSV and adenoviruses, respiratory viruses rarely are carried asymptomatically. Thus, identification of an agent in upper respiratory secretions is strong evidence for its causative role in pneumonia. Conventional virologic techniques provide the most sensitive and specific means of identification (see Chapter 264). However, most of the common respiratory viral pathogens, as well as chlamydiae and mycoplasmas, now are identified readily by "rapid" techniques. The available methods and reagents are expanding rapidly and include fluorescent antibody techniques, enzyme-linked immunosorbent assay, direct DNA probes, and PCR.[40,59,78,148,177] Clinical specimens may be tested directly or after pre-incubation in tissue culture systems. In an individual case, serologic diagnosis of acute respiratory viral infection is, in general, less satisfactory than is virologic diagnosis. The difficulty with serology relates to timing of specimens, choice of antigens to test, and variation in the quality and specificity of available reagents.

In contrast, laboratory facilities for the actual isolation of chlamydiae, mycoplasmas, and rickettsiae are less readily available to the clinician. Thus, serologic techniques are important means for establishing a specific diagnosis. Acute-phase reactants (e.g., cold agglutinins in *M. pneumoniae* infection) are of greatest diagnostic help during acute illness but are not invariably present. Serologic tests also can be helpful in diagnosing chlamydial pneumonitis in infants; high levels of immunoglobulin G–specific antibodies are found uniformly at initial evaluation.[17] *Pneumocystis* infection usually is diagnosed by visualizing organisms in specimens obtained by bronchoalveolar lavage during bronchoscopy or by open lung biopsy. Silver impregnation and direct immunofluorescence staining techniques have the greatest sensitivity. Noninvasive diagnosis by serologic and molecular biologic techniques has not proven to be effective.[147,200,238]

Because of the epidemiologic behavior of nonbacterial respiratory infections, a reasonable guess regarding the specific cause often can be based on such factors as age, season, and associated clinical features. If the presence of a particular nonbacterial agent in a community can be established by isolation or serologic means, however, the probability that other patients with similar manifestations will have illness caused by that agent is increased greatly. Regional viral surveillance programs, such as those performed in Rochester, New York,[99] and Houston,[82] can be particularly helpful to practicing pediatricians in this regard.

TREATMENT

Therapy for nonbacterial pneumonia primarily is expectant and supportive. However, specific therapies are available for some of these conditions. Rapid etiologic diagnosis permits appropriate use of these therapies, particularly for hospitalized patients and compromised hosts. Although these treatments shorten the course of illness, they frequently have a less dramatic therapeutic effect than do specific antibiotic therapies for bacterial infections.

The course of uncomplicated viral pneumonia is not influenced by the administration of antibiotics. However, in most cases in which pulmonary involvement is uncovered, antibiotic therapy is administered because bacterial disease cannot be ruled out with certainty, and combined viral-bacterial infection is a common occurrence.[127] In all but the most mild cases, this approach is both reasonable and practical. Of importance, however, is that antibiotic therapy in routine cases be appropriate for the most common bacterial pathogens *(S. pneumoniae* and *H. influenzae).* The increasing prevalence of penicillin-resistant pneumococci now renders treatment with ceftriaxone or cefotaxime a reasonable choice. Concomitant treatment with a macrolide drug such as erythromycin or azithromycin should be considered in children younger than 3 months and older than 6 years because of the high prevalence of chlamydial and mycoplasmal causes.[124,167] In immunocompromised hosts or when secondary infection is a possibility, *S. aureus* (including methicillin-resistant strains) and other hospital-associated and opportunistic pathogens must be considered.[154]

In fulminant viral pneumonia caused by VZV in a compromised host, specific antiviral chemotherapy with acyclovir may be lifesaving, but as many as 50 percent of patients with this condition have complicating bacterial sepsis that requires antibiotic therapy as well.[64] Treatment with zanamivir or oseltamivir should be considered in children with viral pneumonia in the context of a community epidemic of influenza. Treatment of lymphocytic interstitial pneumonia in pediatric patients with AIDS includes antiretroviral therapy with prednisone pulses for increasing hypoxia.[170] Progressive CMV interstitial pneumonia in bone marrow or solid organ transplant recipients is treated best with ganciclovir and intravenous immunoglobulin, ideally with high-titer antibody activity.[60]

TMP-SMX and pentamidine are equally effective for treating *P. jiroveci* pneumonitis, but the former combination is the drug regimen of choice because of its lower toxicity. TMP-SMX may be given orally (20 mg/kg/day of the TMP component divided every 6 hours) or intravenously (15 mg/kg/day divided every 8

hours). Pentamidine should be reserved for patients who are intolerant of TMP-SMX. Atovaquone is a third therapeutic option, pending more complete information on its pharmacokinetic profile in pediatrics. Completion of a course of therapy with any agent should be followed by direct transition to long-term chemoprophylaxis.

Inhalational administration of the antiviral compound ribavirin has been used successfully to treat viral pneumonia caused by RSV and influenza.[80,103,136] Anecdotal experience and in vitro activity suggest that it also may be beneficial in parainfluenza and measles virus infection.[11] Early studies indicated that ribavirin was of particular value for the treatment of RSV infection in nonventilated infants with underlying cardiopulmonary disease,[102] as well as in previously normal infants with RSV pneumonia and respiratory failure.[233] However, several multicenter re-evaluations of the use of ribavirin therapy for RSV-infected infants with and without respiratory failure yielded equivocal results.[142,172,178,251] These observations, coupled with the high cost of the drug,[65] concerns about its possible teratogenicity in medical personnel,[5] and the complexity of its administration during mechanical ventilation,[51] led to reassessment of its use and a change in American Academy of Pediatrics recommendations from "should be used"[5] to "may be considered."[213]

Bronchospasm is present in a substantial proportion of nonbacterial pneumonias. Airway reactivity may be preexisting, or it may arise as part of the pathogenesis of the pneumonia itself. In most hospitals, intervention with inhaled bronchodilators has become part of the routine management of any patient with wheezing, regardless of age or mechanism. Rigorous pulmonary function studies have shown that only approximately 50 percent of previously normal infants with RSV-associated respiratory failure respond to inhaled albuterol.[105] However, in several double-blind controlled trials, inhaled albuterol and racemic epinephrine both showed a statistically significant overall benefit.[173,214,224,227] Other studies of the use of albuterol and ipratropium in mildly ill infants were less convincing.[75,248] None of the available studies of ribavirin therapy for RSV bronchiolitis and pneumonia controlled for the effects of concomitant inhaled bronchodilator therapy.

The use of systemic corticosteroids in nonbacterial pneumonia should be approached with caution. In patients with preexisting asthma or bronchopulmonary dysplasia and acute deterioration triggered by pneumonia, steroids are a noncontroversial element of treatment. In adult patients with AIDS and rapidly progressive *P. jiroveci* pneumonia, short-course steroid therapy clearly is beneficial.[23,76] Comparable data do not exist for pediatric patients with HIV/AIDS. In infants and children without preexisting lung disease, steroid therapy for viral bronchiolitis with or without concomitant pneumonia has shown neither consistent benefit nor harm.[144,236] The value of steroids probably strikes a balance between their anti-inflammatory effects in short-term use and their immunosuppressive effects with more prolonged administration.

Other key elements of supportive therapy include the following: maintenance of adequate hydration, high humidity, and oxygenation and ventilation; mobilization of lower respiratory secretions; and, particularly in young infants, continuous monitoring of respiration. Because of increased insensible loss caused by fever, hyperventilation, and anorexia, mild dehydration frequently is observed initially, and continuing fluid loss is expected during the acute phase of illness. Thus, restoration of deficits and adequate maintenance of fluid intake are desirable. Maintaining nutrition often is difficult when respiratory distress is present; oral feeding is limited or contraindicated. Parenteral nutrition through peripheral veins is adequate during acute self-limited pneumonia. Situations involving more prolonged hospitalization or mechanical ventilation should lead to early consideration of central alimentation.

Mist tents have fallen into disuse because they hinder observation and because mist has little direct therapeutic benefit.[195] However, high humidity is required to prevent the drying effects of supplemental oxygen therapy; slowing evaporation probably also serves to reduce the viscosity of mucous secretions and the magnitude of insensible fluid loss. Mobilization of respiratory secretions by means of vibration and postural drainage is indicated in nonbacterial pneumonias complicated by atelectasis,[153] but it is not helpful in the absence of excessive secretions or mucus plugging.[184] Progression of infiltrates and hypoxia occasionally occurs secondary to pulmonary edema. If it is recognized, diuretic therapy may be beneficial.

Because of the presence of ventilation-perfusion abnormalities and alveolocapillary block, most children with nonbacterial pneumonia have some degree of hypoxemia. In a child with respiratory distress, provision of supplemental oxygen reduces anxiety and ventilation rates. Increases in inspired oxygen to approximately 30 percent are provided easily by nasal cannulas, which are the most convenient means of administration. More severe respiratory distress or cyanosis requires documentation of respiratory status by means of arterial blood gas determination and more exact regulation of inspired oxygen administered by mask or hood. Noninvasive monitoring by means of oximetry can reduce the need for frequent blood gas sampling and arterial lines.[101] Consistent oxygen saturations of 95 percent or more should be the target. In respiratory failure, mechanical ventilation may be required to maintain oxygenation and to control retention of carbon dioxide.[55,161,243] In this instance, management in an intensive care unit setting, with invasive monitoring of gas exchange, is mandated.

Apnea and bradycardia occur commonly in young infants with RSV, parainfluenza, and influenza viral pneumonia.[29,46] These complications are particularly frequent in infants with a history of premature birth. Although the mechanism for these episodes is uncertain, continuous cardiorespiratory monitoring of any young infant with viral pneumonia is prudent.

Acetaminophen or ibuprofen should be used to control high fever and will benefit the patient in terms of comfort as well as reduction in oxygen and nutritional requirements. Expectorants, antihistamines, and cough suppressants, although widely prescribed for upper respiratory tract infections in children and adults, probably have no place in the management of acute nonbacterial pneumonia. In convalescence, persistent irritative coughing that interferes with sleep may be alleviated by the judicious use of antihistamines or dextromethorphan.[4]

PROGNOSIS

In the pre-antibiotic era, pneumonia (of which most cases were "bronchopneumonia") was the most frequent cause of death in children. At present, a fatal outcome rarely occurs but always is a possibility. It is most likely to occur in young infants or compromised hosts.

The incidence of long-term complications of nonbacterial pneumonia is unknown. However, these conditions probably play a role in the development of some cases of bronchiectasis, chronic pulmonary fibrosis, desquamative interstitial pneumonitis, bronchiolitis obliterans, and unilateral hyperlucent lung (Swyer-James syndrome). These complications are well-documented sequelae of measles and adenoviral and influenza viral pneumonia.[130,140,141,157] They occur most frequently today in children who have survived complex and prolonged hospitalization involving aggressive ventilator management of respiratory failure.[219,220]

At a minimum, children with pneumonia should be re-evaluated clinically 2 to 3 weeks after being diagnosed. Provided

the child is asymptomatic, has returned to normal activities, and has a benign physical examination, a follow-up radiograph is not required.[94] Repeated chest radiographs are necessary for children with complicated clinical courses, underlying pulmonary disease, or previous episodes of pneumonia, or if signs or symptoms of respiratory difficulty persist at the time of follow-up. Approximately 20 percent of patients with even uncomplicated pneumonias will show persistent radiographic abnormalities 3 to 4 weeks after the diagnosis has been established, but a selective approach to follow-up films permits early recognition of atelectasis, unresolved infiltrates, or progressive disease.

PREVENTION

Nosocomial spread of respiratory viruses occurs readily in pediatric wards and involves intermediate carriage by medical personnel who have acquired mild upper respiratory tract infections.[98] A reasonable approach to interdicting nosocomial transmission is to group patients with pneumonia and to exclude from ward duties personnel with symptomatic respiratory illness. With the exception of measles, varicella, and SARS, mask or gown isolation has no effect on transmission. Contact precautions, washing hands, and wearing glasses or goggles will minimize the incidence of respiratory infections among personnel and secondary spread. Blood and secretion precautions (universal precautions) are recommended for all hospitalized patients.

Of the common viral causes of pneumonia, vaccines at present are available for only influenza A and B viruses. Annual influenza vaccination with "split-product" vaccines is now recommended for all children aged 6 to 59 months and for children of any age with chronic respiratory, cardiovascular, renal, hepatic, hematologic, or metabolic disorders; with HIV infection; or receiving long-term aspirin therapy. Immunization also is recommended for health care personnel and the household contacts and caregivers of children with predisposing medical conditions.[208] Adenoviral vaccines have been used widely in the military, but their manufacture was discontinued recently. Attenuated, inactivated, and subunit vaccines against RSV, parainfluenza virus type 3, and *M. pneumoniae* have received considerable investigative effort but have not yet proved to be effective.[121,128,181] They present problems in vaccine development because of the possibility of triggering immunopathologic phenomena that could potentiate rather than prevent illness.[169,250]

In compromised hosts, intramuscular passive immunization with pooled immunoglobulin or varicella-zoster immunoglobulin is an established postexposure measure to prevent the acquisition of measles and varicella pneumonia, respectively.[35] Palivizumab is a "humanized" mouse monoclonal antibody specific for the fusion protein of RSV and is administered intramuscularly.[259] It has replaced RSV-specific intravenous immunoglobulin as a means of preventing RSV lower respiratory tract infection in infants with prematurity or other high-risk conditions.[93,209] Other products, such as specific Fab immunoglobulin fragments produced by recombinant DNA technology, are being studied.[12]

P. jiroveci pneumonia can be prevented in pediatric patients with hematologic malignancy or HIV/AIDS by prophylactic administration of TMP-SMX. This medication has become a part of the routine management of these conditions and has reduced the incidence of *P. jiroveci* infection dramatically.[96,119,216] Unless HIV infection can be excluded reasonably by serial PCR studies, seropositive HIV-exposed infants should receive chemoprophylaxis from 4 to 6 weeks of age up to 12 months of age, regardless of their immune status. Infected children aged 1 to 5 years should continue to receive prophylaxis if their CD4 counts are less than 500 cells/μL or the CD4 percentage is less than 15. The criterion for prophylaxis in older children and adults is a CD4 count less than 200 cells/μL or a percentage less than 15. The recommended dosage of TMP-SMX is 150 mg/m^2/day of TMP divided into two doses given on 3 successive days each week.[216]

Opportunistic CMV pneumonia, a major hazard in seronegative high-risk premature infants and recipients of allogeneic bone marrow transplants, can be prevented effectively by the exclusive use of CMV-free blood products.[260,261] In bone marrow transplant recipients who are seropositive and thus are at risk for reactivation of disease, prophylactic acyclovir, ganciclovir, and intravenous immunoglobulin have been shown to reduce rates of infection and interstitial pneumonia.[174,225,241]

CHAPTER 27

Bacterial Pneumonias

JEROME O. KLEIN

Bacterial pneumonia is an inflammation of the lung caused by a bacterial pathogen. Pneumonias may be classified in anatomic terms, such as lobar pneumonia, bronchopneumonia, and interstitial pneumonia. The disease usually is categorized by the etiologic agent, however, as in pneumococcal or staphylococcal pneumonia.

HISTORY

Pneumonia has been a frequent and serious human illness throughout recorded history. Histologic examination of Egyptian mummies (1250 to 1000 BCE) revealed hepatization of the lungs compatible with acute pneumococcal pneumonia. The disease was well known to the Greeks and Romans, and the symptoms and management (including a drainage procedure for empyema) were described by Hippocrates. Laennec described the pathologic changes and physical signs of pneumonia and pleurisy in 1819, and Rokitansky distinguished lobar pneumonia from bronchopneumonia in 1842. The early history of pneumonias was reviewed by white.[113a]

In 1881, Pasteur in France and Sternberg in the United States independently isolated, cultured, and described the pneumococcus. Each researcher used inoculation of rabbits with human saliva. Pasteur used saliva from a child who had died of clinical rabies, whereas Sternberg used material from a normal subject. A fatal septicemia resulted in the rabbits, and the organisms were isolated from their blood. In 1882, Friedländer described the pneumococcus in pathologic sections of lung and pleura and in fluid obtained by lung puncture from living patients with pneumonia. In the same laboratory, Gram exposed the sections to a sequence of dyes: aniline-gentian violet, a weak solution of iodine, ethanol, and Bismarck brown. Pairs of elongated cocci retained the dark aniline-gentian violet dye. The organism was referred to as *pneumococcus* by Fraenkel in 1886 because of its role as a cause of pulmonary infection.

Early methods of treating pneumonia included bloodletting; leeching; inhalation of chloroform; subcutaneous injection of gold, silver, and platinum solutions; and oral administration of mercury, quinine, and digitalis. The investigations of the pneumococcus in the late 19th century led to the use in 1891 of small subcutaneous doses of rabbit serum for treatment of patients with pneumonia. These treatments usually failed, but after the many antigenically separable types of the pneumococcus were recognized, specific antisera were prepared. These type-specific sera provided prompt and striking symptomatic improvement and a marked reduction in the fatality rate for pneumococcal pneumonia. Problems arose because of hypersensitivity reactions to the animal sera and the difficulty of making type-specific diagnoses. Responses to these problems included partial elimination of some of the animal protein and adaptation of the Neufeld technique for typing of pneumococci in sputum and body fluids. Use of rabbit antisera resulted in a significant increase in survival rates of patients with pneumonia caused by *Haemophilus influenzae*, and antistreptococcal horse serum or human serum obtained from patients convalescing from scarlet fever was used with success in patients with group A streptococcal pneumonia. Serotherapy was discarded after the introduction of the sulfonamides and penicillin.

Soon after the introduction of the sulfonamides for clinical use in 1935, sulfapyridine was identified as the most potent of the compounds for treatment of pneumococcal disease. By 1943, sulfonamide-resistant strains were reported, however.[101] Abraham and colleagues in 1941[3] and Keefer and colleagues in 1943[56] reported the efficacy of penicillin in treatment of life-threatening infections caused by gram-positive cocci, including *Streptococcus pneumoniae*. Penicillin-resistant pneumococci were identified in epidemic form in South Africa in the 1970s and since have been identified throughout the world.

The approval of a heptavalent conjugate polysaccharide vaccine (Prevnar; Wyeth Lederle Vaccines, Pearl River, NY) by the U.S. Food and Drug Administration (FDA) in February 2000 was the culmination of more than a century of efforts to provide protection for infants, the age group with the highest attack rates for pneumococcal diseases. Whole-cell vaccines had been investigated at the turn of the 20th century and were administered to more than 1 million individuals without serious adverse events, but with uncertain benefit. The importance of capsular polysaccharides to provide serotype-specific antigens was described in the 1930s, and a quadrivalent capsular polysaccharide pneumococcal vaccine was successful in reducing the incidence of serotype-specific pneumonia in military recruits.[63] The results of the military trial led to licensure of a hexavalent capsular polysaccharide vaccine for general use after World War II. The introduction of penicillin and other potent antimicrobials focused physicians' attention on treatment rather than prevention, however, and use of the vaccine lagged. As a result of limited use, the first polysaccharide vaccines were withdrawn in the 1950s.

A 14-valent pneumococcal polysaccharide vaccine was introduced in the United States in 1977, and a 23-valent vaccine was introduced in 1983. Most of the polysaccharides were poor immunogens for children younger than 2 years of age, and the vaccines were used only in children who were 2 years old or older and at risk for contracting invasive pneumococcal infections (e.g., children with sickle-cell disease, functional asplenia, or nephrosis). In October 1990, a conjugate polysaccharide vaccine for *H. influenzae* type b was approved by the FDA. Use of the vaccine has led to a significant decrease in the incidence of invasive disease, including pneumonia caused by *H. influenzae* type b. Similar technology was used to produce a pneumococcal conjugate vaccine. Approval of the pneumococcal conjugate vaccine by the FDA in 2000 resulted in recommendations for universal immunization in infants and selected children aged 2 to 5 years old. By spring 2008, more than 180 million doses of the pneumococcal conjugate vaccine had been distributed worldwide.

Further information about early studies of the pneumococcus and bacterial pneumonias is provided in two reference works of great value that were reprinted in 1979 by the Harvard University Press: *The Biology of the Pneumococcus* by Benjamin White and *Pneumonia* by Roderick Heffron. These works were published first in 1938 (White) and 1939 (Heffron) by the Commonwealth Fund, New York.

Watson and colleagues[112] wrote a brief history of the pneumococcus, highlighting landmarks in infectious disease discovery, including the development of Gram stain, the role of the capsule in resistance to phagocytosis, use of polysaccharides as vaccines, and evidence that DNA encodes genetic information. Podolsky[84] wrote an extensive and insightful review of the therapy of pneumonia before the advent of antimicrobial agents, including a description of early views of treatment of pneumonia by

physiologic support and development of specific pneumococcal serum therapy, concluding with the introduction of the sulfonamides. Of interest are the description of U.S. Public Health Service policy in the 1930s that defined health care as a right and the recognition by states and the federal government that pneumococcal pneumonia was a public health responsibility.[84] Hager[45] wrote a description of the quest for antimicrobials by Domagk and colleagues at the German chemical manufacturer, I. G. Farben, leading to discovery of the sulfonamides, the first successful antimicrobial drug for therapy of bacterial pneumonias. Symposia proceedings have focused on the pneumococcus,[87] polysaccharide pneumococcal vaccines,[55] *H. influenzae*,[30] and lower respiratory tract infections in children in developing countries.[9,35]

MICROBIOLOGY

Because of the difficulty of documenting the microbiology of pneumonia in infants and young children, accurate data concerning the incidence and specific agents of bacterial pneumonia in children are lacking. Austrian[7] estimated that bacteria are responsible for one tenth to one third of all cases of acute pneumonias. Of 540 children with community-acquired pneumonia without empyema diagnosed between 1993 and 1999, only 6.5 percent had a positive blood culture, but 42 percent of children with empyema had a positive blood or pleural fluid culture.[21] A presumptive diagnosis of bacterial or mixed bacterial and viral infection based on antigen detection and antibody assays was made in 45 percent of Finnish children who were hospitalized for lower respiratory tract infections.[75] A reduction of 23 percent of pneumonias in children who received the pneumococcal conjugate vaccine suggests that *S. pneumoniae* is responsible for more than one quarter of pneumonias in infants and children.[64] Bacteriologic findings based on results of lung punctures from 1069 children in developing countries identified *S. pneumoniae*, *H. influenzae*, and *Staphylococcus aureus* as the leading pathogens.[92]

Now, as in the past, *S. pneumoniae* is the leading bacterial cause of pneumonia in all age groups except newborns. *H. influenzae* type b was an important cause of pneumonia in young infants in the United States until the introduction of the heptavalent conjugate polysaccharide vaccine in October 1990. In areas with high rates of immunization, pneumonia and invasive disease caused by *H. influenzae* now are uncommon occurrences. Other species of bacteria are important in special groups: Group B streptococci, *S. aureus*, and some gram-negative enteric bacilli are responsible for pneumonia in newborns; group A streptococci may cause pneumonia in children with viral infections, particularly measles, chickenpox, and influenza; and *S. aureus* and gram-negative enteric bacilli causing pneumonia are a concern in children with malignancy or children who have altered host defense mechanisms. Anaerobic bacteria play significant roles in aspiration pneumonia and lung abscess. Only a few cases of pneumonia caused by *Legionella pneumophila* have been reported in children. Other bacteria responsible for occasional cases of pneumonia include *Neisseria meningitidis*, *Bordetella pertussis*, *Bartonella henselae*,[1] *Bacillus anthracis*, *Salmonella typhi*, *Francisella tularensis*, and *Leptospira* causing leptospirosis (associated with pulmonary hemorrhage).[115]

STREPTOCOCCUS PNEUMONIAE

Although approximately 90 immunologically distinct types of *S. pneumoniae* have been identified on the basis of capsular polysaccharide antigens, relatively few types are responsible for most disease in children. Types 1, 3, 6, 7, 14, 18, 19, and 23 are the types most frequently implicated in pneumonia in children; all types but 1 and 3 are included in the heptavalent pneumococcal conjugate polysaccharide vaccine.

The spectrum of lower respiratory tract illness caused by *S. pneumoniae* ranges from a mild to moderate disease that can be managed without hospitalization to a severe, life-threatening disease that may be complicated by empyema or extrapulmonary manifestations, including meningitis and septic shock. The usual case has a sudden onset, lobar involvement, abrupt termination after appropriate chemotherapy is instituted, and rapid restoration of the involved area of the lung to normal. Although the classic pattern of pneumococcal pneumonia has a lobar distribution, bronchopneumonia and interstitial pneumonia are frequent occurrences.

Multidrug-resistant strains of pneumococci were reported from South Africa[5] in 1977. Some of the strains were highly resistant to penicillin G, requiring more than 4 μg/mL for inhibition, and were resistant to other drugs. The increase in resistance to penicillin has been accompanied by increased resistance to other antimicrobial agents, including other β-lactam drugs, tetracyclines, chloramphenicol, macrolides, clindamycin, trimethoprim-sulfamethoxazole, and other sulfonamides. Resistance of pneumococci to fluoroquinolones is uncommon, and no vancomycin-resistant strains of pneumococci have been reported.[40] The rate of multidrug resistant pneumococci varies in different countries. Incidence is highest in the Far East, with Korea, Taiwan, and Thailand reporting resistance rates of greater than 80 percent. Spain and France have the highest rates of pneumococcal resistance in Europe (30-40%), whereas the Netherlands and Germany have resistance rates of less than 5 percent.

Resistance of *S. pneumoniae* to penicillin is caused by alterations of penicillin-binding proteins. Penicillin resistance is defined by the minimal inhibitory concentrations (MIC) of pneumococci, as follows: less than 0.1 μg/mL = susceptibility; 0.1 μg/mL or higher = nonsusceptibility; among nonsusceptible strains, 0.1 to 1 μg/mL = intermediate status; and 2 μg/mL or greater = high-level resistance. No clinical features distinguish infection caused by a resistant pneumococcal strain, and virulence of infection does not seem to be increased in resistant strains.

Prevalence of multidrug resistance varies by region, with rates highest occurring in the Southeast United States and lowest in the Northeast and Pacific regions. These regional differences are unexplained. Results of surveys of antimicrobial resistance of pneumococcal strains are published frequently; a source of current information is available on the Centers for Disease Control and Prevention (CDC) website (www.cdc.gov). A report[32] of antimicrobial resistance among clinical isolates of *S. pneumoniae* in the United States during 1999 to 2000 revealed 34 percent were nonsusceptible to penicillin, including 21.5 percent with high-level resistance; MICs to all β-lactam antimicrobials increased as penicillin MICs increased. Resistance rates among non–β-lactam agents were 25 percent for macrolides, 9 percent for clindamycin, and 30 percent for trimethoprim-sulfamethoxazole. Resistance to vancomycin was not detected. A trend analysis from the same group extending the surveillance to 2002 to 2003 indicated that the rates of resistance to multiple drugs either have plateaued or have begun to decrease.[33]

The clinical implications of in vitro antibiotic resistance are variable. Daneman and colleagues[29] found high rates of clinical failure among patients with bacteremic pneumococcal disease treated with a macrolide antibiotic to which the organism was resistant; clinical failures were significantly more common among cases of pneumococcal bacteria with isolates having an erythromycin MIC of 1 μg/mL or greater than among isolates exhibiting MICs of less than 0.25 μg/mL. Less certain is the association of penicillin resistance with clinical failure in hospitalized patients treated with a penicillin; results of a study of adults with bacteremic pneumonia caused by penicillin-resistant pneumococci suggested that patients with highly resistant strains (MICs 4-8 μg/mL) failed to respond to a penicillin, whereas patients with

strains with lower MICs did respond.[80] A meta-analysis of 3430 adult patients identified a mortality rate of 19.4 percent in the penicillin-nonsusceptible cases of *S. pneumoniae* pneumonia, in contrast to a 15.7 percent mortality rate in the penicillin-susceptible *S. pneumoniae* group.[102]

HAEMOPHILUS INFLUENZAE

H. influenzae type b accounts for most cases of pneumonia caused by *Haemophilus* spp. Pneumonia caused by *H. influenzae* types a, c, or d is reported rarely, but in a study of serotypes isolated from children with pneumonia in developing countries, types a, c, d, e, or f were responsible for 10 percent of cases.[93] Nontypeable strains are responsible for an uncertain proportion of cases of pneumonia and bronchitis, bronchiectasis, and acute exacerbations of pulmonary disease in patients with cystic fibrosis.

In developing countries, nontypeable strains of *H. influenzae* are important causes of pneumonia. The nontypeable strains gain access to the lung through spread from the upper respiratory tract but are less likely than are type b strains to invade the bloodstream. The diagnosis of nontypeable *H. influenzae* pneumonia in a living child is made only by lung aspiration or blood culture.[93] Of 32 isolates of *H. influenzae* obtained from blood or lung puncture of children with pneumonia in Papua New Guinea, 18 were nontypeable, 8 were types other than b, and 6 were type b; all 6 patients with type b obtained from culture of the lung aspirate also were bacteremic. Only 4 of 18 patients with nontypeable *H. influenzae* in the lung puncture were bacteremic.[94] Of 105 isolates of *Haemophilus* spp. from cultures of blood from children with lower respiratory tract infection in Pakistan, 10 were *Haemophilus parainfluenzae*, 61 were *H. influenzae* type b, and 34 were nontypeable.[113] Similar data were reported in patients with lobar pneumonia in the Gambia.[108]

Nontypeable *H. influenzae* is unlikely to be diagnosed as the cause of pneumonia if microbiologic diagnosis relies on cultures of blood alone. These data also suggest that pneumonia caused by nontypeable *H. influenzae* probably is underdiagnosed in developed and developing countries.

The clinical presentation of pneumonia caused by *H. influenzae* is indistinguishable from that caused by *S. pneumoniae* and includes mild, moderate, and severe disease. In a series of cases in children seen at the Boston City Hospital, 17 children with pneumonia and bacteremia caused by *H. influenzae* type b were identified in a 5-year period; only 4 of the children were judged to be sufficiently ill for admission to a hospital.[68] All 13 children with mild to moderate pneumonia and bacteremia were treated successfully as outpatients. The mild course of pneumonia in these patients contrasts with findings of other investigators who based their reports on the records of children admitted to the hospital.[6,19,53,85] A report of 65 children with *H. influenzae* pneumonia hospitalized at Parkland Memorial Hospital in Dallas during the 14-year period beginning July 1964 included 24 children with pleural effusion, 7 with pneumothorax, and 1 who developed pneumatoceles; 10 children had associated meningitis, and 3 had purulent pericarditis.[42] *H. influenzae* type b was the pathogen cultured most frequently from empyema fluids in children receiving care in Bethesda during the period 1974 to 1987.[19]

Beginning in the 1970s, β-lactamase–producing strains of nontypeable and type b *H. influenzae* were reported throughout the United States.[109] The enzyme cleaves the β-lactam ring of susceptible penicillins, rendering the antibiotic inactive against the enzyme-producing strain. In the United States, 33.5 percent and 41.6 percent of strains of *H. influenzae* in two 1997 surveys were β-lactamase–positive.[52,100] Strains of *H. influenzae* that were β-lactamase–negative but resistant to amoxicillin and amoxicillin-clavulanate also have been identified. A survey in the United States in 1994 and 1995[31] identified 38.9 percent of *H. influenzae* resistant to amoxicillin, including 4.5 percent of strains resistant to amoxicillin-clavulanate (presumably resistant on the basis of a mechanism other than production of β-lactamase).

STAPHYLOCOCCUS AUREUS

Pneumonia and other serious infections caused by *S. aureus* are of particular concern in newborns, patients with altered host defenses, and patients with prior viral respiratory infection (e.g., influenza). In the United States and western Europe, the most severe problem with staphylococcal disease in newborns occurred in the 1950s and ended around 1965. The cyclic appearance and disappearance of virulent strains of *S. aureus* has no satisfactory explanation. The phage type 80/81, which was so devastating in the 1950s, no longer is a major problem in the United States or Europe. Nonetheless, cases of fatal and rapidly progressive staphylococcal pneumonia still occur[78] and are likely to become more frequent occurrences with the widespread increased incidence of community-acquired methicillin-resistant *S. aureus* (CA-MRSA).

The mechanism of β-lactam drug resistance of CA-MRSA is based on the MEC A gene, which confers resistance by encoding a penicillin-binding protein with decreased affinity for β-lactam antibiotics. Although the β-lactam antibiotics act by inhibiting bacterial cell wall synthesis in susceptible organisms, the penicillin-binding protein of CA-MRSA permits cell wall synthesis despite the presence of β-lactam antibiotics. Hospital-acquired MRSA usually is multidrug resistant but susceptible to vancomyin and linezolid. CA-MRSA strains are resistant to β-lactam drugs and macrolides, but they usually are susceptible to clindamycin, trimethoprim-sulfamethoxazole, and some tetracyclines (minocycline and doxycycline). Strains of CA-MRSA (but not hospital-acquired MRSA) carry a gene for a cytolytic toxin, Panton-Valentine leukocidin, which is associated with enhanced inflammatory response and increased necrosis and tissue damage. Although most CA-MRSA infections cause disease of the skin and soft tissues, CA-MRSA was the most frequent cause of pleural empyemas in children in Houston based on a retrospective chart review for the period 1993 to 2002.[91]

In older children, staphylococcal pneumonia may not be differentiated clinically or radiologically from other bacterial pneumonias. In young infants, the course usually is severe; the onset is abrupt, with tachypnea, significant dyspnea, and restlessness. Progression of the disease is rapid, and empyema, abscesses, and pneumatoceles are common findings. Although pneumatoceles are associated with staphylococcal pneumonia, they also may be seen in children with pneumonia caused by *S. pneumoniae*, group A streptococci, and *H. influenzae*. Pneumatoceles may persist for many months but are not a significant cause of morbidity, and they usually require no specific therapy.

GROUP A STREPTOCOCCI

Pneumonia caused by group A streptococci is an uncommon occurrence. Surveys of children hospitalized with pneumonia in Dallas[103] during a 9-year period and in Denver[72] and Chicago[53] during a 5-year period identified only five (Dallas), three (Denver), and two (Chicago) cases caused by group A streptococci. A rare outbreak of group A streptococcal pneumonia occurred among 34 U.S. Marines at a military facility in California.[25] Pneumonia caused by group A streptococci may develop after viral infection, such as influenza, measles, and chickenpox, but it also occurs in children without previous illness. The disease is characterized by necrosis of respiratory tract mucosa and lung tissue with edema and localized hemorrhage. Clinical signs include chills, high and

prolonged fever, dyspnea, and pleuritic chest pain. Patients remain febrile for a mean of 10 days,[103] but patients often remain febrile for 2 to 3 weeks after initiation of therapy with appropriate antibacterial drugs. Bacteremia and pleural effusion are frequent occurrences, and pneumatoceles may occur. The typical pleural effusion begins as a serous fluid, progresses to be serosanguineous, and may become fibrinopurulent.

GROUP B STREPTOCOCCI

Early-onset disease in newborns caused by group B streptococci manifests as a multisystem illness during the first week of life and frequently is characterized by pneumonia, the clinical and radiologic pattern of which simulates respiratory distress syndrome.[2] The pattern of group B streptococci on chest radiograph includes diffuse pulmonary granularity and air bronchograms, similar to the pattern seen in infants with respiratory distress syndrome. Apnea and shock are frequent developments, but pneumonias caused by group B streptococci require lower respiratory pressures on mechanical ventilation than does respiratory distress syndrome. At autopsy, hyaline membranes similar to those seen in infants with respiratory distress syndrome have been observed in the lungs of infants who died of pneumonia caused by group B streptococci, and gram-positive cocci were identified within the hyaline membranes.

ANAEROBIC BACTERIA

Improvements in techniques for isolation and identification of the various genera and species of anaerobic bacteria have provided a better understanding of the anaerobic flora of humans and the roles of these organisms in disease. Anaerobes are present on the skin, in the mouth, in the intestines, and in the genital tract. Anaerobic bacteria may be responsible for pneumonia and lung abscesses in a host who is subject to aspiration. Anaerobic bacteria most commonly responsible for pulmonary infection include *Fusobacterium* spp., *Bacteroides melaninogenicus*, *Bacteroides fragilis*, *Peptococcus*, and *Peptostreptococcus*. The initial lesion of anaerobic infection of the lower respiratory tract is a pneumonitis with a slowly progressive clinical course. Lung abscess and necrotizing pneumonia may be a late consequence of the anaerobic pneumonitis.[12,20]

LEGIONELLA PNEUMOPHILA

In August 1976, 221 cases of respiratory illness caused by an unknown agent occurred among 4500 participants at an American Legion convention in Philadelphia. The disease was marked by high fever, recurrent chills, prominent myalgia, abnormal liver function, and a toxic encephalopathy in addition to respiratory signs. Patients had nonproductive coughs, and their radiologic patterns showed patchy bronchopneumonia, which in some cases progressed to lobar consolidation. Some patients responded promptly to therapy with erythromycin.

Investigators at the CDC isolated small pleomorphic rods from lung tissues taken at autopsy. The rods were stained with silver-impregnation methods and were visualized by direct immunofluorescence; however, they were seen poorly or not at all with Gram stain. The organism was designated *Legionella pneumophila*.

The genus *Legionella* includes aerobic, fastidious, gram-negative rods that require cysteine and some form of iron for growth. Eighteen separable species have been identified. The natural habitat of *L. pneumophila* is aquatic reservoirs, including rivers, lakes, air-conditioning cooling towers, and water distribution systems. Almost all cases of respiratory infection in children have been associated with *L. pneumophila* except for one case caused by *Legionella micdadei* (the Pittsburgh pneumonia agent).[60] Diagnosis is made by culture on buffered yeast extract agar, direct fluorescent antibody staining of respiratory tract secretions, demonstration of antibody by indirect immunofluorescence, and polymerase chain reaction (PCR).

Seroepidemiologic studies suggest that subclinical or minor infections occur in children.[73,88] Prospective studies of children with lower respiratory disease identified few cases caused by *L. pneumophila*, however.[4,79] The development of legionellosis in children with leukemia in relapse,[60] with chronic granulomatous disease,[82] receiving immunosuppressive therapy,[110] or with corticosteroid-induced immunosuppression (a patient with multiple pulmonary abscesses)[74] indicates that the organism should be added to the list of agents that cause pneumonia in immunocompromised children.

NEISSERIA MENINGITIDIS

N. meningitidis usually is associated with asymptomatic carriage in the upper respiratory tract, and pneumonia seldom develops. When pneumonia caused by *N. meningitidis* does occur, it usually is caused by group Y and is accompanied in some cases by bacteremia[51,114] and, rarely, empyema.[43] No distinctive clinical pattern occurs in children, and the diagnosis usually is made by culture of blood.[10,44]

GRAM-NEGATIVE ENTERIC BACILLI

Pneumonia caused by gram-negative enteric bacilli occurs in newborns and children with altered host defense mechanisms but is seen rarely in normal infants and children. Pneumonia caused by *Pseudomonas aeruginosa* and, to a lesser extent, by *Burkholderia cepacia* is a particular problem in children with cystic fibrosis and may occur as a severe, progressive disease leading to a fatal, necrotizing bronchopneumonia. Pneumonia caused by *Klebsiella pneumoniae* is severe, with fever, chills, and a pattern of necrosis and destruction of lung tissue. *Salmonella typhimurium* was cultured by lung aspirate from a specimen of lung in a Malawian child with human immunodeficiency virus (HIV) and lobar pneumonia.[66]

EPIDEMIOLOGY

The respiratory pathogens *S. pneumoniae*, *H. influenzae*, group A streptococci, and *S. aureus* are common inhabitants of the upper respiratory tract. These organisms may be isolated from many healthy children, and it is important to differentiate the many children who are colonized (i.e., multiplication of microorganisms without signs or symptoms of disease and without immune response), children who have asymptomatic or inapparent infection (i.e., multiplication of organisms without signs or symptoms of disease but with immune response), and children with disease (i.e., clinical signs or symptoms that result from multiplication of microorganisms). Colonization may persist for several months. The reason for colonization in some individuals and inapparent infection or disease in others is unknown.

Humans are the only known source for the common bacterial pathogens responsible for respiratory disease. Transmission occurs in most cases by droplet spread—the brief passage of the infectious agent through the air when the source and the patient are near each other (usually within several feet). Spread also occurs during talking or sneezing. The incidence of airborne spread in some cases of staphylococcal infection in children

diminished after introduction of the conjugate pneumococcal vaccine in 2000.[39,98]

Bacterial pneumonia occurs uncommonly in epidemic form in the community, although the incidence of disease increases during periods of epidemic viral infection, as occurs with influenza outbreaks. Legionnaires' disease usually occurs in clusters of cases; most outbreaks have been related to airborne spread from contaminated air-conditioning cooling towers. Hospital-acquired infection may be epidemic (e.g., infections in newborn nurseries during the period of prevalence of virulent strains of *S. aureus*). Common-source outbreaks of pneumonia caused by gram-negative enteric bacilli may result from contaminated aqueous solutions used in humidification equipment.

Pneumonia is of particular concern in developing countries. In 1995, pneumonia caused 2.1 million deaths in children younger than 5 years of age; more children died because of pneumonia than because of acquired immunodeficiency disease (AIDS), malaria, and measles combined.[110] Half of the pneumonias were caused by *S. pneumoniae*.[95] In African countries, rates of pneumonia and invasive pneumococcal disease rates are 10-fold higher than in developed countries.[27] Severe and recurrent pneumonias were associated with development of bronchiectasis in indigenous children living in central Australia.[106]

PATHOGENESIS

The most important factors in development of bacterial pneumonias are the virulence of the pathogen, the absence of specific humoral immunity, and the presence of viral respiratory tract infection. Most bacterial pneumonias are a result of colonization of the nasopharynx, followed by aspiration or inhalation of organisms. The lung is protected from bacterial infection by a variety of mechanisms, including filtration of particles in the nares, prevention of aspiration of infected secretions by the epiglottal reflex, expulsion of aspirated materials by the cough reflex, entrapment and expulsion of organisms by mucus-secreting and ciliated cells, ingestion and killing of bacteria by alveolar macrophages, neutralization of bacteria by local and systemic nonspecific and specific immune substances (i.e., complement, opsonins, and antibodies), and transport of particles from the lung by lymphatic drainage. Pulmonary infection may occur when one or more of these barriers are altered, inhibited, or destroyed. Hematogenous spread to the lung by means of infected emboli arising from a suppurative focus, such as an abscess of the skin or soft tissue caused by *S. aureus*, is an infrequent occurrence.

Animal models suggest that the inflammatory responses in the lung are caused by cell wall components of gram-positive organisms or endotoxins of gram-negative bacteria.[26,104] An increase in cell wall components and endotoxin may occur after antibiotic-caused cell death, with resulting increase in inflammation. The first stage in the healing produced by appropriate antimicrobial drugs may be accompanied by clinical deterioration caused by an early increase in inflammation in the lung.

Pneumonia caused by *S. pneumoniae* begins with acute inflammation and hyperemia of the lower respiratory mucosa, exudation of edema fluid, deposition of fibrin, and infiltration of alveoli by polymorphonuclear leukocytes (i.e., "red hepatization"), followed by predominance of fibrin deposition and macrophage activity (i.e., "white hepatization"). Exudate in the alveoli is digested enzymatically and absorbed or removed by coughing. Resolution then occurs, with return of lung morphology and physiology to normal. In contrast, when the pneumonia is caused by *S. aureus* or *K. pneumoniae*, destruction of tissue and formation of multiple small abscesses frequently occur.

Clinicians have observed that symptoms and signs of minor respiratory infection caused by viruses frequently precede development of bacterial pneumonia. The respiratory virus may act by destruction of respiratory epithelium or up-regulation of bacterial adhesion molecules. Studies in animal models of infection with influenza and reoviruses[58] show a limited period of vulnerability of the lung to bacterial challenge after viral infection. The effects of the viral infection seem to be mediated by alterations in the activity of the alveolar macrophage. A brief period of impaired function of these phagocytic cells results from the viral infection. Staphylococcal[38,69] or pneumococcal pneumonias[36,37] may occur during or shortly after infection caused by influenza virus. Severe pneumococcal pneumonia has been associated with outbreaks of influenza,[77] and increased mortality rates from pneumonia in children occur during epidemics of influenza.[34]

Infections with other respiratory viruses were thought to be uncommon antecedents to bacterial pneumonias.[69] Hall and colleagues[46] found that the risk of secondary bacterial infection developing in infants hospitalized with respiratory syncytial viral infection was low (1.2% of 565 children studied over 9 years). In contrast, the conjugate pneumococcal vaccine was effective in reducing chest x-ray–defined alveolar consolidation associated with respiratory syncytial virus by 12 percent, with parainfluenza types 1 to 3 by 44 percent, and with human metapneumovirus by 40 percent, suggesting that concurrent pneumococcal infection was frequent in virus-associated pneumonias.[64,65] By documenting the decrease of pneumonias in immunized patients, the conjugate pneumococcal vaccine has been valuable in identifying the proportion of pneumonias caused by *S. pneumoniae* and identifying the roles of viral and pneumococcal co-infections.

Anatomic, physiologic, or immune defects predispose patients to single episodes and recurrent lower respiratory tract infection.[83] These defects include congenital anomalies (i.e., cleft palate, tracheoesophageal fistula, or sequestration of lung), congenital or acquired defects in immune function, aspiration (e.g., in children with familial dysautonomia, in a comatose patient, in a child who has a nasogastric feeding tube in place, after seizure, during anesthesia),[67] and alterations in the quality of mucus secretions (e.g., in patients with cystic fibrosis) or impairments in cough or swallowing or mucociliary clearance mechanisms.

Various types of pulmonary infections may develop in children who are being treated with cytotoxic and immunosuppressive drugs for malignancy or for collagen vascular disease or who are recipients of organ transplants. Patients with immune deficits may develop pneumonia caused by aerobic and anaerobic gram-negative bacilli, staphylococci, *Legionella* spp., *Nocardia*, various fungi (including *Aspergillus* and *Candida* spp. and *Pneumocystis carinii*), and viruses such as cytomegalovirus. Some infections in patients with depressed immune response represent reactivation of a latent infection. Newborns can acquire pneumonia by several routes, including transplacental infection, aspiration of organisms present in the birth canal during delivery, and postnatal infection in the nursery or at home from human sources or contaminated equipment or materials.

CLINICAL MANIFESTATIONS

The signs and symptoms of bacterial pneumonia vary with the bacterial pathogen, the age of the patient, and the severity of the disease. Some organisms are associated with a specific pattern of disease, such as the lobar pneumonia of *S. pneumoniae* and the empyema, abscess, and pneumatocele formation caused by *S. aureus*; however, any of these manifestations may result from infection caused by any of the bacterial pathogens. In young infants, signs may be nonspecific, and findings may be sparse on physical examination. Radiologic evidence of pneumonia may be found in infants who appear to have minimal disease or whose signs are more likely to be associated with upper respiratory tract infection. In older children, most cases are mild, and undoubtedly

many cases occur and remain unrecognized because signs of disease do not warrant radiography of the chest. A child with pneumonia who requires hospitalization represents a small but unknown fraction of all children with pneumonia.

Symptoms and signs of pneumonia in children may be classified for convenience into five categories: (1) nonspecific manifestations of infection and toxicity, (2) general signs of lower respiratory tract disease, (3) signs of pneumonia, (4) signs of pleural fluid, and (5) signs of extrapulmonary disease. Nonspecific manifestations of infection and toxicity include fever, headache, malaise, gastrointestinal complaints, restlessness, and apprehension. Rigors may occur and vary from symptoms of chilliness to a sign of teeth-chattering chills.

General signs of lower respiratory tract disease include tachypnea; dyspnea, including shallow or grunting respirations; cough; expectoration of sputum; and flaring of the alae nasae. Because of the importance of tachypnea as a sign of lower respiratory tract disease, reference values for normal patients should be known.[89] Respiratory rates are correlated inversely with age during the first 3 years of life and vary from a median of 47 breaths/min in the first months of life to 38 breaths/min at the end of the first year to 28 breaths/min by 3 years of age. In older children, rates are 15 to 25 breaths/min. Subjects who are asleep have lower respiratory rates than do awake subjects. On the basis of these data, definitions of tachypnea for the purpose of diagnosing lower respiratory tract infection are 50 breaths/min in infants 1 to 11 months old, 40 breaths/min in children 1 to 4 years old, and 30 breaths/min in children 5 years old or older.[59]

Other general signs of pneumonia include a protective position and abdominal findings. The patient may lie on the affected side of the lung with legs drawn up because of chest pain. Abdominal distention may result from gastric dilation because of swallowed air or paralytic ileus. The liver may be displaced downward by the right diaphragm or may be enlarged if congestive heart failure complicates the pneumonia.

Signs of pneumonia may be subtle in young infants. Percussion usually is not valuable in an infant or older child if distribution of the pneumonia is patchy. Dullness to percussion is associated more often in young children with the presence of pleural fluid than with the involvement of the parenchyma of the lung. Auscultatory findings may include rales, but findings are less consistent than in older children. Abnormal findings in older children include dullness to percussion, decreased tactile and vocal fremitus on palpation, and decreased breath sounds and rales over involved areas on auscultation. Intercostal retraction indicates recruitment of accessory muscles, which becomes necessary to assist respiration when significant involvement of the lung is present.

Irritation of the pleura is accompanied by chest pain that may be severe and may limit chest movement. A friction rub may be detected over the involved area of pleura. As the effusion enlarges, dyspnea may increase, but pleuritic pain may diminish and become a dull ache. The pain of pleural irritation may be present at the site of inflammation. If the involved area includes the diaphragm, the pain may be referred to the posterior and lateral neck. Abdominal pain may be so severe as to suggest acute appendicitis. Pleural irritation over the right upper lobe may elicit meningismus, a sign of meningeal irritation without evidence of inflammation. Empyema may extend to involve the mediastinum or pericardium, or it may penetrate the chest wall to manifest as a soft tissue abscess (i.e., empyema necessitatis). Signs of extension of empyema should be sought in a patient who does not respond appropriately to chemotherapy and surgical drainage.

Extrapulmonary infection, including abscesses of the skin and soft tissues, otitis media, sinusitis, and meningitis, may occur concomitantly with bacterial pneumonia. Pericarditis and epiglottitis are particularly likely to be associated with pneumonia caused by *H. influenzae* type b.

DIAGNOSIS

MICROBIOLOGIC DIAGNOSIS

Effective chemotherapy is available to treat all forms of bacterial pneumonia in children. Optimal treatment requires definition of the etiologic agent, however. The physician must differentiate viral or mycoplasmal from bacterial pneumonia; if the agent is bacterial, the probable species must be considered. An effort should be made to obtain adequate materials, including sputum, secretions from the posterior nasopharynx, and blood, for bacteriologic diagnosis. The physician also should consider tracheal aspiration in young children unable to produce sputum, thoracentesis when pleural fluid is present, percutaneous lung aspiration in children who are critically ill, and lung biopsy when tissue diagnosis is important.

Methods for Obtaining Material for Examination and Culture

Sputum usually is not available from children until they are 5 years old; younger children usually swallow their secretions. A Gram-stained smear of sputum is valuable in providing immediate information about the bacterial pathogen; the presence of a significant number of organisms associated with or ingested by polymorphonuclear leukocytes suggests the likely pathogen, whereas the presence of epithelial cells indicates that the material is from the mouth and that further attempts should be made to obtain sputum. The adequacy of the specimen for microbiologic evaluation may be defined by the presence of 10 or more polymorphonuclear cells per low-power field and less than 25 squamous epithelial cells per low-power field.

Secretions from the nasopharynx include organisms that may be responsible for pneumonia, but results of culture of the nasopharynx may be unrevealing or misleading because of the high rate of carriage of bacterial pathogens. Tracheal aspiration through a catheter may be of diagnostic assistance when it is performed with direct laryngoscopy, but it is less valuable when the catheter is passed through the nose or mouth because of contamination with organisms present in the upper respiratory tract. Use of a double-lumen catheter ensures that the specimen remains free of contaminants.

Culture of blood provides specific bacteriologic diagnosis. Bennett and Beeson[14] suggested that most patients with pneumococcal pneumonia have bacteremia at some time during their illness. Reports of pneumococcal pneumonia in adults indicate an incidence of bacteremia of approximately 25 percent.[8,50] Data on the occurrence of bacteremia in children are less well documented. In a study of children in Boston,[99] bacteremia occurred in 8 of 100 consecutive febrile children younger than 2 years of age with radiologic evidence of pneumonia who were seen in a "walk-in" clinic. This and other studies of febrile children seen in clinics for ambulatory children reveal many cases of unsuspected bacteremia in children with pneumonia caused by *S. pneumoniae*,[17] *H. influenzae*,[68] and *N. meningitidis*.[10] The proportion of children with pneumonia who are bacteremic is uncertain, but some data are available from studies of concurrent cultures of blood and lung aspirate. Of 43 Gambian children younger than 10 years of age with pneumonia who had concurrent cultures of blood and lung aspirate, bacterial pathogens were cultured from lung aspirates in 19 children, from blood in 4, and from blood and lung in 10.[108]

The availability of flexible bronchoscopy and bronchoalveolar lavage has added another approach to obtain optimal specimens for microbiologic diagnosis of pneumonia.[13] The technique provides a direct view of bronchial and lung pathology, may provide evidence of endobronchial obstructions, and may identify and remove mucus or mucopurulent plugs. These techniques have

been of particular value in the diagnosis of pulmonary disease in children with AIDS.[15]

Thoracentesis should be considered whenever fluid is present in the pleural space and microbiologic diagnosis is unrevealed by cultures of sputum, blood, or tracheal aspirate. Pleural biopsy should be performed at the time of thoracentesis if tuberculosis or tumor is in the differential diagnosis. The area to be aspirated is defined by physical examination (i.e., the point of maximal dullness), chest radiography, and ultrasonography. Gram or acid-fast stain of the fluid may provide immediate information about the pathogen. Fluid should be sent for culture; cytology; and determination of glucose, protein, and pH.

Aspiration of pulmonary exudate (i.e., lung puncture) can provide direct, specific, and immediate information about the causative agent of pneumonia. The procedure is performed similar to a thoracentesis. Lung puncture should be considered for a child who is critically ill and for whom a specific diagnosis is of immediate importance in guiding antimicrobial therapy, a child whose condition deteriorates after receiving initial therapy and for whom an etiologic agent has not been identified, and a child who has an underlying disease complicating the pneumonia or who is receiving drugs limiting normal host defense mechanisms.[57] A reappraisal of lung puncture in children indicated that a bacteriologic cause was identified in approximately 50 percent of cases and that adverse events were few.[107] Performing open or closed lung biopsy is necessary if tissue diagnosis is important.

Transtracheal aspiration is a safe and useful method of obtaining secretions from the lower respiratory tract of adults with pneumonia who are unable to produce adequate sputum. This method bypasses the mouth flora and permits the investigator to obtain direct culture of tracheal secretions. Transtracheal aspiration has not been used in young children with pneumonia because pediatricians lack experience with the technique and are concerned about the safety of the procedure. Only one report is available; Brook and Finegold[20] used transtracheal aspiration without apparent morbidity to determine the bacteriology of lung abscesses in 10 institutionalized children aged 23 months to 14 years.

Special Methods of Isolation and Identification

Clinical microbiology laboratories have facilities for isolation and identification of aerobic bacterial pathogens associated with pneumonia, but anaerobic bacteria require special techniques. Because many anaerobic bacteria are exquisitely sensitive to oxygen, anaerobic transport media must be provided and special methods must be used to handle materials on arrival in the laboratory.

Identification of bacterial antigens from secretions and body fluids is possible with the use of precipitin reaction, counterimmunoelectrophoresis, latex agglutination, and enzyme-linked immunosorbent assay. Identification of antigen is particularly helpful when prior administration of antimicrobial agents prevents successful isolation of bacteria.

Counterimmunoelectrophoresis of nasopharyngeal secretions may distinguish patients with pneumococcal pneumonia from patients who are carriers of this organism.[24] Detection in urine of polysaccharide antigens of *S. pneumoniae* and *H. influenzae* type b has been used for establishing rapid diagnosis of pneumonia.[18,105] Questions about sensitivity and specificity of the technique need to be answered. Preliminary studies suggest value for PCR for detection of *S. pneumoniae* in whole blood and serum in patients with pneumonia.[90,116] Michelow and colleagues[71] reviewed the diagnosis of lower respiratory infections caused by *S. pneumoniae* by culture, PCR (i.e., whole blood, buffy coat, or plasma), serology, and urinary antigen. A similar study was done by Le Monnier and associates of the microbiologic diagnosis of empyema in children by evaluation of culture, PCR, and pneumococcal antigen detection in pleural fluids.[61]

Laboratory Tests

Elevated white blood cell counts (>15,000 cells/mm^3) frequently, but not invariably, occur in patients with bacterial pneumonia. A white blood cell count less than 5000 cells/mm^3 usually is associated with severe and overwhelming disease. Determinations of erythrocyte sedimentation rate and measurement of C-reactive protein did not distinguish virus from bacterial pneumonia in Finnish children.[78]

The presence of an immune response to infection may be used to document bacterial pneumonia in retrospect. Serologic tests for bacterial pathogens of importance in pneumonia are available only from investigative laboratories.

Chest Radiography

Although the diagnosis of pneumonia may be suggested by clinical signs, pneumonia is defined by chest radiography. In addition to plain radiography, tomography and computed tomography may be used to provide special detail about cavitation, calcification, and patency of central airways.

Radiographic findings may not correlate with clinical signs in young infants. Significant pneumonia may be found by radiography in the absence of clinical signs. Pleural effusion may be identified only with the use of a radiograph taken in the lateral decubitus position. The radiologic pattern may lag behind clinical improvement for weeks to months.

A chest radiograph should be obtained at the conclusion of the illness to determine that the pneumonia has cleared and that no underlying process, such as foreign body, congenital malformation, or residual atelectasis, is present. The precise timing for performing such a study is uncertain, but it should be done when resolution is expected, approximately 4 to 6 weeks after initial signs appear.

To establish uniformity of radiologic diagnosis of pneumonia, the World Health Organization (WHO) created in 2001 the Pneumonia Vaccine Trial Investigator's Group to develop criteria for evaluating chest radiographs. The WHO criteria were used to reinterpret radiographs obtained during the clinical trial of PCV7 in Northern California.[47] The WHO working group established the following criteria:

- *Category 1*. Consolidation/pleural effusion—alveolar consolidation, a dense or fluffy opacity that occupies a portion or whole of a lobe or entire lung and that may or may not contain air bronchograms; or pleural effusion—fluid in the lateral space and not just in the minor or oblique tissue; spatially associated with a pulmonary parenchymal infiltrate or obliterated enough of the hemithorax to obscure an opacity.
- *Category 2*. Interstitial pattern/infiltrate—the presence of linear patchy densities in a lacy pattern involving both lungs and featuring peribronchial thickening and multiple areas of atelectasis.
- *Category 3*. Absence of consolidation/infiltrate/effusion.
- *Category 4*. Radiograph quality insufficient for reading.

Of particular interest in the clinical trial of the heptavalent conjugate pneumococcal vaccine conducted in Northern California (see section on prevention) was the insight obtained in the proportion of radiologically identifiable pneumonias that were caused by the pneumococcus.[16] Children immunized with the conjugate pneumococcal vaccine had approximately one third fewer episodes of radiographically confirmed pneumonia than children who received the control vaccine. Because approximately 80 percent of the pneumococcal types thought to be responsible

for pneumonia in infants were in the vaccine, these data suggest that the pneumococcus was responsible for roughly 40 percent of pneumonias identified by abnormal radiographs. Because lobar pneumonia frequently is caused by the pneumococcus, the 63 percent decrease in radiographically confirmed lobar consolidation in infants who had received the pneumococcal conjugate vaccine was less surprising.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of bacterial pneumonia includes nonbacterial pneumonias and noninfectious causes of pulmonary disease. During each period of life, certain nonbacterial agents are prominent causes of pneumonia. Pneumonia in neonates may result from congenital infection or infection acquired at the time of delivery because of rubella, toxoplasmosis, herpes simplex infection, cytomegalovirus infection, or syphilis. In infants 2 weeks to 6 months old, *Chlamydia trachomatis* is an important cause of a syndrome of afebrile pneumonia. Throughout childhood, most pneumonias are caused by respiratory viruses, including adenoviruses, influenza viruses, parainfluenza viruses, respiratory syncytial virus, echoviruses, and coxsackieviruses A and B. *Mycoplasma pneumoniae* is an uncommon cause of pneumonia in preschool-aged children, but is an important cause of pneumonia in school-aged children, adolescents, and young adults. Nonbacterial pneumonias that are susceptible to available antimicrobial agents include disease caused by fungi (e.g., histoplasmosis, blastomycosis), *Rickettsia* (i.e., Q fever), and *Chlamydia* (i.e., TWAR agent and psittacosis).

An important consideration is tuberculosis in children with persistent pulmonary disease who do not respond to penicillin or alternatives to penicillin. All children living in areas that have a high risk for tuberculosis should have a tuberculin skin test if admitted to the hospital with a lower respiratory tract infection.

Noninfectious causes of pulmonary lesions include aspiration of gastric contents, aspiration of foreign body, drug reactions, sequestration of lobe, congestive heart failure, atelectasis, sarcoidosis, malignancy or tumor, alveolar proteinosis, pulmonary hemosiderosis, and desquamating interstitial pneumonia.

Bacterial causes of acute empyema include *S. aureus*, *S. pneumoniae*, *H. influenzae*, gram-negative bacilli, and anaerobic bacteria.[19] Bloody exudates (when thoracentesis occurs without trauma) suggest malignancy, infarct of the lung, connective tissue disorder, pancreaticopleural fistula, or tuberculosis.

CLINICAL GUIDELINES IN DEVELOPING COUNTRIES

Acute infections of the lower respiratory tract are the most important cause of death in children younger than 5 years of age in developing countries.[97] The authors of the Programme for the Control of Respiratory Infections of the WHO developed clinical guidelines for case diagnosis of pneumonia for use in developing countries. In these areas, diagnosis and management are provided for children by health care personnel who work in facilities where laboratory and radiologic tests are limited or do not exist.[86] The goals of the program are to simplify diagnosis to the smallest number of readily identifiable signs, to provide a system for classification of the illness, and to define the basis for use of antibacterial agents. The guidelines include assessment of fever, nutrition, lethargy, and color (i.e., presence or absence of cyanosis); measurement of the respiratory rate; observations of chest wall movement to detect retractions; and auscultation for stridor and wheezes.

The guidelines distinguish levels of disease for purposes of management. *Very severe pneumonia* includes central cyanosis and an inability to drink. *Severe pneumonia* includes chest indrawing, without cyanosis, and the ability to drink. *Pneumonia* includes no chest indrawing, but sustained tachypnea (>60 breaths/min for infants <2 months old, >50 breaths/min for children 2 to 12 months old, or >40 breaths/min for children 12 months to 5 years old). *No pneumonia* includes cough in the absence of chest indrawing and tachypnea. Suggested management includes hospitalization and administration of parenteral antibiotics for children with very severe and severe pneumonia, home care and administration of oral antibiotics for children with pneumonia, and no antibiotics but assessment and treatment of other problems for children with cough but without signs of severe respiratory illness.

Simoes and McGrath[96] evaluated the ability of nurses and nursing assistants in Swaziland to recognize pneumonia using the WHO's protocols. Signs of severe disease, including stridor and abnormal sleepiness, often were overlooked, as was audible wheeze, but tachypnea and chest wall retractions were well recognized. In a study of Chinese children, tachypnea (50 cycles/min for infants 2 to 11 months old and 40 cycles/min for children 1 to 5 years old) was a good predictor of radiologically defined pneumonia and was recommended for use by village health care workers in diagnosing pneumonia. Nasal flaring, retractions, stridor, and cyanosis of the tongue had high predictive values but were observed infrequently.[28] A respiratory rate of more than 50 cycles/min or retractions was predictive of pneumonia in children with cough evaluated in Papua New Guinea.[48]

MANAGEMENT

Therapy should be initiated promptly after bacterial pneumonia is diagnosed or strongly suspected. Initial therapy is guided by knowledge of the likely bacterial pathogens in the child's age group because examination of the sputum or tracheal aspirate usually is unavailable in patients younger than school age. The physician must decide whether hospitalization is required for optimal management of the child. Most children with mild to moderate disease can be treated at home. Hospitalization is required for children with severe disease who require hydration, oxygen, or observation; children who are toxic and have a significant degree of pulmonary dysfunction; and children whose families lack the ability to provide therapy and supportive care. Special concern is warranted for infants in the first year of life, when signs of respiratory disease are subtle and disease may progress rapidly.

INITIAL CHOICE OF ANTIMICROBIAL AGENTS BY AGE GROUP

Neonatal Pneumonia

The treatment of neonatal pneumonia is similar to treatment of other severe neonatal infections. Initial therapy must include coverage for gram-positive cocci, particularly group B streptococci, and gram-negative bacilli.

A penicillin is the drug of choice for gram-positive organisms. Penicillin G or ampicillin is used. The latter drug may provide a theoretical advantage because of greater in vitro activity against some enterococci and some gram-negative bacilli, particularly *Escherichia coli* and *Proteus mirabilis*, when used alone or in combination with an aminoglycoside. If the physician has reason to suspect staphylococcal infection, a penicillinase-resistant penicillin is chosen. Infants with pulmonary signs suggestive of severe staphylococcal pneumonia (e.g., abscesses, pneumatoceles, and/or empyema) should be treated with drugs having known efficacy for multidrug-resistant staphylococci, such as vancomycin or linezolid.

Choice of therapy for suspected gram-negative bacillary infection depends on the antibiotic susceptibility pattern for recent

isolates obtained from newborns. An aminoglycoside such as gentamicin has an effective range of in vitro activity. Amikacin and tobramycin have similar activity but may be effective for strains of gram-negative enteric bacilli that are resistant to gentamicin.

Initial therapy is reevaluated when the results of cultures are available. Duration of therapy depends on the causative agent. Pneumonia caused by group B streptococci or gram-negative enteric bacilli is treated for 7 to 10 days; disease caused by *S. aureus* requires 3 to 6 weeks of antimicrobial therapy, according to the severity of the disease.

Pneumonias in Children 1 Month to 10 Years of Age

Most cases of bronchopneumonias in children aged 1 month to 10 years are caused by respiratory viruses. If the initial clinical and radiologic findings are consistent with viral infection, and the child can be observed closely, antimicrobial agents may be withheld pending the results of cultures. *S. pneumoniae* and *H. influenzae* (nontypeable and type b) are the major bacterial agents responsible for bacterial pneumonia in this age group. The rate of disease caused by *H. influenzae* type b is low in children who were immunized previously with the conjugate vaccine. Although multidrug-resistant organisms among pneumococci vary, the concentrations of parenteral ampicillin are sufficient to achieve concentrations in the blood and lung that can inhibit and kill all but the most resistant strains.

If the child is critically ill, vancomycin should be substituted for ampicillin because pneumococci are not resistant to it. Strains of β-lactamase–producing *H. influenzae* resistant to amoxicillin and other susceptible penicillins have been isolated throughout the United States. Nonetheless, amoxicillin still is appropriate initial therapy for a young child with mild disease. If the child is moderately or seriously ill, drugs with efficacy against *S. pneumoniae* and β-lactamase–producing *H. influenzae*, including ampicillin-sulbactam or cephalosporins (i.e., cefuroxime, ceftriaxone, cefotaxime, or ceftazidime), should be administered by parenteral routes.

S. aureus now is an uncommon cause of pneumonia in this age group. If clinical signs compatible with staphylococcal disease are present, however, initial therapy should include a parenteral penicillinase-resistant penicillin. If the disease is severe, drugs of known efficacy for MRSA, such as vancomycin or linezolid, should be used.

Because *M. pneumoniae* and *Chlamydia pneumoniae* are common causes of pneumonia in school-aged children and adolescents, presumptive therapy should include coverage for *S. pneumoniae*, *M. pneumoniae*, and *C. pneumoniae* in children older than 5 years. Erythromycin, azithromycin, and clarithromycin are appropriate drugs for coverage of both pathogens.

Pneumonia in Children 10 Years of Age or Older

S. pneumoniae, *M. pneumoniae*, and *C. pneumoniae* are the major treatable causes of pneumonia in children 10 years of age or older. *H. influenzae* occurs infrequently, and initial therapy need not include coverage for this organism. Therapy outlined earlier for school-aged children is appropriate for children 10 years or older.

CHEMOTHERAPY FOR SPECIFIC PATHOGENS

Pneumococcal Pneumonia

Penicillin G is the drug of choice for children with pneumonia caused by *S. pneumoniae*. For most children with mild to moderately severe disease, an oral penicillin is suitable. Phenoxymethylpenicillin (penicillin V) administered orally provides significant antibacterial activity and approximately twice the peak serum level provided by an equivalent dose of buffered oral penicillin G. Children who appear to be toxic, who have underlying disease, or who have complications (e.g., abscesses, empyema) require the higher serum and tissue antibacterial activity that is provided by aqueous penicillin G administered intravenously or intramuscularly.

Strains of nonsusceptible *S. pneumoniae* have become prevalent in most communities in the United States. Clinical failures have occurred in some patients with meningitis caused by penicillin-resistant pneumococci, but few failures have been identified in cases of sepsis or pneumonia treated with a penicillin or cephalosporin in an adequate dosage schedule. Susceptibility tests should be done on all isolates of *S. pneumoniae* from sputum and body fluids (i.e., blood, cerebrospinal fluid, and pleural fluid). Presumptive therapy for mild to moderate pneumonias need not be altered because of concern for resistant pneumococci, but severe pneumonias should be treated with high-dose parenteral therapy providing high serum and tissue concentrations and stability to β-lactamases, such as intravenous ceftriaxone and cefotaxime. The most appropriate regimen is chosen when results of culture and susceptibility tests are available. Vancomycin is effective uniformly against all pneumococci, including highly resistant strains, and should be considered if susceptibility tests indicate the strain is multidrug-resistant and uniquely susceptible to vancomycin.

The dosage schedule for mild to moderate disease and severe disease is provided in Chapter 235. The duration of therapy depends on the clinical response, but therapy should be continued for at least 3 days after defervescence and significant resolution of radiologic and clinical signs; usually 5 to 7 days is sufficient.

Pneumonia Caused by *Haemophilus influenzae*

Nontypeable and type b strains of *H. influenzae* are susceptible to various antimicrobial agents, including ampicillin or amoxicillin (non–β-lactamase producers), oral or parenteral cephalosporins, sulfonamides, and aminoglycosides. All of these agents have been used with success in systemic infections (including pneumonia) caused by this agent. Amoxicillin is considered the drug of choice for treating young children with mild to moderate pulmonary disease. Because of the concern for β-lactamase–producing strains of *H. influenzae*, a parenteral second-generation (cefuroxime) or third-generation (ceftriaxone, cefotaxime, or ceftazidime) cephalosporin should be used as initial therapy in patients with severe disease when this microorganism is known or strongly suspected to be the pathogen.

A child with mild to moderate disease should be treated for a minimum of 7 days, including a period without fever of at least 3 days. A child with severe disease should be treated for 2 to 3 weeks.

Staphylococcal Pneumonia

The high incidence of staphylococci resistant to penicillin G, in the hospital and in the community, requires the use of a penicillinase-resistant penicillin whenever staphylococcal pneumonia is diagnosed or suspected. Subsequently, if the culture and sensitivity data indicate that the organism is susceptible to penicillin G, the drug should be used because of its greater efficacy and lower cost. Clinical trials indicate that all penicillinase-resistant penicillins are equally effective in treating staphylococcal pneumonia. The increased incidence of CA-MRSA suggests that initial therapy of patients with pulmonary signs suggestive of staphylococcal infection (e.g., abscesses, pneumatoceles, and emypema) should include parenteral drugs of known efficacy, such as vancomycin or linezolid.

The rapid development of empyema, pneumatoceles, and abscesses demands close observation and meticulous nursing care. The antibiotic should be administered parenterally using a

high-dose schedule for 2 to 3 weeks; an oral preparation then may be given for 1 to 3 weeks. The total duration of antibiotic therapy depends on the initial response, the presence of pulmonary and extrapulmonary complications, and the rapidity of resolution of the pneumonia.

Pneumonia Caused by Anaerobic Bacteria

Most anaerobic bacteria that cause pneumonia, including strains of *B. fragilis*, are highly susceptible to penicillin G. Some strains of *B. fragilis* may be resistant to penicillin G and susceptible to chloramphenicol, clindamycin, or cefoxitin. The duration of therapy depends on the extent of the disease; pneumonia without complications clears rapidly with appropriate therapy; 7 days of therapy usually is sufficient.

Pneumonia Caused by Gram-Negative Bacilli

The initial choice of therapy is guided by the following factors: the source of the infection, the disease process present (e.g., burn, cystic fibrosis), the host susceptibility to infection (e.g., deficient immune mechanisms), and the antimicrobial susceptibility pattern for these organisms in the community or hospital. The basis for choice of antibiotic is similar to that outlined for neonatal pneumonia suspected to be caused by gram-negative bacilli. The duration of therapy must be tailored to the clinical course and the response to therapy. Cases of pneumonia with minimal pulmonary lesions and limited symptoms should be treated for at least 3 days after defervescence. Severe cases of pneumonia should be treated for 2 to 3 weeks.

Therapy for Penicillin-Allergic Children

A child who has a significant history of allergic reaction to any of the penicillins must be considered allergic to all of them, and alternative antimicrobial agents must be considered for therapy. If the patient has a history consistent with IgE-mediated reaction to penicillin, cephalosporins also should be avoided. If the patient has a history of a penicillin reaction that was not IgE-mediated and not serious, administration of a cephalosporin usually is safe.[83] Cephalothin, cefazolin, ceftriaxone, and cefotaxime have been used with success in the treatment of pneumococcal pneumonia. Erythromycin, the new macrolides clarithromycin and azithromycin, and clindamycin are active in vitro against gram-positive cocci, but use for pneumococcal and staphylococcal pneumonias should be determined on the basis of susceptibility tests. Because there are no vancomycin-resistant pneumococci and only rare cases of staphylococci that are resistant, vancomycin is the drug of choice for presumptive therapy of a patient who is allergic to penicillin and who has severe pneumonia likely caused by staphylococcal or pneumococcal infections.

Adjuncts to Chemotherapy

Administration of antimicrobial agents is only part of the management of a child with pneumonia. Close observation, nursing care (including suction of excess secretions), and the following supportive measures are crucial:

1. Maintenance of fluid and electrolyte balance
2. Humidification provided by cool mist
3. Oxygen for severe dyspnea
4. Cleansing of the mouth
5. Sparing use of antipyretics because the temperature course provides a guideline for the therapeutic response

More extensive procedures may be required in special circumstances, as follows:

1. Bronchoscopy is important in documenting the presence of a foreign body, tumor, or congenital anomaly.
2. Intubation of the trachea or tracheotomy may be considered when the patient has difficulty clearing secretions and more efficient suction of the lower respiratory tree is required.
3. Drainage of pleural effusions may be necessary when an accumulation of fluid compromises respiration. Thick, tenacious empyema may require intercostal tube drainage or closed-tube thoracostomy. Empyema caused by *S. aureus* may require placement of a tube, whereas the less viscid effusion associated with *S. pneumoniae* and *Streptococcus pyogenes* rarely requires more than frequent thoracentesis. Empyema caused by *H. influenzae* may be thick and viscid, requiring placement of a chest tube, or less viscid, requiring only thoracentesis. Single or multiple thoracenteses are adequate when the volume of fluid is small and the quality of the fluid allows ready drainage, as usually is the case with empyema caused by *S. pneumoniae* or group A streptococci. When large amounts of fluid are present or the fluid is thick and viscid, a closed drainage system with intercostal chest tube under negative pressure is placed; this placement frequently is necessary for empyema caused by *S. aureus*. The tube should be removed as soon as its drainage function is completed because delay might result in local tissue injury, secondary infection, or sinus formation.The use of video-assisted thoracoscopy early in the course of empyema (within 48 hours after admission to hospital) has significantly decreased the duration of fever and the length of hospitalization for patients with pleural empyemas.[91]
4. Intrapleural instillation of antibiotics or fibrinolytics should be considered in cases of empyema when the fluid is loculated because of fibrous adhesions. If a chest tube is in place, antibiotics can be instilled after irrigation through the tube. In susceptible infections, aqueous penicillin G (10,000 to 50,000 U), ampicillin (10 to 50 mg), or a penicillinase-resistant penicillin or cephalosporin (10 to 50 mg) may be inoculated in 10 mL of diluent (i.e., sterile water or normal saline) after the tube is clamped. The clamp is maintained for 1 hour and then released for drainage. The instillations should be repeated three to four times each day that the tube remains in place. Hawkins and colleagues[49] reported successful resolution of 54 of 58 children with empyema who underwent intrapleural placement of catheters and administration of fibrinolytics consisting of tissue plasminogen activator.

PROGNOSIS

In uncomplicated cases of pneumococcal pneumonia in children in the United States, the mortality rate is very low (<1%). A review of mortality from pneumonia in children in the United States, 1939 through 1996, identified reductions in mortality rates that were thought to reflect expanded access to medical care for poor children.[34] In developing countries, pneumonia is a major cause of mortality, accounting for more than one fourth of deaths in children younger than 5 year old. Half of the pneumonia-related mortality occurs in children younger than 1 year old. The WHO estimates that approximately 4 million childhood deaths are caused each year by pneumonia.

Lung morphology and physiology usually return to normal after completion of appropriate antimicrobial therapy. Fibrothorax is a rare occurrence; almost all children resolve thickened pleurae with no effect on lung growth and function. Even after having extensive disease associated with empyema caused by *S. aureus* or *H. influenzae*, children have normal growth and development and normal pulmonary function after recovery.[70] Deaths still result from bacterial pneumonias; however, most deaths of children result from abrupt, overwhelming disease. Asmar and colleagues[6] reported two deaths in 43 children with pneumonia caused by *H. influenzae*; both deaths occurred before antibiotics could be administered.

PREVENTION

PNEUMOCOCCAL VACCINES

The approval of a conjugate polysaccharide pneumococcal vaccine by the FDA in February 2000, followed by the recommendations of various authoritative groups (e.g., American Academy of Pediatrics, American Academy of Family Physicians, and Advisory Committee on Immunization Practices of the Surgeon General) for universal immunization of infants and selective immunization of children at risk who are 2 to 5 years of age, added the most effective mode of prevention of pneumococcal diseases yet available. The available vaccine (Prevnar; Wyeth Lederle Vaccines, Pearl River, NY) is a heptavalent vaccine in which the individual polysaccharides have been purified and directly conjugated to the protein carrier CRM 197, a nontoxic variant of diphtheria toxin. The conjugate vaccine induces type-specific antibodies in infants 2 months of age. The vaccine currently is distributed in 73 countries, and more than 180 million doses have been distributed worldwide (Paradiso P, personal communication May 2008).

The safety and efficacy of the vaccine for prevention of pneumonia were studied in a trial of approximately 38,000 children in Northern California by Black and colleagues at the Kaiser Permanente Vaccine Study Center.[16] Children were randomly assigned to receive the conjugate pneumococcal vaccine or a conjugate polysaccharide meningococcal group C vaccine. Pneumonia was defined clinically and radiologically. Infants and children who had received the pneumococcal vaccine had a 4.3 percent reduction in clinical episodes of pneumonia and a 20 percent decrease in radiographically confirmed pneumonia. Similar results have been reported from developing countries; a nine-valent pneumococcal conjugate vaccine was found to be effective compared with placebo in prevention of 7 percent of clinical pneumonias and 37 percent of first episodes of radiologically diagnosed pneumonias.[27]

The 23-type pneumococcal polysaccharide vaccine produces a satisfactory independent antibody response, but only in children older than 2 years. The polysaccharide vaccine is recommended for children 2 years of age and older who are at risk for developing invasive disease (e.g., sickle-cell disease, HIV infection or other immunodeficiencies, malignancy, nephrosis) after they have received the appropriate number of doses of the conjugate vaccine.

HAEMOPHILUS INFLUENZAE VACCINES

A polysaccharide vaccine for prevention of *H. influenzae* type b disease was introduced in the United States in April 1985. As was true of other polysaccharide vaccines, infants younger than 18 months of age had an inadequate immune response to the capsular polysaccharide. The development of a conjugate vaccine by coupling the capsular saccharide of *H. influenzae* type b and a protein resulted in protective antibodies in infants 2 months of age. The conjugate *H. influenzae* type b vaccine was approved by the FDA in fall 1990 and has resulted in virtual elimination of disease caused by *H. influenzae* type b in infants and children. The conjugate vaccine has had varying efficacy in different regions. The incidence of pneumonia associated with alveolar consolidation or pleural effusion was reduced by 22 percent in Chilean infants, whereas the vaccine had limited efficacy in prevention of clinical or radiologically confirmed pneumonias in Indonesian children.

Because nontypeable strains of *H. influenzae* are important causes of otitis media, sinusitis, and pneumonia, investigators have sought vaccine candidates, including outer membrane proteins, bacterial adherence proteins, and lipo-oligosaccharides. Questions of strain heterogeneity and choice of the number of antigens needed for optimal protection remain unanswered, and no products have moved beyond preclinical testing.[11]

INFLUENZAVIRUS VACCINE

Secondary bacterial pneumonia may complicate primary influenza virus infections. Extensive use of conjugate pneumococcal vaccines in children (and widespread use of influenza vaccines) should limit the incidence and morbidity of the combined infections. Brundage[21] reviewed the epidemiologically and clinically important interactions between influenza and secondary bacterial respiratory pathogens during the 1918 and subsequent influenza pandemics.

CHEMOPROPHYLAXIS

Chemoprophylaxis for prevention of bacterial pneumonias is limited to patients with immunodeficiency. Children who have sickle-cell anemia or who have functional or anatomic asplenia are at risk for developing overwhelming disease caused by *S. pneumoniae*. Daily antimicrobial prophylaxis is recommended for these children, regardless of their immunization status. The chemoprophylactic regimen used most commonly is daily administration of oral penicillin V (125 mg twice daily for children <5 years; 250 mg twice daily for children >5 years). Children with HIV should receive a regimen of trimethoprim-sulfamethoxazole for prophylaxis against infection caused by *P. carinii*.

PREVENTION OF HEALTH CARE–ASSOCIATED PNEUMONIA

Because a hospitalized child is exposed to a variety of pathogens, including bacteria capable of causing pneumonia, and may undergo procedures that compromise the airway, health care providers should be familiar with techniques for limiting exposures. The CDC periodically has provided guidelines for prevention of health care–associated pneumonia, most recently in 2004.[22,23]

CHAPTER 28

Children's Interstitial Lung Disease and Hypersensitivity Pneumonitis

Minh L. Doan ❂ Leland L. Fan

Children's interstitial lung disease (ILD) encompasses a large, heterogeneous group of mostly rare, diffuse lung disorders of known and unknown etiology.[43] In many of these disorders, injury to the alveolar wall gives rise to an inflammatory response with subsequent repair that potentially can lead to pulmonary fibrosis. Infections of the lung, either chronic or acute with postinfectious sequelae, form the largest category of children's ILD in the immunocompetent and immunocompromised host. This chapter focuses on the entities that are caused by or associated with infection and the entities that mimic community-acquired pneumonia.

CLASSIFICATION

Table 28–1 presents a general classification of children's ILD. Although a complete description of each disorder is beyond the scope of this chapter, certain conditions warrant brief mention because major differences exist between adult ILD and children's ILD in terms of types and distribution of disease. Usual interstitial pneumonitis, a progressive and fatal disorder, is the most common form of adult idiopathic ILD, but it probably does not occur in children. Also, hypersensitivity pneumonitis (HP) in adults is caused by a variety of occupational exposures but in children usually is caused by exposures to avian antigen. In addition, several entities, such as neuroendocrine cell hyperplasia of infancy and pulmonary interstitial glycogenosis, have been identified more recently and seem to be unique to infants and young children. Finally, the genetic basis for certain types of familial lung diseases has been linked to mutations in genes involved in surfactant metabolism.[97,98,131] With the exception of surfactant protein C deficiency, because of high mortality rates, these disorders have been found mostly in children.

DISORDERS ASSOCIATED WITH INFECTION

The role of infectious agents, such as adenovirus,[146] influenza,[76] *Mycoplasma*,[137] and *Chlamydia*,[56] in the development of chronic lung disease in children has been well documented. Virtually any organism that infects the lower respiratory tract is capable of producing chronic, diffuse lung disease if the injury is severe enough, although most infected children have acute, self-limited disease that resolves completely.

TABLE 28–1 Classification of Pediatric Interstitial Lung Diseases

Pediatric Interstitial Lung Diseases of Known Etiology
Aspiration syndromes
Chronic infection (viral, bacterial, fungal, parasitic)
  Immunocompetent host
  Immunocompromised host
Bronchopulmonary dysplasia
Hypersensitivity pneumonitis (and other environmental exposures)
Lipid storage diseases
Pulmonary alveolar microlithiasis

Pediatric Interstitial Lung Diseases of Unknown Etiology
Primary Pulmonary Disorders
Desquamative interstitial pneumonitis
Lymphocytic interstitial pneumonitis and related disorders
Nonspecific interstitial pneumonitis
Cryptogenic organizing pneumonia
Alveolar hemorrhage syndromes
Pulmonary infiltrates with eosinophilia
Bronchiolitis obliterans
Pulmonary alveolar proteinosis
Pulmonary vascular disorders (proliferative and congenital)
Pulmonary lymphatic disorders

Systemic Disorders with Pulmonary Involvement
Connective tissue disease
Malignancies
Histiocytosis
Sarcoidosis
Neurocutaneous syndromes

Unique Forms of Interstitial Lung Disease in Infancy
Lung growth abnormalities[152]
Neuroendocrine cell hyperplasia of infancy[108]
Follicular bronchitis/bronchiolitis[63]
Cellular interstitial pneumonitis of infancy[123]/pulmonary interstitial glycogenosis[13]
Acute idiopathic pulmonary hemorrhage of infancy[36]
Chronic pneumonitis of infancy[68]/inborn errors of surfactant metabolism[97,98,131]

Bronchiolitis Obliterans

Probably the best example of postinfectious chronic lung disease is found in children who develop bronchiolitis obliterans after having severe adenovirus pneumonia.[146] Bronchiolitis obliterans is characterized by a fibrosing process of the small airways that results in severe, irreversible obstruction of the airways. Clinically, patients present with tachypnea, crackles, wheezing, and a productive cough that persist for more than 6 weeks after the initial illness. Chest radiographs show air trapping and atelectasis; on high-resolution computed tomography (CT) scans, mosaic perfusion, central bronchiectasis, vascular attenuation, and atelectasis are common findings.[24] Occasionally, severe involvement of one lung leads to the development of a unilateral, small, hyperlucent lung, known as Swyer-James syndrome.[146]

Patients with severe adenovirus pneumonia have been shown to have immune complexes containing adenovirus antigen in the lung and increased serum levels of interleukin-6, interleukin-8, and tumor necrosis factor-α.[92,93] These studies suggest that abnormal or excessive host immunologic and inflammatory responses may be important in the development of chronic lung disease from adenovirus in infants and young children. Although lower respiratory tract infection with respiratory syncytial virus, parainfluenza, influenza, measles, varicella,[148] *Mycoplasma*, and pertussis[18] also can result in bronchiolitis obliterans, adenovirus is the most common etiologic agent. The need for mechanical ventilation during the initial illness is a strong independent risk factor for the subsequent development of bronchiolitis obliterans.[24]

Lymphocytic Interstitial Pneumonitis

Well recognized because it is an acquired immunodeficiency syndrome (AIDS)–defining condition in children infected with human immunodeficiency virus (HIV),[15] lymphocytic interstitial pneumonitis (LIP) also occurs in association with autoimmune disorders[81,141] and other immunodeficiencies[22] and in idiopathic and familial forms.[99] LIP is not a true interstitial pneumonitis but rather is a form of pulmonary lymphoproliferative disease. It is characterized histologically by a diffuse infiltrate of mature lymphocytes, along with smaller numbers of plasma cells and histiocytes, in the pulmonary interstitium and alveolar wall.[70,71] The infiltrate also may be found along lymphatic pathways and is evident in the bronchovascular bundle and interlobular septa, but it usually spares the pleura. The lymphocytes are small noncleaved cells that may accumulate as small nodules, sometimes with germinal centers. Generally, the lymphocytes are polyclonal, with B cells and a variety of T cells being identified.[106] Although Epstein-Barr virus has been isolated from the lungs of some AIDS-infected[4,39] and non–AIDS-infected patients with LIP,[85] its role in the development of LIP is unclear. Neither fibrosis nor airspace disease is prominent in this disease.

LIP occurs in 30 percent of children infected perinatally with HIV and typically manifests between the second and third years of life with an insidious onset of cough, tachypnea, dyspnea, and hypoxemia.[65,106,117-119,125] Chest radiographs characteristically reveal a diffuse, symmetric reticulonodular or nodular pattern, occasionally with mediastinal or hilar adenopathy.[86] Among HIV-infected children, the incidence of acute lower respiratory tract infection is higher in children with LIP,[128] and these patients ultimately may develop bronchiectasis.[130]

Other Conditions

Other pediatric chronic lung diseases have been associated with various infectious agents. Perinatal infection or colonization with

Ureaplasma urealyticum has been implicated in inducing pulmonary inflammation and subsequent development of bronchopulmonary dysplasia in premature neonates.[64] A more recent meta-analysis suggested, however, that reporting bias may be partially responsible for this association.[122] Parvovirus has been linked to autoimmune disease associated with ILD and other organ involvement.[9] Finally, attempts have been made to link *Stachybotrys chartarum* and its mycotoxins to acute and recurrent pulmonary hemorrhage in infants, although a causal relationship has not been proven.

In a prospective study of immunocompetent children with chronic diffuse infiltrates, Fan and coworkers[45] found an infectious agent as the underlying cause in 10 (20%) of 51 children with ILD. Identified agents included adenovirus alone in four patients, adenovirus and cytomegalovirus in two, varicella in one, Epstein-Barr virus in one, *Chlamydia* in one, and *Toxocara* in one. Chronic infections or long-term sequelae from acute infections account for many cases of ILD of known etiology in children.

ENTITIES THAT MAY MIMIC COMMUNITY-ACQUIRED PNEUMONIA

Acute Eosinophilic Pneumonia

Acute eosinophilic pneumonia is the most severe form of the idiopathic eosinophilic pneumonias. It is characterized by very large numbers of eosinophils infiltrating the alveoli and interstitium, with resultant acute respiratory failure. Acute eosinophilic pneumonia can be idiopathic or result from inciting triggers such as drugs (minocycline, sertraline) and inhalational exposures (new-onset cigarette smoking). Patients present with acute onset of fever, cough, tachypnea, and dyspnea; pleuritic chest pain; and myalgias. On examination, crackles are present in 80 percent of patients; wheezing is a rare manifestation. Hypoxemia is uniformly present, and patients can progress rapidly to respiratory failure. In contrast to patients with other eosinophilic lung diseases, patients with acute eosinophilic pneumonia generally do not have significant peripheral eosinophilia (>350 cells/mm^3) on presentation as a diagnostic clue. Chest radiographs and CT scans show reticular markings with Kerley B lines and alveolar infiltrates and pleural effusions in 50 percent of cases. Bronchoalveolar lavage (BAL) fluid shows marked eosinophilia (>20%) in most patients. Pleural fluid also has increased eosinophils and a high pH, caused by the basic eosinophil granule contents. Treatment with corticosteroids (methylprednisolone, 2 to 4 mg/kg/day) usually results in a rapid and complete resolution.[3,113]

Pulmonary Vasculitis

In children, the spectrum of pulmonary vasculitides includes Wegener granulomatosis, Churg-Strauss syndrome, microscopic polyangiitis, and pulmonary capillaritis. These disorders can manifest as diffuse alveolar hemorrhage, with fever, dyspnea, hemoptysis (not present in one third of patients), anemia, and patchy alveolar infiltrates on chest radiographs. Other patients may have fever and cavitary or nodular lesions on imaging.[60] Diffuse alveolar hemorrhage can be diagnosed with BAL, when sequentially recovered aliquots of fluid show persistently bloody return. Renal involvement may be present sometimes, with microscopic hematuria and red blood cell casts seen on urinalysis. A positive serum antineutrophil cytoplasmic antibody (ANCA) may be seen with Wegener granulomatosis (especially cytoplasmic ANCA), Churg-Strauss syndrome, and microscopic polyangiitis, and the presence of peripheral and pulmonary eosinophilia would support the diagnosis of Churg-Strauss syndrome.[11] Pulmonary capillaritis is associated with a variety of conditions and requires an open lung biopsy for diagnosis because it may manifest as an ANCA-negative, hematuria-negative diffuse alveolar hemorrhage syndrome.[52] Therapeutic options for pulmonary vasculitis include systemic corticosteroids, cyclophosphamide, and intravenous immunoglobulin; aggressive treatment is required in severe cases.

Connective Tissue Disorders

Pulmonary manifestations can precede other systemic findings in children with systemic lupus erythematosus[23] and juvenile rheumatoid arthritis,[114] and these patients may present with acute respiratory symptoms associated with fever. In acute lupus pneumonitis, signs and symptoms include high fevers, dyspnea, tachypnea, crackles, and cyanosis. Chest radiographs may show areas of consolidation and pleural effusions and interstitial infiltrates and elevation of the hemidiaphragms.[87] Other pulmonary manifestations of systemic lupus erythematosus include pulmonary hemorrhage, pulmonary hypertension, ILD, pneumothorax, and shrinking lung syndrome. Multisystem involvement, including renal and skin, may provide clues to the underlying diagnosis. Treatment usually requires corticosteroids.[23]

Hypersensitivity Pneumonitis

Acute and chronic HP can manifest with fever, cough, dyspnea, and pulmonary infiltrates. HP is discussed in detail later.

CLINICAL PRESENTATION

Most children with ILD have insidious symptoms that may go unrecognized for years. Some children have been misdiagnosed as having asthma and have been treated with bronchodilators.[49] Although a history of wheezing can be elicited in half of patients, it can be documented by physical examination in only approximately 20 percent of cases. Clinical suspicion for children's ILD should arise when patients meet at least three of the four following criteria: (1) presenting symptoms of dyspnea, tachypnea, retractions, cough, exercise intolerance, or respiratory failure; (2) presenting signs of crackles, failure to thrive, clubbing, or respiratory failure; (3) hypoxemia; and (4) diffuse abnormality on chest radiographs or CT not attributable to other known processes.[42]

A careful history should be taken to assess the severity of the disease and to obtain information that may contribute to establishing a diagnosis. A search for precipitating factors should include a history of feeding difficulties that may suggest aspiration; any prior acute or severe respiratory infections; and environmental exposures, especially to birds or molds. Hemoptysis may indicate a pulmonary vascular disorder or hemosiderosis. Joint disease or rash may indicate a systemic process, such as a connective tissue disease. A family history of relatives or siblings with similar respiratory conditions may be clues to genetic or familial lung diseases, such as a defect in surfactant proteins.

On physical examination, tachypnea and retractions often are observed, and crackles commonly are heard, particularly at the bases. In severe cases, cyanosis, clubbing, an accentuated pulmonic component of the second heart sound, and evidence of growth failure are seen. Oxygen saturation usually is normal under all conditions in most patients with mild disease, but desaturation may occur with exercise or during sleep as the disease progresses, and ventilation-perfusion mismatch ensues. Patients with more advanced disease are hypoxemic at rest.

DIAGNOSTIC EVALUATION

A systematic approach to children's ILD is essential to physicians confronted with such a large differential of rare conditions.

TABLE 28–2 Diagnostic Studies for Pediatric Interstitial Lung Disease

Rights were not granted to include this table in electronic media. Please refer to the printed publication.

From Fan, L. L.: Pediatric interstitial lung disease. In *Schwarz, M. I., and King, T. E. (eds.): Interstitial Lung Disease, 4th ed. Hamilton, Ontario, B. C. Decker, 2003, pp. 134-151.*

Diagnostic studies can be divided into studies used to assess the extent and severity of disease, to identify disorders that predispose to ILD, and to identify the primary ILD (Table 28–2). In adults with ILD, Raghu[109] suggested a diagnostic process that employs a thorough history and physical examination first, noninvasive tests next, and then invasive studies, including BAL and transbronchial biopsy followed by open lung biopsy if the previous less invasive studies do not provide a specific diagnosis. Based on experience from a retrospective chart review of 48 children with ILD, Fan and colleagues[49] independently developed an algorithm remarkably similar to that of Raghu's and used it prospectively in the evaluation of 51 children presenting with ILD.[45] In that study, a specific diagnosis was established by history and physical examination alone in 1 patient; noninvasive studies alone in 8 others; and invasive studies, including lung biopsy, in another 26. Of the remaining patients, eight had a suggestive diagnosis, and eight had no specific diagnosis. This study suggests that a systematic approach to the diagnosis of children's ILD is useful and that some patients can be diagnosed with noninvasive studies, but most patients require invasive studies, including lung biopsy.

PULMONARY FUNCTION TESTS

In children who are old enough to undergo pulmonary function tests, standard spirometry typically shows a pattern of restrictive lung disease, with reduced forced vital capacity (FVC), forced expiratory volume in 1 second (FEV_1), and a normal or elevated FEV_1/FVC ratio.[49] On measurement of lung volumes, although the total lung capacity (TLC) often is low, the residual volume (RV) may be normal or elevated, resulting in an increased RV/TLC ratio that suggests air trapping and a mixed restrictive/obstructive pattern. These findings also can be documented in infants and young children with the use of infant pulmonary function testing techniques.

HIGH-RESOLUTION COMPUTED TOMOGRAPHY

In the evaluation of children's ILD, high-resolution CT is an important diagnostic modality used to provide precise detail about the extent and distribution of parenchymal disease and to select favorable sites for biopsy. To evaluate the lung parenchyma best with CT scanning, thin sections are necessary to avoid the volume averaging that occurs with 2.5- to 5-mm sections, which obscures the fine parenchymal detail and airway abnormalities. High-resolution CT samples thin sections (usually 1 mm in thickness) at wide intervals (usually 10 mm). With the development of multidetector array or multislice CT, contiguous thin section studies of the entire chest can be performed in a shorter time and with less radiation exposure than with conventional CT.[10]

Inspiratory and expiratory CT scans should be obtained whenever possible. In younger children and infants in whom cooperation is impossible and in whom rapid respiratory rates can cause motion artifact, a controlled-ventilation CT technique using mask ventilation of a sedated patient can be used.[80] Giving several assisted deep breaths to these young children results in a short period of apnea during which the lungs can be inflated to obtain inspiratory images, followed by expiratory images after passive deflation. General anesthesia produces similar results, although frequent large sigh breaths are necessary to prevent dependent atelectasis, which occurs within minutes of intubation.

High-resolution CT may increase the level of diagnostic confidence for the diagnosis of children's ILD, improve diagnostic accuracy, and provide a useful classification system. In a study of 20 children with biopsy-proven ILD, 56 percent of the confident first-choice diagnoses on high-resolution CT were correct.[82] Diseases were classified into five distinct groups based on dominant high-resolution CT features: (1) geographic hyperlucency (bronchiolitis obliterans or bronchocentric granulomatosis), (2) septal thickening (lymphangiomatosis, hemangiomatosis, microlithiasis), (3) ground-glass opacification (desquamative interstitial pneumonitis, LIP, HP), (4) lung cysts and nodules (histiocytosis), and (5) consolidation (aspiration, bronchiolitis obliterans organizing pneumonia). First-choice diagnoses based on high-resolution CT were accurate in 61 percent of cases in a similar study.[25]

BRONCHOALVEOLAR LAVAGE

BAL via flexible bronchoscopy allows for sampling of the cellular and biochemical components of alveolar lining fluid and may be helpful in the evaluation of certain cases of children's ILD. Normal indices for pediatric BAL fluid have been described, against which abnormal results can be compared.[37]

The most common indication for pediatric BAL has been to detect infection in the immunocompromised host, with a diagnostic yield of approximately 50 percent in non–AIDS-infected patients and 75 percent in patients with AIDS.[41] The use of quantitative bacterial cultures may help to differentiate whether recovered organisms represent true infection, colonization, or contamination. Examination of BAL fluid also can identify aspiration or pulmonary hemorrhage by the detection of lipid-laden or hemosiderin-laden macrophages. The presence of lipid-laden or hemosiderin-laden macrophages in BAL may be sensitive but not specific for aspiration or alveolar hemorrhage syndromes.[48] In a murine model, investigators showed that hemosiderin-laden macrophages first appear at 3 days, peak at 1 week, and persist in small numbers for 2 months after a single episode of hemorrhage.[35] BAL also has been used to diagnose pulmonary alveolar proteinosis, lysosomal storage disorders, and histiocytosis.[48]

In immunocompetent children with ILD, Fan and colleagues[48] found that BAL was diagnostic of a primary disorder in only 5 of 29 patients—aspiration was detected in 3, and infection in 2. The differential diagnosis was narrowed in 15 patients by the presence of lymphocytosis, neutrophilia, or eosinophilia. A secondary disorder was uncovered in eight patients. This study suggests that BAL provides some useful information in children with ILD, but that its ability to determine the primary cause is limited.

LUNG BIOPSY

As in adult ILD, lung biopsy is the gold standard for establishing the diagnosis of children's ILD because most diseases are classified in terms of previously defined histopathologic patterns. Although transbronchial or percutaneous needle biopsy may be helpful in certain conditions, a transthoracic approach by either conventional open lung biopsy or video-assisted thoracoscopic surgery (VATS) remains the gold standard for obtaining tissue adequate for diagnosis.

The use of VATS is rapidly becoming the method of choice for lung biopsy in children. Technical modifications have allowed its use even in infants.[116] In a prospective study in a small group of immunocompetent children with ILD, Fan and coworkers[46] found that the diagnostic yield for open lung biopsy (57%) and VATS (54%) was comparable, but the morbidity from VATS was lower in terms of duration of surgery, chest tube insertion, and hospitalization.[46] Although multiple lobe biopsies directed by high-resolution CT have been advocated for the diagnosis of adult and children's ILD, this study did not show a difference in diagnostic yield for single-lobe versus multiple-lobe biopsies. Depending on the handling of the specimen and the expertise of the reviewing pathologist, the diagnostic yield from transthoracic lung biopsy (open lung biopsy and VATS) can be quite high, especially in light of the more recent advances in the understanding of children's ILD.

Lung biopsy material must be handled in a consistent manner to ensure optimal interpretation, and a protocol for such handling was published based on the recommendations of the chILD Pathology Group.[75] A general scheme for division of the biopsy specimen is as follows: (1) microbiology cultures, 35 percent; (2) snap-frozen for polymerase chain reaction or other molecular studies, 10 percent; (3) snap-frozen in cryomatrix for immunofluorescent, laser capture, or other studies requiring frozen sections, 10 percent; (4) fixed in glutaraldehyde for electron microscopy, less than 5 percent; (5) imprints for cytologic examination or rapid identification of organisms, 0 percent; and (6) expanded and fixed in formalin (methods previously described[47]) for light microscopy, 40 percent. It is crucial that the biopsy material be interpreted by a pathologist with considerable expertise in pediatric lung disease because the normal lung of an infant differs greatly from that of an older child or adolescent, and any pathologic finding needs to be interpreted in light of the normal age-dependent variations of lung architecture.

TREATMENT

Supportive care includes providing adequate nutrition, annual influenza vaccination, and aggressive treatment of intercurrent infections; engaging the patient in a carefully supervised fitness and exercise program; having the patient avoid inhalant hazards such as tobacco smoke; and providing selective use of bronchodilators and oxygen for chronic hypoxemia. Patients with underlying systemic disorders need primary treatment for that disorder, such as intravenous gamma globulin for hypogammaglobulinemia. Specific therapy for primary ILD, such as anti-infective therapy for chronic infections, interferon-α for pulmonary hemangiomatosis,[146] and lung lavage for pulmonary alveolar proteinosis, should be used when possible.[84] When environmental agents such as bird antigens are causative, avoiding contact with them is crucial (see the section on HP).

Generally, corticosteroids remain the treatment of choice for most patients with ILD on the presumption that suppression of inflammation may reduce the risk of developing fibrosis.[47] Although controlled clinical studies are lacking, corticosteroids have been used to treat such diverse types of diffuse lung diseases as desquamative interstitial pneumonitis, LIP, and HP.[41] In a retrospective study of pediatric ILD by Fan and coworkers,[49] corticosteroids were judged to be effective in 40 percent (12 of 30) of treated children in terms of improved clinical status, decreased oxygen requirements, and improved pulmonary function. A trial of prednisone or equivalent corticosteroid (1 to 2 mg/kg/day) for at least 6 to 8 weeks probably is warranted.

Alternative but unproven therapy includes pulse steroid therapy, hydroxychloroquine, azathioprine, cyclophosphamide, methotrexate, cyclosporine, and intravenous gamma globulin. Of these, hydroxychloroquine probably has been used most frequently.[5,49,128,133] The precise mechanism of action is unknown, but chloroquine and hydroxychloroquine have shown immunosuppressive effects with the ability to inhibit the functional capabilities of monocytes and the generation of antibody-forming cells. Hydroxychloroquine is preferred over chloroquine because the former has less retinal toxicity. The recommended dose in children for the treatment of ILD is 10 mg/kg/day. A more recent case report described the successful use of infliximab, an anti–tumor necrosis factor-α monoclonal antibody, in reversing bronchiolitis obliterans in a hematopoietic stem cell transplant recipient.[51]

The fact that many alternative pharmacologic approaches are considered for children and adults with ILD implies that conventional therapy often is ineffective. New strategies are being developed based on animal models of pulmonary fibrosis and more recent advances in the cellular and molecular biology of inflammatory reactions. Such therapies would be directed against the action of certain cytokines, oxidants, and growth factors that may be involved in the fibrotic process. The potential to deliver specific inflammatory inhibitors or inhibitors of collagen biosynthesis directly to the lung via aerosolization suggests that disease processes in the lung may be more amenable to novel therapies than are disease processes in other internal organs.

More children are receiving lung transplantation for end-stage ILD. According to the 2006 Registry of the International Society for Heart and Lung Transplantation, between 1991 and 2005, there were 30 reported pediatric lung transplantations worldwide for "idiopathic pulmonary fibrosis," 20 for "interstitial pneumonitis," 14 for "pulmonary fibrosis, other," 8 for "surfactant protein B deficiency," and 7 for "bronchopulmonary dysplasia," together constituting 9 percent of all pediatric lung transplantations.[144] Although the overall 5-year survival after transplantation is still disappointing at approximately 50 percent,[144] outcomes for infants undergoing transplantation for surfactant protein B deficiency seem to be at least similar to the outcomes of infants transplanted for other reasons.[104] A case of recurrent pulmonary alveolar proteinosis in the lung allografts of a child who underwent heart-lung transplantation for lysinuric protein intolerance has been reported.[121]

OUTCOME

The prognosis of children with ILD varies. Infants with neuroendocrine cell hyperplasia of infancy generally do well, although they may be symptomatic and require oxygen for years.[108] At the other end of the spectrum, children with growth failure, pulmonary hypertension, and severe fibrosis do poorly.

The overall mortality rates for children's ILD remain high. In a series of 25 children with fibrosing alveolitis or desquamative interstitial pneumonitis, Sharief and associates[129] reported a poor response to treatment in nine patients, with four deaths. In a review of 28 patients with desquamative interstitial pneumonitis, Stillwell and colleagues[136] reported that only 17 patients survived. In another series of children with a variety of more recently described ILD, Nicholson and coworkers[95] reported four deaths in 17 patients with available follow-up data.

Fan and Kozinetz[44] reviewed the outcome of 99 children with chronic ILD seen in Denver, Colorado, over 15 years (1980 to 1994). As expected, a wide variety of disorders were encountered, and 15 recorded deaths occurred, with a probability that a patient would survive to 24 months, 48 months, and 60 months after onset of symptoms of 83 percent, 72 percent, and 64 percent, respectively. Of the clinical features present at the time of initial evaluation, weight less than fifth percentile, crackles, clubbing, family history of ILD, and symptom duration were not associated with decreased survival rates. A severity of illness score, based on increasing levels of hypoxemia and the presence or absence of pulmonary hypertension, was related significantly to survival, with an increasing score associated with a higher probability of decreased survival rates. A simple scoring system seems to be a useful measure of outcome in children with ILD.

HYPERSENSITIVITY PNEUMONITIS

HP, also known as *extrinsic allergic alveolitis*, is a form of immune-mediated ILD that develops in response to repeated inhalation of finely dispersed organic antigens.[27] HP should be considered in the differential diagnosis of a child who presents with acute or chronic respiratory symptoms associated with fever, and obtaining an environmental exposure history is essential to arrive at the proper diagnosis. A wide variety of organic particles, including mammalian and avian proteins, fungi, thermophilic bacteria, and certain low-molecular-weight volatile and nonvolatile chemical compounds, are known to induce HP in susceptible individuals.[54] Certain systemic medications, such as ciprofloxacin,[134] dapsone,[140] and methotrexate,[28] also have been reported as triggers.

Acute and chronic forms of HP have been described, and repeated exposure can lead to irreversible lung damage. Although exposure to antigens capable of provoking HP occurs commonly in the home and work environment, the overall incidence of the condition in the general population is low. An estimated 5 to 15 percent of individuals exposed to high levels of a specific organic antigen develop clinical disease.

PATHOLOGY AND PATHOGENESIS

Pathologically, HP is characterized by a diffuse, predominantly mononuclear cell inflammation of the small airways and pulmonary parenchyma, often associated with poorly formed, nonnecrotizing granulomas.[126] Foamy macrophages are seen commonly in the airspaces. With advanced disease, interstitial and intra-alveolar fibrosis develops that is indistinguishable from other causes of pulmonary fibrosis.

The mechanisms by which organic dusts induce these characteristic pathologic features of the disease are poorly understood. Evidence supports a type III and a type IV hypersensitivity reaction, as defined by Gell and Coombs.[52b,77] A type III reaction is suggested by the presence of precipitating antibody to the offending antigen, immune complex deposition, and activation of complement. A type IV reaction is suggested by an increased percentage of T lymphocytes in BAL fluid, with a strong predominance of $CD8^+$ subsets and a low CD4/CD8 ratio, and the presence of granulomas on lung biopsy specimen. Considering the small proportion of exposed individuals who develop clinical symptoms, complex interactions among the nature of the antigen, the intensity and duration of the exposure, and the host response in susceptible individuals most likely are involved.

ETIOLOGY

As shown in Table 28–3, HP in adults is caused by a wide variety of occupational and environmental exposures.[126] In contrast, in children, HP is caused mainly by exposure to an array of domestic birds (71%) and fungi (28%), based on a review of 133 reported pediatric cases.* HP also has been reported in a child receiving methotrexate.[28] Familial cases have been identified, with one report describing a mother (who died from the disease) and all of her five children who developed HP from exposure to wild city pigeons.[32]

CLINICAL PRESENTATION

Although a wide variety of antigens can induce HP, the immunologic response and clinical presentation are similar. In the reported pediatric cases referenced previously, the mean age (± standard deviation) was 9.6 (± 3.9) years. The youngest reported patient with HP developed symptoms at 10 weeks of age.[139]

In the acute form, symptoms mimic a flulike illness, with high fevers, chills, dry cough, dyspnea, myalgias, and malaise. These symptoms begin several hours after exposure and diminish during the next 12 to 24 hours, provided that no additional exposure occurs. Physical examination reveals a dyspneic, ill-appearing child, often with bibasilar crackles. Transient hypoxemia and nodular pulmonary infiltrates often are present.

In the subacute form, children have insidious and progressive symptoms. In the reported pediatric cases in which the following specific symptoms were recorded, exercise intolerance was present in 97 percent (93 of 96), cough was present in 96 percent (101 of 105), weight loss was present in 87 percent (46 of 53), and fever was present in 70 percent (51 of 73). On physical examination, crackles were present in 72 percent (66 of 91), and clubbing was present in 35 percent (16 of 46) of cases. The chronic form of HP is an extension of the subacute form resulting from continued antigen exposure, with development of irreversible pulmonary fibrosis.

DIAGNOSIS

A careful and thorough environmental history is a critical component in detecting potential antigens. The presence of the following six predictors can help to establish a clinical diagnosis of HP in adults: (1) exposure to a known offending antigen, (2) positive precipitating antibodies to the offending antigen, (3) recurrent episodes of symptoms, (4) inspiratory crackles on physical examination, (5) symptoms occurring 4 to 8 hours after exposure, and (6) weight loss.[74] Compatible findings on chest radiographs (Fig. 28–1), pulmonary function testing, BAL, and open lung biopsy also aid in establishing the diagnosis.

Detecting precipitating IgG antibodies to the offending antigen can be useful in confirming the diagnosis in a patient with documented exposure and typical clinical features (Fig. 28–2). Fifty percent of individuals who are exposed to a particular antigen develop precipitating antibodies, however, and only a

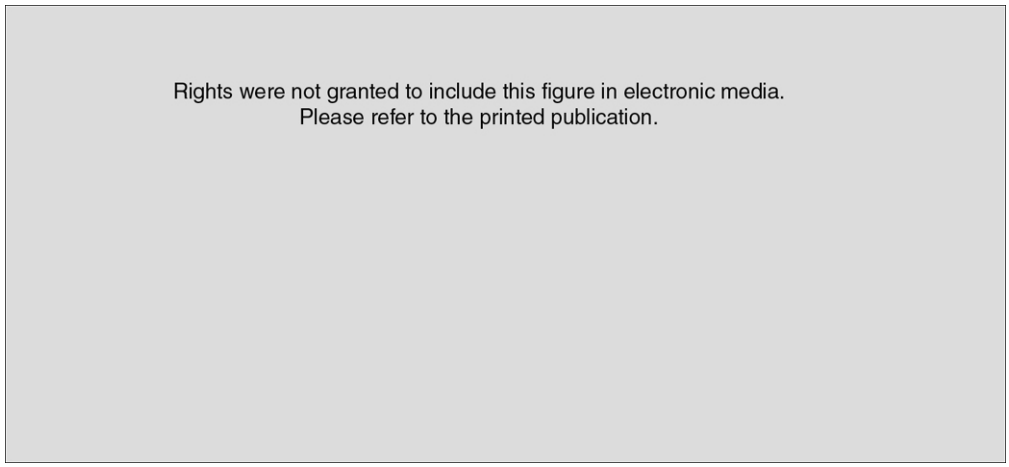

Figure 28–1 Hypersensitivity pneumonitis from cockatiel antigens in an adolescent. Chest radiograph shows bilateral reticulonodular infiltrates. High-resolution computed tomography scan shows diffuse, multiple fine nodules. *(Courtesy of Robin Deterding, M.D., University of Colorado, Denver, CO. From Fan, L. L. Pediatric interstitial lung disease.* In *Schwarz, M. I., and King, T. E. [eds.]: Interstitial Lung Disease, 4th ed. Hamilton, Ontario, B. C. Decker, 2003, pp. 134-151.)*

small percentage of these develop HP.[27] Long-term follow-up has shown that the simple presence of precipitins does not increase the likelihood of developing the condition.[26] Conversely, not all individuals with symptomatic HP have positive precipitins. In reported pediatric cases, positive precipitins were found in 93 percent (120 of 129) of the children tested. Because the quality of antigen material may vary in commercial laboratories, it is preferable to obtain a sample of the suspected antigen directly from the original source and test it against the patient's serum in a reputable laboratory. Researchers have reported using fluorometry to quantify serum IgG antibody against pigeon antigens, with decreasing antibody titers used as a measure of successful antigen avoidance.[89]

To document recurrence of symptoms shortly after exposure to a putative antigen, provocation challenge (inhalation of the antigen in controlled laboratory conditions) has been used in adults.[110] It has not been employed often in children, however, with only 23 of the 133 children reported in the literature having undergone such a challenge, in which 14 (61%) were positive. An in vitro measurement of antigen-induced lymphocyte proliferation compared with unstimulated lymphocyte cultures obtained from BAL or blood also has been described.[101]

Classic features of acute HP on chest radiographs and high-resolution CT scans include poorly defined centrilobular micronodules, with predominance in the upper and middle lung zones (see Fig. 28–1). On high-resolution CT, additional characteristic features are widespread ground-glass attenuation and air trapping, which is especially prominent on expiratory scans.[132] A small percentage of patients also may have lung cysts.[50] In the more chronic phase, diffuse interstitial infiltrates may predominate, with progression to fibrosis and honeycombing that are indistinguishable from usual interstitial pneumonia.[83] Instances of negative CT examinations in patients with biopsy-proven disease have been reported.[57] In the reported pediatric cases of HP, chest radiographs were abnormal in 93 percent (113 of 132).

Pulmonary function tests typically show a restrictive defect, sometimes with an obstructive component. In reported pediatric cases, the mean (± standard deviation) FEV_1 and FVC in the children tested were 54.1 percent (± 19.8) and 52.4 percent (± 20.2) predicted. The pressure-volume curve is shifted down and to the right, consistent with decreased compliance. Low lung volumes and diminished diffusion capacity also are present.[32] Although resting room air oxygen saturation may be normal, desaturation with exercise or sleep may occur. With long-standing disease, resting oxygen desaturation can be seen. In the pediatric cases in which oxygenation was documented, 82 percent (59 of 72) had hypoxemia at rest. Pulmonary hypertension may be present with advanced disease, but in contrast to other forms of pediatric ILD, it may reverse completely with successful treatment.

BAL fluid, obtained by flexible fiberoptic bronchoscopy, typically shows a significant lymphocytosis. In adults, a low CD4/CD8 ratio frequently accompanies the lymphocytosis. The reported normal ratio (mean [± standard error of the mean]) varies from 1.9 (± 0.2) in young normal controls to 7.6 (± 1.5) in elderly controls.[90] Children with HP also have marked lymphocytosis in the BAL compared with healthy pediatric controls (80% versus 12%). Although the CD4/CD8 ratio also may be low compared with that of healthy adults, it is not significantly different from the ratio (0.6) reported in healthy children without lung disease.[111] As with positive precipitins, the presence of BAL lymphocytosis in exposed individuals who are asymptomatic does not predict the development of HP.[26] Analysis of induced sputum shows that it does not reflect accurately the lymphocytosis seen in BAL.[31]

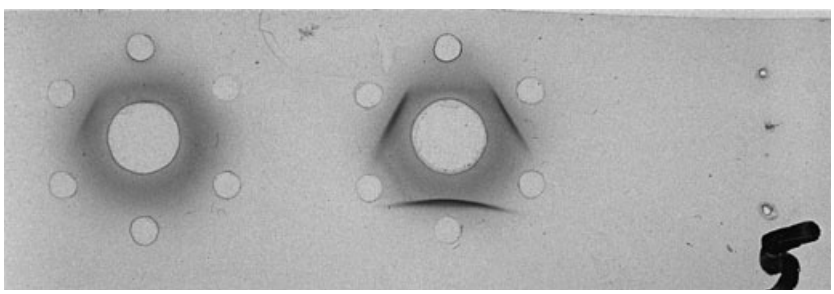

Figure 28–2 Serum-precipitating antibodies against cockatiel antigens in the patient shown in Figure 28-1. *(Courtesy of Robin Deterding, M.D., University of Colorado, Denver, CO.)*

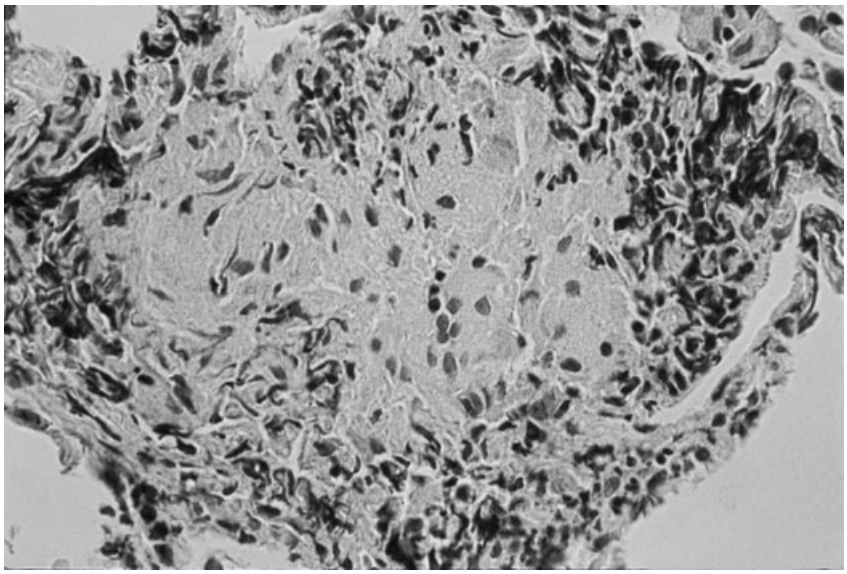

Figure 28–3 Transbronchial biopsy specimen from the patient in Figure 28–1 shows a poorly formed granuloma consistent with hypersensitivity pneumonitis. *(Courtesy of Robin Deterding, M.D., University of Colorado, Denver, CO.)*

Lung tissue obtained by transbronchial (limited to older children and adults) or transthoracic biopsy shows the characteristic histologic features described previously (Fig. 28–3). Of the 83 reported pediatric cases of HP, nine biopsy specimens were obtained, and all showed typical histologic changes.

TREATMENT AND OUTCOME

The mainstay of treatment is eliminating exposure to the offending antigen. In the literature, exposure was eliminated in 97 percent of the pediatric cases (100 of 103), with improvement achieved in all but one fatal case.

The use of corticosteroids often results in rapid improvement of symptoms and reversal of radiographic and lung function abnormalities unless irreversible changes in the lung have occurred. Corticosteroids were used in 70 percent (74 of 106) of the reported pediatric cases, with a positive response occurring in all but the one fatal case. Generally, prednisone was given at 0.5 to 2 mg/kg daily for 2 to 4 weeks, followed by a taper, although specific regimens have not been studied scientifically. Pulsed methylprednisolone also has been used.[19]

The outcome of children with HP, when properly diagnosed and treated, is excellent. In the 106 pediatric cases of HP with reported outcomes, 104 improved or became asymptomatic, 1 patient remained unchanged, and 1 patient died. In this last case, an 11-year-old girl developed classic features after several years of exposure to budgerigars and other birds.[143] Despite removal of the offending antigens and treatment with corticosteroids and penicillamine, she died of respiratory failure 13 months later. The overall prognosis for children with HP is excellent, provided that a prompt diagnosis is made and appropriate treatment consisting of antigen removal and the judicious use of corticosteroids is instituted.

CHAPTER 29

Pleural Effusions and Empyema

J. Gary Wheeler ❂ Richard F. Jacobs

Collections of fluid in the pleural space have been described in the literature as transudates, pleural effusions, exudates, purulent pleurisy, parapneumonic effusions, empyema, and complicated empyema. A great deal of inexactitude exists in the use of these terms, and comparing methods of diagnosis and management from one study to another is difficult. Standardized definitions are used in this chapter to describe pleural fluid collections.

The term *transudative pleural effusion* refers to fluid in the pleural space that is a nonpurulent effusion and typically nonpneumonic in origin. The term *purulent effusions* refers to effusions that are more cellular (exudative) and typically pneumonic in origin. The term *empyema* describes purulent effusions with chemical or microbial evidence of a severe process requiring drainage. *Complicated empyema* describes the processes associated with loculations or a fibropurulent rind requiring aggressive manipulations for cure. *Parapneumonic effusion* is a general term referring to any pleural exudative process resulting from an inflammatory process in the lung. Although these definitions are arbitrary and the literature is inconsistent in the use of these terms, a standard approach to the classification of these four types of effusions and their management has evolved.

The first description of parapneumonic infection is attributed to Hippocrates, who in the 4th century BCE advocated incision and drainage of empyema 2 weeks after the onset of symptoms. Since then, the physiology and microbiology of effusions have been described, and parapneumonic diseases and the management of fluid collections of the pleural space have been defined. In most cases, the directions of Hippocrates still are relevant: ". . . set him upon a stool, which is not wobbly; someone should hold his hands, then shake him by the shoulders and listen to see on which side a noise is heard. And right at this place—preferably on the left—make an incision, then it produces death more rarely."[58]

This description of open drainage to normal atmospheric pressures was recognized to be associated with significant mortality rates from hemodynamic instability in 1918, when the Empyema Commission of the United States Army recommended that the practice be abandoned[57]; thereafter, closed-tube drainage was introduced, and mortality rates decreased. Developments in radiology, antimicrobials, and surgery resulted in further improvements in care. Today, the major cause of mortality is related to the underlying disease because the management of parapneumonic effusions in children is largely successful and without residual morbidity. The physician must understand the risks for development of pleural effusion and empyema and indications for thoracentesis, implications of the results of pleural fluid studies, and the optimal medical and surgical management of the effusions and empyema.

EPIDEMIOLOGY

Parapneumonic effusions are known and expected complications in children with respiratory tract infections. The frequency of effusions may be 20 percent of patients with viral or mycoplasmal pneumonia[28,34,86] and 75 percent of patients with proven *Staphylococcus aureus* pneumonia.[7] Empyema has been reported to occur in 6.3 to 23 of 1000 admissions of children,[64,89] and as a complication of pneumonia in 1 percent of children in the United States.[19] One of the most extensive studies of empyema in children was from Dallas, Texas; 12 episodes per year during a 19-year period were described.[30] A more recent report from Houston, Texas, suggested an increase in the overall number of hospitalizations per 10,000 admissions for empyema from 1993 to 1998 compared with 1999 to 2002 (8.5 versus 17.8)[89]; investigators elsewhere also have reported increases.[16,83]

In adults, empyema follows a primary pulmonary process in 55 to 60 percent of cases, surgery in 20 percent, trauma in 6 percent, spontaneous pneumothorax in 35 percent, and other causes in 2 percent.[57,84] Hoff and associates[41] found that 11 percent of cases in children had an underlying illness, including hyper-IgE syndrome, hypogammaglobulinemia, acute lymphocytic leukemia, cerebral palsy, Down syndrome, and postsurgical and congenital thrombocytopenia. The remaining cases were related to a primary pulmonary process. Freij and associates[30] found a rate of 8.3 percent with similar risk factors. The mortality rate is highest in the first 2 years of life. After reaching 2 years of age, children have better outcomes than do adults; generally, they have less intrinsic lung disease, have greater elasticity of their chest wall, and heal more quickly than older patients do.[15,35]

PATHOPHYSIOLOGY

The pleurae are mesodermally derived tissues that are approximately 30 to 40 μm thick and permeable to liquid and gas.[9,51] The parietal pleurae, which adhere to the chest wall, are fed from the intrathoracic and superior phrenic arteries and have sensory innervation. The visceral pleurae are splanchnic in origin, with blood flow from the pulmonic and pericardiophrenic arteries and no sensory innervation. The lymphatic structures of the visceral pleurae are microscopic vessels called *lacunae*. They are denser in the lower lobes to accommodate greater venous pressure. Parietal structures called *stomas* are 4- to 10-μm-diameter pores that connect the pleurae to lymphatics. These stomas have valvular function during expiration and inspiration and can filter large structures, such as red blood cells and macrophages.[51] The venous drainage of visceral pleura is into the pulmonic veins and from the parietal pleura into intercostal and bronchial veins. Lymphatic structures are woven below and around the mesothelial cells and ultimately drain into mediastinal, intercostal, and mammary nodes. The structure of the pleura is a surface of mesothelial cells and layers of lymphatic sinuses and pores, elastic fibers, and loose vascular connective tissue, with a fibroelastic layer covering the lungs and chest wall.[51]

The precise flow and distribution of pleural fluid have been debated for some time. Because of the differences in venous pressure in the intercostal and pulmonary veins, fluid is thought to flow from the parietal venous system to the visceral system by drifting from the high-pressure parietal tissues into the negative-pressure pleural space, with reabsorption on the visceral side. The latter is caused by a low venous pressure system on the parietal side and the high oncotic pressure of the pulmonic venous system compared with the pleural space.

The dynamics of this process are described in Starling's equation:

$$\text{Fluid movement} = k \cdot [\{HP_c - HP_{ip}\} - \{COP_c - COP_{ip}\}]$$

in which *k* is the filtration coefficient (a measure of the permeability of capillaries to fluid), *HP* is the hydrostatic pressure, and

TABLE 29–1 Characteristics of Pleural Effusions

	Transudative	Purulent Effusion	Empyema	Complicated Empyema
Appearance	Serous	Thin exudate	Turbid	Thick pus
Mean WBC	1000	5300	25,500	55,000
PMN (%)	50	>90	>95	>95
Protein (fluid/serum ratio)	<0.5	>0.5	>0.5	>0.5
LDH (fluid/serum ratio)	<0.6	>0.6	>0.6	>0.6
LDH (IU/L)		>200	>200	>1000
Glucose (mg/dL)	>60	<60	<60	<40
pH*	7.4-7.5	7.35-7.45	7.2-7.35	<7.2
Imaging	Fluid	Fluid	Fluid	Loculations, thick peel, scoliosis

**Should be examined immediately or stored at 0° C.*
LDH, lactate dehydrogenase; PMN, polymorphonuclear neutrophils; WBC, white blood cell count.

COP is the colloid osmotic pressure of capillaries (*c*) and the intrapleural compartment (*ip*).[14] The consensus is that although the impact of Starling forces on venous flow may play a role in the normal situation, parietal lymphatics absorb most of the excess fluids in pathologic situations and play an important role in normal physiology as well, removing 250 to 500 mL/day in adults.[92] They are the only mechanism for absorbing cells and other debris from the pleura.

A few studies in the past have shown that 20 mL of pleural fluid is found normally in 30 percent of resting adults, 70 percent of exercising adults,[7] and 46 to 67 percent of postpartum women.[41] Some fluid may be transported from the peritoneum to the pleura through small communications.[7] This hypothesis is supported by reports of patients with infected abdominal fluid and pleural effusions in whom the same organisms are recovered in both sites.[13]

The *raison d'être* of the pleural space is unknown. Some mammals, such as elephants, do not have a pleural space.[103] This fact has served as the rationale for using some methods of management of pleural disease that have included chemical obliteration of the pleural space. In the normal situation, pleural fluid in small amounts is a necessary requirement for optimal lubrication of the pleural space and for mechanical coupling of the lung and chest wall.[51] The accumulation of excess fluid (i.e., effusion) occurs in a limited set of circumstances, through excess production or deficient absorption. Increased production occurs when vessels are leaky (e.g., in septic shock) or active secretion of fluid with mesothelial inflammation (e.g., pleural infection) is present. Decreased absorption occurs with decreased oncotic pressure (e.g., nephrosis), increased pulmonary hydrostatic pressure (e.g., congestive heart failure), or lymphatic obstruction (e.g., malignancy).[102]

The mechanisms behind pleural effusions may vary among different infectious diseases. Effusion can be a "sympathetic" pleural response to a bacterial infection in the lung associated with inflammatory cytokines and altered venous or lymphatic drainage because of local edema. Direct or hematogenous extension of a bacterial process can occur in the pleura. *Mycoplasma* particularly is pathogenic in patients with sickle-cell disease, presumably because of pulmonary sludging, which increases pulmonic venous drainage pressures and results in accumulation of effusions. In pneumococcal disease, effusions often develop several days after the acute infection, when bacteria no longer can be recovered. These effusions may be related to immune complex disease.[14] In patients with tuberculosis, the most common cause of pleural effusions is thought to be the rupture of an old granuloma into the pleural space, with a hypersensitivity response similar to the skin test response,[15] which partly explains the low yield in cultures.

After an inflammatory process is initiated, it tends to progress through three classic stages.[3] The first, defined as a *purulent effusion*, is the acute exudative stage, with a thin pleural exudate characterized by normal glucose, lactate dehydrogenase (LDH), and pH. The second transitional fibropurulent stage, categorized as *empyema*, is characterized by turbid fluid, decreased glucose concentration (<60 mg/dL) and pH (7.2 to 7.35), and elevated LDH (>200 U/L). The third chronic organizing stage is notable for a very low pH (<7.2) and glucose level (<40 mg/dL), LDH concentration greater than 1000 U/L, and development of loculations and peel. This fluid is found in patients with *complicated empyema*.

Often, the pleural fluid quality can be predicted without sampling the fluid based on the clinical course of the patient. A patient with anasarca caused by heart failure or nephrosis with bilateral effusions may not need to have an effusion analyzed if otherwise stable. If the same patient has fever, examination of the fluid is necessary to exclude a secondary bacterial infection. Analysis of the pleural fluid is most helpful when the underlying disease is unknown or when a primary pulmonic process is suspected. When patients have effusions caused by hydrostatic imbalance, the effusion is a transudate. Its protein and cell count do not exceed the range of normal pleural fluid (5000 cells/mm^3 and <2 g of protein).[7,92] Patients who have an active inflammatory process may have an exudate (defined by excess protein and cells). In children, the most common cause of exudative pleural processes is pneumonia. In adults, most pleural effusions are related to congestive heart failure or malignancy,[56] but pneumonia is the most common cause of empyema.[71] Table 29–1 summarizes the general differences among pleural effusions.

Table 29–2 lists causes of effusions. Some of these causes, particularly iatrogenic causes, such as invasive procedures and drugs, are important to consider in the differential diagnosis of a difficult case. Others are associated with specific syndromes, such as adult respiratory distress syndrome[94] and yellow nail lymphedema syndrome.[97] Motor vehicle accidents have been identified as a common cause of serosanguineous effusions when disruption of normal mechanical lung function and hematoma occur.[81]

MICROBIOLOGY

Among children with parapneumonic effusions, no prospective study has established firmly the frequency with which effusions occur and how many are associated with particular microbes. Although respiratory viruses infrequently cause symptomatic effusions, the sheer number of cases and the presence of asymptomatic cases likely would implicate viral infection as the most common cause. Definite viral disease has been associated with cytomegalovirus, Epstein-Barr virus, measles, and adenovirus.[30,31,45,63] Other pathogens, such as *Mycoplasma* and *Chlamydia*, are difficult to diagnose but may account for a significant number of pneumonic infections in older children and adolescents that

TABLE 29–2 Causes of Pleural Effusion

Capillary leak
Sepsis syndrome
Vasculitis associated with immune complex disease
Connective tissue diseases
Inflammatory bowel disease
Malignancy (lymphoreticular, sarcoma, neuroblastoma)
Toxins (e.g., TSST-1)
Drugs (phenytoin, isoniazid, nitrofurantoin, amiodarone, methotrexate, bleomycin)
Myxedema
Trauma
Increased hydrostatic pressure
Congestive heart failure
Sickle-cell disease
Pulmonary venous hypertension
Superior vena cava syndrome
Pregnancy
Decreased oncotic pressure
Nephrosis
Cirrhosis
Protein malnutrition
Obstructed lymphatics
Congenital lymphangiectasia

Iatrogenic
Drugs
Central line misplacement

TSST-1, Toxic shock syndrome toxin-1.

may be associated with effusions in 20 percent of cases.[28,31,86] Viral, mycoplasmal, and chlamydial organisms rarely are isolated in patients with effusions requiring intervention.

The bacteriology of empyema is constantly evolving. Several past articles have established the role of different bacterial pathogens in childhood effusions. A study of 227 children by Freij and colleagues[30] published in 1984 found *Staphylococcus aureus* (29%), *Streptococcus pneumoniae* (22%), and *Haemophilus influenzae* (18%) as the three most frequent causes of parapneumonic effusions (Table 29–3). Subsequent studies show that the frequency of these pathogens has been affected by vaccine[1,16] and antibiotic use. Pathogens are shown in Table 29–4. *H. influenzae* and *S. pneumoniae* vaccines have led to a decreased incidence of these agents as a cause of empyema, whereas *S. aureus* has become the leading cause with antibiotic-resistant strains, accounting for most cases in community-acquired disease.[89] Among cases of *S. pneumoniae* infections, nonvaccine strains are increasing in number and may become a more severe threat.[17,24] Certain groups of children (e.g., neonates,[30] immunocompromised hosts, patients with preexisting chest tubes that become infected with nosocomial pathogens, patients with a ruptured viscus, and patients with foreign body aspiration) are at higher risk for acquiring gram-negative infections.

Administration of antibiotics before the diagnosis of empyema is made influences the recovery of organisms. In one report, the incidence of prethoracentesis antibiotics was 71 percent in culture-negative effusions and only 41 percent in culture-positive effusions.[41] Pretreatment with antibiotics may be associated with a decrease in the number of positive blood cultures and in the number of patients from whom *S. pneumoniae* are recovered.[71] Freij and associates[30] reported the frequency of parapneumonic effusions occurring in children with pneumonia caused by specific pathogens. The rates of effusion by organism were as follows: group A streptococcus, 86 to 91 percent; *S. aureus*, 72 to 76 percent; *S. pneumoniae*, 57 percent; *H. influenzae*, 49 to 75 percent; *Mycoplasma*, 21 percent; and adenoviruses, 11 to 33 percent.

TABLE 29–3 Distribution of Pathogens by Age

	No. Cases					
Pathogen	***0-6 Months***	***7-12 Months***	***13-24 Months***	***25 Months–5 Years***	***6-15 Years***	***Total***

NR, not reported.

Anaerobes were sought carefully by Brook and Frazier,[13] who found them infrequently in patients younger than 6 years of age. The anaerobes rarely were found in patients with primary pneumonia, occurring most often in patients with lung abscess and aspiration pneumonia.[13] In older patients (7-17 years old), anaerobes were recovered as isolated pathogens in 44 percent of cases.[13] Virtually every bacterial organism has been associated with pleural effusion at one time or another. *Brucella*,[47] *Francisella tularensis*,[82] and *Yersinia enterocolitica*[44] may be associated with the development of pleural effusions. The diagnosis in such cases often is suggested by a unique history in the patient.

Mycobacterial and fungal effusions are rare in children but are well described. In four published reviews, only two patients (from Nigeria) were reported to have *Mycobacterium tuberculosis*.[30,41,59,63] In a series of 303 children younger than 2 years of age with tuberculosis, 3.3 percent had an effusion.[40] In adolescents with tuberculosis, the incidence of effusion likely approximates that of adult disease. In one series of adult patients with primary tuberculous disease, pleural effusion occurred in 29 percent of cases.[20] In another adult series, primarily of reactivation disease, pleural effusion occurred in only 1 percent of the patients.[35] Whether or not co-infection with human immunodeficiency virus (HIV) is increasing the incidence of disease is controversial.[27]

Histoplasmosis has been associated with pleural effusion in 0 to 6 percent of childhood histoplasmosis cases.[73] Blastomycosis has been associated with pleural effusions in 0 to 40 percent of cases.[72,90] Effusions resulting from other fungi (e.g., *Coccidioides*, *Aspergillus*) have been described.[57] Parasitic diseases manifesting with effusions are uncommon but are found in patients with *Entamoeba histolytica* disease, most often from rupture of a hepatic abscess into the pleural space.[57] Echinococcal disease also has been reported.[29]

Pleural effusion associated with adult HIV infection has been reported in 14.6 percent of hospital admissions in one series in which 67 of 160 cases were infectious. Of those cases, 50 were associated with bacterial pneumonia, 10 with tuberculosis, and 5 with *Pneumocystis carinii* pneumonia.[2] Another report on patients infected with HIV suggested that empyema was seen primarily in patients with intravenous drug abuse.[10] We have not seen empyema frequently in our HIV-infected patients, perhaps because of the more recent use of more effective antiretroviral therapy.

Drug resistance in community-acquired pneumonia complicates the management of parapneumonic effusions. Intermediate or fully resistant *S. pneumoniae* were found in 12.8 percent and 10.1 percent of isolates in a study from multiple pediatric centers from 1993 to 2000; 7.5 percent were cephalosporin-resistant.[96] Methicillin-resistant *S. aureus* (MRSA) is a growing concern in empyema. Reports since 2000 have shown that 22 to 78 percent of isolates of *S. aureus* were methicillin-resistant, with many being community acquired.[43]

DIAGNOSIS

CLINICAL PRESENTATION

The clinical presentation of transudative effusions compared with purulent effusions ordinarily is distinctive, but a continuum of symptoms is shared by both. Many of the symptoms associated with pleural processes are caused by the underlying disease that precipitated the effusion, rendering a distinct syndrome difficult to recognize in patients. Disease caused by some pathogens (e.g., anaerobes, fungi, mycobacteria) also may follow a more insidious course, obscuring the symptoms of effusion. A history always should be obtained to identify systemic diseases, such as immunodeficiency diseases, cancer, and rheumatic diseases, or medications that may be associated with effusions.

Symptoms most specific for parapneumonic processes are dyspnea and pleuritic pain. Dyspnea occurs when the volume of the effusion mechanically interferes with breathing, or when pain prevents adequate gas exchange. Pain occurs with irritation of the parietal pleura and on inspiration (i.e., pleurisy). Fever is generated by the inflammatory response and pathogen-specific components (e.g., lipopolysaccharide, toxins). With an acute bacterial process, the fever can be high and hectic, mimicking the fever that occurs with an abscess. Patients in the chronic organizational phase generally have less fever. Cough and malaise are secondary symptoms. Hemoptysis and purulent sputum also may occur. The onset of symptoms of a purulent effusion may be delayed in time and distinct from the symptoms found at the onset of the pneumonia in older children; infants usually have no symptom-free period.[15] In the early phases of effusions, the patient may have no symptoms.

The physical examination usually is revealing. The child is tachypneic in more than 70 percent of cases, but breathing is shallow as a result of the child's attempt to minimize pain. Fever and cough usually occur in more than 90 percent of patients with purulent effusions.[59] The patient may appear toxic, with acute infection. Patients often posture toward the affected side. Classically, auscultation reveals a decrease in breath sounds and occasionally detects a pleural rub, but pleural rubs often are absent in a very young child. Rales from an associated pneumonia may be heard. Depending on the stage of the process, percussion may reveal a level of dullness associated with free-flowing effusion. As the process organizes, it may be less evident. Empyemas can erode through the chest wall into the subcutaneous tissue (i.e., empyema necessitatis) or into a bronchus (i.e., bronchopleural fistula).

IMAGING

The diagnosis most often is made by radiographic examination of the chest. Consolidation of a lobe of the lung is present, with an effusion obscuring the diaphragm (Fig. 29–1). A standard posteroanterior standing view reveals blunting of the costal diaphragmatic gutter. As fluid tracks along the lateral and posterior chest wall, a meniscus configuration is seen. Distinguishing it from pleural thickening may be difficult, and in such cases, a decubitus or cross-table view of the chest allows free-flowing fluid to layer out on the dependent chest wall. In older children and adults, a decubitus layer of fluid of more than 10 mm is considered a sufficient volume of fluid to attempt to extract by thoracentesis.[54] With large volumes of fluid (>1000 mL),[85] compression of the lung and shift of the trachea away from the effusion (Fig. 29–2) may occur. As an empyema develops and organizes, discrete pockets of fluid (i.e., loculations) may form within the pleural cavity (see Fig. 29–2). Occasionally, loculations are confused with lung abscess. Scoliosis also is well defined by the chest radiograph and occasionally is used as an indication for surgery.[41] The observation of an air-fluid level in the pleural space signifies that air has been generated in the pleural space by gas-forming organisms or has entered through a pneumothorax, perforated viscus, or bronchopleural fistula.

Ultrasonography has shown great utility in providing better guidance for thoracentesis of pleural fluid. It is noninvasive and allows empyema to be defined by showing internal echoes and septations (see Fig. 29–2).[90,105] Transudates uniformly are anechoic, although approximately one third of exudates also are anechoic.[105] Ultrasonography is not as precise as is computed tomography (CT) in differentiating a lung abscess from an empyema. CT and magnetic resonance imaging occasionally are required to distinguish parenchymal from pleural disease, identify a non-opaque foreign body, or locate a fistula.[92] CT particularly is useful in a patient whose chest radiograph shows total

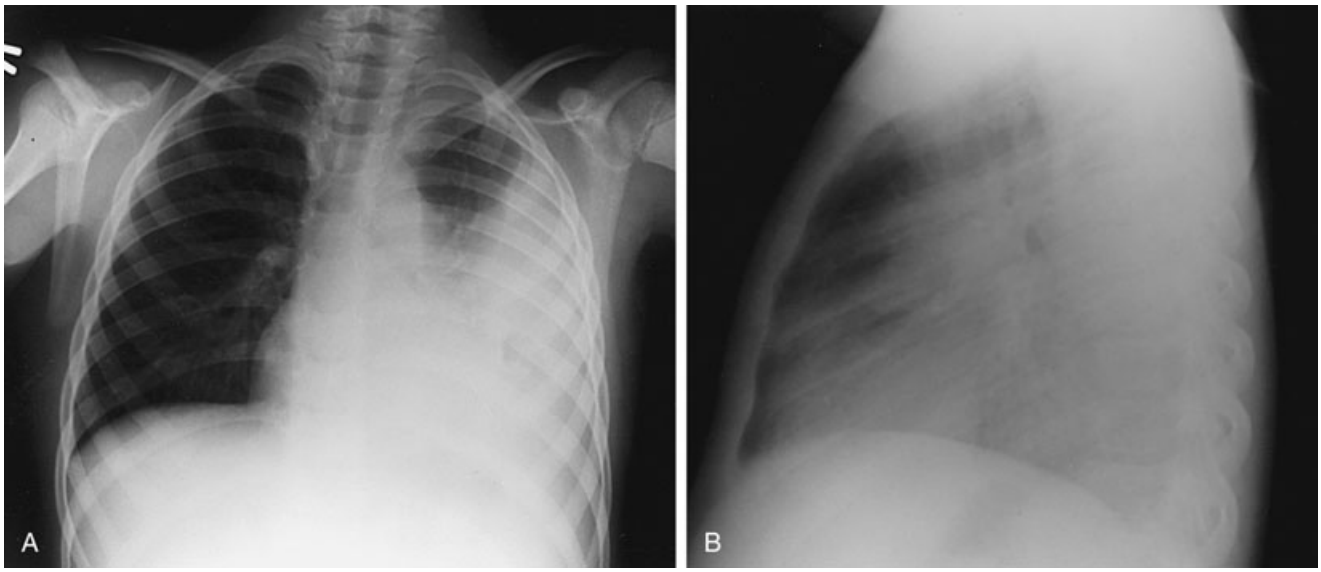

Figure 29–1 Posterior **(A)** and lateral **(B)** chest radiographs show a left pleural effusion in a 9-year-old girl who had symptoms of chest wall pain, fever, and vomiting. After 1 week, chest wall pain and shortness of breath continued, and she was admitted to the hospital and treated with cefuroxime and erythromycin for pneumonia. An ultrasound examination performed 2 days later showed a large pleural effusion that was drained, with a glucose level less than 20 mg/dL, lactate dehydrogenase level greater than 99,000 U/L, protein level 4.5 g/dL, and white blood cell count 51,000 mm^3. Gram stain of the fluid showed gram-positive cocci, but the culture was negative. After failure to respond to intravenous antibiotics alone, the patient was taken to the operating room, where an empyema and several small abscesses were drained, along with decortication and repair of multiple bronchopleural fistulas. The patient was discharged 9 days later and received an additional 10 days of intravenous imipenem-cilastatin. She was well 1 month after hospital discharge.

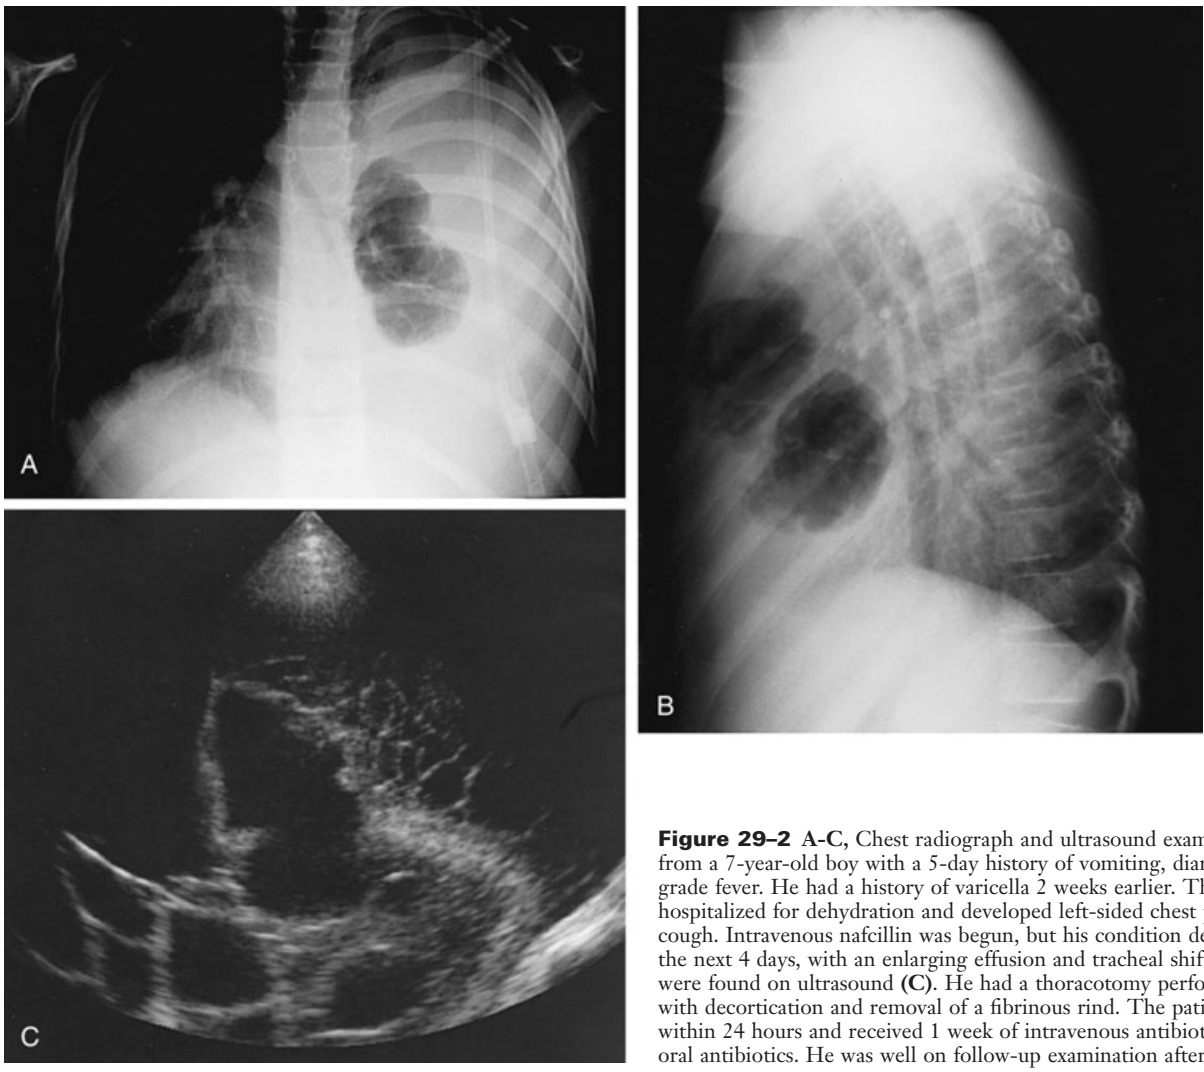

Figure 29–2 A-C, Chest radiograph and ultrasound examination images from a 7-year-old boy with a 5-day history of vomiting, diarrhea, and low-grade fever. He had a history of varicella 2 weeks earlier. The patient was hospitalized for dehydration and developed left-sided chest pain and a mild cough. Intravenous nafcillin was begun, but his condition deteriorated over the next 4 days, with an enlarging effusion and tracheal shift. Loculations were found on ultrasound **(C)**. He had a thoracotomy performed on day 6 with decortication and removal of a fibrinous rind. The patient was afebrile within 24 hours and received 1 week of intravenous antibiotics and 1 week of oral antibiotics. He was well on follow-up examination after discharge.

opacification of the lung, and such tomographic scanning is considered by some physicians to be the study of choice in this situation.[41] Ultrasound can have false-negative results, and CT can have false-positive findings on examination of pleural effusions. One study of adults showed that neither ultrasound nor CT effectively predicted the stage of the effusion or predicted the surgical outcome.[46]

THORACENTESIS

Thoracentesis plays an important role in the management of parapneumonic effusions and in 90 percent of adult cases yields useful information.[22] Some investigators would argue that primary video-assisted thoracic surgery (VATS) should be performed without thoracentesis.[23] Fluid should be obtained from the pleural cavity if fluid is adequate in volume and anatomically accessible and if a microbial diagnosis has not been made or presumed and antibiotic therapy is intended, or if pulmonary function is compromised by the effusion and imaging does not reveal evidence of organization to determine whether further intervention is necessary.

The volume and location of the fluid can be determined precisely by ultrasound examination if the physical examination does not allow localization of the fluid. When a healthy child with apparent or culture-confirmed pneumococcal pneumonia that is community acquired has a small pleural effusion, thoracentesis usually is not required. Small effusions generally can resorb, and a 10 to 50 percent chance of recovering the etiologic organism from blood cultures exists in empyema.[5,30] We suggest, however, that when the clinical presentation is atypical or a moderately sized effusion exists, thoracentesis usually is indicated to define the microbial process. Atypical situations include a history of trauma, foreign body aspiration, prolonged or chronic disease, and underlying systemic diseases (e.g., congestive heart failure, malignancy).

In a classic article published in 1972, Light and associates[56] established the methodology by which transudates could be differentiated from exudates. Such criteria are valuable in determining if antibiotic treatment is indicated, particularly in patients with underlying diseases that predispose them to sterile effusions but who may have a comorbid infectious condition. An exudate was defined by any of the following criteria: a fluid-to-serum protein ratio of greater than 0.5, a LDH fluid-to-serum ratio of greater than 0.6, a glucose concentration less than 50 mg/dL, and a pH less than 7.2. This study was based on the results from 150 adult patients, 103 of whom had exudates.[56]

The criteria of Light and associates have been accepted and are used as guidelines in the management of parapneumonic effusions in adults and children. In 1984, Peterman and Speicher,[69] using adult data, recommended a two-step process to separate transudates from exudates using only the protein and LDH serum-to-fluid ratios in the initial evaluation. If a patient had an apparent exudate, additional studies, including cultures, stains, pH, and glucose, were indicated. Another study of 297 adults compared several criteria for separating transudates and exudates and concluded that the criteria of Light and associates still yielded a high sensitivity (98%) and a specificity of 77 percent. A pleural fluid cholesterol concentration greater than 60 mg/dL also was used and had a sensitivity of 88 percent and specificity of 91 percent for exudates.[79] Although the cholesterol was not recommended for routine use, it was suggested as an extra screening test for patients with congestive heart failure in whom diuretic therapy might lead to increased concentration of pleural fluid protein.[19,38,79]

After an exudate is verified, it must be decided whether chest-tube drainage or other procedures such as VATS are needed. This decision is made by examining several aspects of the pleural fluid. In 1980, Light and associates[55] described pleural fluid findings in adults with exudates in an attempt to determine which patients needed early chest-tube drainage of effusions. Thirty-seven adults with acute pneumonia and parapneumonic effusions were studied. Ten patients were considered to have complicated cases if they required chest tubes or had positive cultures at the time of thoracentesis. No clinical differences were found between the complicated and uncomplicated cases. Patients who required chest tubes had a pleural fluid pH of less than 7.0 and a glucose level less than 40 mg/dL. All patients with uncomplicated effusions had a pH greater than 7.2 and LDH less than 1000 mL. Patients with a pH between 7.0 and 7.2 fell into both categories. Anaerobes were recovered from 6 of 10 complicated cases, and *S. pneumoniae* was recovered from 15 of 27 uncomplicated cases. Cell count and protein analysis were not helpful in separating complicated from uncomplicated cases.

The application of these criteria to children has received limited study. In one series of 61 children, patients who required chest tubes or decortication had a mean pleural fluid pH of 7.24 or 7.10 compared with children who were treated with antibiotics only (pH 7.35). The mean pleural fluid glucose concentration was 74 g/L in the group treated with antibiotics, 10 g/L in the group treated with chest tubes, and 24 g/L in the group treated by decortication.[41] Another, more recent study confirmed that a pH less than 7.2 and low glucose were predictors of re-intervention.[65] These data suggest that the criteria of Light and associates for glucose are appropriate in children, but that the pH at which chest tubes are indicated may be higher for children than for adults. Availability of glucometers and pH meters at the site of thoracentesis is uncommon and might enhance decision-making.

Standard Gram stain and bacterial culture (aerobic and anaerobic) are indicated when thoracentesis is performed in patients in whom diagnosis of infection is considered. The Gram stain usually is positive in patients with bacterial infections; when such infections exist, Gram stain may be used to direct empiric therapy until culture results are known. In one study of children, 12 of 54 sterile effusions from patients with negative blood cultures had a positive Gram stain.[30] Some experts consider that a positive Gram stain indicates a more severe process and that such patients are more likely to require more invasive surgical procedures.[15]

When the total white blood cell count and differential are performed, supportive information may be gained. The results of a peripheral white blood cell count rarely change the clinical management of the patient. The total white blood cell count in empyema fluid can vary from 5000 to 625,000 cells/mm^3, with median values ranging from 5000 to 55,000 cells/mm^3.[30,41] Virtually all cells are neutrophils in bacterial infections. Marked eosinophilia may be seen in parasitic, fungal, tuberculous, or hypersensitivity disease and when blood is found in the pleural space.[15] Numerous small lymphocytes suggest malignancy, tularemia, or tuberculosis.[26,37,69,104] Other studies are required when the history suggests another underlying process. When tuberculosis is suspected by history, specific mycobacterial stains and cultures should be obtained. Identification of mycobacteria by stain and culture may be equivalent to the rate of identification of the disease process by pleural biopsy (approximately 25%).[67] Specific mycobacterial and fungal stains also should be obtained using a Ziehl-Neelsen/auramine stain and potassium hydroxide. Application of newer methods for diagnosis, such as polymerase chain reaction (PCR) and tuberculostearic acid by mass spectroscopy, may be indicated.

When malignancy or metastases are suspected, cytology is necessary.[37] Most effusions in children that prove to be malignant are of lymphoreticular origin. Amylase sometimes is measured and is elevated in cases of esophageal rupture, acute hemorrhagic peritonitis, or pulmonary infarction.[53,85] Countercurrent immunoelectrophoresis and other antigen detection systems

occasionally are used for diagnosis and are useful in pretreated individuals. They are widely available only for disease caused by *S. pneumoniae* and *H. influenzae* type b and not for disease caused by *S. aureus* or anaerobes. Samples for antigen detection require special preparation before analysis because of increased levels of pleural fluid protein, which can create false-positive test results.

Molecular diagnostics is bringing promising advances to the bacteriologic diagnosis of empyema. PCR technology has been compared with routine culture and bacterial antigen and has shown increased sensitivity and good specificity for the diagnosis of *S. pneumoniae* using 16S rDNA or MRSA using the mec-300 gene probe.[24,83] Turnaround times can be quite rapid, exceeding traditional culture methods. The sensitivity of PCR for tuberculous effusions ranges from 20 to 81 percent, and specificity ranges from 78 to 100 percent.[27]

ADDITIONAL DIAGNOSTIC STUDIES

An intradermal test should be applied to any child with a parapneumonic effusion to evaluate tuberculosis as a possible cause. One third of patients with tuberculous effusions have a negative purified protein derivative skin test result.[8] Early morning gastric aspirates are recommended if tuberculosis is suspected.[98] Blood cultures also are indicated because one third of patients can have positive blood cultures and negative pleural fluid Gram stain and culture results.[30] Sputum is a less reliable source from which to determine the microbial cause of an effusion but may be helpful in a patient with purulent sputum and a single predominant organism. It can be diagnostic in older children with reactivation or cavitary tuberculosis and in cases of blastomycosis and histoplasmosis. Cold agglutinins or *Mycoplasma* serology may confirm the cause of a pleural effusion, although the nonspecificity of cold agglutinins and the delay in the increase in antibody titers render these data of marginal use in the acute management of the patient. Viral cultures are useful in only the more unusual cases and generally provide information that is not helpful in the initial management of the patient. Rapid diagnostic antigen assays, such as the rapid tests for influenza A and B, may be useful in defining the primary cause of respiratory disease but do not help exclude secondary bacterial pathogens causing pneumonia and a parapneumonic effusion. When other diseases, such as Wegener granulomatosis[6] and systemic lupus erythematosus, are suspected, disease-specific tests, such as antineutrophil cytoplasmic antibody and antinucleic acid antibody are indicated.

MANAGEMENT

If a patient has an underlying disease process associated with pleural effusion and thoracentesis has excluded bacterial infection (e.g., normal protein and LDH fluid-to-serum ratio, normal glucose level, negative cultures, and Gram stain results), no further treatment is indicated other than treatment of the underlying disease. These patients continue to be at risk for developing infection of the effusion and may require repeat examination of pleural fluid at a later time if infection is suggested clinically.

If a purulent effusion is suggested by imaging, thoracentesis, or surgical findings, empiric antibiotic therapy is indicated. Therapy always should include antimicrobials that are effective against *S. aureus*, *S. pneumoniae*, and *Streptococcus pyogenes*. Empiric therapy choices are becoming more complex as drug resistance patterns continue to change and the ability to make a rapid diagnosis improves (e.g., PCR). In the past, acceptable regimens included nafcillin, first-generation cephalosporins, cefuroxime, and clindamycin. For patients without a confirmed microbial pathogen and sensitivity profile and low incidence of resistant organisms (community-acquired MRSA and penicillin-resistant *S. pneumoniae*), these past regimens based on the level of illness can be used. For mildly ill patients, one can begin with cefazolin or cefuroxime. For moderately ill patients, one can use clindamycin. We use vancomycin therapy for very ill patients and vancomycin and nafcillin for critically ill patients. For moderate to severe disease, cefotaxime or ceftriaxone is added.

In areas with high levels of antibiotic resistance (community-acquired MRSA, penicillin-resistant *S. pneumoniae*), in mild to moderate disease, clindamycin is indicated. For severely ill patients, vancomycin and a third-generation cephalosporin are appropriate. Some experts would add nafcillin, gentamicin, or both to this regimen. In patients who are vaccinated fully against *H. influenzae* (primary series and booster) and for whom the Gram stain is negative, empiric coverage against *H. influenzae* is not required. If *H. influenzae* is suspected, addition of a third-generation cephalosporin (i.e., ceftriaxone or cefotaxime) or single-drug use of cefuroxime or ampicillin-sulbactam would be effective. Ticarcillin-clavulanate, imipenem-cilastatin, meropenem, and piperacillin-tazobactam are useful if anaerobes are considered, particularly if aspiration is thought to play a role, such as in patients with abnormal swallowing. *Streptococcus milleri* has proven exceptionally difficult to manage and can be clindamycin-resistant.

In patients at risk for acquiring gram-negative disease (e.g., neonates, postsurgical patients), addition of an aminoglycoside or an advanced-generation cephalosporin (i.e., cefepime, ceftriaxone, or cefotaxime) is required. Extended-spectrum, semi-synthetic penicillins (e.g., ticarcillin-clavulanate, piperacillin-tazobactam) also are effective, as are carbapenems. Cefepime is helpful in nosocomial pneumonia/empyema because of its current efficacy for *Enterobacter* spp. In patients with renal failure or cephalosporin hypersensitivity, aztreonam is effective therapy for gram-negative infections. Ceftazidime or cefepime, broad-spectrum β-lactams with or without a β-lactamase inhibitor (i.e., ticarcillin–clavulanic acid, imipenem cilastatin, meropenem, or piperacillin-tazobactam), or aminoglycosides are indicated for *Pseudomonas* infection.

Surgical drainage is considered to be a crucial factor in resolving anaerobic infection. Clindamycin and metronidazole are effective, particularly when postsurgical infection or a ruptured gastrointestinal viscus is present. Upper respiratory tract anaerobes may be resistant to penicillins because of β-lactamase–producing oral flora (particularly *Prevotella* and *Porphyromonas* spp.).[13] In these situations, penicillin sensitivity should be documented before a penicillin is used as primary therapy.

For patients who have drug-resistant *S. pneumoniae*, most lung infections without associated central nervous system disease respond to high-dose penicillin (minimal inhibitory concentration >2 μg/mL) or cephalosporins (minimal inhibitory concentration >2 μg/mL).[52,68] In one study, the rates of effusion were similar between penicillin-susceptible and nonsusceptible *S. pneumoniae* isolates.[95] When the pneumococcus is highly resistant to penicillin and cephalosporins and the patient's disease fails to improve, therapy with vancomycin, clindamycin, or both may be required. Recovery of MRSA may require vancomycin therapy. Clindamycin sensitivity should be determined because many MRSA and methicillin-susceptible *S. aureus* isolates are resistant to clindamycin.[88] Susceptibility should be confirmed with performance of a "D" test. Intravenous clindamycin can be switched to oral clindamycin, offering a management advantage over vancomycin. New drugs such as linezolid have limited use at this time because of high cost but may have a role if vancomycin resistance becomes an issue. Daptomycin is specifically avoided in the lung because of its inactivation by surfactant.

With appropriate antibiotic therapy, the duration of fever in uncomplicated cases of purulent effusions usually is less than 48 to 72 hours.[66] When fever persists beyond 72 hours, surgical drainage may be required. The duration of antibiotic therapy is

based on the response of the patient to the medical and surgical therapy provided. In one series of pediatric patients, the total duration of antibiotic therapy for patients with severe pleural infections who did or did not have surgical drainage was comparable (approximately every 12 days).[41] The duration of combined intravenous and oral therapy was 12 to 24 days in the study reported by Freij and associates,[30] with patients with *S. pneumoniae* infection receiving the shortest courses of antibiotic therapy and patients infected with *S. aureus* being treated for longer periods (Table 29–5). A prudent standard is to continue treatment for a minimum of 1 week beyond the last febrile day.

Closed-chest-tube drainage has been the standard treatment of parapneumonic effusions in four classes of patients: (1) patients in whom thick, purulent material is found at thoracentesis; (2) patients with a pleural fluid pH level less than 7.35 and glucose level less than 60 mg/dL; (3) patients for whom antibiotic therapy has not been associated with a timely clinical response (72 hours); and (4) patients in whom pulmonary function is compromised, as shown by severe hypoxemia or hypercapnia. The chest tube is left in place until minimal drainage is noted (usually <50 mL/day).[25]

When closed-chest-tube drainage is not associated with clinical improvement and defervescence of disease, or if the lung parenchyma is trapped by the fibrinopurulent peel or fever persists, decortication often is required. If the pleural involvement is limited, a small incision (minithoracotomy) can be employed.[74] Ultrasonography and CT are required to define these conditions.

Decortication has been advocated as a more expedient way to manage patients. One study reported that patients who had decortication had shorter hospital stays (11.6 days) compared with patients who had thoracentesis or tube thoracostomy (28.3 days).[32] The total number of hospital days also was reduced in another study when patients treated with decortication (16.6 days) were compared with patients treated by chest-tube drainage (21.4 days).[41] In both cases, morbidity from the operative procedure was minimal. Decortication seems to have an advantage in advanced disease in which fibrosis in the pleural cavity has resulted in a large peel. Hoff and associates[41] used an empyema scoring system to assess the need for decortication. Any two of the following are considered indicative of severe disease and need for decortication: anaerobic infection, pH less than 7.2, glucose level less than 40 mg/dL, scoliosis, and lung entrapment.[41]

Other surgical techniques to reduce operative mortality and promote earlier hospital discharge have been proposed.[48,49] VATS is the most popular technique and is gaining support in many centers. Although general anesthesia is required for thoracoscopy, only two small incisions are needed—one through the existing chest-tube tract for a telescope and the second through which operating instruments are passed. This procedure allows adhesiolysis and débridement and should be performed before a thick peel develops.

Proponents of VATS argue that a brief operative procedure and the attendant risks of anesthesia outweigh the child's suffering during thoracentesis (and chest-tube placement) and postoperatively. More importantly, a definitive procedure is done, rather than running the risk of having to perform subsequent chest-tube placements and thoracotomy. The hospital stay is shortened. Doski and colleagues[23] reported a series of 139 children who were studied from 1992 to 1998. By comparing historical cohorts, they showed a shorter length of stay (7 days versus 11 and 12 days) for children who underwent VATS than for groups of children who had thoracentesis, chest-tube drainage, or fibrinolytic therapy and rescue VATS for failure. Twelve of 98 patients who received traditional therapy required thoracotomy, whereas none in the primary VATS group did. A small, randomized study of 20 patients was conducted from 1994 to 1996 and showed that VATS was superior to chest-tube drainage with fibrinolytic therapy. Compared with chest-tube drainage with fibrinolytic therapy, VATS resulted in a higher primary success rate (91% vs 44%), fewer hospital days (8.7 days vs 12.8 days), and lower costs (about $16,000 vs $24,000).[101] Other studies have shown similar results.[33,46,62,76]

The use of radiologist-directed thoracentesis with pigtail catheters (smaller bore than standard chest tubes) for drainage with fibrinolytic therapy has been promoted as a way to reduce the number of operative procedures and achieve shorter hospital stays.[80] This therapy may have value in patients with organizing pleural inflammation and inadequate drainage caused by loculations of pleural fluid without a peel.

TABLE 29–5 Summary of Surgical Management

†Includes only surviving children who required closed-chest-tube drainage only and in whom the exact duration of drainage was known.

DT, diagnostic thoracentesis; D ± T, closed drainage with or without initial thoracentesis; GNR, gram-negative rods; MT, multiple thoracenteses; SD, standard deviation.

From Freij, B. J., Kusmiesz, H., Nelson, J. D., et al.: Parapneumonic effusions and empyema in hospitalized children: A retrospective review of 227 cases. Pediatr. Infect. Dis. J. 3:578-591, 1984.

The use of streptokinase in children with pleural effusion was reported in 1993.[80] The occasional side effects caused by streptokinase reported in adults have generated concern about its safety,[11,78] and its utility has been challenged in adults in a randomized study showing no benefit.[60] Urokinase is less expensive than is streptokinase and has been used in children with minimal adverse effects.[39,50,78,93] In adults and children, these different agents seem to be equivalent,[5,12] although commercial shortages of the products have occurred. Tissue-type plasminogen activator is the fibrinolytic therapy most commonly used at this time. It is less likely to promote allergic reactions.

An early report questioned the benefits of interventional radiologist-placed catheters with fibrinolytics for empyema.[77] A meta-analysis of eight evaluable reports from 2000 to 2004 of operative and nonoperative approaches to empyema suggested that the failure of primary therapy was intermediate for fibrinolytic therapy (9.4%), compared with simple chest-tube drainage (23.6% and either VATS (2.8%) or thoracotomy (3.1%).[4] The differences among these approaches are patient- and center-dependent, and some suggest that with patience even the most severe cases of pleural disease ultimately heal without sequelae.[87] The British Thoracic Society published clinical guidelines for management and concluded that fibrinolytic therapy shortened the hospital stay,[5] as seen in the meta-analysis,[4] but that failure should prompt early consideration of thoracic surgery. The physician must monitor clinical progress carefully and try at the earliest point to identify patients with more complicated disease who would benefit from surgical intervention. The American College of Chest Physicians has suggested that patients requiring surgery include adult patients with large effusions (more than half the hemithorax, loculations, pleural thickening, positive cultures or Gram stains, pH < 7.2, or frank pus).[21] Use of ultrasound also can identify patients with early organization of pleural fluid who have shorter hospitalizations if operative approaches are used.[75] Currently based on limited data, some experts prefer chest-tube and fibrinolytic therapy, whereas other experts choose VATS or minithoracotomy.

Rarely are full thoracotomy and pneumonectomy required for severe pneumonic and parapneumonic disease. An occasional complication of empyema is persistent, organized fluid or air collections in the pleural space, particularly in adults. A high rate of success has been reported using talc pleurodesis in these situations and in patients with noninfectious persistent effusions.[99,103] Long-term complications of this therapy include development of bronchogenic carcinoma and mesothelioma (asbestos-free preparations presumably are not associated with the development of these neoplastic conditions).

One frequent cause of bloody pleural effusions is motor vehicle accidents.[57,81] In one series of 100 children, 56 percent had pleural effusions associated with pulmonary contusions. They were treated with closed-chest-tube drainage; no antibiotics were used, and no infectious complications occurred.[81] Management of pleural hematoma secondary to trauma occasionally is complicated by infection because the bloody pleural fluid is an

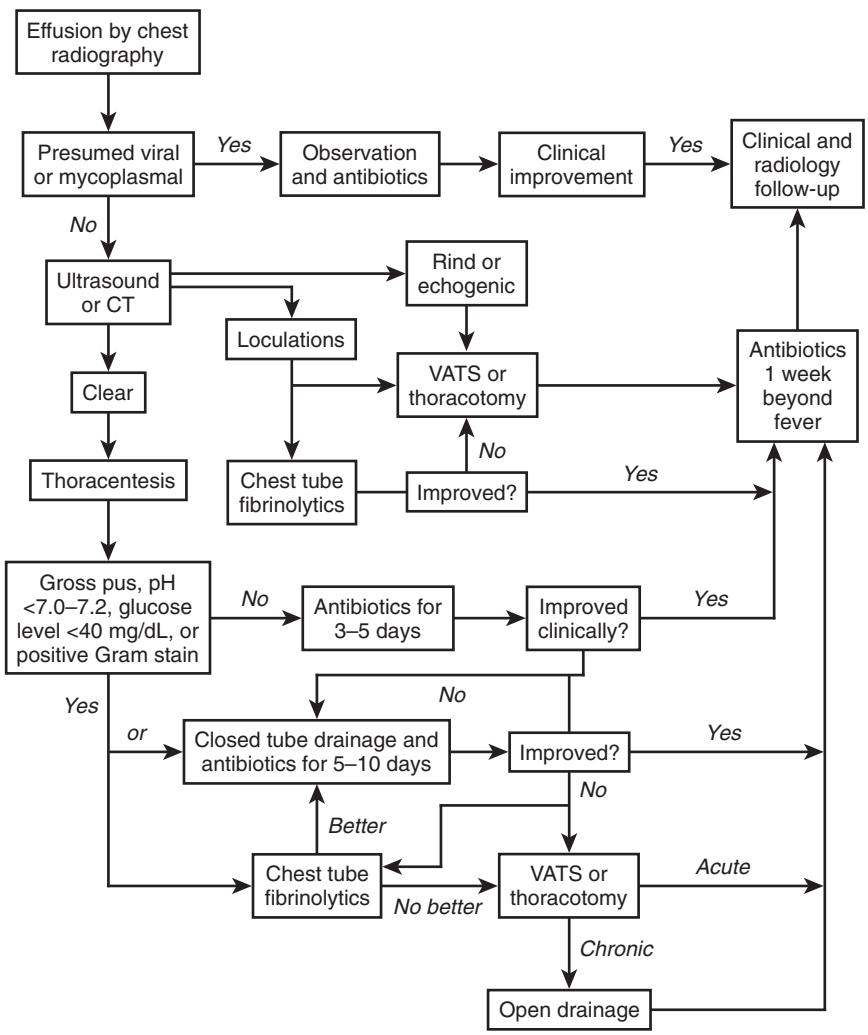

Figure 29–3 Algorithm for the management of pleural fluid collections. CT, computed tomography; VATS, video-assisted thoracic surgery.

excellent growth medium. One study suggested that empyema is less common in post-traumatic effusion with closed-chest-tube drainage than in repeated thoracentesis.[100]

Different biases exist in the management of parapneumonic effusions in children. In suspected empyema based on the clinical history and chest radiograph, we consider that a practical and effective approach is to perform an ultrasound study. If the study suggests complicated empyema (rind or loculations), primary VATS should be performed. If the study result is negative, thoracentesis should be done, and if consistent with empyema, chest-tube placement or VATS should be done. Figure 29–3 is an algorithm incorporating alternatives for the management of pleural collections. Complications from closed-chest-tube drainage include bleeding, infection of the exit wound, bronchopleural fistula, and laceration of the lung. Because of these rare complications, chest-tube placement, performed in the past by the pediatrician, now is delegated more frequently to the surgeon.

In cases of chronic empyema, other approaches are used. A closed tube can be converted into an open drainage tube. This conversion is accomplished safely a minimum of 10 to 14 days into the course of an empyema when the visceral and parietal pleurae fuse, and a pneumothorax can be avoided safely.[57] Other options include open drainage by rib resection and creation of a pleural window. The window ultimately closes with lung expansion and granulation, with disappearance of the pleural space.

PROGNOSIS AND LONG-TERM OUTCOME

The long-term outcome of patients with effusions depends on the underlying cause of the effusion. Patients with empyema who previously were well recover satisfactorily in most cases. Occasional rare complications, such as temporary paralysis of the diaphragm, have been reported.[64] In three retrospective reviews, the percentage of patients who required closed-chest-tube drainage or other surgical procedures ranged from 62 to 80 percent.[30,41,64] The rate of decortication ranged from 4[30] to 43 percent.[41] The relationship of surgical management to the pathogen causing the infection is shown in Table 29–5. The immediate mortality rate for children in recent years has been 0 to 10.8 percent.[30,41,59,64] In one of these studies, the mortality rate was highest for children younger than 1 year old.[30] Studies conducted to evaluate long-term, specific pulmonary disability using pulmonary function tests and lung volumes have shown normalization of these study results over time.[66]

CHAPTER 30

Lung Abscess

J. Gary Wheeler ❂ Richard F. Jacobs

A lung abscess is an area of necrotic material in the parenchyma of the lung initiated or complicated by infectious organisms. Although possibly originating from a pneumonia, it is distinguished by liquefaction and destruction of parenchymal tissue, organization, and cavitation. Necrotizing pneumonia, which on imaging lacks the "rim" representing the organization of the abscess, has a different clinical course and management.[18] A lung abscess may erupt and form an adjacent empyema. Empyema is defined strictly by involvement of the pleural tissues, however.

In the past, lung abscess was described as a disease of male alcoholics that was managed with surgery.[38] Lung abscess in children was recognized early on as having a different etiology and course than lung abscess in adults.[53] As is true of many infectious diseases, it continues to change as the human host and the microbial environment change. The incidence of lung abscess has declined precipitously in the modern era. Smith[46] reported lung abscesses in 0.33 percent of pediatric admissions in 1934, and Emanuel and Shulman[14] reported a rate of 0.012 percent from 1985 to 1990. In major pediatric referral centers in Chicago, Houston, Dallas, and Montreal, the incidence of lung abscesses has ranged in the last 2 decades from 1.5 to 4.7 cases per year.[4,14,28,48] Many of these cases developed in compromised hosts.

Improvements in pediatric diagnosis and care have resulted in a decrease in the numbers of cases related to underlying diseases. The morbidity and mortality rates also have decreased with use of antibiotic therapy and modern critical care. In 1920, Wessler and Schwarz[53] reported a 33 percent mortality rate, with "invalidism" and hemiplegia occurring in another 27 percent. The mortality rates in the two latest U.S. reports of lung abscess were 11 percent (1982-1993)[14] and 4 percent (1985-1990),[47] and 18.5 percent mortality was reported in Taiwan (1987-2003).[10]

Although lung abscesses occur in children of all ages, two studies have suggested that the trend is away from children younger than 5 years of age to an older population.[14,34] In other studies, the median age ranged from 7 to 9.5 years.[4,7,10,14,18,47] No consistent racial or sexual predisposition to this condition in children has been identified. In the 1950s, one series found boys to be more at risk than girls.[24] In adults, a twofold greater risk exists for men.[32,38] Table 30–1 lists specific risk factors for development of lung abscess in pediatric patients. Most factors are related to some predisposition to aspiration, hematogenous spread, or compromised immunity.

TABLE 30–1 Underlying Risks for 46 Secondary Lung Abscesses in Pediatric Patients

Risk	No.
Neuropsychiatric causes	16
Hematologic/oncologic disorders	11
Primary pulmonary disease	8
Immunodeficiency	4
Congenital heart disease	2
Solvent aspiration	1
Foreign body aspiration	1
Prematurity	1
Chromosomal disorder	1
Endocrinopathy	1

Data from references 13 and 44, and unpublished data from Little Rock, Arkansas, 1989 to 1994.

PATHOPHYSIOLOGY

Two main mechanisms explain formation of a lung abscess. The first mechanism is the introduction of pathogens directly into the airspaces, which typically results in solitary abscesses. The abscess typically follows aspiration, with a resultant neutrophilic reaction and necrosis. Aspiration is thought to be the predominant precipitating factor in adults, particularly in individuals with significant dental disease.[6] Most lung abscesses related to aspiration are polymicrobial and include anaerobes. The prevalence of fluoride and the low incidence of dental disease in children may be additional factors for the reduced incidence of lung abscess in children, although aspiration pneumonia does occur in the absence of dental disease.

The second mechanism in the formation of lung abscess is hematogenous spread. Hematogenous seeding of the lung can lead to an initial pneumonia that develops into an abscess with further organization and cavitation. Primary pneumonia rarely progresses to necrosis and abscess in modern times; this phenomenon is explained largely by the ready accessibility of antibiotics. Emboli from the venous circulation (i.e., septic thrombophlebitis) and right side of the heart (i.e., endocarditis) can cause single or multiple lung abscesses, which often are subpleural. Infection in the head and neck area also is a risk factor for vascular spread to the lung, with resultant lung abscess.[43] This complication occurred commonly in past eras. Lung abscesses complicated tonsillectomies in one third of cases in a 1920 report.[53] The abscesses were theorized to result from aspiration during the operative procedure[46] and characteristically developed 13 to 14 days after the procedure.[53] Great improvements in modern pediatric anesthesia with careful efforts made to prevent aspiration have rendered this complication uncommon today.

A lung abscess tends to have irregular margins, with occasional bullae, and it can dissect into adjacent tissues, such as the mediastinum, bronchi, and pleural space. If the abscess ruptures into a bronchus, air enters and an air-fluid level can be seen radiographically. Dissection into the pleural space creates a purulent effusion, with air noted only if an anaerobic process is present. Dissection into the mediastinum causes a widening of the mediastinum. Air is detected if communication occurs with a bronchus or in the presence of anaerobes. Multiple lung abscesses occur more frequently in hematogenous or embolic disease and are found more often with more sensitive tools, such as computed tomography (CT). Modern reviews of children have suggested that single abscesses are found more frequently than are multiple abscesses.[7,14,47]

Microscopically, a lung abscess is definable by a collection of necrotic material (i.e., highly neutrophilic inflammation); a surrounding irregular, fibrotic wall; and microvascular infarcts. Lymphocytes often are present and seem to play a regulatory role in the formation of the abscess.[44] The infrequency of lung abscesses in patients with human immunodeficiency virus (HIV) infection may be explained by this observation.

The role of preceding viral infection in undermining phagocytic host defenses is supported by the observations of preceding respiratory symptoms in patients with lung abscesses.[1] They manifest primarily in cold weather[4,14] and typically after well-defined viral illnesses, such as varicella, measles, and influenza.[24,26,52] The impact of chemotherapy on phagocytes also may explain the increased numbers of lung abscesses in patients with leukemia and other cancers.

On a macroscopic scale, lung abscesses tend to develop in all parts of the lung. If associated with aspiration, the anatomic site depends on whether the subject was supine or erect at the time of aspiration. Supine patients develop abscesses in the posterior upper and lower lobes, and erect patients develop infection in the middle and basilar lower lobes. Generally, the tendency is for aspiration-related abscesses to develop more on the right side than on the left, presumably because of the more vertical anatomy of the right stem bronchus.[14,23]

Physicians have grouped lung abscesses into primary and secondary categories, presuming that primary and secondary abscesses have different microbiologic factors, management approaches, and outcomes. The arbitrary nature of this distinction is apparent when appreciating how much the microbiology, clinical course, management, and outcome of both conditions overlap.[32] Primary abscesses occur in previously normal hosts without a history of trauma or aspiration of a foreign body. Secondary abscesses occur in the setting of underlying medical illnesses predisposing to infection, airway obstruction, embolization, or aspiration. In an earlier series, secondary abscesses were found more often in children younger than 1 year of age,[26] but this difference was not corroborated in a later study.[14] Primary abscesses were found in 64 percent of patients in Chicago,[14] 33 percent in Houston,[47] 45 percent in Little Rock (1989 to 1994) (unpublished data), 30 percent in Toronto (1956 to 1965),[26] and 30 percent in Taiwan (1987-2003).[10]

In the modern era, lung abscess should trigger a search to exclude underlying factors that may have prognostic value and lead to treatment of the underlying disease. The classic lung abscess syndrome in adults is represented by an alcoholic who aspirates during an alcoholic stupor. In children, a classic presentation would be any child with altered mental status, associated swallowing dysfunction, or both conditions. Foreign bodies can obstruct normal clearance of pathogens and precipitate the development of a lung abscess.[14,27] Obstruction also predisposes to lung abscess in adults who have carcinoma of the lung and rarely in children with metastatic disorders. Ineffective cough in patients with neurodegenerative or myopathic disorders is another risk factor for developing lung abscess, similar to that in an adult alcoholic. Patients with leukemia and patients who are receiving chemotherapy also are at increased risk. Occasionally, a bronchogenic cyst can become infected and mimic a lung abscess. Tricuspid or pulmonary valve endocarditis in children with complicated congenital heart disease places them at risk for developing lung abscesses.

Immunodeficiency is another risk factor for development of a lung abscess. Patients with chronic granulomatous disease and hyper-IgE syndrome typically are found to have lung abscesses. Patients with hypogammaglobulinemia may develop abscesses, although bronchiectasis is the more characteristic finding. The same is true for patients with immotile cilia syndromes and cystic fibrosis, although in the latter group, disease abscesses are uncommon.[10] Among pediatric patients, HIV-1 infection has not been reported as a risk factor in series from Chicago and Houston.[14,47] Additional causes are listed in Table 30–1.

MICROBIOLOGY

The microbiology of lung abscesses seems to be evolving as patients and antibiotics change.[38] In the preantibiotic era, streptococci and *Mycobacterium tuberculosis* were the most commonly reported causes of lung abscesses. After penicillin use began and tuberculosis skin testing, treatment, and control programs became widespread, staphylococci most frequently were recovered from lung abscesses.[39] Development of better culture techniques also increased the identification of anaerobes in lung abscess material; in past eras, these organisms probably were present but not recovered. Anaerobes were suspected by the fetid odor of abscesses, the time course of postoperative aspiration infections, and Gram stains of tissue and pus, which showed fusobacteria and spirochetes.[46,53] Table 30–2 summarizes the microbiology of pediatric lung abscesses reported from 1976 to 2006.

The primary role of anaerobes in lung abscesses has been assumed in aspiration pneumonias. Anaerobes are prominent in the oral cavity and have been recovered from the abscesses of patients with dental disease.[6] In many past studies, lung abscess materials were not transported and cultured for optimal anaerobic growth, however. Successful growth was described when specimens were transported in a closed syringe, with culture inoculation beginning in less than 10 minutes.[7] Later studies, in which optimal culture methods were employed, corroborated the role of anaerobes in lung abscesses in children.[7,47] In one study of mentally retarded children with seizure disorders, poor dental care, and suspected aspiration, transtracheal polymicrobial infections with aerobes were found in 9 of 10 samples.[7] An average of 6.2 isolates were recovered per patient. *Peptostreptococcus* and *Bacteroides* spp. were the anaerobes recovered most frequently.[7] In a larger group of 45 children, 15 of whom had primary abscesses, 14 had polymicrobial infections.[47] Older children with neurologic disorders were the primary patients with anaerobes in both studies. Anaerobes, *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae*, and *Staphylococcus aureus* have been recovered from normal patients.[47]

The role of tissue lysins and toxins depends on the pathogen and is thought to be crucial for the development of lung abscesses. In mixed infections, synergy probably occurs among the pathogens as proposed by Smith in 1934.[46]

Nosocomial pathogens are becoming more frequent causes of lung abscesses as a result of the increased numbers of patients with extended hospitalizations and use of advanced-generation antibiotics. The widespread use of third-generation cephalosporins has resulted in resistant *Enterobacter* spp. and other gram-negative organisms being recovered in secondary lung abscesses.

TABLE 30–2 Microbiology of Pediatric Lung Abscess

Organism	No.
Staphylococcus aureus	22
Coagulase-negative staphylococci	2

Klebsiella	8
Pseudomonas	13
Serratia	1
Eikenella	1
Haemophilus	7
Other gram-negative organisms	2
Bacteroides	19
Peptostreptococcus	12
Other anaerobes	26
Candida	4
Aspergillus	5
Mucor	3
Mycobacterium tuberculosis	1
Total	*185*

These data were reported in the literature from 1976 to 2006. The isolates were recovered by direct aspiration of abscess contents, bronchoscopic aspiration, transtracheal aspiration, blood culture, or culture of surgical specimens. Data from case reports focused on procedures are included, whereas data from case reports focused on the organism recovered are not.[4,7,10,12,14,20,22,24,25,27,28,34,36,45,47,48,51]

In the report by Tan and associates,[47] fungal abscesses always were associated with debilitated, chronically hospitalized patients. Immunosuppression no doubt contributes to the recovery of other unsuspected organisms (e.g., *Legionella*, *Neisseria mucosa*, *S. pneumoniae*, *Citrobacter*)[13,19,40,42] and underscores the value of obtaining specimens in chronically hospitalized patients, atypical cases, and patients not responding to empiric treatment.

Among otherwise normal hosts, tuberculosis can be a cause of single and multiple abscesses. The number of tuberculosis cases manifesting as lung abscess has increased dramatically, and tuberculosis is likely to be associated more frequently with lung abscesses in the future. In patients with an international travel history, unusual pathogens such as parasites (e.g., hydatid cysts)[15] and regional bacteria (e.g., *Pseudomonas pseudomallei*) should be considered.

An important lesson for the physician is the relevance of various respiratory cultures to the microbiology of lung abscesses. Rarely is sputum useful in defining the pathogens in a lung abscess because of three factors: (1) sputum typically is contaminated with abundant mouth flora; (2) if the lung abscess is not ruptured, no direct communication of the pathogens in the abscess occurs with the airway; and (3) sputum is difficult to obtain in preadolescent children. Obtaining cough cultures, performed by gagging a young child and culturing the coughed sputum collected on a swab before it can be swallowed, frequently is unsuccessful. A skilled clinician occasionally can acquire useful information, however.

Bronchoscopy is effective in recovering relevant organisms if the abscess has ruptured and has therapeutic value because it may assist in clearing secretions from the airway. It has been performed infrequently in pediatric practice in the past because of a lack of skilled personnel and pediatric equipment. Rigid bronchoscopy rarely is used to drain the abscess but when performed, highly informative microbiologic information may be obtained. Transtracheal aspirates, likewise performed in few pediatric patients, have similar value. The upper airway frequently is colonized in debilitated patients, and microbiologic information obtained must be interpreted with care. Direct aspiration of the abscess, typically under CT or ultrasound guidance,[49] is an ideal way to provide microbiologic data and plan antimicrobial therapy. Aspiration may have therapeutic value in decompressing the abscess.

CLINICAL FEATURES

Most patients with lung abscesses have had symptoms 1 to 3 weeks before being hospitalized.[14] Fever is reported to be associated with 100 percent of primary abscesses[14,26] and 84 percent of a mixed group of primary and secondary abscesses.[47] All patients with secondary abscesses in a small series had fever.[7] Cough occurs in 53 to 67 percent of cases[26,47] and initially may be nonproductive, becoming purulent when rupture into a bronchus occurs. With necrosis, hemoptysis can occur. Ipsilateral chest or shoulder pain also has been described in some patients, particularly older children.[14,27] Weight loss may be present if the abscess is of more than a few days' duration. Other symptoms are listed in Table 30–3.[47]

Some differences in presentation by age exist. Neonates and young infants typically are febrile, without localizing symptoms. Older children also are febrile but may have more cough or tachypnea and focal pain.

The clinical features of a lung abscess vary with the causative organisms and patient risk factors. Patients with bacterial pneumonia can present with dramatic onset of fever and overwhelming respiratory failure, such as in staphylococcal pneumonia. In these cases, the patient often has a recent history of influenza or varicella infection. Staphylococcal abscesses may not be noticed on chest radiographs until the patient already is on ventilatory support because of the time required for an abscess to organize. Similar presentations are typical of group A beta-hemolytic streptococcus and *S. pneumoniae* infections. Often, a patient has received antibiotics, and a temporary defervescence occurs before the hectic fevers of an abscess re-emerge. In the latter situation, the respiratory symptoms may be less notable but virtually always are present.[14] This biphasic presentation was described more than 70 years ago in postoperative aspiration[46] and continues to be typical of many lung abscesses.

TABLE 30–3 Symptoms and Signs in Patients with Lung Abscess

Symptom	No. Cases	%
Fever	38	84
Cough	24	53
Dyspnea	17	38
Chest pain	11	24

Lymphadenopathy	1	2

From Tan, T. Q., Seilheimer, D. K., and Kaplan, S. L.: Pediatric lung abscess: Clinical management and outcome. Pediatr. Infect. Dis. J. 14:*51-55, 1995.*

Subacute presentations are typical in patients with tuberculosis or fungal abscesses and usually are associated with other chronic systemic symptoms, such as anorexia, weight loss, and malaise. Cough may be prominent. Aspiration pneumonia may take an indolent or acute course, depending primarily on the organisms in the abscess, the volume of aspirated material, and the status of the host.

The physical findings in lung abscess are limited. Children usually have fever,[26,47] whereas adults present with fever less frequently (19%).[38] Tachypnea is a variable finding. Typically, auscultation is unrevealing except in cases of very large abscesses, in which loss of normal breath sounds is perceived. Adults and older children seem to have more discrete physical findings, with rales and decreased breath sounds in approximately one third of adult cases,[38] but they are uncommon findings in young children.[3]

An abscess can rupture into the bronchus, the mediastinum, or the pleura. In all cases, these complications are significant. In children, all organisms seem capable of causing these complications, but polymicrobial and anaerobic infections are suspected most often. Rupture into the bronchus may not be harmful if the volume of the abscess cavity does not overwhelm the host's ability to cough and clear the material. In an immunocompromised host, rupture may lead to disseminated pneumonia and further abscesses or death. Among adult patients who died of lung abscess, 22 percent were found to have died of aspiration of the abscess contents.[16]

In an otherwise healthy individual, rupture into the bronchus can be beneficial because it decompresses the abscess and allows the affected tissues to heal more rapidly. It is associated with the sudden production of foul-smelling, abundant, and sometimes blood-stained sputum. Frank hemoptysis is uncommon. Rupture into the mediastinum can be life-threatening, can be associated with chest pain and cardiac compromise, and requires surgery to

drain the resulting mediastinitis. Rupture into the pleural space results in pleuritic pain, enhancement of symptoms on inspiration, and often a more toxic presentation, and may require drainage.

Routine laboratory information is of limited help. The white blood cell count and erythrocyte sedimentation rate are elevated nonspecifically, and a left shift of the white blood cell differential count typically occurs.[14] Certain laboratory tests, such as the purified protein derivative tuberculosis skin test, HIV serology, or sweat chloride test, may be helpful in revealing an underlying cause. Except for the tuberculosis skin test, such studies should not be performed routinely and should be directed by a family history or other findings, such as chronic diarrhea or lymphadenopathy. Blood cultures are helpful but are positive in fever than 10 percent of cases.[14,47]

DIFFERENTIAL DIAGNOSIS

The major differential diagnoses in the management of a lung abscess are anatomic. A lung abscess must be differentiated from pneumonia, necrotizing pneumonia, pneumatocele, loculated empyema, and a purulent pleural effusion with a bronchopleural fistula. CT or ultrasound may confirm an abscess by documenting central cavitation and differentiating pleural from parenchymal tissues. An abscess may be confused with a congenital cyst, pseudocyst, hydatid cyst, saccular bronchiectasis, pneumatocele, or sequestration. Chest CT allows definition of these entities in many cases by identifying the associated structures, such as the vascular supply and pleural borders.

Apart from the anatomic and infectious causes of lung abscess, the other very rare cause is cancer. Unrecognized metastatic disease from Ewing sarcoma or osteosarcomas with associated central necrosis can mimic an abscess or, by obstructing a bronchus, can promote abscess formation.

DIAGNOSIS

The diagnosis of lung abscess almost always is made by imaging the lung. In most cases, the plain radiograph is adequate to define a lung abscess (Fig. 30–1), showing a thickened cavity with an air-fluid level that can be accentuated by placing the patient in the lateral decubitus or erect position. Atelectasis often occurs as an expanding abscess compressing adjacent tissues. Pleural thickening may occur if the abscess is subpleural. Hilar adenopathy occurs in subacute situations. Visualization can be obtained with bronchoscopy if the abscess ruptures into the bronchus, but it is limited by the location of the abscess and skill of the bronchoscopist. The procedure usually is not performed for anatomic diagnosis but rather to obtain microbiologic specimens or exclude a foreign body.

CT is optimal in its ability to identify smaller or multiple abscesses, document the impact of the abscess on adjacent tissues, identify cystic processes mimicking an abscess, and define an abscess for which an organized pneumonia obscures an air-fluid level on plain film.[20] CT scan of a lung abscess reveals an air-fluid level with an active rim, and the abscess is distinguished from necrotizing pneumonia, which lacks enhancement on contrast studies and lacks a distinct air-fluid level.[18] Nuclear imaging is described[11] but used rarely and adds little to the information obtained by CT.

After a presumed abscess is defined by imaging, needle aspiration of the abscess or bronchoscopic recovery of abscess fluid should allow confirmation and identification of the infectious cause of the process. Based on available pediatric studies, whether either procedure hastens recovery or reveals the microbiologic cause in pretreated individuals cannot be predicted. In a case report in which an infant had abscesses in both lungs, the time to recovery was equal in the abscess that was drained and the other abscesses that were treated medically.[29] An adult study using thin-needle aspiration showed positive cultures in 92 percent of patients not pretreated with antibiotics and in 70 percent of patients pretreated.[37]

Directly aspirating a lung abscess may be difficult or unsuccessful if the abscess is not large or peripheral, and complications such as lung laceration and sterile pleural effusions are real risks. Two groups[18,47] have had satisfactory pediatric experience using direct aspiration under CT guidance (Fig. 30–2). Bronchoscopy particularly is valuable if foreign bodies are suspected or pus can be recovered. When material is obtained, a putrid quality is a clue that anaerobic organisms are present. Typically, the abscess contains pure neutrophils. Occasionally, counterimmune electrophoresis or other antigen detection systems may assist in the microbiologic diagnosis when cultures are negative.[16] Because of

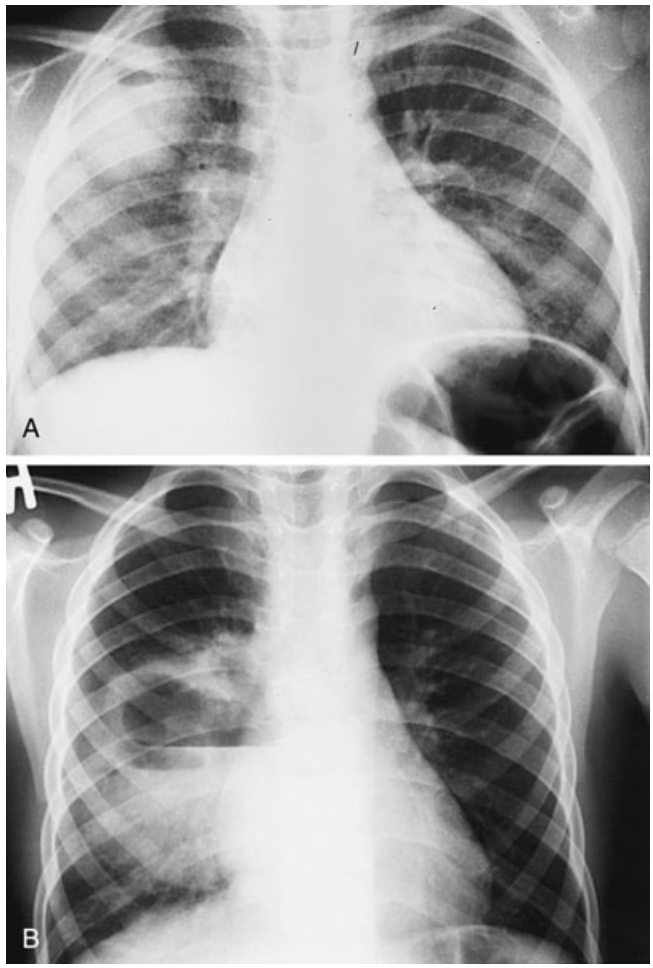

Figure 30–1 **A,** Plain chest film of a 4-year-old African-American boy with symptoms, including cough and fever of 104° F, for 4 days. He was treated initially with oral cefaclor and re-presented with this radiograph showing an air-fluid level in the right upper lobe. On intravenous cefuroxime, he was afebrile in 48 hours and went home on oral cefuroxime axetil after 4 days. **B,** Plain chest film of a 6-year-old African-American boy who presented after 5 days of symptoms with high fever, productive cough, dyspnea, and abdominal pain. The plain chest film reveals multiple air-fluid levels. Nafcillin and cefotaxime were begun. On day 4, an ultrasound-guided diagnostic aspiration recovered thick purulent material, but Gram stain and all cultures, including anaerobic and fungal, were negative. He was afebrile in 7 days and went home on amoxicillin-clavulanic acid at 10 days.

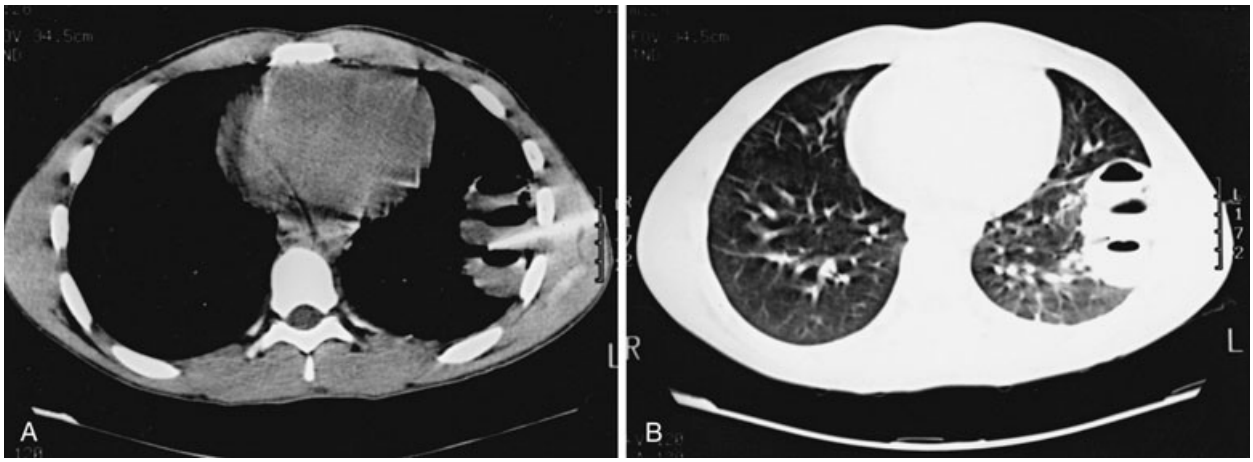

Figure 30–2 **A** and **B**, Computed tomography (CT) scans of a 15-year-old white boy who, 4 days before admission, reported a mild aspiration during fresh-water swimming. He awoke the next day with chest and back pain. He then developed low-grade fever. A plain chest film showed a large, thick-walled abscess in the left lower lobe. CT scans show insertion of a 20-gauge needle into the abscess on the first day of admission **(A)** and detail of the wall thickness and cavitation **(B)**. *Haemophilus influenzae* grew from the aspirate. Ampicillin-sulbactam was initiated and continued for 14 days.

the special handling required, these technologies usually are employed only after standard cultures have failed.

TREATMENT

Although surgery has a role in specific situations, the treatment of lung abscess in children often is successful when antibiotics alone are used.[39] In most cases, the need for surgery is limited to instances of failed antibiotic therapy or to an abscess complicated by rupture into adjacent tissues. Newer techniques, such as hyperbaric oxygen,[8] have been proposed as adjuvant therapy.

The initial choice of antibiotics almost always is presumptive because abscess material may be unavailable. For primary lung abscesses in which no risk factors are identified and in the absence of positive blood cultures, the recommended approach is to begin therapy with a regimen that covers *S. aureus*, *S. pneumoniae*, and the anaerobic microorganisms that normally are found in the upper respiratory tract. Clindamycin, ampicillin plus sulbactam, and ticarcillin plus clavulanate frequently are used in this setting.

For patients at risk for aspiration or who are immunocompromised, gram-negative pathogens also must be considered. This spectrum of pathogens can be addressed with one of several drug regimens: clindamycin and cefotaxime (or an aminoglycoside); ticarcillin plus clavulanate or piperacillin plus tazobactam; or nafcillin (or cefazolin), gentamicin, and metronidazole. The possible emergence of more penicillin-resistant species, such as *Streptococcus milleri* and *Klebsiella*, in community-acquired disease of adults and children supports these broad-spectrum regimens in children.[21,41] Patients with cystic fibrosis are particularly vulnerable to *Pseudomonas* spp. and should receive an aminoglycoside plus an additional antipseudomonal penicillin or cephalosporin. Carbapenem therapy would be an alternative. When endocarditis is present, treatment (e.g., vancomycin plus gentamicin with or without anaerobic coverage) should be provided for staphylococci, streptococci, and enterococci while awaiting results of blood cultures.

S. pneumoniae has been isolated infrequently in lung abscesses (see Table 30–2). Most patients with resistant organisms are still clinically sensitive to achievable doses of penicillins (penicillin G, minimum inhibitory concentrations of 0.12 to 2.0).[35] Drug resistance to *S. aureus* is a much more concerning issue in lung abscess, and empiric therapy with vancomycin is required if methicillin-resistant *S. aureus* is suspected while waiting for confirmation. For a critically ill patient with lung abscess, some experts recommend nafcillin, gentamicin, or both.

With culture information available, therapy is directed specifically at the pathogens isolated. In most patients, oral or intravenous antibiotic therapy has been administered before aspiration of a lung abscess is done, however, and may affect which organisms are recovered.[13] For this reason, coverage should be extended to include organisms that are likely to be present but are not recovered, such as anaerobes, in a setting of aspiration.

All bacterial lung abscesses should be treated with intravenous therapy until the patient is stable and no longer toxic. In approximately two thirds to four fifths of patients, this condition occurs within 3 to 7 days of instituting intravenous therapy.[14,28] After the patient has been afebrile for 48 to 72 hours, initiation of oral therapy may be considered. Certain oral drugs, such as amoxicillin plus clavulanate and clindamycin, achieve therapeutic serum levels and are effective against the spectrum of organisms in lung abscesses.

The length of total therapy for a lung abscess should be 2 to 3 weeks. Complicated infections should be treated intravenously until fever has disappeared and no evidence of continuing inflammation exists. An additional 2 to 3 weeks of oral treatment should follow. Radiographic resolution of a lung abscess that is not drained occurs over the course of weeks. Even with drainage, resolution may not occur more rapidly. Chest radiography should be repeated every 1 to 2 weeks until complete resolution is documented.

Tuberculous lung abscesses may rupture spontaneously into the pleura. Treatment is not directed at the immediate abscess or pleuritis but at preventing spread if it erupts into a bronchus. Preventing reactivation several years later is another goal of therapy.

Clinical failure is defined by persistent fever and toxicity. The length of time treatment with intravenous antibiotics should continue before declaring therapy a failure is not clearly defined. Suggestions in the literature range from 1 to 3 weeks.[2,4,39] When clinical failure occurs, several options are available, including drainage of the abscess, which permits identification of the organisms causing the disease process.

Bronchoscopy may allow direct perforation of the abscess and evacuation of its contents. A risk of fatality occurring from aspiration of abscess contents exists, however.[19]

Needle aspiration (one or more) also is possible under fluoroscopy, ultrasonography, or CT guidance.[18,24,25] Simple CT-guided needle aspiration leads to relief of symptoms in approximately two thirds of cases within 48 hours.[18] The risk of complications seems to be low.[18,25] Percutaneous transthoracic tube drainage has been used in pediatric lung abscesses.[12,27,36,50,51] The risk is lowest if the abscess is peripheral, and adhesion of the opposing pleural surfaces is a consequence of the inflammatory process. When this adhesion occurs, the needle or catheter does not traverse the pleural space. Catheter drainage may be attempted in abscesses larger than 20 cm^3 or 4 cm in diameter[2,18] using 8 to 10 French pigtail catheters. Smaller abscesses are technically difficult to manage.

Chest tube thoracostomy previously was the standard therapy of lung abscesses[31,33]; it is now recommended when conservative therapy fails and may play a role in patients with large abscesses if the abscess abuts the parietal pleura and provides a direct path from the exterior surface to the abscess.[30] A 25-year review of the literature found that significant complications, such as hemothorax, pneumothorax, bronchopleural fistula, empyema, and catheter occlusion, occurred in 9.7 percent of cases, with an overall mortality rate of 4.8 percent.[50]

Surgery for lung abscess is not well described in the pediatric literature. One report that combines surgery for lung abscess and necrotizing pneumonia had no mortality in the postsurgery period and a reversible complication rate of 10 percent.[48] Indications for surgery included associated pyopneumothorax, size of the abscess, and tension pneumatocele. Another possible surgical indication is proximity of a lung abscess to the mediastinum. In the face of antibiotic failure, an open lung procedure and wedge resection may be required, depending on the location of the abscess.[5] The procedure typically is successful and often obviates the need to perform a lobectomy.[22,53] In a complicated case, such as with a gangrenous lung, lobar resection may be necessary. Managing an infant with a lung abscess has required surgery more often than in older children.[45,52]

PROGNOSIS

The outcome for pediatric patients usually is very good when lung abscesses are uncomplicated, and recovery is more rapid than in adults.[32] Most patients have complete symptomatic and radiographic resolution in 3 to 6 weeks, with normal pulmonary function tests at follow-up.[4,14] Complicated disease associated with thoracostomy tubes and empyema more likely leads to residual symptoms (e.g., pleurisy) and persistent effusions or pleural thickening on radiographs. In reports published since 1982, half of patients with lung abscess have required surgical intervention, such as thoracentesis to drain an empyema, lobectomy, or decortication, and 20 percent have required lobectomy or decortication.[4,7,14,47] If patients require lung resection, they may experience immediate surgical complications; long-term exercise tolerance may be limited, and other problems, such as scoliosis, may develop. One study found normal pulmonary functions in patients studied after undergoing lobectomy, however.[34]

Rarely, a residual cavity may develop and become superinfected. The mortality rate is 4 to 11 percent[14,47] for patients with primary and secondary lung abscesses.[14,47] Higher risk of morbidity and mortality occurs in patients with secondary abscesses who have complications caused by either a decrease in host resistance or underlying disease.[14,38,47,48]

CHAPTER 31

Cystic Fibrosis

Lisa Saiman ❁ Peter W. Hiatt

Cystic fibrosis (CF) is the most common inherited lethal disease of whites. It occurs primarily among individuals of Central and Western European origin and affects more than 30,000 Americans and 60,000 people worldwide.[365] The estimated incidence in the United States is 1 : 2000 to 1 : 2600 white,[377] 1 : 19,000 African-American, 1 : 11,500 Hispanic, and 1 : 25,000 Asian-American live births.[226] CF has an autosomal recessive mode of inheritance. Affected individuals are phenotypic homozygotes, and both parents usually are heterozygotes or carriers. The carrier frequency in whites in the United States is approximately 1 in 25, with full siblings of children with CF having a one in four chance of being affected.

Mutations in a single gene located on the long arm of chromosome 7 account for the defective protein in CF.[365] A range of different mutations at the DNA level account for the abnormal protein. The most common mutation (ΔF508) is the absence of three sequential nucleotides, which leads to the deletion (Δ) of phenylalanine (F) at the 508 position on the CF transmembrane conductance regulator protein (CFTR). Approximately 70 percent of individuals with CF have this mutation. To date, more than 1500 mutations in the CFTR gene have been identified,[76] but fewer than 25 occur with a frequency of more than 0.1 percent.[122] Certain populations have higher frequencies of specific mutations, such as W128X in Ashkenazi Jews[226] or G551D in French Canadians.[277]

Five classes of mutations have been proposed to account for reduced CFTR chloride channel function.[141,277,366,391] Class 1 mutations are mutations in which stop codons or frame shift mutations cause early termination of mRNA translation and minimal to no protein production. In class 2 mutations (ΔF508), protein fails to mature, resulting in little expression of CFTR at the cell membrane. Class 3 and class 4 mutations are associated with defective regulation and decreased conductance of chloride at the cell membrane. Protein production and transit to the cell surface occur, but altered chloride conductance is present, or chloride conductance is nonexistent. Class 5 mutations are splice site mutations, which affect the amount of CFTR produced.

Other mutations are associated with unstable CFTR at the cell membrane. The presence of more than 1500 mutations for CFTR has prompted investigators to evaluate the association of genotype with clinical disease. The CF phenotype genotype consortium has shown that certain mutations from classes 3 to 5 are associated with pancreatic sufficiency; however, correlation of CF genotype with the severity of pulmonary disease has been poor. The wide variation in pulmonary disease observed in CF may reflect the effects of environment, patient compliance, polymorphisms in CFTR, and modifier genes that affect the function of the CFTR.

CFTR is a glycoprotein expressed at low levels by surface epithelial cells in the lung, sweat glands, pancreas, liver, large intestine, and testes.[274] Higher levels of expression have been reported in submucosal glands. CFTR protein is a member of a group of membrane transport proteins known as the *ABC-transporter superfamily*.[158] Researchers have confirmed that CFTR functions as an apical chloride channel mediated by cyclic adenosine monophosphate containing 1480 amino acids. It is composed of two membrane-spanning domains, two nucleotide-binding domains that interact with adenosine triphosphate, and a regulatory domain.[6] Activation of the channel is regulated by protein kinase A, which serves as a target for phosphorylation. CFTR in epithelial cell membranes may influence the expression of other proteins important in regulating inflammation, ion transport, and cell signaling, altering the CF phenotype.[286] CFTR regulates the activity of separate calcium-activated chloride channels and down-regulates sodium transport, balancing the rates of chloride secretion and sodium absorption.[116,175,187]

CFTR is responsible for the proper hydration of secretions in the airway, pancreas, and other tissues. An inability to secrete chloride and excessive absorption of sodium and water contribute to altered luminal secretions in patients with CF. In the lung, this alteration leads to decreased airway surface liquid, decreased mucociliary clearance, and a predisposition to chronic bacterial infections.

CLINICAL MANIFESTATIONS

Individuals with CF have exocrine gland dysfunction, which results in progressive suppurative obstructive lung disease, pancreatic insufficiency (85 to 90 percent), elevated sweat electrolytes, male infertility (>95 percent), and female infertility. Less common manifestations include hepatobiliary disease, osteoarthropathy, diabetes mellitus, nasal polyposis, and meconium ileus (Table 31–1).[56,75]

TABLE 31–1 Clinical Features of Cystic Fibrosis at Diagnosis

0-2 years
Meconium ileus
Obstructive jaundice
Hypoproteinemia/anemia
Bleeding diathesis
Heat prostration/hyponatremia
Failure to thrive
Steatorrhea
Rectal prolapse
Bronchitis/bronchiolitis
Staphylococcal pneumonia
2-12 years
Malabsorption
Recurrent pneumonia/bronchitis
Nasal polyps
Intussusception
>13 years
Chronic pulmonary disease
Clubbing
Abnormal glucose tolerance
Diabetes mellitus
Chronic intestinal obstruction
Recurrent pancreatitis
Focal biliary cirrhosis
Portal hypertension
Gallstones
Aspermia

From Maclusky, I, and Levison, H.: Kendig's Disorders of the Respiratory Tract in Children. 5th ed. Philadelphia, W. B. Saunders, 1990, p. 701.

The potential relationship between genotype (the genetic constitution of an individual) and phenotype (the physical expression of that genotype) in CF is an area of active clinical investigation. To date, the correlation of genotype to phenotype has not led to many clear associations between severity or course of pulmonary disease and type of genetic mutations.[43,173] A family-based study of CF involving monozygotic twins, dizygotic twins, and siblings reported that a significant portion of the variability in pulmonary function was attributable to heritability, independent of CFTR genotype.[358] This finding suggests that modifier genes account for a significant amount of the variance observed in CF lung disease. Numerous candidate modifier genes have been investigated to account for the variance in CF pulmonary disease, with more recent reports identifying transforming growth factor-β1 and glutamate-cysteine ligase as candidates.[91,212] In addition to modifier genes, environmental factors, including passive smoke exposure, infection, and socioeconomic status, have been associated with reduced lung function.[68,171,235,287,300] Multiple mutations, incomplete understanding of the physiologic function of CFTR, and the role of modifier genes have delayed understanding of the genotypic influence on phenotype in CF.

A strong association between pancreatic function and genotype has been reported for individuals homozygous for ΔF508.[27] Most subjects homozygous for ΔF508 have pancreatic insufficiency.[72] Obstruction of the pancreatic duct begins in utero, resulting in fibrosis and loss of exocrine pancreatic function. Pancreatic fluid from patients with CF is low in enzyme and bicarbonate concentrations, resulting in maldigestion of fat and protein. Clinically, children commonly present with steatorrhea, protein-calorie malnutrition, muscle wasting, and progressive failure to thrive. A voracious appetite is characteristic, and stools are described as bulky, greasy, and foul-smelling. Approximately 10 to 15 percent of patients have enough preservation of pancreatic function to allow for normal digestion of food (pancreatic-sufficient).[86] At least five mutations from classes 3 to 5 described earlier are associated with pancreatic sufficiency, whereas almost all patients homozygous for ΔF508 have pancreatic insufficiency.[72]

Failure to thrive is a common complication observed at the time of diagnosis. If malnutrition is severe, hypoproteinemia and edema are observed. In addition, malabsorption can lead to vitamin deficiency, especially of fat-soluble vitamins A, D, E, and K. These problems can be reversed with pancreatic enzyme replacement therapy, oral nutritional supplements, and routine vitamin supplements.

Glucose metabolism often becomes impaired with age, as fibrosis of the pancreas occurs in patients with exocrine pancreatic insufficiency. In the 2005 CF registry, 25 percent of adults were reported to have impaired glucose tolerance or CF-related diabetes with and without fasting hyperglycemia. Decreased secretion of insulin and reductions in peripheral glucose use and hepatic insulin sensitivity are observed in patients with impaired glucose tolerance.[220] CF-related diabetes has features of type 1 and 2 diabetes. The prevalence increases with age and is associated with increased morbidity and mortality.[217]

Liver disease in CF is associated with pancreatic insufficiency.[251] Approximately 25 percent of patients with CF develop focal biliary cirrhosis, but less than 5 percent progress to multilobar biliary cirrhosis and portal hypertension. In the absence of CFTR, bile becomes inspissated and associated with periductal inflammation and fibrosis. Liver function tests frequently are abnormal, as is a small, poorly functioning gallbladder. Cholelithiasis has been reported in 12 percent of patients and may be related to loss of bile acids in the stool.[66,107,108] Meconium ileus, the thick inspissated meconium that mechanically obstructs the distal ileum, occurs in 8 to 20 percent of newborns with CF. It also is associated with pancreatic insufficiency.[172] Modifier genes are thought to play an important role in the development of meconium ileus.[24] A similar syndrome (distal intestinal obstructive syndrome) mimicking meconium ileus can occur in older children and young adults with CF.

Absence of the vas deferens with secondary aspermia renders 98 percent of men with CF infertile.[87] Sexual potency is normal, and with microsurgical techniques for sperm aspiration, affected men can become biologic fathers.[211] Men with congenital absence of the vas deferens can have abnormal CF alleles with little clinical expression of disease other than the reproductive system. Infertility in women with CF may be 20 percent related to secondary amenorrhea (malnutrition) and dehydrated cervical mucus.[329]

Pulmonary disease is the primary cause of morbidity and mortality in patients with CF.[378] Expression of CFTR has been localized to the airways and submucosal glands of the lung.[348] Clinical studies in young children with CF have found significant inflammatory changes in the airways in bacterial-positive and bacterial-negative patients.[13,78,140,215,281,347] Imaging studies using high-resolution computed tomography (CT) in infants with CF describe the presence of thickened airway walls and nonhomogeneous air trapping.[80,197,206] The lungs are morphologically normal at birth; within weeks, they begin showing evidence of small airway abnormalities and inflammation. Small and medium-sized airways become obstructed, and neutrophils are the inflammatory cells primarily recovered from bronchoalveolar lavage (BAL) fluid. An intense neutrophilic response leads to the release of proteases that cause chronic injury to the respiratory epithelium and supporting airway structure. The massive numbers of neutrophils subsequently release elastase, which overwhelms the antiproteases in the airway, contributing to enhanced destruction of tissue. Large amounts of neutrophil-derived DNA and cytosol proteins are released into the airway lumen, increasing sputum viscosity and worsening airway obstruction.[78]

Progressive bronchiectasis develops with time, leading to advanced destruction of the airways and parenchyma (Figs. 31–1 and 31–2). Bronchiectatic cysts are prominent, especially in the

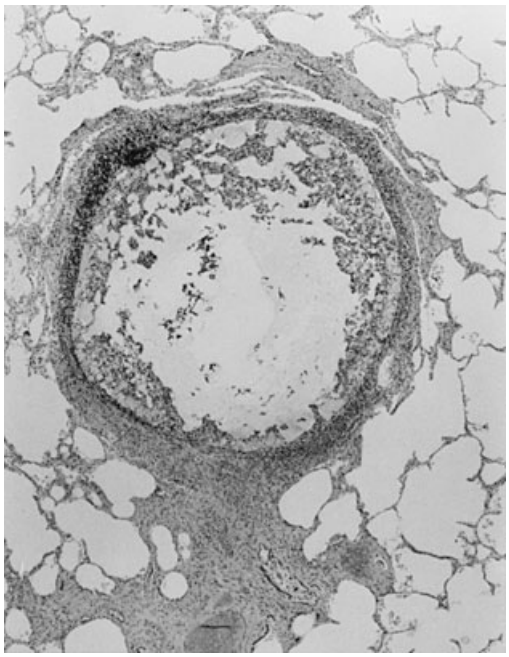

Figure 31–1 Early stages of lung disease in cystic fibrosis are shown in this lung specimen. Airway inflammation and bronchiectasis are present. The surrounding lung parenchyma is normal.

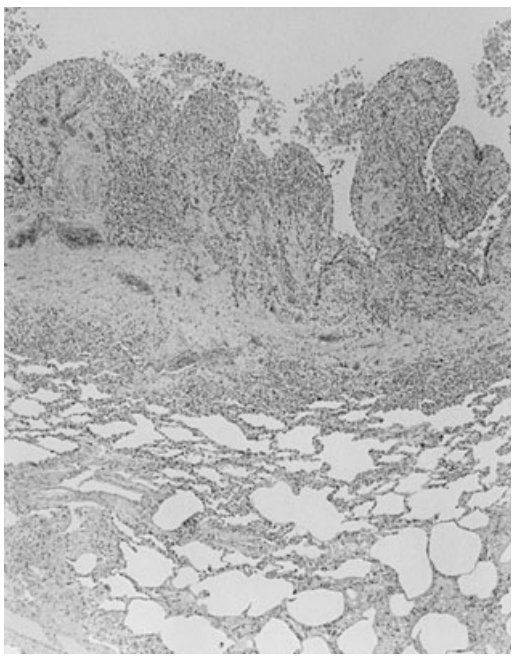

Figure 31–2 Late stages of pulmonary disease. Epithelial ulceration of the airway, loss of smooth muscle from the airway wall, inflammation, and bronchiectasis are present in the large airway at the top of the photomicrograph. Compression of the surrounding lung parenchyma occurs as bronchiectasis increases.

upper lobes. Death eventually occurs from respiratory failure. Progressive deterioration of pulmonary function occurs despite the routine use of anti-inflammatory therapy, mucolytics, airway clearance, and antimicrobial agents. Progressive destruction of the airway and increasing obstruction lead to air trapping, hyperinflation, hemoptysis, and spontaneous pneumothorax.

Many children with CF present during infancy with recurrent wheezing or persistent bronchiolitis. Most infants are asymptomatic at birth; however, many develop tachypnea, wheezing, hypoxia, and hyperinflation after having a respiratory viral infection.[146] These findings often resolve with therapy. As mucopurulent secretions increase, chronic cough develops.[56] Digital clubbing occurs gradually and correlates with severity of lung disease. On examination, there is evidence of crackles and decreased breath sounds secondary to mucopurulent secretions. Acute exacerbations may develop, requiring intravenous antibiotic therapy and frequent hospitalization. Approximately a third of patients with CF in the 2005 U.S. CF registry[75] experienced a pulmonary exacerbation requiring intravenous antibiotics. As lung disease progresses, tolerance for exercise is reduced, dyspnea increases, and respiratory failure develops. There is marked heterogeneity in the rate of progression of pulmonary disease. Some patients live to the sixth decade of life, whereas others die as a result of respiratory failure before their tenth birthday.

In 2005, the median predicted survival for individuals with CF was 36.5 years. Survival for children born in 2000 is expected to increase, with the median age approaching the fourth decade of life. In the United States, 40 percent of people with CF are 18 years old or older, and within 10 years, half are expected to be older than 18 years. As life expectancy has increased, CF has become a disease of children and adults.

DIAGNOSIS

The diagnosis of CF remains a clinical diagnosis in the face of more recent advances in technology. A consensus panel convened by the U.S. Cystic Fibrosis panel recommended a combination of phenotypic features, family history of CF, or positive newborn screen and one or more laboratory tests to diagnose CF.[284] Laboratory tests include identification of known CF mutations, abnormal bioelectric transepithelial membrane properties, and elevated concentrations of sweat chloride. The World Health Organization adopted similar recommendations.[379] Most patients continue to be diagnosed by clinical features and an elevated sweat test. Data from the 2005 U.S. CF registry reported that newborn screening accounted for 17 percent of newly diagnosed patients.[75] In the absence of newborn screening, an in utero diagnosis, or a family history of CF, a strong clinical suspicion is required for early recognition. Most children present with a history of recurrent lower respiratory tract disease and symptoms secondary to malabsorption. Approximately 15 to 20 percent of children have meconium ileus at birth or have a family history of CF or both.

The quantitative pilocarpine iontophoresis sweat test is one acceptable test to establish a diagnosis of CF.[284] A sweat chloride concentration greater than 60 mEq/L is consistent with a diagnosis of CF. Values between 40 and 60 mEq/L are considered borderline, and values less than 40 mEq/L are normal. Some data suggest that sweat chloride concentrations greater than 40 mEq/L in infants younger than 3 months old is highly suggestive of CF. The sweat test should be repeated on two separate occasions. Identification of two CF mutations by genotype is highly specific, but less sensitive. Mutational analysis can be done by several different techniques, with commercial laboratories testing for the most common 30 to 87 mutations. These laboratories identify approximately 90 percent of CF mutations but leave more than 1000 mutations unidentified. Extensive screening for the remaining 10 percent of mutations is expensive and impractical. For rare mutations, gene sequencing is available but expensive.[283,284] The ΔF508 mutation is found in 70 percent of patients with CF in the United States and a similar number of CF patients in the United Kingdom. Because each patient has two chromosomes, however, only 50 percent of patients are homozygous for ΔF508.

Nasal potential difference measurements assess the transepithelial electric potential difference that exists across nasal epithelium. Different patterns of potential difference are found in patients with CF.[284] Abnormalities in chloride transport and sodium absorption alter the transepithelial electric potential difference in CF compared with normal epithelia. The test can be useful in individuals with mild or atypical phenotypic features of CF, but it is not readily available, and it requires experienced personnel to perform.[283,284]

Newborn screening programs have been implemented in some states in the United States and the United Kingdom, Australia, and Europe. These programs identify newborns with CF using low values of trypsinogen in dried blood specimens obtained in routine screening programs for metabolic disorders. Improved nutritional status as a result of newborn screening has been reported in a controlled, randomized trial in Wisconsin.[104] Ninety percent of screened infants diagnosed with CF at birth maintained their weight greater than the 10th percentile compared with only 60 percent of unscreened controls. Children in the screened group were less likely to fall below the 10th percentile for weight and height from early childhood through 16 years of age.[44,105] In addition, cognitive function was improved significantly in the screened group.[182,183] No long-term improvements in pulmonary status were observed in the Wisconsin study; however, several observational studies have reported improved pulmonary outcomes, less colonization with *Pseudomonas aeruginosa*, decreased hospitalization for complications, and improved nutrition in children diagnosed by newborn screening.[5,106,180,188,278,282,386]

In addition to improving nutritional outcomes, newborn screening may result in improved survival rates for children. A systematic literature review of mortality in children with CF reported a survival benefit for patients diagnosed by newborn screening.[67,138] A survival effect also was shown in a study from Wales.[90] Without screening, approximately 60 percent of patients are diagnosed by the time they reach 1 year of age and almost 90 percent by the time they are 5 years. Early diagnosis through neonatal screening seems to improve nutritional outcome, with increasing evidence that these programs are associated with improved pulmonary outcomes and improved long-term survival.

The diagnosis of CF should be based on the presence of one or more clinical features (Table 31–2), a positive newborn screening test, and laboratory evidence of abnormal CFTR function. Laboratory tests include elevated sweat chloride concentration, two identifiable CF mutations, or abnormal in vivo nasal potential difference measurements made across the nasal epithelium.

PATHOGENESIS

The CFTR protein resides in the plasma membrane of epithelial cells and has several functions. In the sweat duct, it acts to absorb chloride; in the lung, it secretes chloride; and in the pancreas, it secretes chloride in exchange for bicarbonate.[342] Organs that are affected by the disease have abnormal chloride and fluid secretion, which impairs fluid movement and leads to ductular obstruction and organ damage. Five classes of CF mutations result in different amounts of CFTR expression and have been observed to produce varying clinical disease. The most common mutation, ΔF508, is a class 2 mutation. The CF protein is misfolded and degraded before reaching the cell membrane.[54,273]

Other classes of mutations produce CFTR that cannot be activated, is decreased in abundance, or has altered conductance. Patients with at least one "mild" allele have some low level of CFTR expression. They retain some degree of pancreatic function, have less severe lung disease, and have sweat chloride concentrations that are borderline normal.[77,79,372] Male patients with congenital bilateral absence of the vas deferens are pancreatic sufficient, exhibit little or no lung disease, can have normal sweat chloride concentrations, and are thought to have CFTR expression that is 10 percent of normal.[9] Carriers for CFTR who are heterozygotes expressing half the expected amount of CFTR are at increased risk for developing pancreatitis, allergic bronchopulmonary aspergillosis (ABPA), and sinusitis.[49,64,93,263]

The range of severity of disease is related to the production of functioning CFTR. The amount of expression of CFTR is important in the pathogenesis of CF. Variation in the severity of disease in individuals with the same genotype indicates other factors, including the environment, genetic modifiers, and medical therapy, are important in long-term outcomes, however.

The exact mechanism by which altered salt and water transport leads to abnormal secretions in the respiratory tract, pancreas, gastrointestinal tract, sweat glands, and other exocrine glands remains under intense investigation. The isotonic, low-volume model has been proposed to account for the pathogenesis of CF.[31,32] In the lung, abnormal respiratory tract secretions leading to decreased airway surface liquid seem to decrease mucociliary clearance and impair defenses to inhaled particulate matter and various microbial pathogens. The airway surface liquid is crucial for lung defense and is composed of a gel and sol layer. The gel or mucous layer is composed of high-molecular-weight mucins with carbohydrate side chains that bind inhaled particulate matter and pathogens. The sol or periciliary liquid layer consists of low-viscosity fluid to hydrate mucins and allows ciliary movement to occur. The periciliary liquid layer is 7 μm in height, allowing cilia to beat freely.

Airway surface liquid volume is regulated by the respiratory epithelium through ion transport processes. Salt concentrations can be changed to regulate the hydration of the airway lining fluid to maintain optimal mucociliary function. The absence of CFTR in the apical cellular membrane decreases the ability of cells to secrete chloride into the periciliary fluid. CFTR inhibits the epithelial sodium channel; in its absence, excessive absorption of sodium occurs. Other channels are available for secretion of chloride (calcium-activated chloride channel) in the respiratory epithelium; however, they cannot compensate for the loss of CFTR. Chloride also can enter the cell through a chloride transporter. The net effect is increased absorption of sodium, chloride, and water, which reduces the periciliary volume, alters the composition of mucins, and decreases mucociliary clearance. The reduction in the periciliary fluid impairs ciliary movement, decreases mucus transport, markedly alters clearance, and sets the stage for airway obstruction, infection, inflammation, and progressive lung destruction.

Altered chloride channel function and fluid secretion help to explain the presence of disease in the sweat gland, intestine, pancreas, and male genital tract. The epithelial cells affected by CFTR mutations in various organs represent different channel and regulatory activities of CFTR but result in deficient secretion

CFTR, cystic fibrosis transmembrane conductance regulator.

of fluids. This deficiency causes accumulation of mucus, obstruction, and various degrees of organ damage. Plugging of pancreatic ducts leads to chronic fibrosis, pancreatic atrophy, and loss of digestive enzymes and islet cells. Similar obstruction in the biliary tract can cause inflammation and focal biliary cirrhosis. Glandular obstruction of the vas deferens causes involution of the wolffian duct and infertility in more than 95 percent of men with CF. Women with CF produce abnormally tenacious cervical mucus, with reported rates of infertility of 20 percent.

Dehydration of airway surfaces and defective mucociliary transport has been termed the *low-volume model*.[32] Obstruction of small terminal airways and of submucosal glands with thickened mucopurulent secretions are the first signs of early disease in infants with CF. Ductular dilation, neutrophil infiltration, glandular hyperplasia, and peribronchiolar inflammation are classic findings of the disease. Mucus adherent to airway surfaces serves as a site for chronic infection. Human cell culture models of normal and CF epithelia have shown the airway surface liquid is decreased in CF,[208,341] and regulation of airway surface liquid volume depends on the regulation of sodium absorption and chloride secretion. Transgenic mouse models overexpressing epithelial sodium channels to mimic CF produce airway obstruction with mucus, neutrophilic inflammation, bacterial infection, and goblet cell hyperplasia.[202]

These findings are similar to observations in humans. Mucociliary clearance is decreased in CF.[31,176,275] Submucosal glands have high expression of CFTR.[100,139] Loss of CFTR function alters the composition of mucins produced by the submucosal glands,[163,176,361] leading to ductular dilation with mucus and obstruction. Mucus is tightly adhered to the respiratory epithelium and increases airway obstruction. Failure to clear mucous plugs, continued mucin secretion, and adherent mucus to the airway surface provides the focus for infection.

The respiratory airways of patients with CF are infected with several bacterial and viral pathogens that occur in an age-dependent order. Chronic infection with *P. aeruginosa* develops in 80 percent of affected individuals by the time they reach 18 years of age.[282] *Pseudomonas* infection is associated with a more rapid decline in lung function and increased rates of mortality[99,115] and becomes the dominant organism colonizing the CF airway. Initial isolates from CF infants and toddlers are unique and suggest an environmental acquisition.[236,321,322] Evidence of person-to-person transmission from chronically colonized CF patients to younger CF children, siblings, and individuals in close contact has been documented.[11,15,53,83,184]

Multiple hypotheses have been proposed to define the mechanism of airway colonization with *P. aeruginosa*. Although several studies have assessed this problem, the exact mechanism of infection and colonization remains debated. The primary hypothesis for airway infection in CF is altered mucociliary clearance secondary to abnormal salt and water transport. As the normal function of CFTR becomes defined, additional hypotheses have been put forward to explain the mechanism of early airway infection and inflammation. They involve altered epithelial cell receptors for bacteria, abnormal mucins that enhance bacterial binding impairing airway clearance, and inactivation of epithelial-derived bactericidal activity.

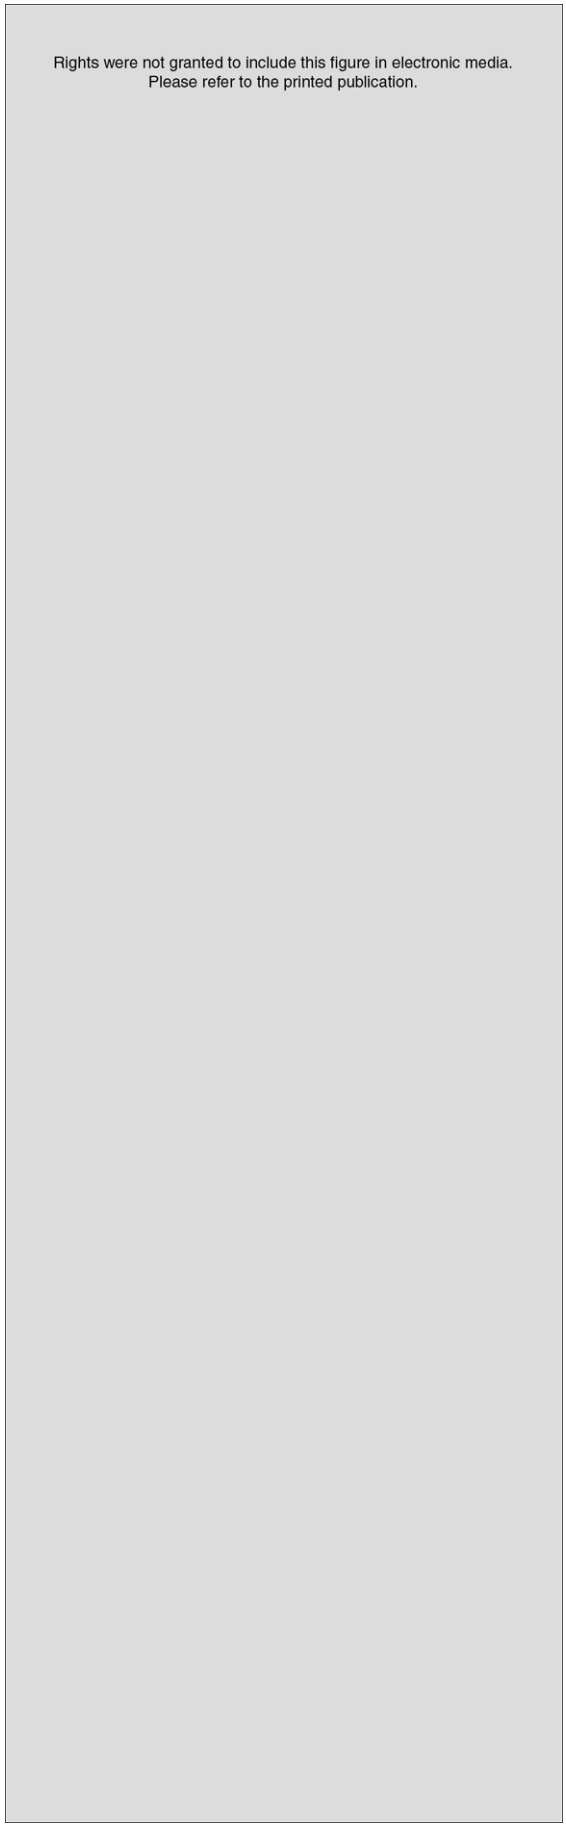
Increasing evidence indicates that the low-airway-surface-liquid-volume hypothesis explains the pathogenic mechanism of lung disease in CF. Dehydration of airway surface liquid and adhesion of mucus to the airway epithelium provide an environment conducive to chronic *Pseudomonas* infection (Fig. 31–3).[380] Depletion of periciliary water decreases ciliary activity, concentrates mucins, and increases adhesion of the mucous layer to the airway surface. Secretion of mucins continues from submucosal glands and goblet cells, producing plugging and airway obstruction. These mucous plaques are poorly cleared from the airway and become the sites of initial infection. Pili extending from the surface of the bacterium are able to bind to mucin.[308] An anaerobic gradient develops within the thickened mucous plugs. *Pseudomonas*, after binding to mucin, is able to penetrate the thickened mucus and grow in an anaerobic environment. *P. aeruginosa* is able to grow in anaerobic conditions because of the production of nitrate reductase, which allows it to cleave oxygen from nitrate.[304] When it is in the anaerobic environment, an alginate polysaccharide is formed. Biofilm-containing macrocolonies of *Pseudomonas* then are established. The established macrocolonies remain within the airway lumen. These macrocolonies are very resistant to antibiotics and host defense and allow chronic infection, inflammation, and airway destruction to occur.[151,250,380]

P. aeruginosa infection of the airway is associated with progressive respiratory impairment and death in most patients with CF. Bacterial colonization and infection of the lower respiratory tract occur early in infants with CF (Fig. 31–4), and airway inflammation often is established at the time the disease becomes clinically manifest.[14] *P. aeruginosa* infection is intermittent before chronic colonization develops.[115,136,281] Initial isolates generally are antibiotic-sensitive and nonmucoid.[37] In contrast, isolates from patients chronically colonized usually are highly antibiotic-resistant, mucoid, and increased in density.[102,324] As lung disease progresses, the phenotype changes and the bacteria adopt a mucoid biofilm mode of growth.[268] As the organism changes from a nonmucoid to mucoid state, differences in the outer membrane proteins are expressed.[143] In addition, hypermutable strains of *Pseudomonas* are isolated and show greater antibiotic resistance.[239] As *P. aeruginosa* converts from a nonmucoid to mucoid phenotype, several bacterial lipoproteins are produced that induce inflammation.[111]

Local production of cytokines and other proteins in response to bacterial infection may play an important role in modulating chronic airway inflammation.[306] Airway inflammation in CF is characterized by marked neutrophilic infiltration, with release of bioactive lipids, oxygen metabolites, myeloperoxidase, and lysozyme.[109] Proteases (e.g., elastase) derived from neutrophils and bacteria directly damage respiratory epithelium and cleave proteins important in host defense.[332,349] Chronic infection, with retention of the by-products of inflammation, ultimately leads to the severe bronchiectatic changes and derangements of gas exchange characteristic of end-stage CF.

Several in vivo studies have assessed the location of bacterial adherence within the lung of CF patients and the attachment of bacteria to CF and non-CF cells in vitro.[20,351] *P. aeruginosa* is found within the lumen of airways of patients with CF obtained from autopsy specimens.[20] These organisms are observed within the inflammatory exudates of the airway and not within epithelial cells lining the lung or in alveolar spaces. In vitro studies have shown adherence of *P. aeruginosa* in areas of epithelial cell destruction.[257,261,351] No adherence to the apical membrane of intact epithelial cells has been noted, however. In contrast, there is evidence in cell culture models that defects in CFTR enhance bacterial binding to immortalized airway epithelial cells.[290] A tetrasaccharide (asialo GM_1) is expressed more on CF than on non-CF cells and promotes *P. aeruginosa* binding to the epithelial membrane. Pseudomonal exoproducts such as neuraminidase increase the amount of asialo GM_1 available for bacterial binding and facilitate bacterial adherence to airway epithelial cells.[42,294]

Mucins also are important in binding bacteria within the airway. Sialylated and neutral forms of mucins bind *P. aeruginosa*.[264] Removal of sialylic acid from mucin by neuraminidase reduces adherence of *P. aeruginosa*. Mucus dehydration can lead to increased concentration of mucins, decreased pH, and a reduction in glutathione, which decreases mucus viscoelasticity.[287] The concentrated mucus impairs neutrophil migration, promotes an anaerobic environment, and reduces mucociliary transport. Mucin, a component of mucus, is decreased in CF, and its decreased content may promote development of infection.[288]



In contrast to the low-airway-surface-volume hypothesis discussed in detail earlier, the "high salt" theory proposes that CFTR maintains low concentration of salt in airway lining fluid. In the absence of CFTR, high concentrations of salt inactivate the secreted antimicrobial substances on airway surfaces.[384] Airway epithelial cells are vital in maintaining a pathogen-free environment within the airway. Smith and colleagues[311] showed that a monolayer of airway epithelial cells was able to kill bacteria when placed on their apical surface. In contrast, CF epithelia were unable to clear the bacterial load. Surface fluid washed from the normal cells showed bactericidal activity; however, fluid from the CF monolayer lacked bacterial killing properties. Goldman and colleagues[130] duplicated the results of this study using a different model. They implicated a human defensin, hBD-1, as the primary agent responsible for bacterial killing. The defensins are low-molecular-weight proteins produced by epithelial cells cytotoxic for bacteria and thought to be salt-sensitive. How deletion of CFTR affects the function of other antimicrobial substances such as lysozyme, which are produced by the respiratory epithelium, remains unclear.

Oxidant stress plays a role in tissue injury observed in CF. Reactive oxygen species are important in killing bacteria and are generated by phagocytic cells and the respiratory epithelium. Oxidants are produced from activated phagocytes, metabolic pathways, inhaled oxidants, and bacteria.[48] Increased oxidant production alters ion transport and increases secretion of mucins.[46,70,167,231,337,339] Excessive oxidant production can cause tissue injury. Increased oxidant production by CF neutrophils has been proposed as a mechanism of airway injury. Activation of reduced nicotinamide adenine dinucleotide phosphate (NADPH) within neutrophils results in production of precursors used by myeloperoxidase to generate chloramines. Chloramines are oxidants with long half-lives and, if produced in excess, potentially can damage the airway epithelium.[34]

One study has examined the activity of NADPH and myeloperoxidase with production of chloramines between CF and non-CF subjects.[374] Significant differences between groups were observed for myeloperoxidase activity and chloramine release. Myeloperoxidase activity and chloramine release were increased

Figure 31–3 Schematic model of the pathogenic events hypothesized to lead to chronic *Pseudomonas aeruginosa* infection in airways of patients with cystic fibrosis (CF). **A,** On normal airway epithelia, a thin mucous layer (*light gray*) resides atop the PCL (*clear*). The presence of the low-viscosity PCL facilitates efficient mucociliary clearance (denoted by *vector*). A normal rate of epithelial oxygen (O_2) consumption (QO_2; *left*) produces no O_2 gradients within this thin ASL. **B-F,** CF airway epithelia. **B,** Excessive CF volume depletion (denoted by v*ertical arrows*) removes the PCL, mucus becomes adherent to epithelial surfaces, and mucus transport slows or stops (*bidirectional vector*). The increased O_2 consumption (*left*) associated with accelerated CF ion transport does not generate gradients in thin films of ASL. **C,** Persistent mucus hypersecretion (denoted as mucus secretory gland/goblet cell units; *dark gray*) with time increases the height of luminal mucus masses and plugs. The increased CF epithelial QO_2 generates steep hypoxic gradients in thickened mucus masses. **D,** *P. aeruginosa* bacteria deposited on mucus surfaces penetrate actively or passively or both (due to mucus turbulence) into hypoxic zones within the mucus masses. **E,** *P. aeruginosa* adapts to hypoxic niches within mucus masses with increased alginate formation and the creation of macrocolonies. **F,** Macrocolonies resist secondary defenses, including neutrophils, setting the stage for chronic infection. The presence of increased macrocolony density and, to a lesser extent, neutrophils renders the now mucopurulent mass hypoxic. (See companion Expert Consult web site for color version.) *(From Worlitzsch, D., Tarran, R., Ulrich, M., et al.: Effects of reduced mucus oxygen concentration in airway Pseudomonas infections of cystic fibrosis patients. J. Clin. Invest.* 109*:317-325, 2002.)*

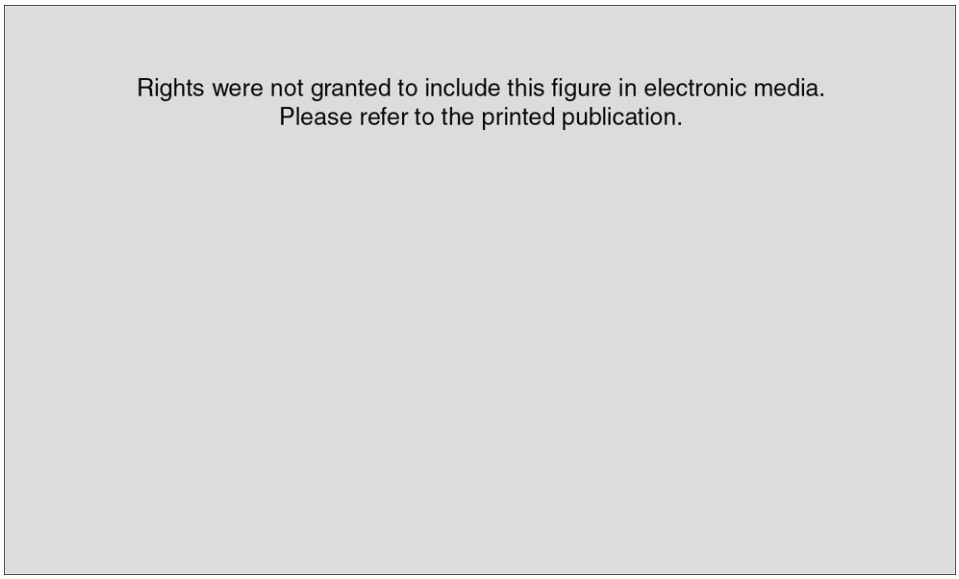


Figure 31–4 Age-specific prevalence of pathogens in patients with cystic fibrosis. *(From CF National Patient Registry, 2000.)*

in subjects with CF. Treatment of CF neutrophils with amiloride reduced oxidant generation, suggesting that altered intracellular ion concentrations or pH may regulate myeloperoxidase activity. Other investigators have suggested alternatively that the circulating neutrophils may be primed to respond to a phagocytic stimulus and that these differences in oxidant generation represent increased neutrophil activity.[135,271]

Antioxidants are produced by enzymatic and nonenzymatic pathways.[48] Mucins, reduced glutathione, alpha-tocopherol, and metal binding proteins function in the airway as antioxidants. The cysteine residues and carbohydrates of mucin account for its antioxidant properties.[71] Secretion of mucins is increased with oxidative stress. In CF, overproduction of mucus with subsequent dehydration may protect bacteria from neutrophil killing, worsening inflammation and causing more harm to the airway. In addition to affecting production of mucins, CFTR also may regulate production of glutathione.[190] Glutathione is an antioxidant found in large amounts in airway lung fluid from normal subjects[47]; however, it is reduced in patients with CF.[285] CFTR may alter glutathione transport, impairing defense to oxidant injury. Whether intracellular glutathione levels are decreased in CF, a factor that could be important in nuclear factor-κB (NF-κB) regulation, remains unclear. Increased oxidant production from neutrophils and impaired antioxidant biosynthesis can be altered by mutant CFTR, increasing the potential for oxidant injury in the CF airway.

Production of cell adherence molecules and inflammatory cytokines is intact in patients with CF.[88,174] Defects in bacterial opsonization, reduction in anti-inflammatory cytokines, and proinflammatory effects of bacterial DNA have been reported, however. Although humoral antibody responses and neutrophil phagocytosis from peripheral blood are normal, increased elastase in the CF airway can alter opsonic receptors, impairing phagocytosis. Large amounts of elastase are present in lavage fluid from airways of patients with CF, overwhelming the normal antiprotease activity. This condition can lead to local impairment in phagocytosis of bacteria within the airway lumen, contributing to bacterial persistence.

Proinflammatory mediators are elevated in BAL fluid from young patients with CF, as are macrophages expressing intracellular cytokines.[170,225,385] Increased numbers of neutrophils and interleukin (IL)-8 in BAL fluid are seen in bacterial culture–negative and bacterial culture–positive infants with CF compared with controls.[155,371] Proinflammatory mediators IL-1, IL-2, tumor necrosis factor-α, and IL-8 are markedly elevated in children with advanced disease.[144,155,371] In contrast, some anti-inflammatory cytokines (IL-10) are found in reduced amounts in BAL from subjects with CF. These observations have prompted some investigators to assess production of IL-10 from bronchial epithelial cells in normal subjects and subjects with CF.[26] Bronchial epithelial cells from normal individuals produce significantly greater amounts of IL-10 compared with cells of subjects with CF. NF-κB is a transcription factor for several proinflammatory mediators and is activated persistently in CF. Inhibitors to NF-κB, including IL-10, are down-regulated.[85,302,360,364]

Enhanced macrophage production of proinflammatory cytokines and decreased production of IL-10 have fostered a hypothesis that the CF gene defect may result in an inability to control airway inflammation after having infections. Alternatively, CFTR could have no effect on production of anti-inflammatory cytokines, and IL-10 could be down-regulated. Although the understanding of this disease pathogenesis is incomplete, airway damage that occurs from excessive inflammation remains a target for new therapeutic modalities.

MICROBIOLOGY OF CYSTIC FIBROSIS

EPIDEMIOLOGY OF PATHOGENS IN CYSTIC FIBROSIS

Most commonly, patients with CF are infected with classic pathogens, including *Staphylococcus aureus*, nontypeable *Haemophilus influenzae*, and *P. aeruginosa*.[8,41,126,214] A few patients may be infected with *Burkholderia cepacia* complex, which can be particularly virulent and, in some patients, associated with increased morbidity and mortality.[68,132,279] More recently, potentially emerging pathogens, such as methicillin-resistant *S. aureus* (MRSA), *Stenotrophomonas maltophilia*, *Achromobacter xylosoxidans*, nontuberculous mycobacteria (NTM), and mold species (primarily *Aspergillus* spp), and, more recently, *Scedosporium* spp., are being reported. Additional potential pathogens include *Ralstonia* and *Pandoraea* spp.[62,193] As described in more detail subsequently, the link between these pathogens and lung disease is not fully elucidated.

The etiologies behind these emerging pathogens are multifactorial. The average life expectancy of patients with CF has increased during the past 4 decades and now is 36.5 years.[75] Patients with CF are treated frequently with prolonged courses

of antimicrobial agents, including oral, intravenous, and aerosolized agents, placing selective pressure on their flora and leading to increased resistance.[38,75] Evidence of health care–associated acquisition of some pathogens, including *B. cepacia* complex, *P. aeruginosa*, and MRSA, is described subsequently. Finally, during the past 2 decades, detection of many potential pathogens has improved as clinical microbiology laboratories processing CF specimens use several selective media and fully speciate non–lactose-fermenting, gram-negative bacilli as described subsequently.[126,145,336,390]

AGE-SPECIFIC PREVALENCE OF PATHOGENS

The U.S. Cystic Fibrosis Foundation has maintained an annual Patient Registry since 1962.[112] The age-specific prevalence for CF pathogens in the United States as reported to this registry in 2005 is shown in Figure 31–4.[75] During the first decade of life, *S. aureus* is the most common pathogen and is harbored by approximately 40 percent of children and adolescents. Nontypeable *H. influenzae* is a less prevalent pathogen and is cultured from the respiratory tracts of 15 percent of children. Over time, *P. aeruginosa* becomes the most prevalent pathogen, but it can be recovered from 30 percent of infants. Approximately 80 percent of American patients with CF are infected with *P. aeruginosa* by the time they reach 18 years old. Overall, *Burkholderia* spp.[191] are recovered from 3 to 4 percent of patients and 10 percent of adults. During the late 1990s, the Cystic Fibrosis Foundation began to collect data on the prevalence of MRSA, *S. maltophilia*, and *A. xylosoxidans*. As shown in Figure 31–4, these organisms are more common than is *B. cepacia* complex and are harbored primarily by adult patients. As noted in patients without CF, MRSA has become increasingly common.[272]

ROLE OF THE CLINICAL MICROBIOLOGY LABORATORY

Ongoing communication between the clinical microbiology laboratory and the CF care team is crucial to ensure that appropriate methodologies are in place to provide appropriate care, to support effective infection control, and to further understanding of the epidemiology of pathogens in CF.[296] Every 5 years, the executive committee of the U.S. Cystic Fibrosis Foundation conducts site visits of accredited CF care centers and meets with the director of the clinical microbiology laboratory in efforts to ensure that standardized practices are in place.[295] In addition, a survey determined that most clinical laboratories processing CF specimens were using selective media and speciating all gram-negative bacilli,[390] which may include molecular identification strategies.

SPECIMEN PROCESSING

Respiratory tract specimens from patients with CF, including specimens obtained after lung transplantation, should be labeled "CF specimens" to ensure proper processing. Timely transport optimizes recovery of pathogens; ideally, specimens should be received by the laboratory within 3 to 4 hours of collection or stored at 4° C and processed within 24 hours. Sputum is the ideal specimen, and at least 1 mL should be collected to ensure an adequate volume is available for plating on selective media. Sputum can be Gram-stained to determine if a specimen contains bacteria and neutrophils rather than epithelial cells. Oropharyngeal cultures often are obtained in children too young to expectorate, but these cultures may not be concordant with specimens obtained from the lower airway.[280] BAL specimens generally are reserved for research protocols, lung transplant recipients, or patients with atypical courses who cannot produce sputum. More recently, induced sputum has been promoted to assess the lower respiratory tract flora of patients with CF who cannot expectorate.[149,244]

SELECTIVE MEDIA

Selective media are needed to isolate specific pathogens, although the use of these media is costly and time-consuming. Current recommendations for selective media are shown in Table 31–3. *S. aureus* strains from patients with CF may be thymidine-deficient and require mannitol salt agar for growth.[295] Detection of *B. cepacia* complex is markedly enhanced by the use of OFBPL (oxidative fermentative bacitracin polymyxin B lactose) agar or *B. cepacia* selective media.[126,145] Multicenter studies conducted by the Centers for Disease Control and Prevention in the 1980s showed that the use of selective media improved the yield of *Burkholderia* spp. from patients with CF.[334] In addition, specimens can be plated on mycosel agar to identify *Aspergillus* spp., although this mold grows well on blood agar. Oropharyngeal swabs from nonexpectorating patients also should be plated on selective media.[307] If NTM are suspected, sputum should be stained for acid-fast bacilli and processed using an additional decontamination step to prevent overgrowth by *P. aeruginosa*.[367] This decontamination step may kill NTM present in low concentrations, however.[21] Quantitative cultures of specimens from sputum are reserved for research purposes.

ANTIMICROBIAL SUSCEPTIBILITY TESTING

The optimal methodology for antimicrobial susceptibility testing for mucoid and nonmucoid strains of *P. aeruginosa* has been elu-

TABLE 31–3 Recommended Media and Processing for Recovery of Cystic Fibrosis Pathogens

Organism	Recommended Media or Processing*†
Staphylococcus aureus	Mannitol salt agar Columbia/colistin–nalidixic acid agar
Haemophilus influenzae	Horse blood or chocolate agar (supplemented or not with 300 mg/L bacitracin) incubated anaerobically
Pseudomonas aeruginosa	MacConkey agar
Burkholderia cepacia complex	OFPBL agar, PC agar, BCSA
Stenotrophomonas maltophilia	MacConkey agar, VIA agar DNase agar confirmatory media or biochemical or molecular identification
Achromobacter xylosoxidans	MacConkey agar Biochemical identification assay
Mycobacterial *spp.*	NALC-NaOH and oxalic acid decontamination step
Yeast	Mycosel agar‡
Other gram-positive organisms	Sheep blood agar supplemented with neomycin and gentamicin (streptococcal selective agar)
Other gram-negative organisms	MacConkey agar

**Detection of some pathogens may be enhanced by prolonging incubation for 4 days to allow slow-growing colonies to become apparent.*

†All media are commercially available.

‡Aspergillus spp. and other molds do not grow well on Mycosel, but do grow well (although not selectively) on many of the media used for cystic fibrosis specimens, especially OFPBL. Standard biochemical and phenotypic methods should be used for confirmation of the identification of molds.

cidated. In studies of 500 multidrug-resistant strains of *P. aeruginosa* from patients with CF, five different antimicrobial susceptibility testing methods were compared: a reference microbroth dilution assay, Kirby Bauer disks, E-tests, and the automated commercial systems Vitek and Microscan. The agar-based diffusion methods (Kirby Bauer disks and the E-test) proved most accurate compared with the reference methods.[39,289] Vitek and Microscan, the commercial systems, had unacceptably high rates of very major (i.e., false-susceptible) and major (i.e., false-resistant) errors.[40] The Clinical Laboratory Standards Institute (formerly the National Committee for Clinical Laboratory Standards) endorses the use of antibiotic-impregnated disks or reference broth microdilution assays to determine the susceptibility of multidrug-resistant strains of *P. aeruginosa* isolated from patients with CF.[229]

An intriguing concept in susceptibility testing is the potential role of susceptibility testing of bacteria grown in biofilms. As described in more detail subsequently, chronic lung infection in CF is thought to reflect a biofilm mode of growth containing bacteria in stationary phase that do not express the antibiotic targets present in log phase bacteria.[69] In vitro studies have shown that the minimal inhibitory concentration (MIC) of log phase bacteria tested in conventional susceptibility testing assays can be very different from the MIC of bacteria growing in stationary phase in biofilms.[147] Log phase–grown *P. aeruginosa* are resistant to macrolide antibiotics (MIC ≥ 128 μg/mL), whereas *P. aeruginosa* grown in biofilms are susceptible to these agents (MIC_{50} 2 μg/mL).[222] Studies are ongoing to compare the outcomes of pulmonary exacerbations treated using the results of conventional susceptibility testing versus the results from biofilm susceptibility testing.

SPECIFIC CYSTIC FIBROSIS PATHOGENS

VIRAL PATHOGENS

Numerous studies have evaluated the role of nonbacterial infections with pulmonary exacerbations in CF. A clear correlation between respiratory viral infection and exacerbations of lung disease has been shown in most of these reports.* Viral lower respiratory tract infections occur more often in younger children and are associated with increased pulmonary disease in 40 percent of cases in CF.[3,355] Respiratory syncytial virus (RSV) has been identified most often with CF pulmonary exacerbations; however, influenza, adenovirus, parainfluenza virus, and rhinoviruses also have been reported.[355] Respiratory viruses are isolated from patients with CF requiring hospitalization, and infection is associated with increased morbidity rates. Infants with CF infected with RSV can experience prolonged hospitalizations, mechanical ventilation, and supplemental oxygen at hospital discharge.[3] Severe viral infections in infants with CF were reported in 31 of 80 children diagnosed by newborn screening. Half of the children hospitalized had a respiratory virus identified at the time of hospitalization, and RSV infection accounted for hospitalization in 7 of the 31 children.[12]

Two studies have reported prolonged bronchiolitis-like syndromes in infants younger than 6 months of age.[119,196] These infants required intensive respiratory therapy, including bronchodilators, chest physiotherapy, and mechanical ventilation. Increased hospitalization was observed for children with CF who were infected with RSV in another study of children younger than 3 years of age.[146] Although prolonged hypoxia and respiratory failure were not observed, pulmonary function was markedly decreased after hospitalization and persisted for several months after infection.[146] Studies in older children with CF have reported reduction in pulmonary function, clinical scores, and radiographic scores and increased hospitalization after viral infection.[65,243,315,362,373] These studies show that infection with respiratory viruses results in clinical deterioration, hospitalization, and decreases in lung function.

Mechanisms to explain the enhanced disease observed with respiratory viral infections are being investigated. Normal airway epithelia use an adenosine-regulated pathway to maintain periciliary fluid volume by regulation of sodium absorption and chloride secretion. In a CF model, this regulation can be normalized by phasic motion simulating movement of the lung. Periciliary volume is restored to normal by release of adenosine triphosphate into the periciliary liquid and activation of alternative chloride channels. Viral infections, such as RSV, up-regulate the extracellular adenosine triphosphatase activity, reducing periciliary fluid volume. Reduction in periciliary liquid volume would promote mucous stasis and plugging.[341] Other investigators have shown impaired innate defense manifested by reduced production of nitric oxide and impaired interferon-γ signaling pathway.[387,388]

The interrelationship between the acquisition of *P. aeruginosa* and viral respiratory infection is unclear. Increased colonization with *Pseudomonas* has been observed during the respiratory viral season,[166] and infection with *Pseudomonas* has been associated with hospitalization for viral respiratory illness. Antipseudomonal antibodies have been reported to increase after having RSV infection, and new infection with *Pseudomonas* has been observed during an acute respiratory illness.[65,256] Other investigators have not observed any change in bacterial infection or change in colonization associated with viral respiratory infection.[238] In cell culture models, RSV acts as a coupling agent between *P. aeruginosa* and enhances attachment to respiratory epithelial cells.[356] Petersen and colleagues[256] and Ong and associates[243] reported more severe pulmonary disease with viral infection in the presence of *P. aeruginosa* colonization, but Przyklenk and coworkers[262] found no correlation. Synergism between bacteria and respiratory virus infection was suggested by Przyklenk and coworkers[262] after an increase in the number of bacterial colony-forming units was found in sputum of subjects with CF. Hordvik and associates[153] and Efthimiou and coworkers[94] noted that patients with CF and severe pulmonary disease recovered slowly from viral infection. The underlying severity of lung disease was crucial in predicting response to viral respiratory infection.

NONTYPEABLE *HAEMOPHILUS INFLUENZAE*

H. influenzae frequently is the earliest pathogen isolated from patients with CF. The advent of the *H. influenzae* vaccine has not had an impact on the prevalence of this organism because patients with CF harbor nontypeable strains. Generally, *H. influenzae* is susceptible to a wide variety of agents and is amenable to treatment. Despite the frequent recovery of this organism from infants and children, the impact of this organism on the clinical course of CF has been difficult to assess because of the frequent occurrence of co-infection with other pathogens.

STAPHYLOCOCCUS AUREUS

Methicillin-susceptible *S. aureus* (MSSA) and MRSA are increasing in prevalence. Patients generally retain the same clone of MSSA for their lifetime.[33,301] Data from the Cystic Fibrosis Patient Registry showed that the overall prevalence of MSSA increased from 37 percent in 1995 to 51.8 percent in 2005.[75] Similarly, MRSA increased from 0.1 percent in 1995 to 17.2 percent in 2005, although the prevalence varied substantially from center to center (range per center, 0 to 24%). The causes

*See references 3, 94, 118, 153, 238, 243, 256, 262, 266, 327, 362, 381.

for this variability are uncertain but could reflect different laboratory practices, different clinical practices, or regional differences in community-acquired MRSA. Although MRSA generally infects older patients, it usually is persistent[272] and can be associated with deterioration in both pediatric and adult patients.[216,345] A more recent report compared the outcomes of patients with MSSA versus MRSA and showed that children (<18 years old) and adults infected with MRSA had worse lung function, more hospitalizations, and more antibiotic use.[272]

Recent hospitalization has been shown to be a risk factor for MRSA, suggesting nosocomial acquisition,[127] but the relative importance of community-acquired MRSA strains (mecA type IV and V) has not been fully elucidated. A more recent case series has suggested that community-acquired MRSA strains expressing Panton-Valentine leukocidin can be associated with increased morbidity, including focal pulmonary infiltrates with cavitary lesions and a greater decline in lung function.[96]

PSEUDOMONAS AERUGINOSA

P. aeruginosa is the most common and important pathogen in patients with CF. Initial strains are nonmucoid, antibiotic-susceptible strains that express pili, flagella, and more highly acylated lipid A component of lipopolysaccharide.[134] *P. aeruginosa* also produces virulence factors, including exotoxin A, exoenzyme S, leukocidin, phospholipase C, elastase, and alkaline protease, which contribute to the pathogenesis of sepsis, acute lung infections, and bacteremia.[50,318,340] These factors may be chemotactic stimuli for neutrophils, and exotoxins may increase the viscosity of secretions and impair ciliary clearance and cause small airway obstruction and ultimately lung destruction.

Over time, *P. aeruginosa* adapts to the CF lung and undergoes genetic and phenotypic alterations. *P. aeruginosa* initially attaches to solid surfaces (e.g., mucin or respiratory epithelial cells), using flagella and type IV pili.[69] Attachment activates genes that synthesize extracellular polysaccharide (alginate),[84] which confers the mucoid phenotype of *P. aeruginosa* unique to chronic infections in CF.[133] Strains associated with chronic infections lack pili, lack flagella, and undergo structural changes in lipopolysaccharide. These changes may render *P. aeruginosa* more resistant to host defenses, including defensins and the innate inflammatory response. The *lasR-lasI* system (quorum-sensing genes) promotes the initial formation of microcolonies, which differentiate into alginate-encased mature biofilms.[69] Bacteria in biofilms avoid ciliary clearance, evade phagocytosis, and are antibiotic-resistant.[309] Biofilms are the proposed mechanism whereby *P. aeruginosa* is able to infect the CF airway chronically and avoid eradication by host defenses and by antimicrobial agents. The CF lung can harbor very high concentrations of *P. aeruginosa*—10^8 to 10^9 organisms per gram of sputum may be present.[376]

Infection with *P. aeruginosa* is associated with increased morbidity and mortality rates caused by recurrent pulmonary exacerbations and a gradual deterioration in lung function.[173,247] Children who are infected with *P. aeruginosa* are more likely to have cough and lower chest radiograph scores than are uninfected children.[156] Investigators have shown that infants younger than 2 years infected with *S. aureus* and *P. aeruginosa* have worse pulmonary function, chest radiograph scores, and 10-year survival rates than do uninfected children.[4] The mucoid phenotype of *P. aeruginosa* is associated with a more rapid decline in lung function.[248]

BURKHOLDERIA CEPACIA COMPLEX

Infection with *B. cepacia* complex and the associated "cepacia syndrome" was reported first in 1979 among adolescent Canadian patients with CF.[161,335] The cepacia syndrome is characterized by a virulent course, high fevers, bacteremia, rapid deterioration in lung function, and early death. Generally, patients with CF do not have bacteremia caused by other pathogens. Different clinical courses can be associated with *B. cepacia* complex, however, including transient colonization, a gradual decline in lung function, or the virulent cepacia syndrome.

TABLE 31–4 Members of the *Burkholderia cepacia* Complex, 2001

**Manuscripts in preparation.*

Through a series of genetic and phenotypic studies, researchers have discovered that *B. cepacia* is actually a complex of several different species, previously called *genomovars*, which are indistinguishable phenotypically but distinguishable genotypically.[63] The genomovars of the *B. cepacia* complex are shown in Table 31–4, but additional genomovars are likely to be described. Several international investigators have described the epidemiology and clinical courses associated with different genomovars, although these studies usually involved a single strain and might not be generalized to all strains of a given genomovar.[192,199,323] Most CF isolates are *Burkholderia cenocepacia* (genomovar III) or *Burkholderia multivorans* (genomovar II). The former may be associated with a more rapidly progressive clinical course,[195] whereas *B. multivorans* is more likely to be associated with transient colonization.[199] Patient-to-patient transmission and clinical deterioration can be associated with *B. multivorans*, however.[192] Most recently, an outbreak of *Burkholderia dolosa* (genomovar VI) occurred, and this newly described genomovar was associated with increased morbidity and mortality rates.[168]

Virulence factors for *Burkholderia* spp. include multidrug resistance, the ability to form biofilms, the ability to reside intracellularly, and the ability to spread from patient to patient potentially via the cable pilus[331] or the *B. cepacia* epidemiologic strain marker.[199] Many outbreak strains do not express these transmission factors, however. Studies are ongoing to unravel potential environmental reservoirs of *Burkholderia* spp.

STENOTROPHOMONAS MALTOPHILIA

S. maltophilia, an intrinsically multidrug-resistant, gram-negative bacillus, is a well-known hospital-acquired pathogen in non-CF patients and is isolated with increasing frequency from the respiratory tract of patients with CF. The overall prevalence of this organism in patients with CF is 12 percent (range 0 to 27% in individual centers).[75,82] In a multicenter, randomized, placebo-controlled study of aerosolized tobramycin conducted in 520 patients 6 years old and older with CF, the baseline prevalence of *S. maltophilia* determined by a core laboratory was 10.7 percent,[41] whereas the national rate among comparably aged patients reported to the Cystic Fibrosis Patient Registry was 2.9 to 3.9 percent, suggesting that many clinical laboratories were failing to identify this potential pathogen. Transient colonization also seems to be a common occurrence; Demko and colleagues[82] reported that 50 percent of patients with CF at their center had

only a single positive culture for this microorganism. Increased use of antibiotics has been shown to be a potential risk factor for acquisition of *S. maltophilia*.[205,338]

The role of this organism as a pathogen in CF is still being investigated. Case-control studies have not shown that *S. maltophilia* has a significant impact on lung function or mortality.[131,205] In contrast, Demko and colleagues[82] found that the 5-year survival of patients with *S. maltophilia* (n = 211) with severe lung function at initial isolation of this organism was 40 percent compared with patients without *S. maltophilia* (n = 471), whose 5-year survival was 72 percent.

ACHROMOBACTER XYLOSOXIDANS

The clinical significance of *A. xylosoxidans* in CF also is unclear. In 1996, the first year that this organism was reported to the Cystic Fibrosis Patient Registry, 2.7 percent of patients harbored this multidrug-resistant, gram-negative bacillus.[74] As described for *S. maltophilia*, however, the nationally reported prevalence most likely is underestimated; 8.7 percent of participants in the aerosolized tobramycin trial had positive cultures for *A. xylosoxidans*.[41] Further complicating the epidemiology of this potentially emerging pathogen are the observations that *A. xylosoxidans* may be misidentified as some other non–lactose-fermenting, gram-negative bacilli, and that *P. aeruginosa*, *B. cepacia* complex, and *S. maltophilia* may be misidentified as *A. xylosoxidans*.[291] In addition, the impact of this organism is difficult to assess fully because *A. xylosoxidans* generally is cultured from patients concomitantly infected with other CF pathogens, but an association has been found between *A. xylosoxidans* and pulmonary exacerbations.[92,103]

ASPERGILLUS SPECIES AND *SCEDOSPORIUM* SPECIES

Patients with CF frequently are colonized with *Aspergillus* spp.; 24.5 percent of participants in the inhaled tobramycin trial indicated they had positive cultures for this mold.[36] Oral and aerosolized antimicrobial agents are risk factors for colonization with *Aspergillus* spp.[22,267]

Of patients with CF, 2 to 10 percent develop APBA, which can be associated with a dramatic loss of lung function.[97,121,207,224] The diagnosis of ABPA can be difficult to establish because of variability in the application of standardized diagnostic criteria, confusion regarding these criteria, and limited recognition by physicians. This immunologically mediated syndrome is marked by a brisk IgE response, specific antibody to *Aspergillus fumigatus*, peripheral eosinophilia, and symptoms of reactive airway disease. Short-lived pulmonary infiltrates may be noted on chest radiograph. Although *Aspergillus* spp. do not normally invade the parenchyma, the airways can become impacted with mucus-containing fibrin, eosinophils, and mononuclear cells, which can cause airway obstruction and bronchiectasis.[97]

A workshop sponsored by the Cystic Fibrosis Foundation sought to further understanding of the diagnostic criteria needed for ABPA in CF.[326] This committee established minimum criteria for the diagnosis, which included (1) new clinical deterioration not attributable to another cause; (2) IgE greater than 500 IU/mL; (3) immediate skin reactivity to *Aspergillus* antigen or IgE antibody to *A. fumigatus*; and (4) precipitants or IgG against *A. fumigatus*, new chest radiograph, or new chest CT findings.

Scedosporium spp. can be isolated from the lungs of patients with CF, but the clinical significance of this microorganism is unknown. In the aerosolized tobramycin trial, 2.4 percent of patients harbored saprophytic fungi,[41] and in a single center, 8.6 percent of 128 patients followed for more than 5 years were colonized or infected with *S. apiospermum*.[58]

NONTUBERCULOUS MYCOBACTERIA

Since the early 1990s, there has been an increasing appreciation that NTM may be pathogens in patients with CF. Olivier and colleagues[241] conducted a natural history study of NTM in patients with CF in 21 CF centers from 1993 to 1997. Using standardized mycobacteriologic methods,[368] these investigators found that the overall prevalence of colonization and infection with NTM was 13 percent. *Mycobacterium avium* complex (MAC) and *Mycobacterium abscessus* were most common, representing 72 percent and 16 percent of isolates, respectively. Patients with NTM were older and had better lung function, a lower prevalence of *P. aeruginosa*, and a higher prevalence of *S. aureus* compared with patients without NTM, suggestive of a "healthy survivor effect." Risk factors for NTM may include geographic proximity to large bodies of water,[241] ABPA, and steroid therapy.[227]

In an individual patient, determining if NTM is colonizing the lung or causing disease can be difficult. Signs and symptoms of mycobacterial disease are nonspecific and may be consistent with CF pulmonary exacerbations. Radiographic signs generally are nonspecific, but small nodules in the lung periphery or progressive "tree and bud" lesions may be noted on high-resolution CT scan.[242] Patients with positive acid-fast bacillus smears and two or more positive cultures are more likely to be infected than colonized with NTM.[7] Patients harboring *M. abscessus* are more likely to fulfill the American Thoracic Society diagnostic criteria for NTM disease than are patients harboring MAC.[137,240] In a study to assess the clinical impact of NTM, 60 incident-case patients with positive NTM cultures were followed for 15 months and did not have increased morbidity compared with control subjects with negative cultures.[240] Because this was a short duration of follow-up, further studies are needed to determine if NTM causes a progressive deterioration in lung function and, if so, the optimal therapy.

TREATMENT OF PATHOGENS IN CYSTIC FIBROSIS PATIENTS

A cornerstone of CF care is the aggressive use of oral, intravenous, and aerosolized antibiotics. The increasing longevity of patients with CF has paralleled the development of effective antibiotics. Antibiotics may be used during several stages of CF lung disease: (1) to prevent acquisition of pathogens, most commonly MSSA; (2) to eradicate initial acquisition of pathogens, most commonly *P. aeruginosa*, in efforts to prevent or delay chronic infection; (3) to treat pulmonary exacerbations caused by classic CF pathogens; (4) to treat patients infected with *P. aeruginosa*, as long-term suppressive therapy; and (5) to treat emerging multidrug-resistant pathogens.

PROPHYLAXIS TO PREVENT ACQUISITION OF *STAPHYLOCOCCUS AUREUS*

Few studies have been conducted on antibiotic prophylaxis in patients with CF, and these studies have focused exclusively on *S. aureus*. The rationale for this strategy is to prevent *S. aureus* infection and to delay acquisition of *P. aeruginosa*.[312,314] From 1985 to 1992, British investigators studied 42 newly diagnosed infants randomly assigned to 12 months of flucloxacillin versus standard care.[23,363] Infants treated with flucloxacillin had fewer infections with *S. aureus* and fewer hospitalizations, but both groups had similar pulmonary function. In a placebo-controlled trial conducted in the United States, 119 patients newly diagnosed with CF (mean age, 16 months) were randomly assigned to receive cephalexin or placebo for 5 to 7 years.[328] No significant differences were found in pulmonary function, the number of

pulmonary exacerbations, nutritional status, or chest radiograph scores in the two groups. In contrast, subjects treated with cephalexin had decreased incidence of infection with *S. aureus* but increased incidence of infection with *P. aeruginosa*. Similarly, an analysis of the German national database showed that patients receiving antistaphylococcal agents had increased acquisition of *P. aeruginosa* and no improvement in lung function.[269]

Antistaphylococcal prophylaxis, although practiced in the United Kingdom in infants, has not been widely endorsed in the United States because of concerns about the emergence of resistance, the increased risk of acquiring *P. aeruginosa*, and the lack of impact on lung function. The different findings in these studies may reflect the different agents studied because cephalexin is broader spectrum than is flucloxacillin or the different durations of therapy, or both. In an era of increasing prevalence of MRSA, strategies to prevent MSSA may prove to be less useful. To date, no studies have been done to assess antibiotic prophylaxis for other pathogens in CF.

EARLY ERADICATION OF *PSEUDOMONAS AERUGINOSA*

An increasingly practiced therapeutic strategy is to use antibiotics to eradicate initial acquisition of *P. aeruginosa* and prevent or delay chronic infection. This strategy was described first in Europe at the Danish Cystic Fibrosis Center.[114,164,333,352,359] The rationale for this approach is that antibiotics may be effective at eradicating initial infection and colonization with *P. aeruginosa* because the organism burden is low, organisms are largely susceptible, and a biofilm has not yet been established.

The optimal regimen for successful eradication is unknown. In some CF centers in Europe, colistin and ciprofloxacin are administered every 3 months after the initial isolation of *P. aeruginosa* has occurred.[114] Compared with historic controls, patients treated with this approach had improved lung function, improved survival rates, decreased prevalence of *P. aeruginosa*, and increased resistance to the therapeutic regimen.[333] In Australia, investigators used intravenous antibiotics followed by ciprofloxacin or aerosolized agents and found that 6 of 24 children no longer had *P. aeruginosa* isolated for 12 months or longer.[13] Compared with children treated with placebo, children treated with inhaled tobramycin within 7 to 12 weeks of initial infection and colonization with *P. aeruginosa* had shorter time to conversion from a positive to negative culture.[370] All 8 subjects treated with inhaled tobramycin compared with 1 of 13 subjects treated with placebo had successful eradication of *P. aeruginosa*.[123]

Despite the concerns about the potential emergence of antimicrobial resistance and lack of long-term studies that show the durability of eradication or an improvement in lung function, the growing consensus has been that early eradication for *P. aeruginosa* has merit. Two large, placebo-controlled studies are ongoing to assess the efficacy of different eradication regimens using different durations of inhaled tobramycin with and without oral ciprofloxacin. Neither of these trials is comparing an active regimen with placebo—evidence that early eradication has been endorsed by most of CF experts.

TREATMENT OF PULMONARY EXACERBATIONS

Pseudomonas aeruginosa

Much effort has been put into standardizing and validating the definition of a pulmonary exacerbation in CF. No currently accepted definition has been adopted universally, however, for use clinically, in quality improvement initiatives, or in clinical research. A combination of clinical signs and symptoms is used to define a pulmonary exacerbation in research trials, and similar factors are used in the clinical setting.

Mild exacerbations often are treated with oral ciprofloxacin[57,150] with or without an inhaled agent such as tobramycin or colistin. Treatment trials supporting the use of inhaled antibiotics for management of an exacerbation are lacking, however.

Several pivotal trials have led to widely accepted principles for intravenous treatment of more severe pulmonary exacerbations. During the 1970s and early 1980s, placebo-controlled trials showed that participants in the placebo group had increased morbidity and mortality rates compared with participants treated with intravenous antibiotics.[128,157,369] Hospitalized participants treated with bronchodilators and chest physiotherapy alone had less improvement in lung function and less reduction in bacterial density compared with patients treated with these interventions plus a β-lactam and an aminoglycoside agent.[270] Treatment with a β-lactam (azlocillin) and an aminoglycoside (tobramycin) agent leads to a significant reduction in bacterial density and a longer time to readmission for a new exacerbation compared with treatment with azlocillin alone.[310]

Studies also have compared various agents, singly or in combination. Most studies enrolled small numbers of patients and concluded that the comparative treatment regimens were equivalent in efficacy, but the studies were insufficiently powered to detect differences.[28,61,129,162,185,213,252,299,305] Many studies showed the emergence of resistance to study drug at the completion of therapy, which did not correlate with clinical response to treatment.[165,246] A larger multicenter trial randomly assigned patients undergoing a pulmonary exacerbation to ceftazidime and tobramycin ($n = 52$) or meropenem and tobramycin ($n = 50$).[25] Participants in the meropenem-treated group had a greater improvement in lung function than did participants in the ceftazidime-treated group (mean increase in forced expiratory volume in 1 second [FEV_1] percent predicted (38.8 percent versus 29.4 percent). Finally, examination of the safety and efficacy of single daily dosing of tobramycin versus multiple daily dosing during a pulmonary exacerbation showed that single daily dosing was associated with the same efficacy and reduced nephrotoxicity; in children, the mean percentage change in creatinine in the single daily dosing group was less than the mean change in the three-times daily dosing group (4.5% vs 3.7%).[313]

Accepted treatment of a pulmonary exacerbation caused by *P. aeruginosa* consists of two parenteral agents from different antibiotic classes to provide synergy and to delay the emergence of resistance.[122,223,265,293] Most commonly, a β-lactam agent with activity against *P. aeruginosa*, such as piperacillin or ceftazidime, is combined with an aminoglycoside agent, generally tobramycin. If a patient is co-infected with another pathogen, such as MSSA, additional agents are added. Treatment trials for pulmonary exacerbations caused by other CF pathogens are unavailable, however.

Antibiotic dosages must be higher or more frequent (or both) in patients with CF because the volume of distribution and clearance are increased in CF.[81] Treatment is administered for 14 to 21 days; treatment outcomes include improved lung function, improved well-being or improved quality of life or both, and a reduction in organism burden. Eradication of pathogens does not occur, however.[245] The Epidemiologic Study of Cystic Fibrosis analyzed the relationship between pulmonary function and treatment strategies for pulmonary exacerbations; centers with patients in the upper quartile of pulmonary function treated pulmonary exacerbations more frequently than did centers in the lower quartile.[221]

Inevitably, *P. aeruginosa* develops increasing resistance to antibiotics. Molecular studies have confirmed that resistance generally develops in the infecting strains, rather than the acquisition of more resistant strains,[237] although superinfection with multidrug-resistant *P. aeruginosa* can occur as described subsequently.[209] Much interest has been generated in optimizing the treatment of pulmonary exacerbations caused by multidrug-resistant *P. aeru-*

ginosa using in vitro synergy testing. Most commonly, checkerboard broth microdilution assays and multiple combination bactericidal testing have been studied.[189,293]

At the Cystic Fibrosis Referral Center for Susceptibility and Synergy Testing at Columbia University, the activity of clinically achievable concentrations of pairs of antimicrobial agents with different mechanisms of action (e.g., a β-lactam agent paired with an aminoglycoside) is tested.[293] To determine if a combination of agents is synergistic, a fractional inhibitory concentration is calculated; synergy is defined as a fourfold reduction in the MIC of agents alone compared with agents in combination.[204] Most multidrug-resistant strains, defined as resistance to all agents in two or more classes of antibiotics,[295] can be inhibited by one or more combinations of agents, but the efficacy of this assay has not been validated in clinical trials. In contrast, a pivotal randomized trial to study the clinical efficacy of multiple combination bactericidal testing synergy studies was performed in Canada and Australia, wherein patients undergoing a pulmonary exacerbation were randomly assigned to treatment guided by multiple combination bactericidal testing versus regimens chosen by individual treating physicians.[2] No significant differences in the time that elapsed until the next pulmonary exacerbation or improvements in lung function between the two treatment strategies were noted.

CF experts have not arrived yet at a consensus regarding the efficacy of inpatient versus outpatient management of pulmonary exacerbations. Outpatient management has advantages; it is less costly, is less disruptive to patients and their families, and involves less risk of acquiring nosocomial pathogens. Patients treated at home were shown, however, to have longer treatment courses and less improvement in lung function.[228] Patients may improve more with hospitalization, as a result of better compliance with antibiotics, bed rest, chest physiotherapy, and bronchodilator treatments.[30]

Staphylococcus aureus and Methicillin-Resistant *Staphylococcus aureus*

The clinical utility of antistaphyloccocal agents is best shown by early studies of infants with CF treated with penicillin before the nearly universal acquisition of β-lactamases by *S. aureus*.[8,214] Infants treated during the antibiotic era had markedly improved survival rates. Experts advocate the use of a first-generation cephalosporin (e.g., cephazolin) or a semisynthetic penicillin (e.g., oxacillin) for treatment of a pulmonary exacerbation associated with MSSA.[122] Treatment trials justifying this approach are lacking, however.

Vancomycin generally is advocated for treatment of MRSA when this organism is considered a pathogen. Although no treatment trials in CF patients using linezolid have been conducted, a case series showed that adults with CF required 600 mg every 8 hours to provide desired pharmacokinetics.[29,298] Linezolid-resistant MRSA did emerge in a child with CF treated for approximately 3 months.[117] Because this agent is available orally and intravenously, the potential for "abuse" exists if clinicians do not use this agent judiciously. Several investigators in Europe have published small case series of various regimens for eradication of MRSA that have included oral agents (e.g., rifampin and fusidic acid) and inhaled agents (e.g., vancomycin).[120,198,201,317] Randomized treatment trials must be performed to establish the safety and efficacy of these strategies.

Burkholderia cepacia Complex

Management of *B. cepacia* complex is more problematic because of higher levels of intrinsic antibiotic resistance and a paucity of clinical trials for this pathogen. Initial isolates may be susceptible to ciprofloxacin, β-lactam antibiotics, chloramphenicol, trimethoprim-sulfamethoxazole, meropenem, and minocycline, but with the exception of *Burkholderia gladioli*, all *Burkholderia* spp. are resistant to aminoglycosides. Temocillin has been used in Europe to treat pulmonary exacerbation caused by *B. cepacia*.[344] Resistance can develop, however, which severely limits therapeutic options. As described for the management of *P. aeruginosa*, combinations of two or three agents are used to treat a pulmonary exacerbation. Even more prolonged courses may be required to improve lung function. Meropenem and minocycline were noted to have the most in vitro activity against 652 multidrug-resistant *Burkholderia* strains isolated from patients with CF and tested at the Cystic Fibrosis Referral Center, and inhibited 28 percent and 33 percent of strains.[197] Treatment may be guided by synergy testing of two or more drug combinations with an evident improvement in pulmonary function.[1,389]

Stenotrophomonas maltophilia and *Achromobacter xylosoxidans*

There are no published treatment trials for patients with CF who are harboring *Saltophilia* or *A. xylosoxidans* undergoing an exacerbation. Although definitive data confirming that these organisms are pathogens in CF are unavailable, clinicians target these multidrug-resistant, gram-negative bacilli if they are consistently recovered from the respiratory tract of an individual patient. At present, the Clinical Laboratory Standards Institute recommends testing ticarcillin-clavulanate, ceftazidime, minocycline, chloramphenicol, trimethoprim-sulfamethoxazole, and levofloxacin against *S. maltophilia*,[60] but CF strains frequently are resistant to these agents.[297]

Nonetheless, similar strategies are used to treat these organisms as described for *P. aeruginosa* or *B. cepacia* complex; two or more parenteral agents are chosen based on susceptibility testing and given for 2 to 3 weeks. In a survey of 263 isolates of *S. maltophilia* from 218 patients with CF isolated from 1995 to 1998, doxycycline, ticarcillin-clavulanate, piperacillin-tazobactam, and trimethoprim-sulfamethoxazole were most active and inhibited 78 percent, 39 percent, 18 percent, and 13 percent of isolates, respectively.[297,389] A survey of 94 *A. xylosoxidans* isolates from 77 patients showed that meropenem and imipenem, or piperacillin with or without tazobactam, were most active.[291]

Nontuberculous Mycobacteria

Treatment of NTM in patients with CF is challenging and guided by the clinical presentation and the mycobacterial species. Before therapy for NTM is initiated, patients should be treated aggressively for the classic CF pathogens they harbor to determine if they clinically improve without the need for specific NTM treatment. If NTM treatment is initiated, a careful history, physical examination, and pulmonary function tests should be done to determine the baseline status of the patient in efforts to monitor response to therapy. Susceptibility testing for NTM is not done routinely for patients who do not have CF. Given the increased antibiotic exposure in CF and the potential for the emergence of resistance, NTM strains isolated from patients with CF should undergo susceptibility testing at a reference laboratory. Treatment can be guided by the initial susceptibility profile.

No treatment trials have been published for NTM in CF, and generally regimens are comparable to the regimens used in patients without CF. Treatment of MAC is straightforward and includes a macrolide agent, rifabutin, and ethambutol. Treatment of *M. abscessus* is more complex. Many experts have a lower threshold for treating *M. abscessus*, given the greater apparent virulence of this species in CF, including after lung transplant.[52] Some experts recommend oral therapy, including a macrolide and linezolid because both have excellent in vitro activity, for stable patients.[35] Some experts add vitamin B_6 to prevent periph-

eral neuropathy, but the pathogenesis of peripheral neuropathy from linezolid is unknown. For more symptomatic patients, intravenous therapy, including cefoxitin or a carbapenem, depending on susceptibilities and amikacin, is recommended. Such patients need to have hearing assessed regularly. Because of the potential for different pharmacokinetic properties in CF and the fact that oral agents may not be well absorbed by patients with CF, serum levels for antimycobacterial agents should be strongly considered.[125,255]

Patients should be followed closely and have monthly sputum testing done for acid-fast bacillus smear and culture. The response to treatment generally is good for patients infected with MAC. Although the optimal duration of treatment has not been studied, experts recommend continuing therapy for 1 year after negative sputum cultures have been obtained. Cure for *M. abscessus* is less likely to occur, and the therapeutic goal may be long-term suppression. After clinical and mycobacterial improvement (i.e., a reduction in organism burden) has been achieved, intravenous antibiotics can be stopped and prolonged oral therapy with a macrolide can be initiated.

Allergic Bronchopulmonary Aspergillosis

Treatment of ABPA also can be very challenging. Although steroids are the treatment of choice because ABPA is immunologically mediated, the response to steroids varies and may have the undesirable consequence of diabetes in this vulnerable patient population. The oral antifungal therapies voriconazole[148] and itraconazole[230] have been used with reported response and toxicity, but no controlled trials have been performed.[223] Monitoring serum levels of itraconazole is desirable because this agent may be malabsorbed if the gastric pH is non-acidic.

Long-Term Suppressive Therapy

INHALED ANTIBIOTICS

Long-term suppressive antibiotic therapy has been used increasingly to treat patients with CF and infected with *P. aeruginosa* to prolong the time between pulmonary exacerbations and to slow the progression of lung deterioration. Numerous oral agents that are not cidal for *P. aeruginosa* (e.g., amoxicillin-clavulanate, trimethoprim-sulfamethoxazole, or tetracycline agents) are used empirically, sometimes in rotation, with anecdotal support coming from patients and physicians. The use of oral antibiotics is widespread; during a 6-month period, 90 percent of patients received at least one course of oral antibiotics.[41] No clinical trials support this practice, however, and it may contribute to antibiotic resistance.

For decades, inhaled agents such as tobramycin, colistin, gentamicin, amikacin, and various β-lactam antibiotics, including carbenicillin and cephaloridine, also have been used for management of chronic infections.[45] Definitive data supporting the use of inhaled agents were derived from a multicenter phase III, double-blind, placebo-controlled, randomized treatment trial of inhaled tobramycin (TOBI) in patients with CF and chronic *P. aeruginosa* infection.[267] Patients received 300 mg of tobramycin twice daily every other month for 6 months. The rationale for administering therapy every other month was to delay the emergence of resistance, to reduce cost, to increase compliance, and potentially to exploit the post-antibiotic effect of aminoglycosides. Subjects randomly assigned to inhaled tobramycin had a 10 percent improvement in FEV_1 compared with subjects who received placebo, who experienced a 2 percent decline in FEV_1. Treated patients also had a reduction in bacterial density, fewer days of hospitalization, and fewer days of intravenous antibiotics. In subset analyses, adolescents had the greatest improvement in pulmonary function. During treatment, patients receiving tobramycin had increased tinnitus that was unassociated with hearing loss. There was minimal systemic absorption of tobramycin because serum levels of tobramycin generally were less than 1 μg/mL.

Although this study confirmed the efficacy of inhaled tobramycin in CF patients with chronic *P. aeruginosa* infection, several questions remain. In routine antimicrobial susceptibility testing, the breakpoint for resistance to tobramycin is MIC of 16 μg/mL or greater. The aerosol route delivers 100-fold higher concentrations of tobramycin without toxicity, however; the median concentration of tobramycin in the phase III trial was 1200 μg/g of sputum.[267] Although the conventional breakpoint for resistance to tobramycin is irrelevant for drug delivered by inhalation, the breakpoint for inhaled tobramycin is unknown. Commercially available susceptibility tests do not measure MICs greater than 8 μg/mL. During the 6-month trial, resistance to tobramycin did occur; a trend was found toward higher MICs in the treatment group (median MIC, 2 μg/mL) compared with the placebo group (median MIC, 1 μg/mL). Only a few subjects had tobramycin MIC of 128 μg/mL or greater, however, and the impact of these higher MICs on clinical efficacy could not be determined because of the small number of such patients.

Investigators also examined the emergence of intrinsically tobramycin-resistant pathogens. Although treatment-emergent *B. cepacia*, *S. maltophilia*, and *A. xylosoxidans* did not increase in the participants randomly assigned to inhaled tobramycin, the incidence of treatment-emergent *Aspergillus* spp., but not ABPA, was increased.

Buoyed by the success of aerosolized tobramycin, other aerosolized agents have been studied. Most recently, aerosolized aztreonam has been developed for long-term suppressive therapy, with a proposed strategy of alternating with aerosolized tobramycin.[124] A phase III trial has been completed, but the results are not yet published.

MACROLIDE ANTIBIOTICS

Much interest has been generated more recently in the use of macrolide agents in CF[154] as long-term suppressive therapy. The rationale for macrolide therapy in CF stems from the successful treatment of diffuse panbronchiolitis with erythromycin, azithromycin, and clarithromycin.[177,186] Diffuse panbronchiolitis is a chronic lung disease, diagnosed primarily in Asian adults, with several clinical features similar to those found in CF, including progressive lung disease caused by mucoid and nonmucoid strains of *P. aeruginosa*.[330] Long-term administration of low-dose macrolide agents to patients with diffuse panbronchiolitis has reduced morbidity and mortality rates.

In vitro studies have provided the scientific rationale for this clinical efficacy. Although macrolides are not cidal for *P. aeruginosa*, subinhibitory concentrations of macrolide agents reduce the production of several virulence factors by *P. aeruginosa*,[218,219] including the formation of biofilm.[160,179] Macrolide antibiotics also may have an anti-inflammatory effect and decrease cytokine production by neutrophils, monocytes, and bronchial epithelial cells.[159,382]

Four azithromycin trials have been conducted in patients with CF so far.[59,101,292,375] Three trials were conducted in patients chronically infected with *P. aeruginosa*[101,292,375] and had similar results; all showed improvement in lung function using similar treatment regimens of azithromycin. Improvements in secondary outcomes, such as decreased hospitalization, decreased antibiotic use, and increased weight gain, also were noted. In the more recent study performed in 82 children and adolescents, most (63 of 82, 77%) with negative cultures for *P. aeruginosa*,[59] participants in the azithromycin-treated group had fewer pulmonary exacerbations and less oral antibiotic use. No differences in lung function or intravenous antibiotics were noted, however, in the

azithromycin-treated group compared with the placebo-treated group. A Cochrane review concluded that short-term (i.e., 3 to 6 months) azithromycin seemed effective in CF, but long-term safety and efficacy remain unknown.[319] Patients treated with azithromycin should be screened for NTM before initiating therapy and annually thereafter because of concern about macrolide resistance in these microorganisms.

LUNG TRANSPLANTATION

Lung transplantation currently is considered a viable therapy for selected patients with end-stage pulmonary disease of CF.[383] Bilateral lung, heart-lung, and living donor lobar lung transplantation all have been performed in patients with CF, but most operations in recent years have used the bilateral lung transplant approach with lungs from deceased donors. By 2006, more than 3000 individuals with CF had undergone lung transplantation worldwide, with nearly 250 procedures performed annually as of 2005.[350] The survival of lung transplant recipients with CF exceeds that of any other diagnostic group for all ages, with projected survival half-life of 6.2 years.[350] Patients with CF nonetheless present special challenges for successful lung transplantation. The life-threatening manifestations of CF generally are limited to the lungs except for patients with advanced liver disease with portal hypertension. Advantages of a lung transplant recipient with CF include relative young age, giving the potential of many years of productive life ahead. In addition, patients with CF have experience with complex medical regimens.

The optimal time to refer potential candidates for evaluation for lung transplant is difficult to determine because the natural history of CF cannot be predicted precisely. In May 2005 in the United States, the United Network for Organ Sharing introduced a new system of lung distribution, which assigns a lung allocation score to each potential candidate. Key parameters used in the lung allocation score include lung function testing, the need for oxygenation, the presence of diabetes mellitus, age, body mass index, the need for ventilatory support, hospitalization in the intensive care unit, and hemodynamic data from cardiac catheterization. Waiting time no longer is considered except in individuals younger than 12 years of age. There are no microbiologic criteria.[95]

Although transplanted lungs do not develop CF, they can become infected with the pretransplant pathogens because the trachea and paranasal sinuses continue to manifest the pathophysiology of CF. Lung transplant recipients with CF are at risk for development of infection via pretransplant microbial flora or newly acquired pathogens.[169,195,316,325] Controversy has ensued about whether microbiologic criteria, specifically pretransplant infection with fungi, NTM, or multidrug-resistant pathogens, should be considered contraindications to performing lung transplantation in patients with CF. Several centers have published their experiences with infections that developed from lung transplantation pathogens; they include invasive aspergillosis; sepsis with *S. maltophilia*, *B. cepacia* complex organisms, and *B. gladioli*; and sternal wound infection.[169] Other centers have reported that morbidity and mortality caused by *P. aeruginosa* infections post-transplant are not higher in patients with CF than in patients who do not have CF.[113,234]

A more recent study indicated that lung transplant recipients with CF and with panresistant, gram-negative organisms other than *Burkholderia* spp. had significantly decreased survival rates after transplantation than a comparable group with antibiotic-sensitive organisms.[142] Patients with CF who are infected with *B. cenocepacia* have increased morbidity and mortality rates from recurrent infection or sepsis or both after lung transplantation. Although Aris and colleagues[10] did not detect patient-to-patient transmission, increased mortality rates were noted with *B. cenocepacia* but not with multidrug-resistant *P. aeruginosa*. Patients infected with genomovar III had increased mortality rates after lung transplantation compared with patients infected with other genomovars before transplantation.[10]

Infection with *M. abscessus* before undergoing transplant can be associated with severe post-transplant complications and death.[55,343] Acquisition of NTM post-transplant can be treated successfully with prolonged combination of antimicrobial therapy.[55,203] Patients with CF are at risk of developing invasive aspergillosis after transplant, but at lower rates than patients without CF.[234,249] Many of these patients with CF were colonized with *Aspergillus* spp. before undergoing transplantations. Treatment with antifungal therapy after surgery should be considered. The U.S. Cystic Fibrosis Foundation held a consensus conference on lung transplantation in 1996.[383] The conferees concluded that microbiologic contraindications to transplantation were limited to active hepatitis B and human immunodeficiency virus. The decision to transplant patients infected with *B. cepacia* complex or multidrug-resistant *P. aeruginosa*, or colonized with *Aspergillus* spp., should be made on a case-by-case basis. Potentially, an understanding of the genomovar infecting a patient may be a useful predictor of mortality.

ANTI-INFLAMMATORY THERAPY

Inflammation associated with chronic bacterial colonization plays a crucial role in CF lung disease. Nonsteroidal agents and glucocorticoids have been used as potential medications for anti-inflammatory therapy. A randomized trial using oral prednisone (1 to 2 mg/kg every other day) showed a reduction in the rate of decline in pulmonary function of patients with CF but was associated with significant steroid-related side effects.[16] Three short-term trials using inhaled steroids have led to mixed results and no clear direction for long-term use.[18,232,357] A systematic review of inhaled steroids for CF was equivocal with respect to efficacy.[17] A multicenter randomized trial of withdrawal of inhaled steroids in CF did not find a difference in pulmonary exacerbations, infection with *P. aeruginosa*, or pulmonary function after inhaled steroids were discontinued.[19] High-dose ibuprofen (20 to 30 mg/kg twice per day) used over a 4-year period showed a decreased rate of decline in pulmonary function with few reported side effects.[181] Macrolide antibiotics decrease inflammation by modulation of inflammatory signaling pathways and decreased cytokine production from inflammatory cells.[98] Several anti-inflammatory agents, including antiproteases, statins, and antioxidants, have been proposed as potential therapies, but they remain under investigation and are not a part of routine clinical practice.

PREVENTION

IMMUNIZATIONS

The use of currently available routine childhood and adolescent vaccines is strongly advocated for patients with CF. Although patients with CF are not at increased risk of developing *Streptococcus pneumoniae* infections, they should receive the pneumococcal vaccine, 7-valent (Prevnar). Annual influenza vaccination is recommended for patients with CF and household members.[104,110] The RSV subunit vaccine, PFP-2 (purified fusion protein vaccine is a fusion glycoprotein that induces serum neutralizing antibodies) has been studied in children with CF for two RSV seasons.[260] Initial studies showed that the RSV subunit vaccine was safe and immunogenic and that it reduced the incidence of lower respiratory tract infections.[259] A large multicenter trial in patients with mild disease failed to show a reduction in the incidence of lower

respiratory tract infection, however.[258] A placebo-controlled trial of RSV monoclonal antibody (Palivizumab) was performed in 186 children.[320] Although Palivizumab was well tolerated, two children were hospitalized (one in each group); the study was not adequately powered for efficacy.

Most recently, the results of a phase III multicenter study of a *P. aeruginosa* vaccine were published.[89] Although this bivalent, antiflagella vaccine was immunogenic and was found to reduce the incidence of *P. aeruginosa* infection and serum antibody titers, it did not prevent chronic *P. aeruginosa* infection, and it did not affect lung function.

INFECTION CONTROL PRECAUTIONS

Although the sources of most pathogens in patients with CF are unknown, it is increasingly recognized that patient-to-patient spread and acquisition from the contaminated health care environment can occur. To date, reports of transmission of bacterial pathogens occurring between individuals with and without CF are rare.[127,152,210] Direct contact, indirect contact, and spread of droplets with infectious secretions all have been implicated as modes of transmission of CF pathogens. Risk factors for transmission were described first for *B. cepacia* complex as shown in Table 31–5.[51,132,194,253,254,346]

Perhaps of most concern have been several reports of clonal spread of *P. aeruginosa* among patients with CF.[209,303,354] These examples have involved obvious phenotypes that triggered an investigation of possible patient-to-patient spread, including an increase in ceftazidime-resistant *P. aeruginosa*[53] or initial colonization of young children with mucoid strains of *P. aeruginosa*.[13,233] These reports have led CF centers in Europe to favor cohorting and segregating patients with *P. aeruginosa*, particularly patients with antibiotic-resistant strains, in hospital and clinic settings.[114,178,209] In the United States, infection control strategies have focused on containment of respiratory tract secretions as described subsequently.[296] Finally, occasional cases of patient-to-patient spread of other potential pathogens, including *S. maltophilia* and *A. xylosoxidans*, have been reported in patients with CF.[276,353]

The U.S. Cystic Fibrosis Foundation convened an expert panel to develop revised recommendations for infection control that addressed inpatient, outpatient (i.e., CF clinic and pulmonary function test laboratories), and non–health care settings, as so much CF care is delivered in the home. These recommendations have implications for treatment, transplantation, and the psychosocial well-being of patients, families, and staff. Several strategies were emphasized (Table 31–6). The guidelines emphasized that all patients with CF could harbor potentially transmissible respiratory tract pathogens, and containing respiratory tract secretions is of paramount importance.

The consensus is that patients harboring *B. cepacia* complex should be cared for apart from other patients with CF and not grouped together because of concern that some strains of *B. cepacia* complex may be more virulent and replace other strains.[200] Patients are hospitalized in single rooms and seen in outpatient settings geographically or temporally apart from other patients with CF. Similarly, patients with CF and MRSA in the respiratory tract should be placed in private rooms without access to common areas.

CONCLUSION

The microbiology of patients with CF is complex and changing. Although the pathogenesis of lung infections is still under active investigation, the current hypothesis suggests multiple etiologies. Appropriate microbiologic processing of respiratory tract specimens is crucial to ensure an accurate understanding of the epidemiology of CF lung disease and to provide appropriate treatment and infection control. Current treatment strategies are directed largely at management of deteriorations of pulmonary function, but increasingly strategies are directed at prevention and preservation of lung function.

TABLE 31–5 Risk Factors Associated with Acquisition of *Burkholderia cepacia* Complex

Risk Factors	Comment
Attendance at CF summer camp[253]	Risk of acquisition (6% incidence) increased with time spent at camp and prevalence of *B. cepacia* at the camp
Slept in same cabin	
Shared a personal item	
Danced with *B. cepacia*–infected camper	
Attendance at summer educational program[194]	3 (20%) of 15 patients acquired same ribotype
Participation in adult CF group	Disband meetings thought to represent extensive social contact
Social contact[132]	
Kissing	
Intimate contact	
Prolonged car rides	
Sibling with *B. cepacia* complex	
Handshaking	2 of 68 cultures positive, 1 from patient and 1 from investigator[254]
	3 patients' hands became contaminated after coughing[132]
Inpatient exposures	Risk of acquisition increased if hospitalized within 3 mo and if hospitalized longer
Recent hospitalization[254]	Interviews with health care workers indicated poor adherence to contact precautions
Use of specific shower	
Sharing hospital room with another patient infected with *B. cepacia*	
Cared for by a medical student	
Respiratory therapy equipment	Reservoirs of large-volume nebulizers grew *B. cepacia*
Sharing equipment	
Hospital nebulizers	
Spirometer[161]	
Mouthpiece filters[132]	

CF, cystic fibrosis.

TABLE 31–6 Infection Control Strategies for Cystic Fibrosis

Guideline	Setting		
	Inpatient	*Outpatient*	*Non–Health Care*
Quarterly cultures of respiratory tract		X	
Appropriate processing of CF respiratory tract cultures	X	X	
Educate patients and families about proper hand hygiene	X	X	X
Implement contact precautions for MDROs, including MRSA	X	X	
Hospitalize patients with MDROs in single-patient room	X	X	
Segregate patients with *B. cepacia* complex from other CF patients	X	X	X
Clean and disinfect respiratory therapy equipment	X	X	X
Avoid socialization among CF patients	X	X	X
Maintain at least 3 ft between CF patients to prevent droplet transmission	X	X	X

CF, cystic fibrosis; MDROs, multidrug-resistant organisms; MRSA, methicillin-resistant Staphylococcus aureus.

INFECTIONS OF THE HEART

CHAPTER 32

INFECTIVE ENDOCARDITIS

Jeffrey R. Starke

Infective endocarditis results when microorganisms adhere to the endocardial surface of the heart. This process usually occurs on heart valves, although septal defects and mural surfaces can be affected. Most episodes of endocarditis begin on endocardium that has been altered by congenital defects, previous disease, surgery, or trauma. The clinical manifestations depend on the degree of compromise of cardiac function and the occurrence of embolic phenomena. Although bacteria are responsible for most cases, instances of infective endocarditis caused by fungi, chlamydiae, rickettsiae, and perhaps viruses have been described. Advances in the practice of general pediatrics and cardiology during the past 3 decades have contributed to changes in the predisposing conditions and etiologic agents of "modern" infective endocarditis. Before the 1950s, rheumatic fever was the major underlying condition, but its incidence has declined greatly since then.[306] Concurrently, improvements in the medical and surgical management of children with congenital heart disease have increased survival rates. At present, approximately 80 to 90 percent of children with infective endocarditis have congenital heart disease.* Many cases occur after cardiac surgery, especially for replacement of valves and creation of shunts with prosthetic materials.[338] The reported incidence of infective endocarditis in neonates is increasing, probably because of the use of sophisticated and highly invasive techniques in neonatal intensive care nurseries.[93,159,327,397]

Historically, infective endocarditis has been classified as acute or subacute, based on the progression of untreated disease.[432] The acute form has a fulminant course, with high fever, systemic toxicity, and death from sepsis in several days to 6 weeks. The most common etiologic agents are *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae*. Children with the acute form often have no underlying cardiac lesion. Subacute disease usually occurs in patients with previous valvular disease or those who have undergone cardiac surgical intervention. It is characterized by a more indolent course (6 weeks to several months) and with low-grade fever, vague systemic complaints, and various embolic phenomena. Viridans streptococci are the most common etiologic agents. This classification ignores the frequent overlap in clinical manifestations caused by various organisms, especially the staphylococci and fungi, which are causes of an increasing number of subacute cases in the postcardiac surgical setting. Classification based on specific etiologic agents is preferable because it has implications for the usual clinical course, predisposing factors, and appropriate medical and surgical management.[217]

EPIDEMIOLOGY

The incidence of infective endocarditis in adults has been difficult to determine because the methods of study and criteria for diagnosis vary among series.[30,118] Accurate figures on the incidence of infective endocarditis in children are difficult to obtain. The most common method of reporting the incidence in pediatric series expresses the number of cases of infective endocarditis as the numerator and the total number of hospital admissions during the analyzed period as the denominator. Zakrzewski and Keith[539] reported an incidence of endocarditis of 1 in 4500 pediatric admissions at the Hospital for Sick Children in Toronto from 1952 to 1962, whereas Van Hare and colleagues[507] at Case Western Reserve in Ohio found an incidence of 1 in 1280 in the period from 1972 to 1982. In a large series from Boston Children's Hospital spanning the period between 1933 and 1972, the incidence before 1963 was 1 in 4500 pediatric admissions, whereas that for 1963 to 1972 was 1 in 1800 admissions.[230] A study from a children's hospital in Australia reported an incidence of 1 in 4500 hospital admissions between 1971 and 1983.[446] More recently, one Japanese center reported an annual incidence of 0.9 cases per 1000 children seen at the cardiology clinic.[156] Although differences in referral patterns at these centers may have introduced bias into these figures, the incidence of infective endocarditis in children appears to be rising. This rise may be explained by the increased survival rate of children with all forms of cardiovascular disease and an increase in the percentage of cases that occur after cardiac surgery and are related to intravascular catheters.[143,238,420] Early surgical correction of many types of congenital heart disease along with effective perioperative antibiotic prophylaxis regimens ultimately may lower the incidence of postoperative infective endocarditis. However, the increasing use of invasive therapeutic modalities, especially intravenous catheters and pacemakers, may lead to an increased incidence of health care–associated endocarditis.[143,312,398]

The average age of children with infective endocarditis is increasing, a phenomenon that may reflect the longer life expectancy created by improved therapy for children at risk.[477] From 1930 to 1950, the mean age for children with infective endocarditis was close to 5 years.[230] Between 1960 and the present, it increased to 8.5 and then to 13 years.[156,167,264,311,420] The number of reports of infective endocarditis in children younger than 2 years had been small but has increased significantly since the late 1980s.[39,167,327,524] The clinical course of infective endocarditis in these young children often is atypical, and some cases are diagnosed at autopsy.[230,375] Before the 1950s, this disease was a rare event in neonates, with only eight autopsy cases reported.[297] Several reports suggest a rapidly increasing rate associated with the development of intensive supportive care in neonates.[46,317,332,362,363] Symchych and colleagues[475] found a 3 percent incidence of bacterial endocarditis among all neonatal autopsies. Endocarditis in neonates frequently occurs on the tricuspid valve when associated with an indwelling central venous catheter.[493] Congenital heart defects also predispose neonates to the development of infectious endocarditis.[93]

Any form of structural cardiac disease may predispose to infective endocarditis, especially with disorders associated with

From Kaplan, E. L.: Infective endocarditis in the pediatric age group: An overview. In *Kaplan, E. L., and Taranta, A. V. (eds.): Infective Endocarditis: An American Heart Association Symposium. Dallas, American Heart Association, 1977, pp. 51-54.*

turbulence of blood flow.[163,454] In autopsy and clinical series, children with ventricular septal defect, tetralogy of Fallot, left-sided valvular disease, and systemic-pulmonary arterial communication were at highest risk, whereas those with pulmonary stenosis, coarctation of the aorta, and secundum atrial septal defect were at low risk.[412,420] Hypertrophic obstructive cardiomyopathy rarely is associated with infective endocarditis.[76] Isolated pulmonic or tricuspid valve endocarditis can occur in "otherwise normal" children and adolescents with sepsis or focal bacterial infection,[351] but usually it is associated with congenital heart disease, intravenous catheters, or intravenous drug abuse.[67,348] A bicuspid aortic valve is recognized as an important risk factor for the development of infective endocarditis, especially in elderly men.[318] The underlying heart diseases in 266 pediatric cases of infective endocarditis are listed in Table 32–1.[238]

A cooperative study on the natural history of aortic stenosis, pulmonary stenosis, and ventricular septal defect reported data from a controlled pediatric population collected over a period of 4 to 15 years.[165] In patients not undergoing surgical correction, the risk of acquiring endocarditis by 30 years of age in those with ventricular septal defects was 9.7 percent versus 1.4 percent for aortic stenosis and 0.9 percent for pulmonic stenosis. Aortic valvotomy in children with aortic stenosis actually increases the relative risk, whereas successful repair of ventricular septal defect significantly decreases long-term susceptibility to infective endocarditis.[166] Similarly, endocarditis is an extremely rare occurrence after ligation of patent ductus arteriosus has been performed. At present, palliative systemic-to-pulmonary shunting is the surgical procedure most often complicated by infective endocarditis.[420] In a review of 115 patients with tetralogy of Fallot, Kaplan and colleagues[240] reported an 8 percent incidence of infective endocarditis after placement of a Pott shunt.

The increasing use of prosthetic valves and valved conduit repairs in children with complex heart disease may lead to a larger number of cases of infective endocarditis in the future.[239,245,483] Most medical centers report an incidence of prosthetic-valve endocarditis of 2 to 4 percent after surgery,[57,168,415,454] with the aortic and mitral valves affected most frequently.[219,299]

Older studies arbitrarily divided prosthetic-valve endocarditis into two categories—early and late—based on whether the infection occurred within 60 days of valve placement or later.[34] The rationale for categorizing by time was based on apparent differences in bacteriologic, pathogenetic, and prognostic associations. So-called early cases most often were caused by coagulase-negative staphylococci (CONS), gram-negative bacilli, and fungi, whereas oral and enterococcal streptococci, along with staphylococci, predominated in late cases.[243] These older reports suggested that early cases were acquired by contamination of an intraoperative valve or were secondary to postoperative extracardiac infections, whereas late cases were acquired by the same mechanisms as native-valve endocarditis. Nosocomial bacteremia that develops at any time after the patient has undergone valve placement is a significant risk factor for development of endocarditis.[131,502] Finally, the mortality rate was thought to be higher in early versus late infection.

However, more recent studies have blurred this arbitrary time distinction between early and late prosthetic-valve endocarditis.[57,219] The risk probably is highest in the first 6 to 12 months and decreases to its lowest point beyond 1 year after valve replacement. CONS are the dominant organisms both before and after the 60th postoperative day.[57,242] Clinical and epidemiologic data also suggest that prosthetic-valve infection caused by staphylococci within the first year after placement probably is acquired at the time of surgery.[34] Identified risk factors for the development of prosthetic-valve endocarditis in adults include native-valve endocarditis, black race, male sex, a mechanical (versus biologic) prosthesis, and prolonged cardiopulmonary bypass time[219]; no comparable information is available for children.

Mitral valve endocarditis occurs frequently on an anatomically normal valve in patients with other predisposing factors.[144] An association between mitral valve prolapse and infective endocarditis has been recognized in adults and children. This heart lesion is detected with increasing frequency in adolescent girls and may be only one component of a developmental syndrome.[438] In adults, 40 to 50 percent of cases of infective endocarditis associated with isolated insufficient mitral valves occur in patients with mitral prolapse.[88] In some series of native-valve endocarditis, mitral valve prolapse has been the most common underlying lesion.[318] The reported incidence of infective endocarditis in patients with mitral valve prolapse has varied markedly among studies, from low rates of 14 per 100,000 per year to 5 of 58 patients monitored prospectively for 9 to 22 years.[199] A retrospective epidemiologic analysis involving matched cases and controls yielded an odds ratio of 8.2, indicative of a substantially higher risk for development of endocarditis in patients with mitral valve prolapse than in normal controls.[85]

That the risk of developing infective endocarditis is not uniform for all patients with mitral valve prolapse has become apparent. The risk is increased in patients with a preexisting systolic murmur (but not for those with an isolated click and no murmur), echocardiographically demonstrated regurgitation, and valvular redundancy.[95,298,308] The signs and symptoms of endocarditis associated with mitral valve prolapse may be more subtle than those of other types of left-sided endocarditis.[144,360] However, significant complications are relatively common occurrences and sometimes require valve replacement during the acute illness or during convalescence.[19,461]

Fungal endocarditis is a rare disorder in children but should be suspected in certain clinical and epidemiologic settings. It is more likely to occur after cardiac surgery and rarely occurs on native heart valves. It occurs more commonly in neonates treated in intensive care settings than in older children.[93] Other predisposing factors include (1) the presence of an indwelling vascular catheter, (2) prolonged use of antibiotics, (3) intrinsic (immunodeficiency diseases, malignancy, malnutrition) or extrinsic (corticosteroids, cytotoxic drugs) immunosuppression, (4) bowel surgery resulting in transient fungemia, (5) intravenous drug abuse, and (6) preexisting or concomitant bacterial endocarditis.

Many conditions other than structural heart disease predispose children to the development of infective endocarditis. The most important is the presence of an indwelling central venous catheter, especially in patients who are seriously ill or immunocompromised.[159,167,284,496,523] The catheter acts as a foreign body and presumably causes microscopic damage by abrading endocardial and valve surfaces; such damage results in nonbacterial thrombotic vegetation.[25] Infection of intracardiac pacemaker

wires also can lead to endocarditis.[13] Infection acquired during the placement procedure and infection of the pacemaker pouch are most common. Infective endocarditis, usually of the tricuspid valve, has developed in children with ventriculoatrial shunts placed for the treatment of hydrocephalus.[238] In patients with arteriovenous fistulas created for hemodialysis, bacterial vegetations may develop in the fistula and on heart valves.[276,401] Rarely, penetrating wounds or foreign bodies can initiate endocarditis.[202,307] Piercings of various body parts also have been associated with endocarditis.[2,394] One important group of patients with an increased risk for development of infective endocarditis is intravenous drug abusers.[314,526] In this group of patients, two thirds have no evidence of underlying heart disease. A predilection for involvement of the tricuspid valve, followed by the mitral and aortic valves, has been noted.[155] Roentgenographic evidence of septic pulmonary emboli and signs of tricuspid insufficiency dominate the clinical findings.[432] Within this group of patients, increased rates of infective endocarditis and mortality are associated with infection by human immunodeficiency virus (HIV), particularly as CD4 cell counts fall to less than 200/mm^3.[389]

Although the incidence of infective endocarditis in children may be rising, the prognosis has improved dramatically during the past several decades. Current mortality rates usually are close to 10 percent.[341,420,437] Most survivors remain hemodynamically stable at long-term follow-up.[147,437] However, patients who experience infective endocarditis appear to be at higher risk for developing recurrent endocarditis than are those with similar cardiac abnormalities who have not had previous endocarditis.[454] The patient's functional class before treatment appears to be most predictive of long-term functional status. In one study, 22 percent of children who survived infective endocarditis required surgery related to the infection, including vegetectomy, evacuation of a hematoma, atrioventricular valve replacement, and placement or replacement of a graft or intracardiac shunt.[420]

PATHOPHYSIOLOGY

Clinical observations, autopsy studies, and work with experimental animal models have demonstrated that the occurrence of several independent events is required for the development of subacute infectious endocarditis. The endocardial surface usually is disrupted by stress or injury commonly caused by the turbulence of blood. This surface damage results in the deposition of fibrin and platelets, which form nonbacterial thrombotic vegetations. If bacteria adhere to these deposits, infective endocarditis will result. The surface of the infected vegetation becomes protected by a cover of fibrin and platelets. A tremendous proliferation of organisms (as many as 10^9 colony-forming units per gram) may ensue.[119] The protective sheath isolates the organisms from the action of host neutrophils and antibiotics. The clinical manifestations and complications of infective endocarditis are related to both the hemodynamic changes caused by local infection and the occurrence of embolization and metastatic infection.

In experimental animals, the valvular surface must be damaged, usually by an intravenous catheter, to produce infective endocarditis.[20] The first step in the pathogenesis of subacute infective endocarditis in humans is the development of hemodynamic factors that favor endocardial damage. In an autopsy study of 1024 patients with infective endocarditis, Lepeschkin[277] showed that the location of the endocardial lesions correlated with the impact of pressure; this finding makes a strong argument for the role of mechanical stress as a critical factor in the evolution of the lesions. When associated with valvular insufficiency, infective endocarditis usually occurs on the atrial surface of the mitral valve and the ventricular surface of the aortic valve. Injection of a bacterial aerosol into the air stream passing through a Venturi tube demonstrates how high pressure drives an infected fluid into a low-pressure sink.[407] This process establishes maximal deposition of bacteria in the low-pressure sink immediately beyond the orifice. Mitral insufficiency creates a Venturi effect when blood is driven from the high-pressure left ventricle into a low-pressure atrium; maximal deposition occurs around the mitral annulus on the atrial side. Similarly, with aortic valve insufficiency, the high-pressure source is the aorta and the low-pressure sink is the left ventricle, which leads to deposition on the ventricular surface of the valve.

Lesions also are created more directly by a jet stream causing endocardial damage. For example, in a small, restrictive ventricular septal defect with a left-to-right shunt, a Venturi effect leads to the development of lesions on the right ventricular septal side of the defect, whereas secondary lesions created by the jet effect are located on the right ventricular wall opposite the defect.[518] Heart defects with a surface area sufficiently large to prevent a significant pressure gradient and those in which smaller volumes minimize the gradient do not create the jet and Venturi effects. This difference helps to explain the rarity of endocarditis in patients with atrial septal defects and the increased risk of infection complicating small, but not large, ventricular septal defects.

Once endocardial damage has occurred, collagen is exposed, and platelet and fibrin deposition ensues in a manner analogous to formation of the primary plug of normal hemostasis after vascular injury.[228,519] The sterile platelet-fibrin thrombus that is formed subsequently is referred to as a nonbacterial thrombotic vegetation. In experimental animals, many exogenous stresses, including exposure to cold, high altitude, high cardiac output states, hormonal manipulations, and passage of a sterile catheter across a heart valve, lead to formation of this lesion. Formation of the vegetation reflects two pathogenic mechanisms: hypercoagulability and endothelial damage.[432] To establish experimental infective endocarditis without initial formation of the vegetation is nearly impossible. Microscopic examination demonstrates that this lesion is the one to which microorganisms attach during the early stages of experimental endocarditis. Nonbacterial thrombotic vegetations have been found in both adults and children with malignancy, chronic wasting diseases, uremia, connective tissue diseases, and congenital heart disease and after the placement of intracardiac catheters,[291,367] and they have been associated with embolism and infarction in distant organs.[42]

Once a nonbacterial thrombotic vegetation has been established, transient bacteremia or fungemia may result in colonization of the lesion. Transient bacteremias are common occurrences, especially with traumatization of a mucosal surface. Table 32–2 lists the incidence of bacteremia in adults and children after various procedures.[130,405] The bacteremia usually is of low grade and is proportional to the amount of trauma produced by the procedure and the number of organisms inhabiting the surface. In addition, "silent" bacteremia probably occurs frequently. Many persons have circulating antibodies to their own oral flora, as well as an increase in peripheral T cells sensitized to the flora of their dental plaque.[432] Some children with congenital heart disease may be at increased risk for having gingival colonization and subsequent development of bacteremia with organisms associated with infectious endocarditis, such as the HACEK *(Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae)* microbes.[457]

The ability of microorganisms to adhere to the platelet-fibrin thrombus is a critical factor in the development of infective endocarditis.[100,188,228] In a canine model, *S. aureus* and the viridans streptococci, which frequently cause infective endocarditis, adhere more readily to normal aortic leaflets than do organisms uncommon in endocarditis.[178] Within isolates of *S. aureus*, strains devoid of microencapsulation are less capable of inducing endocarditis in an experimental model than are encapsulated strains.[21] Specific products released by these organisms, including dextran,

TABLE 32–2 Bacteremia after Various Procedures in Adults and Children

Initiating Event	Percentage of Positive Blood Cultures (%)	Predominant Organisms
Dental extraction (children)	30-65	*Streptococcus*, diphtheroids
Chewing gum, candy, paraffin	0-51	*Streptococcus*, *Staphylococcus epidermidis*
Tooth brushing	0-26	*Streptococcus*

mannan, teichoic acid, and slime, may enhance their ability to colonize the vegetation.[228,254] The amount of dextran produced by various viridans streptococci in broth correlates with both their adherence and their ability to produce endocarditis in the rabbit model.[333,435] *Candida albicans* is readily adherent and produces infective endocarditis in rabbits more easily than does *Candida krusei*, a nonadherent yeast rarely implicated in human infective endocarditis.[433] In addition, endocarditis-producing strains of streptococci and staphylococci are more potent stimulators of platelet aggregation than are other bacteria that do not produce infective endocarditis.[84,197,333] This action may accelerate the formation of an infected vegetation or may increase the removal of organisms from the circulation. The importance of adherence by organisms has been studied by pre-incubating organisms with many classes of antibiotics. After incubation at subinhibitory concentrations, adhesion of streptococcal species to fibrin-platelet matrices and damaged canine valves is decreased.[436] Antibiotics may prevent development of infective endocarditis by both bacterial killing and inhibition of adherence to the vegetation.[172]

Host tissue factors undoubtedly play an important role in adherence of bacteria to the developing thrombus. Once bacteria become adherent to a nonbacterial thrombus, activation of the coagulation system ensues. Some organisms that produce endocarditis may be able to initiate procoagulant activity through microbial enzymes. Activation of the intrinsic coagulation pathway is triggered by exposed connective tissue components and platelet aggregation.[254] However, activation of the extrinsic coagulation pathway probably is the major stimulus for growth of vegetations. Elements of the extracellular matrix, including fibronectin, laminin, and collagen, have been shown to facilitate the adherence of bacteria on fibrin-platelet matrices.[472,495] Fibronectin may be the host receptor for organisms within the nonbacterial thrombotic vegetation.[265,293] Laminin-binding proteins have been found on the cell walls of organisms recovered from patients with endocarditis.[451]

The platelet-organism interaction is complex and not understood completely. *Streptococcus sanguis* produces two cell surface antigens that promote platelet aggregation: a class I antigen promotes adhesion of *S. sanguis* to platelets, whereas coexpression of a class II antigen promotes platelet adhesion or aggregation.[198] The induced platelet aggregation appears to be an important determinant of further development of vegetation and progression of disease in experimental endocarditis. In addition, production of streptococcal exopolysaccharide inversely correlates with platelet adhesion while inhibiting aggregation, thus indicating that surface molecules may enhance endocarditis at only certain pathogenic steps.[469] Platelets also may be involved in host defense within the vegetation. After exposure to thrombin, platelets may release microbicidal proteins with bactericidal activity against some gram-positive cocci; resistance to these proteins may be a virulence factor for *S. aureus* in the development of endocarditis.[357,536]

As bacterial colonization of a nonbacterial thrombotic vegetation progresses, it enlarges by further bacterial proliferation and platelet-fibrin deposition (Fig. 32–1).[336] Kissane [259] described three histologic zones: (1) necrotic endocardium; (2) a broad zone of bacterial colonies, pyknotic nuclear debris, and fibrin; and (3) a thin coating on the surface of fibrin and leukocytes. The location of bacterial colonies below the surface and the minimal infiltration by phagocytic cells create an environment of impaired host resistance that results in extreme bacterial proliferation. The structure of the vegetation diminishes the penetration of antibiotics into the bacterial layer. In addition, the metabolic activity of bacteria within this lesion is slowed, thus rendering antibiotics less effective. The formation of vegetations and erosion of heart valves may cause valvular incompetence and thereby may result in cardiac failure.

Immunopathologic factors may have important roles in both the development and sequelae of infective endocarditis.[32] The susceptibility of a gram-negative bacillus to complement-mediated bactericidal activity is critical to its potential to create endocarditis; only "serum-resistant" organisms produce infective endocarditis in humans and experimental animals.[117] Gram-positive cocci are a more frequent cause of infective endocarditis than are gram-negative bacilli. Gram-positive organisms are resistant to this bactericidal activity; phagocytosis is required for killing.

The frequent presence of hypergammaglobulinemia, splenomegaly, and monocytes in the blood of patients with infective endocarditis indicates stimulation of the humoral and cellular immune systems. Macroglobulins, cryoglobulins, and agglutinating, opsonic, and complement-fixing antibodies have been associated with infective endocarditis.[204,273] Studies in animals pre-immunized with heat-killed streptococci before aortic valve trauma and infection are induced suggest that circulating antibody has a protective role.[434,503] However, antibody to *S. aureus* or *Staphylococcus epidermidis* does not prevent the development of endocarditis in immunized animals, perhaps because this antibody does not enhance opsonophagocytosis.[432] The continuous antigenic challenge created by intravascular organisms leads to increased production of specific antibody (including opsonic,

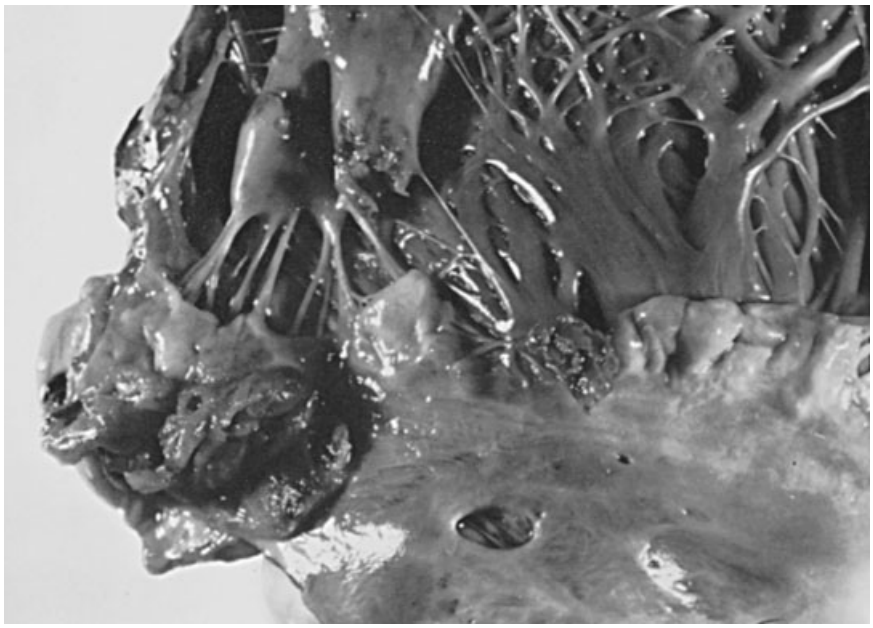

Figure 32–1 Subacute endocarditis of the mitral valve with vegetation and rupture of the papillary muscle caused by *Staphylococcus aureus*. *(Courtesy of Dr. Edith P. Hawkins, Texas Children's Hospital, Houston.)*

agglutinating, and complement-fixing antibodies), cryoglobulins, macroglobulins, and antibodies to bacterial heat shock protein,[391] as well as to the subsequent formation of circulating immune complexes. These complexes are found with increased frequency in patients with a long duration of illness, hypocomplementemia, extravalvular manifestations, and right-sided disease.[36] Quantitative levels of circulating immune complexes may be helpful in distinguishing endocarditic from non-endocarditic sepsis and in monitoring anti-infective therapy. Effective treatment usually leads to a prompt decrease in these levels,[35] whereas relapses may be characterized by rising titers.[246] The diffuse glomerulonephritis occasionally noted with infective endocarditis is caused by subepithelial deposition of immune complexes and complement.[184] Immune complexes can be demonstrated in some diffuse purpuric lesions seen with endocarditis.[292] Bacterial antigens have been found within these complexes.[216]

Further evidence of stimulation of the immune system in infective endocarditis is the development of rheumatoid factor in approximately 50 percent of adults with disease lasting longer than 6 weeks.[525] Titers of rheumatoid factor correlate with hypergammaglobulinemia and, as with immune complex levels, decrease with therapy and increase during relapse. The role of rheumatoid factor in the disease process is unknown, but it may be involved by blocking immunoglobulin G opsonic activity, stimulating phagocytosis, or accelerating microvascular damage.[432] Anti-nuclear, anti-endocardial, anti-sarcolemmal, and anti-myolemmal antibodies also have been identified in patients with infective endocarditis; their role in pathogenesis is unclear.[300]

The pathologic changes that occur in the heart in association with infective endocarditis are secondary to local extension of the infection. The vegetations vary in size from a millimeter to several centimeters; frequently they are singular, but they may be multiple. Valvular stenosis may result from large lesions. Vegetations secondary to certain organisms, especially *Candida*, *Haemophilus*, and *S. aureus* in acute cases, often are large and friable, with a propensity for embolization.[537] Ulcerative lesions may occur and may lead to perforation of the valve and subsequent congestive heart failure. Other local complications include rupture of the chordae tendineae or papillary muscle (see Fig. 32–1), valve ring abscess with subsequent fistula formation and pericardial empyema,[47,62] aneurysms of the sinus of Valsalva or ventricle,[75,160,430] myocarditis, and myocardial infarction.[135] Persistent fever occurring during appropriate medical therapy for infective endocarditis may reflect a persistent vegetation, especially with right-sided disease, or extension of infection into a valve ring and adjacent structures.[113] In such cases, surgery frequently is required.

The pathologic changes in distant organs usually are secondary to embolization with subsequent infarction or metastatic infection. In many cases of infective endocarditis, the causative organism is of low pathogenicity; infections caused by septic emboli often are low-grade because of the reduced propensity of these organisms to invade tissue. However, the emboli in acute *S. aureus* endocarditis frequently cause severe metastatic infections and overwhelming sepsis. Emboli from right-sided heart lesions lodge in the lungs and cause pulmonary infarcts and abscesses, which usually are small and multiple. Left-sided lesions may embolize to any organ but most commonly affect the brain, kidney, spleen, and skin.[260,352] Cerebral emboli have been detected in 30 percent of cases in adults and children and have caused infarction, abscess, mycotic aneurysm, subarachnoid hemorrhage, meningitis, and acute hemiplegia of childhood.[59,180,191,234,313,422] Kidney abscess is a rare occurrence, but infarcts are noted in most patients at autopsy.[330] Amyloidosis involving primarily the kidneys is a rare complication of chronic infective endocarditis.[196] Splenic abscess also is a rare event but can be a fatal complication if undetected.[232] The most common manifestation of embolization to the skin is petechiae. Janeway lesions are septic emboli consisting of bacteria, neutrophils, necrosis, and subcutaneous hemorrhage. Osler nodes are areas of thrombosis and necrosis. They may be related to both immune complex deposition and septic emboli.[5]

CLINICAL MANIFESTATIONS

The signs and symptoms of infective endocarditis are determined by the extent of local cardiac disease, the continuous bacteremia, and the degree of involvement of distant organs as a result of embolization, metastatic infection, and circulating immune complexes.[24] Consequently, the clinical findings are highly variable and mimic those of many other diseases.[418] Unexplained embolic phenomena in any organ should suggest the diagnosis of endocarditis, especially in children with known heart disease.

Patients with acute bacterial endocarditis initially may be seen with florid sepsis; the endocarditis is diagnosed at autopsy. The indolent manifestations of subacute endocarditis may evolve for weeks or months before medical care is sought. Endocarditis frequently occurs in children with preexisting heart disease, so subtle changes in cardiac function may be difficult to detect early in the course. Table 32–3 lists the frequency of the major clinical manifestations of bacterial endocarditis in infants and children.

Fever is the most common symptom of infective endocarditis, but it is absent in 10 percent of cases. It usually is of low grade and has no specific pattern. Chills may accompany the fever, but they rarely are seen in children. Persistent fever during antimicrobial therapy is an uncommon occurrence. Prolonged (>2 weeks) fever is associated with certain etiologic agents (*S. aureus*, gram-negative bacilli, fungi), with culture-negative endocarditis, and with complications such as embolization of major vessels, intracardiac or peripheral abscess, tissue infarction, a need for cardiac surgery, and a higher mortality rate.[48,274] Nonspecific symptoms such as malaise, anorexia, weight loss, and fatigue are common findings. Arthralgia occurs in 24 percent of patients. The arthralgia frequently is multiple and most commonly affects the large joints. Although adults initially may have synovitis,[82] this finding is rare in children. Osteoarticular infection in association with infective endocarditis in adults occurs almost exclusively in intravenous drug users.[429] It is seen very rarely in children. Gastrointestinal complaints are noted in 16 percent of cases and include nausea, vomiting, and abdominal pain. Chest pain occurs in approximately 10 percent of older children and generally is mild and nonspecific. Although chest pain usually is related to diffuse myalgias, it may be secondary to pulmonary complications or cardiac lesions, especially if the tricuspid valve is involved.

Heart murmurs occur in more than 90 percent of children with infective endocarditis, but most patients have underlying heart disease with existing murmurs. The appearance of a new murmur or appreciation of a significant change in a previous one occurs in only 25 percent of cases. Significant blood flow turbulence caused by compromised valvular function must have occurred for a murmur to be detected or to change. The frequent absence of changes in the cardiac examination early in the disease contributes to the long average delay in establishing the diagnosis, especially in children with preexisting heart disease. Congestive heart failure occurs in 30 percent of children with infective endocarditis and is especially common in those in whom a new murmur of valvular insufficiency develops. Endocarditis should be suspected in any child who has rheumatic or congenital heart disease and unexplained deterioration in cardiac function. Although valvular regurgitation is the most common hemodynamic complication of endocarditis, significant obstruction of a valve or shunt requiring rapid surgery rarely occurs.[74]

Neurologic signs and symptoms are reported in approximately 20 percent of children with endocarditis. These signs and symptoms may dominate the clinical findings, especially in patients with endocarditis caused by *S. aureus*.[191,422] The sudden development of cerebral lesions in an infant or child should suggest this diagnosis. The manifestations are those that commonly accompany a cerebral infarct or abscess, namely, acute hemiplegia of childhood, seizures, ataxia, aphasia, sensory loss, focal neurologic deficits, and alterations in mental status.[59] They may be the initial features of endocarditis or may occur years after the infection has been eradicated.[540] Mycotic aneurysms of the cerebral vessels occur rarely in cases of pediatric endocarditis.[63] They usually are single, small, and peripheral but may lead to subarachnoid hemorrhage. Whereas computed tomographic scanning of the brain is useful for delineating central nervous system involvement in patients with infective endocarditis, magnetic resonance imaging may be more sensitive for detecting small infarctions and changes secondary to cerebral edema.[40] Other neurologic manifestations associated with endocarditis include cranial nerve palsies, neuropathy, visual changes, choreoathetosis, seizures, and toxic encephalopathy.

Splenomegaly, a common manifestation of endocarditis in children, occurs in 55 percent of cases. It is found frequently in patients with long-standing disease and other evidence of immune system activation. The spleen generally is nontender and may be associated with mild hepatomegaly. Splenic infarction and abscess are rare events but should be suspected in patients with left upper quadrant abdominal pain that radiates to the left shoulder, a pleural friction rub, or left pleural effusion.

Skin manifestations occur less commonly in children than in adults.[292] Clubbing is found in 10 to 20 percent of children with endocarditis but frequently is related to underlying heart disease. Petechiae are noted in approximately one third of patients, especially those with long-standing disease. These lesions are found most commonly on the extremities, oral mucosa, and conjunctivae. Splinter hemorrhages are linear red or brown streaks seen in the nail beds. They are present in only 5 percent of children with endocarditis and are associated with other conditions.[256] Three other types of lesions are more specific for infective endocarditis but occur in only 5 to 7 percent of patients: Osler nodes, which are small (2 to 10 mm), painful nodular lesions found in the pads of the fingers or toes[5]; Janeway lesions, which usually are painless hemorrhagic macular plaques that frequently occur on the palms and soles[133]; and Roth spots, which are small, pale retinal lesions associated with areas of hemorrhage located near the optic disk.

Other than fever and, perhaps, splenomegaly, no single sign or symptom occurs in more than 50 percent of children with endocarditis. That no classic clinical manifestation exists for this disease is obvious because the chance that even three or more signs will be present is extremely low. The appearance of any one

TABLE 32–3 Clinical Manifestations of Bacterial Endocarditis in Children

Symptom	Average (%)	Range (%)	Physical Finding	Average (%)	Range (%)
Fever	90	56-100	Splenomegaly	55	36-67

of these clinical features in a child with predisposing heart disease should raise suspicion of infective endocarditis and should lead to an appropriate diagnostic evaluation.[75]

The clinical findings of infective endocarditis in infants and neonates are less specific than are those in older children. The onset more often is acute and related to overwhelming infection.[231,321] In the pre-antibiotic era, these children often had other foci of infection, such as osteomyelitis, meningitis, and pneumonia, that dominated the clinical picture. The widespread use of antibiotics since 1941 has caused a decrease in the number of cases of infective endocarditis secondary to other suppurative infections.[321] Although early studies concluded that congenital heart disease was not an important predisposing factor to endocarditis in infants, more recent reports suggest that it is. At present, infants with heart defects undergo corrective and palliative surgery at a younger age than in the past. Infants in whom postoperative endocarditis does develop probably will have clinical findings more similar to those in older children.

Infective endocarditis is a rare occurrence in neonates and frequently is associated with indwelling vascular catheters.[159,309] It may affect the tricuspid valve and have a fairly "silent" clinical manifestation. Persistent bacteremia or fungemia should lead to a search for a cardiac focus of infection. Deterioration in pulmonary function, coagulopathies, thrombocytopenia, and low-grade murmurs often develop in neonates. Skin abscesses and hepatomegaly also are common findings. The prognosis of infective endocarditis associated with neonatal intensive care usually is favorable, perhaps because the diagnosis often is established relatively early and antibiotics are given rapidly.

Reported series of infective endocarditis in children with prosthetic valves are scarce. In early stages of disease, fever may be the only finding because the other signs of endocarditis are masked by the medical and surgical complications occurring in the immediate postoperative period. Late infections generally produce clinical findings similar to those in native-valve endocarditis. Clinical evidence of systemic embolization occurs in as many as 40 percent of patients.[77] Neurologic complications carry a particularly poor prognosis for survival.[252] A new or changing murmur often indicates valvular insufficiency caused by a paravalvular leak. Florid cardiac failure is the major manifestation if local infection or an abscess creates valve instability and acute, severe regurgitation.

The signs and symptoms of infective endocarditis in intravenous drug abusers may be similar, but these patients have several more distinctive features of their illness. Two thirds of these patients have no predisposing heart disease. The valve most commonly affected is the tricuspid, which leads to a predominance of pulmonary signs and symptoms resulting from pleural effusion, pulmonary infarction, and lung abscesses. Signs of tricuspid insufficiency (gallop rhythm, pulsatile liver, regurgitant murmur) are found in one third of cases.[432] Many patients have extracardiac sites of infection that are helpful in establishing the diagnosis.[482]

LABORATORY FINDINGS

The most important diagnostic procedure is the blood culture. Because many bacteria that usually are not pathogenic cause infective endocarditis, scrupulous aseptic technique must be used to distinguish causative agents from contaminants.[370] The yield of organisms is not increased by obtaining blood from arterial puncture or cardiac catheterization.[37] The bacteremia usually is of low grade and continuous. The first two cultures yield the organism 90 percent of the time; in two thirds of cases, all blood cultures are positive.[522] Therefore, isolated positive cultures generally are not significant. Previous outpatient antibiotic therapy may change the yield significantly.[250] In one study, culture positivity in cases of proven endocarditis was 64 percent in patients who received antibiotics before blood was drawn for culture versus 100 percent in patients without exposure to antibiotics.[371]

When *Candida* endocarditis is suspected, several additional points should be considered. Isolation of *Candida* spp. may require incubation for 1 week or longer. All blood cultures from a patient with *Candida* endocarditis may not be positive, in contrast to the usual situation with bacterial endocarditis; several positive cultures may be interspersed among negative cultures. In patients with fungal endocarditis, *Candida* is isolated commonly from other infected sites, such as urine, sputum, synovial fluid, cerebrospinal fluid, lymph nodes, and bone marrow.[424]

Three to five samples of blood for culture should be obtained from different sites within the first 24 hours in children with suspected endocarditis. Although difficult to obtain in smaller children, 3 to 5 mL of blood per culture is desirable for optimal yield. The samples should be injected into thioglycolate and trypticase soy (or brain-heart infusion) broth and held for at least 3 weeks to detect slow-growing organisms. If gram-positive cocci grow in the broth but fail to grow on subculture, nutritionally variant streptococci should be suspected, and subculture should be performed on media with either L-cysteine or pyridoxal phosphate.[60,459] Poured plates may be used to estimate the degree of bacteremia.

Negative blood cultures are noted in 10 to 15 percent of patients with clinically diagnosed endocarditis.[498] However, when patients have not received antibiotic therapy previously and blood for culture is obtained properly, these cases account for less than 5 percent of the total. Potential reasons for negative cultures include the following: (1) right-sided endocarditis; (2) previous administration of antibiotics; (3) fungal (especially *Aspergillus)* endocarditis; (4) endocarditis caused by *Bartonella* spp., rickettsiae, chlamydiae, or viruses; (5) mural endocarditis; (6) slow growth of organisms *(Candida*, *Haemophilus*, *Brucella*, nutritionally variant streptococci); (7) anaerobic infection; and (8) nonbacterial thrombotic endocarditis or an incorrect diagnosis.[186,190,378,498] In some instances, intraleukocytic organisms may be seen in layered peripheral blood, even when cultures are negative.[386] If surgical resection of vegetations or valve replacement is performed, a cause may be demonstrated by appropriate histologic examination and stains for bacteria and fungi.[336] Organisms also may be isolated from extracardiac sites (bone marrow, urine).

Many nonspecific laboratory findings are abnormal in patients with infective endocarditis (Table 32–4). The total white blood cell count rarely is helpful, but peripheral eosinophilia may be seen with Loeffler endocarditis.[203] The erythrocyte sedimentation rate is elevated in 80 to 90 percent of cases. However, frequently it is normal or low when congestive heart failure or renal failure is present. Serum C-reactive protein levels usually are elevated initially and return to normal during the course of successful therapy.[316] An increase during therapy may result from treatment failure, but can it also be caused by drug allergy or

TABLE 32–4 Selected Laboratory Findings of Bacterial Endocarditis in Children

Laboratory Finding	Average (%)	Range (%)
Positive blood culture	87	68-98
Elevated erythrocyte sedimentation rate	80	71-96
Low hemoglobin (anemia)	44	19-79
Positive rheumatoid factor	38	25-55
Hematuria	35	28-47

Data from references 48, 89, 156, 230, 264, 311, 446, 453, 484, and 507.

intercurrent infection. Rheumatoid factor rarely has been measured in a series of pediatric patients, but when measurements have been made, they have been positive in 25 to 50 percent of children with endocarditis. A positive test may be a diagnostic aid in cases of culture-negative endocarditis when other causes are excluded. Serial measurements may provide evidence of efficacy of therapy, although a fall in the titer of rheumatoid factor may lag behind the clinical and bacteriologic response.[514] Hypocomplementemia is seen in association with glomerulonephritis. Anemia is present in approximately 40 percent of patients, especially in those with long-standing disease. Although hemolysis may occur in the areas of turbulence in the heart, more often it is anemia of chronic disease. Because many patients with cyanotic heart disease normally have a compensatory polycythemia, a serial drop in hematocrit is of more significance than is a single measurement. Leukocytosis occurs in a few patients, but leukopenia is a rare finding in the absence of acute endocarditis with overwhelming sepsis. Hematuria and proteinuria, present in 25 to 50 percent of cases, usually are secondary to microemboli in the kidneys and may be accompanied by "pyuria," casts, and bacteriuria.

Circulating immune complexes are present in most adults with subacute endocarditis, as measured by Raji cell radioimmunoassay [485] or the ^{125}I-Clq binding assay.[541] These immune complexes frequently are absent in acute endocarditis. Low levels of immune complexes have been found in 32 percent of adults with septicemia but not endocarditis, in 10 percent of normal controls, and in 40 percent of noninfected intravenous drug abusers.[36] However, levels higher than 100 μg/mL are correlated highly with the presence of endocarditis. Serial measurement of immune complex levels may aid in monitoring therapeutic efficacy.[35] Systematic investigation of immune complexes has been reported infrequently in children with endocarditis. When immune complexes have been sought, most patients, including two of three children with culture-negative endocarditis, have had significant levels.

When infective endocarditis is suspected but blood cultures remain negative, serologic testing for specific organisms may prove helpful. Several techniques measure antibody to teichoic acids, which are major components of the cell wall of *S. aureus*. These antibodies are present in more than 85 percent of adults with staphylococcal endocarditis, but the false-positive rate is as high as 10 percent.[349] False-negative results correlate with a short (<2 weeks) duration of illness. Specific information about the accuracy of this test in children is lacking, and the tests are not readily available. Serologic testing is available or under investigation for many other organisms that cause infective endocarditis, including *Bartonella*, *Brucella*, *Candida*, *Aspergillus*, *Histoplasma*, *Cryptococcus*, *Chlamydia*, and *Coxiella*.[235,257] In general, the usefulness of these tests in children with endocarditis is unproven. Some patients with non-spirochetal bacterial endocarditis who reside in locales endemic for Lyme disease have significantly elevated levels of antibodies reactive to *Borrelia burgdorferi*.[237] Diagnostic confusion may occur because the signs and symptoms of infective endocarditis and Lyme disease can be quite similar. Other techniques, such as broad-range polymerase chain reaction (PCR), have been used to identify *Bartonella* and other causative agents of endocarditis.[51,512]

Radiographic techniques have not been a great aid in establishing the diagnosis of infective endocarditis. The findings on plain chest roentgenograms are nonspecific, but evidence of complications, such as septic pulmonary emboli or congestive heart failure, may be helpful. Computed tomography may help in establishing the diagnosis of an infected shunt.[499] Immunoscintigraphy using technetium-labeled anti-granulocyte antibodies may yield useful information when the echocardiographic findings are equivocal.[334] Cineangiography is the definitive method to determine the anatomic alterations in the heart resulting from infective endocarditis, but it rarely needs to be performed in children.

The electrocardiogram also is useful in the evaluation of patients with endocarditis because it detects arrhythmias and conduction disturbances that complicate the disease. Ventricular ectopy may be related to myocardial ischemia, myocarditis, or myocardial abscess. New conduction defects imply extension of infection beyond the valve ring into the myocardium. Any degree of atrioventricular block, a new left bundle branch block, or a new right bundle branch block with a left anterior hemiblock may represent extension of infection from the aortic valve into the ventricular septum. Junctional tachycardia, Wenckebach atrioventricular block, or complete heart block may be produced by extension of the infection from the mitral valve annulus into the atrioventricular node or proximal His bundle. In general, an unstable conduction block is more likely to develop in patients with aortic valve endocarditis than in those with mitral infection.[111]

Echocardiography has become a valuable adjunct to the diagnosis and treatment of endocarditis in children.[109,173,266,403,416,417,439] Color Doppler is a sensitive modality for detection of valvular insufficiency, and the results may influence surgical and medical treatment decisions.[145] Echocardiography can be performed by the traditional transthoracic approach or the transesophageal approach.[383] The sensitivity and specificity of transthoracic echocardiography continue to be defined, with positive results obtained in 36 to 100 percent of children in various series of pediatric patients.[52,89,109,247,278,285,420]

In general, two-dimensional echocardiography is more sensitive than is the M-mode technique, especially in cases of right-sided endocarditis,[366] and it is superior in diagnosing complications of the destructive process.[24,328] The smallest vegetation detectable is approximately 2 mm, but the acoustic impedance of the mass relative to the surrounding structures is a more important factor than is size in identifying the vegetation. Echocardiography has identified vegetations in culture-negative cases.[247] Its accuracy in prosthetic-valve endocarditis is diminished by the difficulty in resolution around the prosthetic device.[345,463] Serial evaluation of valvular vegetations generally does not assist in assessing the efficacy of antibiotic therapy because diminution or disappearance of vegetations may take place long after successful medical treatment has been completed.[258,410,511]

The use of transthoracic echocardiography to predict the clinical course and need for operative intervention in patients with endocarditis is controversial.[7,177]A synopsis of many reports that have assessed the role of transthoracic echocardiography in the diagnosis and management of infective endocarditis suggests the following: (1) because of variable sensitivity among studies for detection of vegetations, a negative study does not rule out endocarditis, especially when foreign material is present within the heart; (2) false-positive studies are quite rare (the specificity is high); (3) the reliability of transthoracic echocardiography depends on the experience of the examiner and the technical adequacy of the study; (4) transthoracic echocardiography is valuable in assessing local complications of endocarditis on native valves; and (5) in most but not all studies, patients with a vegetation identified by transthoracic echocardiography have an increased risk for the development of systemic emboli and congestive heart failure.[177,223,295,319,404,427,462]

Although some investigators contend that the presence of a vegetation should hasten early surgery, most suggest that a positive echocardiogram is adjunctive evidence that should be considered along with other clinical parameters when considering surgical intervention. One study suggested that the relative risk for having embolic events associated with echocardiographically visualized lesions is microorganism-dependent, with a significant

attributable risk seen only in patients with viridans streptococcal infection.[455] The absence of a vegetation on transthoracic echocardiography may define a subset of patients at low risk for the development of embolic complications.

Transesophageal echocardiography is a newer technique that has been studied extensively in adults with infective endocarditis.[99] It uses a 5-MHz phased-array transducer with Doppler and color flow encoding capabilities mounted on the tip of a flexible endoscope.[432] Biplane transesophageal echocardiography is considered the standard technique and is superior to transthoracic echocardiography because of improved spatial resolution, lack of acoustic interference from the lungs and chest wall, and closer proximity to posterior structures, such as the mitral valve and left atrium.[98] Multiplane transesophageal echocardiography facilitates and abbreviates the examination procedure and may be more accurate in providing the dimensions of a vegetation associated with infective endocarditis.[98,226]

Transesophageal echocardiography generally is well tolerated by children, even with the use of an adult probe (when the child's weight is more than 7 kg),[439] and rarely is associated with bacteremia.[97,269,382] Transesophageal echocardiography usually is more sensitive than is transthoracic echocardiography in the detection of intracardiac vegetations and is positive in 70 to 95 percent of adults with strongly suspected endocarditis.[342,445] It is significantly more sensitive in the detection of vegetations and complications in infected prosthetic valves.[253,372,409,463,476] Transesophageal echocardiography is particularly useful for detecting an aortic root abscess or involvement of the sinus of Valsalva in adults, and it should be considered in children with aortic valve endocarditis and changing aortic root dimensions on a standard transthoracic echocardiograph.[145,319] It appears to be less helpful for detection of vegetations in right-sided endocarditis.[428] Although a negative transesophageal echocardiographic study does not exclude endocarditis,[450] the procedure should be considered for patients with suspected endocarditis and a negative transthoracic echocardiograph, when the transthoracic echocardiography windows are suboptimal, and when perivalvular extension of infection is suspected.[14,212]

To aid in establishing the diagnosis of infective endocarditis, various sets of clinical criteria have been suggested. The von Reyn criteria were described in 1982, but echocardiographic findings were not included in the case definitions.[510] In addition, isolation of a typical infective endocarditis pathogen from blood cultures was not considered. New case definitions and diagnostic criteria were proposed by investigators from Duke,[121] and they have been modified subsequently[268,283] (Tables 32–5 and 32–6). The inclusion of echocardiographic and blood culture findings in these new criteria has resulted in more flexibility, a higher proportion of "definite" cases, and a more accurate reflection of current clinical practice.[324] These criteria have been validated in large series of infective endocarditis in adults and children.[107,121,200,426] In two pediatric series of clinically defined endocarditis, no cases were rejected by the Duke criteria, whereas 25 and 19 percent were rejected by the von Reyn criteria.[107,464] In one study, three of six pathologically confirmed cases were rated as only probable or rejected by the von Reyn criteria, whereas all were definite by the Duke criteria.[107] However, a more recent study found that 12 percent of pediatric endocarditis cases were not classified as "definite" by the modified Duke criteria.[487]

MICROBIOLOGY

Many different microorganisms are capable of causing infective endocarditis in humans. Table 32–7 lists the organisms isolated from patients in major pediatric series. Gram-positive cocci are the etiologic agents in 90 percent of cases in which an organism is isolated. Streptococci remain the bacteria isolated most frequently, although the percentage of cases caused by staphylococci and fungi has been increasing during the past 2 decades.[151,420,507,537] Polymicrobial infective endocarditis, especially in nosocomial settings, also appears to be increasing in incidence.[22] The characteristics of selected organisms and the type of disease that they produce are considered in the following subsections.

STREPTOCOCCI

Several terminologies have been used to classify streptococci. The Lancefield system defines groups (A, B, C, D, E, F, G, H) by serologic reactions. The viridans streptococci are alpha-hemolytic or nonhemolytic, may be Lancefield nontypeable *(Streptococcus milleri*, *Streptococcus mitior*; *Streptococcus salivarius*, most *Streptococcus mutans*, and *S. sanguis*) or typeable *(Streptococcus bovis* group D, some *S. sanguis* group H, some *S. milleri* group F), and display similar characteristics in vivo. They are the most frequent etiologic agents in subacute infective endocarditis and cause 40 percent of cases in children. They may cause rapidly progressive invasive disease.[205,471]

TABLE 32–7 Etiologic Agents of Bacterial Endocarditis in Children

Organism	Average (%)	Range (%)
Streptococci		
Viridans	40.3	17-72
Enterococci	4.0	0-12
Pneumococci	3.3	0-21
Beta-hemolytic	2.7	0-8
Other	1.1	0-16
Staphylococci		
Staphylococcus aureus	23.8	5-40
Coagulase-negative	4.7	0-15
Gram-negative aerobic bacilli	4.0	0-15
Fungi	1.1	0-12
Miscellaneous bacteria	2.4	0-10
Culture-negative	12.6	2-32

Data from references 49, 58, 91, 229-231, 264, 321, 420, 453, 484, and 507.

Viridans streptococci are common pathogens in patients with underlying heart disease but are less common in postoperative patients. They are part of the indigenous flora of the human mouth and gastrointestinal tract, and procedures that disrupt mucosal integrity in these areas predispose patients to development of viridans streptococcal bacteremia. In the pediatric population, most blood and cerebrospinal fluid isolates of viridans and nonhemolytic streptococci are not from patients with infective endocarditis.[189] Most strains are exquisitely susceptible to penicillin, although previous administration of antibiotics may promote infection with resistant strains.[262,279] Nutritionally variant viridans streptococci, reclassified as *Abiotrophia defectiva* or *Granulicatella* spp., are recognized as one cause of culture-negative endocarditis in children.[72,136,286,353,393,406] These organisms grow in broth but will not grow on subculture agar-based plates. Bacteriologic failure has occurred in 40 percent of reported cases of endocarditis caused by these organisms despite susceptibility to the antibiotics used.[24,459] Most viridans streptococci have low pathogenicity; however, the *S. milleri* group has a predilection for suppurative complications.[347] The prognosis of endocarditis caused by non-enterococcal streptococci is excellent with good medical and surgical management; the cure rate is more than 90 percent, although complications (emboli, congestive heart failure) occur in as many as 30 percent of cases.

Enterococcal endocarditis occurs much less frequently in children than in adults[322,481] and accounts for only 4 percent of pediatric cases. The organism normally inhabits the gastrointestinal and genitourinary tracts; instrumentation of these areas may cause enterococcal bacteremia. More than 40 percent of adult patients have no underlying heart disease.[402] Endocarditis should be considered in all infants and children with unexplained enterococcal bacteremia. Although the incidence of enterococcal bacteremia appears to be increasing in some neonatal intensive care units, the incidence of associated endocarditis seems to be very low. Factors that may suggest endocarditis in patients with enterococcal bacteremia include (1) preexisting heart disease, (2) community acquisition, (3) a cryptogenic source, and (4) the absence of polymicrobial bacteremia.[301] Differentiation of enterococci from other group D streptococci *(S. bovis)* is important because their respective therapeutic approaches are different.

Endocarditis caused by beta-hemolytic streptococci occurred more commonly in the pre-antibiotic era than today. Most cases are caused by Lancefield group B or G organisms,[1,16,158,517] whereas group C and A streptococci rarely cause endocarditis.[45,114,174,290,395] Group A, B, or C streptococcal infection may lead to large, bulky vegetations, easily seen by echocardiography, and to embolic complications.[17,331,423] Although group B streptococcal bacteremia is a common finding in newborn infants, endocarditis caused by this organism occurs rarely in this age group. Similarly, *S. pneumoniae* accounted for 10 to 15 percent of endocarditis cases in the pre-antibiotic era but currently causes less than 1 percent.[162,222,364] Pneumococcal endocarditis may involve either the aortic or the mitral valve.[126,171,491] In older studies, fewer than 50 percent of affected children had underlying heart disease, but in more recent series, most children have had existing heart disease.[218] The clinical course often is fulminant.[123,275,384] Concurrent meningitis or pneumonia (or both) occurs frequently. Valvular dysfunction and cardiac decompensation are common findings.[48,56,78] Early surgical intervention may be required because the mortality rate is 75 percent when medical management alone is used.[222]

STAPHYLOCOCCI

Staphylococci cause 20 to 30 percent of cases of infective endocarditis in children, but the relative incidence appears to be increasing.[151] *S. aureus* is the etiologic agent in most cases of acute endocarditis and frequently infects normal heart valves.[152,340] The course often is fulminant when the mitral or aortic valve is involved, with frequent suppurative complications occurring both in the heart (myocardial abscess, pericarditis, valve ring abscess) and in other organs.[129,236,329] *S. aureus* is responsible for more than 50 percent of cases of endocarditis in intravenous drug abusers, but the disease tends to be less severe in these patients.[70,71] The origin of the infecting organism is the addict's own nose or skin, not the injection paraphernalia.[497] Endocarditis associated with indwelling vascular catheters or prosthetic valves frequently is caused by *S. aureus*.[227] Endocarditis must be suspected in any patient with *S. aureus* bacteremia, even when a peripheral focus of infection is present. However, most patients with *S. aureus* bacteremia do not have endocarditis. The rise of methicillin-resistant *S. aureus* (MRSA) has rendered treatment more difficult but has had little impact on the rate of local complications.[210]

The incidence of endocarditis resulting from CONS is rising rapidly.[12] CONS is a common etiologic agent of endocarditis

occurring after cardiac surgery,[251,287] and it is occurring more frequently on native valves.[79,80] This organism is the leading agent in prosthetic-valve endocarditis, for which it causes 25 to 67 percent of early cases and 25 to 33 percent of late cases.[168,219,242] CONS endocarditis also has been associated with mitral valve prolapse and the use of intravascular catheters in premature neonates.[23,359] Although metastatic infection rarely occurs, CONS can be locally invasive; the mortality rate of prosthetic-valve endocarditis caused by CONS approaches 75 percent when valve replacement is not performed.

GRAM-NEGATIVE ORGANISMS

Although gram-negative bacteria cause 4 to 5 percent of cases of infective endocarditis in children, the percentage of children with gram-negative enteric bacteremia in whom endocarditis develops is extremely low. Endocarditis should be suspected in patients with gram-negative infection when bacteremia persists despite administration of usually appropriate antibiotic therapy.[65] Burn patients,[214] immunosuppressed hosts, narcotic addicts, and patients with implanted endovascular devices[335] are at an increased risk for development of gram-negative endocarditis. However, in the early postoperative period after cardiac surgery, sustained gram-negative bacillary bacteremia commonly is caused by other foci of infection and does not imply the presence of endocarditis. Many species of gram-negative enteric organisms have caused infective endocarditis in children, but no clear pattern has emerged. Among the gram-negative organisms more commonly reported are *Brucella*, *Escherichia coli*, *Serratia*, *Klebsiella-Enterobacter*, *Salmonella*, and *Pseudomonas*.[108,263,294,335,473] Endocarditis caused by *Salmonella* has been reported in patients with HIV infection.[142] It most often affects previously abnormal heart valves. Endocarditis is a rare complication of tularemia.[478] Cure of left-sided endocarditis caused by the Enterobacteriaceae seldom is achieved with medical therapy alone.[432] Most information about gram-negative enteric endocarditis is limited to case reports and general medicine reviews; discussion of individual organisms is beyond the scope of this review.

Other gram-negative organisms associated with infective endocarditis are the so-called HACEK coccobacilli.[102,137,211] These organisms caused 57 percent of cases of gram-negative endocarditis seen at the Mayo Clinic in Rochester, Minnesota, from 1958 to 1979.[164] Endocarditis caused by *Haemophilus influenzae* has been reported in only four children.[96,305] Cases caused by *Haemophilus parainfluenzae* and *Haemophilus aphrophilus* occur slightly more commonly.[41,81,101,211,225,296] They generally are seen in the setting of preexisting valvular disease and run a subacute course. However, central nervous system complications and emboli to major peripheral arteries are frequent occurrences.[81] Infective endocarditis caused by other organisms of the HACEK group is an extremely rare event in children.[11,138,339,368,392,521] All the bacteria in this group are fastidious, may require 2 to 3 weeks for primary isolation, and need subculturing onto chocolate agar in an atmosphere of 5 to 10 percent carbon dioxide for optimal growth. These procedures should be performed in all cases of culture-negative endocarditis.

Neisseria gonorrhoeae was responsible for 10 percent of cases in the pre-antibiotic era, but fewer episodes have been reported since 1942.[141,220] This pathogen frequently attacks previously normal heart valves and is manifested as an acute illness.[479] Valvular destruction with a need for valve replacement occurs commonly. At present, nonpathogenic *Neisseria* spp. are isolated more frequently in endocarditis than are gonococci, but they usually attack abnormal or prosthetic valves.[53,194,206,215,381,440] Although 1 percent of cases of infective endocarditis in adults are caused by anaerobic bacteria,[139] reports of anaerobic endocarditis in children are exceedingly rare.[86,354,448,467]

GRAM-POSITIVE BACILLI

Infective endocarditis caused by *Corynebacterium* spp. is an unusual finding but may occur on normal or previously abnormal valves.[38,323] Both toxigenic[105] and nontoxigenic[182,449,486] strains of *Corynebacterium diphtheriae* cause endocarditis in children, a finding demonstrating that the toxigenic and invasive properties of the organism are independent. Infection occurs most often on native valves and may be quite aggressive and lead to major vascular complications. *Listeria monocytogenes* endocarditis rarely occurs, has a high mortality rate, and, unlike other forms of listeriosis, usually is not associated with immunocompromised hosts.[33,66] It has not been associated with listeriosis in neonates. Fewer than 40 cases of *Lactobacillus* endocarditis have been reported.[181,213,470] Endocarditis caused by *Erysipelothrix rhusiopathiae* is found predominantly in adults who are farmers or are exposed to farm animals or products.[176,192] Most cases of *Bacillus* endocarditis involve the tricuspid valve in intravenous drug users, but other patients have been affected, including those with prosthetic valves.[458] *Gemella morbillorum*, formerly known as *Streptococcus morbillorum*, is a gram-positive coccus that normally resides in the gastrointestinal tract and is a rare cause of endocarditis.[132,270]

OTHER ORGANISMS

Many different bacteria, including *Acinetobacter*,[179] *Stenotrophomonas*,[408] *Nocardia*,[516] *Actinomyces*,[267] *Streptobacillus*,[414] and *Rothia*,[468] have been associated rarely with endocarditis.[55] Mycobacterial endocarditis is an exceedingly infrequent event.[157]

Infective endocarditis caused by *Coxiella burnetii*, the causative agent of Q fever, is well documented in northern Africa, Europe, and Australia.[4,54,271,282] Most cases are chronic (occurring over a 6- to 12-month period) and involve the aortic valve.[303] Clues to establishing the diagnosis include exposure to parturient cats or rabbits, massive splenomegaly, hypergammaglobulinemia, and thrombocytopenia.[379] The diagnosis usually is confirmed by measurement of antibodies against phase I and phase II antigens, but the organism has been isolated from leukocytes in a shell vial assay and has been demonstrated by immunohistologic techniques.[54,170] At least 20 well-documented cases of infective endocarditis caused by *Chlamydia psittaci* and *Chlamydia pneumoniae* have been reported.[201,235,310,444] Most patients have had preexisting heart disease and a subacute course.[304] *Mycoplasma* endocarditis is exceedingly rare.[112] *Legionella* has been implicated in several cases of prosthetic-valve endocarditis.[492] *Bartonella quintana* and *Bartonella henselae* have been identified as the cause of endocarditis in "culture-negative" cases.[115,224,452] Most described cases have been in immunocompetent individuals.[380] The diagnosis was established by serology, PCR, or special culture techniques.[26,140,149,396,512]

Although culture of bacteria remains the primary method for establishing the microbial cause of infective endocarditis, the number of organisms causing endocarditis that cannot be cultivated by standard culture methods is growing.[148,207] More recently, universal and species-specific primers have been designed to amplify bacterial DNA directly from resected valves. Among the organisms causing endocarditis identified by these methods are *Bartonella*, *Tropheryma whippelii*, *Coxiella*, *Mycoplasma*, *Haemophilus*, *Abiotrophia*, *Gemella*, *Cardiobacterium*, and *Streptococcus*.[161,175,207,289,390]

FUNGI

Most cases of fungal endocarditis in children have been described as occurring after cardiovascular surgery and prolonged intrave-

nous and antibiotic therapy.[125,326,488] More recently, cases have been reported in neonates[315] and after prosthetic-valve placement.[356] The most common causative organism is *C. albicans*, although disease has been attributed to other *Candida* spp., including *C. krusei*, *Candida parapsilosis*, *Candida stellatoidea*, *Candida tropicalis*, and *Candida guilliermondii*.[388,424,441] Among intravenous drug abusers, *Candida* spp. other than *C. albicans* are more common causes of endocarditis.[413] The clinical manifestation usually is indolent and not specific, with symptoms occurring weeks to months before the diagnosis is established. Signs and symptoms caused by emboli to large vessels, especially those supplying the brain, kidney, spleen, and extremities, should alert the physician to the possible presence of fungal endocarditis. Large, friable vegetations occur frequently and can be detected by echocardiography.[465] Cutaneous and ocular manifestations of systemic *Candida* infection may be present.[50] The prognosis of *Candida* endocarditis is poor and is related to the propensity for septic emboli, the tendency for invasion into the myocardium, and the poor penetration of antifungal agents into the bulky vegetation. The diagnosis frequently is delayed by the tendency for negative or intermittently positive blood cultures to occur in this disease.[233] Surgical intervention usually is required.

Aspergillus spp., including *Aspergillus flavus*, *Aspergillus fumigatus*, *Aspergillus terreus*, and *Aspergillus niger*, are the second most frequent causes of fungal endocarditis, and such infections have been reported in 16 children.[28,29] Two thirds of these patients had underlying heart disease. *Aspergillus* endocarditis has been found in immunocompromised hosts with no previous cardiac problems.[534] The most common initial manifestations are fever and embolic phenomena, especially to the central nervous system.[513] Fewer than 15 cases have been diagnosed ante mortem, three by culture of peripheral emboli. In none of the patients was the antemortem blood culture positive. Most cases occur after open heart surgery; the most likely source of the organism is airborne inoculation of the heart during the operation.[28] Surgical removal of all infected material is recommended, although only one child has been treated successfully. Other fungi that rarely cause endocarditis include *Histoplasma capsulatum*, *Coccidioides immitis*,[272] *Cryptococcus neoformans*, *Torulopsis glabrata*, *Trichosporon beigelii*,[249] and *Fusarium* spp.[185,208]

TREATMENT

In the pre-antibiotic era, infective endocarditis was a uniformly fatal disease. With the current improved methods of diagnosis and therapy, 80 to 90 percent of children with this disease can be expected to survive. Mortality rates are higher for acute staphylococcal infection, fungal endocarditis, and prosthetic-valve endocarditis, although the tendency toward earlier surgical intervention for these entities may improve survival rates. The cornerstone of successful therapy is selection of antibiotics with specific activity against the causative organism. Better analysis of pharmacodynamic variables, such as bactericidal activity and the post-antibiotic effects of various drugs, may assist in the selection of optimal therapeutic regimens.[90,255,529] Although persistent infection occasionally complicates treated endocarditis,[400] deterioration in cardiac function is the major cause of morbidity and mortality.

Several general principles provide the basis for the current recommendations for treatment of endocarditis. Parenteral administration of antibiotics is preferred because erratic absorption of oral antibiotics, especially in infants, can lead to therapeutic failure. Although patient selection criteria for the use of outpatient parenteral antibiotic therapy for endocarditis in adults have been suggested, no data have been published about this practice for children.[9] Prolonged treatment, usually 4 to 6 weeks or longer, is necessary to sterilize the vegetations and to prevent relapse. Bacteriostatic antibiotics are not effective and lead to frequent relapses or failure to eradicate the infection, or both. Antibiotic combinations may produce a rapid bactericidal effect through synergistic mechanisms of action. When synergy exists, smaller doses of each drug may be used, thereby reducing toxic side effects. However, certain drug combinations (e.g., penicillin and chloramphenicol) can be antagonistic, and their use should be avoided.

Blood should be drawn for culture for several days to evaluate the effect of the antibiotics. Negative follow-up cultures do not guarantee the success of therapy, but persistent positive cultures usually require that a change or addition to the antibiotic regimen be made. Observation of the patient's clinical course is extremely important. When fever is present initially, the temperature often returns to normal within a few days after therapy is started. However, fever can persist for weeks in patients whose eventual outcome is good. Such patients must be monitored closely for cardiac arrhythmias and congestive heart failure, which may require intensive care observation and electrocardiographic monitoring. Evidence of major embolic phenomena must be sought diligently by physical examination.

Several laboratory tests may aid in monitoring therapy. In all cases of bacterial endocarditis, the minimal inhibitory concentration (MIC) and minimal bactericidal concentration (MBC) ideally is determined for the antibiotics being used because disk susceptibility testing is unreliable and is not quantitative. When combinations of antibiotics are used, tests for bactericidal synergy, such as broth dilution, "checkerboards," or time-kill curves, may give additional information. The role of monitoring the inhibitory and bactericidal activity of the patient's serum is highly controversial. The Schlichter test determines the maximal dilutions of a patient's serum that in vitro inhibit and kill an inoculum of the organism causing the endocarditis.[399] Standardization of this test is poor, with laboratories using variations in inoculum size, in composition of the broth, in timing of samples (at expected peak or trough antibiotic concentrations in serum), in methods of dilution, and in determining the bactericidal end-point. In the rabbit endocarditis model, peak serum bactericidal titers greater than 1:8 correlate with therapeutic success.[64] A retrospective review of 17 reports of serum bactericidal activity in patients with endocarditis failed to show any correlation between titers greater than 1:8 and therapeutic success.[87] A prospective study suggested adjusting antibiotic doses to achieve peak titers of 1:64 or greater and trough titers of 1:32 or greater.[520] At present, no generally accepted recommendation can be made. In general, to attempt to achieve a peak serum bactericidal titer of at least 1:8 or greater seems reasonable if serious drug toxicity is not encountered. However, this level may not be attainable with certain organisms such as enterococci and gram-negative bacilli. Serum bactericidal testing may be particularly useful when synergistic combinations or less well established antibiotic regimens are used or when response to therapy is suboptimal.[533]

Little information is available concerning optimal antibiotic therapy for infective endocarditis in children; most treatment regimens are adapted from studies of adults with endocarditis.[24,530] In general, these regimens have been equally successful (and generally less toxic) in children. Table 32–8 lists recommended doses of the antibiotics commonly used.

After performing the initial evaluation of a patient with suspected infective endocarditis, the physician must make a clinical judgment about when to initiate therapy. If the findings are strongly indicative of the diagnosis or the child is very ill, treatment should be started as soon as blood has been drawn for culture. Initial empiric therapy depends on the clinical setting in which the tentative diagnosis is made. If the infection is subacute, a combination of penicillin G and an aminoglycoside usually is recommended for its activity against viridans streptococci, enterococci, and most gram-negative organisms. If *S. aureus*

TABLE 32–8 Suggested Intravenous Antibiotic Doses and Schedules for Infective Endocarditis in Children

Antibiotic	Daily Dose/kg	Divided Doses Every
Aqueous crystalline penicillin G sodium	300,000 U	4-6 hr
Ampicillin sodium	300 mg	4-6 hr
Ampicillin-sulbactam	300 mg	4-6 hr
Cefazolin	100 mg	6-8 hr
Ceftriaxone	100 mg	12 hr
Ciprofloxacin	20-30 mg	12 hr
Doxycycline	2-4 mg	12 hr
Gentamicin sulfate	3 mg	8 hr or 24 hr
Imipenem/cilastatin	60-100 mg	6 hr
Linezolid	30 mg	8 hr
Nafcillin sodium	200 mg (max., 12 g)	4-6 hr
Oxacillin sodium	200 mg (max., 12 g)	4-6 hr
Rifampin	20 mg	8-12 hr
Vancomycin hydrochloride	40 mg	6-12 hr

endocarditis is a strong consideration (acute manifestation, narcotic addicts), vancomycin and a penicillinase-resistant penicillin should be added to this regimen. Patients who recently have undergone cardiac surgery, especially prosthetic-valve placement, are treated best with an aminoglycoside and vancomycin to "cover" for health care–associated infection caused by MRSA or CONS; some physicians add penicillin G to this regimen to improve activity against streptococci. When culture and susceptibility data are known, antibiotic therapy can be changed as needed.

Most strains of viridans streptococci, *S. pyogenes*, and nonenterococcal group D streptococci are exquisitely susceptible to penicillin, with an MIC of less than 0.2 μg/mL. However, 15 to 20 percent of viridans streptococci have an MIC of 0.2 μg/mL or greater and are defined arbitrarily as relatively resistant.[209] In addition, some strains (particularly *S. mutans* and *S. mitior)* demonstrate tolerance, that is, an MIC to penicillin of less than 0.1 μg/mL but an MBC that is more than 10-fold higher (1.25 to 50 μg/mL). Most strains of nutritionally dependent streptococci are tolerant to penicillin.[24] Clinical failure may occur in endocarditis caused by these tolerant organisms when penicillin alone is used for treatment.[8,209] However, except for nutritionally dependent streptococci, therapy for tolerant viridans streptococci generally should be the same as for susceptible strains.

Although most experts recommend that patients with endocarditis caused by relatively resistant streptococci be treated with high doses of penicillin combined with 2 to 4 weeks of an aminoglycoside, some authorities consider that penicillin alone usually is adequate therapy.[44,110] Synergy in vitro between penicillin or vancomycin and streptomycin, gentamicin, or kanamycin can be demonstrated against virtually all penicillin-susceptible streptococci.[515] This observation correlates with a faster rate of eradication of bacteria from cardiac vegetations in the rabbit endocarditis model when synergistic combinations of antibiotics are used.[119,122] However, streptomycin is not synergistic for strains with high-level streptomycin resistance; gentamicin is the preferred second drug for these rare isolates.[127] In pediatric patients, gentamicin usually is substituted for streptomycin because of its lower toxicity.

Several regimens have been examined in adults with penicillin-susceptible viridans streptococcal native-valve endocarditis (Table 32–9). A 2-week course of penicillin alone leads to an unacceptable relapse rate. However, a 2-week course of intramuscular procaine penicillin and streptomycin cured 99 percent of adults with penicillin-susceptible streptococcal endocarditis in one report.[531] These results are similar to those obtained with β-

lactams alone for 4 weeks[244] or with penicillin for 4 weeks combined with streptomycin for the first 2 weeks. Gentamicin may be substituted for streptomycin. The 2-week penicillin-gentamicin regimen is the least expensive and is the preferred therapy in uncomplicated cases of penicillin-susceptible streptococcal endocarditis in young adults.[432] In general, the regimen of 4 weeks of penicillin alone is preferred for patients in renal failure or at high risk for developing aminoglycoside-induced ototoxicity. Vancomycin or ceftriaxone administered for 4 weeks can be used in patients with penicillin-susceptible viridans streptococcal endocarditis who have a penicillin allergy.[153,154,442,466] The regimen of 4 weeks of penicillin plus an initial 2 weeks of gentamicin is recommended in adults with a complicated course (symptoms for >3 months)[302] or with infection caused by relatively penicillin-resistant organisms (Table 32–10). Most nutritionally deficient streptococci are tolerant to penicillin. For patients with endocarditis caused by these organisms, a course of 4 to 6 weeks of penicillin with the addition of an aminoglycoside is recommended[24,530] (Table 32–11). In patients with streptococcal

infection of prosthetic valves or other prosthetic materials, a 6-week regimen of penicillin usually supplemented with an aminoglycoside is recommended. (Table 32–12). None of the regimens discussed has been evaluated specifically in children with endocarditis.

Most strains of enterococci have an MIC to penicillin of 0.4 μg/mL or greater and an MBC of 6.25 μg/mL or greater.[346] All β-lactam antibiotics are bacteriostatic against enterococci and cannot be used alone. However, plasmid-mediated β-lactamase production has been found in rare strains of *Enterococcus faecalis.* Ampicillin-sulbactam overcomes the enzyme production and is effective as therapy.[483] Although therapy with penicillin alone is ineffective, the combination of penicillin and an aminoglycoside is synergistic and produces a bactericidal effect on most enterococcal strains.[323] Unfortunately, 20 to 50 percent of enterococcal strains demonstrate very high resistance (MIC >2000 μg/mL) to streptomycin, and synergy between penicillin and streptomycin does not occur.[195,431] High-level resistance to gentamicin has been found in some isolates, and the incidence is increasing in certain locales.[124,288,369] When these isolates are encountered, all aminoglycosides should be tested because the organism may be susceptible to one while resistant to others.[318] Fortunately, these strains rarely cause endocarditis.[346] Although vancomycin-resistant enterococci have emerged as important nosocomial pathogens, they rarely cause endocarditis in children. Optimal therapy for these strains has not been established, but a combination of high-dose penicillin plus vancomycin and gentamicin may be effective in some cases.[61] Vancomycin-resistant enterococcal endocarditis has been treated successfully with oral linezolid.[10,15] The usual regimens for enterococcal endocarditis are listed in Tables 32–11 and 32–13).

Most isolates of *S. aureus* are resistant to penicillin, but endocarditis caused by penicillin-susceptible (MIC <0.1 μg/mL) isolates can be treated with this agent. In general, a semisynthetic penicillinase-resistant penicillin given for 6 weeks is the drug of choice [374,456] (Table 32–14). The addition of gentamicin to nafcillin produces an enhanced bactericidal effect in vitro and in exper-

imental staphylococcal endocarditis in rabbits.[425] However, the value of this combination in patients has not been proved, and generally it is reserved for children with overwhelming infection. In penicillin-allergic patients or in those with MRSA, vancomycin alone has been recommended, although treatment failures in children with endocarditis have been reported.[134,221,280] The addition of rifampin or the use of β-lactam drugs after desensitization is necessary in some cases.[31,340] Ciprofloxacin has been used, but treatment failures have occurred because of the emergence of resistance.[344,480] The combination of vancomycin and rifampin for at least 6 weeks, plus the addition of gentamicin for the first 2 weeks, is recommended for the treatment of endocarditis caused by MRSA, although clinical trial data are not available. Daptomycin also has been used successfully to treat endocarditis caused by MRSA.[150] Nosocomial infections with *S. epidermidis* usually are treated with vancomycin because of the high incidence of methicillin resistance among these isolates. The addition of rifampin and gentamicin to either nafcillin or vancomycin may increase bactericidal activity and is recommended in cases of prosthetic-valve endocarditis secondary to any staphylococci[24] (see Table 32–13).

Therapy for endocarditis caused by gram-negative organisms must be individualized in accordance with in vitro susceptibility and synergy studies. A regimen of 6 to 8 weeks of combination therapy with two or more drugs may be required, especially with endocarditis caused by *Klebsiella* or *Pseudomonas*.[146,373] Surgical intervention frequently is necessary, especially for infection of the mitral or aortic valves. Endocarditis caused by *Haemophilus* and other fastidious gram-negative organisms usually is responsive to ampicillin, ceftriaxone, or ciprofloxacin alone,[24] but the addition of an aminoglycoside may improve the outcome[24,81] (Table 32–15). Anaerobic bacilli generally are susceptible to penicillin, but infection caused by resistant *Bacteroides fragilis* is treated best by combinations including metronidazole, ticarcillin-clavulanate, or imipenem.

Survival rates of only 10 to 20 percent in patients with fungal endocarditis are related to the poor ability of currently available antifungal agents to sterilize the vegetations. Only rare cures with medical therapy alone have been reported.[424] Most investigators contend that early surgical intervention is mandatory in every patient who has conclusive evidence of intracardiac fungal infection.[460,500,501] Fewer than 50 cases of successful treatment of fungal prosthetic-valve endocarditis have been reported, even when surgery was performed.[169]

Although a prolonged course of antifungal therapy before surgery does not improve the outcome, chemotherapy should be given in conjunction with operative treatment. The drug of choice is amphotericin B at a dose of 0.5 to 1.0 mg/kg/day. This antibiotic may be either fungistatic or fungicidal, depending on the infecting organism. Even though the toxicity of amphotericin B appears to be less severe in children than in adults, side effects that may necessitate alterations in the usual regimen may occur and include fever, chills, phlebitis, anemia, hypocalcemia, renal tubular acidosis, nephrotoxicity, and thrombocytopenia. The optimal dosage of amphotericin B is unknown; total doses of 20 to 50 mg/kg commonly are used. 5-Fluorocytosine[320] and rifampin may act synergistically with amphotericin B against many strains of fungi, but their roles in fungal endocarditis are unproven. Fluconazole is less effective than is amphotericin B for the prophylaxis or treatment of experimental *Candida* endocarditis,[532] but it has been used successfully in a few patients.[92,508]

Treatment of culture-negative endocarditis is problematic.[27] In general, the same criteria used to choose empiric therapy for infective endocarditis can be followed. Antibiotics usually are continued for 6 weeks, and ongoing surveillance for an etiologic agent must be performed. In 52 adults with culture-negative endocarditis, survival correlated with the initial clinical response to antibiotics; most deaths were caused by systemic emboli or congestive heart failure.[378]

Surgery has become a valuable adjunct to medical therapy in the management of infective endocarditis.[30,365,377,385] Several echocardiographic findings suggest a possible need for surgical intervention[30,145] (Table 32–16). Among the generally accepted indications for surgical intervention during active endocarditis are (1) refractory congestive heart failure,[325,490,528] (2) uncontrolled infection,[304] (3) more than one serious embolic episode, (4) fungal endocarditis, (5) most cases of prosthetic-valve endocarditis,[6,104,128,419,538] and (6) local suppurative complications including perivalvular or myocardial abscess with conduction system abnormalities.[43,411,443,474,535] The usual indication for surgical intervention is congestive heart failure in left-sided lesions and persistent infection in right-sided disease.[106,509] Among children with endocarditis after cardiac surgery, repair or takedown of infected graft material commonly is the reason for surgery.[83,361] In general, operative mortality is low even if surgery is performed during the active infection.[343,355] The hemodynamic status of the patient, rather than the activity of the infection, is the critical factor in determining the timing of cardiac surgery or valve replacement.[3,241] The aortic valve is the site most often requiring surgical intervention.[337,387,494] Treatment with recombinant tissue plasminogen activator has been used successfully in some cases of endocarditis when surgery could not be performed safely.[183,281]

PREVENTION

Accepted medical practice has been to give prophylactic antibiotics to susceptible patients in an attempt to prevent infective endocarditis.[116,248,447] The rationale for such treatment is based on studies indicating that antibiotics can reduce the incidence of bacteremia after various procedures in humans[130] and can prevent experimental endocarditis in animals.[376] However, no controlled trials have documented the efficacy of endocarditis prophylaxis in humans.[505] Prevention of bacterial infection is most likely to be successful and cost-effective when a single antibiotic is directed against a single pathogen and when the disease occurs with high frequency in the absence of prophylaxis. Prevention of endocarditis has not met these ideals because various drugs have been used against numerous organisms, and the disease rarely occurs even if prophylaxis is not given.[116] Fewer than 10 percent of all endocarditis cases can be attributed to bacteremia caused by previous medical, surgical, or dental procedures.[504] Many cases of prophylaxis failure have been reported,[120] but only 12 percent of such patients received antibiotic regimens recommended by the American Heart Association. For reasons that are not clear, mitral valve prolapse was the condition associated most frequently with failure of prophylaxis.

The most common errors in attempted prevention of endocarditis include inadequate medical histories taken by dentists and other health professionals to identify high-risk patients, initiation of prophylactic antibiotics too early, continuation of preventive therapy too long, the use of low-dose antibiotics, lack of prophylaxis for minor dental procedures, and confusion between prevention of rheumatic fever and prevention of infective endocarditis.[187,193] Several studies have shown that adult patients at risk for development of infective endocarditis often have inadequate knowledge of their cardiac lesion, endocarditis, and recommended prophylaxis.[69,261,506] One study demonstrated that the parents of children with heart defects have a low level of knowledge about the importance of good oral health in preventing endocarditis.[103] Another study cast doubt on the cost-effectiveness of endocarditis prophylaxis for urinary catheterization in children.[68]

The American Heart Association published new and radically different guidelines for the prevention of infective endocarditis in 2007.[527] These new guidelines eliminated many of the procedures for which prophylaxis previously was recommended.[94] Now, it is recommended that prophylaxis be undertaken for all dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. Prophylaxis also can be considered for procedures on the respiratory tract or infected skin, skin structures, or musculoskeletal tissue. Prophylaxis no longer is recommended for gastrointestinal or genitourinary tract procedures. In addition, the number of heart lesions for which prophylaxis is recommended has been reduced to only those with the highest risk of endocarditis (Table 32–17).[527] Finally, the specific regimens for prophylaxis have been changed and simplified to encourage more judicious use (Table 32–18). Although immunization against bacteria that commonly cause endocarditis (e.g., viridans streptococci) has been proposed, this approach remains a theoretic possibility.[18]

TABLE 32–17 Heart Conditions with the Highest Risk of Adverse Outcome from Endocarditis for Which Prophylaxis with Dental Procedures Is Recommended

Prosthetic heart valve
Previous infective endocarditis
Congenital heart disease
Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits
Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or catheter, during the first 6 months after the procedure
Repaired congenital heart disease with residual defects at or adjacent to the site of a prosthetic patch or device
Cardiac transplantation recipients who develop cardiac valvulopathy

CHAPTER 33

Infectious Pericarditis

Sheldon L. Kaplan ❂ Richard A. Friedman

Purulent pericarditis generally refers to bacterial infection of the pericardium. Inflammation of the pericardium may result from numerous nonbacterial microorganisms, however, or may occur with a variety of noninfectious illnesses (Table 33–1). Regardless of the cause of pericarditis, the responses of the pericardium are limited to acute inflammation, effusion with or without tamponade, and fibrosis with or without constriction.[18] Because untreated purulent pericarditis is rapidly fatal, suspecting the disease early and approaching the diagnosis aggressively are important.

ANATOMY AND FUNCTION

The pericardium is composed of two loosely approximated layers: visceral and parietal. The visceral pericardium is composed of mesothelial tissue, which closely follows the contour of the heart and extends for a short distance beyond the atria and ventricles to the great vessels. The outer parietal pericardium is a more fibrous structure, composed of layers of collagen interlaced with elastic fibers. The pericardial sac is attached to the diaphragm below; to the sternum in front; and to the thoracic vertebrae, esophagus, and aorta posteriorly. It is surrounded by the lungs on either side and is related closely to the main bronchi and the mediastinal lymph nodes. The phrenic and vagus nerves supply a network of pain fibers to the parietal pericardium.

The dynamics of the pericardial fluid are poorly understood. The pericardial membrane is active in the transfer of water, electrolytes, and small molecules. Molecules of large molecular weight are absorbed poorly from the pericardial space because lymphatic channels are sparse, and drainage must occur primarily through the epicardial capillaries.[64]

Ainger[1] summarized the function of the pericardium as follows: prevention of overdistention of the heart, protection of the heart from infection and adhesions, maintenance of the heart within a fixed geometric position within the chest, and regulation of the interaction between the stroke volumes of the two ventricles.

BACTERIAL PERICARDITIS

POPULATION AND INCIDENCE

Although purulent pericarditis is not a common infection in pediatric patients, it is an important one to recognize because of its life-threatening nature. In an extensive early review of the literature on purulent pericarditis, half of 425 cases occurred in children younger than 13 years of age.[7] In a review of 162 reported children with pericarditis from 1950 to 1977, 67 percent of the children were 48 months old or younger.[27] From 1962 to 1974, 67 cases were recognized at St. Louis Children's Hospital (Table 33–2).[82] During this 12-year period, pericardial disease of all causes occurred in approximately 1 of every 850 hospital admissions.[82] Twelve (18%) of these children had purulent pericarditis.

TABLE 33–1 Causes of Pericarditis

Idiopathic
Benign
Recurrent
Infectious
Purulent
Bacterial—*Staphylococcus aureus*, *Haemophilus influenzae*, streptococci, *Neisseria meningitidis*, *Streptococcus pneumoniae*, anaerobes, *Francisella tularensis*, *Salmonella*, enteric bacilli, *Pseudomonas*, *Listeria*, *Neisseria gonorrhoeae*, *Actinomyces*, *Nocardia*
Tuberculosis
Fungal—*Histoplasma*, *Coccidioides*, *Aspergillus*, *Candida*, *Blastomyces*, *Cryptococcus*
Viral
Coxsackieviruses B
Other—influenza A and B, mumps, echoviruses, adenoviruses, Epstein-Barr virus, hepatitis, measles, HIV, cytomegalovirus
Other
Rickettsial—typhus, Q fever
Mycoplasmal—*Mycoplasma pneumoniae*
Parasitic—*Entamoeba histolytica*, *Echinococcus*
Spirochetal—syphilis, leptospirosis
Chlamydial—psittacosis
Protozoal—toxoplasmosis
Noninfectious
Postpericardiotomy syndrome
Kawasaki disease
Rheumatic fever
Connective tissue disorders—JRA, SLE, dermatomyositis, periarteritis nodosa
Trauma—blunt or penetrating
Metabolic—uremia, myxedema
Hypersensitivity—serum sickness, pulmonary infiltrates with eosinophilia, Stevens-Johnson syndrome, drugs (hydralazine, procainamide, chemotherapy)
Neoplasm—leukemia, metastatic
Postirradiation

HIV, human immunodeficiency virus; JRA, juvenile rheumatoid arthritis; SLE, systemic lupus erythematosus.

TABLE 33–2 Pericarditis in Children, 1962 to 1974 (St. Louis Children's Hospital)*

Etiology	No. Patients
Unknown	28
Purulent	12
Juvenile rheumatoid arthritis	9
Acute rheumatic fever	8
Uremia	5
Viral	2
Blunt chest trauma	2
Dermatomyositis	1

**Patients with postpericardiotomy pericarditis and patients with small effusions at autopsy were excluded from consideration.*

From Strauss, A. W., Santa Maria, M., and Goldring, D.: Constrictive pericarditis in children. Am. J. Dis. Child. 129:822-826, 1975. Copyright 1975, American Medical Association.

Most cases in younger children are infectious. Acute pericarditis was found in 20 children between 1987 and 1997 in a hospital in Iran.[72] The causes of pericarditis were bacterial in eight (40%), collagen vascular disease in six (30%), viral in four (20%), and secondary to mediastinal mass invasion in two (10%). In another series from Turkey, 18 children with purulent pericarditis were encountered from 1990 to 2000.[11] At the Boston Children's Hospital, fewer than 10 patients seen among more than 1700 patients in consultation by the pediatric cardiologists had pericarditis during the period July 1, 2001, to June 30, 2002.[32] Although rare, purulent pericarditis also can occur in neonates.[51] In most series, a marked male predominance has been noted.

ETIOLOGY

Primary purulent pericarditis is a rare disease; it accounted for only 7 of 50 cases of pericarditis reported by Gersony and McCracken.[33] The disease is associated most often with infection from another site, with hematogenous or direct spread to the pericardium. Feldman[27] reviewed all cases of bacterial pericarditis reported in the English language literature from 1950 to 1977. Bacteria were isolated in 146 (90%) of 162 cases. No other infection was found in 10 patients. The most common concomitant site involved was the lung, especially for *Staphylococcus aureus*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*. When septic arthritis, osteomyelitis, or skin infections were found, *S. aureus* usually was the cause of pericarditis. *Neisseria meningitidis* and *H. influenzae* most often were responsible for concomitant meningitis and pericarditis.

Before the introduction of antibiotics, pneumococcal and streptococcal organisms were the most frequent causes of purulent pericarditis in children. Most cases were associated with pulmonary infections. Nearly half of patients with streptococcal pericarditis had associated postinfluenzal pneumonia. Hemolytic streptococci were isolated most often; 10 percent were nonhemolytic streptococci, and 5 percent were viridans streptococci. Kauffman and colleagues[53] reviewed 113 cases of pneumococcal pericarditis reported since 1900. Preceding pneumonia was present in 93 percent, and empyema was present in 66 percent. Pericarditis was thought to be a late event resulting from delay in administering appropriate therapy for pneumonia.

S. aureus is the organism most commonly responsible for purulent pericarditis in children.[6,27,33,45,72] Most cases are the result of hematogenous seeding of the pericardium from staphylococcal pneumonia with empyema, acute osteomyelitis, or soft tissue abscesses. Occasionally, the pericardium is infected during the course of staphylococcal endocarditis. *S. aureus* is the most frequently recovered organism when purulent pericarditis develops within 3 months after the patient has undergone open heart surgery. The clinical course of acute staphylococcal pericarditis is dominated by severe toxemia. In addition to the necrotizing infection produced by *S. aureus*, the organism may release exotoxins, which produce shock and contribute to the high mortality.

S. aureus was isolated from 73 percent of infants who died of purulent pericarditis in the series reported by Gersony and McCracken.[33] It was responsible for 50 percent of cases in children 1 to 4 years old in the review by Feldman.[27] In seven patients younger than 1 month of age, *S. aureus* was isolated from four. This finding is corroborated in literature from other countries.[19,48,72] In one of the latest series, Thebaud and colleagues[86] reported 19 children with purulent pericarditis in a children's hospital in Paris between 1979 and 1994. The mean age of the children was 3 years (range 3 months to 10 years). The organisms isolated were *S. aureus* (three cases), *H. influenzae* (four cases), group A streptococci (three cases), *S. pneumoniae* (three cases), and *N. meningitidis* (one case). Concomitant infections included pneumonia (six cases), osteomyelitis (three cases), cellulitis (one case), and sinusitis (one case). In the series from Turkey, *S. aureus* was isolated from five patients, and *S. pneumoniae* was isolated from one patient.[11] *S. aureus* pericarditis as a complication of varicella has been reported in several children.[9]

In the prevaccine era, the second most frequently encountered organism was *H. influenzae* type b.[16] It was responsible for 22 percent (35 of 163) of the cases in Feldman's review.[27] A single site of coexisting infection, the lung, was identified in 16 of the 35 cases. Meningitis as a single other site of infection was found in 5 of 35 patients, and multiple involvement was found in 7 of 35.[27] Echeverria and colleagues[24] summarized 33 cases from the literature. Pulmonary infiltrates and empyema were seen in 64 percent of patients. Nearly 85 percent had symptoms of an upper respiratory tract infection in the preceding 5 to 12 days. Because *H. influenzae* type b conjugate vaccine has been given routinely to young infants in developed countries, this organism has been eliminated as a cause of invasive infections, including pericarditis.

Pneumococcal, streptococcal, and meningococcal pericarditis have diminished in frequency since the introduction of penicillin.[7] Go and coworkers[35] summarized the 15 reported cases of pneumococcal pericarditis from 1980 to 1998. One was a child. Only four cases did not have an underlying risk factor. In a surveillance study of invasive pneumococcal infections in eight pediatric hospitals, only three cases of pericarditis have been observed in more than 2500 cases of systemic pneumococcal infection during the 6-year period of 1993 through 1999.[52]

Pericardial involvement occurs in approximately 5 percent of young adults with meningococcemia.[21,42] The clinical course generally is milder than that observed with other types of purulent pericarditis. Pericardial involvement rarely is detected at the time of hospital admission. Pericarditis became apparent by the third day in 13 of 17 patients reported by Dixon and Sanford.[21] In some patients, it did not occur until late in the course of therapy. Whether this late-onset pericardial effusion is a part of the meningococcal infection or is related to immune complexes is unclear.[21,67,77] Primary meningococcal pericarditis that occurs without clinical evidence of meningococcemia, meningitis, or any other focal infection has been reported in 16 patients, including 6 children 18 years old or younger (range, 2 to 18 years).[3] Meningococcal serotype C was identified in 11 (79 percent) of 14 cases for which the serotype was known. Cardiac tamponade developed in 88 percent of the patients. Pericarditis also has been reported in two children with W135 meningococcal infection.[4]

Occasionally, other microorganisms cause acute purulent pericarditis. Feldman[27] reported that 11 (8%) of 146 cases of pericarditis in children were caused by *Pseudomonas aeruginosa*. *P. aeruginosa* caused pericarditis in an immunocompetent adult with cystic fibrosis.[2] Pericarditis can occur with pneumonic tularemia, salmonellosis, sepsis from enteric bacilli, listeriosis, and disseminated gonococcal disease.[7] Anaerobic bacteria should be suspected when pericarditis develops in association with lung abscess, intra-abdominal infection including ruptured appendicitis,[84] or a penetrating wound. Callanan and colleagues[12] reported the rapid development of constrictive pericarditis after purulent pericarditis caused by anaerobic streptococcal infection. The child had a history of blunt trauma to the chest with no evidence of a penetrating wound 3 weeks before cardiac tamponade developed. The incidence of anaerobic infection may be underestimated because of improper handling of specimens for culture.[27] Prolonged symptoms related to pericarditis can be associated with *Mycoplasma pneumoniae* infection.[25]

Mycobacterium tuberculosis, previously a common cause of acute pericarditis in the United States,[6] now is responsible more often for chronic pericardial disease. This infection is a complication of miliary tuberculosis and rarely a primary infection. In the series of 2500 children with tuberculosis reported by Lincoln and Savell,[59] pericarditis was diagnosed in 0.4 percent and found at necropsy in 5 percent of patients. A review of 100 cases of tuberculous pericarditis in South African blacks by Desai[20] revealed a marked male predominance (72%). The duration of symptoms, consisting of cough and peripheral edema, in most patients was 0 to 120 days. Most patients were febrile and had congestive heart failure. Generalized lymphadenopathy occurred in nearly 30 percent of patients, pulsus paradoxus occurred in 50 percent, and a friction rub was audible in 25 percent. Of the 52 patients who had pericardiocentesis, 40 percent yielded fluid, but none was positive for acid-fast bacilli. Pericardial effusion was shown in 82 patients, 16 of whom died of tamponade, and another 16 of whom developed constricting pericarditis.

The four stages of tuberculous pericarditis have been described as dry, effusive, absorptive, and constrictive.[69] Granulomata usually are found in the dry stage and heal with no sequelae. The effusive stage occurs commonly with tuberculous lymphadenitis, and 15 to 200 mL of fluid usually accumulates in the pericardial space. The absorptive stage is characterized by thickening of the pericardium with fibrin deposition. Further fibrin deposition and calcification occur during the constrictive phase. The disease may progress through all stages or remain in one stage.

Latent infection in the mediastinal lymph nodes with spread directly into the pericardium is thought to be the mode of involvement with *M. tuberculosis*.[69] The lymph nodes at the tracheal bifurcation often are the source.

Histoplasma pericarditis generally occurs with pulmonary, rather than disseminated, disease.[71] Coccidioidomycosis[15] and, rarely, blastomycosis[41] also may cause pericardial disease. Other pathogenic fungi include *Aspergillus* and *Candida*. These fungi are more serious considerations in patients who are immunosuppressed, have serious burns, or are receiving long-term, broad-spectrum antibiotics after undergoing cardiac surgery.[74]

PATHOLOGY AND PATHOGENESIS

Pericarditis begins with fine deposits of fibrin adjacent to the great vessels; it causes the pericardial membrane to lose its smoothness and translucency. Numerous granulocytes may extend into the myocardium.[37]

Bacterial pericarditis most commonly results from direct extension of infection from involved lung and pleura. Pulmonary infections may spread to the pericardium through the bronchial circulation.[40] Pericarditis also can develop through hematogenous dissemination from infection elsewhere. Pericarditis also may be the result of an immunologically induced response to a primary infection.

As pericardial fluid accumulates, intrapericardial pressure increases. The rate of increase is a function of the speed of accumulation and the compliance of the pericardium. With slow accumulation of fluid, large volumes can be accommodated because of the gradual expansion of the parietal pericardium. As the compliance of the pericardium reaches its maximum, however, further accumulation of even small volumes of fluid results in an abrupt increase in intrapericardial pressure. If pericardial fluid accumulates at a rapid rate, marked elevation in intrapericardial pressure may occur with much smaller volumes of fluid. In a small child, 100 mL can cause severe tamponade, whereas 3 L may accumulate slowly in an older child and not result in tamponade.[1]

The most significant hemodynamic effect of pericardial effusion is restriction of ventricular filling. Ventricular end-diastolic, atrial, and venous pressures increase on the right and left sides of the heart equally. When restriction of ventricular filling becomes more pronounced, the ventricular stroke volume and cardiac output decrease. In an attempt to maintain cardiac output, tachycardia and peripheral vasoconstriction occur. Systemic arterial blood pressure and pulse pressure are reduced markedly. Tamponade occurs when these compensatory mechanisms fail to maintain adequate cardiac output.

CLINICAL MANIFESTATIONS

A diagnosis of purulent pericarditis should be suspected in any patient with septicemia who develops cardiomegaly. The classic signs and symptoms of pericarditis are precordial pain, pericardial friction rub, evidence of cardiac fluid, and muffled heart sounds.[14] Chest pain is not a common symptom, especially in small children; the reported rates vary from 15 to 80 percent.[5,7,33,45,64,68,87] Acute abdominal symptoms may be the presenting complaints of some children.[22]

The most common symptoms and signs of pericarditis are fever, tachypnea, and tachycardia. They also are presenting features of associated systemic infection. If the cardiac shadow is radiographically enlarged, with or without a friction rub, and the tachypnea and tachycardia are out of proportion to the fever, myocardial dysfunction or pericarditis should be suspected.

An evanescent or ubiquitous rub may be detected. The typical sound of a rub is that of a high-frequency murmur,[70] which may have a to-and-fro or triphasic pattern but may not have any correlation with the cardiac cycle.[28] Frequently, the rub is heard better with the patient leaning forward or kneeling.[28] A rub may be differentiated from a murmur by pressing the diaphragm of the stethoscope firmly against the chest wall; this pressure amplifies the rub, and the typical scratchy quality becomes more apparent as the examiner opposes the visceral and parietal pericardium by compression of the chest. Rubs have been known to increase with inspiration.[79] Although a rub is less likely to be heard in the presence of a large effusion, it still may exist.[28] The heart sounds usually are muffled, and the palpable ventricular impulse generally is diminished. Both findings may be present in congestive heart failure, but they may be absent with tamponade.

Cardiac tamponade may be an early complication of pericarditis associated with a systemic infection. Cardiac tamponade means that there is compression of the heart by a tense pericardial sac, usually full of fluid, resulting in a decrease in venous return to the cardiac chambers and a decrease in cardiac output. During inspiration, the intrathoracic pressure decreases, and venous return to the cavae increases. The tense pericardial sac limits the amount of blood that can enter the right atrium because of diastolic compression; a paradoxical increase in jugular venous pressure occurs during inspiration (i.e., Kussmaul sign) (Fig. 33–1).[54]

During inspiration, a small decrease in systolic blood pressure and cardiac output normally occurs and is caused by an increase in pulmonary venous capacitance. It is exaggerated with pericardial tamponade (>10 mm Hg decrease in blood pressure) because of the restricted inflow into the cardiac chambers. This clinical sign has been called *paradoxical pulse*, but it actually is an exaggeration of the normal respiratory cycle (Fig. 33–2).[36]

DIAGNOSIS

The radiographic appearance of a rapidly increasing cardiothoracic ratio without increasing pulmonary vascular markings is more suggestive of pericardial effusion than of congestive heart failure caused by myocardial dysfunction (Fig. 33–3). Fluoroscopy alone generally is of little value; myocardial dysfunction and pericarditis can impair cardiac contractility.

The size of the pericardial shadow does not indicate the severity of hemodynamic effects. It is a function of the rapidity of accumulation and the volume of pericardial fluid. When acute infection results in sudden cardiac tamponade, the heart size may be normal. A large, globular heart shadow with no evidence of increased pulmonary vasculature, particularly in a patient who has signs of right-sided heart failure, is strong evidence for pericardial disease. The lack of pulmonary overcirculation helps to distinguish this condition from myocarditis; however, determining whether pulmonary infiltrates also exist may be difficult.

A plain lateral chest radiograph may show findings consistent with a pericardial effusion.[56] Separation of more than 2 mm between the anterior mediastinal and subepithelial "fat stripes" suggests an effusion. Obliteration of the retrosternal space without evidence of thymic or right ventricular enlargement also indicates pericarditis.

The extent of electrocardiographic abnormalities may be explained by the amount of pericardial effusion and the presence of superficial myocardial injury or myocarditis. Pericardial effusion gives rise to low-voltage QRS complexes as a result of the damping effect of pericardial fluid between the chest wall and the myocardium. Accumulation of fluid and fibrin under pressure also may produce an injury pattern manifested by ST-segment deviation. More than 90 percent of patients have elevation of the ST segment, which occurs most frequently in leads I, II, V_5, and V_6. Widespread T-wave inversion indicative of epicarditis may be seen in the same leads in which ST-segment elevation occurs.

Spodick[80] described four stages of electrocardiographic changes in acute pericarditis. In stage I, ST-segment elevation is pronounced, and the PR segment may be depressed. In stage II, the ST segment begins to return to the isoelectric line, the amplitude of the T wave diminishes, and the PR segment is depressed. By stage III, the ST segment has returned to the isoelectric line, and the T-wave inversion occurs. An incompletely inverted T

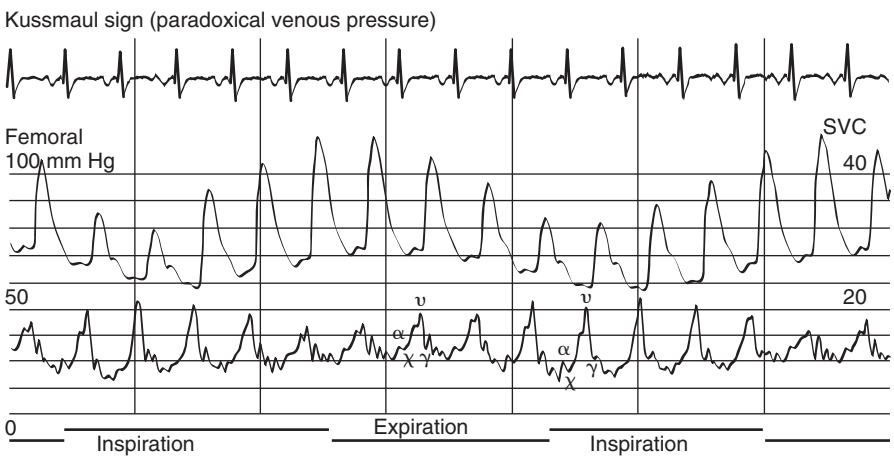

Figure 33–1 Simultaneous recording of right atrial and femoral artery pressures. Notice the increased V wave and exaggerated decrease in the femoral artery pulse with inspiration.

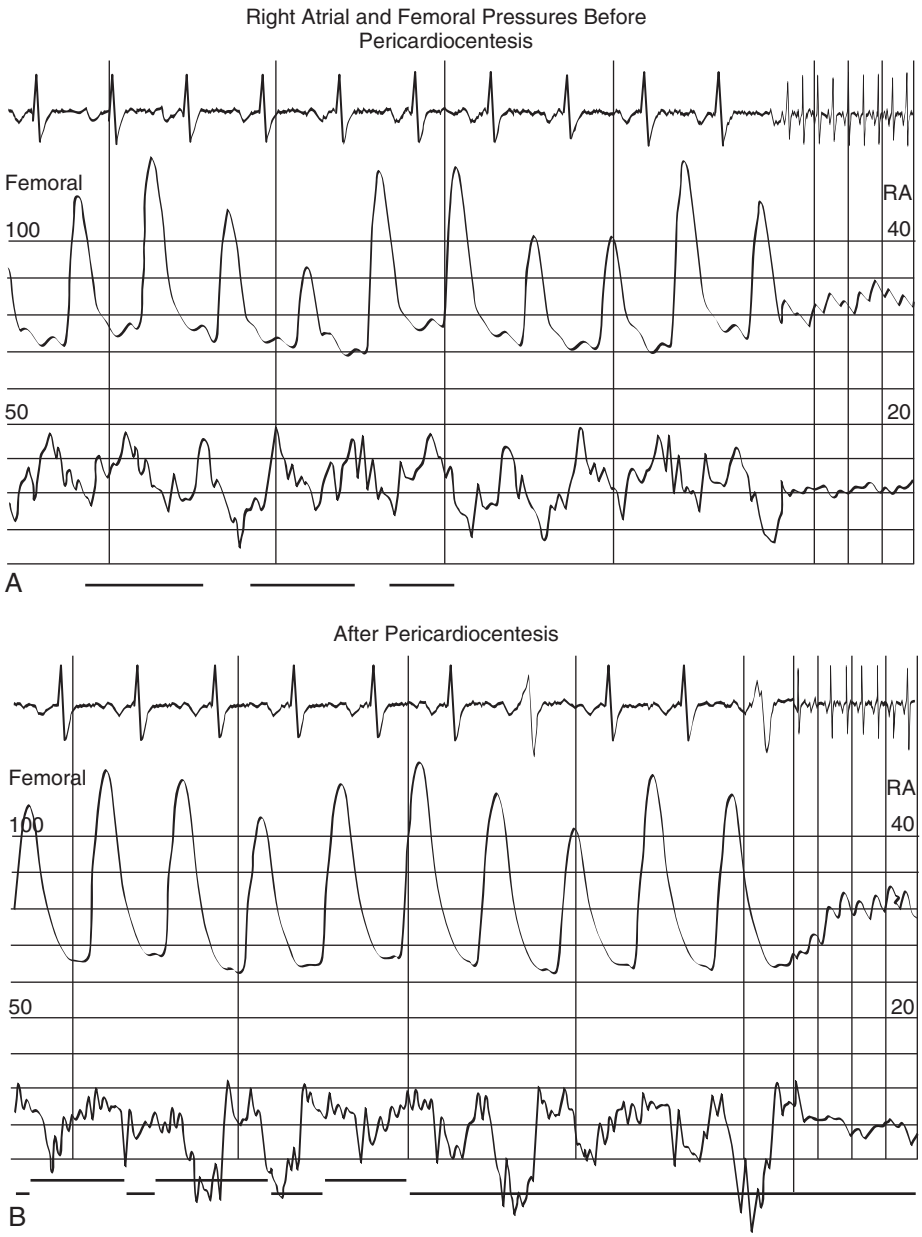

Figure 33–2 **A** and **B,** Recordings of femoral artery and right atrial pressures before **(A)** and after **(B)** pericardiocentesis. **A,** There is an exaggerated decrease in the fall of femoral artery pressure with inspiration and a sustained increase in right atrial pressure. **B,** The recording shows a more normal variation of femoral pressure and a lower right atrial pressure.

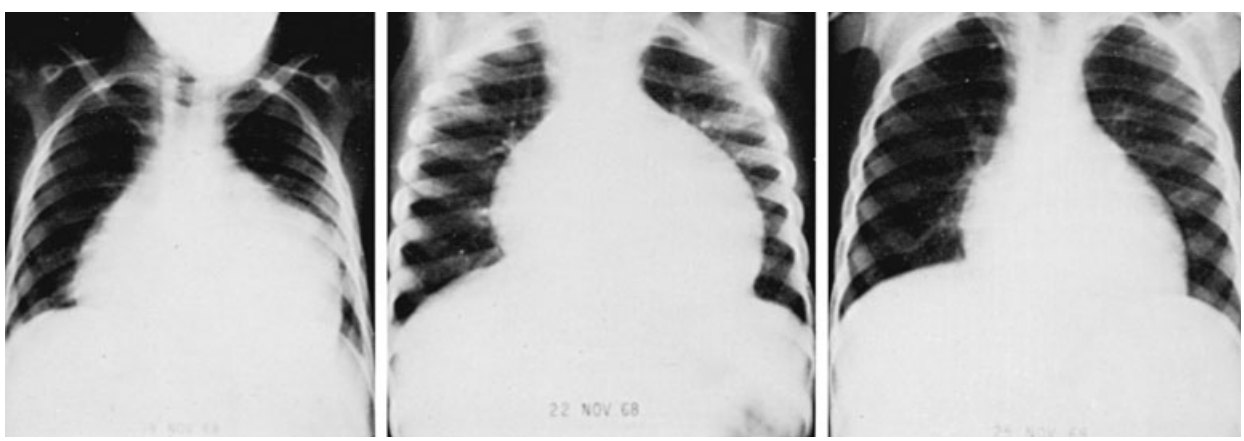

Figure 33–3 In a patient with pericarditis, the first two radiographs show an enlarged cardiac shadow without an increase in pulmonary vascular markings. The third radiograph shows a marked decrease in apparent heart size after pericardiocentesis.

wave (i.e., a diphasic wave or an upright T wave with a notched summit) sometimes is observed. In stage IV, these changes may resolve completely. T-wave abnormalities may persist for life, however, and do not indicate active disease.

Ginzton and Laks[34] compared the electrocardiograms of 19 patients with acute pericarditis with those of 20 healthy patients. By forming a ratio of the amplitude of the ST-segment and T-wave height in all patients, a value of 0.25 or greater in lead V_6 had a positive and negative predictive value of 1.0 for determining the presence of pericarditis. This finding also was true in leads I, V_4, and V_5, although the predictive values were not as high as in lead V_6. Using Spodick's criteria for their patients, Ginzton and Laks[34] were unable to distinguish healthy, normal individuals from patients with acute pericarditis. Their method may prove to be more reliable, although a large study enrolling children has not been performed.

Electrical alternans is seen in a large pericardial effusion. Electrical alternans refers to the alternation in electric amplitude of the T wave and the QRS complex with each cardiac cycle. It is thought to result from the rotational and pendular motion of the heart suspended in pericardial fluid.

Deviations from classic patterns occasionally occur, and single electrocardiographic changes are common findings. All 12 children reported by Okoroma and colleagues[68] had ST-segment elevation, whereas only 3 had concomitant low voltage.

Although many textbooks cite the frequent occurrence of dysrhythmias with pericarditis, these occurrences are unusual in the absence of coexisting heart disease. In one study, 20 of 49 patients with acute pericarditis had no underlying heart disease.[81] Seven patients had no dysrhythmias documented on 24-hour Holter monitoring, and 10 of 20 had infrequent single ectopic beats. Only three patients had supraventricular tachycardia.

M-mode echocardiography is the most sensitive method for diagnosing significant pericardial effusion (Fig. 33–4).[39,46] With a small to moderate effusion, only a "fluid space" is seen posteriorly (see Fig. 33–4B). With a larger effusion, fluid is seen anteriorly and posteriorly, and the septal motion becomes grossly abnormal. The heart may give the appearance of freely swinging (see Fig. 33–4A). Newer echocardiographic techniques, such as two-dimensional sector scanning, are not more useful than the conventional M-mode.

Friedland and colleages[30] prospectively performed transthoracic two-dimensional echocardiography in 36 children with staphylococcal bacteremia; 89 percent had at least one suspected focus of infection, and 19 had community-acquired infections. Vegetations were detected in four children without clinical manifestations of endocarditis. Two other children, including one without suggestive clinical features, had significant pericarditis detected. The researchers concluded that echocardiography should be considered for children with bacteremia caused by *S. aureus*, even when an obvious noncardiac source of infection exists.

Computed tomography and magnetic resonance imaging of the chest are other modalities used to examine the pericardium.[8] They may help to differentiate a bacterial pericarditis from other conditions involving the pericardium. Occult or unsuspected pericarditis has been discerned with radionuclide techniques in immunocompromised patients and in trauma patients.[38,76]

A pericardial effusion may be diagnosed by noticing a discrepancy between the position of a catheter placed adjacent to the lateral wall of the right atrium and the right cardiac border. An injection of radiopaque contrast material into the right atrium may delineate these findings further. Pressure measurements at the time of cardiac catheterization reveal the elevated right atrial pressure and emphasize further the exaggeration of venous, systemic, and left ventricular pressures imposed by inspiration (see Fig. 33–2). Injection of carbon dioxide or air into the pericardium percutaneously may delineate further the pericardial effusion fluoroscopically and differentiate freely moving fluid from loculated areas (Fig. 33–5).

The diagnosis of purulent pericarditis is established definitively only by direct examination of pericardial fluid. Purulent fluid is characterized by a predominance of polymorphonuclear leukocytes; however, it also may occur early in the course of viral and tuberculous pericarditis. Proper handling of pericardial fluid is crucial to recovery and identification of the etiologic agent, as follows:

1. Fluid should be placed directly into broth capable of supporting aerobic and anaerobic microorganisms. The fluid should be plated directly onto agar media, such as blood agar, chocolate agar, or MacConkey agar.
2. Cultures also should be submitted for identification of *M. tuberculosis*, fungi, and viruses.
3. Several slides should be prepared for immediate examination by Gram stain and stain for acid-fast bacilli. Unstained slides should be stored in case of controversy or the need for special histochemical stains.
4. Antigen detection for *S. pneumoniae* or polymerase chain reaction for other microorganisms may be useful in selected

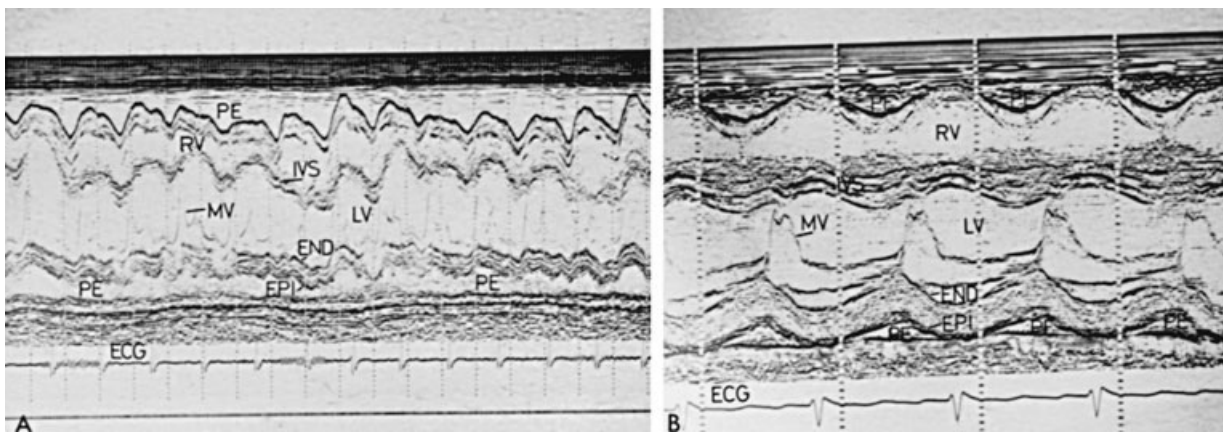

Figure 33–4 **A** and **B**, Serial echocardiograms of a child before pericardiocentesis **(A)** and after pericardiocentesis **(B)**. **A,** Note the large effusion anteriorly and posteriorly with the "swinging" movement of the septum and anterior and posterior walls. **B,** The heart movement is normal, and there remains only a small effusion anteriorly and posteriorly. cases, particularly when the patient has received prior antimicrobial therapy.[58]

The causative microorganism is isolated from blood cultures in many patients. When indicated, cerebrospinal fluid also should be cultured. Because purulent pericarditis often occurs after infections of the lung or pleural space, thoracentesis can reveal the etiologic agent in many cases. Documentation of empyema together with evidence of pericardial disease correlates highly with purulent pericarditis.

Acid-fast bacilli are seen on stained smears of pericardial fluid from 15 to 42 percent of patients with tuberculous pericarditis.[6] Examination of pericardial biopsy specimens by routine methods and with special stains such as the auramine O stain can increase the frequency of identification of *M. tuberculosis*.[66] A negative purified protein derivative skin test does not exclude the diagnosis of tuberculous pericarditis.

Grossly bloody pericardial fluid is observed frequently in patients with *Histoplasma* pericarditis, and an aspirate of the effusion reveals a predominance of mononuclear leukocytes. Growth of *Histoplasma capsulatum* from pericardial fluid rarely is successful. Showing the typical intracellular yeast forms on special stain of pericardial tissue also is helpful. Elevation of the yeast phase of the complement-fixation titer in pericardial fluid allows one to make a more rapid diagnosis.[71] Serum precipitin antibodies to *H. capsulatum* also indicate acute histoplasmosis and are helpful when present. Detecting the polysaccharide of *H. capsulatum* in urine or other body fluids is a rapid and sensitive means by which to establish the diagnosis of histoplasmosis.

DIFFERENTIAL DIAGNOSIS

Any patient with a rapidly increasing heart size in the absence of increasing pulmonary vascular markings should be suspected to have a pericardial effusion. Purulent pericarditis must be differentiated from pericardial effusion caused by collagen diseases, other infectious agents (e.g., viral, tuberculous, rickettsial, protozoan), neoplastic disorders, metabolic disorders, and congestive heart failure.[14] Glycogen storage disease, congenital heart disease, primary myocardial disease, cardiac tumors, and coronary artery aberrations (i.e., anomalous origin from the pulmonary artery, medial wall necrosis, and Kawasaki disease) may be confused with pericardial effusion.[14] Appropriate analysis of pericardial fluid usually permits differentiation of purulent pericarditis from pericarditis caused by other disorders.

TREATMENT

Purulent pericarditis is a potentially life-threatening illness that requires pericardial decompression and open drainage, appropriate antimicrobial therapy, and intense supportive therapy. Ainger[1] stated that more than half of children with purulent pericarditis require early or emergency drainage of the pericardium for relief of critical tamponade. Although bedside needle pericardiocentesis may be lifesaving or necessary for establishing a rapid diagnosis, Fowler and Manitasas[28] reported three deaths related to pericardiocentesis performed by inexperienced physicians. Complications include arrhythmias resulting from myocardial injury, laceration of the coronary arteries leading to hemopericardium and tamponade, and pneumothorax. Ledbetter[57] described a 10-year-old girl with staphylococcal pericarditis who developed an aortic aneurysm after undergoing multiple pericardiocentesis procedures for recurrent tamponade. The subxiphoid approach is recommended, and Hoffman and Stanger[44] have described the proper technique.

Decompression and drainage of the pericardium are safest in a controlled environment, such as in an operating room or under fluoroscopy in the catheterization laboratory. If the patient is awake and agitated, premedication may be required.

If pericardiocentesis does not relieve symptoms successfully, and evidence of tamponade continues, immediate surgical drainage is necessary. Multiple attempts may prove unsuccessful and can lead to serious complications. The pus surrounding the heart may be too thick to be aspirated, as has been seen especially with *H. influenzae* infection.[62] Surgical creation of a pericardial window with a drain occasionally is necessary for complete removal of fluid, which accumulates rapidly. In preparation for evacuation of the pericardial fluid during tamponade, adequate cardiac output can be maintained by stimulating the heart with pharmacologic agents that cause a chronotropic and an inotropic effect. Isoproterenol administered intravenously at a rate of 0.05 to 0.10 μg/kg/min is our drug of choice. It does not replace evacuating the fluid, but it gains time until the aspiration or drainage can be done.

Medications that tend to decrease heart rate and intravascular volume are contraindicated because they compromise the patient further. Wyler and colleagues[89] warn against the use of halothane anesthesia because of its known depressant effect on myocardial function. They described two patients who had reversible cardiac arrest when this agent was used during surgery to relieve tamponade.

Controversy exists regarding the approach and extent of surgery.[26,28,29,55,63,75] A left anterolateral thoracotomy through the fifth intercostal space or a subxiphoid approach with removal of the xiphoid process seems best. Most surgeons favor the creation of a pericardial "window"; however, some favor more extensive removal of pericardial tissue. This decision may be influenced by the severity of pericardial inflammation or the presence of bloody pericardial fluid because these conditions have greater potential for producing acute or chronic constriction. Care must be taken during the procedure not to injure the phrenic nerves.

Morgan and colleagues[62] reviewed 15 children with purulent pericarditis between 1971 and 1981. *H. influenzae* occurred in 7 of 15 patients. Most patients had pericardiocentesis followed by an anterior interphrenic pericardiectomy and recovered completely. In a series of nine children with *H. influenzae* pericarditis, all received a limited left thoracotomy with subxiphoid approach for pericardiostomy, and no deaths occurred.[16] Video-assisted thoracoscopic approaches to managing pericarditis have been described, but further experience is necessary for pediatric patients.[60] For selected patients for whom surgery cannot be performed in a timely manner, the instillation of intrapericardial streptokinase or urokinase or other thrombolytic agents has been successful in draining purulent pericarditis and preventing the need for a more extensive surgical procedure.[50]

Antimicrobial therapy alone is insufficient for the successful treatment of purulent pericarditis. The survival of patients with purulent pericarditis is improved significantly when early pericardial drainage is performed (Table 33–3). In the preantibiotic era, draining the pericardium decreased the mortality rate from nearly 100 percent to 45 percent.[7] Occasionally, patients with meningococcal pericarditis have been managed successfully without pericardial drainage.[18] Fyfe and colleagues[31] described 73 of 79 patients with *H. influenzae* pericarditis seen between 1928 and 1984. The mortality rate before 1960 was 64 percent (7 of 11 patients), although five of seven deaths were reported before the antibiotic era. From 1960 to 1969, the mortality rate was 36 percent, and from 1970 to 1979, it decreased to 11.5 percent. From 1980 to 1984, 25 cases with no mortality were reported.

When the etiologic agent cannot be detected rapidly, the initial antibiotic regimen should consist of two or more drugs. Because *S. aureus* is a major pathogen, a penicillinase-resistant penicillin, such as nafcillin or oxacillin, must be included in a dose of 200 mg/kg/24 hr (maximum 12 g). In regions where infections caused by methicillin-resistant *S. aureus* have occurred in the community, when strains of *S. pneumoniae* resistant to the extended-spectrum cephalosporins are present, or when the infection is nosocomially acquired, vancomycin should be given, 40 to 60 mg/kg/day in four divided doses (maximum 4 g). Cefotaxime (200 to 300 mg/kg/day in three or four divided doses) or ceftriaxone (100 mg/kg/day in one or two doses) should be administered to provide protection against *S. pneumoniae* (including penicillin-resistant strains), *N. meningitidis*, and *H. influenzae* type b for children who may be inadequately immunized.

An aminoglycoside antibiotic should be added to the above-mentioned combined drug therapy when purulent pericarditis occurs after cardiac surgery, in association with genitourinary infections, or in the immunocompromised host. For patients who are allergic to penicillin, vancomycin, clindamycin, or cefazolin is substituted for the treatment of susceptible *S. aureus*; some patients who are allergic to penicillin are sensitive to cephalosporins.

The duration of therapy is empiric and is determined partly by the nature of concomitant infection. Generally, after a pathogen is isolated and the antimicrobial susceptibilities are known, the most specific antimicrobial agent is continued intravenously for 3 to 4 weeks.

Using chemotherapy to treat tuberculous pericarditis has had a major impact on mortality. Before its use, the mortality rate in the acute phase was 80 to 90 percent. The other 10 to 20 percent of patients died of constrictive pericarditis or miliary tuberculosis.[69] The use of three or four drugs, including isoniazid, pyrazinamide, rifampin, and possibly streptomycin, for 9 to 12 months is recommended. The role of corticosteroids in preventing progression to constriction or decreasing mortality is unclear.[23,61,69] In selected cases, pericardiectomy may be indicated to prevent constrictive pericarditis.

Amphotericin B, alone or with other systemic agents, is indicated for treatment of fungal pericarditis. It rarely is required for successful therapy of *Histoplasma* pericarditis, for which nonsteroidal anti-inflammatory drugs are recommended for 2 to 12 weeks, depending on the clinical resolution of symptoms and physical findings of pericarditis.[88] Steroids may be tried for 1 to 2 weeks. As with bacterial pericarditis, open pericardiectomy is crucial for the successful treatment of *Candida* pericarditis.[74]

General supportive therapy in the acute stage of infection may include the administration of oxygen, volume expansion to increase ventricular filling pressure, and isoproterenol to facilitate systolic emptying. Digitalis and diuretics should be used cautiously and only when indicated by decreased myocardial function. Serial electrocardiograms may indicate the presence of occult arrhythmias and alert the physician to the degree of myocardial involvement. The patient must be monitored carefully for signs of reaccumulation of pericardial fluid and for the development of acute constrictive pericarditis. Strauss and colleagues[82] reported this complication in 2 of 12 children with purulent pericarditis. Acute constriction may develop within weeks of the initial pericardial infection[5,10] and has been reported at 8 days.[73] Constrictive pericarditis may be suspected by increasing jugular and central venous pressure, weight gain, enlarging liver, worsening dyspnea, and decreased urinary output. The persistence of heart failure when the cardiac silhouette is becoming smaller also suggests the development of constrictive pericarditis. Complete pericardiectomy should be performed promptly when constriction is suspected.

TABLE 33–3 Influence of Pericardial Drainage on Survival in Purulent Pericarditis in Children

Treatment	Survived	Died
Antibiotics alone	5	28
Antibiotics and pericardial drainage	45	10

PROGNOSIS

The current mortality rate for acute purulent pericarditis ranges from 25 to 75 percent. Accurate statistics are difficult to compute from the literature because the nature and severity of underlying disease have not been considered. Factors that contribute to mortality are delay in recognition, absence of early surgical drainage, presence of cardiac tamponade, degree of myocardial involvement, etiologic agent (particularly *S. aureus*), and age of the patient. Long-term follow-up of children with purulent pericarditis is recommended. They should be followed carefully for the presence of a constrictive component as a sequela to the acute infection. Most children recover fully, however, and return to normal activity.

VIRAL PERICARDITIS

In 1951, Christian[17] suggested that viral infections were responsible for cases of idiopathic or benign pericarditis. A viral cause has not been substantiated in many patients, however.

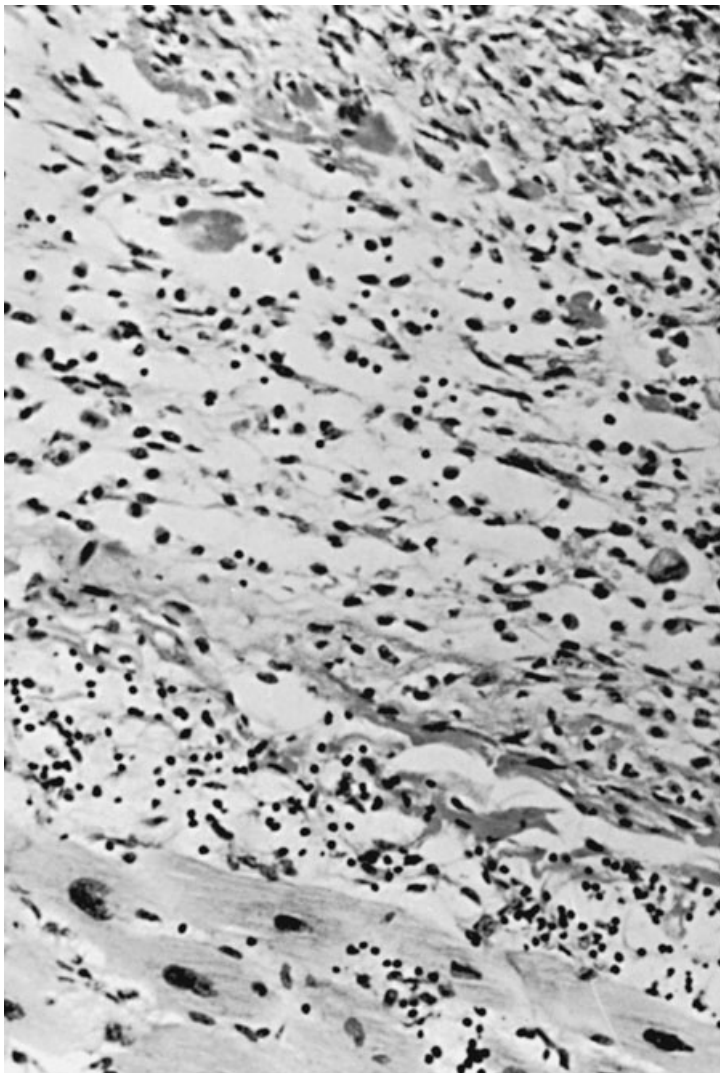

Figure 33–6 In this case of viral pericarditis, there is a layer of fibrin and fibroblasts along the pericardial surface. The mononuclear cell infiltrate in the epicardium extends into the outer myocardium (hematoxylin and eosin staining, ×400). *(Courtesy of Edith P. Hawkins, M.D., Texas Children's Hospital, Houston.)*

ETIOLOGY

The principal viruses implicated in pericarditis are the coxsackieviruses.[65] Adenoviruses have been recovered less frequently.[49] Associations with varicella,[85] cytomegalovirus,[13] smallpox vaccinations, influenza,[43] influenza vaccinations,[83] and infectious mononucleosis[47,78] have been reported.

CLINICAL MANIFESTATIONS

In approximately 40 to 75 percent of cases, the patient has a history of upper respiratory tract infection for 10 days to 2 weeks preceding the onset of symptoms. Fever and chest and abdominal pain are the most common symptoms.[17] A friction rub may be heard in 50 to 80 percent of cases.[87] Children with viral pericarditis generally are less toxic and experience smaller elevations in body temperature than do children with purulent pericarditis. Some appear acutely ill, however. Large amounts of pericardial fluid accumulation and tamponade are rare findings.

INVESTIGATIVE TECHNIQUES

The electrocardiographic, radiographic, echocardiographic, and nuclear scanning findings described for patients with purulent pericarditis also are observed in patients with viral pericarditis. The peripheral leukocyte count may reveal fewer polymorphonuclear leukocytes than in patients with bacterial pericarditis. Mononuclear cell infiltrates in the pericardium with extension into the myocardium may be seen (Fig. 33–6).

If obtained, pericardial fluid should be sent for cell count and viral culture. Nasopharyngeal and rectal samples also should be obtained and cultured for viruses. Acute and convalescent sera should be obtained so that appropriate titers can be measured if a virus is isolated.

COURSE AND PROGNOSIS

Viral pericarditis generally resolves spontaneously over the course of 3 to 4 weeks.[65] Large pericardial effusions and tamponade are rare occurrences.[14] Generally, bed rest for approximately 1 week and analgesics for pain are the only therapy that is required. Constrictive pericarditis is a rare occurrence, but pericarditis may recur.[65]

CHAPTER 34

MYOCARDITIS

Jesus G. Vallejo

Myocarditis is defined clinically and pathologically as inflammation of the myocardium. The clinical presentation and cause may be quite varied. This entity may go unrecognized in numerous patients whose illness may resolve spontaneously, or it may lead to significant morbidity and mortality.

In the early part of the 20th century, most cases of myocarditis were classified as idiopathic, and a diffuse or focal interstitial inflammation was identified on histologic examination. Rheumatic fever, diphtheria, and other bacterial infections were the only diseases recognized as associated with myocarditis, although some experts suspected that viruses might play a significant etiologic role in many cases.[157] After the discovery in 1947 of the coxsackievirus group and the subsequent isolation and identification of other viruses, the number of cases of myocarditis classified as idiopathic diminished rapidly.[35]

EPIDEMIOLOGY

The diverse clinical manifestations have made the true incidence of myocarditis difficult to determine. The clinical course of acute myocarditis can be insidious, with limited inflammation and cardiac dysfunction, or it can be overwhelming, leading to severe cardiac injury and cardiac failure. As a clinical entity, myocarditis is an uncommon occurrence in children. At Texas Children's Hospital, Houston, Texas, between 1954 and 1977, myocarditis represented 0.3 percent of the 14,322 patients seen by the Cardiology Service.

Because not all cases of myocarditis are recognized clinically, a much higher incidence is recorded in autopsy series. An autopsy incidence of 1.15 percent was found from 4343 studies performed between 1954 and 1977 at Texas Children's Hospital. This rate is considerably lower than the incidence of 6.83 percent reported by Saphir and Simon[157] in 1944 for 1420 autopsies performed on children. In Saphir's series, 32 of 97 cases had or probably had rheumatic carditis,[156] whereas only 2 cases occurred in the Texas Children's Hospital series. The discrepancy is even more pronounced when these observations are compared with those of Burch and colleagues,[26] who showed evidence of interstitial myocarditis in the hearts of 29 of 50 infants and young children undergoing routine postmortem studies.

Some of the discrepancies between the clinical and autopsy series may be explained by the fact that the manifestations of myocarditis are subclinical in many cases and may be recognized only by changes on electrocardiogram (ECG) or perhaps not at all. In many instances, myocarditis is only one component of a generalized illness, and the cardiac dysfunction, if mild, may be overlooked.

ETIOLOGIES

Myocarditis may occur with many common infectious illnesses that affect infants and children (Table 34–1). In most cases of myocarditis, the etiologic agent is never identified, however. In the United States and Western Europe, viruses are the most common causes of acute myocarditis. Myocarditis generally is a sporadic disease, but epidemics have been reported. Most epidemics have been caused by coxsackievirus group B and have affected infants in the newborn period.[46,52] Gear and Measroch[62] were the first to identify coxsackievirus B in association with myocarditis after an epidemic occurred in a nursery in a maternity home in southern Rhodesia.

The association between virus infection and the development of myocardial disease also was made by Grist and Bell,[70] who presented comprehensive serologic data correlating enterovirus infection with acute viral myocarditis. In the World Health Organization record during the 10-year period from 1975 through 1985, the coxsackieviruses B represented the most frequent inflammatory agents in cardiovascular disease (34.6/1000), followed by influenza B virus (17.4/1000), influenza A virus (11.7/1000), coxsackievirus A (9.1 per 1000), and cytomegalovirus (CMV) (8/1000).[27] Karjalainen and colleagues[90] prospectively examined 104 conscripts during the 1978 influenza A virus (H1N1) epidemic in Sweden. The incidence of myocarditis was 9 percent of the 67 verified cases of influenza virus infection.

The development of molecular techniques such as polymerase chain reaction (PCR) has improved the testing of endomyocardial biopsy specimens for potential viral pathogens. A study using PCR identified viral genome in 38 percent of endomyocardial biopsy specimens from patients diagnosed with acute myocarditis.[21] Of the positive PCR samples, 23 percent were positive for adenovirus, 14 percent for enterovirus, and 3 percent for CMV. Parvovirus B19, influenza A virus, Epstein-Barr virus, herpes simplex virus (HSV), and respiratory syncytial virus were detected in less than 1 percent of cases.

Investigators also have speculated for decades on the possibility that acute myocarditis is a common forerunner of idiopathic dilated cardiomyopathy (DCM). Evidence supporting this hypothesis was presented first by Orinius and Pernow,[136] who found cardiac disease in humans years after an apparent uncomplicated coxsackievirus infection. Subsequently, Bowles and colleagues,[22] using a slot-blot hybridization technique, provided conclusive evidence for the presence of enterovirus in endomyocardial biopsy samples from patients with DCM. In another study, Bowles and associates[21] detected viral genomes in 20 percent of 149 patients with the diagnosis of DCM. In these

patients, adenovirus was identified in 12 percent and enterovirus in 8 percent of DCM cases. In all age groups, adenovirus and enterovirus were the viruses most commonly detected in acute myocarditis and DCM.

The discovery that coxsackievirus and adenovirus use the same receptor to infect host cells has provided an explanation for why these unrelated viruses account for most myocarditis cases. Bowles and colleagues[20] proposed that mutations in the coxsackie-adenovirus receptor could represent a host factor for the development of myocarditis or DCM. These investigators screened patients with myocarditis or DCM, including 24 patients in whom a viral etiology was identified by PCR and reverse transcription PCR. In addition, 50 patients who presented with heart failure and had echocardiograms diagnostic for DCM, but in whom no etiology was identified, were screened. Three silent substitutions and an intronic substitution were detected, but no apparent disease-causing mutations were detected. These data suggested that mutations in the coxsackie-adenovirus receptor are unlikely to play an important role in the pathogenesis of viral myocarditis or DCM.

Myocarditis also has been reported as a complication of infection with many other viruses (see Table 34–1). The teratogenicity of the rubella virus in the first 4 months of pregnancy is well known. Ainger and colleagues[3] showed that, because of the persistence of the virus in the fetus, extensive involvement of the myocardium may lead to severe myocarditis. Of 47 infants with congenital rubella, 10 had myocarditis, and 4 died. Morbidity in the survivors was severe. Rubella immunization programs have succeeded in reducing the number of congenital cases, and since 2001, only five infants with congenital rubella syndrome have been reported. Three were born in 2001, one was born in 2003, and one was born in 2004. This epidemiologic evidence strongly suggests that rubella no longer is endemic in the United States.[146]

Osama and colleagues[137] prospectively evaluated 312 cases of varicella over a 1-year period. Eighteen (5.8%) of the 312 cases showed evidence of myocarditis. A statistically significant increase in myocarditis was found in patients who complained of skeletal myalgia.

Currently, neonatal HSV disease in the United States occurs in approximately 1 in 3200 deliveries, resulting in an estimated 1500 cases of neonatal HSV infection annually.[25] Most (85%) infected infants acquire their infections during birth, in the peripartum period. The spectrum of disease ranges from unapparent infection to a fatal encephalopathy. Myocardial involvement has been described, and herpesvirus has been isolated from the myocardium at autopsy.[48,197] Recognition of genital herpes and delivery of the infant by cesarean section reduce the incidence of myocarditis caused by this agent.

In December 2002, the U.S. Department of Defense began mandatory smallpox vaccination for select service members and employees without contraindications to vaccination, and in January 2003, the U.S. Department of Health and Human Services implemented a voluntary civilian smallpox vaccination program. As of June 15, 2003, the Department of Defense identified more than 50 cases of suspected, probable, or confirmed myopericarditis occurring within 30 days of vaccination in these individuals, based on clinical evaluation of symptoms, ECG, cardiac enzyme assays, echocardiography, and the exclusion of ischemic coronary artery disease. Myocarditis occurred in 7.8 per 100,000 primary vaccinees in the U.S. army, an incidence that was 3.6-fold more than that in unvaccinated individuals.[72]

Reports of respiratory diphtheria are rare in the United States in all age groups. The last culture-confirmed case of respiratory diphtheria in a U.S. adolescent was reported in 1996.[179] Acute mortality of this disease is due to toxin-mediated diphtheritic cardiomyopathy, suffocation by the pseudomembrane, disseminated intravascular coagulation, and renal failure. Approximately one third of cases have ECG findings suggesting myocardial involvement, although the rate of cardiac involvement may be 84 percent in severe cases.[15]

PATHOLOGY

Isolated or idiopathic myocarditis is a rare pathologic entity. The pathologic cardiac findings usually are nonspecific; similar gross and microscopic changes occur regardless of the causative agent.[66,132,142,150] Grossly, all four chambers of the heart are enlarged, and the cardiac weight is increased. The heart usually is flabby and pale. In some instances, especially with coxsackievirus B infections, petechial hemorrhages may be seen on the

epicardial surfaces; pericardial fluid may be tinged with blood. On cut section, the ventricular muscle walls may be thinned. Occasionally, the ventricles are hypertrophied or increased in thickness because of edema. The valves are spared. The endocardial surface usually is unaffected but occasionally may be thickened and appear glistening white. This important observation suggested to some investigators that endocardial fibroelastosis, which manifests as congestive cardiomyopathy, represented a progression from acute viral myocarditis.[73,85]

In a study of 64 hearts of children who had myocarditis or endocardial fibroelastosis, Hutchins and Vie[85] found 18 with endocardial fibroelastosis only, five with myocarditis only, and 41 with features of both diseases. When time from onset of illness to death was 2 weeks or less, only myocarditis was evident. When the time interval was 2 weeks to 4 months, a combined picture was seen, whereas only endocardial fibroelastosis with trivial myocarditis was evident when the time from onset of disease to death was more than 4 months.

These findings were supported further by Hastreiter and Miller,[73] who found microscopic evidence of myocarditis after transthoracic needle biopsy of the myocardium in a child who had the classic clinical picture of endocardial fibroelastosis, including left ventricular hypertrophy on ECG. Fruhling and associates[58] extended these observations by showing coxsackievirus B3 in the myocardium of 13 of 28 infants with endocardial fibroelastosis. Ni and associates[130] analyzed 29 myocardial samples from patients with autopsy-proven endocardial fibroelastosis using specific PCR for enterovirus, adenovirus, mumps, CMV, parvovirus, influenza, and HSV. In 90 percent of samples, viral genome was amplified; more than 70 percent of the samples were positive for mumps viral RNA, whereas 28 percent amplified adenovirus. These data suggest that endocardial fibroelastosis also is a sequela of mumps virus infection.

Saphir and Field[156] observed mural thrombi in the left ventricular cavity in some patients with myocarditis and minute emboli in coronary and cerebral vessels. Coronary emboli, although rare, may play a role in the causation of cardiac dysrhythmias, which sometimes accompany myocarditis.

The microscopic picture of acute myocarditis typically shows a focal or diffuse interstitial collection composed predominantly of mononuclear cells, lymphocytes, plasma cells, and eosinophils. Polymorphonuclear leukocytes rarely are seen, unless the cause of the carditis is bacterial. Virus particles and inclusion bodies rarely are recognized.[144,150]

In severe infections caused by any agent, but especially coxsackieviruses and diphtheria, a loss of cross-striation in the muscle fibers, edema, and, sometimes, extensive necrosis of the myocardium occur. The diphtheria exotoxin has a particular affinity for conductive tissue; dysrhythmias, including complete heart block, are common findings in this form of myocarditis. The exotoxin interferes with protein synthesis by inhibiting a translocating enzyme in the delivery of amino acids.

Although the perivascular accumulation of lymphocytes and plasma cells is described in coxsackievirus B myocarditis, it is a minor finding. When myocarditis is caused by rickettsiae,[184] varicella,[123] trypanosomes,[138,141] or other parasites,[181] or when it occurs as a reaction to sulfonamide,[189] this pattern dominates.

Myocarditis seen with bacterial infections usually differs from that of presumed viral origin (Figs. 34–1 to 34–4). Microabscesses and patchy focal suppurative changes may be observed. Frequently, a perimyocarditis may be seen with concomitant bacterial infection of pericardium and myocardium.

Giant cells with or without granulomata are markers for the diagnosis of giant-cell myocarditis.[84] Granulomata have been observed in the myocardium of patients with tuberculosis, syphilis, rheumatoid arthritis, rheumatic heart disease, sarcoidosis, and certain fungal and parasitic infections. Occasionally, giant cells have been seen in interstitial myocarditis (idiopathic or Fiedler). In many cases, giant-cell myocarditis occurs, but no cause is found.

Two types of giant cells are recognized, one of which seems to be myogenic in origin and is thought to represent transitional forms of myocardial fibers. This type of cell has been found without granulomata. The second, more characteristic giant cell probably is derived from interstitial histiocytes. The latter type typically is seen in patients with myocarditis of nonviral cause, whereas the former is a response to viral infection. Hudson[84] described similar cells in an adult who had received neo-mercazole (carbimazole) therapy, and Hodge and Lawrence[79] reported two cases of granulomatous myocarditis associated with phenylbutazone therapy.

PATHOGENESIS

The pathogenesis of myocarditis is poorly understood, insofar as the disease progresses through different phases with distinctly different mechanisms and clinical manifestations. The

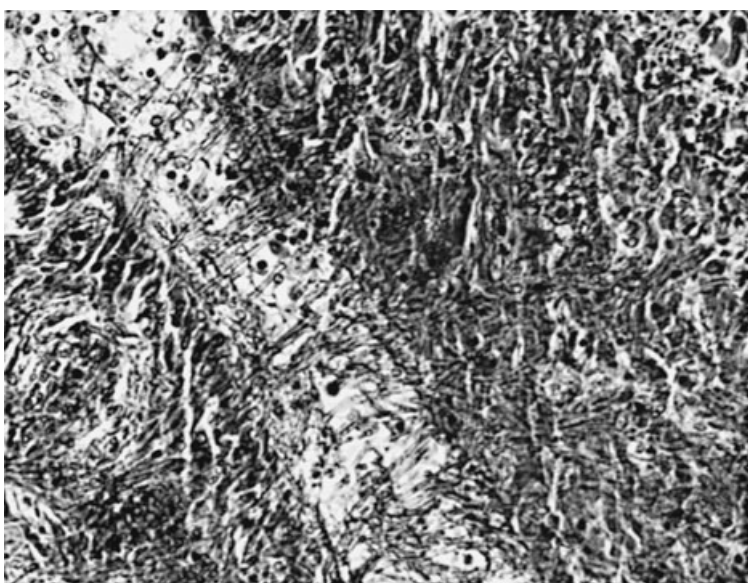

Figure 34–1 *Candida albicans* myocarditis. Notice the focal necrosis of the myocardium with central masses of hyphae and necrotic debris surrounded by mononuclear cell infiltrate (hematoxylin and eosin staining, ×160). *(Courtesy of Edith Hawkins, M.D., Houston, TX.)*

pathophysiology of myocarditis in humans was derived largely from experimental models of coxsackievirus infection. More recently, Liu and Mason[106] have suggested that myocarditis should be viewed as a continuum that comprises three separate phases: acute viral infection (phase I), autoimmunity (phase II), and DCM (phase III).

Phase I of the disease is triggered by the entry and proliferation in the myocardium of the causative virus. Impairment of left ventricular function in mice with histopathologically graded moderate cellular infiltration after coxsackievirus B3 infection supports the important pathophysiologic role of direct viral damage of the myocardium.[173] Phase I concludes with activation of the cellular immune response, which attenuates viral proliferation but also may enhance cardiac injury. Ideally, the immune response should down-regulate to a resting state when viral proliferation is controlled. If immune activation continues unabated despite elimination of the virus, autoimmune disease may result, initiating phase II of the disease. The continuous activation of T cells long after viral clearance occurs is detrimental to the host because cytokine-mediated and direct T-cell–mediated myocyte

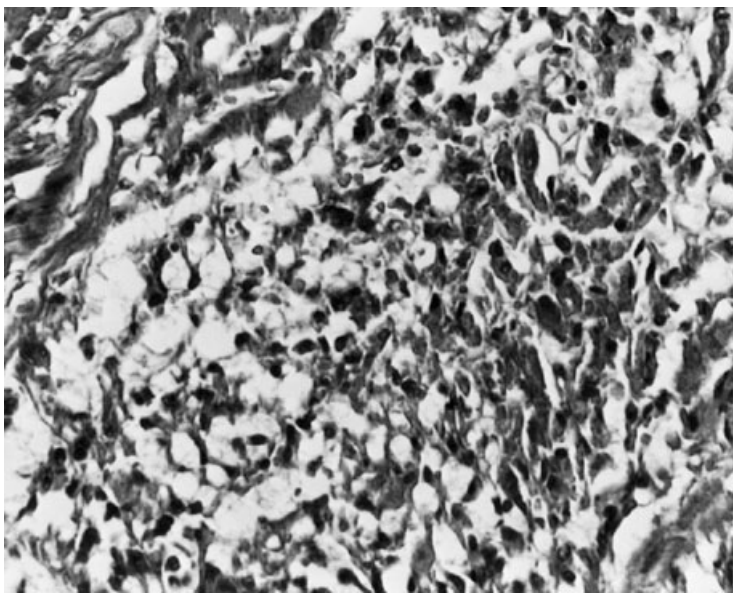

Figure 34–4 Section of myocardium. Vaccinia (smallpox vaccine) myocarditis. Note mononuclear cell infiltrates and fatty degenerative changes (hematoxylin and eosin staining, ×400). *(Courtesy of Edith Hawkins, M.D., Houston, TX.)*

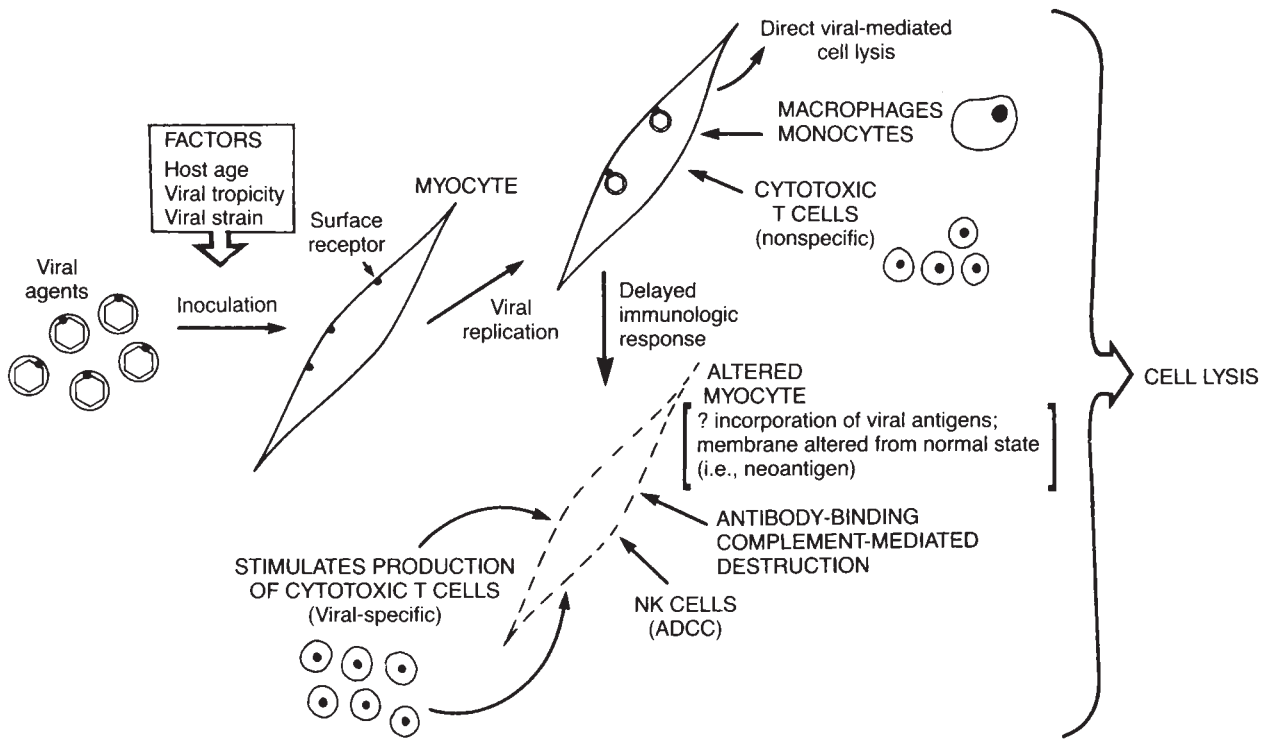

Figure 34–5 Schema for pathogenesis of myocarditis. Viral agents attach to cells by means of surface receptors. After a cell is infected, the cell cycle is changed. Direct virus-mediated cytolysis occurs. Cellular effectors of injury (i.e., macrophages, monocytes, and nonspecific cytotoxic T cells) are involved in the primary reaction. Myocytes that survive are altered in their structure. Cytotoxic T cells specifically targeted against the altered myocyte, natural killer (NK) cells, and complement-activated, antibody-mediated cardiocytolysis or antibody-dependent cellular cytotoxicity (ADCC) participate in the secondary reaction. *(Partially adapted from Maisch, B., Trostel-Soeder, R., Stechemesser, E., et al.: Diagnostic relevance of humoral and cell-mediated immune reactions in patients with acute viral myocarditis. Clin. Exp. Immunol.* 48*:533, 1982.)*

injury leads to impairment of contractile function (Fig. 34–5). Long-term remodeling and progression to DCM characterize phase III of the disease.[82]

The basic function of innate immunity is restriction of the early proliferation of infectious agents. Numerous effector cells and molecules work in concert to restrict this initial spread of an infectious focus. The responding cells include natural killer cells, natural killer/T cells and γδ T cells. Several lines of evidence suggest that mediators of the innate immune system, such as tumor necrosis factor (TNF) and nitric oxide, play an important role in the pathogenesis of viral myocarditis.[115,198] Elevated levels of TNF have been reported in patients with viral myocarditis, and TNF mRNA and protein are consistently up-regulated in the hearts of these patients.[117,158] In mice, the exogenous

administration of TNF aggravates myocarditis, and the neutralization of TNF by antibodies or soluble receptors attenuates the disease.[99,195] These data suggest that TNF production is detrimental in the setting of myocarditis.

More recent studies also have shown that TNF and nitric oxide are beneficial to the host by virtue of their antiviral effects. Mice with defective TNF or nitric oxide expression have increased myocardial injury, a significant increase in viral titers in the heart, and significantly higher mortality rates after infection with encephalomyocarditis virus or coxsackievirus B3.[183,198] These observations highlight the complexity of the innate immune response and suggest that innate immune mechanisms play a dual role in the setting of viral myocarditis. Although the prevailing notion has been that production of cytokine in the heart during viral infection is detrimental, the host-pathogen relationship is changed fundamentally when the host is unable to produce molecules such as TNF or nitric oxide.[183,198]

An important component of the innate immune system uses pattern recognition receptors, such as the Toll-like receptors (TLRs), to recognize pathogen-associated molecular patterns present in microbes.[4] TLRs induce the production of cytokines and interferons and modulate the adaptive immune response. The role of TLRs in the pathogenesis of viral myocarditis is still being explored. More recent studies suggest that cardiac inflammation during viral infection depends on TLRs. Fairweather and colleagues[53] reported that mice with defective TLR4 signaling had decreased coxsackievirus B3 replication and less severe myocarditis 12 days after infection compared with wild-type mice. The presence of TLR4 also was associated with increased production of interleukin-1β and interleukin-18 and increased viral replication in the heart.

In a similar study, Fuse and associates[59] reported that mice deficient in myeloid differentiation factor 88 (MyD88), an adapter protein involved in TLR signaling (except TLR3), also had less myocarditis and attenuated viral replication in the heart after infection with coxsackievirus B3. Coxsackievirus B3–infected, MyD88-deficient mice had significantly higher levels of interferon-β but reduced expression of the coxsackievirus-adenovirus receptor in the heart. The enhanced interferon expression and lower expression of the coxsackie-adenovirus receptor in the heart could explain the attenuation of disease in the MyD88-deficient mice. The final answer on the role of TLRs in the pathogenesis of viral myocarditis awaits further investigation, however.

Although the host genetic factors responsible for the changes observed in the three phases of myocarditis have yet to be defined completely, Woodruff and Woodruff,[192] using a murine model, were the first to show a role for T lymphocytes in the pathogenesis of viral myocarditis. In this study, depletion of T lymphocytes using antithymocyte serum or thymectomy and irradiation led to a decrease in mortality rates and in the inflammatory infiltrate after CVB3 infection. Huber and associates,[83] using BALB/c mice infected with coxsackievirus B3, showed that cytolytic T cells were the agents responsible for the major part of myocardial cell injury. In addition, proinflammatory mediators, such as TNF, released by infiltration cells also adversely affect cardiac function.

Opavsky and colleagues[135] defined the specific contributions of T-cell subsets (CD4 and CD8) and the T-cell receptor beta chain to the pathogenesis of viral myocarditis. When $CD4^{-/-}$ or $CD8^{-/-}$ mice were exposed to CVB3, loss of $CD8^{+/+}$ immune cells did not affect survival significantly, but viral proliferation was attenuated. In contrast, $CD4^{-/-}$ mice showed a trend toward an improvement in survival and a small but significant decrease in the inflammatory infiltrate at 14 days after infection. Mice deficient in CD4/CD8 immune cells and T-cell receptor beta had the best outcome in terms of decreased mortality. A marked decrease in inflammatory infiltrate was noted in CD4/CD8 double knockout mice. Although no significant change occurred in viral titers, a marked decrease in myocardial TNF mRNA 4 days after infection was seen in CD4/CD8 double knockout mice. These same investigators have shown that the T-cell receptor–associated tyrosine kinase $p56^{lck}$ is crucial for coxsackievirus B3 proliferation in the heart and activation of T cells to target the heart.[105] Mice deficient in $p56^{lck}$ were protected against the development of myocarditis, providing further support for the hypothesis that T-cell activation during viral myocarditis contributes to increased inflammation and myocyte destruction in the host.

The ongoing injury that persists may be considered an autoimmune process.[83,191] In murine models, cellular and humoral autoimmunity clearly are involved in the progression to chronic heart disease. Paque and colleagues[140] provide support for this concept. Using CD-1 mice infected with coxsackievirus B3, they found a potassium chloride–extractable antigen in the hearts of mice previously infected with a coxsackievirus B that was specifically immunoreactive with immune mouse peritoneal exudate cells (i.e., stimulated production of a migration inhibitory factor). No viral activity was detected in the animals that had this extractable antigen.

Similar experiments in a primate model confirmed earlier findings in mice and lent further support to similar circumstances in humans.[139] Experimental evidence also has shown that the antigen responsible for cytotoxic T-cell activity is not detectable by antiserum that contains antibodies directed at structural components of the viral capsid. Autoantibodies that have been associated with myocarditis in patients and mice include those directed at cardiac myosin, adrenoreceptor adenine nucleotide translocator, and sarcolemmal and myolemmal proteins. The role played by these autoantibodies in the pathogenesis of myocarditis is unclear; antisarcolemmal antibodies that cross-react with enteroviral epitopes have been shown to damage cardiac myocytes.

More recent studies also have shed light on the mechanisms by which coxsackievirus B3 may contribute directly to the development of myocarditis and DCM. Badorff and colleagues[10-12] reported that the 2A protease encoded by coxsackievirus B3 cleaves dystrophin in cultured myocytes and in infected mouse hearts, leading to disruption of dystrophin and the dystrophin-associated glycoprotein α-sarcoglycan and β-sarcoglycan complex. Dystrophin provides a structural link between the muscle cytoskeleton and extracellular matrix to maintain muscle integrity. Xiong and associates[194] compared the effects of coxsackievirus B3 infection in dystrophin-deficient (*mdx*) and wild-type mice. Coxsackievirus B3 infection significantly enhanced sarcolemmal disruption in the *mdx* mice compared with wild-type mice; the disruption was detectable 2 days postinfection and continued to increase after initial infection. Viral titers were higher in the hearts of *mdx* mice than in the hearts of wild-type mice, indicating greater viral replication in the absence of dystrophin. The observed differences seemed to be a result of more efficient release of coxsackievirus B3 from dystrophin-deficient myocytes. The expression of wild-type dystrophin in cultured cells decreased the cytopathic effect induced by coxsackievirus B3 and the release of virus from the cell. The expression of a cleavage-resistant mutant of the dystrophin protein inhibited coxsackievirus B3–mediated cytopathic effect and viral release further.

PATHOPHYSIOLOGY OF VENTRICULAR DYSFUNCTION IN MYOCARDITIS

With extensive interstitial inflammation, muscle-cell injury, or both, myocardial contractility is reduced. Consequently, the heart enlarges and the end-diastolic volume of the ventricle increases. In the normal heart, an increase in filling volume leads, by the Starling mechanism, to an increased force of contraction, ejection fraction, and cardiac output. In patients with myocarditis, the myocardium is unable to respond in this manner and

cardiac output is reduced. Systemic blood flow may be maintained, however, by use of the cardiac reserve, mediated by the sympathetic nervous system and leading to vasoconstriction of the skin vessels and an increase in heart rate. With progressive disease or any stress (e.g., infection, anemia, fever), the heart may be unable to meet the oxygen demands of the tissues, and the clinical picture of congestive cardiac failure may become evident. Increased end-diastolic volume leads to progressive increase in ventricular end-diastolic pressure, which leads to increased filling pressure, and left atrial and pulmonary venous hydrostatic pressure may be elevated above the colloid osmotic pressure, which normally prevents transudation of fluid across the capillary membranes. Pulmonary congestion and edema and systemic venous engorgement (manifested in infants primarily as hepatic enlargement) are common findings in the more acute forms of myocarditis. In some infants and young children, the presentation is predominantly that of right-sided heart failure.[149]

An appreciation of the disturbance of myocardial function may be gained from the angiographic frames shown in Figure 34–6. The left ventricle is dilated considerably, and the outline is irregular in diastole and systole. The ejection fraction is reduced significantly at 35 percent instead of the normal 60 to 75 percent.

Another means of evaluating left ventricular function is the noninvasive technique of cardiac ultrasound. Gutgesell and colleagues[71] established normal standards for children. An example is shown in Figure 34–7A. The normal shortening fraction (i.e., percentage change in ventricular dimensions between end-diastole and end-systole) is 35 ± 4 percent, regardless of age (range 28–44%). Figure 34–7B illustrates the case of a 4-year-old child with idiopathic myocarditis and shows ventricular dilation with markedly reduced motion of the left ventricular posterior wall and septum, leading to a shortening fraction of only 12 percent. Further assessment of ventricular function can be achieved by measuring systolic time intervals obtained from simultaneous recording of the ECG and the semilunar valve opening and closing points on the echocardiogram.[71]

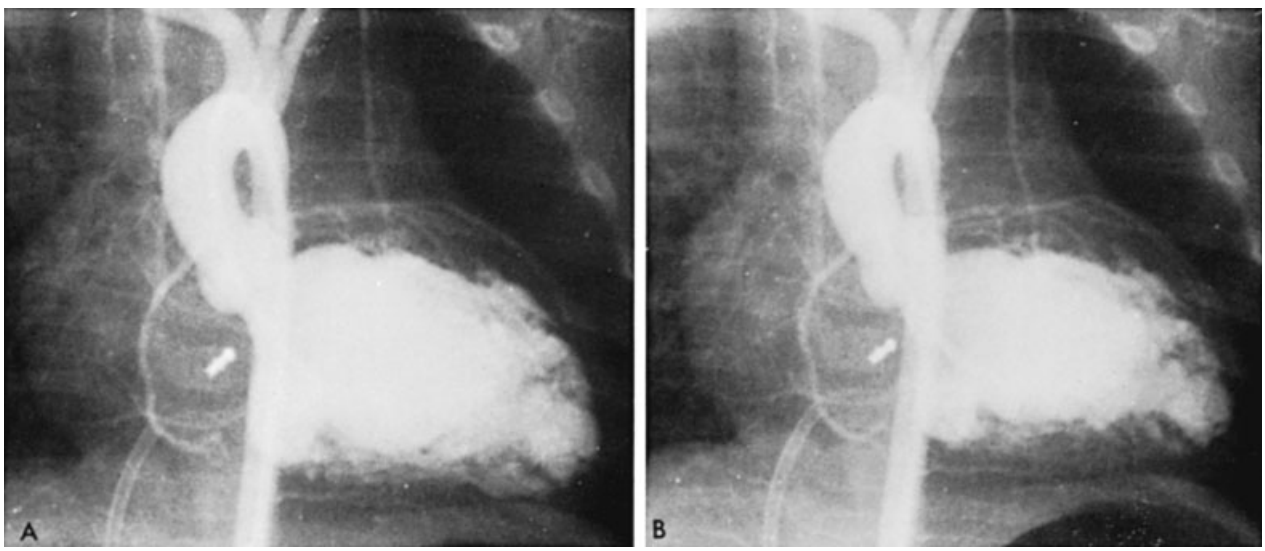

Figure 34–6 **A** and **B,** The end-diastolic **(A)** and end-systolic **(B)** frames from a left ventriculogram of a patient with idiopathic myocarditis show irregularity of the wall and poor contractility.

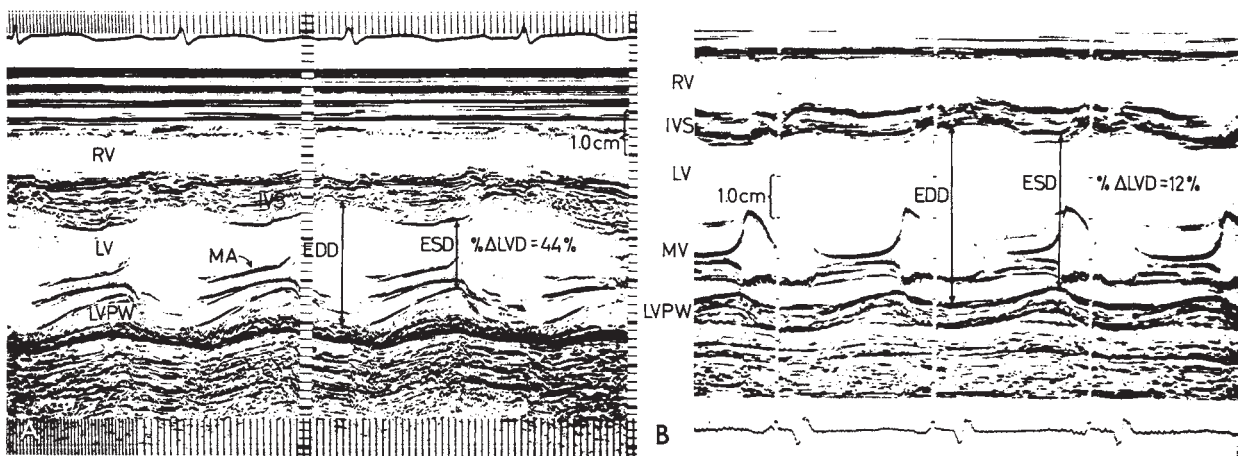

Figure 34–7 **A,** Normal echocardiogram of a 4-year-old child. **B,** Echocardiogram of a 4-year-old child with idiopathic myocarditis shows left ventricular dilation and severely reduced shortening fraction. EDD, end-diastolic dimension; ESD, end-systolic dimension; IVS, interventricular septum; LVPW, left ventricular posterior wall; MA, mitral apparatus; MV, mitral valve, %ΔLVD, percent change in left ventricular dimension (shortening fraction).

CLINICAL PRESENTATION

The clinical presentation of myocarditis varies with the age of the patient and the virulence of the organism. At one end of the spectrum is a fulminant, rapidly fatal illness, and at the other, no apparent clinical disturbance at all. A newborn especially is susceptible to the severe form of myocarditis usually caused by the coxsackieviruses B,[38,92] but it also is recognized with rubella[3] and HSV[193] infections and with toxoplasmosis.[84]

In many of these infections, myocarditis is only one component of a generalized illness, often with severe hepatitis and encephalitis.[17,92] In some instances, however, infections with these organisms may produce only a mild clinical disturbance.[24,86] In the report by Brightman and colleagues,[24] a nursery epidemic of coxsackievirus B5 infection in preterm infants was recognized only by chance because a virologic survey was in progress at the time in the institution. No cases of myocarditis were documented, and all the infants recovered. Findings included lethargy, failure to gain weight, and, in some infants, evidence of aseptic meningitis.

As described in the review by Kibrick and Benirschke[92] of 25 infants with coxsackievirus B myocarditis, vague symptoms such as lethargy and anorexia may herald the onset of the severe disease, emphasizing that close attention should be paid to all symptoms, especially in a newborn, no matter how nonspecific. Four infants had episodes of vomiting, and fever was documented for more than half of the cases; occasionally, the temperature was subnormal. Cyanosis; respiratory distress; and tachycardia, cardiomegaly, or ECG changes occurred in 19 of 23 infants. Tachypnea (a respiratory rate >60/min in a newborn) is an early sign of heart failure in a young infant and should alert the clinician to this diagnosis.

In older infants and children, the manifestations of myocarditis generally are less fulminant than are the manifestations in newborns.[149,154,185,190] An acute and fatal illness has been associated, however, with idiopathic myocarditis[104] and myocarditis caused by enteroviruses,[92] adenoviruses,[75] mumps,[100] chickenpox,[137] diphtheria,[15] CMV,[176] and many of the other causative agents listed in Table 34–1. Some older children have been reported with acute, substernal chest pain consistent with angina and have ECG changes of acute myocardial infarction.[81,119] The usual clinical picture is that of an acute or a subacute illness, which often begins with a mild upper respiratory infection and a low-grade fever.[9] Some infants have only vague, nonspecific suggestions of disease (e.g., irritability, periodic episodes of pallor) before the onset of cardiorespiratory symptoms, which begin a few days to 2 weeks after the onset of the initial symptoms. Abdominal pain may be a prominent complaint in some children.[185]

On examination, these infants and children often are anxious and apprehensive, but some appear apathetic and listless. Pallor may be striking, and mild cyanosis may be present. The skin may be cold and mottled. Respirations are rapid and labored, and grunting may be prominent. The pulse is thready, and blood pressure usually is normal or slightly reduced, unless the infant is in profound shock. The precordium is quiet, without a prominent cardiac impulse. Resting tachycardia invariably is present in children who are critically ill with myocarditis. The heart sounds are muffled, and a prominent gallop rhythm usually is heard. Fine and colleagues[55] found the most sensitive clinical sign of myocarditis to be a soft S_1 at the apex. A prolonged PR interval, which may be a nonspecific finding in many febrile illnesses, also can cause a soft S_1, however, without any other evidence of myocarditis.[162] A high-pitched systolic murmur of mitral insufficiency is heard in some cases. The breath sounds are harsh. Scattered rhonchi and, occasionally, fine crepitations in the lung bases may be detected.

Almost uniformly, the liver is enlarged; edema is a rare finding. Some infants are less distressed and have signs of only mild congestive cardiac failure, without the signs of peripheral circulatory failure. Other infants have no signs of cardiac compromise, and myocarditis is recognized only as part of a generalized illness by a disturbance in the ECG pattern.

DIAGNOSIS

CLINICAL CHARACTERISTICS AND RADIOGRAPHIC EVIDENCE

Myocarditis often is difficult to diagnose, but it should be suspected in any infant or child who presents with congestive heart failure and who has or recently has had a febrile illness. The history should include information regarding travel, exposure to tuberculosis, recent drug ingestion, and illnesses in other family members or schoolmates. A quiet precordium in the presence of a gallop rhythm and decreased intensity or muffling of the heart sounds are findings that strongly suggest the diagnosis. A tachycardia out of proportion to the level of fever also should be viewed with suspicion. A physiologic S_3 is a common finding in normal healthy children and in children with anemia and fever. Sometimes, as with fever and associated tachycardia, the cardiac rhythm may have a gallop cadence. In association with it, however, the precordium is hyperactive, and the heart sounds are crisp and have increased intensity. An unusually prominent S_3 suggests a disturbance of ventricular compliance without other evidence of compromised cardiac function and should be investigated further with an echocardiogram, a chest radiograph, and an ECG.

Chest radiographs of infants and children who have signs of congestive cardiac failure invariably show cardiomegaly, usually of a severe degree (Fig. 34–8). All four chambers may be enlarged, and evidence of pulmonary venous congestion often is found.

Sometimes, especially in newborns, the first sign of illness is acute circulatory collapse, and, in this circumstance, the cardiac size may be normal. The same is true of children who have an arrhythmia rather than congestive heart failure. Other patients may present with Stokes-Adams attacks caused by complete heart block.[103]

The occurrence of an arrhythmia, especially after a febrile illness, should alert the clinician to look for other signs of myocarditis.[33,165] Lind and Hulquist[104] detected significant dysrhythmias in five infants with isolated myocarditis. Four of the five infants died, and three of these infants had paroxysmal atrial tachycardia. Paroxysmal atrial tachycardia has been reported in patients with viral myocarditis[33,164] and has been described in patients with diphtheritic myocarditis.[15] Atrial ectopic tachycar-

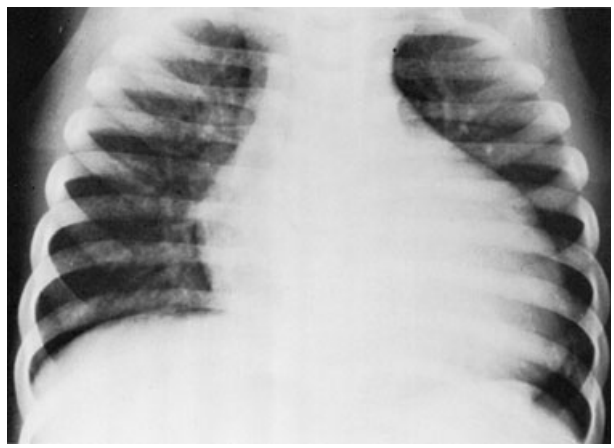

Figure 34–8 Marked cardiomegaly with a mild increase in the pulmonary venous pattern in the upper lobes.

dia may mimic sinus tachycardia and, if not carefully evaluated, may be the primary cause for significant myocardial dysfunction. Complete heart block has been described in children in association with acute idiopathic myocarditis[88,103] and with rubella,[107] coxsackievirus,[159] and respiratory syncytial virus[13,63] infections. In some instances, complete heart block is permanent, and in others, it is temporary.[13,64,88] The ECG is an essential diagnostic tool for all patients with suspected myocarditis.

The classic ECG pattern in myocarditis is one of diffuse low-voltage QRS complexes (<5 mm total amplitude) with low-amplitude or slightly inverted T waves and a small or absent Q wave in leads V_5 and V_6 (Fig. 34–9). The low-voltage signal may be present in the standard leads and the precordial leads. Figure 34–10 shows the ECG of an infant with acute myocarditis and shows a pattern of acute myocardial ischemia. Figure 34–11A shows multifocal extrasystoles and severe intraventricular conduction delay in a patient with diphtheritic myocarditis; the ECG of this child returned to normal over the course of 3 months (see Fig. 34–11B). The ECG from a 5-month-old infant who had mild fever, diarrhea, and vomiting for 3 to 4 days before admis-

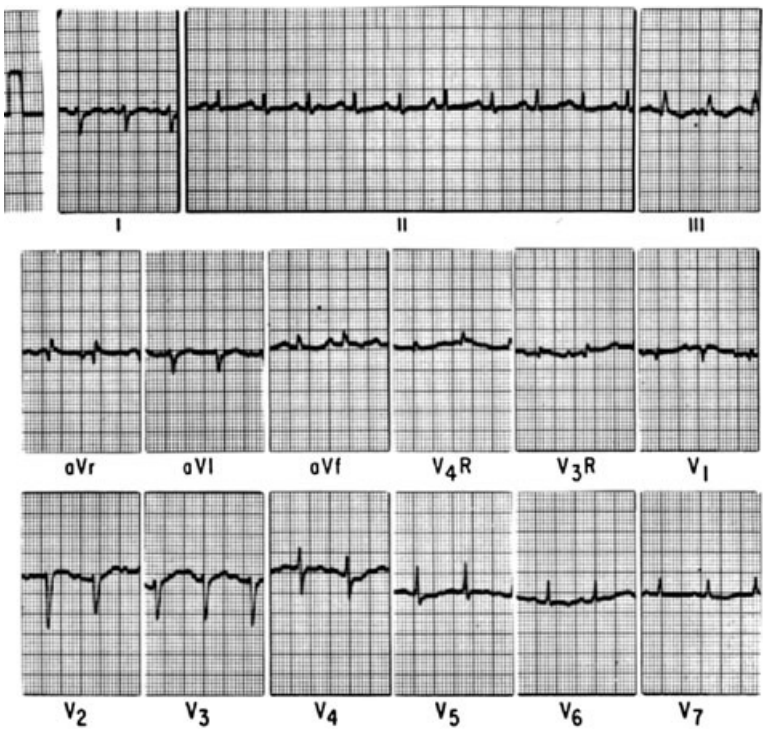

Figure 34–9 Diffuse low-voltage or QRS complexes with T-wave flattening and 1-mm Q waves in the lateral precordial leads represents the classic pattern in myocarditis.

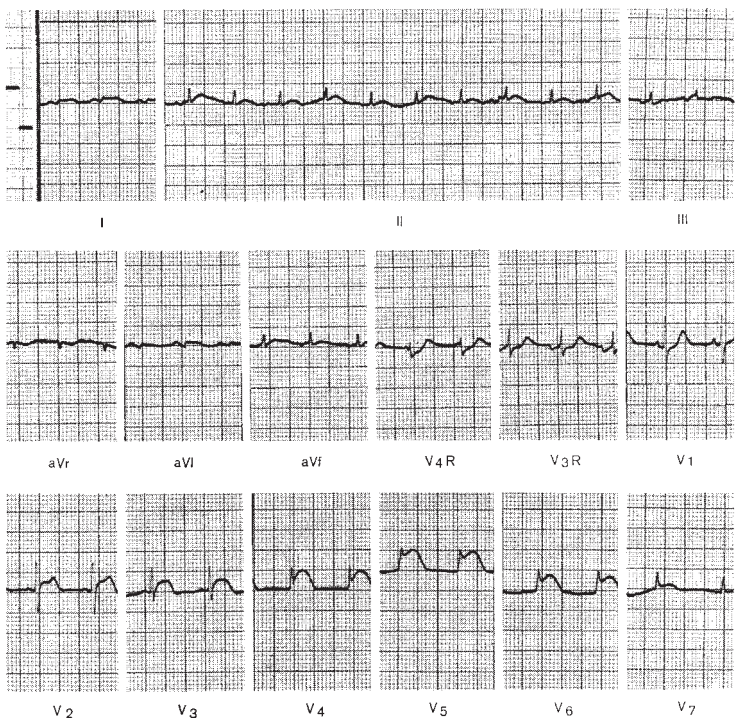

Figure 34–10 In addition to low voltage, there is evidence of acute myocardial ischemia with 4- to 5-mm ST-segment elevation dominantly in the middle and lateral precordial leads.

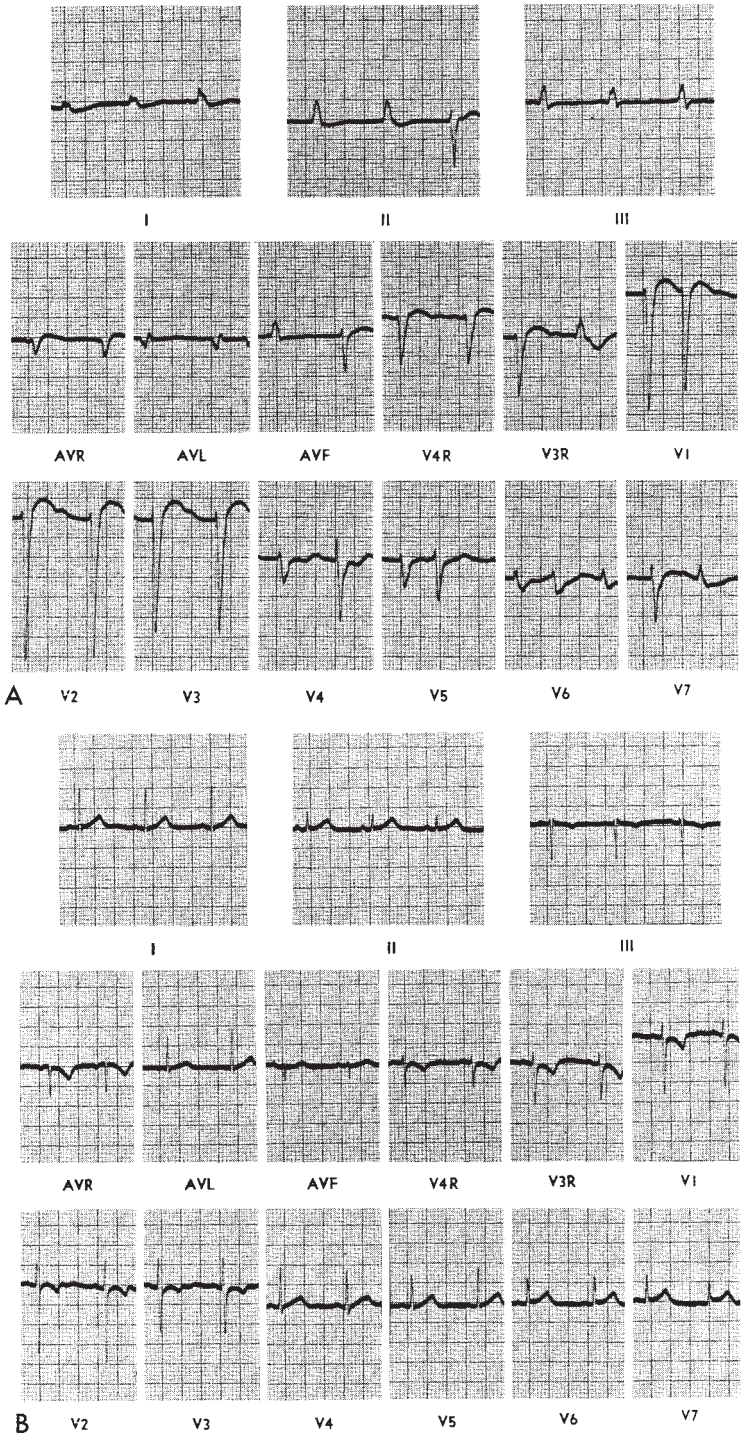

Figure 34–11 **A,** Multifocal premature beats are caused by atrioventricular dissociation and left bundle branch block resulting from diphtheritic myocarditis. **B,** A normal electrocardiogram is shown for the same patient 3 months after an episode of myocarditis.

sion is shown in Figure 34–12. The 2:1 atrioventricular block was associated with normal QRS complexes. This abnormality persisted in the absence of clinical symptoms for 1 year. Figure 34–13 shows a left bundle branch block that was identified in a 10-month-old infant with acute idiopathic myocarditis. Anomalous origin of the left coronary artery from the pulmonary artery was suspected but was excluded by catheterization. This ECG pattern persisted for at least 6 months.

Karjalainen and colleagues[90] studied the ECGs of 87 conscripts 18 and 30 years old, 28 of whom had myocarditis. The most frequent findings were T-wave changes of reduced amplitude or inversion in the left chest leads. Sinus tachycardia followed by premature ventricular depolarizations was the most common dysrhythmia. Take and colleagues[171] examined serial ECGs of 16 patients with confirmed viral myocarditis. They found four patterns: (1) complete normalization in the presence of severe myocardial damage in the acute stage; (2) "pseudoinfarction" patterns with Q waves and poor R-wave progression; (3) permanent conduction disturbances that might require pacemaker support; and (4) chronic dysrhythmias, predominantly ventricular tachycardia and supraventricular tachycardia.

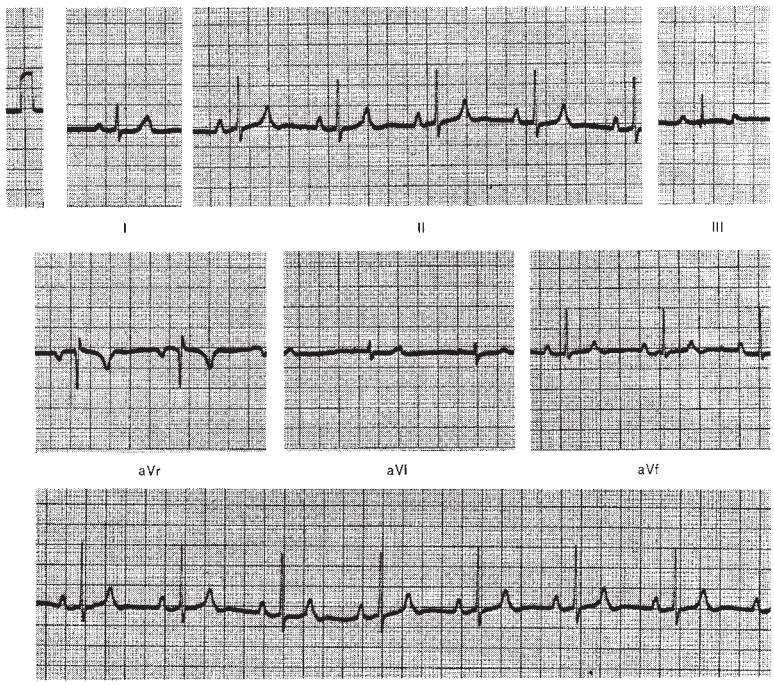

Figure 34–12 Second-degree atrioventricular block with an effective ventricular rate of 60 beats/min. The blocked P wave is placed on top of the T wave in each cycle.

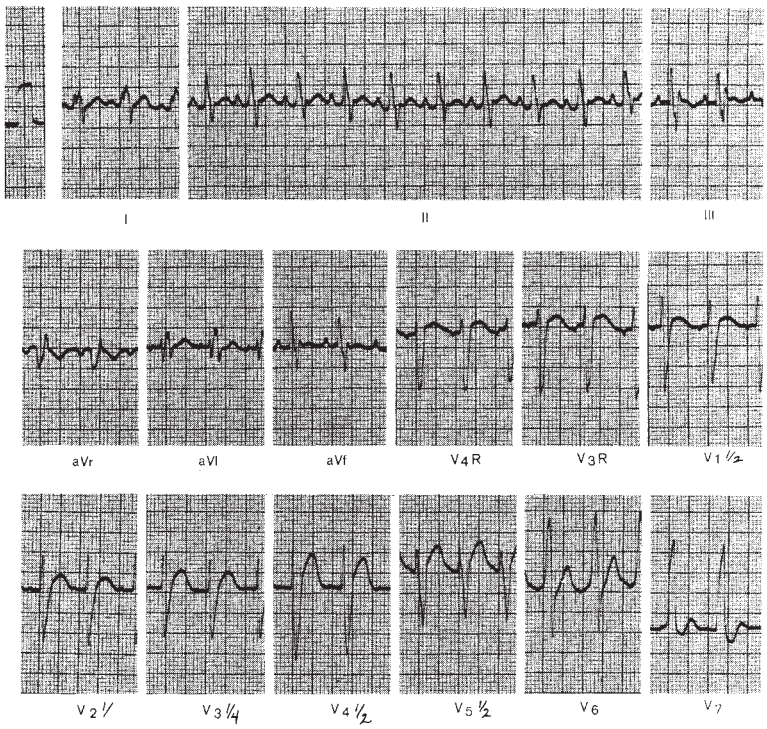

Figure 34–13 Sinus tachycardia (rate 150 beats/min) and left bundle branch block.

Hoshino and coworkers[80] induced coxsackievirus B3 myocarditis in Syrian golden hamsters and found that 80 percent of them had ST-segment or T-wave (or both) changes in the surface ECG. Most of the changes were seen between days 2 and 4, when mortality rates were highest. The endocardial third of the myocardium was most involved histologically, suggesting that the subendocardial myocardial injury corresponded to the observed ST-segment and T-wave changes. Kishimoto and coworkers,[97] using DBA/2 mice, induced myocarditis with encephalomyocarditis virus. Acute changes were correlated with advanced atrioventricular block and with atrial and ventricular premature depolarizations. Sinus tachycardia and low voltage were seen in the late stages in the animals that survived. Over the long-term, the QRS voltages recovered toward normal, possibly reflecting loss of myocardial edema or development of ventricular hypertrophy, or both, as a compensatory mechanism for poor ventricular function.

Although T-wave and ST-segment changes are the most sensitive indices of myocardial ischemia, they also seem to be nonspecific. Prolongation of the PR interval is another nonspecific

ECG finding frequently noted in patients with febrile illnesses. Scott and colleagues[162] showed a 1.49 percent prevalence of these findings in a group of 737 infants and children with respiratory tract infections, but they also found a similar incidence among 108 control children without respiratory infection or other febrile illness. Abt and Vinnecour[1] recorded PR prolongation and T-wave changes in infants and children who had pneumonia without other signs of myocarditis. The QT interval has been prolonged in cases of acute myocarditis, but it also seems to be a nonspecific finding associated with certain infectious diseases, such as measles[151] and poliomyelitis.[89] A diagnosis of myocarditis cannot be established with certainty on the basis of these nonspecific changes.

Noninvasive diagnostic myocardial imaging techniques that are useful in the detection of myocarditis include echocardiography, nuclear imaging with gallium 67–labeled or indium 111–labeled antimyosin antibodies, and magnetic resonance imaging (MRI). Echocardiography is recommended currently in the initial diagnostic evaluation of all patients with suspected myocarditis.[153] The echocardiogram is useful in assessing ventricular function and helps to exclude pericardial effusion as the cause of the cardiomegaly.

Nuclear imaging has been advocated as a potentially helpful laboratory screening test. Some evidence suggests that using gallium 67 to screen patients with idiopathic DCM may select a subgroup of patients who could benefit from endomyocardial biopsy. The biopsy specimen could be used to confirm the presence of active inflammation. O'Connell and colleagues[131] studied 68 patients with DCM who underwent 71 parallel studies with endomyocardial biopsy and gallium scanning. For five of six patients, biopsy samples that showed myocarditis also showed dense gallium uptake, and only 9 of 65 negative biopsy specimens had "equivocally positive" gallium scans. A 36 percent incidence of myocarditis on biopsy was found for positive scans, and only a 1.8 percent incidence of myocarditis on biopsy was found for negative scans. No large studies enrolling children with viral myocarditis have been performed. The use of gallium imaging has diminished over time, mainly because of a lack of specificity.

Indium 111 antimyosin imaging[42] and the presence of major histocompatibility complex class I and II antigens measured by radioimmunoassay using monoclonal antibodies[76] can detect patients with active myocarditis. High titers (1:20) of an IgG antibody (i.e., heart-reactive antibodies) measured by indirect immunofluorescence have been reported in patients with biopsy-confirmed myocarditis.[129] Although none of the methods is yet clinically applicable to all patients, these noninvasive tests offer some hope that the diagnosis of inflammatory heart disease will become safer.

More recent studies suggest that contrast-enhanced cardiac MRI may be a promising technique for diagnosing myocardial inflammation and myocyte injury. Gagliardi and associates[60] reported the first case series on the use of cardiac MRI for the diagnosis of acute myocarditis in 11 infants and children. The authors reported 100 percent specificity and 100 percent sensitivity for T2-weighted spin echo cardiac MRI sequences compared with endocardial biopsy. Cardiac MRI may be a good tool for selecting patients for endomyocardial biopsy.

To undertake a hemodynamic study in patients with a classic picture of acute myocarditis, including an ECG that reveals low voltage, is unnecessary and potentially dangerous. If the clinical or ECG presentation is atypical (i.e., left ventricular hypertrophy with left axis deviation, infarction pattern, or left bundle branch block), the infant should be studied for exclusion of an anomalous origin of the left coronary artery or another unsuspected anomaly.

Endomyocardial biopsy has become a safe and effective means for sampling heart muscle.[5] The technique originally was introduced in 1962 in Japan by Sakakibara and Konno,[155] but it did not gain wide acceptance in the United States for another 10 or more years. Its widest application has been in monitoring the effectiveness of immunosuppressive therapy in heart transplant recipients who may undergo the procedure multiple times.

Endomyocardial biopsy used for establishing the diagnosis of myocarditis and possibly classifying the phase (i.e., active, healing, or healed) of viral infection may have a direct impact on the type of therapy employed. Classification of myocarditis based on histologic evidence found on biopsy specimens has proved to be a difficult and sometimes controversial task. No widespread agreement exists on the criteria for establishing the diagnosis of myocarditis from biopsy samples. Sampling error owing to the small amounts of tissue obtained and the focal nature of sampling and the disease process may lead to misdiagnosis. Samples usually are obtained from the right ventricular septum or apex and should contain at least three and optimally five pieces of tissue. Some investigators[180] have found sampling from other areas of the heart (e.g., left ventricle) to be more sensitive, but these techniques have not been applied widely.

Cases of "borderline myocarditis" (i.e., specimens containing increased numbers of inflammatory cells, but without evidence of myocyte necrosis) may require a repeat biopsy to confirm the diagnosis. Dec and colleagues[40] confirmed the diagnosis of myocarditis in four of six patients with an initial diagnosis of borderline myocarditis. These investigators did not show any significant advantage to sampling the left ventricle during the repeat study. Overinterpretation or misinterpretation has been cited as a major problem in the reading of biopsy specimens. Some studies[168,169,182] used this technique to establish a diagnosis of myocarditis in patients presenting with idiopathic congestive cardiomyopathy and in patients with serious ventricular dysrhythmias with otherwise structurally normal hearts. Edwards and associates[51] looked at 170 endomyocardial biopsy samples and found that more than five lymphocytes per high-power field were consistent with a diagnosis of active lymphocytic myocarditis.

Using endomyocardial biopsy, Fenoglio and coworkers[54] diagnosed myocarditis in 34 patients presenting with congestive heart failure of unknown origin. They classified these patients on the basis of clinical and histologic findings in an attempt to establish subgroups of patients who might benefit from immunosuppressive therapy. Three groups were established: acute, rapidly progressive, and chronic. Immunosuppressive therapy was thought to be significantly beneficial for the last group only in terms of clinical improvement.

Dec and colleagues[41] studied 27 patients referred for endomyocardial biopsy because of congestive heart failure of unknown origin. Two thirds of the patients had biopsy samples read as positive for myocarditis, but in contrast to the study of Fenoglio and coworkers,[54] in which the histologic grouping was slightly different, no correlation was found between histologic classification and outcome. Outcome did not differ between the group receiving immunosuppressives and the group not receiving immunosuppressives. Biopsy results were negative for 30 percent of the patients who already met all the clinical criteria of myocarditis and were positive for two of five patients without any clinical evidence of myocarditis (i.e., viral-like illness, pericarditis, or laboratory evidence of viral infection).

Olsen[134] reviewed 1200 biopsy specimens from patients with a clinical diagnosis of idiopathic DCM and found that slightly more than 25 percent had a diagnosis of myocarditis established on the basis of critical evaluation of their tissue specimens. No large study of pediatric patients has been conducted to confirm this finding in young patients.

Most physicians would agree that many cases of idiopathic DCM probably are the sequelae of unrecognized acute viral myo-

carditis. The role of endomyocardial biopsy in attempting to salvage patients by selecting them for specific therapy has some validity. The hope is that early intervention in some patients guided by this technique would prevent them from progressing to needing transplantation or to death from intractable heart failure.

MOLECULAR DIAGNOSTIC STUDIES

In Situ Hybridization

In 1986, Bowles and colleagues[22] showed the utility of molecular biologic analysis of tissue samples in establishing the diagnosis of myocarditis. Using in situ hybridization, they were able to show enteroviral RNA in the myocardium of patients suspected to have myocarditis. These investigators also showed that enteroviral RNA could be identified in the myocardial tissue samples obtained from patients with end-stage DCM, and the suggestion that some cases of DCM were caused by a previous episode of subclinical myocarditis gained scientific support. The ability to diagnose enteroviral myocarditis and the finding of enteroviral RNA in patients with DCM later were confirmed by other investigators.[9,23] Because of questions of excessive false-positive results, variations among laboratories, and the difficulty in performing the test routinely in hospital laboratories, this method never gained practical popularity.

Polymerase Chain Reaction

Jin and associates[87] first described the usefulness of PCR in identifying the viral genome in myocardial samples obtained from patients with suspected myocarditis. Using reverse transcription PCR, which employs RNA to amplify the corresponding complementary DNA before final DNA amplification, the researchers were able to identify an enteroviral genome from cardiac tissue samples. Patients with DCM were shown to harbor an enteroviral genome within myocardial specimens. Confirmation of the utility of PCR in the etiologic diagnosis of a viral genome in patients with clinical myocarditis and idiopathic DCM quickly followed.[32,50,67,77,127,145,186] Controversy existed, however, because reports of high levels of false-positive results,[50] contamination,[32] and low sensitivity[188] were published. The strength of this rapid (<5 hours) and powerful method of amplification of a specific viral genome is also its weakness. The method depends on the quality and quantity of nucleic acid extraction, but contamination may be commonplace in some laboratories. If any requirements are altered, amplification may not occur, leading to false-negative or false-positive (i.e., contamination) results.

Numerous publications have shown that PCR is a rapid and sensitive method for establishing the diagnosis of enteroviral myocarditis and that it is probably the test of choice in the diagnosis of all virus-induced cardiac disease. Towbin and colleagues[178] used PCR to diagnose adenoviral myocarditis in a fetus with nonimmune hydrops fetalis. In this case, the adenoviral genome was amplified from fetal blood and maternal blood at 29 weeks' gestation and again at delivery at 34 weeks' gestation using blood from the infant and mother and placental specimens. Treatment with digoxin in utero helped the fetus improve clinically, and the infant had normal cardiac function at delivery. Using viral primers designed to amplify enterovirus, adenovirus, CMV, and HSV nucleic acid, Martin and associates[111] reported 34 patients with suspected acute myocarditis, for whom 68 percent of samples analyzed were PCR-positive. In this report, samples from 17 control patients were PCR-negative. Adenovirus was the most common viral genome identified (58%), and enteroviruses were the second most common (29%). A few reported cases were PCR-positive for HSV and CMV.

Lozinski and coworkers[108] confirmed the importance of adenovirus in their study of cases of myocarditis for which no cause had been found previously; in this case, 66 percent of the previously unidentified cases were identified as adenovirus. In a more recent study by Bowles and colleagues,[21] viral genomes were detected in 20 percent of 149 patients with the diagnosis of DCM. In these patients, adenovirus was identified in 12 percent and enterovirus in 8 percent of DCM cases. In all age groups, adenovirus and enterovirus were the viruses most commonly detected in acute myocarditis and DCM.

Schowengerdt and colleagues[161] showed that a variety of viruses might be the inciting cause of rejection in patients after undergoing heart transplantation. Using PCR of endomyocardial biopsy specimens, the investigators showed a direct correlation between histologic rejection and PCR-positive viral study results. Studying patients undergoing serial endomyocardial biopsies, they found that the viral genome could be amplified in transplant-rejecting patients who previously had negative PCR analyses. In these cases, as the rejection grade improved, the PCR results again became negative. The most common viruses correlated with rejection were adenoviruses, CMV, and parvovirus. The researchers postulated that this form of rejection probably is another form of myocarditis, and this hypothesis has been supported by other clinical studies.[187]

VIROLOGIC AND BACTERIOLOGIC STUDIES

For each infant or child with a diagnosis of acute myocarditis, an attempt should be made to identify the offending organism. If the patient is seen early in the illness, isolation of the virus from throat washings, stool, blood, or the myocardium may be possible. Support for an active infection is obtained by showing a fourfold increase in antibody titer to the virus that has been isolated.[19,74,160]

Lerner and colleagues[102] suggested criteria that would help define an etiologic association between a coxsackievirus infection and myocarditis. High-order associations included isolation of the virus from the myocardium, the endocardium, or pericardial fluid and localization of type-specific virus in myocardium, endocardium, or pericardium at sites of pathologic change. Moderate-order associations are determined when virus is isolated from pharynx or feces, and a fourfold increase in type-specific, neutralizing, hemagglutination-inhibiting, or complement-fixing antibodies is shown, or when virus is isolated from pharynx or feces with a concurrent serum titer of 1:32 or greater of type-specific, IgM-neutralizing or hemagglutination-inhibiting antibodies. Schmidt and colleagues[160] stress the usefulness of the IgM-specific antibody titer. Coxsackieviruses B1, B3, B4, B5, and B6 are identifiable with this method. Immunofluorescent methods may be used during histologic analysis to identify specific antigens in the myocardium.[26] In chronic illness, attempts at virologic identification are less fruitful.[69]

Blood for aerobic and anaerobic cultures should be obtained from any infant with fever and signs of compromised cardiovascular function. The erythrocyte sedimentation rate and white blood cell count usually are elevated in acute myocarditis; occasionally, a leukemoid reaction may be identified.[3] A normal value for these tests does not exclude myocarditis. Elevations of serum glutamic oxaloacetic and glutamic pyruvic transaminase levels have been detected, especially in diphtheritic myocarditis, but they may be elevated in any patient with acute myocardial damage. Although a high level of serum transaminase activity usually is an ominous prognostic sign, Tahernia[170] found the ECG to be a more sensitive indicator of the ultimate outcome in children with diphtheritic myocarditis. Creatine phosphokinase and lactate dehydrogenase enzymes also should be measured.

DIFFERENTIAL DIAGNOSIS

Any cause of circulatory failure, especially when acute in onset, may mimic myocarditis. In newborns, heart failure associated with hypoxia, hypoglycemia, and hypocalcemia is well recognized, whereas circulatory collapse may occur with any infection and without direct involvement of the myocardium. A careful history may help to elucidate possible precipitating factors. Biochemical investigations to exclude hypoglycemia and hypocalcemia always should be conducted in any newborn who has signs of heart failure. Blood cultures should be obtained when infection is suspected.

Many infants with structural cardiac defects (e.g., hypoplastic left heart syndrome, aortic valve stenosis) may not have audible murmurs when severely ill. Murmurs usually appear, however, with treatment and improvement in cardiac function. The precordium usually is hyperactive, rather than quiet, and the heart sounds are clear and increased in intensity, rather than muffled. The ECG usually shows severe right ventricular hypertrophy in the former condition and shows right ventricular or left ventricular hypertrophy in the latter; the ECG is useful in the differential diagnosis. The findings on an echocardiogram often are diagnostic.

Beyond the immediate neonatal period, the major disease entities that require differentiation from myocarditis are endocardial fibroelastosis, anomalous left coronary artery arising from the pulmonary artery, Cori type II glycogen storage disease (i.e., Pompe disease), medial necrosis of the coronary arteries, left atrial myxoma,[128] and other congestive cardiomyopathies of undetermined cause. Common to all of these disorders is moderate to severe cardiomegaly, usually associated with congestive cardiac failure, gallop rhythm, and the infrequent occurrence or absence of murmurs. The murmurs are associated primarily with an anomalous left coronary artery and endocardial fibroelastosis. They are not more than grade 3/6 in intensity, are high-pitched, are apically located, and represent some degree of mitral insufficiency. Idiopathic myocarditis occurs primarily in patients older than 6 months of age,[149,150] whereas most of the conditions described earlier manifest before the infant is 6 months old.

Endocardial fibroelastosis, a common cause of congestive cardiac failure in infants, is impossible to differentiate from acute myocarditis on the basis of clinical examination alone. An anomalous origin of the left coronary artery should be identified. The ECG usually shows left axis deviation of the QRS complex in the frontal plane, left ventricular hypertrophy, and a pattern of anterolateral myocardial infarction. It is recognized as a QR pattern with inverted T waves in standard leads I and AVL, a broad Q wave with inverted T waves in precordial leads V_5 and V_6, and loss of anterior forces in the mid-precordial leads. For definitive diagnosis, cardiac catheterization is essential.

Pericarditis, frequently caused by viruses, usually occurs in children rather than in infants. The clinical history may be identical to that of patients with myocarditis; however, considering the degree of cardiomegaly, cardiovascular function is compromised less than in patients with myocarditis, although cardiac tamponade may occur in some cases. Differentiation from myocarditis may be made clinically if the patient has a friction rub, no gallop rhythm, and a typical pattern of chest pain. Further studies may be required, however, to make a conclusive diagnosis. The echocardiogram is invaluable in establishing this diagnosis. It is the most sensitive and least traumatic technique available and easily identifies an effusion. Myocarditis and pericarditis may occur together. This combination is seen most frequently in the pancarditis of rheumatic fever, but it also may occur in coxsackievirus B infections and in many collagen vascular and autoimmune diseases. Myocarditis has been associated with rheumatoid arthritis,[120] systemic lupus erythematosus,[44] and ulcerative colitis.[56,126]

TREATMENT

STANDARD APPROACHES

Intensive medical care is required during the acute stage of the illness. Heart rate, respiratory rate, and blood pressure should be monitored frequently, and a careful assessment of urine output and fluid intake is mandatory. All patients require bed rest. Experimental studies in mice have shown that exercise increases replication of virus in the myocardium and increases the mortality rate from myocarditis by 100 percent.[61] Although extrapolating directly from experimental studies in animals to the human situation always is dangerous, suggesting strict bed rest during the early stages of acute myocarditis seems to be a prudent measure. For infants or children with signs of congestive cardiac failure or shock, oxygen should be administered to maintain a normal arterial blood oxygen tension.

No specific therapeutic modality is known that can reverse the myocardial injury directly, but much can be done to maintain adequate tissue perfusion, prevent metabolic disturbances, and support myocardial function. When congestive cardiac failure is identified, digitalis should be administered. This agent should be used with caution, given the increased expression of proinflammatory cytokine and increased mortality rates observed in murine myocarditis treated with high-dose digitalis.[116] Diuretics also are used frequently to treat cardiac failure. Diuretics have no direct beneficial effect on the myocardium; they should be used cautiously because rapid reduction in extracellular fluid volume may lead to shock, and the loss of potassium associated with vigorous diuresis may precipitate digitalis toxicity. The frequency of administration depends on the clinical state of the patient.

In some instances, especially in newborns, the primary presentation may be shock. The blood pressure usually is maintained close to normal levels until late in the course of disease; it cannot be a reliable index of the severity of the patient's condition. Cold extremities, increasing heart rate, and low urine output are much more sensitive indicators of a reduction in effective circulating blood volume. Although the hearts of these infants and children respond poorly to volume loading, a colloid transfusion may help in selected patients. Albumin as a 5 percent solution in Ringer's lactate or whole blood may be administered. The total amount administered should be guided by the response of the patient in terms of perfusion, urine output, heart rate, and central venous pressure.

These patients may require a high filling pressure (e.g., 12 to 18 mm Hg) to achieve any cardiac output, compared with 5 mm Hg, which would achieve sufficient filling in the normal heart. If the patient remains in shock despite administration of these high filling pressures, a positive inotropic agent is required. Dopamine exerts an inotropic effect on the heart and concomitantly dilates the renal vessels, improving urine output. The usual dose is 2 to 10 μg/kg/min. As the dose increases to 20 μg/kg/min, dopamine has a more dominant alpha-adrenergic effect and may increase systemic peripheral resistance; experts avoid doses greater than 15 μg/kg/min. Dobutamine, which is a sympathomimetic amine that stimulates $beta_1$-adrenergic, $beta_2$-adrenergic, and alpha-adrenergic receptors, may be useful when used in combination with dopamine. It has significant inotropic activity while decreasing left ventricular filling pressure. Dobutamine does not induce the positive chronotropic effect and increased ventricular irritability that are seen with dopamine. Used in combination with low doses of dopamine (<10 μg/kg/min), dobutamine (in doses ≤10 μg/kg/min) may result in significant positive inotropism, while preventing a sinus tachycardia that may compromise cardiac output further.

Isoproterenol, a commonly used inotropic agent, should be avoided because it causes a significant increase in heart rate and may affect cardiac function adversely. When these drugs are used,

ensuring normal acid-base balance is important because action of the agents is decreased significantly by acidosis.

Sodium nitroprusside, phentolamine, and the nitrates have been used in adults. These agents have been used less extensively in children, primarily in the early postoperative period after open heart surgery, to improve cardiac function. They improve cardiac output by indirectly reducing systemic arterial resistance or venous filling pressure, or both. One study showed a marked improvement in the reduction of inflammation, necrosis, and dystrophic calcification in mice infected with coxsackievirus B3 when they were treated with captopril, an angiotensin-converting enzyme inhibitor, early after development of infection.[148] Besides its known afterload-reducing effects, this agent, which contains sulfhydryl groups in its chemical structure, is capable of scavenging oxygen free radicals in vitro. This ability may enable the drug to reduce myocyte damage by free radicals during the acute phase of the infection.

Another study failed to show any significant correlation between improved ventricular function and histologic improvement in patients with myocarditis treated with immunosuppressive therapy. Rather, an increase in the ejection fraction during the first 3 months of therapy seemed predictive of a good outcome.[39] Intravenously administered afterload-reducing agents should not be used, unless facilities are available for constant monitoring of the left ventricular filling pressure (i.e., mean wedge pressure) and unless that pressure is elevated.

Arrhythmias should be recognized and treated vigorously. Digitalis should be used with caution, and intravenous administration of this drug should be used only if the oral route is impossible. Rather than used as inotropic support, digitalis can be used to help control supraventricular arrhythmias. Levels must be monitored, especially when renal function is questionable. Lidocaine should be administered intravenously for acute treatment of complex ventricular arrhythmias, such as couplets and ventricular tachycardia. In cases of intractable ventricular arrhythmias, intravenously administered procainamide can be used. Monitoring the serum level on a daily basis beginning several hours after the drip is started is essential to prevent toxic side effects. Alternatively, amiodarone given intravenously can be used for life-threatening ventricular arrhythmias. Measures of contractility using echocardiographic techniques also are vital because procainamide is a negative inotrope.

A temporary pacing catheter should be inserted when complete heart block occurs. In many instances, the temporary pacing catheter allows time for spontaneous recovery of atrioventricular conduction. A permanent pacemaker may be required; if so, it should be inserted as an elective, rather than emergency, procedure. Only a demand pacemaker should be used because in most instances a return to normal rhythm is expected; use of this type of pacemaker avoids the risk of competition between the patient's inherent rhythm and the pacemaker, as would occur with a fixed-rate device. If infants or children experience Stokes-Adams attacks, a transthoracic pacing wire may have to be inserted as an emergency procedure.

Antibiotics should not be given routinely, unless a bacterial infection is suspected. Appropriate cultures need to be obtained before use of antibiotics.

The use of immunosuppressive agents in the treatment of viral or suspected viral myocarditis is controversial. Immunosuppressant therapy in animal models of viral myocarditis has not been shown to be beneficial. One reason for the lack of efficacy of immunosuppressant therapies may relate to the duality of the effects of the immune system. Corticosteroids enhanced viral titers in the early phase of viral murine myocarditis, whereas cyclosporine caused greater mortality and cardiac insufficiency in encephalomyocarditis virus myocarditis.[123,177] Other studies suggested an exacerbation of virus-induced cytotoxicity when such agents were given in the acute setting and possible interference with the production of interferon.[93,94] A report of 13 children with biopsy-confirmed myocarditis treated with prednisone approximately 3 weeks after symptoms occurred showed a marked reduction in inflammation on the follow-up biopsy specimen.[31] This study was uncontrolled, however, and may not truly represent an accurate account of the role of immunosuppressive therapy.

Mason and colleagues[113] used endomyocardial biopsy as a means of diagnosing and following the effects of immunosuppressive therapy in 10 patients. Eight patients received a combination of prednisone and azathioprine, and two patients received prednisone alone. Four patients improved clinically and histologically while on therapy. Two patients who had medications discontinued had relapses, which were reversed with reinstitution of therapy. Only one patient worsened while on therapy, and that patient died. Although the study by Mason and colleagues[113] was uncontrolled, the reversal of congestive heart failure seen in the two patients who were restarted on therapy suggests the beneficial effect of these agents.

Daly and colleagues[36] treated nine patients using combined immunosuppressive therapy with prednisolone and azathioprine. Seven of the nine patients showed definite hemodynamic and histologic improvement after 2 months of therapy. After 4 months off therapy, only four of the seven patients still showed significant improvement, however. One patient improved with reinstitution of therapy, and two patients deteriorated.

Dec and colleagues[41] treated nine patients in their study with single or combined immunosuppressive therapy. They saw improvement in 4 of 9 patients; however, 6 of 18 patients not receiving immunosuppressive agents also improved, nullifying any statistically significant difference between the two groups. Lymphocytic myocarditis was found in 6 of 12 patients with no obvious cardiac disease, but with high-grade ventricular dysrhythmias, and who had undergone right ventricular endomyocardial biopsy.[182] All six patients received combined immunosuppressive therapy with prednisone and azathioprine. At follow-up, five of six patients had been cured of the dysrhythmia, and active myocardial inflammation had disappeared, as confirmed by repeat biopsy. Although this study was uncontrolled, the fact that none of the patients progressed to a cardiomyopathic state or died of his or her illness suggests a beneficial effect.

Kereiakes and Parmley[91] tabulated most of the studies showing the effects of immunosuppressive therapy in patients with myocarditis. Sixty percent of 82 biopsy-confirmed cases of myocarditis showed improvement with steroids alone or in combination with azathioprine. Patients with lower grade inflammatory changes seem to do better than did patients with higher grade changes. Complications of immunosuppressive therapy, including opportunistic infections and a cushingoid state, have been reported and may limit the amount and type of therapy.[113,168]

Hobbs and associates[78] used combined prednisone and azathioprine to treat 34 adults with biopsy-confirmed myocarditis. Survival was no better for patients with histologic improvement than for patients with persistent infiltrates. Most patients experienced side effects, some of them lethal, from the corticosteroids. The potential benefits of this type of therapy must be weighed against the risks of immunosuppression in each patient with myocarditis. This therapy apparently does not prevent the observed ECG changes seen in untreated patients or the associated neuritis.[175]

Although numerous anecdotal and small case series suggested that patients with viral myocarditis might benefit from early steroid or immunosuppressive therapy, the results of the Myocarditis Treatment Trial suggested that treating patients who received a histopathologic diagnosis of myocarditis with immunosuppressive therapy for 24 weeks (prednisone plus cyclosporine or prednisone plus azathioprine) did not lead to an

improvement in ejection fraction compared with conventional therapy.[114] The major limitation of this study was the unexpectedly low rate of positive biopsy specimens (<10%) and the extension of enrollment to 2 years after the initial clinical presentation. For many patients, the disease possibly already had progressed from ongoing immune-mediated cardiac injury to DCM, and any form of therapy may have been ineffective in this setting.

Various immunomodulatory therapies have been proposed for the autoimmune phase of viral myocarditis. Kishimoto and colleagues[98] found that immunoglobulin therapy suppressed coxsackievirus B3-induced murine myocarditis and increased survival in C3H/He mice after infection with encephalomyocarditis virus. Intravenous immunoglobulin (IVIG) therapy reduced various proinflammatory markers, including TNF, interferon-γ, macrophage inflammatory protein-2, interleukin-6, plasma catecholamines, and soluble intercellular adhesion molecule-1.[98] Exogenous immunoglobulins modulate diverse immune response mechanisms; however, the exact mechanisms by which IVIG modifies myocarditis remains to be determined. Drucker and associates,[47] who investigated the use of IVIG in 21 of 46 children with myocarditis, showed that patients who received this drug had better left ventricular function at follow-up. Survival tended to be higher at 1 year, although the data did not reach statistical significance because of the small number of patients in the study. More recently, in a prospective placebo-controlled trial with IVIG in adult patients with recent-onset DCM or myocarditis, treatment with IVIG did not result in an improvement in left ventricular function compared with placebo-treated patients.[118]

At present, no form of immunosuppressant therapy has proved to be effective in the clinical setting. Routine immunosuppressive therapy no longer is recommended for patients with myocarditis and a stable clinical course. Many clinicians still recommend aggressive immunosuppressive therapy, however, for patients with fulminant myocarditis or a deteriorating clinical course or both.

PROGNOSIS

The prognosis of acute myocarditis caused by coxsackievirus B infection in a newborn is poor. Kibrick and Benirschke[92] reported a 75 percent mortality rate among 25 infants with coxsackievirus B myocarditis. The greatest number of deaths occurred in the first week of the illness. No apparent sequelae occurred in the six infants who survived, although no long-term follow-up data were available. The outlook in other infants and children with clinically recognized myocarditis is better, but mortality rates remain significant (10-25%). Hastreiter and Miller[73] observed complete recovery in 50 percent of patients. Another 25 percent became asymptomatic, but abnormal ECGs or chest radiographs persisted. An abnormality may not be evident on the ECG unless the patients are exercised.[16] Despite lack of symptoms, many adult patients have a reduced working capacity associated with exercise stress testing.[18]

The outcome of myocarditis is related partly to the cause. Patients with diphtheritic myocarditis who have arrhythmias or conduction abnormalities have a very poor prognosis. Tahernia[170] found in his study that all patients with disturbances of conduction died. Begg[15] also reported a 100 percent mortality rate for patients with diphtheritic myocarditis who developed supraventricular tachycardia.

Chronic arrhythmias may persist long after the acute disease has passed. Friedman and colleagues[57] performed a retrospective analysis of 12 patients with biopsy-confirmed myocarditis and complex ventricular arrhythmias at the time of presentation (11 with ventricular tachycardia). Five of the 12 patients still were receiving antiarrhythmic therapy at a median follow-up of 50 months. Complex ventricular arrhythmias still were present in these patients (three with ventricular tachycardia and two with couplets or multiforms), requiring ongoing therapy. The investigators concluded that although the arrhythmias were controlled more easily than at presentation of the patients, ongoing surveillance was essential in ensuring the suppression of these potentially life-threatening arrhythmias. Children who recover from myocarditis, regardless of cause, should be followed indefinitely.

MYOCARDITIS IN CASES OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Infection with human immunodeficiency virus (HIV) may affect the heart adversely. Cardiac dysfunction, including congestive heart failure, may occur; many patients who have died and undergone autopsy are shown to have myocarditis. Anderson and associates[6] retrospectively analyzed 71 consecutive necropsy patients who died of acquired immunodeficiency syndrome (AIDS) and found that 52 percent had evidence of myocarditis. Opportunistic agents could account for only a few of the cases, and most were considered idiopathic.

Another study examined autopsy specimens of 26 consecutive cases. Lymphocytic myocarditis was seen in nine patients (35%), and another seven patients had lymphocytic infiltrates without myocytolysis.[14] Acierno[2] correctly pointed out that a distinction must be made between AIDS-associated myocarditis and secondary myocarditis caused by known pathogens or idiopathic myocarditis.

Reilly and colleagues[147] found a 45 percent incidence of myocarditis in 58 consecutive autopsy cases. Congestive heart failure, ventricular tachycardia, and other ECG abnormalities were seen in nearly 60 percent of the patients. Two patients died suddenly, both with myocarditis. In a prospective study of asymptomatic HIV-infected patients, the reported mean annual incidence of progression to DCM was 15.9 cases per 1000 patients. Endomyocardial biopsy specimens revealed myocardial inflammation in 63 of 76 (83%) of these high-risk patients. HIV-infected cardiac myocytes were detected by in situ hybridization in 58 of 76 (76%) patients.

In a prospective multicenter study of 205 vertically HIV-infected children enrolled at a median age of 1.9 years and 600 HIV-exposed children enrolled prenatally or as neonates, the 5-year cumulative incidence of cardiac dysfunction ranged from 18 to 39 percent in HIV-infected children.[167] Myocardial inflammation, with or without cell destruction, is a frequent finding in patients infected with HIV. Whether this response is due to the virus itself or to opportunistic agents or other toxic reactions is unclear. Specific therapy for myocarditis in these patients has not been elucidated, and no recommendations, other than inotropic support with anticongestive and afterload-reducing agents, can be made.

PARASITIC MYOCARDITIS

Parasitic myocarditis is an uncommon form of heart disease in the United States. Chagas disease is caused by infection with *Trypanosoma cruzi*, however, and it is a long-lived infection that affects approximately 17 million individuals in Latin America.[152] Although several countries in Latin America have well-established vector-control programs, contact with contaminated feces or urine from infected triatomine insects remains the main mode of infection.

The major cardiovascular manifestation of Chagas disease is an extensive myocarditis that typically becomes evident years or decades after the initial infection. The disease is transmitted to

humans by various species of blood-sucking reduviid insects. After inoculation, the protozoa multiply and migrate widely throughout the body. Host control of this parasite has been shown to depend on humoral and cell-mediated adaptive responses and elements of the innate immune system.[65]

More recently, a role for TLR signaling in resistance to *T. cruzi* is suggested by the observations that mice deficient in MyD88, an adapter molecule required for signaling events by most TLRs, show enhanced susceptibility to infection with this protozoan parasite.[28] Acute Chagas disease usually is an illness of children, but it can occur at any age.[122] Histologic examination of the heart during the acute phase reveals intracellular parasites with a marked cellular infiltrate, particularly around myocytes that have ruptured and released the parasites.[138] A well-established fact is that intracellular parasites are found in cardiac myocytes only during the acute phase of illness.

Severe myocarditis develops in only a few acute cases, and most deaths are caused by the resultant congestive heart failure and pericardial effusion. Nonspecific ECG changes are seen, but the life-threatening arrhythmias that are frequent occurrences in chronic Chagas disease generally do not occur. In most patients with more acute disease (90% of cases), symptoms resolve gradually over weeks to months.

Chronic progressive Chagas disease develops in 10 to 20 percent of previously asymptomatically infected individuals.[49] It is manifested by a chronic, diffuse, progressive fibrosing myocarditis that involves the myocytes and the atrioventricular conduction system.[124,125] On gross examination, the heart usually is enlarged and flaccid. Thrombus formation frequently occurs, and thrombus may fill much of the apex of the left ventricle in some cases.

Immune-mediated cardiac injury, caused primarily by infiltrating mononuclear cells, probably is the main mechanism responsible for the development of chronic Chagas heart disease. This hypothesis is supported by several observations. Animal models of *T. cruzi* infection have shown lysis of nonparasitized cardiac myocytes by immune effector cells[8]; depletion of $CD4^+$ T-lymphocyte subpopulations abrogates myocardial injury in a murine model of chronic Chagas disease; and myocardial damage can be induced in healthy animals by passive transfer of $CD4^+$ T cells from *T. cruzi*–infected mice.[45] Although $CD4^+$ T cells seem to be crucial in myocardial injury, $CD8^+$ T cells may have a protective role. Mice depleted of $CD8^+$ T cells have a robust parasitemia, but almost no inflammatory infiltrates are seen in the parasite-infected tissues.[172]

Histologic examination reveals focal but widespread areas of cellular infiltrates composed of plasma cells, eosinophils, mast cells, and macrophages.[124] Extensive fibrosis occurs, replacing previously damaged myocardial tissue. In contrast to the situation observed in acute disease, the presence of parasites (a rare finding) in tissue has little correlation with myocardial pathology. Inflammatory changes in the right bundle branch and the anterior fascicle of the left bundle branch explain the frequent occurrence of right bundle branch and left anterior fascicular block.[125]

The clinical manifestations of chronic Chagas disease range from isolated rhythm disturbances to advanced disease characterized by cardiomegaly, chronic congestive heart failure, and arrhythmias. Syncope also is a frequent problem of the disease. In one series of 53 patients with chronic Chagas disease, the most frequent causes of recurrent syncope were ventricular tachycardia (43%) with a poor prognosis and paroxysmal atrioventricular block (21%) with a favorable prognosis.[112] Sudden death caused by ventricular fibrillation is a constant threat and may develop before cardiomegaly or heart failure is diagnosed.[30]

The diagnosis of chronic Chagas disease cannot be made solely on the basis of histologic examination of the heart. Serologic testing is the method of choice for establishing the diagnosis of chronic Chagas disease. Several highly sensitive serologic tests for the detection of anti–*T. cruzi* antibodies, such as indirect hemagglutination, complement fixation, indirect immunofluorescence, and enzyme-linked immunosorbent assay, are available.[95,163]

Benznidazole and nifurtimox are the only available drugs with activity against *T. cruzi*. Although these two drugs have been thought to be ineffective or too toxic, or both, for treating chronic infections, in one report a 60-day course of benznidazole therapy eliminated infection in more than 60 percent of chronically infected children.[7] The current emphasis on the management of Chagas disease is on prevention of infection. In 1991, the Latin American countries of Argentina, Bolivia, Brazil, Chile, Paraguay, and Uruguay initiated a program to decrease transmission of the parasite through vector control and the screening of blood donors. According to more recent studies, transmission has been virtually eliminated in much of the region.[196]

Myocarditis is one of the most serious complications of trichinosis. The disease develops when undercooked meat contaminated with infective larvae of *Trichinella* is eaten. Myocardial invasion by *Trichinella spiralis* has been well described, but encystment within the myocardium has been reported only rarely.[96] At autopsy, the heart may be dilated and a pericardial effusion may be identified. Histologically, a prominent focal infiltrate composed of lymphocytes and eosinophils with interstitial edema and scattered hemorrhages commonly is found.[165]

Myocarditis usually is mild, with few clinical signs and symptoms. This myocarditis may range from chest pain to fatal congestive heart failure, however, and may mimic acute myocardial infarction.[34,68] The frequencies of ECG abnormalities among 154 cases of trichinellosis were determined to be 56 percent.[143] The abnormalities on ECG most frequently observed were a nonspecific ventricular repolarization disturbance (with ST-T wave changes), followed by bundle branch conduction disturbances, and sinus tachycardia. Despite ECG evidence of myocardial involvement, less than 0.1 percent of patients with trichinosis die of this complication.[68]

The definitive diagnosis of trichinosis is based on the presence of the larval forms in tissue biopsy samples, usually from a large tender area such as the gastrocnemius muscle. Serologic testing is available through state laboratories and the Centers for Disease Control and Prevention. Typically, serum antibody titers become positive during or after the third week of illness. The efficacy of mebendazole or albendazole in the treatment of myocarditis caused by *Trichinella* infection has not been evaluated adequately.

Toxocara canis, the principal cause of visceral larva migrans, is a rare cause of myocarditis. Most reported cases have occurred in children younger than 3 years of age.[37,181] Children especially are susceptible to infection with *Toxocara* because of their habit of crawling on the ground and putting objects into their mouths. The myocardial lesions noted on histologic examination have included granulomata and extensive eosinophilic infiltrates with foci of muscle necrosis. The clinical presentation may be acute respiratory distress caused by congestive heart failure, requiring administration of oxygen and diuretic therapy. Asymptomatic infection involving the heart also has been reported.[37]

The definitive diagnosis of *T. canis* infection requires microscopic identification of the larvae in biopsy specimens of the liver or heart, but this finding is infrequent. An enzyme immunoassay for *Toxocara* serum antibodies, which is available at the Centers for Disease Control and Prevention, can provide presumptive evidence of toxocariasis.

Toxoplasma gondii may cause myocarditis as part of disseminated infection or, less frequently, as an isolated cardiac infection. In infants with congenital toxoplasmosis, the clinical manifestations usually are those of meningoencephalitis, but at autopsy, extensive myocardial involvement has been documented.[199] Outside the newborn period, infection with this intracellular

parasite most commonly occurs in immunosuppressed patients with malignant diseases, patients with AIDS,[29] and patients who have undergone cardiac or bone marrow transplantation.[109] Histologic examination of the heart reveals focal interstitial infiltrates consisting of histiocytes, lymphocytes, plasma cells, eosinophils, and very few polymorphonuclear cells.[174] *Toxoplasma* is seen as basophilic masses within a pseudocyst in normal or damaged myocardial fibers.

Clinical manifestations may include arrhythmias (atrial and ventricular), atrioventricular block, atypical chest pain, pericarditis, and heart failure. The diagnosis of toxoplasmic myocarditis requires the exclusion of other specific forms of heart disease and the establishment of evidence of toxoplasmosis with serologic testing. The diagnosis may be aided by endomyocardial biopsy.[109] Treatment with pyrimethamine and sulfonamides (especially sulfadiazine) has been reported in patients with isolated toxoplasmic myocarditis, but the response to therapy has varied. In one series of toxoplasmic myocarditis, relapses occurred in 17 percent of cases after therapy.[101]

Myocardial disease also has been reported after infection with *Echinococcus granulosus* and *Plasmodium falciparum*.[96] Cardiac involvement is estimated to occur in less than 2 percent of cases of echinococcosis.[43] When it does occur, the cysts usually are located in the intramyocardial region and protrude into the adjacent cardiac chambers. The clinical manifestations depend primarily on the location and size of the cyst. Rupture of the cyst is the most dreaded complication because it may lead to pericarditis, anaphylactic shock, or pulmonary emboli. Two-dimensional echocardiography is the preferred imaging study to detect and localize cysts.[133] Myocardial changes also have been documented in fatal malaria, particularly when caused by *P. falciparum*. Histologically, blocking of the coronary arteries and capillaries with parasites, local hemorrhage, and deposit of pigment occurs. Clinical findings suggestive of cardiac involvement are rare, however. In a series of 49 patients with falciparum malaria, no ECG evidence of cardiac involvement was found.[166]

Myocarditis also has occurred in association with primary amebic meningoencephalitis caused by *Naegleria*. In a retrospective study, focal or diffuse myocarditis was documented in more than 40 percent of cases.[110] Myocardial involvement is not a clinically significant manifestation of this uniformly fatal central nervous system infection.

CHAPTER 35

Acute Rheumatic Fever

Diana R. Lennon

Acute rheumatic fever is an inflammatory disease of the heart, joints, central nervous system, and subcutaneous tissues that develops after a nasopharyngeal infection by one of the group A beta-hemolytic streptococci. The pathogenesis of this disease, a clinical syndrome without a specific diagnostic test, remains an enigma, and specific treatment is unavailable. Prevention of initial and recurrent attacks is possible, however, with penicillin prophylaxis. Rheumatic fever is especially important because of the heart disease that often ensues, and such disease may lead to chronic progressive damage and premature death. As succinctly stated by Lasegue many years ago, "Rheumatic fever licks the joints and bites the heart"[186]—a statement that holds true today.

The unexpected upsurge in this disease in the United States in the late 1980s and 1990s and reports of increasing numbers of invasive group A streptococcal infections have renewed interest in group A streptococci and their abilities. In addition, recognition that rheumatic fever is the leading cause of acquired heart disease in children and young adults worldwide has led to action.[147]

EPIDEMIOLOGY

The overall incidence and severity of acute rheumatic fever have decreased in recent years in developed Western countries and in prosperous countries of Asia.[2] Reliable morbidity data on the occurrence of acute rheumatic fever in total populations are lacking because studies often consider only a segment of a population. The trend seems clear, however. Some of the best long-term data come from Denmark, where rheumatic fever has been a reportable disease for many years[201]; a steady decline has been occurring since 1900, except for a peak during World War II (Fig. 35–1). In the United States, rheumatic fever is not a reportable disease, but mortality rates (Fig. 35–2) and hospital discharge rates (Fig. 35–3 and Table 35–1) have shown a steady decline. Although this decline was already under way, it seems to have been accelerated by the introduction of penicillin.[126]

The dramatic decline in the incidence of rheumatic fever began in the United States in the late 1940s (see Fig. 35–2). During the late 1950s, the 1960s, and the early 1970s, studies in the United States showed annual rates of 13.5 to 62.5 first attacks per 100,000 children 5 to 14 years of age; however, these studies are not strictly comparable in design.[35,52,82,150,170,176] Some of them were conducted in low-income urban areas, locations in which the incidence of rheumatic fever was thought to be higher. Secondary prevention of rheumatic fever with penicillin prophylaxis to protect against recurrent attacks probably became widespread in the 1960s. Denny and colleagues[64] showed the possibility of preventing initial attacks with injectable penicillin in 1950 in military camps. Similar conclusive controlled studies were not repeated in the general or pediatric populations or with oral penicillin.

Figure 35–1 Reported annual incidence of acute rheumatic fever in Denmark, 1862 to 1962. *(Adapted from Public Health Board of Denmark: Reported rheumatic fever incidence in Denmark, 1862-1962.* In *Vendsborg, P., Fauerholdt, L., and Olsen, K. H.: Decreasing incidence of a history of acute rheumatic fever in chronic rheumatic heart disease. Cardiologica 53:332-340, 1968. Used with permission of S. Karger A. G., Basel.)*

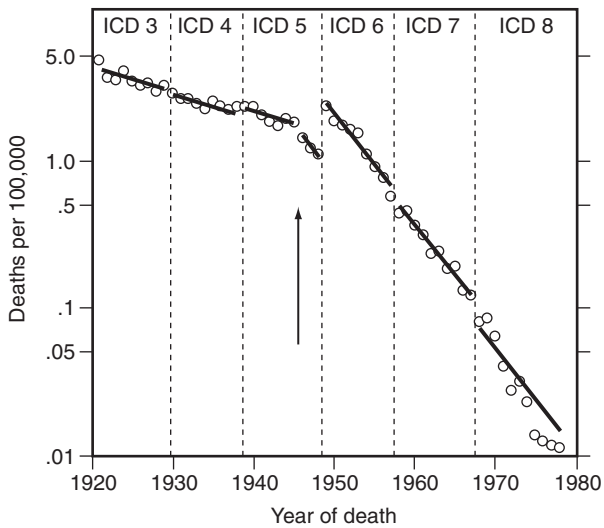

Figure 35–2 U.S. national mortality rates from rheumatic fever in individuals 5 to 19 years old, 1921 through 1978. Values are age-adjusted to the 1950 U.S. population. Trend lines are fitted for each era (1921 through 1945 and 1946 through 1978) separately and take International Classification of Diseases (ICD) revisions into account. The *arrow* separates the two eras. *(From Massell, B. F., Chute, C. G., Walker, A. M., et al.: Penicillin and the marked decrease in morbidity and mortality from rheumatic fever in the United States. N. Engl. J. Med. 318:280-286, 1988.)*

The most compelling evidence that appropriate medical intervention helps reduce the number of initial attacks of rheumatic fever comes from a study by Gordis[82] of health care availability in an inner-city Baltimore population at risk. The rate of acute rheumatic fever was reduced by 60 percent over the course of a decade in only the census tracts receiving a comprehensive care program, with that reduction occurring only in patients with an identifiable preceding clinical respiratory infection. A similar trend with small numbers of patients was seen for the Navajo and Papago Native American populations in school-based intervention programs[14,52] and in an Alaskan program.[33] Other school-based interventions[155] have reduced streptococcal prevalence rates but have not gone the necessary further step to show a reduction in rheumatic fever morbidity in a controlled, carefully demarcated population.

An unexplained high incidence of acute rheumatic fever persists in Hawaii, especially in Polynesian and part-Polynesian children.[46] Similarly, rates are inexplicably higher in larger populations of Polynesian children in New Zealand.[113] In some areas of the continental United States, the rate of endemic rheumatic fever continues to exceed that of the general population in some children traditionally considered to be at risk (urban African-Americans), although not in others (recent Hispanic immigrants).[70] In contrast, in a hospital-based study in another urban area, Hispanic children, reflecting the pediatric population being served, were the most affected.[88]

Since the beginning of 1985, the number of patients with acute rheumatic fever in several centers on the U.S. mainland has increased.* Although these numbers are not large, they represent a definite increase in the outbreak areas (Table 35–2).[193] The resurgence in Utah since 1985 has led to more than 600 cases.[130] Nationally, the number of diagnoses of acute rheumatic fever may have continued to decline gradually from 1984 through 1990.[193] The populations (aside from clusters in military populations)[10,204] generally do not seem to be those considered to have been at risk in the past: Most patients are white and middle class and live in suburban or rural communities with ready access to medical care. In the Utah and Tennessee outbreaks,[200,210] the families were larger than the state average. The military outbreaks[10,205] were the first in 2 decades in U.S. military personnel. Factors other than the widespread use of antibiotics and improved availability of health care may be important. Overcrowded living circumstances long have been considered to be a risk factor,[153] although this hypothesis was not substantiated as an important risk factor by conditional logistic regression in a modern-day study.[202]

The disquieting feature in these more recent outbreaks was the severity of the illness, especially in the Salt Lake City, Utah, outbreak: 72 percent of patients had clinical carditis (Table 35–3), 19 percent had severe carditis with or without congestive heart failure, and three patients required mitral valve replacement. Because this report was from a cardiology center, however, it may reflect a referral bias. Earlier U.S. reports documented clinical carditis in initial attacks of rheumatic fever in 40 to 51 percent

of patients (1951 through 1965).[125] Longitudinal observations at the same institution suggest a decreasing frequency of clinical carditis (73% from 1921 to 1930; 51% from 1951 to 1960).[32,131]

Rheumatic fever in its milder form with arthritis is the sole major manifestation without a serologic search for other causes of polyarthritis, or echocardiography may cause difficulty in making a diagnosis, and the patient may not be admitted to the hospital, which could affect estimates of rates of carditis in studies that are not population-based. With the use of Doppler echocardiography, carditis rates in the Utah patients increased to 91 percent (see Table 35–3). The duration of secondary penicillin prophylaxis and endocarditis prophylaxis is an important consideration for patients with nonclinical carditis. The place of echocardiography in the diagnosis and management of rheumatic fever is evolving (see section on laboratory findings).

A more recent assessment of hospitalized acute rheumatic fever disease in the United States in children younger than 21 years of age found a low rate of 14.8/100,000 hospitalized children (503 cases).[138] The prevalence of rheumatic heart disease, which represents the result of many years of exposure to the risks of acquiring acute rheumatic fever, seems to have declined in the United States over the course of many years.[143]

Many different racial and ethnic groups have been deemed unusually susceptible to rheumatic fever. They usually have been minority groups within a given area who are of lower socioeconomic status than the general population (e.g., Malays in Singapore, Arabs in Israel, Bantus in South Africa, Maori in New Zealand, African-Americans in the United States, aborigines in Australia).[2,39,124] In the United States, when differences in socioeconomic status or degree of crowding were taken into account,[85] the differences in the incidence of rheumatic fever,[84] prevalence of rheumatic heart disease,[143] and mortality from acute rheumatic fever and rheumatic heart disease generally declined or disappeared,[162] at least in the population studied. Rates in African-Americans were slow to decline, however. Rates became very low in the 1970s, at least in some areas, but cases persisted in other areas.[70,108]

Gordis and associates[83] caution that some other socioeconomically determined factor closely paralleling crowding could be the actual determinant of rheumatic fever. Most authorities agree that the reduction in the incidence and severity of rheumatic fever that has been noted in the United States and Western Europe might be due partly to a higher standard of living and less crowding. In a case-control study in the former Yugoslavia, home dampness, change of place of residence during the last 5 years, low maternal education, body weight below normal, frequent sore throats, and a positive family history of rheumatic fever were found to be significant risk factors.[202]

A relationship between group A streptococcal throat infection and rheumatic fever was recognized following observations of the latter occurring after outbreaks of scarlet fever.[150] The attack rate noted after group A streptococcal throat infection varied widely (from 3% at Warren Air Force Base[165] to 0.39% in Chicago children[178]). Further observations in the latter study revealed that exudative pharyngitis, a positive throat culture with persistence of group A streptococci beyond 21 days, and the development of significant antibody (antistreptolysin O [ASO]) responses were associated with a higher attack rate that approached 3 percent in the children studied.

Rheumatic fever, similar to streptococcal infection, occurs most commonly in children 5 to 15 years of age. First attacks of rheumatic fever rarely occur in children younger than 3 years of age or in adults older than 40 years because of the relative infrequency of streptococcal infection at these ages and perhaps other factors.

The incidence of acute rheumatic fever is highest in the spring and winter months in temperate zones and coincides with the seasonal variation in streptococcal pharyngitis. This incidence may be related to the greater tendency for spread of streptococcal infection by closer contact during the colder and damper months,[113,186,202] at least in some climates. In other climates, a seasonal peak for acute rheumatic fever is less pronounced.[31]

PATHOGENESIS

Evidence points toward acute rheumatic fever being preceded by a group A streptococcal upper respiratory tract infection. The events that occur after such infection and that culminate in rheumatic fever are poorly defined, suggesting a complex interaction of numerous factors. With the resurgence of interest in this disease after the outbreaks in the 1980s, laboratory data collected with the use of modern technologies have led to some new insights.[179,180] Pathogenesis involves the host, the environment (see section on epidemiology), and group A streptococci, individually and collectively.

So-called rheumatogenic strains of group A streptococci have been the subject of much discussion, more recently in relation to the latest focal upsurges in rheumatic fever.[25,29,97] Because no factor has been described or isolated, however, such strains remain a hypothesis. To date, rheumatic fever has been shown to occur only after nasopharyngeal infection,[206] although debate and research continue.[55,101] Why the site of infection seems to predispose individuals to the development of rheumatic fever remains an enigma, perhaps related to skin lipids.[100] Acute glomerulonephritis develops after skin or throat infections with a nephritogenic type of group A streptococci (e.g., M-49, M-12).[206]

Certain streptococcal M protein serotypes are implicated strongly and repetitively in epidemics of acute rheumatic fever. Serotypes M-3, M-5, M-14, M-18, and M-24 have been reported more than once in outbreaks, and M-1, M-6, M-19, M-27, and M-29 have been reported once only.[24] Distinct nucleotide sequences that determine different gene subfamilies encoding the M or M-like protein antigenic domain ("emm gene") may be the

cause of these variations in streptococcal rheumatogenic potential, depending on the site of infection.[23] Other equally prevalent M types rarely, if ever, have been associated with epidemics of the disease[24] or have failed to cause recurrences in susceptible patients.[28] The current resurgence lends limited support for this concept: No predominance of a single serotype within a specific geographic zone was identified in any of the published outbreaks (Table 35–4; see Table 35–2). Specific M types and their production of mucoidal colonies (see Table 35–4), considered to be related to the amount of M protein and virulence,[207] may be more relevant to epidemic than to endemic rheumatic fever.

In Auckland, New Zealand, an average of 45 new cases of acute rheumatic fever occur annually in children (annual age-specific rate of 20/100,000/yr). Nine years (1984 to 1992) of surveillance of group A streptococcal isolates from hospitalized pediatric patients (one centralized children's facility for 8 of the 9 years in question) yielded 2410 isolates. Only 3 of 38 throat isolates (32 from well-documented cases of rheumatic fever, 6 from siblings) were strains described as possibly rheumatogenic (one each of M-1, M-3, and M-6).[129] None was described as mucoidal.[129] In that series, M types 6, 53, 55, and 66 (and NZ 1437, now known as M-89, when sibling isolates were included as cases) were statistically more likely to be associated with a case of acute rheumatic fever. Both streptococcal collections[97,129] (see Table 35–4) are limited samples and may not be representative. In addition, as in most series, group A streptococcal isolates are isolated from a few cases and are not supported by streptococcal or type-specific antibody data.

Strain selectivity is a further consideration. No documented evidence has shown that all members of an M type may be equally able to elicit acute rheumatic fever. Some streptococci from a particular serotype may be associated with acute rheumatic fever and acute poststreptococcal glomerulonephritis, although the two sequelae rarely occur simultaneously.[120,128,129] M types have been shown to be composed of genetically diverse streptococci, not all of which may be established within a community.[128] Genetic analysis of serotype M18 from acute rheumatic fever cases in Utah separated by 12 years showed strains nearly genetically identical.[179] The M type denotes possibly nothing more than a shared type-specific marker, with the property of rheumatogenicity as yet remaining elusive. Streptococcal strains that are opacity factor–negative (a lipoprotein lipase) are unlikely to be rheumatogenic, according to some investigators (see Table 35–4).[97,210] This finding does not hold up in all geographic areas.[129] Surveillance of group A streptococci in different geographic zones must be encouraged to guide vaccine development.

TABLE 35–4 Group A Streptococci Isolated from Patients with Rheumatic Fever and from Their Siblings (1986 to May 1988)

From Kaplan, E. L., Johnson, D. R., and Cleary, P. P.: Group A streptococcal serotypes isolated from patients and sibling contacts during the resurgence of rheumatic fever in the U.S. in the mid-1980s. J. Infect. Dis. 159:*101-103, 1989.*

Although current evidence strongly implicates an immunologic mechanism in the pathophysiology of rheumatic fever, the details of how the disease develops are unclear.[26,53,130,184] Evidence to date strongly suggests an abnormal cell-mediated and humoral immune response to cell membrane streptococcal antigens, which, because of molecular mimicry of human tissues, may result in continued damage to the cardiovascular and nervous systems.[36,184] The findings of circulating immune complexes in most patients[54] and the deposition of C3 and immunoglobulin in the myocardium of patients dying of acute rheumatic fever support an abnormal immune response in rheumatic fever.[102]

M proteins from some rheumatogenic group A streptococcal types share antigenic determinants with myosin, with the sarcolemma of cardiac muscle,[60,61] and with antigens of articular cartilage and synovium.[16] The immune response to streptococci may mistake the host antigens as foreign and result in tissue damage. Other streptococcal antigens, such as the group A carbohydrate component, are candidates for mistaken cross-reaction with a glycoprotein in human heart valves.[81] Group A streptococci have components that can amplify or down-regulate the immune response.[36] The mechanisms for molecular mimicry leading to central nervous system dysfunction are less defined.[130]

The site of the initial streptococcal infection may be important—lymphatic channels have been shown between the tonsils and the heart.[36] Unusual compartmentalization of rheumatic antigen–positive non–T cells has been shown in patients with acute rheumatic fever, with no positive cells detected in rheumatic tonsils but increased numbers in peripheral blood.[86]

Cell-mediated immunity to streptococcal antigens also is enhanced in patients with rheumatic fever.[184] The lymphocytic infiltrate of heart valves was found to be composed predominantly of $CD4^+$ helper cells.[163] Increased expression of HLA-DR on fibroblasts, which can present antigens to $CD4^+$ lymphocytes (cytotoxic/suppressor T cells), has been observed on the heart valves of patients with acute carditis.[66] The cytotoxicity induced in normal human helper and suppressor cells in vitro by purified protein from a type M-5 group A streptococcal organism has been shown to destroy several human cell types, including cultured myocardial cells.[62] T-cell subset study results are conflicting,[141,184] but production of interleukins is reported to be enhanced.[141,142,221] The role of M protein and streptococcal pyrogenic exotoxins as superantigens is being explored and perhaps might explain the exaggeration of the streptococcal immune response.[127,195]

The genetic background of the human host seems to influence susceptibility to rheumatic fever. Aggregation of rheumatic fever cases in families has been recognized for some time.[156] Low concordance for inheritance has been reported in monozygotic twins,[192] although affected siblings have significant concordance for arthritis, residual rheumatic heart disease, and chorea.[181] Patarroyo and associates[149] found that the B lymphocytes of patients with rheumatic fever have a specific marker (883 alloantigen) associated with host rheumatic susceptibility.[218,219] It seems to transcend ethnicity,[90,149] although studies in India were less supportive and may be similar to an immune response gene.[184] This work has been extended with the use of monoclonal antibodies to family members of patients with rheumatic fever.[69,168] Class I HLA molecules have not been associated with acute rheumatic fever. Many studies in different populations have shown an association with HLA-DR, but without a single HLA marker for susceptibility.[184] Genetic factors alone seem highly

unlikely to be responsible for susceptibility to rheumatic fever.[126] No predictive marker for susceptibility to rheumatic fever has been defined.

VACCINE DEVELOPMENT

Immunity to group A streptococci and to rheumatic fever is thought to depend largely on antibodies to M protein, a major virulence determinant; such antibodies can opsonize the bacteria in the presence of neutrophils.[107b] Immunity was thought to be strain-specific and to depend on antibodies to the variable serotype-specific regions of the protein, and earliest vaccine development has followed this pathway.[19] Two early landmark studies showed that vaccines containing purified M protein evoked protective immune response in humans.[20,159] Antibodies against the variable amino-terminal end of the M protein opsonize streptococci in a type-specific manner, but the results of experiments in animals suggest that the conserved carboxyl-terminal end also may be an immune target. Some human evidence suggests that this conserved epitope acts as a subunit vaccine.[160] Complexities in this area include the risk of inducing cross-reacting antibodies that could injure rather than protect.[15,133] Separation of the peptide fragments of M proteins (epitopes) that evoke type-specific and not cross-reacting antibodies is an important step.[34,54]

With more than 120 different defined serotypes of group A streptococci, vaccine development[29,31a] falls into two broad approaches: vaccines based on common protective antigens of group A streptococci and multivalent vaccines based on type-specific N-terminal regions of the M protein. A 26-valent vaccine with components guided by North American surveillance of acute rheumatic fever, invasive infections, and pharyngitis has been shown to be safe and immunogenic in adults.[137] This vaccine includes 80 to 90 percent of important serotypes in North America, and epidemiologic studies indicate that vaccine coverage may be incomplete in other areas such as in Asia[161] or in New Zealand.[129] Information for serotype prevalence in many areas of high endemicity of acute rheumatic fever is urgently needed.

RHEUMATIC FEVER IN DEVELOPING COUNTRIES

Rheumatic heart disease is considered by some physicians to be one of the few preventable chronic diseases.[9] Despite impressive declines in incidence in developed countries (see Figs. 35–1 to 35–3), globally, rheumatic heart disease remains the most common form of acquired heart disease.[105,217] Four fifths of the world's population live in developing countries, where the prevalence of rheumatic heart disease suggests that the incidence of acute rheumatic fever remains at high levels in areas characterized by crowded living quarters and lower socioeconomic conditions. In Soweto, South Africa, the prevalence of rheumatic heart disease in the 1970s was estimated at 7.1 per 1000 schoolchildren.[136] A recent estimate using echocardiography in two developing country settings increased this estimate by nearly tenfold.[122]

Given the difference in medical care delivery, evaluation of the incidence of acute rheumatic fever must be viewed with caution. Estimates suggest, however, an annual incidence of 200 to 400 cases per 100,000 population in Soweto.[105] In India, the prevalence of rheumatic heart disease in school children has been estimated to be 1 to 5.4 cases per 1000.[148] The incidence of rheumatic fever (as judged by hospital admissions for rheumatic heart disease between 1966 and 1980) has remained stable in India during this period of rapid decline in the United States and the West.[2] Community-based secondary penicillin prophylaxis programs in developing countries are considered cost-effective and more achievable than is primary prevention.[105] An estimate of the global burden of group A streptococcal diseases has been undertaken by the World Health Organization (www.who.int/ch-add-health).

PATHOLOGY

The unique pathologic lesion of rheumatic fever is the Aschoff body, which generally is considered to be a granuloma that results from injury to collagen fibers. Classically, Aschoff bodies are found in the heart, usually in the left atrial appendage, but similar foci can be found in the synovia of the joints and in and around joint capsules, tendons, and fascia.[171]

The early pathologic response to rheumatic fever may be an exudative reaction with Aschoff-like bodies as an inflammatory focus. They are cardiac or extracardiac, with a central area of fibrinoid necrosis surrounded mostly by polymorphonuclear leukocytes. Clinically, this condition may be manifested as arthritis and spontaneously subside in 2 to 4 weeks. No residual joint damage results. The proliferative phase of classic Aschoff nodules, which consists of central necrosis surrounded by a rosette of large mononuclear cells, giant multinuclear cells, and other cell types, is confined to the heart and usually causes pancarditis with simultaneous involvement of all three layers (the pericardium, the myocardium, and the endocardium). This event may result in permanent valvular damage in the following order of frequency: the mitral valve, the aortic valve, the tricuspid valve, and, rarely, the pulmonary valve.

The heart disease encountered clinically usually is mitral regurgitation, aortic regurgitation, or both. The scarring that leads to valvular stenosis (mitral or aortic) typically takes decades to develop but may occur much faster in hyperendemic areas. This process is not the full story, however, because although rheumatic mitral valve stenosis occurs more commonly in India[174] and occasionally in other less advantaged populations, it was never a common occurrence in the United States or the United Kingdom at the height of rheumatic fever incidence.[191]

The presence of Aschoff bodies is not evidence of rheumatic activity because these lesions are found in biopsy specimens of the left atrial appendage many years after an acute attack of rheumatic fever. Little is known about the pathology of Sydenham chorea, and the pathologic changes cannot be related to the clinical manifestations. Patients rarely die of this form of rheumatic fever.

CLINICAL COURSE

The stage is set for the development of rheumatic fever in a susceptible host after a pharyngeal infection by one of the types of group A beta-hemolytic streptococci.[115,125,182] If the infection is not treated, most individuals recover from the acute effects of the disease. Acute rheumatic fever develops in approximately 1 to 3 percent of children with known epidemic untreated exudative pharyngitis and a culture positive for group A streptococci. The frequency decreases to less than 1 percent, as shown in the one controlled study involving children,[178] when patients with less severe or less precisely diagnosed streptococcal infections are included.

This finding has been replicated more recently in a large community-based study in an endemic area in New Zealand. The attack rate observed was approximately 0.2 percent[114] with bacteriologic diagnosis and treatment of group A streptococcal throat infection and its effect on rheumatic fever.

The preceding pharyngitis is not recognized as an illness by the patient or parents in approximately 10 to 33 percent of cases of acute rheumatic fever, although 50 to 60 percent of patients

remember having a sore throat.[82] In the New Zealand series, episodes of sore throat (with appropriately increased streptococcal serology) in this carefully monitored series preceded development of acute rheumatic fever cases in 14 of 19 (74%) of the cases enrolled in the program at the time of presentation.[114] In some series, this figure is lower (see Table 35–2). The infection is followed by a latent period that averages 19 days in duration,[164] during which time the patient seems well. The range seems to be between 1 and 5 weeks but has been difficult to establish.[41] In the New Zealand series, the average latent period was 27 days (range, 2 to 49 days) for seven rheumatic cases with proven group A streptococcal pharyngitis.[114] The average latent period is the same for recurrent attacks as for initial episodes.[41]

Acute rheumatic fever then begins. Table 35–3 suggests a clinical profile in the United States, although recurrent cases with their increased risk for carditis are included. In a prospective study in India, 67 percent of initial episodes were associated with migrating arthritis involving one or more of the large joints[173] accompanied by a fever of 38º C to 39º C, malaise, and anorexia. Just as the redness, swelling, and pain in a knee subside, the whole process may start again in the ankle. The elbows and wrists also are likely to be involved. Typically, multiple joints are involved, in tandem with overlap over the course of time, when symptoms are not suppressed by anti-inflammatory therapy. The whole polyarthritic episode usually subsides over 4 weeks, with no residua remaining.

Carditis generally appears early in the, illness (first 2 to 3 weeks) if it is going to occur.[1] The joint inflammation may be low-grade in some individuals, without limitation of motion or outward manifestations of redness and swelling (arthralgia). The literature supporting monarthritis that does not develop into migrating polyarthritis in acute rheumatic fever is unconvincing.[38,89,104,114,157,212] The clinician should act cautiously, however, in an area endemic for rheumatic fever in the early phase of presentation. The development of polyarthritis in a patient with a culture-negative monarthritis (e.g., a hip joint in a patient without prior antibiotic exposure) may be aborted by nonsteroidal anti-inflammatory drugs (NSAIDs). An early echocardiogram may assist in establishing the diagnosis.[3]

At examination, the striking findings are the patient's pallor and discomfort, especially on movement of the affected joints. The pulse is rapid. Examination of the heart may reveal in at least half of patients a grade II/IV apical pansystolic murmur that is transmitted to the axilla (mitral insufficiency) with or without an apical mid-diastolic flow murmur (Carey-Coombs murmur); half of these patients also may experience an early diastolic grade II/IV murmur at the left sternal edge (aortic insufficiency). In addition, less commonly, the child can have congestive heart failure or cardiac enlargement, indicative of active carditis. Carditis is more likely to occur in younger children. Pericarditis may be suspected with muffled heart sounds, a frictional rub, or chest pain. It becomes less common as acute rheumatic fever in a population becomes less severe. Death is a rare, but well-described, sequela of the acute phase of the disease. Murmurs of mitral and aortic stenosis are associated with chronic, but not with acute, rheumatic valve disease.

The distinctive rash, erythema marginatum, is observed in 10 percent of patients (Fig. 35–4). It is neither pruritic nor painful. The pink, slightly raised macules usually seen initially on the trunk and proximal ends of the extremities and never on the face fuse centrally and coalesce to form a serpiginous pattern. The lesions may disappear after a few hours or may reappear intermittently over the course of weeks, especially after a warm shower or bath. Subcutaneous nodules, usually associated with severe carditis, also occur uncommonly (<10% of patients). They are firm and painless and are found over bony surfaces or prominences and over tendons. Acute rheumatic fever is not likely to be diagnosed on the basis of the latter two major criteria without another major criterion.

Sydenham chorea, or St. Vitus' dance, may be the only manifestation of rheumatic fever, or it may be associated with other disease manifestations. It becomes less common as acute rheumatic fever becomes less severe in a population. Chorea is characterized by purposeless (most often bilateral, uncoordinated, involuntary) movements, mostly of the hands, feet, and face, which develop over the course of weeks and are accentuated by excitement and emotional stress. They disappear during sleep. Sensation remains intact. The speech can be explosive and indistinct, and the handwriting can be clumsy. Handwriting is a useful objective means of monitoring the course of the disease. The child has difficulty counting rapidly and holding the protruded tongue still. The fingers and wrists are hyperextended when the fingers are outstretched, and the palms usually are turned outward when the arms are held above the head. Handgrip generally is weak and may consist of spasmodic contractions followed by rapid relaxation.

The patient may be easily irritated and quarrelsome. Chorea typically is a delayed manifestation of rheumatic fever and may develop after other signs of the disease have subsided. Chorea commonly appears 2 to 6 months after the streptococcal infection. Most observers think that residual heart disease occurs less commonly when chorea is the only manifestation of rheumatic fever, but in the echocardographic era this hypothesis may prove not to be the case.[3] The importance of prophylaxis to prevent recurrent attacks and possible subsequent carditis was reaffirmed in Kuwait.[119] Permanent serious residual neurologic deficits have

Figure 35–4 Erythema marginatum in an 8-year-old girl with acute rheumatic fever.

not been observed. A 25-year review found the duration of chorea to be 1 to 22 weeks, with a median of 12 weeks.[145] Rare cases may last 2 to 3 years.[4,13,37] Recurrent attacks are common and may occur despite faithful adherence to prophylaxis with intramuscular benzathine penicillin.[22,194] The neuropsychiatric sequelae of chorea were reviewed recently.[139]

Some cases of chorea are mild or atypical and may be confused with motor tics or the involuntary jerks of Tourette syndrome. Confusion may ensue between Sydenham chorea and these conditions. The term *pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS)* refers to a subgroup of children with tic or obsessive-compulsive disorder, whose symptoms may develop or worsen after an episode of group A streptococcal infection. The following five criteria have been used to define the PANDAS subgroup[106,189]:

1. The presence of a tic disorder or obsessive-compulsive disorder or both
2. Prepubertal age of onset (usually between 3 and 12 years of age)
3. Abrupt onset of symptoms or episodic course of symptom severity, or both
4. Temporal association between exacerbations of symptoms and streptococcal infection (approximately 7 to 14 days)
5. Presence of neurologic abnormalities during periods of exacerbation of symptoms (typically adventitious movements or motoric hyperactivity)

The evidence supporting PANDAS as a distinct disease entity has been questioned.[106] In any population with a high prevalence of acute rheumatic fever, clinicians should rarely (if ever) make a diagnosis of PANDAS and rather should err on the side of overdiagnosis of acute rheumatic fever and secondary prophylaxis. If acute rheumatic fever is excluded, secondary prophylaxis is not needed, but such cases should be followed up carefully to ensure that they do not develop carditis in the long-term.

The average duration of an attack of acute rheumatic fever is approximately 3 months when unaltered by anti-inflammatory therapy.[125] Less than 5 percent of cases persist longer than 6 months with active symptoms, so-called chronic rheumatic fever.[191]

LABORATORY FINDINGS

The degree of inflammation in patients with acute rheumatic fever is measured by nonspecific indicators, such as the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).[115,125,182] Unless the patient has taken corticosteroids or salicylates, these test results almost always are positive in patients with polyarthritis or acute carditis, whereas they often are normal in patients with chorea. The magnitude of the ESR is proportional to the intensity of the inflammatory reaction but is not site-specific (i.e., it can be high with polyarthritis or carditis). The ESR may be decreased in congestive heart failure, whereas CRP may be elevated in congestive heart failure attributable to any cause. The ESR may remain elevated for 6 weeks to 3 months in an untreated attack of acute rheumatic fever. Anti-inflammatory agents may reduce the ESR, but it rebounds if the drugs are stopped before the rheumatic process has run its course. Although chronic elevation of the ESR (>6 months) is not understood, it is not sufficient reason on its own to limit a patient's activities.[191] The CRP may reflect the patient's rheumatic activity more precisely than may the ESR.[125]

Chest radiographs are useful for detecting cardiomegaly, which may be caused by dilation, preexisting heart disease, or pericardial effusion. The degree of enlargement is helpful in judging severity. The electrocardiogram may show a prolonged atrioventricular conduction time, usually evidenced by a prolonged PR interval or even greater degrees of heart block.[167] Generally, an increase in the PR interval in tracings with comparable rates is considered significant.[125] Upper limits of normal by age are available.[115] Atrioventricular conduction abnormalities per se bear no relation to the ultimate prognosis of patients. Changes of myocarditis and pericarditis also are seen.

The roles of two-dimensional and Doppler echocardiography in establishing the diagnosis and determining the prognosis of acute rheumatic fever are becoming clearer.[1,71,72,115,182,198-200,213] In a prospective blinded study using febrile controls and strict color and pulsed Doppler criteria, pathologic left-sided heart regurgitation could be differentiated from physiologic regurgitation.[1] Several centers using similar strict criteria have observed subclinical carditis in acute rheumatic fever.[73,74,199,200] The status of echocardiographic evidence as a major or minor Jones criterion remains to be settled by the American Heart Association.[71] It has important implications for patients with polyarthritis or chorea as a sole major criterion[3,182] or patients without major criteria and only echocardiographic evidence of mitral or aortic regurgitation. In an area of high endemicity (New Zealand), strict criteria have evolved and are incorporated into common usage.[115] In a prospective study of prevention of acute rheumatic fever, three additional cases (3 of 59 [5%]) met the case definition for acute rheumatic fever using the New Zealand Rheumatic Fever diagnostic criteria, which allows echocardiographic carditis to be a major or minor criterion in the presence of other major or minor criteria and evidence of preceding streptococcal infection.[114]

A positive throat culture for group A beta-hemolytic streptococci as evidence of a recent streptococcal infection seldom is found, and 50 percent of such patients could be carriers of the organism.[99] In the New Zealand prospective study of patients with sore throat episodes (n = 14) and enrolled in the program, 57 percent (8 of 14) had a positive throat culture and appropriately increased serology.[114] A positive culture may be helpful if it can be related to the time of the acute infection.

Corroboration of a previous streptococcal infection may be documented by numerous streptococcal antibody tests.[175,211] Antibody titers may be elevated in the absence of clinical or bacteriologic evidence of streptococcal pharyngitis (5 of 19 acute rheumatic fever cases in the New Zealand program).[114] The ASO titer is the most popular antibody test. It measures the inhibition of rabbit red blood cells by specific antibody to streptolysin O, an extracellular product of beta-hemolytic streptococci that in its reduced form hemolyzes red blood cells. The "normal" level for an ASO titer usually is defined as the highest titer exceeded by only 20 percent of a population, but it is influenced significantly by age, geography, season, and other factors.[98,175] ASO titers of 500 Todd units or greater are rare findings in normal schoolchildren and are good evidence of a recent streptococcal infection. ASO titers less than 250 Todd units could be considered normal; titers of 250 to 320 Todd units should be considered borderline elevated. Approximately 50 percent of patients with acute rheumatic fever have ASO titers in this range, and approximately 60 percent have titers of 500 Todd units or greater.[182] Conversely, ASO titers can be normal in 20 percent of patients with acute rheumatic fever.[185]

A recent streptococcal infection is more likely to be shown if more than one antibody titer is measured (e.g., antistreptokinase and antihyaluronidase).[185] Anti–deoxyribonuclease B is the most favored test because of its better reproducibility.

The Jones criteria (Table 35–5) call for an elevated or increasing titer of an antistreptococcal antibody.[182] The onset of clinical acute rheumatic fever usually coincides with the peak of the streptococcal antibody response. It may stay elevated for many weeks. The absence of an elevated antistreptococcal titer, if three different antibodies are measured, means, however, that the clini-

cian can be 95 percent certain that the patient has not had a streptococcal infection within the recent past. In patients with pure chorea, antibody levels may have declined to normal because of the length of the latent period between the development of streptococcal infection and the manifestation of this symptom. A slide agglutination test is available (Streptozyme antibody test; Wampole Laboratories, Stamford, CT). This test cannot be recommended at this time because of inconsistencies in results caused by variations in different lots of test material.[216]

The synovial fluid in joints affected by acute rheumatic fever contains 10,000 to 100,000 white blood cells/mm^3, which are mostly neutrophils. The protein concentration is approximately 4 g/dL, glucose levels are normal, and a good mucin clot is present.[92] A more recent report corroborates the cellular findings and highlights similarities with septic arthritis.[89]

DIAGNOSIS

The signs and symptoms of rheumatic fever vary greatly, depending on the stage of the disease, the epidemiology of the rheumatic fever in that place at that time, the severity of the disease, and the sites of involvement. In the absence of a diagnostic test or pathognomonic sign, Jones suggested a series of criteria (major and minor) (see Table 35–5) that have stood the test of time, with ongoing modifications.[71,123]

The keystone on which the Jones criteria (1992 update[182]) rest is the demonstration of a recent streptococcal infection. Because few patients with acute rheumatic fever have positive throat cultures, demonstration of a previous streptococcal infection by a rising titer of one or more of the extracellular streptococcal antibodies is crucial confirmatory evidence to establish a recent streptococcal infection. The mere presence of an elevated titer to one or more of the streptococcal antibodies (see the section on laboratory findings) means only that the subject has had a recent group A beta-hemolytic streptococcal infection.

Clinical manifestations in outbreaks in the 1980s are summarized in Table 35–3. Before this time, during the period of declining incidence in the United States, carditis was found in fewer than half of rheumatic patients and generally was less severe.[131] Joint involvement alone was the most common manifestation, so arriving at a diagnostic certainty was difficult. A common avoidable error is the premature administration of salicylates or corticosteroids before the signs and symptoms become distinct; such therapy leaves in doubt the necessity of administering secondary prophylaxis without a firm diagnosis.

In contrast to the revised Jones criteria (1965), more updated criteria (1992)[182] are designed to establish a diagnosis of the initial attack of acute rheumatic fever; a previous attack of rheumatic fever or rheumatic heart disease no longer is a minor manifestation. Echocardiography currently is not a stand-alone criterion for the diagnosis of acute rheumatic fever in the United States using these criteria (see the section on laboratory findings); however, chorea and indolent carditis are considered stand-alone criteria for establishing the diagnosis of rheumatic fever. Recurrences of rheumatic fever in patients with a reliable past history of rheumatic fever or clear-cut rheumatic heart disease can be diagnosed by the demonstration of a single major or several minor criteria if supporting evidence of a recent group A streptococcal infection is present.

So-called poststreptococcal arthritis has been discussed as a possible entity when the initial symptoms and signs are atypical for acute rheumatic fever, fail to respond to salicylate therapy, or both. In some cases, rheumatic heart disease has ensued.[63a] In all such patients who fulfill the Jones criteria, a diagnosis of rheumatic fever should be considered, particularly for the purpose of administering secondary penicillin prophylaxis.[15]

Criteria have been proposed for establishing the diagnosis of poststreptococcal reactive arthritis that have yet to stand the test of time. A variable response to salicylates in series of this disease has not often been well documented with serum salicylate levels.[80] A shorter latent period is proposed, but the latent period between a group A streptococcal throat infection in original investigations of rheumatic fever varied (mean, 18.6 days), with 10 percent developing disease within 8 days (see the section on clinical course).[164] If this diagnosis is considered and rheumatic fever per se is not supported, vigilant follow-up for cardiac sequelae should ensue, and penicillin prophylaxis would be reconsidered. This diagnosis should be considered with caution in areas endemic for rheumatic fever. An atypical presentation of chorea (e.g., hemichorea) warrants consideration of neuroimaging.[222]

DIFFERENTIAL DIAGNOSIS

Many other diseases might be confused with acute rheumatic fever,[110] including rheumatoid arthritis, suppurative bacterial arthritis (especially gonococcal arthritis in adolescents), reactive arthritis (e.g., after *Yersinia*[107] or *Mycoplasma*[140] infection), infective endocarditis, sickle-cell anemia, leukemia, Lyme disease,[158] and poststreptococcal reactive arthritis (see earlier). In polyarthritis without clinical or echocardiographic evidence of carditis and fulfilling the Jones criteria, rheumatic fever is a diagnosis of exclusion. A follow-up echocardiogram after 2 to 3 weeks may reveal late presenting carditis.[1,203]

With the help of the Jones criteria and time, these diseases usually can be excluded. Heart involvement with rheumatoid arthritis is a rare occurrence. In suppurative arthritis, showing the infecting bacteria by smear and recovery by culture provide the answer. With sickle-cell disease, the bone is affected and not the joint, and a sickle-cell preparation helps establish the diagnosis. A blood smear usually establishes the diagnosis of leukemia.

The diagnosis of isolated Sydenham chorea based on presenting symptoms may be confirmed by an abnormal echocardiogram in the absence of clinical carditis. Other, much rarer

considerations, especially in an area not endemic for rheumatic fever, include systemic lupus erythematosus (SLE), Wilson disease, juvenile Huntington chorea, and various medications.[40,110]

Common errors include diagnosing acute rheumatic fever and prescribing NSAIDs when a single joint is involved (see the section on clinical course)[212]; when an innocent murmur is present; when a nonspecific rash, especially an urticarial or an erythema multiforme rash, erroneously is called erythema marginatum; and when other symptoms similar to chorea (e.g., tics, phenothiazine-induced extrapyramidal syndrome) are misinterpreted.[95] Committing a child to many years of penicillin prophylaxis requires careful decision-making at the time of establishing the diagnosis.

TREATMENT

Therapy for acute rheumatic fever is symptomatic:[41,57,110,136,190] control the inflammation, decrease the fever, and keep cardiac failure in check. Neither salicylates nor corticosteroids are thought to affect severity or outcome.[7] Cardiac drugs (e.g., diuretics, angiotensin-converting enzyme inhibitors, beta blockers) may improve impaired function. The long-term benefits have not been studied systematically. If the physician thinks that a patient has acute rheumatic fever, a trial of salicylates may be useful as symptomatic therapy. If the diagnosis is uncertain, however, pain relief such as acetaminophen should be used as an interim measure to allow migrating polyarthritis to occur. This approach has not been evaluated critically.

Characteristically, the joint inflammation and fever subside in 24 to 48 hours with salicylate treatment if the serum level is 10 to 20 mg/dL, which usually is achieved by a dose of 60 to 100 mg/kg/24 hr (not exceeding 6 g/day in divided doses). This dose may be increased, but the clinician is advised to measure serum salicylate levels and adjust the dose regimen accordingly. A higher dose may result in the undesirable development of salicylism (tinnitus and hyperpnea). Except for occasional patients with rheumatoid arthritis, no other forms of arthritis respond in this dramatic way to aspirin. Salicylate therapy is recommended for 1 to 2 weeks and then can be reduced gradually, keeping in mind that inflammatory markers suggesting ongoing disease activity may persist 3 months or longer. Joint symptoms may recur, obviating a more gradual withdrawal of aspirin.

Most acute rheumatic fever episodes subside within 6 weeks, and 90 percent resolve within 12 weeks. Approximately 5 percent of cases require 6 months or more of salicylate therapy.[186] If lengthy therapy is required, influenza and varicella vaccines are important considerations to reduce the potential for developing Reye syndrome.[50] Newer NSAIDs for the treatment of acute rheumatic fever have been studied in limited fashion.[91,197] Naproxen (10 to 20 mg/kg/day given in two divided doses; maximum dose 1250 mg) had a dramatic effect similar to that of aspirin and is well-tolerated. Advantages are twice-daily administration, the availability of elixir, less hepatotoxicity, and no need to determine serum levels.

No evidence has substantiated that steroid therapy is superior or that treatment with steroid or aspirin decreases the severity or prevents the development of residual heart disease.[6,7,47] Both treatments are palliative and not curative. They are, however, effective anti-inflammatory agents for controlling the acute exudative manifestations of rheumatic fever. Steroids are more likely to reduce acute symptoms promptly and may be indicated for severely ill patients in whom inflammatory edema of the myocardium may be life-threatening during the acute stage of the illness.[8,115] The effect of NSAIDs has not been evaluated adequately.

A randomized controlled trial of intravenous immunoglobulin, a proven immunomodulator, in acute rheumatic fever failed to alter the natural history. No detectable difference was noted in the clinical, laboratory, or echocardiographic parameters found during the subsequent 12 months.[203]

Bed rest has not been studied critically.[125] Restriction of physical activity until the rheumatic process has become quiescent is a time-honored method of treatment. It has been based on the assumption that the workload of the inflamed heart is related to the degree of residual scarring. Suggested guidelines include 6 weeks of bed rest, depending on whether carditis is present, followed by gradual ambulation indoors over the course of a further 6 weeks before outside activity, in modified fashion, occurs.[169] Patients with severe carditis who have congestive heart failure are managed more conservatively.

All patients should receive intramuscular benzathine penicillin, even if the throat culture does not reveal group A beta-hemolytic streptococci. Patients then can be placed on the secondary preventive treatment regimen, which may be either oral penicillin V, 250 mg twice a day, or injections of benzathine penicillin, 1.2 million U every 4 weeks. The parenteral route has been shown to be more effective by the author's group[146] and others (Fig. 35–5).[75,215] In high-risk situations (e.g., after a recurrence in a compliant patient), administration of benzathine penicillin every 3 weeks has been advised (see the section on prevention for more detail).[117]

Rarely, a patient has congestive heart failure.[115] A diuretic or fluid restrictions or both are recommended for mild to moderate failure. Angiotensin-converting enzyme inhibitors should be considered for more severe failure, particularly if aortic regurgitation is present. Experience with beta blockers in acute rheumatic carditis is very limited, and their use is not recommended.

Chorea is benign and self-limited. Mild or moderate chorea does not require any specific treatment aside from rest and a calm environment, perhaps in the hospital. Overstimulation or stress can exacerbate the symptoms. The potential toxicity of recommended medication for severe distressing or limiting chorea should be taken into consideration. Aspirin does not have a significant treatment effect.[125] A randomized trial of prednisone in Sydenham chorea showed efficacy.[151] More studies are awaited to confirm this finding.

Small studies of intravenous immunoglobulin have suggested more rapid recovery from chorea,[188] but they have not shown reduced incidence of long-term valve disease in acute rheumatic fever without chorea.[203] Until more evidence is available, intravenous immunoglobulin is not recommended except for severe chorea refractory to other treatments.

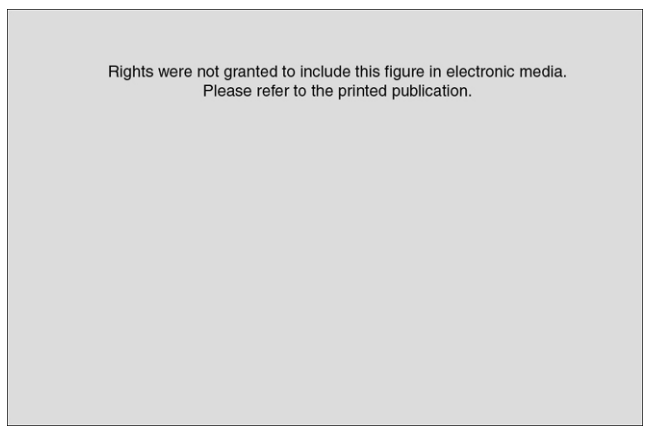

Figure 35–5 Influence of oral and intramuscular penicillin prophylaxis on the recurrence of rheumatic fever. Time is between the last attack and recurrence (years). *(From Newman, J. E., Lennon, D. R., and Wong-Toi, W.: Patients with rheumatic fever recurrences. N. Z. Med. J. 97:678-680, 1984.)*

Carbamazepine and valproic acid now are preferred to haloperidol, which previously was considered the first-line medical treatment for chorea.[63,76] A small prospective comparison of these three agents concluded that valproic acid was the most effective.[152]

Other antichorea medications should be avoided because of potential toxicity. Because of the small potential for liver toxicity with valproic acid, the recommendation is that carbamazepine be used initially for severe chorea requiring treatment and that valproic acid be considered for refractory cases. A response may not be seen for 1 to 2 weeks, and successful medication may reduce, but not eliminate, the symptoms. Medication should be continued for 2 to 4 weeks after chorea has subsided and then withdrawn gradually. Recurrences of chorea usually are mild and can be managed conservatively, but in severe recurrences, the medication can be restarted if necessary.

CARDIAC SURGERY IN RHEUMATIC HEART DISEASE

Aggressive surgical therapy, with increasing acceptance that mitral repair rather than replacement is the treatment of choice for mitral regurgitation,[12] may be indicated in patients with severe active rheumatic heart disease. Extensive published experience in South Africa[17,44] and France[44] with excellent results has challenged the concept that congestive heart failure and death during active carditis are caused exclusively by myocarditis, rather than incompetence of the valve. Studies on left ventricular mechanics support this new evidence.[77] In addition, primary myocardial involvement as evidenced by histologic abnormalities of the myocardium has been well documented during acute rheumatic fever.[144,190] Careful postoperative management, including at least 4 months of physical rest, diuretics, and vasodilation with angiotensin-converting enzyme inhibitors, is thought to improve the long-term outcome by avoiding increased blood pressure and myocardial contractility before the repair has consolidated.

Surgery usually is deferred until active inflammation has subsided. Rarely, valve leaflet or chordae tendinae rupture leads to severe regurgitation; this event requires emergency surgery, which can be performed safely by experienced surgeons, although the risk seems to be slightly higher than when surgery is performed after active inflammation has resolved.[5] Valve replacement, rather than repair, usually is done during the acute episode because of the technical difficulties of repairing friable, inflamed tissue. Nonetheless, very experienced surgeons may achieve good results with repair in this situation.

PROGNOSIS

The prognosis for patients with acute rheumatic fever depends on the initial manifestations, as shown in the 20-year follow-up study from the pre-penicillin era by Bland and Jones.[32] A patient with marked cardiomegaly, congestive heart failure, or pericarditis had about a 70 to 80 percent chance of dying in the 10 years before the advent of secondary prevention programs, open heart surgery, and use of prosthetic valves. The prognosis today is not as poor, although the recurrence rates (with the attendant increased risk of carditis in individual patients) reported after some outbreaks[199,220] suggest a careful look at secondary prevention and its delivery. The risk of having rheumatic heart disease at 1-year[7] and 10-year[49] follow-up is 70 percent for patients with cardiomegaly or heart failure and who survive. Most of these patients have mitral insufficiency, and approximately 50 percent also have aortic insufficiency.

Approximately 50 percent of patients initially are left with residual heart disease after an attack of rheumatic fever. This rate is about the same as it was 25 to 30 years ago. Approximately 25 percent of these patients return to normal cardiac status, however, with a higher chance if the cardiac involvement is mild. Of patients with no or questionable carditis[7] during their attack of rheumatic fever, only 6 percent were found to have heart murmurs when re-examined 10 years later. Heart disease was present at follow-up in 30 percent of the patients initially found to have only apical systolic murmurs and in 40 percent of patients with basal diastolic murmurs during the acute phase. Patients with chorea may have a slightly lower incidence of residual heart disease.[118] More data from the echocardiographic era are required.

PREVENTION

Denny and associates[64,208] made one of the most important research contributions in the last 50 years when they showed that rheumatic fever can be prevented in most susceptible subjects if the preceding pharyngeal infection by one of the group A beta-hemolytic streptococci is treated adequately.[57] These studies used depot penicillin G. The effectiveness of other antimicrobial agents (benzathine penicillin, chlortetracycline, sulfadiazine, oxytetracycline) in the prevention of rheumatic fever also was studied. Eradication of the streptococcus was shown to be essential,[41] and a 10-day course of penicillin treatment was found to be more effective than a 5-day course.[208] From these studies, penicillin, a bactericidal agent with activity against streptococci, became the drug of choice.

Efficacy studies against rheumatic fever per se were performed, mainly in military populations with injectable penicillin. Only one inconclusive study was done in children.[178] These studies more recently have been subjected to meta-analysis,[172] with a relative risk of 0.20 (95% confidence interval 0.11, 0.36; $p < .00001$) favoring the intervention. The ability of oral penicillin to eradicate streptococci in throats is not equal to the ability of injectable penicillin to do so.[18] A school-based, randomized, controlled trial of sore throat clinics using oral penicillin in an area in New Zealand endemic for acute rheumatic fever (43,827 person-years of observation) revealed a clinically useful result, but with uncertainty about the effect size. A meta-analysis of published literature on community-based or school-based controlled studies to prevent first attacks of rheumatic fever revealed a risk of 0.62 (95% confidence interval 0.45, 0.85; $p = .003$), which favors these interventions, suggesting approximately 40 percent efficacy.[111] Our study used supervised oral penicillin treatment[114]; the treatment regimen was unclear in the other studies.[45,52,154] A complete explanation for the decline in rheumatic fever remains unclear.

Streptococcal pharyngeal infection should be identified before treatment is started. Guidelines using clinical parameters have evolved[43,116] and have been tested empirically to guide rational management.[134,135] Streptococcal pharyngeal infection can be diagnosed by throat culture or by using a rapid diagnostic antigen-detection kit.[30,57,79] Most tests have high specificity, so a patient with acute pharyngitis and a positive test result should be treated. Many of the tests have suboptimal sensitivity and should be confirmed by a throat culture. One study found that in one third of individuals with false-negative rapid antigen-detection test results, streptococcal antibody titers increased subsequently, suggesting infection.[78]

Military studies have shown that primary preventive treatment with penicillin is effective even if started 9 days after the infection develops,[42] so physicians can wait 24 to 48 hours for verification of infection by recovery of group A beta-hemolytic streptococci. A dose of 1.2 million U of benzathine penicillin intramuscularly (0.6 million U if weight is ≤27 kg) usually is adequate treatment. Because of the discomfort and a possible, but

small, risk associated with intramuscular penicillin,[94] oral penicillin V (250 mg two or three times a day for children; 500 mg two or three times a day for adolescents and adults) may be preferred in areas in which the incidence of rheumatic fever is low. Erythromycin estolate (20 to 40 mg/kg/day in two to four divided doses; maximum 1 g/day) may be used in patients who are allergic to penicillin. Erythromycin ethyl succinate (40 mg/kg/day two to four times daily; maximum 1 g/day) is an alternative therapy. Accruing evidence supports the use of once-a-day amoxicillin.[48,67,112,177]

All oral treatments should be given for 10 days.[57] Although certain new wider spectrum agents have been administered in shorter courses with the desired streptococcal eradication, on the basis of penicillin's narrow spectrum of antimicrobial activity, the infrequency with which it produces adverse reactions, and its modest cost, it is the drug of choice for nonallergic patients.[30]

Reappearance of acute rheumatic fever in a specific geographic region should draw attention to therapeutic, preventive, and epidemiologic measures for control of the disease. A targeted approach to particularly high-risk population groups in schools may be cost-effective and efficacious.[9,33,52,155,170,196] Because treatment of pharyngitis seems likely to have contributed to the declining incidence of rheumatic fever, obtaining throat cultures (or a rapid antigen-detection test) and administering penicillin treatment, if positive for group A streptococci, still are recommended in low-risk populations, although this recommendation is being challenged by some physicians.[134,135] In addition, a negative culture avoids unnecessarily prescribing antibiotics in the 70 to 80 percent of children with a sore throat attributable to viral pharyngitis, although clinical assessment may obviate having to obtain a throat culture.[135,176]

Prompt administration of antibiotic therapy may shorten the duration of symptoms in patients with group A beta-hemolytic streptococcal pharyngitis.[166] Cultures should be used selectively in age groups in which rheumatic fever rarely occurs (e.g., <4 years of age or >20 years). Signs and symptoms usually not associated with streptococcal infection, such as simple coryza, hoarseness, cough, conjunctivitis, anterior stomatitis, and diarrhea,[58,135] may help target the approach in a low-risk population.

A follow-up throat culture taken after a course of treatment for streptococcal pharyngitis is not recommended routinely, unless the patient remains symptomatic or is from a family with a rheumatic member.[30] Such follow-up cultures probably identify long-term carriers for whom repeated courses of antibiotics generally are not indicated.[30] Streptococcal carriers seem to pose little threat to themselves regarding the development of sequelae from streptococcal infection or dissemination of the organism to people around them. When a symptomatic viral upper respiratory tract infection develops in such a carrier distinguishing whether the group A streptococci isolated indicate current streptococcal infection or identify that individual as a chronic carrier frequently is impossible. In one study, only 43 percent of children with paired sera from whom group A streptococci were recovered showed a significant antibody response to one of two different streptococcal antibodies.[99]

Often, a reasonable approach is to administer a single course of therapy. Indications for obtaining cultures from household contacts vary according to circumstances.[57] Family contacts of high-risk patients should have a culture performed and receive treatment if the culture is positive.

In the pre-penicillin era, 75 percent of individuals developed a recurrence of acute rheumatic fever.[32] Penicillin prophylaxis is well established in its ability to prevent recurrent attacks, with intramuscular long-acting preparations being superior to oral twice-daily delivery.[75,121] Persistent worsening rheumatic heart disease is prevented.[125] Secondary prophylaxis is considered the most cost-effective management of acute rheumatic fever and its sequelae.[187]

Recurrent attacks of rheumatic fever can be prevented by continuous penicillin prophylaxis, administered either orally or parenterally.[121] The parenteral route has been shown to be more effective (1.2 million U of benzathine penicillin intramuscularly at 28-day intervals).[214] In a comprehensive study, children experienced a recurrence rate of only 0.4/100 patient-years of observation (Table 35–6). A Cochrane systematic review found an 87 to 90 percent reduction with parenteral penicillin in four studies.[122] An international study of allergic reactions to long-term benzathine penicillin prophylaxis found that the benefits of preventing recurrence far outweighed the risk of development of a serious allergic reaction.[94] In areas of particularly high risk, administration of benzathine penicillin every 21 days may be more efficacious, although this study was not performed systematically.[118] Serum levels of penicillin toward the end of the time can be unreliable,[96] although this decision should be offset against practicability, cost, and probable compliance.

In a carefully monitored, community-based series with high compliance rates on four weekly injections of penicillin,[87] the penicillin failure rate per se was very low at 0.07/100 patient-years.[183] The program failure rate was 1.4/100 patient-years, with failure primarily resulting from nonadherence. This is in an environment endemic for rheumatic fever, where children had a 1:3 annual chance of having *Streptococcus pyogenes* detected in their throats.[114] A study in Egypt[103] showed that two weekly injections of penicillin resulted in an almost 50 percent reduction in recurrences. This result occurred, however, in an environment in which the rate of recurrences was approximately 45 percent of cases in the four-weekly penicillin comparison arm. A more recent publication supports the use of 1 percent lidocaine hydrochloride as a diluent for benzathine penicillin G to increase tolerability.[6a]

Patients allergic to penicillin may be given erythromycin (250 mg twice a day). Penicillin and sulfadiazine are oral regimens that have been studied for efficacy (see Table 35–6). Sulfadiazine is not readily available in the United States.[11] The lesser efficacy of oral regimens is related at least partly to compliance difficulties.

The risk of rheumatic fever occurring after a group A streptococcal infection increases from an attack rate of 1 to 3 percent with the first attack of streptococcal pharyngitis to 25 to 75 percent with subsequent attacks.[64] Patients who have had carditis are at increased risk for development of further carditis. Patients who have not had clinical carditis have considerably less risk of having cardiac involvement after a recurrence.[68,119] In the echocardiographic era, the dogma that a patient who escapes carditis in the first attack is highly likely to remain free of rheu-

TABLE 35–6 Prophylaxis and Attack Rates of Streptococcal Infection and Rheumatic Fever Recurrence

	Parenteral Benzathine Penicillin	Oral Penicillin	Oral Sulfadiazine
No. years	560	545	576

Adapted from Wood, H. F., Feinstein, A. R., Taranta, A., et al.: Rheumatic fever in children and adolescents: A long-term epidemiologic study of subsequent prophylaxis, streptococcal infections, and clinical sequelae, III: Comparative effectiveness of three prophylaxis regimens in preventing streptococcal infections and rheumatic recurrences. Ann. Intern. Med. 60(Suppl. 5):31-45, 1964.

matic heart disease, even if prophylaxis fails in subsequent attacks, has been challenged.[68,183]

The risk of having a recurrence depends on several other factors, such as the length of time since the most recent attack, and the risk of acquiring streptococcal throat infections according to occupation or living circumstances. If possible, the length of prophylaxis should be individualized. The suggested length ranges from a minimum of 5 years of prophylaxis to a maximum of lifelong prophylaxis.[50] This approach has been validated in a study from Chile.[21]

A more recent publication supports the New Zealand approach.[115,169,183] All patients, regardless of cardiac status, receive at least 10 years of prophylaxis or until they reach 21 years of age (see earlier). Two recurrences in this series occurred in teenagers inadvertently discharged after at least 5 years of prophylaxis. Appropriate discharge of individuals as per the recommended parameters with mild or no carditis apparently was safe. Of equal importance is the prevention of infective endocarditis in patients with rheumatic heart disease or in patients who have had rheumatic fever by the administration of antimicrobial drugs before and after surgical procedures on the eyes, ears, mouth (dental extractions), nose, throat, and gastrointestinal and genitourinary tracts,[59] although opinions are changing on this subject.[213a]

CONCLUSION

Although having effective prophylaxis against a disease[132] for which the pathophysiology is understood incompletely and for which no pharmacologic cure exists is gratifying, rheumatic fever and its sequelae still occur in numerous young people, especially in the developing world and in disadvantaged populations in the developed world.[217] This rate is largely a reflection of complacency about rheumatic fever and rheumatic heart disease by physicians and health care funders, although it also is likely to reflect living conditions and health care access. Renewed educational efforts regarding prevention of rheumatic fever are needed by physicians and the public. The available preventive methods should be applied vigorously.

CHAPTER 36

Mediastinitis

Morven S. Edwards

The mediastinum is the extrapleural portion of the thoracic cavity situated between the two pleural sacs. The superior and inferior portions are separated arbitrarily by a line extending from the lower manubrium to the fourth thoracic vertebra. The superior mediastinum contains the thymus gland, trachea, esophagus, and aortic arch. The inferior mediastinum is divided into the anterior compartment, containing lymphatic tissue and fat; the middle compartment, containing the heart, pericardium, aorta, bifurcation of the trachea, main bronchi, and numerous lymph nodes; and the posterior compartment, containing the esophagus, thoracic duct, descending aorta, and vagus nerve. *Mediastinitis* refers to inflammation of the tissues located in the mediastinum. Infections of the mediastinum are uncommon occurrences, but often they pose a serious threat to vital structures and can prove extremely difficult to diagnose.

Acute mediastinitis is a fulminant, septic process, and chronic mediastinitis is an indolent infection that produces late symptoms caused by compression of adjacent structures. Acute mediastinitis is subclassified as (1) traumatic, occurring as a consequence of perforation of the esophagus; (2) infection extending to the mediastinum from adjacent structures; and (3) postoperative mediastinitis, usually occurring after thoracic surgery (Table 36–1).

ACUTE MEDIASTINITIS

ACUTE MEDIASTINITIS DUE TO ESOPHAGEAL PERFORATION

The esophagus is a thin-walled organ, and esophageal perforation is the most common cause of acute mediastinitis.[43] Perforation usually occurs at one of the three sites of anatomic narrowing of

II. Chronic mediastinitis

the esophagus: (1) the proximal end, located at the level of the cricopharyngeal muscle; (2) the midthoracic segment, where the aortic arch and left main stem bronchus indent the esophagus; or (3) the transdiaphragmatic segment. A correlation exists between the location of the perforation and the injury. Proximal perforations usually are caused by instrumentation or ingestion of a foreign body. The proximal segment is the narrowest, and perforations generally are located in the posterior wall, adjacent to the prevertebral and retrovisceral spaces. Perforations at the aortic arch usually are caused by ingested foreign bodies. Transdiaphragmatic perforations usually are spontaneous. In most such cases, a longitudinal tear occurs on the left posterolateral wall just above the cardia, where the esophagus has little connective tissue support and its intrinsic musculature is weak.

Retching or vomiting can generate sufficient force to cause esophageal perforation, also known as Boerhaave syndrome, but its occurrence is rare.[1] Traumatic perforation can occur after blunt trauma, from ingestion of a foreign body, or as a complication of endoscopic or open surgical procedures. In one large series of acute purulent mediastinitis, ingestion of a foreign body was a major cause of esophageal injury.[7] Children with mediastinitis from erosion of the esophagus caused by a foreign body tend to have small and well-contained perforations. Sharp objects, such as pins and bone fragments, can cause immediate transmural penetration. More commonly, and especially with blunt objects such as coins, teeth, and food particles (e.g., corn chips), the foreign body becomes impacted in the esophagus.[39] Eventually, suppurative necrosis of the wall occurs, with symptoms occurring days, weeks, or months after the ingestion.[22]

Perforations from instrumentation can produce precipitous clinical deterioration during the procedure from transmural laceration.[43] Alternatively, a superficial tear can occur from which infection subsequently extends, and several hours or days can elapse between instrumentation and the onset of symptoms. Repair of esophageal atresia is a common condition associated with a tear of the esophagus in childhood. In one review, 7 of 41 infants had a clinically significant esophageal disruption requiring reoperation 1 to 18 days after repair of esophageal atresia.[6] Mediastinitis complicated repair of esophageal atresia in 3.6 percent of 223 cases in another large series.[41] Postoperative perforations of the esophagus usually represent infectious complications of anastomotic leaks occurring after esophageal resection or of esophageal-pleural fistulas that develop after thoracic surgery. Most of these infections do not become apparent until weeks or months after surgery.

The predominant symptoms of acute mediastinitis after perforation of the esophagus are neck and chest pain, respiratory distress, and dysphagia. Chills, fever of 37.8º C to 39º C (100º F to 102º F), and leukocytosis also are common. Infants can present with tachypnea, tachycardia, stridor, or a supplemental oxygen requirement.[22] Some patients have a staccato breathing pattern characterized by an inspiratory halt with resumption of inspiration after a brief rest.[12] The onset of symptoms usually is abrupt, and the course is fulminant. Approximately 20 to 30 percent of patients are comatose or hypotensive when first seen.[1] Physical examination often reveals cervical tenderness and subcutaneous emphysema in patients with proximal perforations, whereas patients with perforations of the lower esophagus are more likely to have signs suggesting an acute abdominal catastrophe. Examination of the lung fields often shows nonspecific abnormalities. The Hamman sign (a "crunching" sound heard in synchrony with the heartbeat along the left sternal border or cardiac apex) is observed in approximately 50 percent of cases of mediastinal emphysema, but it also occurs with left pneumothorax, dilated esophagus, gastric dilation, bullous emphysema, and pneumoperitoneum.

The principal findings on chest radiographs are a widened mediastinum, subcutaneous and mediastinal emphysema, and pleural effusions. Pleural effusions occur more commonly with perforations of the lower than the upper esophagus and usually involve the left side. Basilar or retrocardiac infiltrates ascribed to chemical pneumonitis can occur in the pulmonary segment adjacent to the site of perforation. Additional changes often include basilar atelectasis, pneumothorax, or a hydropneumothorax. Radiopaque foreign bodies can be detected with plain radiographs, but often they are seen better with mediastinal computed tomography (CT).

Gas in the soft tissues seen on radiography is highly suggestive of perforation of the esophagus if interpreted in the context of a compatible clinical presentation. Gas in the prevertebral tissue or superior mediastinum occurs most commonly with perforation of the upper esophagus. Other conditions, such as chest wall trauma or perforation of the trachea, also can cause mediastinal emphysema.

The diagnosis of acute mediastinitis caused by perforation of the esophagus often can be made on the basis of the clinical setting coupled with routine chest radiograph findings. Contrast-enhanced CT or magnetic resonance imaging (MRI) can provide additional anatomic detail and confirmation of the diagnosis.[47] The findings include esophageal thickening, fluid collections in the mediastinum adjacent to the perforation, and extraluminal air.[2] Other routine laboratory tests are not helpful. Analysis of pleural fluid usually shows a sterile exudate early in the disease course. Pleural fluid amylase levels often are normal within the first 24 hours after perforation. After 24 hours, the pleural fluid amylase level is elevated disproportionately compared with serum levels. Esophagoscopy is unnecessary and is contraindicated except for removing a foreign body.

The standard treatment comprises surgical drainage and repair and antimicrobial therapy and should be undertaken for large perforations, when there is communication with the pleural space or abdomen, when vascular erosion is a concern, and in the setting of underlying esophageal pathology. Nonsurgical management can be considered for children in whom the perforation is a small, well-contained lesion in the upper esophagus in the absence of underlying esophageal pathology.[10,22] Supportive measures include intravenous fluid support, maintenance of an adequate airway, esophageal rest (i.e., no food), and careful monitoring of vital functions.

Selection of antimicrobial treatment optimally is determined by bacteriologic studies. Blood and pleural fluid cultures should be obtained, but they usually are sterile except late in the course. Consequently, decisions with regard to antimicrobials necessarily are empiric and should be directed against oral anaerobic bacteria and streptococci.[5,8]

Mortality rates are 15 to 40 percent and are especially high when recognition of the infection in its early stages is delayed.[1,7,41,43] Mortality rates for children are lower than the rates for adults. An exception is postoperative perforation of the esophagus, which tends to follow a more indolent course.

ACUTE MEDIASTINITIS DUE TO EXTENSION OF INFECTION FROM ADJACENT STRUCTURES

The mediastinum is anatomically well situated for involvement when infection extends downward from the oropharynx. Fascial planes from the supraclavicular region and abdomen traverse the mediastinum, and the lymphatic duct is located in the mediastinum. The lung, situated laterally to the mediastinum, is a frequent locus of potentially serious infection. Despite its position as an anatomic crossroad, however, extension of infection to the mediastinum from adjacent structures occurs infrequently.

In the pre-antibiotic era, retropharyngeal or peritonsillar abscess, Ludwig angina, dental abscess, and other infections of the head and neck were common causes of acute mediastinitis.[8,14,46,51] Since the advent of penicillin, infections of the head and neck usually are contained at the site of origin. The principal spaces that serve as conduits to the mediastinum when these infections do spread are the visceral division of the deep cervical fascia that envelops the esophagus, trachea, larynx, and thyroid gland and the carotid sheath, which extends from the base of the skull, passes through the posterior pharyngomaxillary space along the prevertebral fascia, and enters the chest. Conditions other than pharyngitis and peritonsillar and dental abscesses that have preceded the development of mediastinitis include mastoiditis, laryngectomy, mediastinotomy, tracheostomy, and surgery or trauma of the oropharynx. Mediastinitis can complicate placement of airway stents for management of tracheal or bronchial stenoses in children.[21]

Children have developed mediastinitis after incurring intraoral injuries caused by falling with an object such as a toothbrush in their mouths.[25] Infection spreads to the mediastinum through the retropharyngeal space. Other sharp objects, such as fish bones, can perforate the esophagus, with resultant infection.[36] A penetrating wound to the oropharynx can be caused by falling on a sharp or pointed object such as a pencil. Occasionally, foreign bodies retained in the esophagus for months to years can have life-threatening complications, such as bronchoesophageal fistula or mediastinitis. Reported items causing such morbidity include coins, a heart pendant, a clothespin spring, and a toy soldier.[17] Mediastinitis rarely results in a complication of suppurative pleuropulmonary infection. Extension of infection from vertebrae, ribs, or sternum also is unusual. The main radiographic feature by plain chest radiograph is widening of the mediastinum. Contrast-enhanced cervicothoracic CT scan is crucial for establishing the diagnosis and can reveal heterogeneous infiltration, gas in tissues, abscesses, and fluid collections (Fig. 36–1).

The major bacteria responsible for suppurative infections that originate in the oral cavity and extend to the mediastinum are streptococci and anaerobic oral flora.[8,35] Mixed infection with aerobes and anaerobes should be anticipated when empiric therapy is initiated. Group A streptococcus is a common pathogen when the oropharynx is the original portal of entry. Other streptococci, including *Streptococcus milleri*, *Streptococcus anginosis*, and group F streptococcus, are common isolates. Anaerobic bacteria, principally *Prevotella* spp., *Bacteroides* spp., *Fusobacterium* spp., and peptostreptococci, are the major anaerobic pathogens. Gram-negative aerobic bacteria, including *Pseudomonas aeruginosa*, *Serratia* spp., and *Neisseria* spp., are isolated less often.[28] Clindamycin often is regarded as the agent of choice for streptococci and anaerobes, although some authorities prefer other regimens, including penicillin plus metronidazole, cefoxitin, cefotetan, meropenem, or a β-lactam–β-lactamase inhibitor.[8,13]

Surgical drainage combined with appropriate antibiotic therapy is the cornerstone of treatment. Transcervical incisions usually are employed when spread to the superior mediastinum has occurred. Extension of the infection below the level of the fourth thoracic vertebra requires a parasternal or paravertebral approach, depending on whether the anterior or posterior mediastinum is involved.

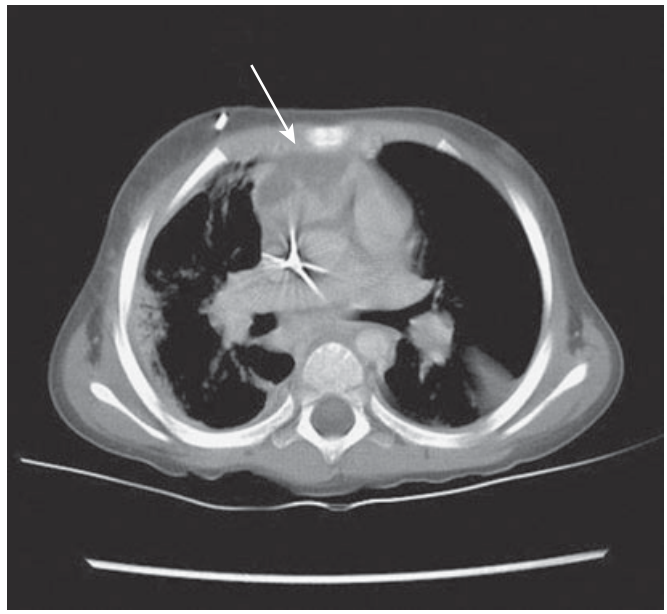

Figure 36–1 Contrast-enhanced computed tomography scan shows a 3 × 3 cm heterogeneous enhancing abscess *(arrow)* in the anterior mediastinum of a child acutely ill with *S. pneumoniae* bacteremia and pneumonia with empyema. Cultures from the mediastinal abscess at the time of surgical drainage were sterile.

TABLE 36–2 Risk Factors for Pediatric Poststernotomy Mediastinitis

Young age
Severe illness (assessed by high ASA score)

POSTOPERATIVE MEDIASTINITIS

Sternal wound infections are an uncommon complication of median sternotomy for cardiac surgery in children.[3,27,31,38,48] The Centers for Disease Control and Prevention classifies surgical site infections in cardiac patients as superficial or deep wound infection, sternal osteomyelitis, or mediastinitis.[20] Mediastinitis is a serious complication, with potential involvement of contiguous structures, including prosthetic valves, grafts, pericardium, lung, and chest wall. Contemporary incidence data for mediastinitis after median sternotomy in children is 0.2 to 1.4 percent of procedures.[3,27,31,48] The incidence is higher after cardiac transplantation.[27] Postoperative wound infection is more often a complication of double-outlet right ventricle repair, truncus repair, atrial switch, or valvulatory or conduit procedures than of repair of atrial septal defect, ventricular septal defect, or tetralogy of Fallot.[38] Mediastinal infection has developed from an infection of a retained epicardial pacemaker lead.[19]

Some of the well-established risk factors for development of poststernotomy mediastinitis in adults are not applicable to children. Table 36–2 lists factors that are linked to risk for develop-

ment of poststernotomy mediastinitis in children. Obesity and diabetes mellitus, which are risk associations in adults, have not been assessed as potential risk factors in more recent pediatric series. Factors not associated with risk for infection include emergency surgery or prior infection.[31] Intraoperative introduction of organisms is considered the source of most infections. Outbreaks of mediastinitis with *Mycobacterium chelonei* or *Mycobacterium fortuitum* presumably reflect contact with nonsterile water.[23] Epidemics have been traced to operating room personnel who can serve as the source of *Staphylococcus aureus* or other bacteria.[15]

In three contemporary pediatric series, median age at diagnosis of mediastinitis after pediatric cardiac surgery ranged from 6 weeks to 3 years.[3,27,48] Median time to onset of infection after surgery was 10 to 14 days, with a range from 4 to 50 days. The time to infection after initial sternotomy was longer for infections caused by gram-positive bacteria than for infections caused by gram-negative bacteria or fungi in one report.[48] The presenting features include erythema, purulent drainage or tenderness of the sternal incision, wound dehiscence, sternal instability, persistent or recurrent postoperative fever, and leukocytosis. A common clinical sequence is fever and systemic toxicity followed by signs of a sternal wound infection with cellulitis or purulent drainage. The CT abnormalities include mediastinal soft tissue swelling, pleural effusion, and sternal dehiscence or erosion, but CT of the chest does not always reveal abnormalities.[33,50] Consideration should be given to use of alternative testing modalities, such as MRI, when infection is suspected. Lack of compelling radiographic evidence of infection should not delay surgical drainage when clinical signs are evident.

Empiric antibiotic treatment should be initiated based on the expected pathogens and modified according to the results of blood and wound cultures. Approximately two thirds of infections are caused by gram-positive bacteria, one fourth by gram-negative bacteria, and the remainder by yeasts and fungi. The most frequent pathogen is *S. aureus*, which accounts for more than half of infections; coagulase-negative staphylococci and enterococci (including vancomycin-resistant isolates) constitute the remainder of the gram-positive isolates.[3,27,48] In adults, methicillin-resistant *S. aureus* mediastinitis is associated with higher rates of overall mortality, mediastinitis-related mortality, and treatment failure than is infection caused by methicillin-sensitive *S. aureus*, but this association has not been reported for children.[32]

Approximately half of children have associated bacteremia, and infection with *S. aureus* is an independent risk factor for development of bacteremic postoperative mediastinitis.[44] Among gram-negative organisms, *Pseudomonas aeruginosa*, *Serratia* spp., and *Citrobacter* are common isolates. Infection is polymicrobial in one fourth of patients.[3,27,48] *Candida* spp. should be considered in any patient with infection of the mediastinum, particularly when broad-spectrum antimicrobials have been used.[9] Almost any microorganism gaining entry to the mediastinum theoretically can serve as the nidus for infection, and *Mycoplasma hominis*, *Ureaplasma urealyticum*, *Nocardia*, and *Aspergillus* all have been reported, albeit rarely.[16,26,30,49] Heart and lung transplant patients are prone to acquisition of infection with less common and more resistant pathogens, such as *Aspergillus fumigatus* and *Burkholderia cepacia*.[27] *M. fortuitum* can cause apparently culture-negative mediastinitis and has been reported in a child who had undergone a Fontan operation.[45]

Adequate surgical débridement is crucial to successful treatment of postoperative mediastinitis. The sternotomy wound should be reopened, and the sternum and mediastinum should be irrigated and débrided for removal of all devitalized tissue. Some wounds can be managed with direct sternal closure and mediastinal drain; open-wound packing and delayed rectus abdominis flap, pectoralis muscle flap, or omental reconstruction is required in some children.[4,37,48] Pectoralis muscle flap has been an effective treatment even in neonates.[11,48] Early consultation with the hospital plastic surgery and reconstructive team is advisable in patients in whom sternal reconstruction is anticipated.[48] Infection superficial to the sternum can be treated simply with incision, packing, and a short course of antibiotics, usually for 10 to 14 days. Systemic antibiotics must be given for at least 3 to 6 weeks for children with postoperative mediastinitis.

CHRONIC MEDIASTINITIS

Chronic mediastinitis histologically can be fibrosing or granulomatous. Both are rare conditions in which a definite cause often remains elusive. The clinical presentations are identical, and considerable overlap can occur in histologic findings. Fibrosing mediastinitis, also known as *sclerosing mediastinitis*, can be focal or diffuse; calcification within the lesion is observed more often when the process is focal. Some authors propose that common etiologic mechanisms are responsible and that mediastinal fibrosis represents the end stage of mediastinal granuloma, whereas others suggest that the two are distinct entities.[42] Nonetheless, fibrosing mediastinitis stands apart in being associated sometimes with a fibrotic process at another anatomic site, such as the retroperitoneum.

Chronic mediastinitis occurs in virtually any age group. It is rare in very young children, but has been described in toddlers.[40] Many patients are asymptomatic, and the lesion initially is detected by routine chest radiographs showing a widened superior mediastinum near the tracheal bifurcation or the hilum with a lobulated configuration. Concomitant changes in the pulmonary parenchyma that are seen on chest radiograph vary. Symptoms, when manifested, usually reflect compression of adjacent structures, such as the superior vena cava, pulmonary vessels, esophagus, and tracheobronchial tree. The most common symptoms include cough, pleuritic chest pain, dyspnea, and pleuritic chest pain.[42] Low-grade fever, anemia, and weight loss can be present.

When an inciting cause for chronic mediastinitis can be identified, it usually is linked to infection with *Histoplasma capsulatum*. Two types of mediastinal fibrosis caused by histoplasmosis are recognized. Mediastinal granuloma is caused by coalescence of a cluster of mediastinal lymph nodes to form an encapsulated mass that may be large and compress adjacent structures, especially the superior vena cava or esophagus. Surgical resection often is feasible but is advocated only when the obstruction is significant. Fibrosing mediastinitis is thought to result from an exuberant inflammatory response to *H. capsulatum* and to represent a resolved, rather than an active, infectious process. Less common causes of fibrosing mediastinitis include tuberculosis, blastomycosis, cryptococcosis, aspergillosis, zygomycosis, autoimmune disease, nocardiosis, actinomycosis, and lymphoma.[18,24,29,34,40,42]

The diagnostic evaluation of patients with possible chronic mediastinitis should include a chest radiograph and contrast-enhanced CT or MRI. A vascular imaging study may be required if there is evidence of venous or vena caval obstruction or if arterial involvement is present. Tuberculin skin test and histoplasmosis serology should be obtained. Cultures of sputum for *Mycobacterium tuberculosis* and pathogenic fungi rarely are positive. Antigen assay for *H. capsulatum* using blood and urine usually is negative, and skin tests are not helpful. Complement-fixation titers usually exceed 1:8 in patients with chronic histoplasmosis.

Surgical resection of affected tissues can be associated with high morbidity rates, but can be curative. Biopsy of the lesion by mediastinoscopy provides a means to exclude a malignant process and obtain tissue for histopathologic evaluation. Antifungal therapy is not likely to affect resolution of the process when surgically excised tissue shows *H. capsulatum* in the setting

of sterile cultures. Dense fibrosis of mediastinal structures without a granulomatous component does not respond to antifungal treatment. Newer agents used for histoplasmosis, such as fluconazole and itraconazole, also have an uncertain role in therapy.

CENTRAL NERVOUS SYSTEM INFECTIONS

CHAPTER 37

BACTERIAL MENINGITIS BEYOND THE NEONATAL PERIOD

Ralph D. Feigin ❂ William B. Cutrer

Bacterial meningitis is an inflammation of the meninges caused by bacterial infection. The term *leptomeningitis* denotes inflammation of the arachnoid and pia mater, the usual distribution of meningitis. Infections of neonates, including bacterial meningitis, are presented in Chapter 73, and infections of the central nervous system (CNS) caused by mycobacteria are discussed in Chapter 99.

INCIDENCE AND EPIDEMIOLOGY

Before the discovery and use of antibiotics, bacterial meningitis generally was fatal. Antibiotic therapy has improved dramatically the prognosis in patients with bacterial meningitis, although it continues to be a significant cause of morbidity and mortality in children. The number of deaths attributed to many other infectious diseases in the United States decreased by 10-fold to 200-fold between 1935 and 1968, whereas the number of reported deaths caused by bacterial meningitis decreased by only half during the same period.[379,380] In 1972, the Centers for Disease Control and Prevention (CDC) estimated that in the United States, 29,000 cases of meningitis were caused by *Haemophilus influenzae* type b, 4800 cases were caused by *Streptococcus pneumoniae*, and 4600 cases were caused by *Neisseria meningitidis*.

Population-based studies in South Carolina, Minnesota, Vermont, and New Mexico in the 1970s suggested that the actual incidence of bacterial meningitis ranged from 5.4 to 7.3 cases per 100,000 population.[63,130-133] Studies reported in 1995 suggested that the incidence in children aged 1 to 23 months ranged from 0.7 (for *H. influenzae* type b) to 6.6 (for *S. pneumoniae*) cases per 100,000 population.

Before the widespread use of conjugate *H. influenzae* type b vaccine, *H. influenzae* type b was the most common cause of bacterial meningitis in children in the United States, Canada, and Scandinavia, but this pattern was not universal.[162] Davey and associates[81] reported that between 1968 and 1977, *N. meningitidis* was the most common cause and *H. influenzae* type b was the second most common cause of bacterial meningitis for children and young adults in Great Britain. Data from 2001 showed that meningococcal meningitis accounted for 48 percent of meningitis in children in England.[82] Mortality rates in this group of patients were 3.5 percent for children with meningococcal meningitis, 7.7 percent for children with *H. influenzae* meningitis, and 30 percent for patients with pneumococcal meningitis.

By 1995 in the United States, the most frequent cause of bacterial meningitis in children aged 1 month to 24 months was *S. pneumoniae*, followed by *N. meningitidis*, group B streptococcus, and *H. influenzae* (Table 37–1). In children younger than 1 month, the most common cause of bacterial meningitis was group B streptococcus, followed by *S. pneumoniae*.[333] *Escherichia coli* and *Listeria monocytogenes* are other common causes of meningitis in neonates 2 to 6 weeks of age.[7,35] *N. meningitidis* was the most common cause for individuals 2 to 29 years old, followed by *S. pneumoniae*.

Infants 6 to 12 months old seem to be at greatest risk for acquiring bacterial meningitis; 90 percent of reported cases occur in children between 1 month and 5 years of age.[130] The age distribution of patients with bacterial meningitis has not changed appreciably during the past 40 years.[285,349]

EPIDEMIOLOGY OF *HAEMOPHILUS INFLUENZAE* MENINGITIS

The most dramatic change in the epidemiology of bacterial meningitis since the advent of antibiotics has occurred in the past 2 decades as a result of licensure of conjugate vaccines against *H. influenzae* type b.[330] The first vaccine available was *H. influenzae* type b capsular polysaccharide (polyribosylribitol phosphate [PRP]), which was licensed in April 1985 for use in children 18 to 59 months of age. Newer vaccines with improved immunogenicity for children of younger ages were developed by covalently linking the capsular polysaccharide with protein antigens. In October 1990, the first conjugate, PRP diphtheria CRM_{197} protein conjugate (HbOC), was approved for infant use, and in 1991, the Advisory Committee on Immunization Practices (ACIP) and the American Academy of Pediatrics (AAP) recommended universal infant immunization at 2, 4, and 6 months of age with either HbOC or PRP-meningococcal protein conjugate (PRP-OMP) vaccines.[12,64] Currently, four different conjugate vaccine preparations exist: PRP-T (tetanus toxoid), PRP-OMP, PRP-CRM_{197}, and PRP-D (diphtheria toxoid), which is not licensed in the United States.[395]

The *Haemophilus influenzae* Study Group[5] noted that the number of cases of *H. influenzae* meningitis in children younger than 5 years old reported through the National Bacterial Men-

TABLE 37–1 Age-Specific Incidence in 1995 of Bacterial Meningitis per 100,000 Population

Age	*Haemophilus influenzae*	*Streptococcus pneumoniae*	*Neisseria meningitidis*	Group B Streptococcus
<1 mo	0	15.7	0	125
1-23 mo	0.7	6.6	4.5	2.8
2-29 yr	0.1	0.5	1.1	0.1
30-59 yr	0.2	1	0.3	0.05
>60 yr	0.07	1.9	0.1	0.1

From Schuchat, A., Robinson, K., Wenger, J. D., et al.: Bacterial meningitis in the United States in 1995. N. Engl. J. Med. 337:970-976, 1997.

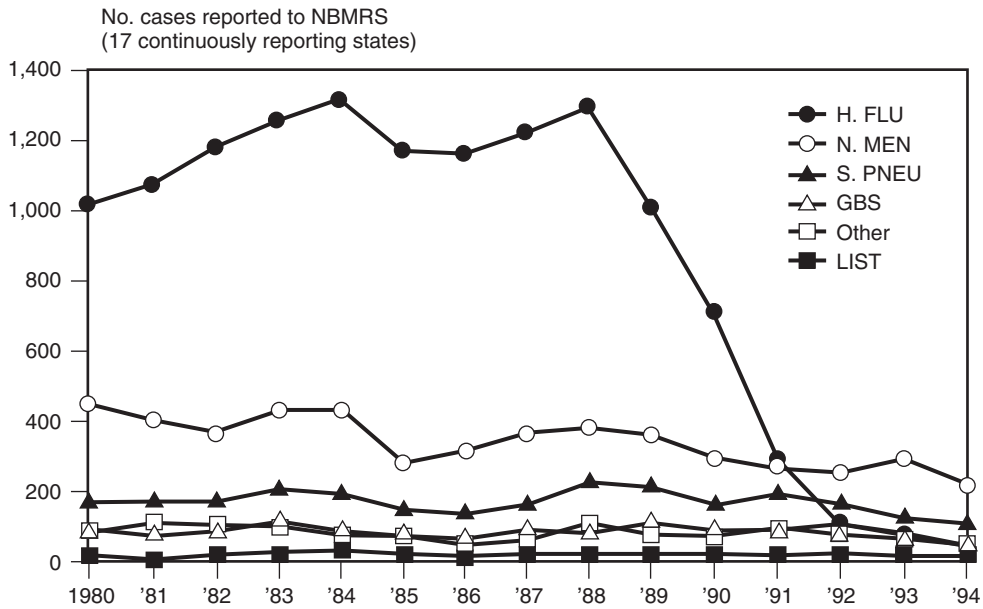

Figure 37–1 Incidence of bacterial meningitis in individuals from birth to 19 years of age. A marked decline in the incidence of *Haemophilus influenzae* type b meningitis is noted during the period between 1988 and 1994. GBS, group B streptococcus; H. FLU, *H. influenzae* type b; LIST, *Listeria monocytogenes*; NBMRS, National Bacterial Meningitis Reporting System; N. MEN, *Neisseria meningitidis*; S. PNEU, *Streptococcus pneumoniae*.

ingitis Reporting System began declining rapidly in 1988 (Fig. 37–1). In another CDC surveillance project conducted from 1989 to 1997, the race-adjusted incidence of invasive *H. influenzae* type b disease among children younger than 5 years declined from 34 to 0.4 per 100,000, a 99 percent reduction.[66] CDC data for 1998 to 2000 show that the incidence of *H. influenzae* infection remains low: 0.4, 0.4, and 0.3 per 100,000 children younger than 5 years in 1998, 1999, and 2000, respectively.[68] The average annual incidence of *H. influenzae* type b infection remains higher in select populations within the United States, including American Indians/Alaskan Natives (14 per 100,000), Hispanics (1 per 100,000), and nonblack Hispanics (0.6 per 100,000).[68]

Schoendorf and colleagues[332] evaluated national trends in mortality from meningitis from 1980 to 1991. From 1980 through 1987, mortality rates from *H. influenzae* meningitis decreased an average of 8.5 percent a year, from 1.72 per 100,000 children in 1980 to 0.94 per 100,000 children in 1987. From 1988 to 1991, mortality rates decreased an average of 48 percent a year, with a death rate of 0.11 per 100,000 children in 1991. The estimated case-fatality rate for *H. influenzae* meningitis was 3.3 percent from 1980 to 1987 and 2.3 percent from 1988 to 1991. In comparison, mortality rates from *S. pneumoniae* decreased 10 percent annually from 1980 to 1987 and 3 percent annually from 1988 to 1991. Similarly, mortality rates from meningococcal meningitis decreased by 13 percent annually from 1980 to 1987 and 12 percent annually from 1988 to 1991.

The dramatic decrease in the incidence of *H. influenzae* meningitis probably has been affected by several factors. The precipitous drop that occurred shortly after universal immunization of infants strongly suggests that this practice has affected the epidemiology of this disease. Conjugate vaccination protects against nasopharyngeal colonization,[268] decreasing the carriage rate of *H. influenzae* type b and diminishing the reservoir for transmission and providing immunity from infection. These factors would lessen the likelihood of development of infection in underimmunized children as well. Other changes in medical practice, such as the widespread use of outpatient antibiotics and improvements in supportive care, may have some effect, as shown by the decrease in case-fatality rates for *H. influenzae* meningitis, the steady decrease in mortality rates before vaccination, and the decrease in instances of meningococcal and pneumococcal disease.

Before universal vaccination was initiated, the incidence of *H. influenzae* meningitis varied worldwide. The incidence of *H. influenzae* meningitis in Scandinavian children younger than 5 years averaged 16 to 28 cases per 100,000 children from 1975 to 1984.[288] The incidence of *H. influenzae* type b meningitis in three Pacific Island countries was 70 to 84 cases per 100,000 children younger than 5 years old in 2003[314] and 67 to 158 cases per 100,000 in Indonesian children younger than 5 years old in 1998 to 2002.[151] The incidence of *H. influenzae* meningitis in the Netherlands was 22 cases per 100,000 children younger than 5 years old.[381] A universal vaccination program in the Netherlands seems to have led to a marked decrease in the incidence, with six reported cases of meningitis caused by *H. influenzae* in a 1-year period after im-plementation of universal vaccination of infants compared with 34 cases per 100,000 children in a 1-year period before vaccination.

The incidence of *H. influenzae* meningitis is markedly higher in nonindustrialized populations. Before the vaccination era, Alaskan Eskimos had an annual incidence of 282 cases per 100,000 children younger than 5 years of age.[393] The Navajo and White Mountain Apache Native Americans had a much higher incidence compared with that of Native Americans in other regions of the United States,[77,242] and the incidence among Australian Aboriginals and among certain African populations, such as those in Gambia and Senegal, was 3 to 10 times higher than that of populations in the United States and Europe.[43,154,176] The incidence of *H. influenzae* meningitis was decreased in Gambia from more than 60 cases per 100,000 children to none per 100,000 in children younger than 5 years old after implementation of *H. influenzae* type b vaccination in May 1997.[6]

Good epidemiologic data concerning the incidence of *H. influenzae* infection are lacking in many other areas of the world. Measuring the extent of *H. influenzae* disease often is difficult, time-consuming, and expensive. In an attempt to decrease complexity, cost, and time required to collect data concerning the incidence of *H. influenzae* infection, the Hib Rapid Assessment Tool was developed. More and more countries are using such tools to estimate the local *H. influenzae* disease burden and to

help determine the need for implementation of a local vaccination program.[395]

In one study, the incidence of *H. influenzae* meningitis was 3.5-fold higher in blacks than in whites, but this distribution of cases seemed to be related more closely to poverty than to race.[130] In whites, no increase in incidence occurred in overcrowded households, but the incidence was higher in rural than in urban areas. Fraser and associates[130] postulated that the increased incidence in rural whites and in blacks was related to lack of access to early medical care.

Ward and colleagues[391] studied prospective data obtained in 19 states to determine the risk of spread of severe *H. influenzae* illness among household contacts of patients with *H. influenzae* meningitis. The risk in children younger than 1 year of age was 6 percent; in children younger than 4 years, 2.1 percent; and in children younger than 6 years, 0.5 percent. The risk of *H. influenzae* disease occurring in household contacts younger than 6 years old is similar to the risk of secondary meningococcal disease occurring in all household contacts, indicating a need for effective antimicrobial prophylaxis.

Spread of *H. influenzae* disease in daycare centers also is well documented.[32,156,252,392] The precise risk of acquiring secondary *H. influenzae* type b infection in daycare centers is unclear.

Recurrent invasive *H. influenzae* type b disease has been reported. Detailed studies suggest that age and high incidence of disease alone are not the only factors contributing to the recurrence of the disease.[55] Patients who have recurrent disease caused by *H. influenzae* type b may represent a subset of a population with unusual disease susceptibility. In addition, children who develop invasive infection caused by *H. influenzae* type b after receiving appropriate conjugate vaccine frequently have subnormal immunoglobulin concentrations and should undergo immune evaluation.[186]

EPIDEMIOLOGY OF MENINGITIS CAUSED BY *STREPTOCOCCUS PNEUMONIAE*

The highest rate of invasive pneumococcal infection occurs in children younger than 2 years old. In a population-based surveillance study of invasive pneumococcal infection in southern California, the age-specific incidence of invasive pneumococcal disease for children 2 years or younger was 145 cases per 100,000. In the pre-vaccine era (before 2000 in the United States), for children 2 to 4 years old and 5 to 14 years old, the age-specific incidence decreased to 25 per 100,000 and 5 per 100,000, respectively.[406] The age-specific incidence for pneumococcal meningitis was 21, 12, 6, 2, and 0.5 cases per 100,000 for the age groups 0 to 6 months, 7 to 12 months, 13 to 24 months, 25 to 60 months, and older than 60 months, respectively. Since the initiation of *S. pneumoniae* vaccination, the incidence of invasive *S. pneumoniae* infections has declined. Data from CDC surveillance shows that from 1998-1999 to 2003, there has been a 94 percent decline in *S. pneumoniae* infection related to *S. pneumoniae* serotypes present in the vaccine (80 cases per 100,000 to 4.6 per 100,000 among children <5 years old).[69]

The risk for development of sepsis or meningitis caused by *S. pneumoniae* depends to some extent on the serotype with which the child is colonized. Although 90 pneumococcal serotypes have been identified, invasive disease, including sepsis and meningitis, in children younger than 6 years old is associated most commonly with serotypes 14, 6B, 19F, 18C, 23F, 4, and 9V.[58] The seven-valent pneumococcal conjugate vaccine (PCV7), added to the national vaccination schedule in 2000, contains each of the above-mentioned most common strains.

The risk of contracting pneumococcal meningitis is 5-fold to 36-fold greater among blacks than among whites and is independent of income or population density.[130] In one study, 11 percent of the black population with pneumococcal pneumonia had sickle-cell disease, a factor known to predispose an individual to development of pneumococcal disease.[130] On the basis of these data, Fraser and associates[130] suggested that 1 of every 24 children with sickle-cell disease may develop pneumococcal meningitis by the time they reach 4 years of age. This incidence is 36-fold greater than the incidence of pneumococcal meningitis in a normal black population and 314-fold greater than that in white children.

Daycare attendance, underlying disease, and lack of breast-feeding were risk factors for acquiring invasive pneumococcal infections in a large case-control study that included children from the United States and Canada.[237] Although cigarette smoking is a major risk factor for the development of invasive pneumococcal disease in adults, whether exposure to cigarette smoke increases the risk of developing systemic pneumococcal infection in children remains unclear.[162,280] The greatest mortality rate occurs in very old and very young patients and has been estimated to be 20 to 60 percent.[123,132,133,146]

Pneumococcal infections generally occur sporadically. Household contacts of a patient with pneumococcal disease are not considered to be at increased risk of acquiring secondary infection. The occurrence of concurrent pneumococcal disease (meningitis and bacteremia) in the household setting has been reported, however.[24,344] Although uncommon in the United States, *S. pneumoniae* has been associated with epidemics in locations such as Northern Ghana.[235]

The incidence of systemic infection with penicillin-resistant *S. pneumoniae* has been increasing steadily worldwide since it first was reported in Australia in the 1960s.[175] Systemic infection with penicillin-resistant pneumococci has become an increasing problem in the United States since the mid-1980s.[359,365,366] In 1995, a CDC multistate surveillance study showed that 35 percent of *S. pneumoniae* cerebrospinal fluid (CSF) isolates were resistant to penicillin.[333]

The first report of meningitis caused by resistant pneumococci was published in 1974,[274] and numerous case reports have appeared subsequently. Tan and colleagues[366] found that patients with systemic infections caused by penicillin-resistant pneumococci were more likely to have received a course of antibiotics within 1 month before acquiring their infection than were matched control subjects who had infections caused by pneumococci but whose isolates were susceptible to penicillin.

More recently, an increase has occurred in the number of cases of systemic infection and meningitis caused by *S. pneumoniae* organisms resistant to penicillin and third-generation cephalosporins. In 1998, CDC surveillance of multiple areas around the United States found that 24 percent of pneumococcal isolates associated with invasive infections were nonsusceptible to penicillin; 14 percent of isolates were nonsusceptible to cefotaxime.[398] As with many studies, rates of resistance were higher among children younger than 5 years old. In a prospective study involving eight children's hospitals nationwide during a 6-year period starting September 1993, a significant increase in the proportion of isolates nonsusceptible to penicillin or ceftriaxone was found. In the sixth year of the study ending August 1998, 37 percent and 11 percent of invasive isolates were nonsusceptible to penicillin and ceftriaxone.[203] Isolates of penicillin-resistant and third-generation cephalosporin–resistant *S. pneumoniae* have been recovered in other regions of the world as well.[136,139,305] Treatment failures in patients with *S. pneumoniae* meningitis resistant to penicillin and third-generation cephalosporins have led to changes in the empiric therapy of suspected bacterial meningitis, as discussed in the treatment section.[22,49,139,212,347]

Data from the Active Bacterial Core Surveillance of the Emerging Infections Program Network after introduction of the pneumococcal conjugate vaccine show an 87 percent decrease in rates of antibiotic-resistant disease by vaccine serotypes.[225] Their

results show that rates of invasive pneumococcal disease with penicillin-nonsusceptible strains and strains nonsusceptible to multiple antibiotics "peaked in 1999 and decreased by 2004."[225] In children younger than 2 years old invasive pneumococcal disease with penicillin-nonsusceptible strains decreased from 70.3 to 13.1 cases per 100,000.[225] The proportion of disease caused by penicillin-nonsusceptible strains varied by location within the United States from 9.4 percent in California to 29.5 percent in Tennessee.[225] The incidence of invasive *S. pneumoniae* disease caused by cefotaxime-resistant *S. pneumoniae* strains has increased in children younger than 2 years of age however, in the post-vaccination period, from approximately 10 percent in 1999 to almost 15 percent in 2003.[225] The decreases in disease caused by vaccine-type *S. pneumoniae* strains were coupled with an increase in non-vaccine serotype *S. pneumoniae* strains, especially with serotype 19A (increased from 2 to 8.3 cases per 100,000).[225]

EPIDEMIOLOGY OF MENINGOCOCCAL MENINGITIS

The carriage rate for *N. meningitidis* in the civilian population has been estimated at various times to range from 1 to 15 percent. Carriage rates in military personnel during epidemic periods have been considerably greater. Meningococcal carriers generally are adults (>21 years old) who harbor the organism for months.

No correlation has been noted between meningococcal meningitis and crowding within households, but disease seems to be more prevalent in urban than in rural areas. In a civilian population, meningococcal meningitis generally is a disease of children and young adults who have been exposed to an adult carrier, usually in the same family, or to individuals with disease or who are carrying the organism in a daycare setting. The estimated likelihood of severe meningococcal disease in family contacts occurring simultaneously with the first case is 1 percent.[231] The rate is 1000-fold greater than the risk in the community. The risk of meningitis being acquired in daycare center contacts of children with meningococcal disease is 1 per 1000.

In a CDC surveillance study of invasive meningococcal disease in the United States, the average annual incidence of disease was 1.1 per 100,000 population for the years 1992 to 1996[310] and remained the same through 2002.[70] The highest age-specific incidence occurred in infants younger than 1 year old (9.2 cases per 100,000),[70] with the peak incidence occurring in infants 4 to 5 months old (15.9 cases per 100,000). The age-specific incidence declined sharply until the 10- to 14-year age range, at which point it began to increase again during the adolescent and early adult years. During the teenage range, the incidence peaked between 15 and 19 years of age (1.5 to 2.2 cases per 100,000). From 1990 to 2002 in the United States, mortality rates for meningococcal disease were 0.1 deaths per 100,000 population per year, with 58 percent of deaths occurring among individuals younger than 25 years old. Infants had a higher mortality rate than that of individuals in different age groups, but they experienced a decline from 1.3 deaths per 100,000 in 1990 to 0.42 deaths per 100,000 population in 2002.[339] Meningococcal disease mortality rates increased each year in individuals between the ages of 10 and 19 years, which was followed by a decline in mortality rates in the years following and throughout most of adulthood.[339]

In the United States, serogroups B, C, and Y account for most meningococcal disease. Meningococcal infections caused by serogroup B caused greater than 50 percent of infection in infants younger than 1 year. In the 1990s, serogroup Y became more common among older patients and caused more pneumonia than did the other serogroups. The overall incidence of serogroup Y infection increased from 2 percent during 1989 to 1991 to 37 percent during 1997 to 2002.[70] A study of the epidemiology of meningococcal disease in New York City from 1989 to 2000 revealed a threefold decrease in rates of serogroup B disease and almost no cases in children younger than 5 years old. The authors noted the coincident increase in the use of *H. influenzae* conjugate vaccine containing serogroup B meningococcal outer membrane protein and postulated the existence of a possible correlation.[263] CDC data reveal that 75 percent of meningococcal infections in individuals older than 11 years are caused by serogroups C, Y, and W-135, all of which are included in the newly available conjugate vaccine. An increased risk of contracting meningococcal infection also exists in college students, especially freshmen who reside on campus in dormitories.[179]

Another change in the epidemiology of meningococcal disease in the United States relates to the increasing number of outbreaks (>10 cases per 100,000 population during 3 months), generally caused by serogroup C. Although these outbreaks account for only 2 to 3 percent of the total number of cases, they cause tremendous public concern and anxiety, which frequently result in misunderstanding of the nature of an outbreak by the media and the public.[189]

An otherwise unprecedented outbreak of meningococcal disease occurred in a sixth-grade elementary school classroom.[106] Five children from a class of 24 developed meningococcal meningitis. In addition, two siblings of one of the index cases also developed meningococcal infection. Detailed epidemiologic investigation suggested that close contact in the classroom (nose-to-nose distances of ≤34 inches) correlated with an increased rate of carriage of *N. meningitidis* and with an increased risk for development of invasive meningococcal disease.

Major outbreaks of meningococcal meningitis have occurred worldwide. In the late 1980s and early 1990s, major epidemics of meningococcal meningitis caused by a specific clone (III-1) of serogroup A *N. meningitidis* occurred throughout sub-Saharan Africa.[2,168,172,292,318] The origins of a pandemic spread of clone III-1 were traced to epidemics in Asia in the early 1980s, with spread through the Near East.[1] An outbreak occurred during the annual pilgrimage to Mecca in 1987,[260,261] with pilgrims carrying clones back to their countries of origin, including the United States and the United Kingdom. Epidemics of closely related strains of clone III-1 serogroup A meningococcal meningitis occurred in the Sudan,[318] Ethiopia,[172] and Chad in 1988,[261] and in Kenya[292] in 1989. A report in 1992 described an epidemic of clone III-1 in the Central African Republic in an area traditionally outside the "meningitis belt."[168] These epidemics generally begin during the dry season and decline at onset of the rainy season. According to the World Health Organization, "in major African epidemics, attack rates range from 100 to 800 per 100,000 population, but individual communities have reported rates as high as 1000 per 100,000."[253] Major outbreaks have occurred in Brazil,[88] in Finland,[288] and at multiple sites in Africa.[399] A clonal outbreak of serogroup W135 (ET-37ST-11 clonal complex) occurred in 2000 among Hajj pilgrims returning to Europe from Saudi Arabia. In 2001, outbreaks with serogroup W135 also occurred in Niger and Burkina Faso.[364]

Shifts within a community or within a country as a whole from one serogroup to another also are associated with an increased incidence of disease for several years after the new serogroup is introduced into the community.[310] The mechanisms underlying the changing patterns of meningococcal serogroups that cause disease are unknown.

Meningococcal infections also occur more frequently in patients with a deficiency of the terminal components (C5-C8) of the complement system.[100,239,319] More recently, an increased risk for contracting meningococcal meningitis has been reported in individuals with an inherited deficiency of C9[273] and with properdin deficiency.[353] Individuals with a complement-depleting underlying illness also are at particular risk for acquiring invasive disease.[290] Screening for complement deficiency in pediatric patients with meningococcal disease is recommended.[232]

PATHOPHYSIOLOGY

ORGANISMS ENCOUNTERED

Any organism may produce meningitis in a susceptible individual. *S. pneumoniae* and *N. meningitidis* are the responsible agents in approximately 95 percent of healthy children older than 2 months. In compromised hosts, infection with other organisms may occur more frequently. The specific organism sometimes may be predicted on the basis of the type of deficit that is present in the host.

ROUTES OF INFECTION

Bacterial infection of the normally sterile leptomeningeal spaces can occur from a distant focus through the bloodstream or by direct invasion from a contiguous focus. Meningitis usually is the result of hematogenous dissemination of organisms from a distant site of infection,[349] often from the respiratory tract. The meninges are seeded with microorganisms during a bacteremic period. Bacterial meningitis in children with otitis media generally follows bacteremia, although direct invasion of the meninges may occur as a complication of otitis media.

The route of infection in bacterial meningitis has been studied by use of a variety of animal models, but the experimental infection was initiated in most cases in a manner that did not mimic human disease. Bacterial meningitis has been induced in rats[264] and monkeys[325] after intranasal inoculation of *H. influenzae* type b. Bacteremia developed hours before meningitis could be detected histologically, a finding that supports the concept that meningitis follows hematogenous dissemination from nasopharyngeal colonization or infection. Marginating bacteria could be detected by fluorescent staining initially in the lateral and dorsal longitudinal (sagittal) sinuses and subsequently spread to the leptomeninges. In the rat model, otitis media seemed to develop by spread of infection from the subarachnoid space to the inner ear and then to the middle ear.

Meningitis may develop after bacterial invasion from a contiguous focus of infection, as in infection of the mastoid or paranasal sinuses, or as a complication of otitis media. Fracture through the paranasal sinuses as a result of head trauma may precede development of meningitis caused by *S. pneumoniae* and *H. influenzae*, which may be recurrent. Direct invasion also may occur in individuals with dermoid sinus tracts or meningomyeloceles, when a direct communication between the skin and the meninges is present. In this setting, infection usually is produced by organisms found on the skin. Recurrent meningitis has been reported in patients with basiethmoidal encephaloceles[362] and a congenital defect in the stapedial footplate.[183] Surgical obliteration of the fistula with temporal muscle and fascia prevented the recurrence of meningitis. Meningitis also may develop subsequent to osteomyelitis of the skull or vertebral column. Rarely, meningitis may develop in the normal host with commensurate microorganisms after having a tooth extraction or getting dental fillings.[74,340]

Neurosurgical procedures, particularly procedures designed for diversion of CSF in children who have hydrocephalus, may lead to development of meningitis. A chemical meningitis also may occur after neurosurgical procedures, especially procedures involving the posterior fossa.[127] In these patients, evidence of inflammation develops rapidly, with elevation of temperature occurring on the first postoperative day.

Infection of the CNS may result from environmental contamination or manipulation. Meningeal infection may be acquired in utero transplacentally or during delivery through contact with the cervix or vaginal canal, which may be colonized with a variety of organisms, particularly group B streptococci and *L. monocytogenes*.[7,25] A newborn, a patient with cystic fibrosis, or a burned child may develop septicemia and meningitis as a result of persistent heavy colonization with *Staphylococcus aureus*. A humidified atmosphere promotes the colonization and growth of such organisms as *Serratia marcescens* and *Pseudomonas aeruginosa*. Placing a patient in this setting leads to an increased frequency of infection with these organisms. Indwelling catheters can predispose a patient to infection by bacterial (and fungal) organisms that generally are of low virulence in the normal host.

FACTORS PREDISPOSING THE HOST TO BACTERIAL MENINGITIS

Factors that predispose the host to the development of infection in other sites also predispose the host to the development of bacterial infection of the CNS. A strong interrelationship exists among factors relating to the host, the organism, and the environment with regard to the pathogenesis and outcome of meningitis. Although presented separately, they must be considered a complex interplay of factors that leads to infection.

An increased incidence of bacterial meningitis is observed in the very young; boys are affected more frequently than girls, and the severity of disease also is increased in these groups. Fraser and associates[133] reported that the greatest morbidity after bacterial meningitis occurred in children affected between birth and 4 years of age. A newborn is predisposed to development of septicemia and meningitis by factors that reflect physiologic deficiencies or immaturity of host defense mechanisms, including (1) decreased phagocytic and bactericidal activity of polymorphonuclear leukocytes, (2) defects in the response of neonatal leukocytes to chemotactic factors, (3) a deficiency in the capacity of leukocytes to support opsonization, and (4) defects in microtubular length and number that decrease the motility of the neonatal leukocytes compared with leukocytes from older children. Deficiencies in serum complement components (C1q, C3, and C5), low levels of serum properdin, and low concentrations of serum IgM and IgA have been documented repeatedly. Despite transplacental acquisition of IgG, antibodies against specific infective agents may be lacking. The precise age at which each of these factors reaches the concentration and functional activity noted in older children and adults is unclear and undoubtedly varies from individual to individual. In part, meningitis in children aged 1 month to 1 year may reflect qualitative or quantitative differences of the inflammatory and immunologic responses in older children compared with infants.

The increased risk for development of meningitis in the normal host with less than completely mature immunologic and inflammatory responses to infection may be attributable to age alone. This factor is exemplified in the report of Cole and associates,[72] who studied the risk of recurrent bacteremia in young children. Within 18 months of having bacteremic illness, none of 42 children older than 24 months had a documented additional episode of bacteremia or systemic infection. Fifteen of 135 children (11%) younger than 24 months at the time of the initial bacteremic disease had at least one additional documented bacteremic illness, however. Of these 15 children, 14 contracted both infections before reaching 2 years of age. Seven of these 15 children had meningitis. Only two patients had documented congenital or hereditary disorders of immunoglobulin or complement concentration or function.

A genetic determination for the predilection of some normal children for the development of bacteremia and meningitis has been suggested.[373] The ability of the host to produce, within the CSF, interleukin-12 (IL-12) and tumor necrosis factor-α (TNF-α)–induced interferon-γ is important in the natural immunity to various microorganisms that may cause meningitis.[223]

Congenital or acquired abnormalities of the immune system may predispose the host to the acquisition of bacterial infections. Congenital deficiency of the three major immunoglobulin classes may predispose the host to the acquisition of severe bacterial infection. Congenital defects of thymic-dependent, small lymphocyte function or combined T and B defects are detrimental to host defense. A deficiency of $CD4^+$ helper-inducer T cells in patients with bacterial meningitis has been reported and may contribute to the impaired antibody synthesis to bacterial capsular polysaccharides in this disease.[303] Multiple studies have shown that deficiencies of various components of the complement system and increased consumption or loss of complement have been associated with increased risk for development of bacterial meningitis caused by encapsulated organisms.[319]

An increased incidence of overwhelming infection, including meningitis, occurs after splenectomy, but the likelihood of development of such infection depends on the age of the child at the time of splenectomy, the time since splenectomy, and the original indication for splenectomy.[101] Congenital asplenia or polysplenia also has been associated with an increased incidence of septicemia and meningitis caused by *S. pneumoniae*,[101] *H. influenzae* type b, and gram-negative enteric microorganisms. Children with sickle-cell disease and other hemoglobinopathies have meningitis caused by *S. pneumoniae*, *H. influenzae*, and *Salmonella* spp. more frequently than do normal children.

Children with malignant neoplasms with or without neutropenia seem to be susceptible to development of meningitis caused by organisms of low virulence that pose a minimal threat to healthy children, presumably because of abnormalities in immunologic function.[355] Decreased production of normal immunoglobulins, delayed and defective antibody responses to antigenic stimuli, production of abnormal immunoglobulins, depression in the clearance mechanisms of the reticuloendothelial system, and depression of cellular immunity have been documented in children with malignant neoplasms involving the reticuloendothelial system. In addition, the use of irradiation or immunosuppressive agents and antimetabolites predisposes the host to the development of infection in the CNS. Attributing the occurrence of bacterial meningitis in this population directly to these agents rather than to the disease for which this therapy has been provided may be difficult. Meningitis occurring after neurosurgical manipulation for tumors of the CNS in non-neutropenic children usually develops within 1 month of the neurosurgery.[355]

Malnutrition also predisposes children and adults to infectious disease. Impaired cellular immune responses, low levels of serum complement, impaired phagocytic activity of neutrophils, and decreased serum concentrations of transferrin have been documented in malnourished children.[114]

Patients with systemic diseases, such as diabetes mellitus, renal insufficiency, adrenal insufficiency, cystic fibrosis, hypoparathyroidism, and exudative enteropathy, have an increased frequency and severity of CNS infections.[47] Children with diabetes mellitus, coma caused by drug overdose, and Cushing syndrome have been shown to be at increased risk for development of bacteremia or meningitis caused by *H. influenzae* type b.[236] Some type of underlying condition was noted for 21 percent (37 of 181) of the children with pneumococcal meningitis in a multicenter surveillance study.[20] The most common of these conditions was some disorder of the CNS, which occurred in 16 children (9%). Defective chemotaxis, phagocytosis, and bactericidal function accompany these disorders and may explain in part the increased susceptibility of these individuals to infection.[114,115]

In the normal host, bacterial infections at sites other than the leptomeninges are associated with an increased incidence of CNS infection. Infection may spread hematogenously to the meninges in children with endocarditis, pneumonia, or thrombophlebitis or by direct extension from sinusitis, mastoiditis, or osteomyelitis of the skull. Development of meningitis after lumbar puncture in children younger than 1 year has been described.[126,371]

An increased risk for development of meningitis also occurs in children after placement of cochlear implants. Reelhuis and colleagues[304] reported the incidence of meningitis caused by *S. pneumoniae* in patients after receiving cochlear implants to be 138.2 cases per 100,000 person-years, which represents a more than 30-fold increase over the age-controlled general population.[304] From 1999 to 2002, some children were implanted with cochlear devices, including a positioner, which were removed from the market subsequently as a result of an associated marked increase in incidence of pneumococcal meningitis. When removing the influence of cochlear devices containing a positioner, the incidence of pneumococcal meningitis among children with cochlear implants was still 16 times higher than that of an age-matched control population.

PATHOLOGY

The most detailed account in English of the pathologic changes occurring with meningitis was written in 1948 by Adams and colleagues.[4] They described the meningeal, cerebral, and vascular changes found post mortem in 14 patients who died of *H. influenzae* infection 14 hours to 76 days after the onset of disease. Although most patients in their series received inadequate treatment (effective antibiotic therapy was unavailable), the pathologic findings they describe differ little from the findings of subsequent reports by Smith and Landing,[350] Rorke and Pitts,[309] and Dodge and Swartz,[96] whose patients died despite administration of antibiotics. These descriptions are summarized later.

A meningeal exudate of variable thickness may be found (Fig. 37–2). Purulent material is distributed widely but may accumulate around the veins and venous sinuses, over the convexity of the brain, in the depths of the sulci, in the sylvian fissures, within the basal cisterns, and around the cerebellum. The spinal cord may be encased in pus. Ventriculitis (purulent material within the ventricles) has been noted repeatedly in children who died of their diseases. Subsequent experience suggests that ventriculitis may be a common finding in children with bacterial meningitis who survive, particularly neonates. Invasion of the ventricular wall with perivascular collections of purulent material has been noted. Loss of ependymal lining and subependymal gliosis may be seen. In some studies, purulent exudate tended to be thicker

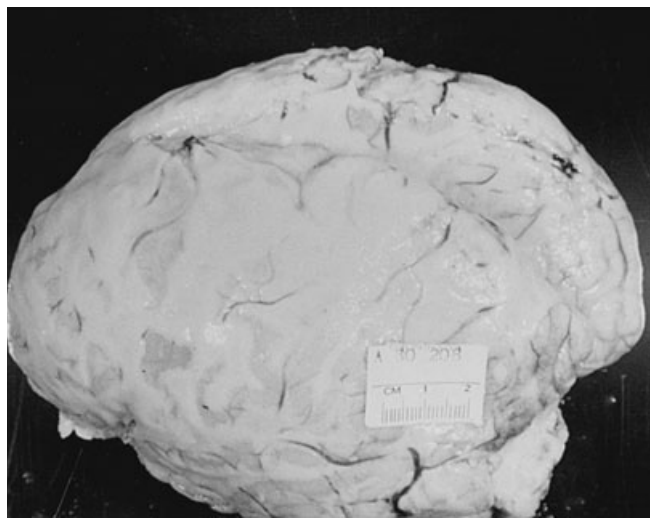

Figure 37–2 Note extensive purulent exudate over entire cerebral cortex in a patient who died as a result of bacterial meningitis.

over the convexity of the brain in patients with pneumococcal meningitis than in patients with other forms of meningitis.[96,309]

Vascular and parenchymatous changes have been shown at necropsy. Polymorphonuclear infiltrates extending to the subintimal region of small arteries and veins have been associated with the exudative meningeal process. Thrombosis of small cortical veins associated with necrosis of the cerebral cortex may be noted. Occlusion of one of the major venous sinuses, subarachnoid hemorrhage secondary to a necrotizing arteritis, and necrosis of the cerebral cortex in the absence of identifiable thrombosis of small vessels rarely may be observed. Reactive microglia and astrocytes may be identified in the cerebral cortex, particularly subadjacent to regions of heavy subarachnoid exudate. Because no bacteria are found in the cerebral cortex, these pathologic changes should be viewed as a noninfectious encephalopathy. "Toxic or circulatory factors" were suggested as possible causes by Adams and associates.[5] Dodge and Swartz[96] suggested systemic hypoxia and fever as additional possible causes. They also noted that an increase in intracranial pressure might interfere with cerebral circulation.

Impaired consciousness, deficits in motor and sensory functions, seizures, and retardation may be observed. Damage to the cerebral cortex, reflecting the effects of vascular occlusion, hypoxia, bacterial invasion, toxic encephalopathy, bacterial factors, inflammatory mediators, small molecule effectors, or some combination of these factors, provides an adequate explanation for these observations.

Hydrocephalus that develops in patients beyond the newborn period is an uncommon complication of meningitis. Most often, hydrocephalus is communicating and is the result of adhesive thickening of the arachnoid around the cisterns at the base of the brain. Less frequently, the aqueduct of Sylvius or the foramina of Magendie and Luschka are obstructed by fibrosis and reactive gliosis. The ensuing ventricular dilation may be coupled with coexistent necrosis of nervous tissue because of the meningitis itself or because of occlusion of cerebral veins and, rarely, arteries. Cerebral necrosis plus increased intraventricular pressure may result in total dissolution of the cerebrum.

Subdural effusions occur frequently during the course of meningitis. The exact pathogenesis is unknown. The high incidence of effusion and the fact that subdural fluid collections may be found early in the course of bacterial meningitis in children suggest, however, that subdural effusions should be considered a concomitant occurrence with meningeal inflammation rather than a complication of the disease. Numerous veins traverse the subdural space, and inflammation of these veins and of the dural capillaries could produce an increase in vascular permeability and loss of albumin-rich fluid into the subdural space. The ratio of albumin to gamma globulin is higher in the subdural fluid of children with meningitis than in serum.[159] When the inflammatory process subsides, formation of fluid generally ceases, but its presence may persist because of a continued transudation through newly formed vessels in the subdural membrane.

Subdural empyema, as opposed to subdural effusion, occurs rarely. It was observed in only 2 of the cases reported by Adams and associates,[5] in 1 of 34 patients examined by Smith and Landing,[350] and in 1 of the patients studied by Dodge and Swartz.[96]

Many factors contribute to the increase in intracranial pressure in patients with meningitis. Endotoxin and fragments of the cell wall of gram-positive organisms are capable of inducing the release of IL-1 and TNF from macrophages and other sources.[93,256] These substances, in addition to other interleukins and arachidonic acid metabolites, affect many systems, including endothelial cells, and profoundly affect the function of the vasculature and its interaction with neutrophils and other inflammatory cells. These substances play an important role in the pathogenesis of increased intracranial pressure and cerebral edema in patients with meningitis by altering cerebral blood flow, intracranial blood volume, and permeability of the cerebral vasculature.[278] Experimentally, the main components of the blood-brain barrier, endothelial cells, astrocyte-end feet, and pericytes, have been found to be sensitive to the effects of such inflammatory mediators.[29] Intercellular junctions, which normally are tight, are open in experimental meningitis, which is associated with an increased permeability to circulating albumin.[298] Pinocytotic vesicles also are noted within the cytoplasm of endothelial cells. Swelling of cellular elements (cytotoxic edema) also has been noted.

Alterations in CSF resorption exacerbate cerebral edema and increased intracranial pressure further. In experimental meningitis, resorption of CSF is diminished as an accumulation of proteins, leukocytes, and other materials interferes with the function of the arachnoid villus.[329]

During the course of meningitis, excess secretion of antidiuretic hormone (ADH) occurs, which induces water retention and exacerbates electrolyte abnormalities already created secondary to the inflammatory processes occurring in the CNS. Cellular electrolyte disturbances may depolarize neuronal membranes, predisposing the host to seizure activity. Increased oxidation of glucose, increased lactate production, and depletion of high-energy compounds such as adenosine 5′-triphosphate and phosphocreatine are observed. Hypoglycorrhachia results primarily from decreased transport of glucose across the inflamed choroid plexus and from increased use of glucose by host tissues. Use of glucose by bacteria and polymorphonuclear leukocytes is of less relative importance.[96,328]

PATHOGENESIS

Most cases of bacterial meningitis progress through four steps: (1) infection or colonization of the upper respiratory tract, (2) invasion of the blood from a respiratory focus, (3) seeding of the meninges by a blood-borne organism, and (4) inflammation of the meninges and brain. Less commonly, infection of the leptomeninges can occur by contiguous spread or hematogenous dissemination from another remote site. The nasopharyngeal mucosa is colonized with *S. pneumoniae*, *N. meningitidis*, or other microorganisms, resulting most commonly in an asymptomatic carrier state or minor upper respiratory tract illness. This attachment is mediated by specific microbial cell surface components. *N. meningitidis* strains possess fimbriae that bind to cell surface receptors on nasopharyngeal mucosal cells[90] and apparently are transported across specialized cells within phagocytic vacuoles.[363]

When in the bloodstream, the common pathogenic organisms (*S. pneumoniae*, *H. influenzae*, *N. meningitidis*, *E. coli* K1, and group B streptococcus) are capable of evading host defense mechanisms through capsular polysaccharides, which inhibit neutrophil phagocytosis and classic complement-mediated bactericidal activity. These bacteria traverse the blood-brain barrier, most likely at the cerebral capillaries and choroid plexus. Fimbriae of *E. coli* have been shown to facilitate attachment in these regions.[286] *N. meningitidis* has been shown to invade via interaction of Opc membrane protein with serum fibronectin and an endothelial surface integrin, which leads to tyrosine kinase activation and subsequent intracellular signaling pathways.[354,378] *S. pneumoniae* has been shown to invade the blood-brain barrier via complex interaction of CbpA protein and platelet-activating factor on activated endothelial cells.[219] When in the CSF, and because of insufficient opsonic and phagocytic activity in the CSF, organisms multiply rapidly, liberating cell wall or membrane components (lipopolysaccharide, lipoteichoic acid, peptidoglycan, bacterial toxins).

Host defenses within the CSF before and after bacterial invasion seem to rely on two important mechanisms available to the

host to clear bacteria.[343] One clearance system requires a type-specific antibody, a functional classic complement system for opsonization, and the presence of competent polymorphonuclear leukocytes for phagocytosis. A second system, which is independent of polymorphonuclear leukocytes, involves activation of the alternative complement cascade and other components of the innate immune system. This sequence begins with the recognition of a "pathogen-associated molecular pattern," such as bacterial lipopolysaccharide, peptidoglycan, or lipoteichoic acid. The pathogen-associated molecular patterns are recognized by host "pathogen recognition receptors," such as C-reactive protein (CRP), mannose-binding lectin, and Toll-like receptors (TLRs). Mannose-binding lectin and CRP can initiate the alternate complement pathway. TLRs (primarily TLR-2 and TLR-4), which can recognize different pathogen-associated molecular patterns, trigger an intracellular signaling pathway that leads to the production of proinflammatory transcription factors such as nuclear factor-κB and the subsequent gene transcription of proinflammatory cytokines such as TNF-α and interferon-β.[245]

Complement and opsonic proteins either are found at very low concentrations or are absent entirely within normal CSF.[128,343] The CSF is devoid of the factors required for bacterial clearance. When bacteria first invade the meninges, the lack of complement and opsonic proteins within the sanctuary of the CNS may permit the bacteria to multiply unrestrained for some time. The slow response of polymorphonuclear leukocytes and the lack of serum-specific antibody available during the initial inflammatory response enhance the probability that bacterial infection will be established.[41,103,152,389,408]

The specific pathophysiologic changes in bacterial meningitis are the result of the bacterial products and the inflammatory response of the host to those products. Initial bactericidal antibiotic therapy results in a rapid release of bacterial products, such as endotoxins, teichoic acid, and peptidoglycans. Augmented permeability of the blood-brain barrier can be induced by bacterial products alone, which cause disruption of the tight junctions between capillary endothelial cells and marked increase in pinocytotic activity within endothelial cells. An influx of serum albumin into the CSF is accompanied by other low-molecular-weight proteins, including components of the complement cascade.[193]

TNF-α and IL-1 seem to be key mediators in initiation of meningeal inflammation. Both proteins stimulate vascular endothelial cells to induce adhesion and passage of neutrophils into the CNS and trigger inflammatory processes. Astrocytes and microglia are capable of producing TNF-α.[374] TNF-α concentrations are elevated (1) in CSF, but not in serum; (2) in animal models of bacterial meningitis; and (3) in patients with bacterial meningitis caused by *H. influenzae*, *N. meningitidis*, *S. pneumoniae*, and *Streptococcus agalactiae*,[269] but not in patients with culture-proven viral meningitis.[301] A complete understanding of TNF-α and the precise role it plays in meningitis has not been achieved. TNF-α levels can be correlated with meningeal inflammation and severity of disease, but lack of TNF-α in the animal model is associated with "increased mortality and stronger deficits in spatial memory."[147]

IL-1 activity can be detected in infants and children with bacterial meningitis, and its presence is correlated significantly with CSF inflammatory abnormalities, TNF-α concentrations, and adverse outcome.[269] TNF-α and IL-1 are capable of inducing phospholipase A_2 activity, which triggers the production of platelet-activating factor and activates the arachidonic acid pathway. This process leads to the generation of prostaglandins, thromboxanes, and leukotrienes from membrane phospholipids of endothelial and polymorphonuclear cells, which modulate multiple aspects of the inflammatory process.

These cytokines activate adhesion-promoting receptors on cerebral vascular endothelial cells, resulting in attraction and attachment of leukocytes to sites of stimuli. These leukocytes release proteolytic compounds that allow intercellular junctions to be traversed. These enzymes in conjunction with platelet-activating factor and the arachidonic acid metabolites injure the vascular endothelium, resulting in increased permeability of the blood-brain barrier and activation of the coagulation cascade.

Superoxide and hydrogen peroxide are secreted by TNF-α-stimulated macrophages, including brain microglia, and leukocytes.[296,303] Hydrogen peroxide induces extensive neuronal damage.[281] In addition, macrophages secrete excitatory amino acids, such as glutamate, which potentially kill *N*-methyl-D-aspartate receptor–positive cells.[227]

For gram-positive bacterial meningitis, lipoteichoic acid peptidoglycans are the bacterial surface elements that induce inflammation.[376] The threshold concentration that triggers inflammation is approximately 10^5 bacterial cell equivalents of cell wall pieces.[376] For gram-negative meningitis, endotoxin is the major inflammatory component, with peptidoglycan serving as an important cofactor.[57] The inflammatory threshold is approximately 2 pg of endotoxin, or approximately 10^5 bacterial cell equivalents.[401]

Cytokines now seem to be the primary drivers of the inflammatory response. The following cytokines are involved in the inflammatory response noted in bacterial meningitis: IL-1, IL-3, IL-4, IL-6, IL-8, IL-10, IL-12, IL-18, interferon-γ, macrophage inflammatory protein, transforming growth factor-β, and TNF-α.[91,134,382,409]

The chemokines are a superfamily of small chemoattractant cytokines that play an important role in the initiation and modulation of inflammation in bacterial meningitis.[357] Complement factors are up-regulated in bacterial meningitis. The activated complement cascade in CSF, acting on up-regulated complement receptors on brain cells, potentially mediates direct brain damage.[53] Complement factors also are chemoattractants that enhance CSF leukocytosis and indirectly produce brain damage in patients with bacterial meningitis.[102]

The most potent final effectors of brain damage in bacterial meningitis seem to be host-derived, low-molecular-weight mediators, such as hydrogen peroxide, hydroxyl radicals, and hypochlorous acid.[299] Nitric oxide also can be induced in brain cells in response to bacterial products.[210] Nitric oxide and superoxide radicals react to form peroxynitrite anion, which decomposes and forms nitrogen dioxide, hydroxyl radicals, and strong oxidant compounds.[36] Peroxynitrite seems to be an important neuronal toxin.[218] Neuronal damage caused by reactive oxygen species and reactive nitrate species occurs via at least two separate pathways. Reactive oxygen species and reactive nitrate species lead to lipid peroxidation and subsequent cell membrane instability and via activation of poly(adenosine diphosphate ribose) polymerase and its subsequent cellular energy depletion.[219]

The various pathways to neuronal cell death are shown in Figure 37–3. Meningitis causes damage in the cortex and the hippocampal region via different mechanisms. Cortical damage is mainly via cellular necrosis surrounded by an area of caspase-3-dependent apoptosis. Damage in the hippocampus is mediated not only via the classic caspase-3-dependent pathway but also by caspase-independent apoptosis mediated by apoptosis-initiating factor.[40,42,257] The caspase-independent apoptotic pathway seems to be important earlier (by 18 hours after infection), whereas the classic caspase-dependent pathway assumes importance later.[257] Braun and Tuomanen[53] have provided a detailed review of the molecular mechanisms of brain damage in bacterial meningitis. In addition, a review by Scheld and coworkers[327] focuses specifically on neuronal injury. The role of inflammatory mediators and oxygen radicals in the pathogenesis of bacterial meningitis is described in detail in a review by Leib and Tauber.[234]

The increasing concentrations of chemotactic factors in the subarachnoid space lead to accumulation of large numbers of neutrophils in the CSF, and the growth of bacteria is not slowed

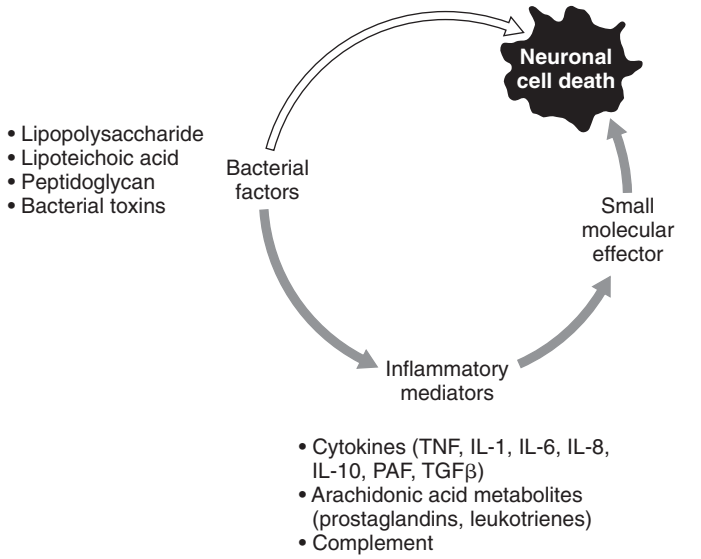

Figure 37–3 Pathways to neuronal cell death. Although bacterial products can induce directly some neuronal toxicity, host-derived inflammatory agents are the primary source of final mediators of injury. IL, interleukin; PAF, platelet-activating factor; TGF, transforming growth factor; TNF, tumor necrosis factor. *(From Braun, J. S., and Tuomanen, E. I.: Molecular mechanisms of brain damage in bacterial meningitis. Adv. Pediatr. Infect. Dis. 14:49-71, 1999.)*

significantly by this response.[102] Impaired phagocytosis by neutrophils in the meningeal spaces may be related to weak activity in fluid medium, lack of complement activity and opsonization, and poor penetration of IgM and IgG through the blood-brain barrier, even during acute *H. influenzae* and *S. pneumoniae* meningitis.[153] Leukocyte entry into the CSF is still important, however. Brandt and colleagues[52] showed that blockage of leukocyte entry into the CSF was associated with poorer prognosis (likely secondary to an increase in bacterial counts in the blood) but did not affect the risk of brain damage.

Bacterial cell wall fragments, endotoxin, or both also contribute to vascular permeability. In experimental *E. coli* meningitis, the CSF endotoxin concentration increased markedly after treatment with β-lactam antibiotics. This increase was associated with an increase in brain water content. This effect could be blocked by polymyxin or a monoclonal antibody, both of which inactivate endotoxin.[368]

The inflammatory and vascular events described earlier act synergistically to produce the clinical symptoms and long-term sequelae that are noted in patients with bacterial meningitis. As described subsequently, altered vascular permeability leads to vasogenic edema, inflammatory and electrolyte changes lead to cytotoxic edema, and alterations in production and absorption of CSF lead to interstitial edema. The cytokines also trigger increased cerebral blood flow and further formation of edema, resulting in increased intracranial pressure.[23] The increased intracranial pressure and vasculitis lead to a subsequent decrease in cerebral blood flow, which does not seem to be caused by loss of autoregulation.[23] Activation of the coagulation cascade predisposes the patient to venous, microvascular, and, rarely, arterial thrombosis. Direct neurotoxic damage by inflammatory cells also may contribute to the neuropathologic changes seen in bacterial meningitis.

CLINICAL MANIFESTATIONS AND PATHOPHYSIOLOGIC RELATIONSHIPS

Inflammation of the meninges generally is associated with nausea, vomiting, irritability, anorexia, headache, confusion, back pain, and nuchal rigidity. In many cases, Kernig and Brudzinski signs are noted. Kernig sign is present when the leg is flexed 90 degrees at the hips and cannot be extended more than 135 degrees. Brudzinski sign is present if the thighs and legs are flexed involuntarily when the neck is flexed. All of these findings suggest irritation of inflamed sensory nerves, which produces a reflex contraction of certain muscles in an attempt to minimize pain. These findings also can be the result of increased intracranial pressure and an associated distortion of nerve roots. These signs can be accompanied by hyperesthesia and photophobia. Currently, no satisfactory pathophysiologic explanation for photophobia exists. Signs of meningeal inflammation may be minimal in the infant, but irritability, restlessness, and poor feeding may be noted. Nuchal rigidity and Kernig and Brudzinski signs may occur late in a young child. Nuchal rigidity may not be elicited in comatose patients or when signs of focal or diffuse neurologic impairment are present. At the time of initial evaluation, 60 to 80 percent of children have a stiff neck.[195] A review of 1064 cases of bacterial meningitis in children beyond the neonatal period revealed that 16 (1.5%) had no meningeal signs during their entire period of hospitalization, despite the presence of CSF pleocytosis.[145] Fever, a hallmark of infection, generally is present; its absence in a patient with signs of meningeal inflammation, although infrequent, is not unusual.

Increased intracranial pressure is the rule; it may be reflected by complaints of headache in older children and by a bulging fontanelle and diastasis of sutures in infants. Papilledema is an uncommon finding in acute meningitis, presumably because of the brief duration of increased pressure at the time of diagnosis. When papilledema is observed, venous sinus occlusion, subdural empyema, or brain abscess should be sought.

Signs of cerebral edema may be present. Vasogenic edema occurs as a consequence of increased permeability of the blood-brain barrier. Interstitial edema may occur secondary to decreased clearance of CSF at the arachnoid villi and subsequent obstructive hydrocephalus. Cytotoxic cerebral edema mediated by the release of toxic factors from neutrophils and bacteria leads to increased concentration of intracellular water and sodium and loss of intracellular potassium. In many cases (88 percent in one prospective study[107]), meningitis is associated with the release of ADH, causing water retention and a relative dumping of sodium by the kidney. If the patient is given excessive free water during therapy, a further increase in intracranial pressure may be noted.

Transient or permanent paralysis of cranial nerves may be noted. Deafness or disturbances in vestibular function are common findings; optic nerve involvement with blindness rarely occurs. Involvement of the eighth cranial nerve may reflect

disease at the level of the cochlear and vestibular end-organs, which may be related to concomitant infection of the inner ear. Paralysis of extraocular and facial nerves may be noted. Torticollis has been reported in two children with partially treated meningitis.[250] Obtundation, stupor, coma, and focal neurologic signs may be seen in children with bacterial meningitis.

The relative frequency with which these findings are noted is shown in Table 37–2, in which data for 235 children with bacterial meningitis who were enrolled prospectively have been analyzed according to the type of organism responsible for meningitis. Overall, 14.9 percent of children were semicomatose or comatose at the time of admission; rates for children with pneumococcal or meningococcal meningitis were higher than rates for children with *H. influenzae* disease. Focal neurologic signs were present at the time of admission in 16.5 percent of the total group (34.3% of children with pneumococcal meningitis). The presence of focal neurologic signs at the time of admission indicated a poor prognosis and could be correlated with persistent abnormal neurologic examinations at 1, 3, and 6 months ($p < .01$) and at 1 year after discharge ($p < .03$). The presence of focal signs at the time of admission also correlated with the presence of retardation ($p < .001$), as determined by detailed psychometric testing after discharge.

Generally, when focal signs are noted in the absence of seizures, cortical necrosis, occlusive vasculitis, or thrombosis of cortical veins has occurred. Thrombosis of meningeal vessels or cortical necrosis may be associated with hemiparesis or quadriparesis and with focal seizures. These signs may appear during the first 3 or 4 days of illness or, less commonly, may be noted after the first or second week of infection. A highly significant association ($p < .001$) between neurologic signs indicative of cerebral injury and late (1 to 15 years after the acute infection) afebrile seizures has been noted.[293] Ataxia has been a presenting sign of meningitis in numerous children and adults. Schwartz[336] described four children who presented with ataxia as an initial symptom. Adolescents with meningitis may present with behavioral abnormalities that may be confused with drug abuse or psychiatric disorders.[28]

Approximately 20 percent of children with bacterial meningitis experience seizures before admissions, and approximately 26 percent have them during the first or second day in the hospital. Green and colleagues[164] retrospectively examined the frequency of seizures before or at the time of presentation in children with meningitis. They found that 111 of 410 (27%) children with bacterial meningitis had seizures at or before the time of diagnosis; 88 of these children had complex seizures (focal, prolonged, or more than one in a 24-hour period). They found that all children with bacterial meningitis who presented with seizures had other signs or symptoms of meningitis, such as altered level of consciousness, nuchal rigidity, or complex seizures and petechial rash. The frequency of seizure activity is similar for children with *H. influenzae* type b or pneumococcal meningitis; seizures occur in children with meningitis caused by these organisms approximately twice as frequently as in children with meningococcal meningitis. In one study of 181 children with pneumo-coccal meningitis, 41 (23%) developed seizures before admission; 75 percent of preadmission seizures were generalized.[20]

Overall, seizures are noted in approximately 30 percent of children with bacterial meningitis. Seizures noted before or during the first several days of hospitalization are of no particular prognostic significance. Specifically, their occurrence does not herald the development of a permanent seizure disorder. Seizures that are difficult to control or that persist beyond the fourth hospital day and seizures that occur for the first time late in the hospital course may be of greater significance and have been associated with permanent sequelae of meningitis. Children with focal seizures have a greater likelihood for development of sequelae of meningitis than do children with generalized seizure activity. Focal or prolonged seizures probably indicate serious cerebral vascular disturbances or cerebral infarction. Seizures that occur before admission have correlated positively with abnormal audiometric studies and permanent hearing handicaps. Seven percent of patients with bacterial meningitis have focal or generalized seizures 3 months to 15 years after recovery from bacterial meningitis.[293]

Collections of fluid in the subdural space can be shown in 50 percent of infants and children during acute illness.[96] In a prospective study of infants 1 to 18 months old with bacterial meningitis, subdural effusions were noted in 43 percent of infants with *H. influenzae* meningitis, 30 percent of infants with pneumococcal meningitis, and 22 percent of infants with meningococcal meningitis. Subdural effusions were found in 24 percent (25 of 103) of children undergoing neuroimaging in the multicenter pediatric surveillance study of pneumococcal meningitis.[20,351] No greater incidence of neurologic sequelae or developmental delay was found on long-term follow-up in patients with effusion compared with patients with bacterial meningitis who did not have effusion.[348,351]

Subdural effusions may cause enlargement in head circumference or may be responsible for abnormal transillumination of the skull. Vomiting, seizures, a full fontanelle, focal neurologic signs, or persistent fever may be noted sometimes, but these signs occur with such frequency in children with bacterial meningitis who do not have subdural effusions that it is difficult to attribute their occurrence to the subdural effusion.[110]

Blindness and optic atrophy may be related to optic arachnoiditis or infarction of the occipital lobe. Spastic paraparesis with sensory loss in the lower extremities may be secondary to meningomyelitis, spinal cord infarction, or both.

Arthralgia and myalgia are noted in many patients with bacterial meningitis, reflecting the systemic nature of the disease. Arthritis also may occur and does so most commonly during the course of meningococcal disease; generally, it is transient. Early

TABLE 37–2 Frequency of Selected Findings in Children with Bacterial Meningitis

	Total Group	*Haemophilus influenzae*	*Streptococcus pneumoniae*	*Neisseria meningitidis*	Others
No. patients	235	151	35	26	23
Level of consciousness (%)					
Irritable or lethargic	184 (78.3)	117 (77.5)	24 (68.6)	21 (80.8)	22 (95.7)
Somnolent	16 (6.8)	13 (8.6)	1 (2.8)	1 (3.8)	1 (4.3)
Obtunded-semicomatose	27 (11.5)	15 (9.9)	8 (22.9)	4 (15.4)	0 (0)
Comatose	8 (3.4)	6 (4)	2 (5.7)	0 (0)	0 (0)
Focal neurologic signs on admission (%)	37 (16.5)	22 (14.6)	12 (34.3)	2 (7.7)	1 (4.3)
Seizures before admission (%)	48 (20.4)	35 (23.2)	8 (23)	3 (11.5)	2 (8.7)
Seizures in hospital (%)	61 (26)	43 (28)	12 (34)	5 (19)	1 (4.5)

findings of arthritis may be related to direct invasion of the joint by the meningococcus. Arthritis that develops late in the course of meningococcal or *H. influenzae* meningitis may be an immune complex–mediated event. Petechial or purpuric lesions may be seen in 50 percent of patients with meningococcal meningitis[96] but also may accompany any infectious or noninfectious disease process in which vasculitis occurs. Purpura, shock, and hypothermia indicate a poor prognosis.

Pericardial effusions may be present; they generally resolve during the course of antibiotic therapy. In some cases, pericardial effusions are the cause of persistent fever, and pericardiocentesis or an open drainage procedure may be required.

Shock may be associated with any form of overwhelming bacteremia, but it occurs most often in patients with fulminant meningococcemia. In a prospective study, 3.8 percent of children with meningococcal meningitis developed profound hypotension. In the same study, shock occurred in 5.5 percent of children with *H. influenzae* meningitis. Endotoxin has been detected by Limulus lysate assay in the blood and CSF of children with meningococcal and *H. influenzae* meningitis.[311] Sixteen percent of the children in the multicenter pneumococcal meningitis study were in shock on admission.[20] Signs of disseminated intravascular coagulation may accompany hypotension in these patients.

Facial cellulitis (including buccal and periorbital cellulitis), pneumonia, epiglottitis, endophthalmitis, and other suppurative manifestations can manifest at the time of admission in any patient with bacterial meningitis. In one study of children with buccal cellulitis, less than 10 percent (7 of 73) had concomitant bacterial meningitis documented by lumbar puncture as part of their initial evaluation.[26] Five of the seven children had no clinical evidence of meningeal irritation. *H. influenzae* and *S. pneumoniae* were cultured from two patients with periorbital cellulitis, and no clinical evidence of meningeal irritation or abnormal CSF cell counts or chemistries was found.[320] In the largest review of facial cellulitis caused by *S. pneumoniae*,[160] 15 of 52 children had a lumbar puncture performed; 2 (13.3%) had a pleocytosis (18 white blood cells [WBCs]—52% polymorphonuclear leukocytes, and 9 WBCs—91% polymorphonuclear leukocytes). The Gram stain and cultures of the CSF specimens were negative. Lumbar puncture should be considered for children with facial cellulitis who are younger than 18 months and possibly bacteremic with *S. pneumoniae*.

DIFFERENTIAL DIAGNOSIS

The signs and symptoms described earlier suggest meningeal or intracranial pathologic processes but are not pathognomonic of acute bacterial infection. Tuberculous meningitis, fungal meningitis, aseptic meningitis, brain abscess, intracranial or spinal epidural abscesses, bacterial endocarditis with embolism, subdural empyema with or without thrombophlebitis, ruptured dermoid cysts, ruptured spinal ependymomas, and brain tumors may show similar signs and symptoms. Differentiation of these disorders depends on careful examination of CSF obtained by lumbar puncture and additional immunologic, radiographic, and isotopic studies as delineated later.

DIAGNOSIS

Early diagnosis and treatment of bacterial meningitis are imperative in reducing mortality rates and morbidity. Physicians must perform a lumbar puncture on any child in whom they suspect the diagnosis after a careful history and physical examination have been performed, unless specific contraindications to this procedure (e.g., clinical signs of increased intracranial pressure in a patient with a closed fontanelle and closed sutures) are present.

An association between performance of a lumbar puncture during bacteremia and the later development of meningitis has been reported.[126] This association was evident only in children younger than 1 year old. Perceptive physicians select children for lumbar puncture in whom clinical signs suggest developing meningitis before the CSF findings are diagnostic. These data suggest a need for careful observation and, if appropriate, hospitalization and antimicrobial therapy for infants younger than 1 year who undergo lumbar puncture and who concomitantly have risk factors (e.g., concurrent high temperature and WBC counts) for the development of bacteremia. Table 37–3 summarizes CSF findings characteristic of various inflammatory diseases of the CNS.

Measurement of pressure, often neglected in infants and young children, is an important component of each CSF examination. When the pressure is very high, only enough fluid to permit a careful examination should be removed. Compression of the jugular vein should be avoided unless compression of the spinal cord is suspected. Xanthochromic CSF derives its color primarily from bilirubin pigment. Hemorrhage, bilirubin staining in icteric patients who have meningitis (i.e., neonates, patients with leptospirosis), or an elevated protein concentration of CSF may be associated with xanthochromia.

CSF should be examined immediately. The total number of WBCs should be counted in a counting chamber, and after cytocentrifugation, a differential cell count should be done on a Wright-stained smear of the sediment. The normal CSF of children 3 months or older contains less than 6 WBCs/mm^3. Ninety-five percent of children older than 3 months have no polymorphonuclear leukocytes in the CSF; the presence of a polymorphonuclear leukocyte in the CSF may be regarded as abnormal. When a lumbar puncture has been performed in a febrile child and a single polymorphonuclear leukocyte has been noted, careful clinical observation is imperative, and treatment should be considered until the results of the culture of the CSF are known.

If the lumbar puncture has been traumatic, a total cell count can be done in a counting chamber. The red blood cells (RBCs) can be lysed by acetic acid, and a cell count can be repeated. If the total number of WBCs compared with the number of RBCs is greater than that in whole blood, one can assume the presence of CSF pleocytosis. One simple way to estimate the WBC count in the presence of RBCs is to allow 1 WBC per 1000 RBCs/mm^3. CSF protein should be measured (usually elevated in bacterial meningitis), and the CSF glucose concentration should be compared with the blood glucose concentration that has been obtained concomitantly. In patients with bacterial meningitis, depression of CSF glucose and of the ratio of CSF to blood glucose (normally approximately 66%) is the rule.

Separate smears should be made, and one smear should be Gram stained for bacteria. A Kinyoun stain for mycobacteria is performed if tuberculous meningitis is suspected. The probability of visualizing bacteria on a Gram stain of CSF depends on the number of organisms present. The percentage of positive smears is 25 percent with less than 10^3 colony-forming units (CFU)/mL, 60 percent in the range of 10^3 to 10^5 CFU/mL, and 97 percent with greater than 10^5 CFU/mL.[226] Quellung and agglutination reactions can provide immediate identification of various organisms if the appropriate type of specific antisera is available.

Treating a child with bacterial meningitis with an antibiotic before performing initial lumbar puncture usually does not alter markedly the morphologic or chemical results obtained (Table 37–4). In patients with *H. influenzae* meningitis (Table 37–5) who were pretreated, CSF cultures frequently grew *H. influenzae*; there is a tendency to pretreat children with pneumococcal or meningococcal disease to render the CSF sterile (see Table 37–4). Even when children received appropriate antibiotics for meningitis intravenously for 44 to 68 hours, the bacterial character

TABLE 37–3 Cerebrospinal Fluid Findings in Suppurative Diseases of the Central Nervous System and Meninges

Condition	Pressure (mm H_2O)	Leukocytes/mm^3	Protein (mg/dL)	Sugar (mg/dL)	Specific Findings
Acute bacterial meningitis	Usually elevated; average 300	Several hundred to >60,000; usually a few thousand; occasionally <100 (especially meningococcal or early in disease); polymorphonuclears predominate	Usually 100-500, occasionally >1000	<40 in more than half the cases	Organism usually seen on smear or recovered on culture in >90% of cases
Subdural empyema	Usually elevated; average 300	<100 to a few thousand; polymorphonuclears predominate	Usually 100-500	Normal	No organisms on smear or by culture unless concurrent meningitis
Brain abscess	Usually elevated	Usually 10-200; fluid rarely is acellular; lymphocytes	Usually 75-400	Normal	No organisms on smear or by culture predominate
Ventricular empyema (rupture of brain abscess)	Considerably elevated	Several thousand to 100,000; usually >90% polymorphonuclears	Usually several hundred	Usually <40	Organisms may be cultured or seen on smear
Cerebral epidural abscess	Slight to modest elevation	Few to several hundred or more cells; lymphocytes predominate	Usually 50-200	Normal	No organisms on smear or by culture
Spinal epidural abscess	Usually reduced with spinal block	Usually 10-100; lymphocytes predominate	Usually several hundred	Normal	No organisms on smear or by culture
Thrombophlebitis (often associated with subdural empyema)	Often elevated	Few to several hundred; polymorphonuclears and lymphocytes	Slightly to moderately elevated	Normal	No organisms on smear or by culture
Bacterial endocarditis (with embolism)	Normal or slightly elevated	Few to <100; lymphocytes and polymorphonuclears	Slightly elevated	Normal	No organisms on smear or by culture
Acute hemorrhagic encephalitis	Usually elevated	Few to >1000; polymorphonuclears predominate	Moderately elevated	Normal	No organisms on smear or by culture
Tuberculous infection	Usually elevated; may be low with dynamic block in advanced stages	Usually 25-100, rarely >500; lymphocytes predominate except in early stages when polymorphonuclears may account for 80% of cells	Nearly always elevated; usually 100-200; may be much higher if dynamic block	Usually reduced; <50 in 75% of cases	Acid-fast organisms may be seen on smear of protein coagulum (pellicle) or recovered from inoculated guinea pig or by culture
Cryptococcal infection	Usually elevated; average 225	Average 50 (0-800); lymphocytes predominate	Average 100; usually 20-500	Reduced in more than half of cases; average 30; often higher in patients with concomitant diabetes mellitus	Organisms may be seen in India ink preparation and on culture (Sabouraud medium); usually grow on blood agar; may produce alcohol in cerebrospinal fluid from fermentation of glucose
Syphilis (acute)	Usually elevated	Average 500; usually lymphocytes; rarely polymorphonuclears	Average, 100; gamma-globulin often high, with abnormal colloidal	Normal (rarely reduced)	Positive reagin test result for syphilis; spirochete not demonstrable by usual techniques of smear or by culture gold curve
Sarcoidosis	Normal to considerably elevated	0 to <100 mononuclear cells	Slight to moderate elevation	Normal	No specific findings

of the chemical and morphologic findings could be discerned in most cases.[46]

The CSF should be cultured on a blood agar plate and a chocolate agar plate. The CSF specimens always should be cultured, even when the fluid appears to be crystal-clear and acellular or nearly so.

In the 1970s, countercurrent immunoelectrophoresis was shown to be a useful technique for rapid diagnosis (within 1 hour) and management of bacterial meningitis caused by *H. influenzae* type b, *S. pneumoniae*, *N. meningitidis* (groups A, C, W135, and D), and group B streptococcus. It may be used to detect antigens from K1 strains of *E. coli* or *L. monocytogenes*.[117,248] The methodol-

ogy is sensitive and can detect nonviable bacteria, permitting the detection of bacterial antigen, even in patients who have been pretreated with appropriate antibiotics. If this technique is employed, it is imperative to use antisera that have the greatest possible sensitivity and specificity.[187,338] Group B meningococcal antiserum, which is available commercially, is unreliable. When pneumococcal antisera are used, material obtained from the State Serum Institute in Copenhagen, Denmark, has proved to be highly efficacious; sensitivity is enhanced by using the various pools of pneumococcal antisera in addition to the omniserum. A negative result of countercurrent immunoelectrophoresis does not exclude the diagnosis of bacterial meningitis.

Latex particle agglutination commercial kits are available for detecting the polysaccharide antigens of *H. influenzae* type b, *S. pneumoniae*, *N. meningitidis*, and group B streptococcus. Latex particle agglutination is superior to countercurrent immunoelectrophoresis in detecting PRP antigen of *H. influenzae* type b in CSF and serum. Nonspecific agglutination of latex particles in serum, urine, and other body fluids may result in an indeterminate test result.[80,188,326,394] A commercial latex particle agglutination kit containing antibody-coated latex particles for *H. influenzae* type b, *S. pneumoniae*, and *N. meningitidis* serogroups is available. The Food and Drug Administration does not recommend latex agglutination testing of urine of infants for group B streptococcus as a method for inferring invasive disease with this organism. Latex agglutination of urine for group B streptococcus or *N. meningitidis* should be avoided because of the high frequency of false-positive results.

The clinical utility of rapid antigen detection in CSF has been questioned in recent years since the decline in frequency of invasive infections caused by *H. influenzae* type b. A positive test response rarely alters the approach to therapy. Maxson and associates[247] examined this issue and suggested that bacterial antigen tests be reserved for patients with suspected bacterial meningitis whose initial CSF Gram stain was negative and whose culture was negative after 48 hours of incubation. Perkins and associates[289] reviewed all latex particle agglutination tests done during a 10-month period at two hospitals and reached the same conclusion. Finlay and colleagues[124] suggested that latex agglutination testing of CSF be used only when the Gram stain is negative when it is consistent with meningococci. In the latter case, clarifying the meningococcal serotype quickly may have implications in large outbreaks for recommending meningococcal vaccine for type A, C, Y, or W135 disease.

The rapidity with which results of bacterial antigen tests are obtained renders them tempting as a means to establish an early diagnosis. The degree to which they affect clinical decisions is unclear.[247] Performing these tests is unnecessary for every patient suspected to have bacterial meningitis, but they could play a role in certain circumstances, such as when a patient's clinical presentation suggests bacterial meningitis and pretreatment with antibiotics or with a traumatic lumbar puncture. Antigen detection is useful in developing countries, where CSF culture yields are lower.[85]

Polymerase chain reaction (PCR) analysis of CSF has been used to detect microbial DNA in patients with bacterial meningitis. Primers are available for the detection of *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type b simultaneously. Species-specific amplicons have been detected in 89 percent of patients with proven streptococcal, meningococcal, or *H. influenzae* type b meningitis.[300] No false-positive results were noted.

Kotilainen and associates[224] used PCR and DNA sequencing techniques in a prospective study of CSF from patients with suspected bacterial meningitis. The bacterial 23S rRNA gene was amplified from the CSF of 5 of 46 adults with possible infection of the CNS. After sequencing of the 16S or 23S rRNA gene PCR products, 98.3 to 100 percent homology with *N. meningitidis* was observed in all five patients. This PCR method was not timely enough for routine laboratory use because it required 2 to 5 days to obtain results that could be reported to the physician.

Dagan and associates[78] have described the use of PCR for detection of *S. pneumoniae* within CSF. du Plessis and associates[97] have developed a seminested PCR strategy based on the amplification of the pneumococcal penicillin-binding protein 2B gene to detect penicillin-susceptible or penicillin-nonsusceptible *S. pneumoniae* within CSF. PCR detected pneumococci in all of the 18 culture-positive CSF specimens (of 285 total specimens tested). No false-positive results were noted. This test required only a few hours to perform and used only 15 μL of CSF.

Advances in the field have made the use of PCR technology a more viable option in the diagnostic approach to meningitis. The use of real-time PCR has shortened the time needed for completion of specimen analysis from several days to several

hours. PCR technology can be applied in a broad-spectrum manner, such as testing for amplification of bacterial 16s rRNA[334] or in a bacteria-specific manner using specific probes for *Neisseria* and *Streptococcus* spp.[78,262] or other bacterial pathogens. One diagnostic strategy combines the use of broad-range, real-time PCR for detection of bacterial presence in the CSF and is followed by bacterial identification after subsequent DNA sequencing.[89] The use of such PCR techniques is helpful in patients pretreated with antibiotics in whom the culture may be negative.[89,284] The possible addition of gene microarray technology offers the potential to probe for multiple different bacterial species simultaneously.[177]

PCR also is useful in rapidly documenting viral antigens within CSF, reducing the use of antibiotics in selected patients who are treated for presumptive bacterial disease but who may have viral meningitis.[312,331,383] Dicuonzo and associates[92] also documented the great sensitivity of oligoprobes on amplified DNA for the diagnosis of *H. influenzae*, streptococcal, and *Mycobacterium tuberculosis* meningitis. No false-negative results occurred in culture-positive CSF specimens.

Measurement of CRP has been proposed as a test that may be valuable in distinguishing bacterial from viral meningitis. In some studies, overlap in CRP determinations between these groups of patients has been observed. For this reason, we do not consider that one can rely on the CRP result to distinguish bacterial from viral meningitis with sufficient certainty.[112,150,191] Nonetheless, in the best study to date, serum CRP was superior to CSF parameters in distinguishing Gram stain–negative bacterial from viral meningitis.[356] Among 92 patients with viral meningitis, 93 percent had serum CRP levels within the normal range (<20 mg/L). Only one child with Gram stain–negative bacterial meningitis had a serum CRP value within the normal range.

Numerous metabolic changes have been reported to occur in the CSF and blood of patients with meningitis (Table 37–6). CSF lactate has been noted to be elevated significantly in patients with bacterial meningitis. The increase in CSF lactate apparently is related to decreased cerebral blood flow, cerebral hypoxia, and a change to anaerobic metabolism by the brain. Concentration of CSF lactate tends to parallel the CSF cellular response.[315] Although the concentration of CSF lactate in patients with bacterial meningitis generally is greater than that in patients with aseptic meningitis, such is not always the case. In some patients with aseptic meningitis, CSF lactate has been in the range generally observed in patients with bacterial infections. Conversely, in patients who proved to have bacterial meningitis but who had equivocal clinical and CSF findings, measurement of CSF lactate failed to differentiate bacterial from nonbacterial infection.[315] The determination of the concentration of CSF lactate cannot be used reliably to differentiate viral from bacterial meningitis in an individual patient.[220]

Depression of the pH of CSF also has been described in patients with bacterial meningitis. The depression of pH in CSF is more transient than is the elevation of CSF lactic acid, and its measurement is of even less value in the differential diagnosis.[397]

TABLE 37–6 Metabolic Changes Reported in Patients with Bacterial Meningitis

CSF lactate increased
CSF pH decreased
CSF lactate dehydrogenase increased
Creatine phosphokinase increased
Aspartate transaminase increased
CSF and blood elastase-α-proteinase inhibitor increased
CSF vasopressin increased

CSF, cerebrospinal fluid.

Lactate dehydrogenase, creatine phosphokinase, and aspartate transaminase may be elevated in patients with bacterial meningitis. In some cases, total lactate dehydrogenase activity within CSF may be similar in patients with bacterial and aseptic meningitis, but lactate dehydrogenase isoenzymic analysis may permit differentiation of bacterial from nonbacterial infection. This procedure is time-consuming and cumbersome and does not permit establishing a specific etiologic diagnosis in any patient.[198,276]

Despite the application of impeccable clinical judgment, examination of CSF, and use of one or more of the rapid diagnostic techniques, situations arise in which differentiation of bacterial from aseptic meningitis remains problematic. In these cases, a predominance of polymorphonuclear leukocytes generally is found in the CSF, the CSF cell count is less than 100 cells/mm^3, the CSF glucose concentration is normal or nearly so, and the Gram stain result is negative. Most children with aseptic meningitis have a predominance of polymorphonuclear leukocytes on their initial CSF examination.[277] In addition, although patients exhibit signs and symptoms suggestive of meningitis, they do not appear acutely ill. Some investigators have advocated withholding antibiotic therapy in these patients and repeating the lumbar puncture after 6 to 12 hours of close observation.[3,113] Usually, the repeated examination of CSF either substantiates the impression of aseptic meningitis (a shift to a lymphocytic differential is noted) or points more conclusively to a bacterial process. This course of action is not recommended if the patient has been pretreated with antibiotics or is younger than 1 year old. Occasionally, children have a mild CSF pleocytosis, which may have a predominance of polymorphonuclear leukocytes, after they experience seizures.[403,405] Generally, CSF abnormalities should not be attributed to seizures, unless other causes of CNS inflammation have been excluded.

Other approaches to differentiate bacterial from viral meningitis have been suggested. Evaluation of CSF ferritin concentration has been proposed as a test with considerable predictive value. Kim and associates[209] showed in pediatric patients that CSF ferritin concentration is significantly elevated in bacterial meningitis compared with viral meningitis. Using a proposed cutoff of 15.6 ng/mL of CSF ferritin, the test had a sensitivity of 96.2 percent and a specificity of 96.6 percent in differentiating bacterial from viral meningitis.

Additional laboratory data are helpful and should be obtained. Blood cultures should be obtained in every patient suspected to have bacterial meningitis. In one prospective study in which blood was obtained for culture from every patient, the cultures were positive in 80 percent of children with *H. influenzae* meningitis, in 52 percent of children with pneumococcal meningitis, and in 33 percent of children with meningococcal meningitis.[108] Forty-four percent of the entire group had received some form of antibiotic therapy before admission to the hospital and before these blood cultures were performed. If these individuals were excluded, positive blood cultures were obtained from 90 percent, 80 percent, and 91 percent of children with meningitis caused by *H. influenzae*, *S. pneumoniae*, and *N. meningitidis*, respectively.

A thorough search for foci of infection adjacent to or remote from the meninges should be conducted. Repetitive neurologic evaluation also should be performed, and appropriate laboratory studies should be undertaken to define the extent of neurologic dysfunction.

When the concentration of bacteria within the blood is high, a Gram-stained smear of a buffy coat obtained from the blood may reveal the presence of microorganisms. If petechial lesions are present, a smear of the lesions after puncture with a small lancet may reveal microorganisms on Gram stain. A chest radiograph may be helpful in disclosing a focus of infection.

Radioisotope scanning may be helpful in selected patients, such as patients with a leak of CSF. The pattern of distribution of radioactivity recorded by gamma camera coincides with the

accumulation of purulent material. Increased concentration of isotope may relate to the inflammatory response within the meninges or in the periventricular region or to alteration in the blood-brain barrier.[155] Localized concentrations of radionuclide may be seen in children with meningitis, most likely as a result of cerebral vasculitis or infarction.[96] Confirmation of impaired cerebral circulation, including occlusion and narrowing of arteries, sluggish circulation, and retrograde flow, has been provided by the studies of Gado and associates.[140] In these studies, resolution of the arterial lesions was shown in subsequent angiograms in two patients, despite the persistence of neurologic deficits; these findings prompted the authors to suspect vascular spasm at the earlier stage of disease. Hydrocephalus contributed to sluggish circulation through intracerebral vessels in two patients. Tyson and colleagues[377] showed at least transient disturbance in the circulation of CSF in 45 percent of patients with meningitis, but persistent hydrocephalus is a rare complication of purulent meningitis.

Computed tomography (CT) and magnetic resonance imaging (MRI) are noninvasive techniques that permit the prospective and repetitive assessment of children with meningitis. These techniques permit detection of ventricular dilation, subdural effusion, decrease in brain mass, and presence of vascular lesions or of brain infarcts (Fig. 37–4). With these procedures, ventricular dilation may be noted acutely in many children who never develop hydrocephalus after recovery from their disease.[108] Neuroimaging may be indicated in the following situations: (1) focal neurologic signs, (2) persistently positive CSF cultures despite administration of appropriate antibiotic therapy, (3) persistent elevation of CSF polymorphonuclear leukocytes (>30 to 40%) after more than 10 days of therapy, and (4) recurrent meningitis.[215]

Recurrent bacterial meningitis may be the result of a communication between the nasal passage or ear and the meninges. If rhinorrhea or otorrhea is present, a leak may be suspected, but documenting that CSF is present and locating the site of leakage are difficult when the sample is small or contaminated. Sectional (2 mm) coronal cranial CT has been reported to be an easy, noninvasive method for delineating anatomic abnormalities in children with recurrent meningitis.[362]

Figure 37–4 Computed tomography scan of a 2-year-old child with bacterial meningitis. Moderately severe ventricular dilation and the presence of bilateral extracerebral fluid collections overlying the convexities of the brain (subdural effusions) are noted. Note the several prominent vessels that run through the subdural space.

Meurman and associates[255] showed that an extra band of transferrin is located in the β_2-fraction after protein electrophoresis of CSF. This extra β_2-transferrin band could not be shown in serum, nasal secretions, saliva, tears, or perilymph and endolymph. The amount of sample required is small (<50 μL). We have applied this immunochemical method successfully in documenting that fluid found draining from the nose or ear was CSF. Differential suction may permit demonstration of the site of the anatomic communication among the nose, the ear, and the meninges. Moderate contamination with other body fluids does not invalidate the method. The method also is noninvasive and safe for the patient.

TREATMENT

ANTIMICROBIAL THERAPY

Prompt treatment of bacterial meningitis with an appropriate antibiotic is essential. Antibiotic selection should include consideration of such factors as the CSF penetration of the antibiotic, the activity of the drug in purulent CSF, the mode of administration of the drug, and the intrinsic pharmacodynamic relationships of CSF drug concentrations to bactericidal activity.[346] The initial selection always should be made before definitive cultures are available and ideally should be based on incidence and susceptibility patterns in the local community.[213]

For many years, ampicillin and chloramphenicol were preferred as the initial empirical therapy for children older than 3 months and thought to have bacterial meningitis. The development of newer cephalosporins and other antibiotics that have excellent bactericidal activity against *H. influenzae* type b, *N. meningitidis*, and *S. pneumoniae* within the CSF led to the current approaches to initial therapy of childhood meningitis. Cefotaxime and ceftriaxone are included in the empiric treatment regimen of choice in most centers.[211]

Cefotaxime is a third-generation cephalosporin that has a broad spectrum of activity against gram-positive and gram-negative organisms. It possesses a high level of resistance to hydrolysis by β-lactamase. Cefotaxime penetrates the blood-brain barrier and provides bactericidal activity in the CSF equivalent to or greater than that of antibiotics that have been used conventionally for treatment of bacterial meningitis in children.[265] It is an excellent choice for inclusion in empiric therapy in children 1 month or older but must be used with ampicillin for initial therapy in children younger than 1 month because *L. monocytogenes* and enterococci cannot be treated with cefotaxime but are sensitive to ampicillin. Vancomycin in a dose of 60 mg/kg/day in four divided doses is recommended in addition to cefotaxime for empiric therapy of children with meningitis because of the frequency with which penicillin-resistant and cephalosporin-resistant pneumococci have been isolated in recent years worldwide. Cefotaxime is given as a daily dose of 225 to 300 mg/kg/day in three or four divided doses intravenously. The higher dosage is preferred by some experts because the higher CSF concentrations achieved by high-dose therapy may be beneficial for patients whose disease may be caused by *S. pneumoniae* when the organisms are of intermediate susceptibility to third-generation cephalosporins.[75]

Ceftriaxone is another third-generation cephalosporin that possesses broad antimicrobial activity against the organisms that cause bacterial meningitis. Ceftriaxone readily penetrates the CSF of patients with inflamed meninges. In patients who receive adjunctive therapy with dexamethasone, meningeal inflammation

may be reduced, possibly decreasing the penetration of antibiotics into the CSF. Gaillard and colleagues[141] found that concentration of ceftriaxone in the CSF of children with bacterial meningitis treated with dexamethasone was similar to that found in children not treated with steroids. The half-life of ceftriaxone in serum is approximately 4 hours; a twice-daily dose regimen provides serum and CSF concentrations far in excess of the minimal bactericidal concentrations of most organisms that cause bacterial meningitis. Several prospective randomized studies have shown that ceftriaxone is comparable to ampicillin plus chloramphenicol for the treatment of bacterial meningitis in children.[21,33,56,76,87,157,361]

Ceftriaxone therapy has been associated with an increased incidence of diarrhea, which is mild and self-limited. An increased incidence of "gallbladder sludge," or precipitation of ceftriaxone salts in the gallbladder, diagnosed by ultrasound, also occurs and generally is asymptomatic but occasionally is associated with clinical symptoms of cholecystitis.[21,324] Ceftriaxone also has a high protein-binding capacity and can displace bilirubin from albumin in vitro[169] and needs to be used cautiously in neonates.

When ceftriaxone is used for the treatment of bacterial meningitis, it can be administered in a dose of 100 mg/kg/24 hours in two divided doses or one daily dose intravenously. Although a once-daily dose has proved to be effective,[49,135,167] is convenient, and lends itself particularly to home therapy for selected patients (after an initial period of hospitalization), we do not advocate single daily dosing; dosing errors, delayed doses, or missed doses undoubtedly occur, and inadequate treatment could result. Although ceftriaxone can be given intramuscularly, a single dose by this route may be impractical.[49] The solution used for intramuscular administration should contain no more than 250 mg/mL. A 15-kg child receiving a daily dose of 80 mg/kg would require 4.8 mL of fluid, a volume too large for injection in a single site in an infant. In addition, for penicillin-nonsusceptible but ceftriaxone-susceptible organisms, administration twice a day may be preferred.[75]

Ampicillin and chloramphenicol have been and continue to be effective as initial treatment of bacterial meningitis when organisms are susceptible to these agents, but they are used infrequently. Ampicillin may be provided intravenously in a dose of 300 mg/kg/24 hours in six divided doses. An initial bolus of 100 mg/kg is given. Chloramphenicol is administered intravenously in a dose of 100 mg/kg/24 hours in four divided doses. No loading dose of chloramphenicol is required.

An increasing number of strains of *S. pneumoniae* that are relatively or completely resistant to penicillin and third-generation cephalosporins have been identified.[54] Tan and coworkers[367] reported a retrospective analysis of five children who had pneumococcal meningitis caused by strains that were penicillin-resistant and that had minimal inhibitory concentrations (MICs) to cefotaxime or ceftriaxone of 0.5 to 2 μg/mL compared with strains that were penicillin-resistant but susceptible to cefotaxime or ceftriaxone (MIC ≥0.25 μg/mL); they found no difference in clinical outcome at the time of discharge. After publication of this report and others with similar findings, the National Committee for Clinical Laboratory Standards established the current guidelines for interpreting the MIC for cefotaxime or ceftriaxone for pneumococci isolated from patients with bacterial meningitis. The guidelines indicate that strains with an MIC of 2 μg/mL or greater are considered resistant, strains with an MIC of 1 μg/mL are intermediate, and strains with an MIC of 0.5 μg/mL or less are considered fully susceptible.[275]

Vancomycin has been used successfully to treat penicillin-resistant pneumococcal meningitis[50,137] and experimental models of cephalosporin-resistant pneumococcal meningitis.[139] In eight reports of treatment failures with third-generation cephalosporins, a variety of treatment regimens were used, all successfully. Vancomycin, alone or in combination with rifampin, chloramphenicol, or both, was used most frequently. The recommendation for empiric therapy of bacterial meningitis advocated by the AAP Committee on Infectious Diseases is to include vancomycin in addition to a third-generation cephalosporin in patients aged 1 month or older.[9] If nonsusceptibility to penicillin (MIC ≥0.1 μg/mL) and cephalosporins (MIC ≥0.1 μg/mL) is documented, treatment is continued with vancomycin plus cefotaxime or ceftriaxone (a synergistic effect is achieved when they are used together) with or without rifampin to complete an appropriate course. Vancomycin should be given at a dose of 60 mg/kg/24 hours in four divided doses. Peak serum concentrations of vancomycin in children whose renal function is normal should be 30 to 40 μg/mL.

Antibiotic tolerance is the ability of an organism to grow in the presence of antibiotics and frequently is a precursor phenotype to resistance. Clinical isolates of *S. pneumoniae* that are tolerant to vancomycin have been reported in the United States.[279] Meningitis caused by a vancomycin-tolerant organism in a patient was treated successfully with cefotaxime (300 mg/kg/day in four divided doses) plus vancomycin (60 mg/kg/day in four divided doses) and rifampin (20 mg/kg/day in two divided doses). Chloramphenicol also may be a suitable alternative for the treatment of these organisms if the pneumococcus proves to be sensitive to this antibiotic. Pneumococcal isolates resistant to penicillin or extended-spectrum cephalosporins frequently are nonsusceptible to chloramphenicol, however.

Cefuroxime is a second-generation cephalosporin that has been shown to be effective in vitro against *H. influenzae* type b, *S. pneumoniae*, and *N. meningitidis*. Initial clinical studies found that cefuroxime had equivalent effectiveness compared with ampicillin plus chloramphenicol. Subsequent studies showed delayed sterilization of the CSF, however; relapse during or after treatment was higher, and more frequent sensorineural hearing loss occurred than with use of ampicillin, chloramphenicol, cefotaxime, and ceftriaxone.[19,86,228,230,323] Cefuroxime *should not be used* to treat bacterial meningitis in children.

Ceftazidime has been efficacious in the treatment of meningitis caused by *P. aeruginosa*.[180,258,306,307] Cefoperazone and cefoxitin within CSF may fail to reach concentrations required to kill all susceptible strains of *H. influenzae* and *S. pneumoniae* and cannot be recommended for the treatment of bacterial meningitis in children.[59,121] Cefpirome concentrations in CSF of patients with bacterial meningitis were found to be significantly higher than the minimum bactericidal concentrations for *N. meningitidis*, *H. influenzae*, and *S. pneumoniae*,[402] but studies documenting its effectiveness in large numbers of children have not been done.

Cefepime is a fourth-generation cephalosporin that has been studied for the treatment of bacterial meningitis. In vitro, cefepime offers no advantage over cefotaxime or ceftriaxone for penicillin-resistant *S. pneumoniae*.[207] In addition, no in vitro data exist for the efficacy of cefepime against cefotaxime-resistant pneumococci. In two clinical trials, the efficacy of cefepime was found to be equivalent to the efficacy of either cefotaxime or ceftriaxone.[316,317] No penicillin-resistant or ceftriaxone-resistant pneumococci were encountered in either study, however. The role of cefepime for the treatment of bacterial meningitis is unclear.

Aztreonam is an antimicrobial agent that belongs to the monobactam family of antibiotics. It is effective against most gram-negative organisms, including *P. aeruginosa*. Limited data suggest its efficacy in the treatment of *Pseudomonas* and *H. influenzae* meningitis, suggesting a potential role for this agent in the treatment of patients who are allergic to penicillin and who are infected with these or other gram-negative organisms.[208,229,375]

If a history of *significant* allergy to penicillin or cephalosporin (anaphylaxis, urticaria, exfoliative dermatitis) is documented, vancomycin plus rifampin or chloramphenicol may be used. A cross-

reactivity of approximately 10 to 15 percent has been noted for cephalosporins in penicillin-allergic patients.

When meningitis is caused by *Streptococcus pyogenes*, ampicillin or penicillin provides effective therapy. If meningitis is caused by a penicillin-resistant strain of *S. aureus*, oxacillin or nafcillin should be used, 200 mg/kg/24 hours intravenously in six divided doses. Vancomycin is effective against *S. aureus* strains resistant to penicillin and to semisynthetic penicillin derivatives[170] or *S. aureus* meningitis in patients who are penicillin allergic. Vancomycin also may be useful in treatment of meningitis caused by *Flavobacterium meningosepticum*.[94] Metronidazole is effective in treatment of anaerobic infection of the CNS when response to conventional therapy has been suboptimal. A dose of 40 mg/kg/24 hours in three or four divided doses results in CSF concentrations of greater than 10 μg/mL.[39]

Imipenem and meropenem have been evaluated for the treatment of meningitis. These carbapenems are active against the bacteria that cause meningitis, but the use of imipenem-cilastatin has been associated with drug-induced seizures.[404]

The safety and efficacy of meropenem and cefotaxime were compared in a prospective randomized trial of 190 children with bacterial meningitis.[216] Seizures occurred within 24 hours before administration of antibiotic therapy in 16 percent of patients randomly assigned to receive meropenem and in 7 percent of patients randomly assigned to receive cefotaxime. Seizures occurred in patients after administration of therapy in 6 percent of children receiving meropenem and in 1 percent of children receiving cefotaxime. None of these seizures could be attributed to drug therapy. All patients responded to therapy with clinical improvement, and bacterial eradication was proved by repeated lumbar puncture in 100 percent of patients in both groups. No significant difference in short-term outcomes occurred between the two groups.

Odio and associates[282] compared the efficacy and safety of meropenem with cefotaxime for the treatment of bacterial meningitis in 258 children who were randomly assigned to the meropenem or cefotaxime group. Clinical cure with or without sequelae was achieved in 97 percent and 96 percent of the meropenem-treated and cefotaxime-treated patients, respectively. At 7 weeks after treatment was concluded, 54 percent of patients treated with meropenem and 58 percent of patients treated with cefotaxime had no sequelae. Seizures were noted in 12 percent of the patients treated with meropenem and in 17 percent of patients treated with cefotaxime; none of the seizures was considered to be drug-related. These data suggest that meropenem is effective in the treatment of bacterial meningitis in children. Few children with pneumococcal meningitis in either study had isolates that were nonsusceptible to cefotaxime. No conclusions can be drawn regarding the usefulness of meropenem in treating pneumococcal meningitis caused by isolates with a cefotaxime or ceftriaxone MIC equal to or greater than 2 μg/mL. Meropenem should be studied further in children who may have meningitis that is caused by organisms resistant to extended-spectrum cephalosporins. For meropenem-susceptible isolates, meropenem alone or in combination with other drugs may provide a satisfactory alternative for patients who do not tolerate vancomycin.[75]

In animal models, the addition of bacterial protein-synthesis inhibitors, such as clindamycin[48] and rifampin,[149] has been associated with a neuroprotective effect, suggesting the possibility of their use as an adjunct therapy. Bottcher and associates[48] showed decreased bacterial cell wall release, a lessened pro-inflammatory response (including decreased leukocyte recruitment), less free radical formation, and decreased apoptosis and cellular damage after the addition of clindamycin to standard antibiotic therapy.

Table 37–7 provides current recommendations for antibiotic treatment of various microorganisms. An appropriate antibiotic should be continued until the patient is afebrile for 5 days, but for at least 7 to 10 days in every patient. Although some data support a shorter course of therapy, we continue to recommend 10 days of treatment for pneumococcal and *H. influenzae* type b meningitis and 7 days for *N. meningitidis* meningitis.[190,240,246] If clinical improvement is noted within 24 hours, a repeated lumbar puncture is unnecessary, in most cases, during the course of treatment or after treatment has been completed. If infection is caused by *S. pneumoniae* that is resistant to penicillin and to third-generation cephalosporins, we recommend a repeated lumbar puncture at 48 to 72 hours to document bacterial sterilization of the CSF. If clinical improvement is slower than anticipated or is not noted, a repeated examination of the CSF is indicated at any time.

In the 1970s, lumbar puncture frequently was performed at the conclusion of therapy. Data from studies performed at that time (Table 37–8) reveal that WBC counts and protein concentrations within the CSF generally had not returned completely to normal and that the CSF-to-blood glucose ratio may have remained depressed. In every case, Gram stain of the CSF should reveal no organisms and cultures should be sterile. If a lumbar puncture is performed at the conclusion of therapy, we consider re-treatment to be mandatory if organisms are seen or grown. It also may be considered if more than 30 percent of the cells are polymorphonuclear leukocytes, or if the CSF glucose concentration is less than 20 mg/dL, and the CSF-to-blood glucose ratio is less than 20 percent.

Bacteriologic relapse after treatment of meningitis (particularly that caused by *H. influenzae* and treated with ampicillin) was highlighted in numerous reports.[27,71,73,173,174] Precise assessment of the frequency of relapse in children who have received an appropriate antibiotic to which the organism is sensitive or an appropriate dose intravenously and for an extended period has been difficult. The relapse rate is currently less than 1 percent.

Some physicians have discharged children with meningitis from the hospital before the conclusion of a course of therapy and prescribed home management. Benefits of home therapy include a decreased risk of acquiring nosocomial infection, a return of the child to his or her normal environment sooner, and a decrease in the total cost of therapy. Financial savings of outpatient, once-daily ceftriaxone for pediatric meningitis have been estimated to be $200 per day.[295]

Bradley and colleagues[49] reported the results of 54 children with bacterial meningitis treated as outpatients for 1 to 8 days (mean 4.6 days) with intramuscular ceftriaxone given once daily. Each dose was given in conjunction with a physician's examination. Each child had to be afebrile for 24 to 48 hours before initiation of home therapy, free of neurologic dysfunction except for auditory or vestibular dysfunction, and without evidence of inappropriate secretion of ADH before being considered for outpatient therapy. No child required readmission or developed neurologic sequelae or relapse. Powell and Mawhorter[295] reported a retrospective review of 26 patients with meningitis or other serious bacterial infections who received some portion of their therapy as an outpatient with ceftriaxone; none of the patients experienced relapse or recurrence.

Waler and Rathore[390] suggest 10 criteria for considering outpatient therapy for children with bacterial meningitis, as follows: (1) the child has received inpatient therapy for at least 6 days, (2) the child is afebrile for at least 24 to 48 hours before initiation of outpatient therapy, (3) the child has no significant neurologic dysfunction or focal findings, (4) the child has no seizure activity, (5) the child is clinically stable, (6) the child is taking all fluids by mouth, (7) the first dose of outpatient antibiotic is received in the hospital, (8) the antibiotic is administered in the office or emergency department setting or by qualified home health nursing, (9) daily examination is performed by a physician, and (10) parents are reliable and have transportation and a telephone. The dose of ceftriaxone of 80 to 100 mg/kg/24 hours intramuscularly may need to be aliquoted to account for the volume of diluent needed to achieve a concentration of no greater than 250 mg/mL. If oral

TABLE 37–7 Recommendations for Antibiotic Therapy

Organism	Antibiotic(s)	Recommended Dosages (IV)
Bacteroides fragilis	Chloramphenicol	100 mg/kg/day in 4 dd
	Metronidazole	30 mg/kg/day in 4 dd
Bacteroides other than *B. fragilis*	Penicillin G	300,000 U/kg/day in 6 dd
Clostridium	Penicillin G	300,000 U/kg/day in 6 dd
Corynebacterium	Penicillin G	300,000 U/kg/day in 6 dd
	Erythromycin	50 mg/kg/day in 4 dd
Enterobacter, *Klebsiella*, *Escherichia coli**	Ampicillin	300 mg/kg/day in 6 dd
	Gentamicin	7.5 mg/kg/day in 3 dd
	Amikacin	15 mg/kg/day in 3 dd
	Cefotaxime	200 mg/kg/day in 4 dd
	Ceftriaxone	100 mg/kg/day in 2 dd
	Ticarcillin	300 mg/kg/day in 4 dd
Haemophilus influenzae	Ampicillin	300 mg/kg/day in 6 dd
	Cefotaxime	200 mg/kg/day in 4 dd
	Ceftriaxone	100 mg/kg/day in 1 or 2 dd
	Chloramphenicol	100 mg/kg/day in 4 dd
Listeria monocytogenes	Ampicillin	300 mg/kg/day in 6 dd
	Gentamicin	7.5 mg/kg/day in 3 dd
	TMP-SMX	20 mg/kg/day in 4 dd (TMP component)
Neisseria meningitidis	Penicillin G	300,000 U/kg/day in 6 dd
Neisseria gonorrhoeae	Penicillin G (if sensitive to penicillin)	300,000 U/kg/day in 6 dd
	Ceftriaxone	100 mg/kg/day in 1 or 2 dd
Proteus mirabilis (indole-negative)	Ampicillin	300 mg/kg/day in 6 dd
P. mirabilis (indole-positive)	Cefotaxime	200 mg/kg/day in 4 dd
	Gentamicin	7.5 mg/kg/day in 3 dd
	Amikacin	22.5 mg/kg/day in 3 dd
	Ticarcillin	300 mg/kg/day in 4-6 dd
Pseudomonas	Gentamicin	7.5 mg/kg/day in 3 dd
	Ticarcillin	450 mg/kg/day in 4 or 6 dd
	Piperacillin	300 mg/kg/day in 4 or 6 dd
	Amikacin	15-20 mg/kg/day in 3 dd
	Ceftazidime	150-200 mg/kg/day in 3 dd
	Meropenem	120 mg/kg/day in 3 dd
Salmonella	Ampicillin	300 mg/kg/day in 6 dd
	Cefotaxime	200 mg/kg/day in 4 dd
	Gentamicin	7.5 mg/kg/day in 3 dd
	Chloramphenicol	100 mg/kg/day in 4 dd
Staphylococcus aureus (penicillinase-negative)†	Penicillin G	300,000 U/kg/day in 6 dd
S. aureus (penicillinase-positive)†	Oxacillin or nafcillin	200 mg/kg/day in 6 dd
S. aureus (resistant to semisynthetic penicillins)	Vancomycin *plus*	60 mg/kg/day in 4 dd
	Rifampin	20 mg/kg/day in 2 dd
Staphylococcus (coagulase-negative)	Vancomycin plus	60 mg/kg/day in 4 dd
	Rifampin	20 mg/kg/day in 2 dd

moprophylaxis to eradicate nasopharyngeal carriage before discharge, unless they were treated with cefotaxime or ceftriaxone.

ADJUNCTIVE THERAPY

As described earlier, the pathogenesis and subsequent sequelae of bacterial meningitis are as much a consequence of the host response to infection as of the bacterial organisms themselves. Anti-inflammatory agents used as adjuncts to antimicrobial therapy may decrease the degree of tissue injury during the course of the disease. Corticosteroids have been suggested as an adjunct to therapy of bacterial meningitis because they may (1) decrease intracranial pressure by decreasing meningeal inflammation and brain water content; (2) modulate the production of cytokines, which lessens the meningeal inflammatory response; and (3) decrease the incidence of sensorineural hearing loss or other neurologic complications of meningitis.[227,281]

Corticosteroids may play a role in acute management of increased intracranial pressure and cerebral herniation, although no data specifically indicate that corticosteroids decrease cerebral edema caused by bacterial meningitis. Odio and colleagues[281] found that dexamethasone therapy in children with bacterial meningitis decreased opening lumbar CSF pressure 12 hours after administration of the first dose, but this effect was lost by 24 hours of treatment. The significance of these findings is unclear because the steroids were not given as specific therapy for increased intracranial pressure, and most of the subjects were not showing signs of impending herniation.

In experimental *H. influenzae* meningitis, administration of dexamethasone 1 hour before, but not 1 hour after, administration of ceftriaxone was associated with significantly reduced TNF-α concentration and indices of inflammation in the CSF.[270] Administration of dexamethasone has been associated with decreased concentration in CSF of prostaglandin E_2 and decreased leakage of some proteins from serum into CSF in rabbits with experimental pneumococcal meningitis.[192] Among patients with bacterial meningitis, steroid-treated patients had significantly lower concentrations of IL-1β, TNF-α, platelet-activating factor, and prostaglandin E_2 in their CSF than those of patients who received antibiotics alone.[254,271,281] Patients tend to become afebrile sooner when they receive dexamethasone, but they have an increased incidence of secondary fevers.[388]

Although the understanding of the pathophysiologic events associated with initiation of the acute inflammatory response has been enhanced by more recent data, the ability of dexamethasone to reduce long-term complications of bacterial meningitis in pediatric patients remains controversial. In a prospective, randomized, double-blinded, placebo-controlled study evaluating adults in Europe with bacterial meningitis, de Gans and colleagues[84] showed a decrease in mortality rates in all patients and in unfavorable outcomes in patients with pneumococcal meningitis. By contrast, no pediatric studies of the use of dexamethasone for treatment of bacterial meningitis have shown an overall change in mortality rates.

In randomized, placebo-controlled trials of dexamethasone as adjunctive therapy in bacterial meningitis[227,281,322,388] and in retrospective studies[158,206] published since 1988, 68 percent (227 of 333) of steroid recipients in the six randomized trials had meningitis caused by *H. influenzae* type b; the remaining 32 percent had meningitis caused by *S. pneumoniae* (50 of 333) or *N. meningitidis* (56 of 333).[297] A meta-analysis of nine controlled trials published before 1991 failed to document a reduced risk of neurologic abnormality at hospital discharge or follow-up examination.[181] A more recent meta-analysis of randomized clinical trials of dexamethasone as adjunctive therapy for bacterial meningitis suggests a beneficial effect for *H. influenzae* meningitis and a possible beneficial effect in preventing severe hearing loss in *S. pneumoniae* meningitis, but only if it is given early.[251]

Most patients with *S. pneumoniae* meningitis in the studies that were reviewed were not treated with vancomycin. This issue is important because the penetrance of vancomycin across the blood-brain barrier is not optimal, and selected studies show that it is reduced further when dexamethasone is used concomitantly.[20,51,138,259] Despite the theoretical clinical concerns, CSF concentrations of vancomycin and ceftriaxone are adequate for treatment of penicillin-susceptible and penicillin-nonsusceptible *S. pneumoniae* when dexamethasone is given at recommended dosages.[104]

Odio and associates[281] found that the administration of dexamethasone immediately before the initiation of cefotaxime therapy was associated with a reduced incidence of neurologic sequelae (14% compared with 38% in patients receiving cefotaxime alone). They found no significant difference in auditory sequelae compared with control subjects. The frequency of neurologic sequelae in placebo-treated patients was significantly higher than that noted in other studies.[322,370,388]

Studies by Lebel and associates[227] and Schaad and colleagues[322] failed to show a significant reduction in the incidence of neurologic sequelae in comparisons of steroid-treated and placebo-treated patients. A prospective, multicenter, placebo-controlled study evaluated 143 children with bacterial meningitis caused by *H. influenzae* type b (58%), *S. pneumoniae* (23%), and *N. meningitidis* (17%).[388] Patients were treated with ceftriaxone and placebo or ceftriaxone and dexamethasone administered within 4 hours of the first dose of antibiotics. No significant difference in neurologic or developmental outcome was found between patients who received steroids or placebo.

Sensorineural hearing loss is a significant sequela of bacterial meningitis. In the two randomized studies by Lebel and associ-

ates,[227] patients treated with dexamethasone were significantly less likely to have moderate or severe bilateral sensorineural hearing loss; however, in one study, patients were treated with cefuroxime, which has been shown to result in delayed sterilization of the CSF and a higher rate of hearing loss compared with ceftriaxone.[323] An additional 100 infants and children with bacterial meningitis were treated with ceftriaxone for 10 days and either dexamethasone or placebo for 4 days. A significant reduction in moderate to severe hearing loss in children with *H. influenzae* type b meningitis ($p < .001$) was reported. No significant differences in other neurologic sequelae were found between the two groups. In addition, two patients receiving dexamethasone developed gastrointestinal bleeding severe enough to require transfusion, and two others developed heme-positive stools.[227] Odio and associates[281] found no significant difference in the incidence of moderate or severe hearing impairment between placebo and steroid groups (16% and 6%) respectively.

The Swiss Meningitis Group[322] found that treatment of children with dexamethasone 10 minutes before administration of ceftriaxone and then for 2 days subsequently resulted in persistent hearing loss in 5 percent (three) of children who had received dexamethasone and in 15 percent (eight) of children who received placebo, a difference that was not significant. One child treated with steroid and five children treated with placebo had unilateral hearing loss only. The group also documented a transient mild to moderate hearing impairment in five children treated with dexamethasone and four children treated with placebo; in six of the nine children, the impairment was caused by a conductive disturbance. Dexamethasone did not alter the incidence or natural history of the transient hearing impairment.

In a multicenter study,[388] audiologic measurements were made early in the course of the disease (within 24 hours of admission) and 6 weeks to 12 months after recovery from disease. The authors found no significant difference in the incidence of persistent moderate or severe hearing loss between children who received dexamethasone within 4 hours of antibiotics and children who received placebo, with the exception of bilateral deafness in children with *H. influenzae* type b meningitis (5 of 72 in the placebo-treated group versus 0 of 67 in the dexamethasone-treated group; $p = .02$). The overall incidence of moderate to severe hearing loss was 14.7 percent (10.3% unilateral and 4.4% bilateral) in the dexamethasone-treated group and 22.9 percent (13.5% unilateral and 9.4% bilateral; $p = .33$ for bilateral loss) in the placebo-treated group. These authors found that 22 children (8 in the dexamethasone-treated group and 14 in the placebo-treated group) had bilateral moderate or severe hearing loss at the initial evaluation. Only one child with *H. influenzae* meningitis and unilateral deafness at initial examination progressed to bilateral deafness. At follow-up, the resolution of hearing loss was nearly identical for each group, with 8 of the 22 children having normal hearing at follow-up, 5 having unilateral deafness, and 9 having bilateral deafness.

These results suggest that hearing loss occurs early in the course of meningitis and that early auditory brain stem response results need to be interpreted cautiously with regard to long-term audiologic sequelae. A strong relationship was noted between hearing loss early in the disease and a low concentration of CSF glucose at manifestation of meningitis, a finding that has been reported previously.[95]

Data from animal studies highlight a potential negative effect of dexamethasone therapy.[233,410] Leib and associates[233] examined infant rats with pneumococcal meningitis and found that the rats treated with dexamethasone had increased hippocampal apoptosis and deficiencies in learned behavior.

The AAP Committee on Infectious Diseases states that dexamethasone therapy should be considered for pneumococcal meningitis in infants and children 6 weeks and older.[9] Dexamethasone also is recommended for treatment of infants and children with *H. influenzae* type b meningitis by the Red Book Committee.[12] The reluctance on the part of some experts to recommend dexamethasone for pneumococcal meningitis is predicated on data that fail to show any diminution in morbidity or mortality rates from meningitis when meningitis is caused by *S. pneumoniae* and dexamethasone is used. The CSF concentrations of vancomycin, ceftriaxone, cefotaxime, and rifampin when they are given in dosages recommended for meningitis in children treated with dexamethasone *generally* are adequate to treat meningitis caused by most nonsusceptible strains of *S. pneumoniae*. Dexamethasone can lead to decreased fever and a misleading impression of clinical improvement, even though sterilization of the CSF has not been achieved.

Dexamethasone should not be used if aseptic or nonbacterial meningitis is suspected; if it is started before the diagnosis of nonbacterial meningitis is made, it should be discontinued immediately. It should not be used in "partially treated" meningitis. No data exist on which to base a recommendation for use of dexamethasone in the treatment of bacterial meningitis in infants younger than 6 weeks or in infants with congenital or acquired abnormalities of the CNS, with or without a prosthetic device. One prospective study in infants concluded that adjunctive dexamethasone therapy does not improve the outcome of neonatal bacterial meningitis.[79] Dexamethasone plus vancomycin may decrease the transport of vancomycin into the CSF of experimental animals with pneumococcal meningitis, but this finding was not observed in nine children who were treated with vancomycin and dexamethasone (0.6 mg/kg/day).[217] Dexamethasone should be used cautiously when vancomycin is used to treat meningitis caused by *S. pneumoniae* that may be resistant to penicillin, third-generation cephalosporins, or both.[51,201]

If dexamethasone is used, it should be used in all patients, regardless of disease severity, and it should be administered as early as possible in the course of treatment in a dose of 0.15 mg/kg/dose intravenously every 6 hours for no more than 4 days. One study[322] found no difference in children treated for 2 days instead of 4 days with 0.4 mg/kg/dose every 12 hours.

Except for hearing loss after *H. influenzae* type b meningitis, no clear evidence establishes that dexamethasone dramatically alters the long-term sequelae of meningitis, and its use is not without risk of causing adverse events. The markedly decreased frequency of meningitis caused by *H. influenzae* type b and the increased frequency of meningitis caused by *S. pneumoniae* nonsusceptible to penicillin (for which therapy with vancomycin may be necessary) suggest that initiation of dexamethasone should be considered carefully and that the clinician caring for the patient should evaluate the risk-to-benefit ratio of such therapy.

Research studies seek additional therapies that could be used to help reduce further mortality, morbidity, or both. Five main areas serve as the targets for therapeutic development: (1) bacterial killing and the release of bacterial products, (2) host recognition of bacteria or its products and the initiation of the inflammatory response, (3) modulation of the inflammatory response with adjuvant dexamethasone, (4) inhibition or interruption of the host inflammatory/neurotoxic mediators, and (5) modulation of the apoptotic pathways.[163] Inhibitors of inflammatory mediators and mediator effector molecules such as TNF-α, matrix metalloproteinases, and nitric oxide and antioxidants, neuroprotective factors (melatonin[148] and brain-derived neurotrophic factor[42]), and other anti-inflammatory therapies (triptans[184]) are being studied in experimental animal models of bacterial meningitis. Although their use is attractive theoretically because of the damage produced by the inflammatory cascade, none has emerged as a realistic potential candidate for general clinical use at present.

SUPPORTIVE CARE

In addition to antibiotic therapy, management of bacterial meningitis includes measures that apply generally to critically ill children.[215] Careful monitoring and attention to detail are essential. Pulse rate, blood pressure, and respiratory rate should be measured carefully every 15 minutes until stable and then every hour while the patient is in the intensive care unit. Temperature should be measured every 4 hours. A thorough neurologic examination should be done at the time of admission and at least daily thereafter. A rapid assessment of neurologic function should be done several times a day for the first several days of treatment. Body weight should be measured daily for at least the first 3 or 4 days. Head circumference should be measured in children younger than 18 months at the time of admission and repeated daily if concerns about increased intracranial pressure persist.

The following laboratory data are suggested if results of lumbar puncture indicate bacterial meningitis: (1) total peripheral WBC count and differential, (2) hemoglobin concentration, (3) hematocrit, (4) platelet count, and (5) serum electrolytes (serum and urine osmolalities may be useful in selected patients). Urine volume and specific gravity should be monitored. A low WBC count may suggest a poor prognosis. Anemia associated with *H. influenzae* type b septicemia has been reported[341,342] and has been attributed to immune hemolysis of RBCs that are coated with soluble bacterial antigens.[341]

Every child with meningitis should be evaluated carefully to identify inappropriate secretion of ADH, recognize seizure activity, and detect the development of subdural effusions. Determinations of body weight, serum electrolytes (serum and urine osmolalities in selected patients), urine volume, and specific gravity should be made at the time of admission and observed closely (every 6 to 12 hours) for the first 24 to 36 hours that the child is in the hospital and daily for several days thereafter. Initially, the child should receive nothing by mouth because of the risk of vomiting and aspiration. In addition, delivery of all fluid intravenously ensures greater accuracy in measurement of intake and output during the critical early days of therapy. Inappropriate secretion of ADH has been documented in 88 percent of children enrolled in a prospective study of bacterial meningitis.[107] Elevated serum concentrations of ADH in the presence of hyponatremia have been documented by direct measurement of ADH concentration in serum obtained from the same children.[111]

An electrolyte solution containing approximately 40 mEq/L of sodium and chloride, 35 mEq/L of potassium, and 20 mEq/L of acetate or lactate should be administered at a rate of 1000 to 1200 mL/m^2/24 hours in a patient without evidence of dehydration or shock. Fluid restriction is continued until it can be documented (frequently within 2 hours), on the basis of objective measures, that ADH secretion is not a factor or has resolved. The best indicators of retention of fluid in excess of solute are body weight and serum sodium concentration. As serum sodium concentration approaches normal (140 mEq/L), fluid administration may be liberalized progressively to normal maintenance levels of 1500 to 1700 mL/m^2/24 hours.

Powell and associates[296] found that elevated concentrations of arginine vasopressin in patients with bacterial meningitis who were clinically dehydrated responded to maintenance fluids plus deficit replacement with 0.9 percent saline. This study confirms that the syndrome of inappropriate secretion of ADH should not be diagnosed in the presence of dehydration. Decreased intravascular volume is a physiologic stimulus for the release of ADH, and its release is not inappropriate. Fluid restriction is not advocated for patients who are dehydrated; rehydration should be performed with careful and frequent assessment of fluid and electrolyte status.

Singhi and colleagues[345] examined the effect of fluid restriction on body water and outcome of 50 consecutive children who had been hospitalized with acute meningitis. These children were divided into two groups—patients with hyponatremia and patients without hyponatremia. Patients in both groups were randomly assigned to receive either normal maintenance or restricted fluids (65 to 70% of the volume of that received by the maintenance subgroup). Eleven to 15 patients were randomly assigned to any of the four subgroups in the study. No significant difference in overall outcome or intact survival was found when comparisons were made between fluid-restricted and non-fluid-restricted groups or within each group between the subgroups that received restricted fluids or maintenance fluids. After combination of the subgroups that received restricted fluids with the subgroups that received maintenance fluids, however, a trend toward higher intact survival and lower mortality rates was noted in the non-fluid-restricted groups. Nonetheless, children who had an extracellular water reduction of 10 mL/kg or greater in 48 hours had a significantly lower intact survival rate (10 of 28, 36%) than that of children with less than 10 mL/kg or no reduction of extracellular water (15 of 22, 64%). The mortality rate also was higher in the former group (7 of 28, 25%) than in the latter group (2 of 22, 9%). The authors concluded that fluid restriction did not improve the outcome of acute meningitis and that a decrease in extracellular water volume at 48 hours may increase the likelihood of having an adverse outcome.

This study is particularly difficult to interpret within the context of previous information in the literature. In studies of large numbers of children with bacterial meningitis, evidence of inappropriate secretion of ADH correlated significantly ($p < .01$) with abnormal neurologic findings, even 3 months after discharge, and with low IQ scores.[116] The original studies were in patients who were *not* fluid restricted.[110] As a result of these findings, coupled with documentation of inappropriate secretion of ADH, a recommendation was made to restrict fluids in patients who are hyponatremic at admission. Fluids are restricted only until evidence of inappropriate secretion of ADH can be excluded (usually within 2 hours).

The average patient in subsequent studies reported by Kaplan and Feigin[197] was fluid-restricted for only 0.75 days. The mortality rate in the largest single study reported by Feigin[105] of individuals who were fluid-restricted was 0.5 percent compared with 9 and 25 percent in the groups reported in the studies by Singhi and associates.[345] Singhi and associates[345] did not assess other important outcome variables, such as the number of patients with hearing loss or patients whose psychometric performance might or might not have been impaired. The total number of patients in any of their study groups was relatively small. Although their data are intriguing, other differences, either in the population studied or in the management of the patients, may have accounted for these differences.

In addition to the increased mortality rates of the patients studied by Singhi and associates[345] noted earlier, an extraordinarily high frequency of hydrocephalus and a very high frequency of seizures and status epilepticus were noted compared with groups of patients who have been studied in the United States. Because cerebral edema and increased intracranial pressure have been noted as major disturbances in seriously ill patients with meningitis and because many of the deaths and some of the sequelae have been related to the effects of cerebral edema and intracranial hypertension, we continue to recommend fluid restriction in patients with hyponatremia who are not dehydrated and liberalization of fluids as soon as the effects of excess ADH secretion have been dissipated (usually <1 day).

Meningitis complicated by shock creates a complex fluid management problem. Shock associated with meningitis is secondary

to septicemia and generally is treated with intravenous infusion of large quantities of fluid to maintain blood pressure and adequate tissue perfusion (see Chapter 69). Patients with meningitis without shock or dehydration benefit from initial fluid restriction to avoid worsening of cerebral edema and severe hyponatremia with subsequent seizures. Children with meningitis and shock should receive sufficient quantities of isotonic fluid to maintain a systolic blood pressure of 80 to 90 mm Hg, a urine output equal to or greater than 500 mL/m^2/24 hours, and adequate cerebral perfusion as indicated by mental status. Central venous pressure monitoring is useful to guide fluid resuscitation and to prevent fluid overload. The addition of albumin (1 g/kg) to intravenously administered fluids may decrease the total volume of fluid needed to maintain adequate perfusion. Vasopressors, such as dopamine, dobutamine, and isoproterenol, also may provide support of blood pressure and perfusion and reduce requirements for intravenously administered fluids.

When increased intracranial pressure is suggested by such signs as progressive lethargy, increased muscle tone, or bulging anterior fontanelle, elevating the head approximately 30 degrees may be helpful. Increased intracranial pressure associated with deterioration in mental status or signs of cerebral herniation (Fig. 37–5) may be treated more vigorously with mannitol administered intravenously (0.5 g/kg) infused during 30 minutes and repeated as necessary. If steroids are used for this purpose, the recommended steroid is dexamethasone in a dose of 10 to 12 mg/m^2/day in four divided doses for no more than 4 or 5 days.[199] Other supportive measures to ensure appropriate delivery of oxygen and nutrients to the brain include a quiet environment, elective intubation, and the use of sedatives.[34]

Head circumference measurement and transillumination permit assessment of the development of subdural effusions or may suggest other causes for an enlarging head. CT may be helpful in detecting large subdural effusions or hydrocephalus. Because effusions can be considered part of the pathophysiologic changes that occur with bacterial meningitis, obtaining CT scans to evaluate effusions does not need to be part of the routine evaluation of a child with meningitis. Neuroimaging (CT or MRI) should be performed in children with focal neurologic signs. In children with hemiparesis or quadriparesis, CT or MRI may document cerebrovascular abnormalities. CT also should be performed in children with papilledema on an emergency basis before proceeding with the initial lumbar puncture. *Administration of antibiotics should not be delayed for diagnostic imaging in patients in whom bacterial meningitis is suspected.*

Subdural effusions should be treated with subdural paracentesis only when one suspects that the effusions are responsible for seizures or for prolonged fever as a result of subdural empyema. Paracentesis also may be useful if the effusion is responsible for symptoms of increased intracranial pressure or is the cause of focal neurologic signs.[107,116] In most cases, subdural taps are not required.

Seizures, when noted, are treated expeditiously. A patent airway must be maintained, and appropriate anticonvulsants must be administered. Sodium phenobarbital (7 mg/kg loading dose) may be administered parenterally followed by a maintenance dose of 5 mg/kg/day in two divided doses. If necessary, diazepam (≤0.2 mg/kg) or lorazepam (0.05 mg/kg/dose, 4 mg maximum) infused intravenously for 1 to 2 minutes may be used. If prolonged seizure control is needed, phenytoin (5 mg/kg/day) in two divided doses may be used. Phenytoin generally does not depress the respiratory center to the same extent as phenobarbital does, and it may benefit the patient by inhibiting the secretion of ADH. If the seizure activity no longer is apparent after the second hospital day and the patient has no focal neurologic signs at the time of discharge from the hospital, anticonvulsants may be discontinued. Phenytoin and phenobarbital can induce hepatic microsomal enzymes; their use may increase the metabolism rate of chloramphenicol and possibly cause a significant decrease in the serum concentration of this antibiotic if it has been used for treatment of meningitis.[294]

An electroencephalogram is indicated in patients with meningitis and seizures when focal seizures are noted, seizures persist more than 72 hours after presentation, seizures occur after the third day of hospitalization, a subdural effusion is noted, or prolonged alteration in sensorium is present. An electroencephalogram may be valuable in distinguishing abnormal intermittent posturing from movements associated with seizure activity.

Persistent fever (>8 or 9 days' duration) has been noted.[27] In the multicenter pneumococcal study, the mean duration of fever was 4.4 ± 3.9 days.[19] Suppurative complications, including subdural or pleural empyema, septic arthritis, and pericarditis, should be sought carefully. The rare occurrence of brain abscess in association with bacterial meningitis also may lead to persistent fever. Nosocomial intercurrent infection, usually viral, may cause prolonged fever in a child with meningitis. Complications of therapy, such as suppurative thrombophlebitis or a urinary tract infection after prolonged catheterization, are additional considerations. Persistent fever may be related to the severity of the infection. Poor therapeutic response (especially in multidrug-resistant organisms) occurs, and repeated lumbar puncture must be considered on an individual basis. Drug fever often is cited, but rarely is the cause of persistent fever and remains a diagnosis of exclusion.

Figure 37–5 Inflammation and hemorrhage of cerebellar tonsils from a child with cerebellar herniation through the foramen magnum due to bacterial meningitis. *(From Kaplan, S.: Current management of common bacterial meningitides. Reproduced with permission of Pediatrics in Review 7:77, copyright 1985.)*

PROGNOSIS AND SEQUELAE

The prognosis in patients with bacterial meningitis depends on many factors, including the following: (1) the age of the patient, (2) the time course or progression of illness before antibiotic therapy is effective, (3) the specific microorganism causing the disease, (4) the number of organisms[119] or the quantity of capsular polysaccharide material present in the meninges and CSF at the time of diagnosis, (5) the rapidity with which CSF is sterilized after initiation of antibiotic therapy, and (6) the presence of disorders that may compromise host response to infection.[230]

The younger the patient and the greater the antigenic load at the time of admission, the worse the prognosis. Bacterial colony counts seem to be a more reliable indication of sequelae than is antigen concentration. Seizures, subdural effusions, bacteremia, and a more prolonged period of fever occur more frequently in children who have more than 10^7 CFU/mL of a particular organism in the CSF at the time of admission.[120] Children with colony counts equal to or greater than 10^7 CFU/mL

also are significantly more likely to experience hearing loss and speech disturbance than children with meningitis, but lower concentrations of bacteria within CSF specimens.[120] The presence of TNF in serum has been associated with a fatal outcome in patients with meningococcal meningitis.[386] Elevated concentrations of IL-1β and TNF within the CSF of patients with bacterial meningitis also have been correlated significantly ($p < .002$) with a higher incidence of neurologic sequelae of disease.[269]

The mortality rate for bacterial meningitis in children who are beyond the neonatal period has been reduced to 1 to 5 percent. Although antibiotic therapy has reduced the mortality rate, 50 percent of the survivors of meningitis have some sequelae of disease.[96,116,144,360] Most studies from which estimates of sequelae have been derived have been retrospective, and the patients were enrolled for many years (1951 to 1968). Although antibiotic treatment of these individuals may have been relatively standardized during this period, ancillary methods employed in their care were not controlled.

The frequency of complications of meningitis can be assessed most appropriately by prospective evaluation. In 1975, Sell[337] began a prospective study of 50 infants and children who recovered from *H. influenzae* meningitis. Fifty percent of this group were entirely normal, 9 percent were normal except for behavioral problems, and 28 percent had significant handicaps. The major handicaps noted included hearing loss (10-11%), language disorders or delayed language development (15%), impaired vision (2-4%), mental retardation (10-11%), motor abnormalities (3-7%), and seizures (2-8%).

Twenty-one postmeningitic children were paired with a sibling and tested by the Wechsler Intelligence Scale for Children. The mean IQ of the postmeningitic children was 86, and the mean IQ of control children was 97 ($p < .05$). Comparison of results for individual pairs revealed that 29 percent of postmeningitic children scored 1 full standard deviation below their siblings; no survivor had a score 1 standard deviation higher than a sibling. Feldman and Michaels[118] reported that children who recovered from meningitis caused by *H. influenzae* and who were evaluated 10 to 12 years later maintained grades and scores comparable with those of their siblings as they progressed to middle school. Their academic success may require more school and family support to compensate for the minor differences in IQs that had been noted.

A study by Taylor and associates[370] attempted to gain additional insight into the sequelae of *H. influenzae* meningitis, with particular emphasis placed on neuropsychologic function. Although the study was retrospective, it permitted a more detailed neuropsychologic assessment made at an earlier age than that reported by investigators in previous studies. In addition, the index patients were compared with their siblings who were closest in age and the same sex, and the study was controlled for occupational and educational status. Only 14 percent of children who had had *H. influenzae* meningitis had any residual neurologic sequelae. Mean full-scale IQ was 102 for the index children and 109 for the control children.

The more recent results of our large prospective study of bacterial meningitis in children revealed that 32.8 percent of children had abnormalities detectable on neurologic examination at the time of discharge, but by 5 years after discharge, specific deficits were noted in only 11.1 percent of the total group.[109] As a result of the onset of late seizures in some of these patients, the frequency of neurologic sequelae 15 years after discharge was 14 percent.[293] Specific complications or sequelae of meningitis in these patients are shown in Table 37–9. Shortly after discharge, hemiparesis or quadriparesis was noted in 30 patients (12.4% of the total group), but at 1 year after discharge, paralysis was noted in only 5 patients. These data reflect the tendency for even major neurologic defects to clear unpredictably with time. This important observation suggests the need to maintain cautious optimism in discussing long-term complications of meningitis with parents.

In 1995, Grimwood and colleagues[166] reported the results of a prospective cohort study of 158 meningitis survivors, 3 months to 14 years old, who were treated in a single center between 1983 and 1986. Between 1991 and 1993, 130 children (82% of the original cohort) were evaluated at a mean age of 8.4 years and a mean of 6.7 years after their meningitis. Blended, audiologic, behavioral, neurologic, neuropsychologic, and sociodemographic assessments were compared with those of sex-matched and grade-matched control children. A systematic increase in the risk of abnormality or for poorer functioning was noted across all categories tested in children with meningitis versus control children. The differences reached statistical significance for tests of fine motor function, intelligence, neuropsychologic function, school behavior, and auditory figure-ground differentiation.

Eleven children who had experienced meningitis (8.5% of the cohort studied) had major deficits (hydrocephalus, persistent seizures, spasticity, blindness, IQ < 70, or profound hearing loss). Twenty-four (18.5%) of the survivors of meningitis and 14 (10.8%) of the control children had minor deficits (IQ of 70 to 80, inability to read, abnormalities in speech discrimination possibly referable to mild to moderate hearing loss, and school behavior problems). Overall, one in four of the children in this study had either a serious disabling sequela or a

functionally important behavior disorder or neuropsychologic or auditory dysfunction that adversely affected academic performance.

This prospectively followed cohort was re-evaluated 12 years post-meningitis; impairment, although not severe, still persisted in the post-meningitis patients compared with controls.[18] Children post-meningitis were "more than twice as likely as controls to require special educational assistance" and "took longer to complete tasks, made more errors, were less organized, and struggled within problem-solving situations." Decreased performance in language tasks and executive skills also were seen in children whose age was less than 12 months at onset of meningitis.

Meta-analysis of 19 reports of prospectively enrolled and evaluated cohorts from developed countries published between 1980 and 1990[31] determined the mean probability of mortality to be 3.8 percent for *H. influenzae* type b, 7.5 percent for *N. meningitidis*, and 15.3 percent for *S. pneumoniae*, with an overall probability of 4.8 percent. The mean probabilities of sequelae in the survivors were deafness, 10.5 percent; mental retardation, 4.2 percent; spasticity, paresis, or both, 3.5 percent; and seizure disorder, 4.2 percent. The mean probability of no detectable sequelae was 83.6 percent.

Other specific sequelae or complications of bacterial meningitis that have been observed include cranial nerve involvement, hemiparesis or quadriparesis, muscle hypertonia, ataxia, permanent seizure disorders, and development of obstructive hydrocephalus. Subdural effusions (as noted earlier) are so frequent in young children that they can be considered a part of the general disease process, rather than a persistent or troublesome complication of the meningeal infection. Development of brain abscess after bacterial meningitis is exceedingly rare[122]; when it is found, the possibility that it preceded the development of meningeal infection must be considered, and a careful search for other sites of infections such as endocarditis should be initiated.

Arditi and associates[20] reviewed the outcomes of 180 children with 181 cases of pneumococcal meningitis who were enrolled in a prospective multicenter study between 1993 and 1996. Fourteen (7.7%) of 180 children died. No deaths were related to treatment failure caused by an antibiotic-resistant strain. Of the 166 surviving children, 41 (25%) developed motor defects, and 48 (32%) of 151 children had moderate to severe unilateral or bilateral hearing loss. By CT or MRI of 103 patients, brain infarcts were noted in 39 (38%); subdural effusions, in 25 (24%); hydrocephalus, in 22 (21%); cerebritis, in 12 (12%); and brain edema, in 6 (6%).

So far, the outcome of patients with pneumococcal meningitis caused by penicillin-nonsusceptible or cefotaxime-nonsusceptible isolates has not differed from that caused by susceptible strains.[20,125,205] This finding is explained in part because vancomycin has been administered empirically to most children with suspected bacterial meningitis since the mid-1990s in the United States and in other parts of the world where treatment failures have been reported as a result of antibiotic-resistant *S. pneumoniae*.[283]

Evoked response audiometry was used to detect hearing deficits in the patients described by Feigin and Dodge.[109] Some deficit in auditory nerve function was documented by this sensitive technique in 6 percent of children with *H. influenzae* meningitis, in 31 percent of children with pneumococcal meningitis, and in 10.5 percent of children with meningococcal disease.

Significant hearing loss after bacterial meningitis has been reported frequently. The mechanisms responsible for hearing deficits include spread of infection along the auditory canal and cochlear aqueduct, serous or purulent labyrinthitis, and, with time, replacement of the membranous labyrinth with fibrous tissue and new bone.[38,194,238,241,308] Damage to inner ear structures and subsequent hearing loss also is affected by the immune response of the host. TNF-α has been shown to produce cytolytic effects by the production of oxygen-free radicals. Animal studies have shown a decreased incidence of hearing loss when animals are treated with antibody blockade of TNF-α[16] and scavaging of oxygen-free radical by antioxidant therapy.[214]

Deafness generally is noted early in the course of bacterial meningitis and is independent of the therapy provided.[95,196,202,267,337,385] Ataxia has been reported as a presenting sign of bacterial meningitis in children with hearing loss noted at a later date.[200,336] Presumably, the insult to the vestibular and auditory systems occurred concomitantly in these children. The early loss of hearing noted by several investigators suggests that hearing loss is *not* associated specifically with the use of a particular antimicrobial agent. Early diagnosis and treatment apparently do not prevent the development of deafness in many children who develop hearing loss as a consequence of bacterial meningitis.

Estimates of the frequency of hearing loss in retrospective studies vary from 2.4 to 29 percent.[195,272] In our prospective studies, 7 percent of children have experienced marked to extensive (≥75-dB loss) hearing losses.[196,202] Overall, 48 of 151 (32%) of the children with pneumococcal meningitis in the multicenter study had unilateral or bilateral moderate to severe hearing loss.[20] Occasionally, hearing loss noted early may improve over weeks to months.[308]

In our studies, no correlation has been found between hearing loss and either the age of the patient at the onset of meningitis or the duration of illness before admission.[95,202] A significant correlation was noted between hearing loss and the presence of seizures before admission, the duration of fever in the hospital after therapy had been initiated (which presumably reflects more severe disease), treatment with antibiotics administered orally before a definitive diagnosis of bacterial meningitis was established, and a depressed CSF-to-blood glucose ratio at the time of admission.[95,202,204] Koomen and associates[221] developed a nomogram to predict the probability of development of hearing loss using five factors—duration of symptoms before admission, absence of petechiae, CSF glucose level, infection by *S. pneumoniae*, and ataxia—and were able to identify effectively patients at risk for developing hearing loss with excellent sensitivity (100%) using a cutoff of 0 on the point scale.

Because hearing deficits occur so commonly in patients with bacterial meningitis, hearing evaluation by evoked response audiometry in young, uncooperative children is recommended routinely at the time of or shortly after discharge from the hospital. Repeated audiometric evaluation is recommended after discharge if the results of the initial examination are abnormal. Pure tone audiometry can be used for older, cooperative children. Differentiation of hearing deficits resulting from conductive disturbances from deficits related to damage to the eighth cranial nerve is important. Some children who have repetitive episodes of otitis media may experience conductive loss that is unrelated to the meningitis.

In our studies, the mean IQ (±1 standard deviation) of the entire group of patients (235) after recovery was 94 (±23 standard deviations), with a range of 33 to 150. Twenty-nine children (17.3%) had IQs less than 80, and 22 (11.6%) had IQs less than 70. A comparison of these patients with their siblings and other control children revealed no significant difference in mean IQ. A significantly greater proportion ($p < .01$) of children who recovered from meningitis had IQs less than 80 compared with children from control groups. These results differ from those of Sell,[337] which were noted previously. Tejani and associates[372] also prospectively evaluated children who had recovered from bacterial meningitis using siblings as controls. They reported no significant differences in verbal performances or full-scale IQs between patients with meningitis and the sibling control population.

The prospective nature of these studies has permitted an assessment of factors that herald a poor prognosis and that may be discernible at or near the time of admission. Evidence of inappropriate secretion of ADH was correlated significantly ($p < .01$) with abnormal neurologic examinations at 3 months after discharge and with low IQs. The age of the child correlated inversely with the development of subdural effusion ($p < .01$), the occurrence of hearing deficits ($p < .02$), and low IQ ($p < .05$). The significantly increased impact of the disease on young children could be documented conclusively. The presence of focal neurologic findings in patients who were not postictal at the time of admission correlated significantly ($p < .001$) with abnormal neurologic examination, which was noted previously. Focal deficits indicating cerebral injury noted at admission or during the course of hospitalization were associated significantly ($p < .001$) with the development of late (1 to 15 years after discharge) afebrile seizures.[293] Focal neurologic findings at the time of admission proved to be a reliable predictor of permanent sequelae of bacterial meningitis. Focal deficits at admission also correlated significantly with low IQs ($p < .001$), even at 2 and 3 years after discharge from the hospital. The quantity of antigen in the initial CSF specimen and the number of organisms present also correlated significantly ($p < .01$) with sequelae of meningitis.[116]

Systematic review of neurocognitive impairment in children after CNS infection revealed deficits in cognition and motor function to be very common.[60] Koomen and associates[222] reported one third of Dutch children with non-*H. influenzae* type b meningitis were found on follow-up to have academic or behavioral limitations or both. Childhood meningitis survivors also were found to have a higher incidence of nonspecific symptoms, such as headaches, and significantly more symptoms of inattention, hyperactivity, and impulsiveness compared with nearest-age siblings.[37]

Only one study assessed the value of the Pediatric Risk of Mortality (PRISM) score in predicting outcomes of bacterial meningitis.[244] This study was done in a subgroup of children requiring mechanical ventilation. The best predictor of death and functional states on follow-up evaluation was the PRISM score. When the score was less than 20 within the first 24 hours of admission to the pediatric intensive care unit, a favorable outcome was noted in 82 percent. When the score was 20 or higher, a favorable outcome was noted in only 30 percent ($p < .009$).

CT has revealed evidence of cerebral infarction in children who had a diagnosis of bacterial meningitis established within 1 or 2 days of the onset of symptoms of a febrile illness.[352] In most of these cases, abnormalities in cerebrovascular dynamics (arteritis, thrombosis, thrombophlebitis), ventricular dilation, or both have been observed. In some of these cases, infarction has been associated with profound hypotension related to endotoxemia (personal experience). Brain infarction apparently is *not* related causally to a delay in diagnosis and therapy in many cases.

PREVENTION

HAEMOPHILUS INFLUENZAE MENINGITIS

Since the 1980s, methods of preventing meningitis caused by *H. influenzae* type b have improved. The dramatic decrease in the incidence of *H. influenzae* type b invasive disease and meningitis has been attributed to the introduction of vaccines that initially were found to be effective at 15 months of age[12] and then later found to be effective at 2 months of age.[352] Currently, three conjugate vaccines are approved for infants beginning at 2 months of age: HbOC, PRP-OMP, and PRP conjugated to tetanus toxoid (PRP-T). The ACIP and the AAP recommend universal infant immunization with HbOC or PRP-T at 2, 4, and 6 months of age or PRP-OMP at 2 and 4 months of age.[10,64]

Passive immunization of infants also has been studied with use of bacterial polysaccharide immunoglobulin.[8,321] This preparation given in a single intramuscular dose of 0.5 mL/kg provides significant protection for infants from *H. influenzae* type b disease for 3 or 4 months.

The most comprehensive study concerning the spread of *H. influenzae* type b infection among household contacts was coordinated by the CDC.[391] Data collected from 19 states were analyzed prospectively. *H. influenzae* meningitis was reported in 1403 patients. Eighty-two percent of exposed families were investigated for the occurrence of *H. influenzae* disease within 30 days of its onset in the index patient. Systemic disease caused by *H. influenzae* type b developed in 9 of 1687 contacts (0.5%) who were younger than 6 years. The risk of infection in patients younger than 4 years was 2.1 percent; the risk in children younger than 1 year was 6 percent. The risk of secondary infection of household contacts in the 30 days after onset of meningitis in the index case was 585 times greater than the age-adjusted risk in the general population and was similar to the risk of secondary meningococcal disease in household contacts. This nationwide study provided an important impetus for finding a chemoprophylactic regimen that could prevent secondary infection in household contacts.

A nationwide, collaborative, placebo-controlled trial was conducted subsequently among household (children <6 years old) and daycare center contacts of individuals with invasive *H. influenzae* type b disease.[30] Four of 765 placebo-treated contacts experienced secondary disease versus none of 1112 rifampin-treated contacts ($p = .027$).

The AAP Committee on Infectious Diseases recommends that rifampin be provided orally once each day for 4 days in a dose of 20 mg/kg (maximum dose 600 mg/day) to all household contacts (children and adults) regardless of age in households with at least one unvaccinated contact younger than 4 years.[10] The dose for infants younger than 1 month is not established, but it may be reduced to 10 mg/kg. Rifampin prophylaxis is not required, however, when all of the household contacts younger than 4 years have been fully immunized. All members of households with a fully immunized but immunocompromised child, regardless of age, should receive rifampin because of concern that the immunization may not have been effective.

When two or more cases of invasive disease have occurred within 60 days and unimmunized or incompletely immunized children attend a daycare facility, rifampin should be administered to all personnel and attendees. When a single case has been reported, the use of rifampin is controversial, and many experts recommend *no* prophylaxis.[10] Unimmunized or incompletely immunized children should receive a dose of vaccine and should be scheduled for completion of the recommended age-specific immunization schedule.

No data document the safety of rifampin administered during pregnancy. Prophylaxis with rifampin is not recommended for pregnant women who are contacts of infected infants.

Patients receiving rifampin should be advised routinely that their urine, sweat, and tears will be stained orange. Individuals should be advised to refrain from using contact lenses while receiving rifampin therapy because the lenses may be stained permanently.

PNEUMOCOCCAL INFECTION

In a large randomized trial conducted by Black and colleagues,[45] more than 37,000 infants received either the seven-valent pneumococcal vaccine containing polysaccharides of serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F conjugated to CRM_{197} or meningococcal serogroup C oligosaccharide conjugated to the same protein. Vaccines were administered at 2, 4, 6, and 12 to 15

months of age. The pneumococcal conjugate vaccine was found to be 97.4 percent efficacious in preventing acquisition of invasive pneumococcal infections caused by vaccine serotype isolates. As a result of this study, the seven-valent pneumococcal protein conjugate vaccine is recommended by the ACIP and the AAP Committee on Infectious Diseases for all children younger than 24 months of age to prevent invasive pneumococcal infections.[14,67] Vaccine also is recommended for children 25 to 60 months of age with high risk of acquiring invasive disease and should be considered for otherwise normal children in this age range with other risk features that may increase their risk for development of systemic pneumococcal infection. Antibiotic chemoprophylaxis of children exposed to pneumococcal meningitis is not recommended regardless of immunization status.[9] In asplenic patients (functional and anatomic), daily chemoprophylaxis against pneumococcal infection is recommended with oral penicillin therapy.[9] The reader is referred to the CDC and AAP statements for the details of these recommendations.

MENINGOCOCCAL INFECTION

We advocate the use of chemoprophylaxis in all household members of a patient with meningococcal meningitis and in daycare and nursery school contacts, preferably within 24 hours of the diagnosis of the primary case.[11] Prophylaxis may be provided for individuals who had contact with the patient's oral secretions through kissing or sharing toothbrushes or eating utensils during the 7 days before onset of disease in the index case. Prophylaxis is not recommended routinely for health care personnel unless they have had close exposure through mouth-to-mouth resuscitation, intubation, or suctioning before antibiotic therapy was initiated. Schoolroom classmates and hospital contacts of patients usually are not given prophylactic treatment.

Minocycline and rifampin have proved to be 80 to 90 percent effective in eradicating carriage of meningococci.[171] Both drugs are secreted in the saliva in concentrations greater than the MICs for meningococci. The use of minocycline has been accompanied by frequent and significant vestibular reactions, even after a single dose of 100 mg, and, in our opinion, generally should not be used.[61-63,400]

Rifampin is the drug of choice in most instances and can be used in a dose of 600 mg twice daily for four doses in adults and in doses of 10 mg/kg/dose for four doses in children 1 to 12 years of age. A dose of 5 mg/kg every 12 hours for four doses can be used in children 3 months to 1 year of age.[266] The emergence of rifampin-resistant strains in treated meningococcal carriers has been reported to occur with a frequency of 0 to 27 percent.[83,99,396]

A single intramuscular dose of ceftriaxone has proved to be an effective alternative to rifampin for prophylaxis in meningococcal contacts.[335] This approach to prophylaxis may be particularly useful in circumstances in which compliance with the use of oral rifampin is considered questionable. The efficacy of ceftriaxone has been confirmed for only group A strains, but its effect is likely to be similar for other serogroups. Ceftriaxone has the advantage of easier dosage and administration and safety in pregnancy.[11] Ceftriaxone may be given intramuscularly in a dose of 125 mg for individuals younger than 12 years old and in a dose of 250 mg for individuals 12 years and older.

Ciprofloxacin given to adults in a single oral dose of 500 mg has been effective in eradicating meningococcal carriage.[11] Ciprofloxacin presently is not recommended for individuals younger than 18 years old or for pregnant women.

Because secondary cases may occur several weeks or more after onset of disease in the index case, meningococcal vaccine may be used as an adjunct to chemoprophylaxis when an outbreak is caused by a serogroup contained in the vaccine. The CDC has outlined recommendations for the administration of the meningococcal serogroup C vaccine to control outbreaks.[65]

A serogroup-specific quadrivalent polysaccharide meningococcal vaccine against group A, C, 4, and W135 *N. meningitidis* is approved for use in the United States in children 2 years old and older. The vaccine consists of 50 μg each of the respective purified bacterial polysaccharides. It may be given subcutaneously as a single 0.5-mL dose and can be given concurrently with other vaccines. Immunization with the meningococcal quadrivalent polysaccharide vaccine is recommended for children aged 2 to 10 years in high-risk groups, including children with anatomic or functional asplenia and children with terminal deficiencies of the complement system or with properdin deficiency.

In January 2005, the Food and Drug Administration approved a quadrivalent meningococcal conjugate vaccine, MCV4, which includes serotypes A, C, Y and W-135 for individuals 11 to 55 years old. Because of the conjugate vaccine's ability to induce a T-cell-dependent immune response and subsequently longer immunologic memory compared with polysaccharide vaccines, it is advantageous. The ACIP and the AAP made recommendations that the MCV4 vaccine be given to young adolescents at the 11- to 12-year visit, adolescents at high school entry or 15 years of age (whichever comes first), and students entering college planning to live in a dormitory,[15,44] with the goal of immunizing all adolescents by 2008. In addition to its use in the approved age group, MCV4 has been evaluated for use in the younger pediatric population. Pichichero and associates[291] showed an equivalent safety and tolerability profile of MCV4 compared with the quadrivalent polysaccharide vaccine and "significantly higher and more persistent serum bactericidal antibody responses against meningococcal serogroups A, C, Y, and W-135."

A single dose of serogroup C vaccine seems to be approximately 70 percent effective, for a period of 6 to 9 months, in preventing meningococcal disease in children who are older than 2 years.[369] Single 50-μg injections in children younger than 2 years of age do not produce adequate antibody responses.[369] A serogroup A polysaccharide vaccine has been field tested by the World Health Organization and is effective in children aged 3 months or older.[287,387] Serogroup-specific monovalent vaccines may be used to control outbreaks of disease caused by either type A or type C meningococci and may be valuable for travelers to countries with epidemic disease.[11,105] The vaccine is administered as a single dose parenterally in the volume specified by the package insert. Reactions noted after immunizations previously have been mild and infrequent; localized erythema of 1 or 2 days' duration is not unusual. The safety of the vaccine in pregnant women has not been established.

An effective serogroup B meningococcal vaccine has not been produced to date. The polysaccharide capsule cross-reacts with fetal neural tissues causing autoantibodies. Different strategies have been tried to develop a safe vaccine against serogroup B meningococcus, including use of outer membrane proteins (OMP) and lipopolysaccharide components.[182] Although OMP vaccines possess efficacy in older children and adults, the highest rates of serogroup B disease are in infants and young children, in which the OMP vaccines do not show efficacy.[70] Complete sequencing of the *N. meningitidis* serogroup B genome offers new membrane protein targets for vaccine targeting.[178] Similar to other protein conjugate vaccines, meningococcal C conjugate vaccines are more immunogenic than is the pure polysaccharide vaccine in infants younger than 2 years of age.[243] Because of a high incidence of meningococcal disease in the United Kingdom, a meningococcal serogroup C CRM_{197} was administered in a phased program beginning November 1999 to all children younger than 18 years.[302] Surveillance studies to assess short-term efficacy have shown a 97 percent efficacy for teenagers and a 92

percent efficacy for toddlers in the prevention of meningococcal serogroup C infection.

CHAPTER 38

Parameningeal Infections

Xavier Sáez-Llorens ❂ Javier Nieto Guevara

BRAIN ABSCESS

Brain abscess is an uncommon infection, but it remains a serious and life-threatening disease in children despite advances that have been made in diagnosis and management. Abscess formation may occur in the parenchyma of the central nervous system, in the subdural space, or in the epidural space. It can originate from contiguous site infections (e.g., skull osteomyelitis, chronic otitis), from underlying vascular anomalies (e.g., congenital cyanotic heart disease), after head trauma or neurosurgical procedures, or from cryptogenic sources. These conditions can alter neurologic function by direct destruction of nervous tissue, by infarction after inflammatory occlusion of veins and arteries, or by compression caused by mass effect.

Advances in diagnostic and therapeutic modalities since the 1990s have improved the prognosis of this serious disease. The mortality rate associated with brain abscesses seems to be decreasing. This reduction probably is the result of the advent of head imaging and its use to guide precise location and management, improvement in surgical techniques, and advances in antibiotic development. Goodkin and coworkers[43] identified 54 patients aged 5 days to 34 years of age who were diagnosed with a brain abscess at the Boston Hospital from 1945 to 1980 and 1981 to 2000. They found a reduction in the number of abscesses that occurred in the setting of sinus or middle ear infection (26% versus 11%, respectively) and an increase in the number of children who were treated with antibiotics alone (1% versus 22%). These investigators did not observe, however, any additional decline in the mortality rates in their institution between 1981 and 2000. Fischer and associates[17] found a reduction in mortality rate from 36 percent before 1970 to 14 percent after 1970. Tekkok and Erbengi[45] described a similar decline, from 30 percent in the era before the use of computed tomography (CT) to 6 percent in the last 5 years of their study and zero in the last 3 years of their study. Other case series also have reported a mortality rate of zero.[29]

Although the mortality rate seems to be decreasing, a significant percentage of children continue to have residual neurologic deficits, including epilepsy, permanent motor or sensory dysfunction, visual field defects, and personality changes.[17,20,25] Some children also require placement of a ventriculoperitoneal shunt.[10]

PATHOGENESIS AND PATHOLOGY

Brain abscess is a focal, intracerebral infection that begins as a localized area of cerebritis and eventually ends in a collection of pus surrounded by a well-vascularized capsule. For practical purposes, brain abscesses usually are classified according to the likely entry point of the infection (Table 38–1). Ear and mastoid infections are associated with formation of an abscess at the temporal or cerebellar locations; sinus and dental infections give rise to purulent collections in the frontal lobe; and metastatic spread from distant foci in children with congenital cardiac or pulmonary right-to-left shunts commonly results in involvement of any parenchymal area, including parietal or occipital regions.[17,28,41]

The most common origin of microbial infection in children remains direct or indirect cranial infection arising from the middle ear, paranasal sinuses, or teeth. Seeding of the brain presumably occurs via transit of infecting microbes through the valves and emissary veins that serve these regions. A direct erosion of skull and dura by osteomyelitis-induced sinus or middle ear infection can be another mechanism of bacterial spread.[7] Resulting abscesses tend to be solitary and superficial. Metastatic inoculation of the brain from distant extracranial sources (pulmonary infection, endocarditis) tends to provoke multiple cerebral abscesses, with a distribution that reflects the regional cerebral blood flow of the area affected, usually the middle cerebral artery network.[7]

In children with cyanotic congenital heart disease, bacteria are not filtered out by the pulmonary vascular bed, which allows for systemic spread.[10] This situation rarely occurs in patients younger than age 2 years, and the abscess or abscesses usually are in areas of brain perfused by the middle cerebral arteries. Evidence of associated endocarditis is rare in these cases, although acute bacterial endocarditis may be complicated by septic infarction of the brain and abscess formation.[36]

TABLE 38–1 Primary Source, Usual Location of Lesion, and Associated Neurologic Findings in Children with Brain Abscess

Primary Source	Location of Abscess	Associated Neurologic Findings
Upper respiratory site		
Sinusitis	Frontal lobe	Headache, behavioral changes, motor speech disorders, depressed consciousness, forced grasping and sucking, hemiparesis
Chronic otitis/mastoiditis	Temporal lobe	Dyspraxia and aphasia (dominant hemisphere), ipsilateral third cranial nerve palsy, ipsilateral headache, upper homonymous hemianopsia, motor dysfunction of face and arm
	Cerebellum	Dizziness, vomiting, ipsilateral ataxia and tremor, sixth cranial nerve palsy, nystagmus (toward lesion)
Dental infection	Frontal lobe	
Head trauma	Related to injured site	Variable by region involved
Postoperative	At operative site	Variable by region involved
Metastatic spread	Multiple lesions	Variable by region involved
	If parietal lobe involved	Visual field defects in inferior quadrant, homonymous hemianopsia, dysphasia (dominant hemisphere), dyspraxia and contralateral spatial neglect (no dominant hemisphere)

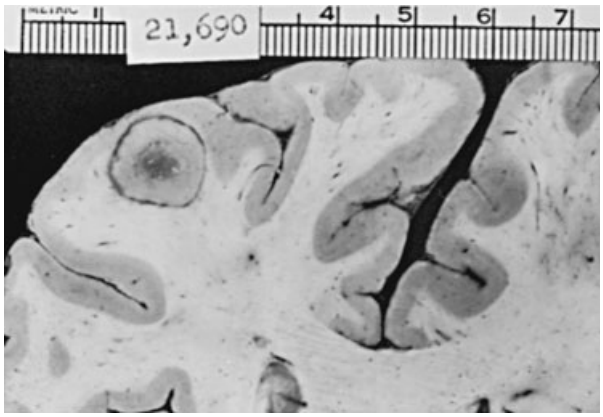

Figure 38–1 Circumscribed cerebral abscess of hematogenous origin.

Formation of an abscess by direct bacterial implantation may complicate compound skull fractures, scalp wounds, anterior cranial fossa or temporal bone fractures, and chronic cerebrospinal fluid (CSF) fistula. Abscesses also rarely may develop during the course of bacterial meningitis.[40] Despite identification of all these potential routes, 20 to 30 percent of cases are classified as cryptic brain abscess for which no obvious predisposing factor can be identified.

The brain is remarkably resistant to microbial infection. Despite the common occurrence of occult bacteremia in infants and children, cerebral abscess is a quite rare disease. This resistance is attributable in part to the abundant blood supply of the brain and the relative impermeable blood-brain barrier.[1] Although certain underlying brain morbidities, such as previous stroke, intracerebral hematoma, or underlying neoplasm, may serve as a nidus of abscess formation in adults, affected children have no apparent predisposing brain lesion. In animal models of infection, induction of abscess usually requires direct inoculation of numerous organisms into the animal's cerebrum.[34]

Experimental animal studies and use of CT scanning techniques have provided evidence of the clinical evolution of a brain abscess.[2] In the early stage of cerebritis (days 1 to 3), a focal area of acute inflammation, vascular dilation, microthrombosis, rupture of small vessels, and edema are present. The center of the lesion then undergoes liquefaction. Expansion of the cerebritis and formation of a necrotic central focus are seen in the late cerebritis stage (days 4 to 9). Establishment of a ring-enhancing dense collagenous capsule of well-vascularized tissue with peripheral gliosis or fibrosis or both occurs at the early capsule stage (days 10 to 14). Finally, during the late capsule stage (>14 days), host defenses act to wall off the abscess, and a well-developed capsule results.

Death can occur if the volume of pus and surrounding edema induce a significant increase of intracranial pressure (ICP) leading to brain herniation. In addition, cerebral abscesses can rupture into the ventricular system or through the cortex into the subarachnoid space, resulting in acute deterioration and a life-threatening event.[10] Figure 38–1 shows the gross appearance of a well-defined abscess of hematogenous origin. Various microscopic features are illustrated in Figures 38–2, 38–3, and 38–4.

The spectrum of microorganisms cultured from brain abscesses has changed with time. This change reflects improved microbiologic isolation techniques, early and aggressive treatment of primary infections, and better neurosurgical procedures. In most more recent series, the predominance of *Staphylococcus aureus* has decreased, and identification of anaerobes has increased.[6,13,47]

Anaerobic bacteria isolated from brain abscesses include species of *Bacteroides*, *Peptostreptococcus*, *Fusobacterium*, *Veillonella*, *Propionibacterium*, *Prevotella*, and *Actinomyces*. Aerobic and microaerophilic streptococci, staphylococci, *Haemophilus* spp., gram-negative enteric bacilli, and *Pseudomonas aeruginosa* also are implicated frequently. In children with impaired host defenses, fungal etiology (*Candida*, *Aspergillus*, *Cryptococcus*, *Histoplasma*, *Coccidioides*, and *Mucor* spp.) or uncommon pathogens, such as *Toxoplasma*, *Nocardia*, *Mycobacterium*, and *Listeria* spp., can be identified.[17] Parasites such as amebae, *Cysticercus*, *Schistosoma*, or *Paragonimus* are very rare causative pathogens.[18] *Citrobacter koseri (diversus)* and *Enterobacter sakazakii* are particularly able to cause brain abscesses in neonates.

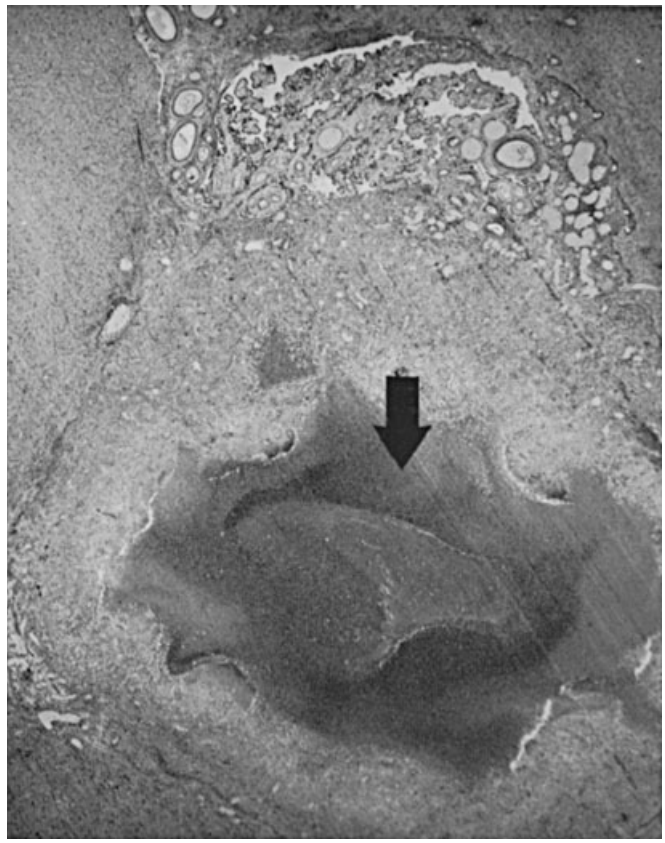

Figure 38–2 Area of necrosis and liquefaction in a cerebral abscess *(arrow)*.

In order of etiologic importance, the predominant organisms causing brain abscess in children are aerobic and anaerobic streptococci (60-70% of cases), gram-negative anaerobic bacilli (20-40%), Enterobacteriaceae (20-30%), *S. aureus* (10-15%), and fungi (1-5%).[3-6,13,17,28,34,35,41,47] Multiple aerobic and anaerobic organisms are isolated in approximately one third of patients, especially in patients with chronic otitis. No growth is reported from 30 percent of properly handled purulent specimens. A reasonable speculation of the likely causative microbes can be made according to the predisposing source of infection (Table 38–2).

CLINICAL MANIFESTATIONS

The clinical presentation of a brain abscess depends on the size of the collection, its location, the multiplicity of lesions, the host's immune status, and the age of the patient. Generally, symptoms and signs can be related to the effect of a space-occupying mass, to the focal neuronal dysfunction of the parenchymal region

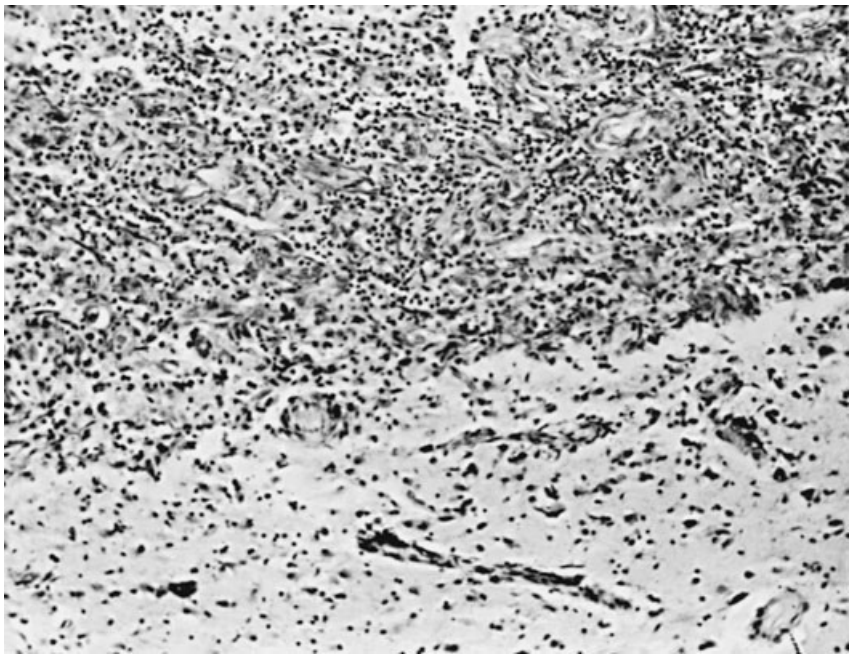

Figure 38–3 Astroglia and fibroblasts forming the capsule of a cerebral abscess.

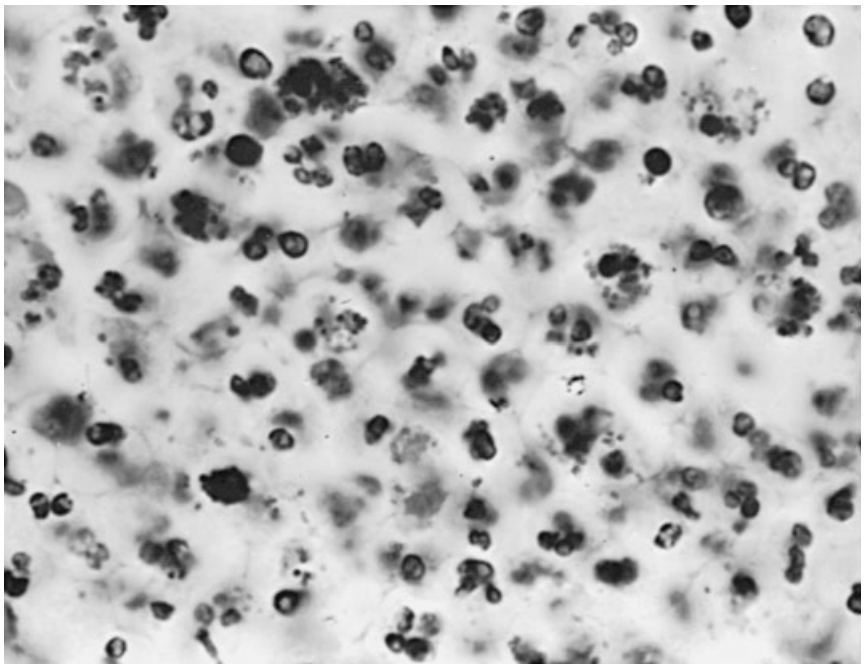

Figure 38–4 Mononuclear and polymorphonuclear leukocytes are in the center of a cerebral abscess.

involved (see Table 38–1), or to accompanying clinical findings of the underlying predisposing infection. Because on early evaluation most children with cerebral abscess present with vague or nonspecific signs and symptoms, the physician must have a high index of suspicion to recognize the condition as early as possible (Table 38–3). When a patient develops significant alterations in mental status, the prognosis is most ominous.[10,41]

In older children and adolescents, headache is the most common initial symptom. Irritability occurs more commonly in infants and small children. The nature of the headache has no particular distinguishing features and usually is poorly localized. A sudden worsening of a preexisting headache can indicate rupture of the brain abscess into the ventricular space, which has a poor prognosis.[8,16]

Absence of fever should not be used to exclude the diagnosis of brain abscess because this sign is detected in only approximately one half of affected children. Drowsiness, confusion, and vomiting occur frequently during the acute phase of disease. Lethargy, stupor, and coma usually are later events and potentially associated with adverse outcome. Papilledema is present in less than one fourth of the cases, but its presence requires immediate neurosurgical assessment and CT scanning.

Focal neurologic disturbances reflect the location of the abscess and can be detected in 30 to 50 percent of cases on presentation (see Tables 38–1 and 38–3).[48] Frontal location is characterized by development of motor speech disorders, memory deficits, personality changes, and depressed consciousness. Hemiparesis occurs with lesions in the postfrontal region or as a con-

TABLE 38–2 Primary Source, Usual Etiologic Pathogens, and Recommended Empiric Antibiotic Therapy in Children with Brain Abscess

Primary Source	Usual Etiologic Microorganisms	Recommended Empiric Antibiotic Combination
Upper respiratory infection		
Sinusitis/dental infection	Viridans and anaerobic streptococci, *Haemophilus* spp., *Fusobacterium* spp., *Bacteroides* spp. (non-*fragilis*)	Penicillin or cefotaxime/ceftriaxone + metronidazole or ampicillin + chloramphenicol or sulbactam
Chronic otitis/mastoiditis	Aerobic and anaerobic streptococci, gram-negative enteric bacilli, *Bacteroides* spp. (including *B. fragilis*), *Pseudomonas aeruginosa*	Penicillin + metronidazole + ceftazidime
Head trauma	*Staphylococcus aureus*, aerobic streptococci, gram-negative enteric bacilli	Oxacillin/nafcillin (vancomycin) + cefotaxime/ceftriaxone
Postoperative	*Staphylococcus epidermidis*, *S. aureus*, gram-negative rods, *P. aeruginosa*	Vancomycin + ceftazidime
Metastatic spread		
Endocarditis	*S. aureus*, viridans streptococci	Oxacillin/nafcillin (vancomycin) + cefotaxime/ceftriaxone + metronidazole
Pulmonary infection	Aerobic streptococci, *Actinomyces*, *Fusobacterium*	Oxacillin/nafcillin (vancomycin) + cefotaxime/ceftriaxone + metronidazole
Congenital heart disease	Viridans streptococci, *Haemophilus* spp., *Haemophilus aphrophilus*	Cefotaxime/ceftriaxone + metronidazole or ampicillin + chloramphenicol or sulbactam
Bacterial meningitis	*S. pneumoniae*, *Haemophilus influenzae* type b, *Salmonella* spp., *Citrobacter* (neonates)	Cefotaxime/ceftriaxone ± vancomycin (resistant pneumococcal strains)
Cryptogenic source and immunosuppression*	Any type of microorganisms	Oxacillin/nafcillin (vancomycin) + ceftazidime + metronidazole
	Nocardia, fungi, *Mycobacterium tuberculosis*	Oxacillin/nafcillin (vancomycin) + ceftazidime + metronidazole

**In areas with significant prevalence of methicillin-resistant staphylococcal strains or penicillin allergy, immunosuppressed children should be treated with broad coverage and with consideration of amphotericin B therapy. Antituberculous therapy should be considered for children with exposure to tuberculosis. Antibiotic regimens are likely to vary by geographic location based on resistant organisms.*

TABLE 38–3 Frequency of Presenting Signs and Symptoms in Children with Brain Abscess

Symptoms	%	Signs	%
Headache	60-70	Focal neurologic deficits	35-50
Fever	50-80	Papilledema	30-40
Vomiting	35-55	Meningeal signs	25-35
Seizures	30-45	Hemiparesis	20-30
Mental changes	30-40	Nerve palsy	10-20
Coma	15-20	Ataxia	5-15

sequence of uncal herniation. Abscess in the temporal lobe is characterized by a contralateral homonymous upper quandrantopia. If the dominant hemisphere is affected, nominal dysphasia and aphasia are characteristic symptoms. Patients with cerebellar abscesses classically exhibit dizziness, nystagmus, defective conjugate eye movements, ataxia, tremor, and hypotonia. Seizures occur in at least 30 to 45 percent of patients, may be focal or generalized, and may occur at any time during the course of the disease. If the parietal region is involved, visual field defects, homonymous hemianopsia, dysphasia, and dyspraxia can be present.

The rapidity with which symptoms develop can vary substantially. Most patients are symptomatic within 1 week of the onset of formation of an abscess. Immunocompromised children can have a more insidious progression of clinical findings. The presentation of brain abscess in infancy can be suspected by bulging fontanelle, vomiting, irritability, and an enlarging head circumference. Seizures occur commonly, particularly in small infants, and at any time during the course of the disease.[14] School-aged children with cyanotic congenital heart disease, notably tetralogy of Fallot or transposition of the great vessels, also can exhibit symptoms and signs related to their chronic cardiac disease.

RUPTURE OF BRAIN ABSCESS INTO THE VENTRICULAR SYSTEM

Rupture of an abscess into the ventricle with consequent ventricular empyema is a dreaded complication because the mortality rate is greater than 50 percent, and residual neurologic deficits, including hydrocephalus, are the rule in patients who survive. Frequently, rupture occurs before the diagnosis of abscess has been established and surgical removal can occur. A sudden worsening in the patient's clinical state heralds this event. High fever, shock, meningismus, and altered consciousness are prominent clinical signs.

Rupture of the abscess into the ventricle is seen more frequently in patients with deep-seated abscesses or in immunocompromised patients.[44] Although a modest pleocytosis and elevated protein concentration in CSF may have been identified earlier, the findings of 50,000 to 100,000 polymorphonuclear leukocytes and markedly reduced glucose concentration in the CSF are usual findings. Organisms may be seen on smear of the CSF and cultured from the fluid. In other words, the patient has developed purulent meningitis, and treatment must include high doses of antibiotics and surgery (see the treatment section).

The concurrence of abscess and meningitis in the past has led to the assumption that brain abscess can be a complication of meningitis; this rarely, if ever, is the case, although meningitis may develop during the incipient stages of abscess formation after intracranial invasion of organisms from a contiguous extracranial source. In such circumstances, the abscess may seem to be a consequence of the leptomeningitis. Given a potential source of infection in the ear or paranasal sinuses, the clinician must be wary and appreciate the possibility of this sequence of events. Abscess has been reported to complicate *Citrobacter* meningitis in infants, but careful pathologic study has shown vasculitis and liquefaction necrosis of the white matter without capsule formation.[47]

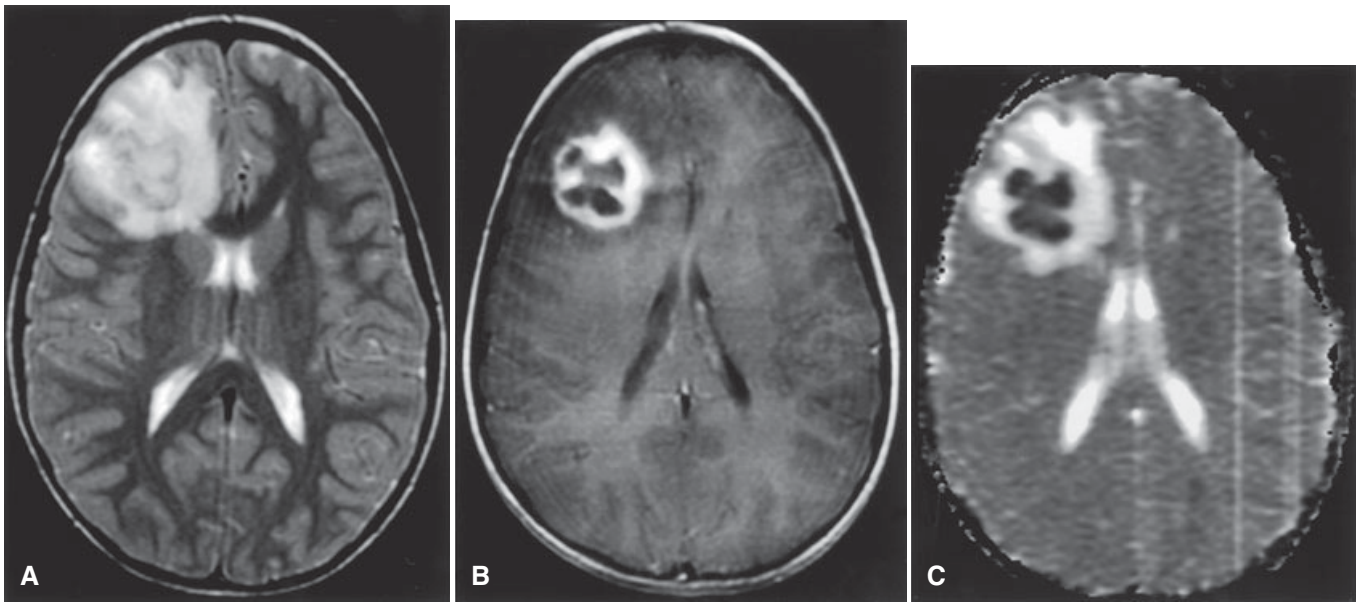

Figure 38–5 Bacterial abscess in a 10-year-old girl. **A,** Axial T2-weighted magnetic resonance (MR) image shows an irregular mass in the right frontal lobe with a hypointense wall *(arrows)* and surrounding vasogenic edema. **B,** Gadolinium-enhanced T1-weighted MR image shows intense, smooth enhancement of the capsule. **C,** Apparent diffusion coefficient map from a line-scan, diffusion-weighted study shows decreased signal within the cavity, compatible with restricted diffusion and suggesting an abscess cavity rather than tumor necrosis. *(Courtesy of F. Kim, M.D., Northwestern University School of Medicine, Chicago.)*

LABORATORY DIAGNOSIS

Laboratory tests frequently are not helpful in supporting the clinical diagnosis of brain abscess.[10,33,41] Children usually have unremarkable leukocyte counts, and the erythrocyte sedimentation rate can be normal. Blood cultures rarely are positive. Performance of a lumbar puncture is potentially dangerous because it can be associated with brain stem herniation.[9] In addition, CSF analysis uncommonly provides useful clinical information. Usual CSF findings include an elevated protein, mild mononuclear pleocytosis, and hypoglycorrhachia. CSF cultures usually are negative, unless the abscess has drained into the ventricular system or has been a complication of meningitis.

Culturing abscess material obtained at the time of surgical drainage provides the best opportunity to make a microbiologic diagnosis. Proper handling and processing, with attention given to optimal anaerobic and aerobic isolation techniques, can identify the causative organism in most cases, especially when antimicrobial therapy has not been instituted previously.[33] When the clinical condition warrants immediate use of empiric antibiotics, Gram stain of the purulent material frequently can help direct selection of the appropriate antibiotic.

DIAGNOSIS

Magnetic resonance imaging (MRI) is the modality of choice for the diagnosis and localization of cerebral abscesses. Similar MRI findings can be observed in infarction, demyelinating disorders, and neoplastic processes. Diffusion-weighted MRI and magnetic resonance spectroscopy have been shown to be effective methods in differentiating cerebral abscesses from tumors.[5,34] Figure 38–5 illustrates the appearance on MRI of a right frontal cerebral abscess in a 10-year-old girl. CT scanning remains an excellent alternative, however, if MRI is unavailable (Fig. 38–6). Intrave-

Figure 38–6 Contrast-enhanced computed tomography (CT) scan shows a ring-enhancing left frontal cerebral abscess *(arrows)* in a 3-week-old boy with concurrent *Enterobacter* meningitis. *(Courtesy of C. D. Robson, M.D., Harvard Medical School, Boston, MA, and P. D. Barnes, M.D., Stanford University School of Medicine, Stanford, CA.)*

nous administration of contrast material is advised because the abscess may be missed otherwise.[12,26] Serial CT or MRI scanning, performed weekly or biweekly, provides evaluation of the response to therapy and of the need for repeating the surgical procedure. MRI is more accurate than is CT for establishing the diagnosis of cerebritis, cerebellar, edema formation, and brain stem purulent collections.[19,24] On T1-weighted sequences, brain abscesses appear hypointense and show ring enhancement after administration of intravenous gadolinium. In contrast, on T2-weighted images, the typical mature abscess has a hyperintense central area of pus surrounded by a well-defined hypointense capsule and surrounding edema.

Because specific images allow precise lesion staging, this information provides important clues for the surgeon to suspect the likelihood of encountering purulent material of a well-developed abscess at the moment of drainage. The presence of gas within the abscess cavity on head imaging suggests communication of the abscess with air outside the skull, although gas-forming bacteria in the abscess cavity rarely may be responsible.[49]

Plain skull films generally are normal in children with brain abscess. In small infants, separation of cranial sutures indicates intracranial hypertension. Radionuclide brain scan, arteriography, and ventriculography have been replaced largely by CT and MRI for the diagnosis of brain abscess. Indium-labeled leukocyte scans and thallium-brain single photon emission computed tomography (SPECT) to differentiate brain abscess from tumor in questionable cases have not been studied adequately in the pediatric population, but these methods seem promising in affected adults.[39]

Abnormalities on electroencephalography may be localized and can help in excluding a more generalized, bilateral intracranial disease, such as encephalitis. Unilateral slow waves (delta, 1 to 3/sec) characterize the usual electroencephalographic findings in cases of cerebral abscess.

After the diagnosis of brain abscess has been established, a careful search should be made for a source of infection serving as a site of origin for hematogenous spread or direct inoculation of organisms into the central nervous system. In addition to obtaining data from the history and physical examination, the physician should extend the MRI or CT evaluation to include the mastoids and paranasal sinuses. An echocardiogram should be obtained to assess for concurrent endocarditis. Other testing should be guided by the history and physical examination findings.

TREATMENT

No prospective clinical trials have compared various surgical and medical treatment strategies available to guide the management of cerebral abscesses in children. Most surgical and medical treatment guidelines are based on populations consisting primarily of adult patients. Appropriate management of brain abscesses apparently requires a combined surgical and medical approach,[31] with isolated medical management limited to patients who are neurologically intact and in whom the abscess is in the cerebritis stage[21] or the abscess or abscesses are small,[38] or to patients who are too unstable to undergo a surgical procedure.

The initial treatment of solitary and multiple brain abscesses relies on the aspiration of the cavity contents followed by the initiation of empiric antibiotic coverage while the cultures are processing. CT-guided or MRI-guided stereotactic aspiration is accurate, minimally invasive, and associated with few complications. Mamelak and colleagues[32] suggested performing head imaging biweekly or on any sign of clinical deterioration, with further aspiration if the cavity enlarges or fails to diminish in size after 3 to 4 weeks. Because excisions may be associated with increased risk of developing neurologic sequelae, surgery should be reserved for patients who do not respond to the strategy of repeated aspiration and medical management, and when an abscess results in a significant mass effect.

While results of cultures are pending, the selection of antibiotics should be guided by the primary source of infection, pertinent patient history, and results of microscopic examination of the pus (see Table 38–3). The appropriate duration of antimicrobial therapy for brain abscess is unclear. A 6- to 8-week course of parenteral antibiotics has been recommended traditionally, provided that the etiologic organisms are susceptible and adequate surgical drainage is achieved.[33] In selected cases with uncomplicated infection and complete surgical removal of a well-delineated abscess, shorter courses of treatment (3 to 4 weeks) are likely to be sufficient.[42] Nonetheless, many authorities recommend 2 to 3 months of additional oral antimicrobial therapy to prevent relapses.[10] In fungal, nocardial, and helminthic infection, surgical intervention frequently is required because of failure of medical treatment. Surgical procedures can be used to reduce increased ICP, obtain pus for microbiologic diagnosis, and enhance the antibiotic efficacy. In carefully selected patients (illness duration ≤2 weeks, neurologically intact, no signs of increased ICP, and abscess ≤3 cm in diameter), medical therapy alone can be successful.

With the advent of head imaging and the current methods of treatment employing head imaging, an overall reduction in the mortality rate has occurred; however, a high proportion of children with cerebral abscesses develop neurologic deficits. Eradication of potential sources of infection before the abscess has developed is logical preventive medicine. Early diagnosis and treatment are imperative and can be facilitated by the liberal use of MRI or CT scanning when this diagnosis is even a remote consideration.

ADJUNCTIVE AGENTS

The use of corticosteroids for treatment of brain abscess is controversial. These agents usually are indicated to control life-threatening intracranial hypertension that is associated with risk of herniation or when significant symptoms and signs are presumed to be the result of cerebral edema. Severe brain edema may necessitate the additional administration of intravenous mannitol. Steroids interfere with the inflammatory response, retard the encapsulation process, increase development of necrosis, potentially reduce antibiotic concentrations inside the purulent collection, and alter CT images.[37]

Anticonvulsants are recommended in children who have developed seizures potentially to prevent further episodes. Duration of anticonvulsant therapy should be individualized and guided by an electroencephalographic study in the follow-up phase of disease. Most authors recommend providing at least 3 months of prophylaxis if no more seizures have occurred.[10]

SUBDURAL EMPYEMA

Pyogenic infection in the subdural space is designated as subdural empyema or sometimes, but less correctly, as subdural abscess. The sources of infection and microorganisms responsible are the same as those encountered in brain abscess. It is a rare disease; only 1 case was seen at St. Louis Children's Hospital during a period when 122 patients with bacterial meningitis and 3 patients with cerebral abscess were treated. The primary source of subdural empyema in this single case was not found, which increasingly is true for the pediatric experience. Farmer and Wise[15] and Jacobson and Farmer[27] found associated meningitis in six of eight

infants with subdural empyema (seen over a 16-year period), suggesting that the latter was a complication of the former. We also have encountered this situation, albeit rarely, and the subdural fluid usually is turbid, rather than frankly purulent.

In older children, the infection apparently does not follow leptomeningitis. Although leptomeningitis may complicate subdural empyema, infections of the paranasal sinuses and mastoid region, usually chronic, spread to the subdural space directly because of osteomyelitis or by way of infected veins that penetrate the skull. Extension to cortical veins and to major venous sinuses frequently is associated with subdural empyema, as discussed elsewhere in this section. Why in some cases the infection is restricted to one or another anatomic site or sites (e.g., epidural space, subdural space, parenchyma of the brain or blood vessels) is unknown. Subdural empyema may be hematogenous in origin. It is an infrequent but recognized complication of intracranial surgery. The anatomy of the subdural space is such that the infection often extends widely over one or both cerebral hemispheres, and accumulation of pus in the parafalcine region occurs commonly.

CLINICAL MANIFESTATIONS

The symptoms and signs of the primary source of infection may be prominent, subtle, or absent. Increasingly severe headache, high fever, signs of meningeal irritation, and progressive neurologic deficits referable to the site of the lesion are reported in the typical untreated case. Focal or generalized seizures are prominent, especially in cases of cortical injury from associated vasculitis. Signs of increased ICP become prominent as the mass of pus enlarges. In infants, a fullness of fontanelle, vomiting, and depressed responsiveness are seen. Transillumination of the skull can be positive. Older children also may develop papilledema. As the ICP increases, symptoms and signs progress, ultimately leading to temporal lobe or cerebellar herniation and the characteristic syndromes of these complications.

DIAGNOSIS

The laboratory findings reflect the active infectious process. Peripheral leukocytosis and a predominance of polymorphonuclear leukocytes with immature cells frequently are seen. The CSF in infants reflects the common association with leptomeningitis, and the findings depend on when the fluid is examined. Before the meningitis has been treated adequately, organisms may be cultured; the glucose concentration may be low and the protein concentration high in the CSF. Later, the CSF findings are the same as those for treated meningitis, but viable organisms can be recovered from the subdural collections when the CSF is sterile. Specific antigens may be shown in subdural collections by tests such as countercurrent immunoelectrophoresis in the absence of viable organisms. In older children, the characteristic CSF findings include elevated pressure with a few to a few hundred or more leukocytes, with polymorphonuclear leukocytes predominating. The protein concentration frequently is elevated, the glucose concentration is normal, and the fluid is sterile.

In the past 2 or more decades, subdural empyema in children has become more difficult to diagnose clinically because of antimicrobial therapy. When initiated early, antimicrobial therapy may attenuate the dramatic nature of the disease, especially the symptoms and signs of acute infection. Because the diagnosis of subdural empyema often is confused with that of brain abscess, radiographic studies are necessary to establish the correct diagnosis. CT scanning (Fig. 38–7) and MRI are effective noninvasive techniques, as previously discussed in relation to brain abscess.

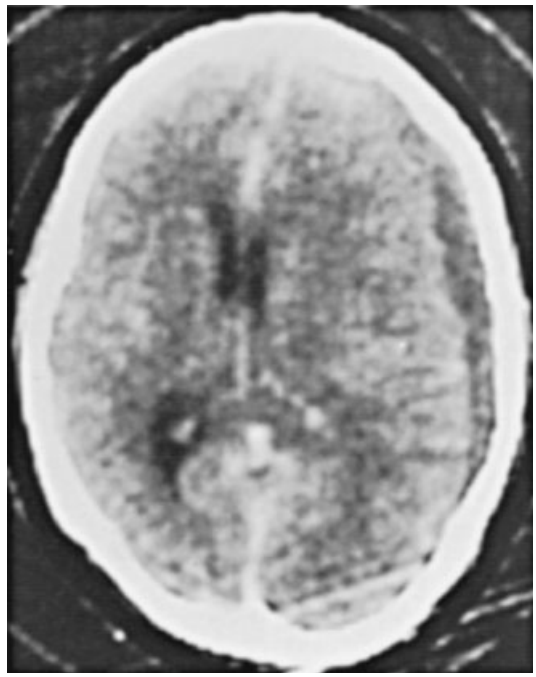

Figure 38–7 CT scan shows a subdural empyema with marked displacement of the ventricular system.

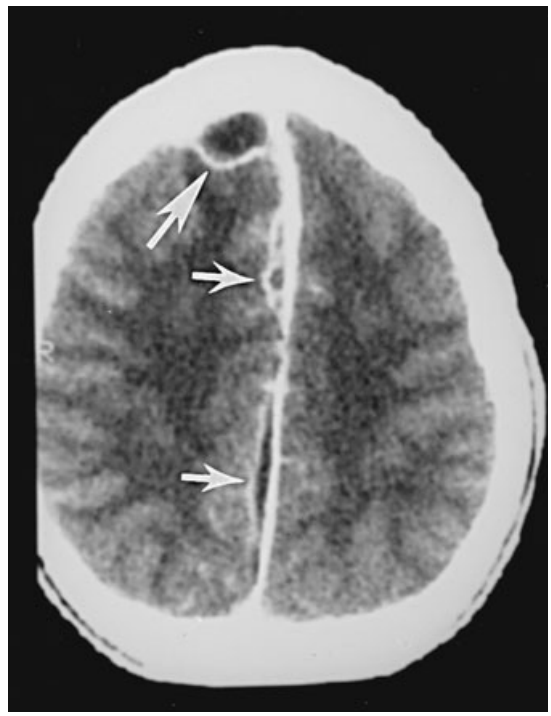

Figure 38–8 Contrast-enhanced CT scan shows a right frontal epidural abscess *(large arrow)* concurrent with an interhemispheric subdural abscess *(small arrows)* in a 13-year-old boy who developed headache, fever, and vomiting after fracture of the right frontal sinus. *(Courtesy of C. D. Robson, M.D., Harvard Medical School, Boston, MA, and P. D. Barnes, M.D., Stanford University School of Medicine, Stanford, CA.)*

Cerebral CT can show a failure of the cerebral vessels to approximate the inner surface of the skull. These studies reveal the extent of subdural disease and may define an epidural abscess or other infectious exudate collection concurrent with subdural empyema (Fig. 38–8).

TREATMENT

Until a causative organism is identified, the patient should receive broad-spectrum antibiotics intravenously in dosages appropriate for bacterial meningitis. After the offending organism is identified, the sensitivities of that organism to specific medications dictate selection of more precise antibiotic therapy. In infants, antibiotic therapy may be sufficient when the fluid is cloudy only, but if thick, purulent material is obtained by subdural paracentesis or, in older children, if the clinical and radiographic evidence indicates a subdural empyema, surgery is requisite. Depending on individual circumstances, craniotomy or multiple burr holes with irrigation of the subdural space should be accomplished.

Mortality and morbidity rates are high (20-40%) in most series but lower in some.[43,50] Early diagnosis and treatment are imperative. The early use of CT scanning seems to be responsible for improved therapeutic results.[50]

EPIDURAL ABSCESS

Because the dura mater is adherent to the inner aspect of the cranium, epidural abscesses rarely attain a large size, and they consequently do not exert significant pressure on the brain. They are important because they can serve as a focus for spread of infection into the subdural space, leptomeninges, or brain. The infection may involve local penetrating vessels and lead to their occlusion, with extension to venous sinuses and other vessels. Infection of the middle ear, mastoid bone, or ancillary air sinuses may lead to epidural abscess, as in the case of subdural empyema and brain abscess. Often, epidural abscess coexists with the other lesions and presumably develops first. Osteomyelitis may be evident, which usually is the case with mastoiditis and often is evident after head injury with comminuted fracture of the skull or after intracranial surgery. A case of an adolescent boy with osteomyelitis and epidural abscess complicating a wrestling injury was reported.[46]

Local pain, tenderness, and fever may be the only signs. Treatment usually includes antibiotic drugs and surgery in the presence of osteomyelitis. Exclusion of associated intracranial infections is mandatory; the epidural infection serves to raise these diagnostic possibilities.

SPINAL EPIDURAL INFECTIONS

Spinal epidural infections may be acute or chronic, and they may be restricted in their extent or extend longitudinally over many segments of the spinal cord because the epidural space offers no resisting structures. Most often, the process affects the posterior region of the spine, with maximal pus or granulomatous tissue found over the dorsal aspect of the cord or spinal roots. In Danner and Hartman's[11] series from the New York Hospital, however, in approximately half of the patients, the pus primarily was anterior to the cord. In the case of spinal osteomyelitis, the pus may be more viscous ventrally. Occasionally, the purulent material may encircle the neural elements. In infants and children, this condition is rare; no case was encountered at the St. Louis Children's Hospital during the 39 months in which 122 cases of bacterial meningitis were seen. In an extensive report by Baker and colleagues[4] covering a 27-year period at the Massachusetts General Hospital, only 6 of 39 patients were younger than 20 years of age, and the youngest was 11 years old. The incidence ranged from 0.2 to 1.2 hospital admissions each year. In approximately half of the patients in this series, acute purulent material was discovered at operation or autopsy, with *S. aureus* incriminated in more than half of the cases. In the remainder, a granulomatous process was found, associated with a wide variety of bacteria. No instance of tuberculous infection occurred, although in many regions of the world, this organism remains an important consideration. Nonbacterial infective agents may include fungi or parasites.

The neural dysfunction probably results from direct compression of the spinal cord, roots, and nerves, but impaired circulation from associated inflammation and occlusion of vessels is at least a contributory factor in some cases. Determining with certainty the extent to which each of the previous mechanisms contributes to neural dysfunction often is difficult. Extensive necrosis of the cord may result in advanced cases in which a prompt diagnosis has not been made.

SOURCES OF INFECTION

In tuberculous and other chronic infections, osteomyelitis and intervertebral disk infection are common occurrences, but adults primarily are affected. Acute spinal epidural infections usually occur after hematogenous spread from furuncles, pharyngitis, dental abscesses, decubitus ulcers, and urinary tract and wound infections.[30] They may complicate spinal surgery, and lumbar puncture rarely has been implicated as a source.[6] Osteomyelitis seldom occurs. The patient may have a history of minor trauma to the back. Presumably, trauma results in local tissue injury or hemorrhage, forming a nidus for the developing infection.

CLINICAL MANIFESTATIONS

Fever is the rule, and the temperature is higher in patients with acute infections. Patients appear septic, and toxic delirium occurs frequently. Heusner,[22] in his classic article dealing primarily with acute epidural abscesses, divided the clinical phases as follows: (1) spinal ache, (2) root pain, (3) weakness, and (4) paralysis. Although certain therapeutic implications render this separation a useful way to consider the disorder, phases 3 and 4 are combined in the following discussion. That the various stages often overlap is axiomatic.

Phase 1: Spinal Ache

Spinal ache was a universal finding in Heusner's experience.[22] In a report from Baker and associates,[4] all 39 patients had backache of various degrees of severity. Local tenderness was absent in only two of their patients and should be searched for by carefully tapping over the spine.

Phase 2: Root Pain

Root pain is characteristic and is an early symptom that may assist in localization of the pathologic process. Root pain especially is prominent with lumbosacral disease in which roots are implicated without involvement of the spinal cord. The diagnosis is suspected infrequently until functional motor and sensory losses occur, which is unfortunate because therapy is most effective during the early stages. Progression to symptoms and signs of spinal cord involvement usually occurs within a few days except when the process is granulomatous, in which case the course tends to be prolonged, extending over several or more weeks.

Phases 3 and 4: Weakness and Paralysis

After weakness and impaired sensation referable to disease of the spinal cord appear, the progression to paralysis can be rapid, and immediate surgical treatment is imperative to maximize the likelihood of reasonable functional recovery. Even appropriate therapy at this stage often is ineffective, however, in restoring

normal neurologic functions. Death occurs in at least 20 percent of cases; this rate has not changed significantly since 1948, despite the availability of a wide range of antibiotic agents.

DIAGNOSIS

The diagnosis of spinal epidural infection is established by MRI of the spine (Fig. 38–9). Imaging also may reveal evidence of concurrent osteomyelitis of the spine, which is found in approximately 20 percent of chronic lesions. After epidural abscess is discovered, immediate neurosurgical intervention is necessary to prevent long-term neurologic sequelae. At the time of surgery, stains and cultures for aerobic and anaerobic bacteria, mycobacteria, and fungi should be obtained. If lumbar puncture is attempted when epidural abscess is suspected, the spinal needle (with stylet) is advanced slowly into the lumbar region, with periodic removal of the stylet and with suction applied gently *before* the thecal sac is entered.

If purulent material is obtained, the diagnosis is established, and the pus must be examined by a Gram-stained smear and cultured on various media under aerobic and anaerobic conditions. The leptomeninges should not be penetrated if purulent material is encountered; otherwise, CSF should be obtained. Characteristically, the CSF is clear or slightly opalescent and yellow if there is a block. Pleocytosis with a few too many hundred cells (with lymphocytes predominating) reflects a contiguous infectious process, but in the absence of meningitis, no organisms can be identified and the CSF glucose concentration should be normal. The protein concentration always is elevated, and the level may be very high (several hundred to 2000 mg/dL) in the case of a partial or total manometric block.

The differential diagnosis includes myelitis caused by bacterial meningitis, syphilis, viruses, and a parainfectious process and by the syndrome of acute transverse myelopathy of unknown cause. Spinal ache is most prominent in acute transverse myelopathy, but as a general rule, the entire illness is compressed in time, with paresis or paralysis evolving over the course of hours or a few days from the onset of disease. Impaired circulation of CSF does not occur in this or the aforementioned disorders. Rarely, a lymphoma may mimic a spinal epidural abscess. Spinal cord tumors, vascular malformations, and arachnoiditis are considerations when the course of disease is prolonged and evidence of sepsis is minimal or absent, as occurs with chronic epidural infections.

Figure 38–9 Gadolinium-enhanced, sagittal, T1-weighted MR image shows a rim-enhancing lumbar spinal epidural abscess *(arrows)* in a 15-year-old boy with a 3-week history of lower back pain, followed by rapidly progressing left leg numbness and decreased bowel and bladder function. *Staphylococcus aureus* was cultured from purulent fluid removed after L4-L5 laminectomy was performed. *(Courtesy of C. D. Robson, M.D., Harvard Medical School, Boston, MA, and P. D. Barnes, M.D., Stanford University School of Medicine, Stanford, CA.)*

TREATMENT

Prompt surgical removal of purulent or granulomatous material is essential. Surgery should be combined with intravenous administration of an appropriate antibiotic. Initial empiric antibiotic coverage is similar to that for brain abscess, although antifungal therapy need not be included, unless cultures or stains are positive for fungi. Treatment typically should be continued for 3 to 4 weeks, but it should be prolonged for twice this period if the patient has osteomyelitis. Despite advances, the morbidity and mortality rates for spinal epidural abscess remain high. One third of children with the disease die, and another third are left with permanent neurologic sequelae, including weakness, incontinence, and sensory abnormalities. Rapid diagnosis and treatment are essential to ensure a successful outcome.

CHAPTER 39

Fungal Meningitis

J. Thomas Cross, Jr. ✪ Richard F. Jacobs

Fungi are rare causes of meningitis in children. *Candida albicans*, *Cryptococcus neoformans*, and *Coccidioides immitis* are the isolates found most commonly in pediatric patients. Making a diagnosis can be difficult. Fungal meningitis frequently is chronic, and patients may have few symptoms. The lack of obvious meningeal signs and symptoms and the uncommon incidence of a fungal cause often delay establishing the diagnosis. Inherent problems with the diagnosis of fungal infections of the central nervous system (CNS) begin with the basic microbiology of the organisms. Their fastidious growth, the prolonged time needed for culture, and the requirement of special media can render making a diagnosis of meningitis difficult.

Because cultivating many fungi from the cerebrospinal fluid (CSF) frequently is difficult, the use of serologic tests for antibodies and antigens helps define the infection more quickly and with more sensitivity. These tests can be done on CSF, serum, and, in some instances, urine.[177] For most infections, amphotericin B is the drug of choice, although its supremacy is being tested by some of the newer azoles and the introduction of lipid formulations of amphotericin B. Namdar and colleagues[113] compared Abelcet, Amphotec, and AmBisome in neonatal and pediatric patients. CNS disease caused by fungi generally has high morbidity and mortality rates.

EPIDEMIOLOGY

The epidemiology of fungal meningitis depends on many factors. The geographic location of the patient or travel to an endemic area can be an important clue to defining the cause of the infection. The geographic distribution of fungal meningitis varies in the United States and worldwide. Histoplasmosis generally occurs in endemic areas of the Mississippi River valley.[176] Coccidioidomycosis occurs in the San Joaquin Valley and the desert Southwest of the United States and in Mexico.[3,118] Cryptococcosis distribution is worldwide, rather than in discrete endemic areas, but it seems to be associated with pigeon droppings and nesting areas of other birds.[98] Blastomycosis has a sporadic pattern of infectivity but generally occurs in states bordering the Mississippi and Ohio River basins, with occasional outbreaks occurring in the Great Lakes region and Canada.[50,83,143] *Candida* spp., *Aspergillus* spp., *Sporothrix schenckii*, and other fungal pathogens generally are not defined by geographic boundaries but depend more on environmental exposures and the immunocompetence of the individual. Uncommon species of yeasts and fungi, including *Rhodotorula rubra*, *Aureobasidium mansoni*, *Clavispora lusitaniae*, and *Bipolaris spicifera*, have been reported in nosocomial cases of meningitis.[68,89]

Many fungal infections (particularly infections caused by *Candida* spp. and *Histoplasma*) do not usually cause meningitis, unless the host is immunocompromised. The number of cases of cryptococcal meningitis has increased dramatically in association with the acquired immunodeficiency syndrome (AIDS) epidemic. A review from the mid-1980s by the Centers for Disease Control and Prevention showed an incidence rate of 6.8 percent for cryptococcal meningitis in patients with AIDS; however, the rate in pediatric patients with AIDS was 10 times lower (0.6%).[140] In the pre-AIDS era, patients known to be at risk for acquiring

disseminated cryptococcosis included patients with lymphoma, patients on high-dose corticosteroid therapy, and patients with underlying cellular immune dysfunction.[23] Risk factors for developing *Candida* meningitis are similar to those for candidemia and include prolonged antimicrobial therapy, indwelling venous catheters, hyperalimentation, corticosteroid use, recent intra-abdominal surgery, and intravenous drug abuse.[137,157] Pediatric cases occur most commonly in neonates, particularly in very-low-birth-weight newborns.[9,58,70,73,149] In the early 1980s, 3.8 percent of infants weighing less than 1500 g in a large pediatric teaching hospital developed systemic fungal infections, most of which were caused by *Candida* spp. The mean birth weight was 809 g, with 86 percent of the infants weighing less than 1000 g.

Inhalation is the most common means by which many fungi infect the host. Other fungi can be inoculated directly into the skin; this inoculation can occur in the outdoor environment or in the hospital setting (e.g., intravenous catheters), especially in very-low-birth-weight infants.[9]

CLINICAL MANIFESTATIONS

Infections caused by *Candida* spp. in very-low-birth-weight newborns can be particularly difficult to diagnose because of the broad range of symptoms. Most infants with disseminated candidiasis with meningitis present with respiratory distress and a supplemental oxygen requirement, and most progress to require mechanical ventilation.[9] *Candida* usually is identified in endotracheal washings, urine, and blood in patients with *Candida* meningitis, but infants have symptoms on average 11 days before the diagnosis is made. Ophthalmologic examinations may be very important in identifying disseminated *Candida* infections.[28] A careful funduscopic examination also can help determine if increased intracranial pressure is present with papilledema. Marked abdominal distention also occurs commonly in disseminated *Candida* infections in low-birth-weight infants and frequently is associated with guaiac-positive stools. Most patients also have temperature instability, elevated white blood cell counts, and feeding intolerance. Hepatomegaly may indicate the presence of systemic infection.

Physical manifestations that are diagnostic for other causes of fungal meningitis (e.g., *Cryptococcus*, *Blastomyces*, *Histoplasma*) rarely are found because the infections usually are chronic. Looking carefully for other manifestations of fungal infections, especially the presence of skin lesions, is very important, however. All superficial lesions, nodules, and draining abscesses should be investigated because they may give a clue to the cause of subacute and chronic infections (e.g., *Coccidioides*, *Blastomyces*, *Cryptococcus*).[62] Fungal stains, including India ink, should be performed on all biopsy specimens and drainage material, and all specimens should be processed for culture. Bone involvement is a common occurrence with certain fungal infections (e.g., *Cryptococcus*, *Blastomyces*).

The significance of isolating a fungus from CSF cannot be overemphasized. The finding of fungal organisms should be considered a true infection, and appropriate antifungal therapy should be initiated. A single CSF culture for *Candida* or an unlikely meningeal pathogen (*Paecilomyces*) with an otherwise normal CSF should lead the physician to consider the possibility of contamination.[5] Repeat CSF cultures should be sought in such patients.

INFECTION WITH SPECIFIC ORGANISMS

Candidal Meningitis

Candidal meningitis is rare in children. Arisoy and associates[5] reported that 2 percent of all positive CSF cultures were fungal organisms. *Candida* spp. accounted for 94.5 percent of the fungal isolates. Nine of 23 patients were newborns, 8 of whom were very-low-birth-weight infants. Risk factors for positive CSF fungal cultures from neonates included antimicrobial therapy, umbilical catheterization, total parenteral nutrition, intubation, and prematurity.[43,44] Risk factors in children beyond the neonatal period included concurrent bacterial infection, chronic systemic or CNS disease, and the presence of central venous catheters. Histopathology models in animals have revealed hyphal invasion, vasculitis, abscesses, and acute and chronic inflammatory infiltration of meninges and brain parenchyma.[72]

Children with human immunodeficiency virus (HIV) infection are at risk for acquiring disseminated *Candida* infections, including meningitis. In one study, 27 percent of HIV-infected patients with disseminated *Candida* infections had CNS involvement.[95] Nearly all HIV-infected patients who develop *Candida* infection do so as a result of nosocomial infection. Predisposing factors include oral candidiasis, central venous catheters, prolonged antibiotic therapy, and total parenteral nutrition. In HIV-infected patients, neutropenia is not a major risk factor. Simultaneous pulmonary disease, particularly viral, bacterial, or *Pneumocystis carinii* pneumonias, exists in most HIV-infected patients with disseminated *Candida* infection. Most patients are febrile for more than 14 days, with peak temperatures greater than 39º C before the diagnosis is established.

The incidence of infection with *Candida* spp. other than *C. albicans* has increased dramatically in immunocompromised children, particularly children with malignancies. In a case series of children with leukemia, *Candida tropicalis* meningitis was uniformly fatal.[47] In addition to patients with malignancies and HIV infections, other children at risk for developing infection have been reported, including a child with myeloperoxidase deficiency.[97]

Candida spp. have become another concern because of the development of resistance. Intensive efforts to develop standardized, reproducible, and clinically relevant susceptibility testing methods for the fungi have resulted in the development of the NCCLS M27-A methodology for susceptibility testing of yeasts for the azole agents.[131] Reliable breakpoints are unavailable for amphotericin B. Isolates of *Candida glabrata* and *Candida krusei* with increasing resistance to amphotericin B have been described.[175] *Candida lusitaniae* has shown resistance to amphotericin B, and meningitis in an adult patient with a resistant strain has been reported.[138] *C. krusei* has been noted to have azole resistance, particularly in immunocompromised patients receiving suppressive azole therapy. These fungal infections already are difficult to treat, without the added burden of drug resistance. If patients with *Candida* spp. (including *C. albicans*) meningitis are slow to clear infection, or unexpected relapse occurs, susceptibility testing is recommended.

Candida meningitis usually responds to therapy with intravenous amphotericin B alone or in combination with oral flucytosine. The use of flucytosine is controversial; however, most reports support its use in meningitis. Flucytosine has been difficult to use in low-birth-weight infants because of the immaturity of their gastrointestinal tracts and the risks of their developing necrotizing enterocolitis. Amphotericin alone for systemic candidiasis, including meningitis, in neonates has been used successfully in patients who could not tolerate oral medication.[22] The *most* important factor in successful treatment was the initiation of therapy quickly, as soon as systemic *Candida* infection was suspected and frequently before the organism was isolated. Prolonged delays in initiating therapy result in high mortality rates.

Amphotericin B initiated at a dose of 0.25 mg/kg body weight diluted in 5 percent or 10 percent dextrose-water can be infused over 2 to 4 hours. In most neonates, the dose can be increased in 0.25-mg/kg increments at 6- to 12-hour intervals until the

desired 1-mg/kg daily dose is attained. In older children and adolescents, a test dose may be given, with an initial dose of 0.1 mg/kg (1 mg maximum). If this dose is tolerated, the initial dose of therapy (0.25 mg/kg) is given. Many authorities now believe that a test dose is unnecessary and that cautious infusion of the first dose is adequate.[39] In severely ill patients, the dose can be increased rapidly in 6- to 12-hour intervals to 1 mg/kg/dose. Flucytosine generally is recommended in a dose of 150 mg/kg/day, divided every 6 hours. The use of flucytosine often requires monitoring and adjustment of the dosage based on serum determinations.

Large, controlled trials using the azoles and newer agents for *Candida* meningitis are lacking. Huttova and coworkers[67] reported eight neonates with candidal meningitis treated with intravenous fluconazole with and without amphotericin B. Numbers from the study were too small to make conclusive recommendations. Lipid formulations of amphotericin B increasingly are preferred in adults, and liposomal amphotericin B was used successfully in five of six cases of *Candida* meningitis in newborns.[139] Optimal dosing is unknown, but many physicians prescribe liposomal amphotericin B or amphotericin B lipid complex at a dose of 5 mg/kg daily. Marr and associates[104] reported on the use of fluconazole plus flucytosine for the treatment of *Candida* meningitis in a very-low-birth-weight infant. Voriconazole has excellent penetration of the CNS and is active against most *Candida* isolates causing CNS infections; however, the clinical experience with voriconazole is too limited to recommend its use at this time.[74] Caspofungin and the other echinocandins do not achieve adequate CSF concentrations for treatment of *Candida* meningitis.[35,127]

Cryptococcosis

Cryptococcal meningitis was rare in the United States in the pre-HIV era. With the growth of the AIDS epidemic, however, this infection has become a common cause of meningitis in adults in certain areas of the United States and infects 2 to 9 percent of adults with AIDS.[29,38,85,183] It remains an uncommon finding in pediatric patients.[114,132] Cryptococcosis is a systemic fungal infection, and meningitis is its most serious manifestation. Patients with initial pulmonary involvement may have few symptoms but can present with fever, cough, weight loss, and dyspnea on exertion.[105] In adult studies, progressively severe headaches without the presence of fever were common manifestations.[159] Patients with cryptococcal meningitis frequently have few symptoms but can present with nausea, dizziness, and irritability. Nuchal rigidity usually is absent. Careful examination for cranial nerve palsies, which are found in approximately one fifth of adult patients, should be performed. Diplopia, in particular, is one of the most common manifestations of cryptococcal meningitis. Papilledema is seen in nearly one third of patients with cryptococcal meningitis.[37] Patients with coexistent AIDS frequently have very few symptoms.[38]

Pediatric patients with cryptococcal meningitis usually present with signs and symptoms not referable to the CNS.[148] Leggiadro and associates[94] reported on 13 children with AIDS, compiled from 11 institutions, who were diagnosed with extrapulmonary cryptococcosis. Meningitis was diagnosed in 62 percent of these patients and was the most common clinical manifestation of extrapulmonary disease. Patients who initially responded to antifungal therapy did not die of the fungal infection but died of other illnesses related to their immunodeficiency. Death can occur, however, even in an immunocompetent child receiving effective therapy.[135]

Leggiadro and associates[93] reported on eight children with acute lymphoblastic leukemia who developed extrapulmonary cryptococcosis. Of these immunocompromised children, 63 percent had meningitis. Fever was the most common symptom, occurring in 60 percent of the children with meningitis. Headache was present in only 40 percent. A significant number of the children (40%) were completely asymptomatic and had lumbar punctures performed as routine management of acute lymphoblastic leukemia, with the subsequent unexpected growth of *C. neoformans* on culture. One child had cutaneous lesions, and another had ptosis and an unsteady gait. Treatment in this series of patients included amphotericin B (intravenous, intrathecal, or both), alone or combined with oral flucytosine. In these patients with acute lymphoblastic leukemia, relapse was a major complication, occurring in 60 percent of patients thought to have been treated successfully. The relapses occurred within 2 to 6 months of completing therapy. Treatment of the relapses generally included combination therapy of amphotericin B and flucytosine, with the occasional use of intrathecal amphotericin B.

Other illnesses that may lead to cryptococcal meningitis include systemic lupus erythematosus being treated with corticosteroids alone or in combination with azathioprine,[2,93,97,129] chronic mucocutaneous candidiasis,[69,170] and hyper-IgE syndrome.[154] Zoonotic transmission from a pet cockatoo was described in an immunocompromised adult.[115]

Direct examination of the CSF using the India ink test can provide an immediate presumptive diagnosis of cryptococcal meningitis. The sensitivity of this test varies, but in studies of adult patients with AIDS, positive results with the stain approached 75 percent.[29] Other useful stains include silver, periodic acid–Schiff, and mucicarmine. Gram stain of CSF is insensitive and unreliable.

Diagnosis of cryptococcal meningitis is aided by the use of serologic tests. The most common test is the cryptococcal capsular polysaccharide antigen test, which can be performed on serum, CSF, or other sterile body fluids. The sensitivity of this test is nearly 100 percent for the serum of patients who are HIV-positive.[30,85,183] The CSF antigen test in some studies seems to be less sensitive, with a 91 percent sensitivity.[29] False-positive results caused by cross-reactions of antigens in disseminated infections with *Trichosporon beigelii* have been reported.[107] Culture still is the gold standard for establishing the diagnosis and monitoring the success of therapy.

Treatment of cryptococcal meningitis is prolonged and, in immunocompromised patients, frequently requires lifelong maintenance therapy. In adults with HIV infection, multiple regimens have been suggested. Practice guidelines have been published for patients with cryptococcal meningitis who are HIV-negative or HIV-positive.[136] For HIV-negative patients, amphotericin B (0.7 to 1 mg/kg/day) plus flucytosine (100 mg/kg/day in four divided doses) for 2 weeks and then fluconazole (400 mg) for a minimum of 10 weeks, or, alternatively, amphotericin B (0.7 to 1 mg/kg day) plus flucytosine (100 mg/kg/day) for 6 to 10 weeks, is recommended. A repeat lumbar puncture is recommended at 2 weeks. If cultures still are positive, prolonged induction therapy should be continued, and fluconazole when started for therapy should be continued for 6 to 12 months. The investigators who proposed the guidelines do not recommend initiating therapy with fluconazole alone. The use of AmBisome (4 mg/kg) for 6 to 10 weeks is a possible alternative if the patient cannot tolerate amphotericin B or azole therapy.

For HIV-infected patients, the practice guideline study group recommends induction therapy of amphotericin B (0.7 to 1 mg/kg/day) plus flucytosine (100 mg/kg/day in four divided doses) for 2 weeks and then fluconazole (400 mg/day) for a minimum of 10 weeks.[136] When flucytosine cannot be administered, amphotericin B is an acceptable alternative; however, a trial from Thailand evaluated sterilization of the CSF in 64 patients and revealed that the combination of amphotericin B plus flucytosine was the most rapidly fungicidal regimen.[20] The use of lipid formulations of amphotericin B may be helpful in patients who cannot tolerate amphotericin B because of renal toxicity.[33] AmBisome has been effective at doses of 4 mg/kg/day.[92]

In patients with renal compromise associated with amphotericin B, flucytosine levels must be monitored carefully. The recommendation is that the dose of flucytosine be reduced to 75 to 100 mg/kg/day and continuing doses be adjusted to maintain serum flucytosine levels of 25 to 60 μg/mL.[6,48] Serum cryptococcal antigens are not useful in monitoring response to therapy, and the use of CSF cryptococcal antigens to monitor response to therapy also is controversial. Therapy is best judged to be successful by the demonstration of sterility of CSF fungal cultures.

In pediatric patients, a combination of amphotericin B and flucytosine has been used most frequently. In children with AIDS, amphotericin B in a dose of 0.5 to 1 mg/kg/day with or without flucytosine (150 mg/kg/day in four divided doses) is recommended for 4 to 8 weeks, followed by maintenance therapy with fluconazole (3 to 6 mg/kg/day) indefinitely.[174] HIV and AIDS guidelines change frequently, and the physician should consult the most recent guidelines for changes, particularly with regard to need for maintenance therapy.

Histoplasmosis

Infection with *Histoplasma capsulatum*, usually a benign and self-limited disease, is endemic in many parts of the United States. Disseminated disease, including meningitis, is a rare occurrence in children.[80] Case reports of adults generally describe immunocompromised individuals.[54,164] Clinical presentations reported in the literature show a wide variability in the manifestation of meningitis. In these cases, 39 percent of patients presented with meningitis associated with acute dissemination, 25 percent presented with single histoplasmoma that manifested as symptomatic mass lesions alone or with dissemination, 25 percent presented with chronic meningitis without evidence of dissemination, and the remaining patients presented with meningitis as a manifestation of recurrent disease. Rarely, embolization to the brain caused by *Histoplasma* endocarditis has been associated with meningitis.[176]

Meningitis occurring in patients with AIDS has become common in endemic areas. In one report, disseminated histoplasmosis caused 8 percent of the AIDS-defining illnesses in children.[141] The duration of symptoms varies. In patients who do not have AIDS, the symptoms generally last longer than 6 months and can last 7 years.[41,54,122,171] In patients with AIDS, symptoms usually manifest more acutely and in a much shorter timeframe.[176] In this series, neurologic findings occurred in all but 6 percent of the patients.[176] The most common signs and symptoms include depressed consciousness (29%), headaches (24%), confusion (22%), cranial nerve deficits (19%), other focal deficits (16%), seizures (14%), personality changes (12%), and ataxia (11%). Findings more commonly observed with acute bacterial meningitis, such as meningismus, a Babinski sign, or papilledema, were seen in fewer than 8 percent of the cases. In adult patients who do not have AIDS, the death rate is approximately 12 percent, with a relapse rate of 44 percent. In adult patients with AIDS, the death rate is 100 percent in some series.[4,176]

Diagnosis can be aided by serologic testing. High levels of anti-*H. capsulatum* antibodies were detected in the serum of 70 percent of patients tested. CSF serology was helpful in 75 percent of patients who were tested. Culture of the CSF was positive for fewer than half of the cases in one review.[80] In a second series in patients with AIDS, blood cultures were positive for 49 percent, bone marrow cultures were positive for 53 percent, respiratory secretions cultures were positive for 58 percent, and brain or meninges cultures were positive for 75 percent of those tested. Serologic testing can be negative because 10 to 25 percent of patients with disseminated disease lack a positive antibody response. The serology also can be false-positive in patients with other fungal diseases or tuberculosis. The antibody response to acute *Histoplasma* infection may remain elevated for years, without evidence of dissemination or meningeal disease. The use of *Histoplasma* antigen has become widely held as a useful test in immunocompromised patients with disseminated *Histoplasma*. Data from Wheat and associates[176] showed that antigen was found in the urine of six of seven patients with AIDS and meningitis.

Treatment with liposomal amphotericin B (3 to 5 mg/kg/day for a total dose of 100 to 150 mg/kg for 6 to 12 weeks) is considered standard therapy in adults.[178] The liposomal form provides higher CNS levels than does the deoxycholate form. For the deoxycholate form, a total dose of at least 30 mg/kg is considered by many physicians to be necessary to ensure a cure. The use of intrathecal amphotericin B is not recommended for *H. capsulatum* meningitis. A practice guideline for adults written before the previous article recommends that liposomal amphotericin B (3 to 5 mg/kg/day or every other day for 3 to 4 months) be considered for patients who have failed therapy with amphotericin B followed by fluconazole.[179] Johnson and colleagues[75] reported on a trial comparing amphotericin B with liposomal amphotericin B (AmBisome, LAmB) as induction therapy and showed the agents had similar efficacy for treating disseminated histoplasmosis. LeMonte and associates[96] found that amphotericin B combined with fluconazole might have antagonistic effects for treatment of histoplasmosis, but data are needed to determine the efficacy of combination therapy for meningitis.

Patients with AIDS for whom induction therapy was successful must remain on an anti-*Histoplasma* agent indefinitely. A few cases of children with disseminated histoplasmosis and AIDS have been reported, but none with meningitis, and in these children, antifungal therapy must be continued indefinitely.[25,141] The case report by Schutze and associates[141] showed that ketoconazole was ineffective for preventing recurrence of nonmeningeal disseminated disease, and because ketoconazole has poor CNS penetration, it is likely to be ineffective for prophylaxis of meningitis. In patients with AIDS, some success has been achieved with the use of itraconazole for suppressive therapy in disseminated disease. Few data exist, however, on the use of itraconazole for suppressive therapy for meningitis or other CNS lesions caused by *Histoplasma*. For maintenance therapy, fluconazole (high-dose), itraconazole, or intravenous amphotericin B in a weekly dose of 1 mg/kg are available. In one case report, fluconazole was effective in an adult with *Histoplasma* meningitis refractory to amphotericin B therapy.[158]

Coccidioidomycosis

C. immitis (*C. posadasii* in Texas and Central and South America) meningitis is a more common cause of chronic meningitis than is *Histoplasma*.[76] Approximately 1 percent of children with symptomatic pulmonary disease develop disseminated disease.[77] Of patients with disseminated coccidioidomycosis, 15 to 20 percent develop meningitis.[77,82] History of exposure is a crucial factor in diagnosing this disease and relies on careful questioning of the patient about travel to or residence in an endemic area.[155,156] Exposure of wounds to colonized soil has been implicated in at least one pediatric case.[112] An association between facial cutaneous coccidioidomycosis and meningitis has been described.[7]

CSF shows a mononuclear pleocytosis with an elevated protein and decreased glucose concentration. Diagnosing coccidioidal meningitis is made easier by the availability of reliable serologic tests. Smith and associates[150] showed that complement-fixing antibodies appeared in the CSF only in patients with meningitis and provided a sensitivity of 76 percent. Ninety-six percent sensitivity was seen when the complement-fixation test was incubated at 4º C.[119] McGinnis,[106] in his review of the literature based on pooling five studies, showed that *Coccidioides* could be cultured from the CSF in 76 percent of patients with meningitis and was seen on direct examination of the CSF in only 8 percent of the

cases. He concluded that these values were too high and were likely skewed because of reporting bias. Other experts in the field also consider that the rate of positive CSF cultures is much lower (approximately 33%), and that finding the organism in the CSF by direct examination rarely occurs.[153]

Coccidioidomycosis in infancy was described more than 40 years ago and continues to be a problem today.[160] Infants usually have severe disease with high mortality rates and morbidity. In the 1980s, two studies described children with *Coccidioides* spp. meningitis who were treated with oral, intravenous, or intrathecal imidazoles.[64,145] The authors reported promising results with the use of ketoconazole and imidazole therapy compared with standard intravenous or intrathecal amphotericin B.

If untreated, *Coccidioides* meningitis is uniformly fatal. Therapy with intravenous and intrathecal amphotericin B reduced the mortality rate to 30 percent.[119] The use of fluconazole has been found in adult studies to have a success rate of 79 percent.[52] It seems to be safe in clinical use, despite a case report of a pregnant woman with *Coccidioides* meningitis treated with fluconazole who delivered an infant with congenital malformations. The infant was thought to have an autosomal recessive disorder (Antley-Bixler syndrome), however, and not teratogenic malformations caused by fluconazole.[91] Fluconazole may be the superior agent for sustaining remission of meningitis caused by *Coccidioides* because of its oral bioavailability, the toxicity associated with amphotericin B, and the elimination of the need for intrathecal administration.[125]

Galgiani and coworkers[51] have written practice guidelines for the treatment of coccidioidomycosis in adults. Therapy with oral fluconazole is preferred, with most authorities recommending 400 mg/day orally, although some physicians begin with higher doses of 800 to 1000 mg/day. Fluconazole in a dose of 400 to 600 mg/day for 9 to 12 months has been shown to be effective in adults.[52,162] A corresponding dose of 6 mg/kg/day in pediatric patients also has been used, but no controlled studies using this agent in pediatric patients have been published. If treatment is begun with azole therapy, it should be continued for life.[36]

Itraconazole has proven efficacy in nonmeningeal coccidioidomycosis, with 63 percent of adult patients treated showing a complete response.[163] Doses of itraconazole of 400 to 600 mg/day have been reported to be effective in adults. Because itraconazole has variable oral bioavailability, many authorities recommend monitoring for adequate serum drug levels.[169] The use of itraconazole for meningeal involvement led to great hope for the use of an oral agent in this disease.[161] Adult patients with *Coccidioides* meningitis had high relapse rates (40-50%), which rendered them dependent on lifelong therapy with itraconazole.[60] The alternative of continued intrathecal amphotericin B renders this treatment much more appealing.

Well-developed, controlled clinical trials with large numbers of children do not exist for the azoles; some authorities consider intravenous and intrathecal amphotericin B to be the standard therapy for coccidioidal meningitis. It also is recommended for patients who do not respond to fluconazole or itraconazole treatment. Some experts initially use a combination of oral azole with intrathecal amphotericin B with the thought that responses are more prompt with this approach. Amphotericin B can be administered intrathecally into the lumbar area or into the cisterna magna, or by using an Ommaya reservoir.[34,53,87,182] In younger children, intraventricular or intracisternal therapy using the Ommaya reservoir allows ease of administration but has the disadvantage of increasing susceptibility to secondary bacterial infection.

The initial dose of amphotericin B administered into the CSF is 0.025 mg. The dose is increased by doubling until a maintenance dose of 0.1 to 0.5 mg is attained. After this dose has been achieved, therapy can be given every other day, alternating with the intravenous administration of amphotericin B. Therapy is continued until the child's condition has stabilized, at which point intrathecal therapy gradually can be stretched out to every 3 weeks. This program is continued until the CSF indices are normal and culture results have been negative for at least 1 year.

Use of voriconazole has been successful in two case reports, and other similar anecdotal references have been reported at referral centers; some centers use voriconazole, 4 mg/kg every 12 hours orally, for salvage therapy.[32,51,128] Miconazole, an imidazole compound that no longer is commercially available, was used in the treatment of *Coccidioides* meningitis and, in combination with oral ketoconazole, had good results in nine children.[145]

Blastomycosis

Blastomyces dermatitidis is an uncommon cause of chronic meningitis and is difficult to diagnose premortem unless the patient has other signs of systemic blastomycosis. When systemic blastomycosis occurs, it can involve the CNS in 5 percent of cases.[18] Common sites for this organism include bone, genitourinary tract, and skin.[10,19] Although examination of CSF obtained by lumbar puncture usually is negative (9% sensitivity), ventricular fluid (four of four patients tested) seems to have a higher yield.[86] Typically, fungal meningitis is associated with a lymphocytic pleocytosis; however, meningitis caused by *B. dermatitidis* frequently has a neutrophilic predominance.[63] Previously, blastomycosis most often affected patients who were immunocompetent. Patients with AIDS are at a high risk for developing chronic infection.[63] Because of the difficulty in diagnosing meningitis caused by *B. dermatitidis* and its similarities to tuberculous meningitis, patients usually are treated for presumptive tuberculous meningitis.[57,111] Although meningitis is the most common form of CNS blastomycosis, solitary mass lesions also can occur.[133]

Diagnosis relies on the characteristic histopathologic appearance in tissues and occasionally on culture of CSF obtained from the ventricles. If the difficulty in performing these procedures is prohibitive, looking for other sources of blastomycosis, including sputum and urine, is indicated. A study in patients with AIDS showed that examination of sputum was useful for establishing the diagnosis of disseminated blastomycosis.[120]

Treatment of systemic blastomycosis, including meningitis, relies on amphotericin B in a dose of 1 mg/kg/day.[152] The duration of therapy is unknown, but adults with systemic disease usually require a minimum of 2 g to prevent relapse of nonmeningeal disease.[121] In adult patients who have been "cured" of their meningitis, doses of 2400 to 3150 mg were required, which would correspond to a total dose of 35 to 45 mg/kg in a child. The use of lipid formulations of amphotericin B has not been reported for CNS blastomycosis, but this treatment according to current practice guidelines of the Mycoses Study Group may be an alternative for patients unable to tolerate amphotericin B because of toxicity.[27] Azoles should not be considered for primary treatment of CNS blastomycosis. Schutze and colleagues[140] reported that children respond less satisfactorily to oral azole therapy than do adults.

Aspergillosis

CNS infections with *Aspergillus fumigatus* and other *Aspergillus* spp. in immunocompromised patients usually are fatal. Conditions that place the patient at risk include organ transplantation, malignancies, and neutropenia. In most reported cases, patients were receiving high-dose corticosteroid therapy in addition to broad-spectrum antibiotics.[11,88] Many patients had fever, and pulmonary findings preceded neurologic manifestations. *Aspergillus* infection of the CNS usually is acquired by hematogenous spread from the lungs. Other modes of acquisition include extension from a contiguous focus (sinuses) and intravenous drug abuse.[110]

Brain abscesses are the most typical manifestation of *Aspergillus* spp. infection in the CNS, but meningoencephalitis, isolated spinal cord lesions, aqueductal stenosis, and mycotic aneurysms also have been described.[26,45,168,172,181] Magnetic resonance imaging has been suggested to be superior to computed tomography for the delineation of CNS lesions in patients with bone marrow transplantation.[108] The lesions are consistent with acute infarcts.

Some early reports of CNS aspergillosis were in infants who appeared to be normal.[1,101] The diagnosis of meningitis relies on CSF cultures, but the results of a bronchoscopy or biopsy frequently are more helpful and provide a more expedient diagnosis. Use of *Aspergillus* antigen in the CSF has been helpful, and it may be used for serial observations during the course of therapy.[173] Because the disease is uniformly fatal, the importance of treating pulmonary aspergillosis before the development of meningeal involvement cannot be overemphasized. Amphotericin B in doses of 1 to 1.5 mg/kg/day is recommended, with or without the addition of flucytosine, rifampin, or both agents.[58,167] Itraconazole has been used successfully in one case report, as has voriconazole.[109,173]

Sporotrichosis

Sporothrix schenckii, although primarily a lymphocutaneous disease, has been reported to cause meningitis.[42,49,84,123,147] Many of the cases described more recently have occurred in adults with AIDS as an underlying risk factor.[40,134] Meningeal seeding may occur through hematogenous spread from the lungs, as is seen in most other fungal infections.[42] Meningeal involvement with sporotrichosis produces CSF indices and abnormalities similar to those seen with the other fungal meningitides.[41] CSF fungal culture is insensitive for the diagnosis of meningitis caused by sporotrichosis. The use of *S. schenckii* antibody in the CSF has been effective in diagnosing meningitis in patients without other overt signs of this infection.[142]

Treating this infection is very difficult. Amphotericin B alone has been successful occasionally.[81] Some experts recommend the addition of flucytosine, but no studies have evaluated the efficacy of this combination. The azoles, particularly itraconazole, had excellent results in nonmeningeal disease, but successful treatment of meningitis with this agent has not been proved.

Mucormycosis

Meningitis caused by *Mucor* spp. or other Zygomycetes usually occurs as a result of direct extension from paranasal sinus disease. Infection with these organisms most commonly is seen in the immunocompromised host and particularly in patients with diabetes mellitus or patients receiving high doses of corticosteroids. Patients (particularly dialysis patients) undergoing chelation therapy with deferoxamine are at risk for developing infection.[16,17,79,180] The association with deferoxamine therapy is seen with *Cunninghamella*.[130] *Mucor* spp. have been reported as a cause of CNS disease in children but very rare rarely.[61,71] Treatment employs amphotericin B in doses of 1 to 1.5 mg/kg/day, but it usually is unsuccessful. Surgical excision of rhinocerebral infection is recommended along with antifungal therapy.

Other Fungal Infections

Acremonium spp. are common soil fungi that may cause chronic meningitis in humans.[117] *Xylohypha bantiana*, an uncommon dematiaceous fungus, caused a fungal brain abscess in an adolescent girl; this report increases the number of cases reported in the literature to nearly 40.[116] Cerebral chromoblastomycosis also has been reported.[146] Other fungal organisms causing CNS infection include *Paracoccidioides brasiliensis* (i.e., South American blastomycosis),[124] *Prototheca wickerhamii*,[78] *Blastoschizomyces capitatus*,[55] *Rhodotorula* spp.,[103,126] *Pseudallescheria boydii*,[13] *Aureobasidium mansoni*,[68] *Clavispora lusitaniae*,[68] and *Bipolaris spicifera*.[89]

DIAGNOSIS

Specific information about the diagnosis of individual organisms is provided in the previous sections. Table 39–1 provides specific data for some fungal meningitides. Overall, the problem with diagnosing many of these infections is that most patients have nonspecific signs and symptoms without reference to the CNS. Standard culture media may not be useful for these organisms, and it can take weeks before an organism is identified on culture. The use of antigen and antibody testing has proved quite useful for the diagnosis of *Cryptococcus*, *Coccidioides*, and *Histoplasma* infections. The hope is that polymerase chain reaction technology may be helpful in the future, as it has been for bacterial and mycobacterial diagnoses. Neonates may have only a mild CSF pleocytosis. In one series of 16 neonates with definite *Candida* meningitis, the median CSF white blood cell count was 53 cells/mm^3 (range, 0 to 1120 cells/mm^3).[46]

CSF examination may be helpful in some instances. As much CSF as can be removed safely should be obtained, especially at the time of ventriculography or pneumoencephalography.[41] A minimum of 5 mL of spinal fluid has been suggested, based on

TABLE 39–1 Fungal Cerebrospinal Fluid Characteristics

Organism	WBCs	Protein	Glucose	Smears	Serology	Cultures
Blastomyces	Variable up to 15,000 cells/mm^3 with PMNs or lymphocytes	Elevated up to 300 mg/dL	Normal or low	Rare on smear	No good serology	CSF cultures rarely positive; increased yield with ventricular taps
Candida	Mean 600 cells/mm^3 up to 1900 cells/mm^3 with lymphocytes or PMNs	Elevated	Low or normal	40% positive on smears	Serology not helpful	CSF cultures useful
Coccidioides	100-750 WBCs, mostly lymphocytes	150-2000 mg/dL	21-62% serum	Rare on smear	CSF CF antibody positive in 75-95%	CSF cultures positive in 33-60%
Cryptococcus	40-400 WBCs, mostly lymphocytes	High	Low	India ink positive in 25-50%	CSF and serum cryptococcal antigen positive in 85-90%	CSF cultures positive in 75%
Histoplasma	0-300 WBCs, lymphocytes, or PMNs; most 11-101/mm^3	Usually elevated, but can be normal	Usually low (<40 mg/dL) to normal	Rare on smear	Polysaccharide antigen in urine, blood, CSF positive in 61%	CSF cultures positive in 27-65%

CF, complement fixation; CSF, cerebrospinal fluid; PMNs, polymorphonuclear leukocytes; WBCs, white blood cells.
Data from references 57, 64, 106, 175.

experimental work.[99] Repeated cultures of large volumes of CSF may be helpful.[41] The fluid obtained should be centrifuged and the sediment saved for culture and India ink preparation. The supernatant is sent for serologic tests. The India ink test should be interpreted with caution and must be followed with cultures because artifacts frequently can cause misinterpretation.[41] The cumulative efficacy of repeated lumbar punctures for cryptococcal meningitis improved the sensitivity of the India ink smear from 26 percent in one lumbar puncture to 52.6 percent with the second.[106] If large volumes are available, membrane filtration may be used to concentrate the fungal elements. The membrane containing the fungi is placed aseptically on isolation media and incubated at 30° C for 4 weeks. The CSF that passes through the membrane can be used for serology or chemistry determinations.[106] The remaining CSF can be inoculated onto Sabouraud glucose agar, blood agar, and brain-heart infusion agar or into broth media or into both types of media. CSF cultures generally are unhelpful for *Histoplasma*, *Blastomyces*, and other dimorphic fungi.

Serologic techniques are extremely useful for *Cryptococcus* and *Coccidioides*. Approximately 100 percent sensitivity is seen with serum cryptococcal antigen tests in HIV-positive patients.[30,85,183] The CSF antigen test in HIV-positive patients seems to be less sensitive (91%) in some studies.[29] In patients not infected with HIV, the sensitivity of the serologic test in the CSF approaches 90 percent.[65] For coccidioidal meningitis, the sensitivity rate is greater than 76 percent.[119,150]

Candida can be cultured but may require a prolonged incubation period, necessitating institution of empiric therapy while awaiting results of cultures. For other organisms, such as *Histoplasma*, *Blastomyces*, and *Coccidioides*, culturing other body fluids, such as blood, urine, sputum, or draining wounds, can be helpful.

ANTIFUNGAL AGENTS AND TREATMENT GUIDELINES

Amphotericin B remains the treatment of choice for most CNS fungal infections in children. Amphotericin B has less than 5 percent oral bioavailability and is more than 90 percent protein-bound.[14] It has a prolonged terminal elimination half-life of 15 days, with only approximately 3 percent of the parent compound found unchanged in the urine.[8] CSF concentrations are approximately 2 to 4 percent of those found in serum.[53,166] The recommended dose varies depending on the organism and the severity of the illness. In most children and infants, a dose of 1 mg/kg/day seems to be satisfactory, particularly in view of the increased clearance of the drug compared with clearance in adults.[12,151]

Toxicity and adverse effects are universal with the use of amphotericin B. Acetaminophen and diphenhydramine may be helpful in reducing the incidence of fever, nausea, and chills. The effective use of hydrocortisone to reduce febrile reactions has been documented.[165] Great variability in patient responses to this treatment occurs, however. The use of corticosteroids can potentiate water retention and amphotericin B–induced hypokalemia; the dosage of corticosteroids should be kept to a minimum.[53] If chills occur, they can be stopped with the use of meperidine.[21]

Amphotericin B induces reversible impairment of renal function in 80 percent of patients during the first 2 weeks of therapy.[24] In most cases, renal function returns to normal after cessation of administration of the drug. The manifestations of toxicity include renal tubular acidosis, azotemia, oliguria, and potassium-magnesium wasting. Other nephrotoxic drugs worsen the azotemia. Renal failure in adult studies has been shown to be ameliorated by the use of salt loading.[66] The adult studies used 500 mL of a 0.9 percent sodium chloride solution as prehydration and posthydration therapy; in children, 10 mL/kg seems to work as well. Hypokalemia along with hypomagnesemia occurs frequently and may require supplementation. A normocytic, normochromic anemia occurs in many patients who receive amphotericin B, with an 18 to 35 percent decrease in hemoglobin seen after 10 weeks of therapy; this anemia seems to be related partly to changes in erythropoietin levels.[102]

One approach to minimize amphotericin B toxicity while maintaining the drug's pharmacologic spectrum and clinical utility is the use of liposomal and lipid-complexed formulations. The three formulations approved for clinical use include amphotericin B lipid complex (Abelcet; Liposome Company, Princeton, NJ), amphotericin B colloidal dispersion (Amphotec, Amphocil; Sequus Pharmaceuticals, Menlo Park, CA), and liposomal amphotericin B (AmBisome; NeXstar Pharmaceuticals, Boulder, CO; Fujisawa USA, Deerfield, IL). Although each of these lipid delivery systems is unique and has different pharmacokinetic and pharmacodynamic profiles, no clinical comparisons of lipid formulations have been done in children. Their use is discussed briefly in the case reports that exist for the individual infections listed previously. Most of the published pediatric literature describes cases in which AmBisome has been used.

Ketoconazole has not been an effective agent for treating most fungal CNS disease processes. It has been supplanted by the newer azoles, fluconazole and itraconazole, because of their better bioavailability and more favorable results in clinical trials.

Fluconazole is a very effective agent for the suppression of cryptococcal meningitis in patients with AIDS and immunocompetent patients and seems to be superior to amphotericin B for prolonged maintenance therapy in patients with AIDS. Fluconazole absorption by the gastrointestinal tract is not affected by the presence of food or gastric acidity.[15] Fluconazole is highly water soluble and minimally bound to plasma proteins.[90] The terminal elimination half-life of fluconazole is 22 to 31 hours, with 80 percent of the drug excreted unchanged in the urine.[31] Fluconazole readily penetrates into CSF in inflamed or noninflamed meninges, achieving levels that are 60 to 80 percent of serum levels. Rifampin, cyclosporine, and phenytoin have significant interactions with fluconazole. Adverse effects are uncommon, especially compared with the effects associated with amphotericin B. Less than 5 percent of patients have nausea and vomiting. Asymptomatic elevations of plasma aminotransferases occur in less than 1 to 7 percent of patients.[31]

Data for itraconazole use in pediatrics are limited, and itraconazole is not recommended at this time for CNS fungal infections in children. Itraconazole has increased absorption when taken with food.[168] Itraconazole is highly protein-bound (>99 percent); less than 1 percent is excreted unchanged in urine.[59] CSF concentrations are low compared with those of fluconazole; however, itraconazole is much more lipophilic, allowing it to show efficacy in treatment of some fungal meningitides. Additional data on it and the other azoles, particularly for treatment of coccidioidal meningitis in children, should be forthcoming in the next several years,. Promising results from an adult study have been published.[161]

CONCLUSION

With the large increase in the number of immunocompromised children caused by the epidemic of HIV, the advent of new antineoplastic agents, the growth of organ transplantation, and the increased use of corticosteroids, the relative rarity of fungal meningitides has been replaced by a burgeoning upswing in the incidence and prevalence of these infections. New modalities for diagnosis are needed because many of these fungal infections still require weeks for identification. We expect that trials in progress will help determine the role of azoles, amphotericin B, lipid

formulations of amphotericin B, or combinations of these drugs as the optimal treatment of many fungal meningitides.

CHAPTER 40

Eosinophilic Meningitis

Barbara W. Stechenberg

Eosinophilic meningitis may include any meningitis, infectious or noninfectious, in which one finds a cerebrospinal fluid (CSF) pleocytosis with a significant percentage of eosinophils. The diagnosis of eosinophilic meningitis can be made by the presence of 10 or more eosinophils in the CSF or if at least 10 percent of the CSF leukocytes are eosinophils.[18] Such a finding strongly suggests invasion of the central nervous system (CNS) by a helminthic parasite. In the last 20 years, the term *eosinophilic meningitis* has been applied more specifically to a typical form of meningitis caused by *Angiostrongylus cantonensis*, a rat lungworm found primarily in the Pacific Islands and Southeast Asia. *Gnathostoma spinigerum* and *Baylisascaris procyonis* also may be considered in particular circumstances.

The first documented case of eosinophilic meningitis was reported from Taiwan in 1945.[1] The patient was a 15-year-old boy who developed severe headache and vomiting. Examination of the CSF revealed 528 leukocytes, of which 50 percent were eosinophils. Ten actively moving nematodes also were recovered from the specimen. Since the early 1960s, many new cases have been reported, with particularly large numbers coming from Thailand,[26,27] Tahiti,[32] Taiwan,[47] and Hawaii.[12a,15]

ETIOLOGIC AGENTS

The organism that presumably is involved in most cases is the rodent lungworm. *A. cantonensis*, which as an adult is 17 to 25 mm long and 0.25 to 0.36 mm at its maximum width, has a smooth cuticle, and has three minute lips at the cephalic end. The male has a copulatory bursa supported by bursal rays.

In its life cycle, rodents such as *Rattus rattus* are the principal hosts. These rodents ingest mollusks containing third-stage larvae, which travel from the liver and lung into the general circulation. The larvae selectively leave the circulation to enter the CNS within the first 48 hours. There they develop into young adults in approximately 2 weeks.[44] From the brain, they travel to the pulmonary arteries, where their eggs are laid. The eggs hatch in the pulmonary capillaries; the first-stage forms then travel from the alveolar spaces up the rat trachea to the gastrointestinal tract, from which they are eliminated in the feces. The larvae can survive for approximately 2 weeks under humid conditions. The third-stage larvae develop in the intermediate hosts in approximately 2 weeks.

Another form of eosinophilic meningitis has been attributed to the nematode *G. spinigerum*. The adult *G. spinigerum* is stout and reddish and has a globose cephalic bulb that is separated from the body by a slight constriction. The head and anterior part of the body have spines. Males may be 11 to 25 mm long, and females may be 25 to 54 mm long. The adults lie coiled in lesions along the alimentary canal, from which they release eggs into the feces, where they become embryonated. The eggs hatch on reaching water, releasing a larva that is ingested by a copepod (*Cyclops*) and continues to develop. When the infected copepod is eaten by a fish, frog, snake, or bird, a third-stage larva develops and becomes encapsulated in the intermediate host. When it is ingested by the definitive host (cats, dogs, hogs, mink, humans), the parasite localizes in the stomach wall.[35]

The adult worms of *Baylisascaris procyconis*, the raccoon ascarid, reside in the intestines. They are large, tan-colored roundworms; the female is 20 to 22 cm long, and the male is 9 to 11 cm long. Infection in raccoons usually is subclinical, with the adult female worm producing 115,000 to 179,000 eggs/worm/day, most of which are shed in feces.[12] Young raccoons have a higher prevalence of infection and higher parasitic burden; in their first few months of life, they ingest eggs that are in their environment or sticking to their mothers' fur.

EPIDEMIOLOGY

The geographic distribution of eosinophilic meningitis depends on the distribution of *A. cantonensis*. Many cases have been reported from Taiwan and Thailand. Other areas include Vietnam, the Society Islands (especially Tahiti), Hawaii, the Marshall Islands, and Ponape. Rodents infected with the worm have been documented in other areas of the Pacific Islands and Asia. Disease has been reported from Cuba, Egypt, and many other countries. As infected rodents are carried to other countries on cargo ships, spread of these organisms will continue to increase. Two cases have been diagnosed in the continental United States in travelers from endemic regions.[10,14] An outbreak was described in 12 of 23 young adults who had traveled together to Jamaica.[17,38]

The seasonal incidence of the disease varies in different areas. The months of highest prevalence usually correspond with the more humid periods in each country.

Patients with eosinophilic meningitis have eaten terrestrial snails, slugs, fish, or fresh-water shrimp, all of which can serve as intermediate hosts for the parasites.[41-43] In Thailand, the most common source is the *Pila* snails, which are eaten raw or pickled.[25] They may be served as an appetizer with alcoholic beverages, which may explain partly the increased incidence of the disease in men.[26] The giant African snail *Achatina fulica* is found commonly in Taiwan and may carry thousands of roundworm larvae, explaining the higher incidence of recovery of organisms from the patients in Taiwan.[43] The larvae also may remain infective in water for approximately 60 hours. Cases have been associated with the ingestion of leafy vegetables, presumed to be contaminated by slugs or snails.[15]

The distribution of disease among age groups varies. In Thailand, most of the cases occur in the third to fourth decades of life, but in Taiwan and Hawaii, most cases occur in children younger than 15 years old.[26,47] Although eosinophilic meningitis rarely occurs in very young children, one report documented disease in five children younger than 2 years.[37]

The first confirmed cases of *B. procyonis* neural larva migrans were described in the 1980s in 10-month-old and 18-month-old boys from Pennsylvania and Illinois, respectively.[11,13] Both boys had rapidly progressive, fatal eosinophilic meningoencephalitis. Subsequent reports of fatal and nonfatal disease have been reported from areas with large raccoon populations. They have occurred in rural, urban, and suburban areas. Two risk factors for acquisition of severe infection are contact with raccoons, particularly baby or young animals, or their feces or a contaminated environment, and pica or geophagia. Outdoor contamination of children's play areas by raccoons and proximity of raccoon communal latrines to human habitation may contribute to risk.[33]

PATHOGENESIS

The pathogenesis of this disease in humans has not been studied rigorously but is presumed to parallel the pathogenesis in the rodent host. The larvae are ingested, make their way into the general circulation, and selectively enter the CNS. The number of nematodes found on autopsy specimens has varied. In a 5-year-old Taiwanese girl, 150 nematodes were found on the surface of the cerebrum and cerebellum and in the subarachnoid spaces, and more than 500 were recovered from the normal saline in which the spinal cord and meninges were placed. *A. cantonensis* also were found in the pulmonary arteries.[47]

Pathologic specimens have shown a leptomeningitis in which plasma cells and eosinophils predominate. Tortuous tracks of variable size in the brain and spinal cord parenchyma surrounded by variable reaction and degenerating neurons may be present. Granulomata may form around dead *A. cantonensis*.[24,31]

Hemorrhagic, necrotic tracks caused by the organisms have been associated more commonly with *G. spinigerum* infection.[4] *Angiostrongylus* is capable of causing a vascular reaction, however, including thrombosis and rupture of vessels and arteritis, leading to formation of an aneurysm.[24] The tracks caused by *G. spinigerum* may be larger and more necrotic.

In baylisascariasis, information about the pathology is based on a few fatal cases with massive larvae invasion of the CNS.[12] Swelling of the brain, leptomeningeal congestion, and evidence of herniation have been seen. Necrosis is most marked in the periventricular white matter. Large deposits of eosinophils are present along necrotic migration tracks.

CLINICAL MANIFESTATIONS

On the basis of information obtained from patients with a history of ingestion of the intermediate hosts, the incubation period is 7 to 30 days. Most patients with typical eosinophilic meningitis have an abrupt onset of disease; a more insidious onset may be noted in 20 percent of cases. Headache is the most common and distressing symptom. It usually is intermittent but is frequent and severe. Other common symptoms are nausea, vomiting (often projectile), intermittent somnolence, malaise, anorexia, constipation, and fever with temperatures usually reaching a maximum of 38º C to 39º C in the early phase of the disease, although many patients have no documented fever. Nuchal rigidity is seen more commonly in older patients, often in association with severe headache. Paresthesias occur in a large variety of locations and are expressed as pain, numbness, itching, or a sense of worms crawling on the skin. Some patients also note diplopia with or without strabismus. Convulsions are unusual occurrences.

The findings on physical examination are normal in half the patients. Physical findings may include mild hepatomegaly, mild changes in deep tendon reflexes (usually decreased), nuchal rigidity, absent abdominal wall reflexes, and, less commonly, ophthalmoplegia or facial paralysis. Twelve percent of Thai patients had abnormal ophthalmoscopic examinations.[14]

Examination of the CSF reveals grossly turbid or opalescent fluid in most patients, with leukocyte counts usually 100/mm^3 to 5000/mm^3. All counts usually reach their maximum in the first 3 weeks of disease, decreasing sharply thereafter. Generally, the percentage of eosinophils in the CSF is high, often greater than 50 percent. Fluids with higher cell counts tend to have a higher percentage of eosinophils.[27,47] The proportion of eosinophils may decrease after the first 4 weeks. CSF protein concentration is moderately high (often 50 to 200 mg/dL), but the glucose concentration usually is normal.

Peripheral white blood cell count varies, but the differential cell count often shows striking eosinophilia. Examination of the feces may reveal concurrent infestation with other parasites, such as *Ascaris* or *Trichuris*.

The clinical manifestations of the eosinophilic radiculomyeloencephalitis thought to be associated with *G. spinigerum* overlap to some degree with the manifestations of typical eosinophilic meningitis. Headache is less prominent, however. Many patients report sharp, shooting pains of the trunk or limbs, flaccid paralyses, and impairment of superficial sensation.[28] Impairment of the sensorium may be sudden in association with cerebral hemorrhage. Grossly bloody spinal fluid is a common finding when myeloencephalitis is present, but it is extremely rare in typical eosinophilic meningitis.

Patients with baylisascariasis develop an acute fulminant eosinophilic meningoencephalitis; early features include low-grade fever, increasing lethargy, ataxia, somnolence, and irritability. There is progression to posturing, spasticity, and ocular or cranial nerve involvement. Seizures are common occurrences. Continued deterioration to coma and death, or, with survival, to a persistent vegetative state or severe deficits, may occur.

DIAGNOSIS

The diagnosis of cerebral angiostrongyliasis usually is based on the clinical presentation with associated CSF eosinophilia and an epidemiologic history consistent with possible exposure to the *A. cantonensis* larvae. Rarely, larvae may be recovered from the CSF. Two thirds of patients also have peripheral eosinophilia. Enzyme-linked immunosorbent assay helps to confirm the diagnosis.[39] The absence of focal findings on computed tomography and abnormal enhancement in the globus pallidus may be valuable in establishing a diagnosis.

Gnathostomiasis often is associated with xanthochromic or bloody CSF with an eosinophilic pleocytosis. Peripheral eosinophilia often is pronounced. Computed tomography and magnetic resonance imaging show areas of hemorrhage.[35] Western blot serologies are available,[9] but definitive diagnosis is by recovery of the pathogen, which may be found in subcutaneous tissue.

Baylisascariasis should be suspected in a child with CSF and peripheral eosinophilia, with severe encephalopathy with diffuse white matter disease on neuroimaging,[34] and with or without eye disease in North America or Europe. A history of exposure to raccoons or their feces would strongly suggest the diagnosis. In the absence of brain biopsy, the diagnosis is made serologically.[13]

DIFFERENTIAL DIAGNOSIS

Other helminths may invade the CNS of humans and may be associated with an eosinophilic pleocytosis,[45] including *Taenia solium*, the pork tapeworm causing cerebrospinal cysticercosis; *Schistosoma* spp.; *Paragonimus westermani*; and *Echinococcus*. The diseases produced generally have a chronic and intermittent course. Signs of a space-occupying lesion and convulsions are found frequently. Visceral myiasis with invasion of the CNS by botfly larvae may cause CSF eosinophilia.[3] The larvae of *Trichinella spiralis* can invade the CNS, but pleocytosis seems to be an unusual occurrence.[3] Neurologic involvement in visceral larva migrans caused by *Toxocara canis* rarely occurs; it may occur in association with CSF pleocytosis and eosinophilia.[21,40]

Coccidioidomycosis is the one fungal infection that may be associated with CSF eosinophilia when infection involves the meninges.[30,36] In one series, 30 percent of cases with coccidioidal meningitis had significant CSF eosinophilia.[30] Neurosyphilis and tuberculous meningitis rarely have been associated with eosinophils in the CSF, as have several malignant neoplasms, particu-

larly lymphomas, involving the CNS.[16,22] Other known causes of significant eosinophilic pleocytosis include intrathecal injection of various foreign proteins, rabies vaccination, the insertion of rubber tubing into the CNS during neurosurgery, lymphocytic choriomeningitis,[14] and Rocky Mountain spotted fever.[8] Eosinophilic pleocytosis has been documented in infants with congenital toxoplasmosis and late-onset group B streptococcal meningitis.[20,46]

Eosinophilia in the CSF indicating hypersensitivity has been difficult to document, although one case report described the association of eosinophilic meningitis and ibuprofen therapy.[29] Eosinophilic meningitis developing after implantation of a ventriculostomy catheter impregnated with rifampin and minocycline has been reported.[2] A study documented more than 5 percent eosinophils in the ventricular fluid of patients with shunt-associated pathology, particularly malfunction.[19]

TREATMENT

In a study in Thailand in which the disappearance of headache was used as the criterion for improvement in patients with *A. cantonensis* meningitis, no significant differences were noted among groups when 284 patients were treated with analgesics alone, 96 patients were treated with analgesics and steroids (30 to 60 mg of prednisone daily for 5 days), and 56 patients were treated with analgesics and antibiotics (penicillin or tetracycline).[23] A study that compared adult patients given a 2-week course of prednisolone (60 mg/day) with patients treated with a placebo showed a significant decrease in the number of patients with headache and in the duration of headache in the prednisolone-treated group.[6] Treatment with thiabendazole also has been tried without significant benefit. The combination of albendazole or mebendazole with prednisolone has shown promise.[5,7] Treatment of gnathostomiasis is supportive, although steroids have been used to decrease meningeal inflammation. Baylisascariasis has no effective antihelminthic therapy.

COURSE AND PROGNOSIS

In most patients, eosinophilic meningitis is a self-limited disease characterized by repeated attacks of severe headache, vomiting, intermittent fever, and somnolence. Many patients experience a dramatic improvement soon after undergoing a lumbar puncture, so repeated lumbar punctures may be performed at weekly intervals to relieve the headache. In most patients, most symptoms disappear within 4 weeks of onset, often within a few days after the first lumbar puncture is performed, leaving no sequelae. The mortality rate in large series from Thailand and Taiwan has been less than 5 percent; the incidence of permanent sequelae also has been less than 5 percent for *Angiostrongylus* infection.[27,46] The mortality in gnathostomiasis is higher, ranging from 7.7 to 25 percent.[35] No evidence suggests that immunity develops after recovery from infection; many recurrences have been reported.[27,32,47] In baylisascariasis, the mortality rate is high, and survivors often have severe sequelae.

PREVENTION

Disease can be prevented only by control of rodents and proper cooking of mollusks, shrimp, fish, and other intermediate hosts. Careful washing of fruits and vegetables that may be contaminated by rodent feces also is important. The larvae may remain infective in water for 60 hours, so protection of the water supply should be attempted. Prevention of baylisascariasis depends on eliminating exposure to raccoon feces.

CHAPTER 41

Aseptic Meningitis and Viral Meningitis

James D. Cherry ❂ David E. Bronstein

Aseptic meningitis is an inflammatory process of the meninges. It is relatively common and is caused by many different etiologic factors. The cerebrospinal fluid (CSF) is characterized by pleocytosis, increased protein, and the absence of microorganisms on Gram stain and on routine culture. Usually, the illnesses are self-limited; with some etiologies, however, the resulting diseases may be severe, protracted, recurrent, or progressive, and lead to disability and death.

Serous meningitis, *lymphocytic meningitis*, and *nonparalytic poliomyelitis* are terms that were used in the past to denote aseptic meningitis. Viral meningitis is an inflammation of the leptomeninges caused by infections with many different viruses. Viruses are the causes of most cases of aseptic meningitis.

HISTORY

Aseptic meningitis is a syndrome that first was described by Wallgren in 1925.[289] Wallgren's criteria for this diagnosis included (1) an acute onset with obvious signs and symptoms of meningeal involvement; (2) alteration of CSF typical of meningitis, which may show a small or large number of cells; (3) absence of bacteria in the CSF, as shown by appropriate culture; (4) a relatively short, benign course of illness; (5) absence of local parameningeal infection (e.g., otitis, sinusitis, trauma) or a general disease that might have meningitis as a secondary manifestation; and (6) absence from the community of epidemic disease, of which meningitis is a feature. In 1951, Wallgren[290] redefined aseptic meningitis as a syndrome likely to be encountered in many different infectious diseases.

The clinical occurrence of aseptic meningitis first was recognized in epidemic poliomyelitis and in mumps at the beginning of the 20th century.[93,296] Rivers and Scott[225] reported the recovery of lymphocytic choriomeningitis (LCM) virus from the CSF of several patients with aseptic meningitis in 1935, and in 1934, Johnson and Goodpasture[148] proved that mumps was caused by a virus. The discovery of coxsackieviruses in 1948 by Dalldorf and Sickles[74] and the introduction of tissue culture in 1949 by Enders and colleagues,[94] which resulted in the discovery of echoviruses, paved the way for the widespread investigation into the etiology of aseptic meningitis.

Rasmussen[220] reported on 374 cases evaluated at the Walter Reed Army Institute of Research laboratory between 1941 and 1946 and found the probable or definite etiology in 26 percent of "viral" disease of the central nervous system (CNS). Mumps and LCM viruses were the two etiologic agents identified in his study.

In 1953, Adair and associates[5] reviewed 480 additional cases of aseptic meningitis occurring in military personnel and their dependents from 1947 through 1952 and were able to confirm the etiology in 25 percent of those patients. Herpes simplex virus (HSV) and *Leptospira* spp. were added to the previously identified mumps and LCM viruses as causes of aseptic meningitis. Meyer and associates[188] extended these studies to include 713 more children and adults with acute CNS syndromes of "viral" etiology admitted to military and Veterans Administration hospitals between 1953 and 1958. Of these 713 patients, 430 had the clinical syndrome of aseptic meningitis. Approximately 80 percent of these patients were hospitalized in the United States. An etiologic diagnosis was determined in 71 percent of patients with aseptic meningitis. In addition to the agents identified earlier, poliovirus, coxsackieviruses of groups A and B, echoviruses, and arthropod-borne viruses were identified as causes of aseptic meningitis.

Lepow and colleagues[174,175] reported the probable viral etiology in 54 percent of the 407 patients they studied in Cleveland between 1955 and 1958. In 1958, Lennette and associates[173] determined a viral etiology in 65 percent of 511 children and adults with presumed viral CNS disease in Los Angeles; 368 of these patients were diagnosed as having aseptic meningitis. Sköldenberg[253] analyzed 3117 patients admitted to the Hospital for Infectious Diseases in Stockholm between 1955 and 1964 with the diagnosis of aseptic meningitis, with or without encephalitis or myelitis, and a virologic or clinical diagnosis (or both) of an associated viral infection was established in 72.6 percent. Berlin and associates[25] performed a surveillance study of aseptic meningitis in pediatric ambulatory clinics and emergency departments of three Baltimore hospitals between July 1986 and December 1990. They identified a single viral agent in 169 (62%) of the 274 cases with laboratory study; 168 enteroviruses and 1 adenovirus were identified. Today, with the use of polymerase chain reaction (PCR) and culture and appropriate serologic study,

TABLE 41–1 Etiologic Agents, Factors, and Diseases Associated with Aseptic Meningitis

Viruses
Arboviruses (in the United States: West Nile, St. Louis, California, Colorado tick fever, Eastern equine, Western equine, Venezuelan equine, and Powassan)*
Coronaviruses
Cytomegalovirus
Encephalomyocarditis
Enteroviruses (echoviruses, coxsackieviruses A and B, polioviruses, enteroviruses) and parechoviruses
Epstein-Barr
Hendra and Nipah
Herpes simplex type 1
Herpes simplex type 2
Human herpesvirus-6
Human herpesvirus-7
Human immunodeficiency virus (HIV-1)
Human T-cell lymphotrophic virus (HTLV-1)
Influenza A and B
Lymphocytic choriomeningitis
Measles
Mumps
Parainfluenza
Parvovirus B19
Rhinoviruses
Rotaviruses
Rubella
Varicella-zoster
Variola

Postvaccine
Measles
Mumps
Polio
Rabies
Vaccinia

Bacteria
Atypical mycobacteria
Bartonella henselae
Borrelia spp. (relapsing fever)
Borrelia burgdorferi (Lyme disease)
Brucella spp.
Leptospira spp. (leptospirosis)
Mycobacterium tuberculosis
Nocardia spp. (nocardiosis)
Pyogenic—partially treated
Treponema pallidum (syphilis)

Rickettsia
Coxiella burnetii
Ehrlichia canis
Rickettsia rickettsii (Rocky Mountain spotted fever)
Rickettsia prowazekii (typhus)

Mycoplasma
Mycoplasma hominis
Mycoplasma pneumoniae

Chlamydia
Chlamydia pneumoniae
Chlamydia psittaci

Ureaplasma
Ureaplasma urealyticum

Fungi
Blastomyces dermatitidis
Candida spp.
Coccidioides immitis
Cryptococcus neoformans
Histoplasma capsulatum
Other: *Acremonium* spp., *Alternaria* spp., *Aspergillus* spp., *Blastoschizomyces capitus*, *Cephalosporium* spp., *Cladosporium trichoides*, *Drechslera hawaiiensis*, *Fusarium* spp., *Paecilomyces* spp., *Paracoccidioides brasiliensis*, *Penicillium marneffei*, *Phaeohyphomycosis*, *Pseudallescheria boydii*, *Sporothrix schenckii*, *Trichosporon beigelii*, *Ustilago* spp., *Zygomycetes* spp.

Parasites (Eosinophilic Meningitis)
Flukes: *Paragonimus westermani*, schistosomiasis, fascioliasis
Roundworms: *Angiostrongylus cantonensis*, *Gnathostoma spinigerum*, *Baylisascaris procyonis*, *Strongyloides stercoralis*, *Trichinella spiralis*, *Toxocara canis*
Tapeworms: cysticercosis

Parasites (Noneosinophilic Meningitis)
Acanthamoeba
Naegleria fowleri
Toxoplasma gondii (toxoplasmosis)

Parameningeal Infections

Malignancy
Central nervous system tumor
Leukemia

Immune Diseases
Behçet syndrome
Lupus erythematosus
Sarcoidosis

Miscellaneous
Antimicrobial agents
Epidermoid, dermoid, other cysts
Foreign bodies (shunt, reservoir)
Heavy metal poisoning
Intrathecal injections (e.g., contrast media, antibiotics)
Kawasaki disease
Other drugs

**In other areas of the world, many other arboviruses are important.*

the etiology of most cases of aseptic meningitis can be determined.

ETIOLOGY

Table 41–1 lists etiologic agents and factors in aseptic meningitis. At present, the diagnostic work-up of aseptic meningitis usually is not undertaken vigorously, and the etiologic agent is identified in only approximately 10 percent of all cases. Epidemiologic study and intensive investigations at some centers indicate, however, that most cases result from viral infections. Enteroviruses account for approximately 85 percent of all cases of aseptic meningitis.[44,78-80,195] The following enteroviruses have been associated with aseptic meningitis: polioviruses 1 to 3; coxsackieviruses A 1 to 14, 16 to 18, 21, 22, and 24; coxsackieviruses B 1 to 6; echoviruses 1 to 9, 11 to 21, 24 to 27, and 29 to 33; enterovirus 71; and parechoviruses 1 and 2.

In recent years, multiple outbreaks of aseptic meningitis caused by enteroviruses have been described, including outbreaks caused by echovirus 30 in several countries throughout Eastern and Western Europe, China, Japan, Australia, the Arabian Gulf, the United States, and Brazil.* Echovirus 13 was responsible for reported outbreaks of aseptic meningitis in the United States,

*See references 9, 19, 26, 51, 54, 58, 88, 99, 119, 132, 152, 161, 204, 223, 245, 275, 283, 284, 292, 310.

England, Wales, Germany, Belgium, Spain, France, Lithuania, Israel, Japan, Korea, and Australia.* Enterovirus 71 caused a major epidemic in Taiwan from 1998 to 1999, with multiple cases of hand, foot, and mouth syndrome associated with aseptic meningitis and other neurologic manifestations.[142,177,178,181,249,291,292,304,306] Similar outbreaks of aseptic meningitis caused by enterovirus 71 were reported in Malaysia, Japan, and Australia.[59,106,140,187,248-250] Other enteroviruses involved in more recent outbreaks include echovirus 4 in Italy and Israel/Palestine,[129,217] echovirus 9 in Japan and regions of the United States,[8,57] echovirus 11 among institutionalized children in Israel,[218] echovirus 16 in Cuba,[241] and echovirus 33 in New Zealand.[144] In the United States, the most common specific enteroviral types in the vaccine era are coxsackievirus B5 and echoviruses 4, 6, 9, and 11, with echoviruses 9 and 30 being the most frequently identified etiologies of aseptic meningitis since 2003.[54,56,226]

Sharing seasonality with the enteroviruses, several arboviruses cause CNS disease in North America. Although encephalitis is the most recognizable manifestation of many of these infections, some arboviruses commonly are associated with aseptic meningitis as well.[117,226,230] Since the mid-1990s, outbreaks of West Nile virus meningitis and encephalitis have occurred in Romania, Russia, and Israel.[63,214,278] First detected in the Western Hemisphere in 1999 in New York City, West Nile virus subsequently spread across North America from the Atlantic to the Pacific coasts and into Canada and Mexico.[35,96,145,201,212] Between 1999 and 2005, greater than 18,000 cases were reported in the United States, with more than 700 deaths.[55,134] An estimated 1 in 150 infections results in severe neurologic illness, with meningitis as the primary manifestation in 16 to 40 percent of hospitalized patients.[150] Although the incidence of neuroinvasive disease increases with age, West Nile virus has been responsible for meningitis in young children and adolescents, occurring in at least one quarter of the 150 pediatric cases diagnosed in the United States in 2002.[65,103,133] Even in regions with increased incidence of West Nile virus, episodes of meningitis caused by enterovirus greatly outnumber those caused by West Nile virus.[150]

Before the introduction of West Nile virus, arboviruses accounted for approximately 5 percent of cases of aseptic meningitis in North America, with St. Louis encephalitis virus being the most common.[36,41,46,48] Infection with La Crosse encephalitis virus (a California encephalitis virus subtype) often resembles herpes encephalitis, but it may manifest as aseptic meningitis in children. In a study of 127 patients, mainly children, hospitalized in the southern United States with La Crosse virus infection, headache, fever, vomiting, and seizures were predominant findings. Thirteen percent of these patients had aseptic meningitis.[186] Other California serogroup viruses, such as Jamestown Canyon virus and snowshoe hare virus, and other arboviruses, such as Colorado tick fever, result in aseptic meningitis more frequently than encephalitis.[117,226,262] Tick-borne encephalitis can manifest as aseptic meningitis in endemic areas. Tick-borne encephalitis virus cases were reported more recently in studies conducted in Slovenia and Sweden, and in mild cases, the clinical presentation was that of aseptic meningitis.[125,176,182]

Aseptic meningitis is an occasional manifestation of acute and recurrent genital infections with HSV-2.[15,24,71,87,254,274] In contrast to HSV-1 CNS infections, which without treatment usually are fatal, HSV-2 aseptic meningitis in otherwise immunocompetent patients is a benign, self-limited illness. Herpes family viruses other than HSV-1 and HSV-2 also are potential causes of aseptic meningitis. Although neurologic involvement in primary varicella-zoster viral infections usually is an encephalitis rather than a benign meningitis, pleocytosis is noted occasionally in herpes zoster.[78,218,222,295] Varicella-zoster virus has been identified by PCR in the CSF of patients who had acute aseptic meningitis but no cutaneous lesions.[1,92,147] A variety of neurologic disorders, including aseptic meningitis, are rare complications of Epstein-Barr virus infection.[97,105,121,266,280] Most noncongenital infections with cytomegalovirus in nonimmunocompromised patients are unrecognized; however, occasional instances of aseptic meningitis have been noted.[78-80]

The role of human herpesvirus-6 (HHV-6) in causing meningitis is unclear; although HHV-6 has been found in CSF samples from infants with meningitis, the virus also is detectable in the CSF of asymptomatic individuals.[11,38,305,308] Similarly, PCR identified HHV-7 in the CSF of six children with neurologic diseases, including aseptic meningitis, meningoencephalitis, facial palsy, vestibular neuritis, and febrile seizures.[215] The role of HHV-7 as a causative agent in aseptic meningitis remains to be determined.

Occasionally, meningitis or meningoencephalitis occurs as a manifestation of acute illness with HIV-1 infection.[16,128] Neurologic manifestations develop 3 to 6 weeks after primary infection at the same time as an infectious mononucleosis–like illness.

Although LCM virus was an important historical cause of aseptic meningitis, it rarely is recognized today as a cause of meningitis except in animal-exposure outbreak situations.[17,21,28,81,188] In 1974, eight cases of aseptic meningitis caused by LCM virus were found in New York State.[81] Many sporadic instances of LCM virus infection probably go unrecognized. Physicians should be alert to the possibility in all situations of rodent (pet or wild) exposure. Encephalomyocarditis virus is another rodent virus that rarely is recognized in humans.[293] It is associated with a variety of neurologic manifestations, including aseptic meningitis.[107]

Adenoviral types 1, 2, 3, 5, 6, 7, 12, 14, and 32 have been associated with meningitis and meningoencephalitis.[25,69,78-80,98,159,210,251,257] Although they occur infrequently, adenoviral CNS infections tend to be more severe than are enteroviral infections. Rarely, aseptic meningitis has been noted during illnesses caused by rhinoviruses, influenza A and B viruses, parainfluenza viruses, parvovirus B19 virus, rotaviruses, and coronaviruses.* Most infections with measles, rubella, and variola viruses that involve the CNS are encephalitic.[42,43,45,192]

In the pre-vaccine era, mumps virus was the agent responsible for the greatest number of cases of aseptic meningitis; today in the United States, use of vaccine has rendered mumps rare, although mumps outbreaks with associated cases of aseptic meningitis occur occasionally.[47,57] Aseptic meningitis and encephalitis resulting from administration of mumps vaccine have been noted in Canada, Brazil, Japan, and Europe.† The Leningrad 3, Urabe Am 9, and three Japanese strains of vaccine viruses have been implicated. In the United States, where the Jeryl Lynn vaccine strain has been used exclusively, the rate of encephalitis in vaccinees has been no higher than that of the observed background incidence of similar illness in the population.[47] More recently, a preliminary analysis of the Vaccine Safety Datalink project showed a possible increased risk of developing aseptic meningitis 8 to 14 days after receiving immunization with Jeryl Lynn mumps vaccine strain. A follow-up case-control evaluation of hospitalized cases failed to show an increased risk, however.[30]

Neurologic illness is a rare complication of measles, smallpox, polio, and rabies viral vaccines. In most instances, the illnesses are complex and severe, but occasionally, aseptic meningitis is the only manifestation.[25,42,45,53,191,246,261] A case of aseptic meningitis caused by vaccine-derived poliovirus was reported in the Philippines in 2001.[53] It was in association with two pediatric cases of acute flaccid paralysis that occurred during the same time period.

Viral isolates from all three patients revealed type 1 poliovirus derived from the Sabin vaccine strain.

Certain bacteria are important to recognize as etiologic agents in aseptic meningitis because the illnesses are treatable and early initiation of therapy is crucial. Of greatest importance is tuberculous meningitis. Early treatment of this illness nearly always results in complete cure, whereas diagnostic delay or inadequate treatment frequently results in permanent neurologic sequelae. Lyme disease, relapsing fever, brucellosis, leptospirosis, and rickettsial infections are illnesses acquired either directly or indirectly from animals, in which aseptic meningitis may be a part of the disease process.* *Mycoplasma pneumoniae* is an important cause of neurologic illness.[89,124,215,279] Pönkä[216] noted that 8 of 560 hospitalized patients with *M. pneumoniae* infections had aseptic meningitis, and 18 had encephalitis or meningoencephalitis. *Mycoplasma hominis* and *Ureaplasma urealyticum* are rare causes of neonatal meningitis.[108,183,286,287] Meningitis and meningoencephalitis have been associated with *Chlamydia pneumoniae* infections.[12,123,255,267] Partially treated common bacterial meningitides are a common cause of meningitis in which cultures of CSF fail to grow organisms. Antigen detection systems, such as latex agglutination, can be useful in identifying the causative agents in some of these cases.

Numerous fungi and yeasts cause meningitis.[238] Although many fungal meningitides occur almost exclusively in immunocompromised patients, children and adults with normal immune status experience meningitis most commonly caused by the following: *Blastomyces dermatitidis*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Cladosporium* spp., *Histoplasma capsulatum*, and *Paracoccidioides brasiliensis.* In infants who are premature or younger than 1 month of age, *Candida albicans* is an important cause of meningitis, associated with significant morbidity and mortality.[22,120,196]

Parasites occasionally cause aseptic meningitis. Eosinophilic meningitis is caused by *Angiostrongylus cantonensis*, a rat lungworm.[60,128,228,294] Aseptic meningitis caused by *A. cantonensis* has been observed on several islands in the Pacific, and the infection may be acquired by the consumption of freshwater shrimp. *Baylisascaris procyonis*, the intestinal roundworm of raccoons, is a rare cause of neural larva migrans in infants and young children and manifests as acute fulminant eosinophilic meningoencephalitis.[109,110,300] Between 1973 and 2002, 14 probable or confirmed cases were described in eight states throughout the United States, reported approximately once every 1 to 2 years. The infection was fatal in 6 of the 14 children, and all documented survivors were neurologically devastated.[300]

A sterile CSF pleocytosis occurs in 12 to 13 percent of young infants with bacterial urinary tract infections[6,100,269] and in approximately one third of patients with Kawasaki disease who undergo lumbar puncture.[82,116] Numerous drugs and biologicals have been implicated in aseptic meningitis.† Of most importance in pediatrics are trimethoprim-sulfamethoxazole and intravenous immunoglobulin. Other causes of aseptic meningitis are listed in Table 41–1.‡

EPIDEMIOLOGY

Because many different types of organisms cause aseptic meningitis, no unified epidemiologic pattern exists. The epidemiology of the specific individual infectious agents or diseases is presented in detail in the various chapters of this book, and only a brief overview is presented here.

Because approximately 85 percent of all cases of aseptic meningitis are caused by enteroviral infections, the basic epidemiologic pattern of aseptic meningitis reflects these agents. In temperate climates, most cases occur in the summer and fall; infection with enteroviruses is spread directly from person to person, and the incubation period usually is 4 to 6 days. Epidemiologic considerations in aseptic meningitis caused by agents other than enteroviruses depend markedly on season, geography, climatic conditions, animal exposures, and many other factors related to the specific pathogens.

CLINICAL MANIFESTATIONS

Aseptic meningitis has many different causes (see Table 41–1), and clinical manifestations vary with the different diseases. In some instances, the signs and symptoms resulting from meningeal inflammation dominate the clinical illness, whereas in other instances, the main signs and symptoms reflect other organ system involvement. Clinical manifestations in aseptic meningitis, regardless of etiology, also vary markedly by patient age.

ENTEROVIRUSES

Enteroviruses are the most common cause of aseptic meningitis, and they can be considered the prototype for a description of general clinical manifestations of aseptic meningitis.* Even among the enteroviruses, however, significant differences in clinical manifestations exist among the different viral types. Some general aspects of epidemic enteroviral aseptic meningitis are presented by viral type in Chapter 178.

The onset of illness generally is acute, although it may be insidious over the course of a week or so, or may be preceded by a nonspecific acute febrile illness of a few days' duration. Almost all children have fever, and most older children have headache, which most often is retro-orbital or frontal in location. Photophobia is common. Temperature elevation varies, ranging from 38° C to 40.5° C (100.4° F to 105° F), and usually lasts approximately 5 days. Occasionally, fever is biphasic, with the initial elevation occurring before the onset of neurologic signs and symptoms. Anorexia, nausea, and vomiting are common, and abdominal pain and diarrhea also are reported frequently.

Meningeal signs (stiff neck and back, tightness of the hamstring muscles, Brudzinski and Kernig signs) usually are present, but deep tendon reflexes usually are normal or hyperactive. Seizures occur occasionally, usually when concomitant high fever is present. Muscle weakness rarely is reported, but myalgia occasionally is noted. In young children, fever, irritability, and lethargy are the most common findings. Infants may be irritable and show resentment to handling, and the fontanelle may be tense.

Other manifestations of enteroviral infections also occur in children with aseptic meningitis. Most common is pharyngitis, which may occur during infection with all of the neurotropic enteroviral types. Rash occurs commonly, but varies by viral type. With echovirus 9 meningitis, 30 to 50 percent of children have rashes, whereas with echovirus 6, exanthem is rare. Cases of meningitis caused by enterovirus 71 frequently are accompanied by hand, foot, and mouth syndrome. Enanthem, pleurodynia, pericarditis, myocarditis, and conjunctivitis are other findings noted in children with enteroviral aseptic meningitis. Illness often is biphasic with fever, an interlude, then return of fever and neurologic manifestations.

*See references 3, 8, 9, 32, 50-53, 58, 76, 85, 102, 111, 122, 126, 129, 130, 135, 137, 142, 152, 155, 156, 169, 178, 221, 229, 234, 235, 237, 239, 252, 265, 270, 297.

CSF leukocyte counts vary from a few cells to a few thousand cells; the median is in the range of 100 to 500 cells/mm^4. The percentage of neutrophils also varies greatly. Initially, a predominance of neutrophils commonly occurs, but later, CSF examinations show a decline in the percentage of neutrophils. The CSF protein usually is elevated mildly, and the glucose concentration usually is normal; rarely, hypoglycorrhachia is noted.

The duration of illness varies. Usually, disability because of neurologic involvement lasts 1 to 2 weeks.

ASEPTIC MENINGITIS CAUSED BY OTHER AGENTS

In meningitis caused by arboviruses, involvement of the brain often occurs as well (meningoencephalitis). With St. Louis and California viral infections in children, the illness commonly is benign, without changes in sensorium or other findings indicative of brain involvement. Similarly, meningitis without encephalitis is present in a significant proportion of patients with neuroinvasive West Nile virus infections.[133,212] Seizures occur more commonly in arboviral meningitides than in enteroviral illnesses of otherwise comparable severity.[131] When neurologic disease caused by mumps is recognized, usually evidence of brain involvement is present. Examination of the CSF in mild cases of mumps often reveals pleocytosis.

Tuberculous meningitis usually has a gradual onset over the course of 2 to 3 weeks.[160,193,227] Initially, personality changes, irritability, anorexia, listlessness, and low-grade fever may be present, followed by signs of increased intracranial pressure, such as drowsiness, stiff neck, cranial nerve palsies, inequality of the pupils, vomiting, and convulsions. Finally, coma, irregular pulse and respirations, and high fever occur. In fungal diseases, the course of meningitis is similar to the course of tuberculosis. In tuberculosis and several fungal meningitides, such as those caused by *C. immitis*, *H. capsulatum*, and *C. neoformans*, historical and radiographic evidence of pulmonary disease may be present.

Aseptic meningitis caused by *M. pneumoniae* is unique in that it frequently occurs a few days to 3 weeks after a respiratory illness (pharyngitis, bronchitis, or pneumonia).[124,179,256,279] In nonenteroviral aseptic meningitides, the CSF findings generally are similar to those in enteroviral disease. Generally, the likelihood of a predominance of neutrophils is less in other aseptic meningitides, and low glucose levels are likely in parameningeal bacterial infections, partially treated bacterial meningitides, brain tumors, leukemic infiltration, *M. pneumoniae* infections, fungal infections, and tuberculosis.

RECURRENT ASEPTIC MENINGITIS (MOLLARET MENINGITIS)

In 1944, Mollaret[194] described three patients with recurrent aseptic meningitis whom he had observed over the course of 15 years. Subsequently, many other cases have been reported, and some cases have been noted in children.[34,67,68,138,213,263,272] The illness is characterized by recurrent attacks of fever with meningeal signs and symptoms. The attacks last several days and are separated by symptom-free periods lasting weeks or months. In addition to a lymphocyte predominant pleocytosis, CSF samples obtained from certain patients contain large mononuclear cells (Mollaret cells). The disease remits spontaneously. HSV-2 has been identified by PCR or DNA probes in the CSF of most patients with recurrent meningitis.[18,67,91,167,213,271,272,242,281] Other viruses, such as HSV-1 and Epstein-Barr virus, and noninfectious causes, such as systemic lupus erythematosus, intracranial cysts, and environmental exposures, also have been identified as less frequent etiologies of recurrent meningitis.[121,163,236,240,263]

DIFFERENTIAL DIAGNOSIS

Careful analysis of the history and epidemiologic circumstances may point toward one of the specific causes listed in Table 41–1. During the summer and autumn, the presence of pleurodynia, herpangina, or unexplained febrile eruptions in the community suggests the possibility of enteroviral infections. Acute paralytic disorders in other patients suggests poliomyelitis or West Nile virus. Exposure to mosquitoes and encephalitis in horses implicates certain arboviruses, and exposure to ticks may be suggestive of Lyme disease, relapsing fever, or rickettsial disease, depending on the geographic location and other symptoms of the illness. A history of swimming in waters contaminated by urine from infected animals and exposure to rats in urban slums suggest leptospiral infection. Knowledge of clear-cut exposure to or concurrent evidence of mumps or of one of the common exanthems is helpful in delineating the differential diagnosis. The association of pneumonia or other respiratory illness preceding aseptic meningitis strongly suggests the possibility of *M. pneumoniae* as the etiologic agent.

Most difficult from the diagnostic, therapeutic, and prognostic points of view are instances of incipient or partially treated bacterial (especially when caused by *Haemophilus influenzae*) or mycobacterial meningitis. The clinical findings; the dosage of antibiotic previously used; the spinal fluid smear, latex agglutination, or other rapid antigen identification test; the culture; and the glucose level may be helpful in diagnosing bacterial meningitis. The quantitative determination of C-reactive protein in the CSF also may be useful in differentiating bacterial from viral meningitis.[2,70,77,207,208] Lindquist and associates[180] found that the determination of CSF concentrations of lactate was the most useful test in differentiating bacterial from nonbacterial causes of meningitis. Studies suggest that the presence of tumor necrosis factor-α in the CSF is rare in viral infections, but common in bacterial disease.[7,90,113] When tuberculous meningitis is suspected, a careful evaluation of contacts, a careful examination of an appropriately stained smear from the pellicle of the CSF that was allowed to settle, and a positive tuberculin reaction may confirm the diagnosis. Because combined bacterial and viral infection has occurred, examinations of CSF should be repeated if any doubt exists. The possibility that the observed meningeal reaction is of neither viral nor bacterial origin must be considered. Finally, CNS tumor must be considered in the differential diagnosis, particularly if hypoglycorrhachia and prominent signs of increased intracranial pressure are present.[166]

SPECIFIC DIAGNOSIS

Obtaining a meticulous history is essential. The clinician must evaluate exposure of the patient in the past 2 to 3 weeks to illness in contacts; exposure to mosquitoes, ticks, and animals during recent vacations, picnics, and so on; awareness of illness in animals, especially horses and other Equidae, in the patient's environment; recent travel from the home area; recent injections or medications of any kind; and the possibility of accidental exposure to heavy metals.

The CSF must be examined carefully to exclude disorders that respond to specific therapy. Smears for bacteria, appropriate rapid antigen identification tests, and cultures of the CSF are mandatory; the history and clinical findings may indicate the need for performing acid-fast stain and culture of the sediment for mycobacteria. Other circumstances may indicate the need for excluding fungal or protozoal infection; atypical cells may require cytopathologic study to exclude neural neoplasms, which may manifest acutely.

In any patient suspected to have viral meningitis, spinal fluid, blood, feces, and throat swabs should be collected and sent to a

laboratory offering viral diagnostic services. An additional serum specimen should be collected 10 to 21 days later so that paired sera can be examined for antibody titer increases. This pairing is particularly useful in arboviral, LCM viral, encephalomyocarditis viral, leptospiral, borrelial, rickettsial, mycoplasmal, and toxoplasmal infections. Although these studies may not provide an immediate diagnosis, they may give early warning of a specific epidemic, and they are useful for prognostication, particularly in very young infants.

The introduction of PCR has facilitated the etiologic diagnosis of CNS viral infections, particularly infections caused by enteroviruses and herpesviruses.* PCR detects enterovirus in the CSF more rapidly than does cell culture and has been shown to shorten the duration of hospitalization for children with meningitis, reducing costs.[202,264] PCR is the test of choice for detecting CNS infections caused by HSV, and molecular techniques also have been used to identify in CSF such rare causes of meningitis and meningoencephalitis as varicella-zoster virus, HHV-6, parvovirus B19, and rotavirus.[20,147,165,282] Although such techniques are of limited value for many arboviruses with short periods of viremia and presence in the CSF, real-time PCR analysis of CSF samples used during the 1999 West Nile encephalitis outbreak in New York had 57 percent sensitivity and 100 percent specificity.[64,170]

TREATMENT

Hospitalization usually is necessary because of the possibility of treatable bacterial disease and the frequent need for fluid therapy for dehydration. Treatment is symptomatic. Headache and hyperesthesia are treated with rest; analgesics; and a reduction in room light, noise, and visitors. Antipyretics are recommended for fever. Using acetaminophen rather than aspirin is prudent because of the risk for developing Reye syndrome associated with the latter antipyretic. Codeine, morphine, and the phenothiazine derivatives often are used for pain and vomiting, but they rarely are necessary in children, and they should be avoided because they may induce misleading signs and symptoms. The investigational antiviral drug pleconaril has been shown to be effective in the treatment of enteroviral meningitis; however, this drug presently is unavailable.[84,231,233] Treatment for such illnesses as tuberculous meningitis, fungal meningitides, and other illnesses for which specific therapies are available is covered in specific chapters of this book.

Several weeks after the patient has apparently recovered, a careful neuromuscular assessment should be conducted to ensure that muscular weakness is not a sequela. Bilateral audiometry is recommended, especially when mumps virus was involved.

PROGNOSIS

The prognosis in aseptic meningitis depends on the etiology. Some illnesses have an ominous prognosis (tuberculous meningitis, parameningeal infections, rickettsial infections), but patients usually do well if appropriate specific therapy is instituted early in the course of the illness. In *C. immitis* meningitis, the prognosis for cure is guarded even with early optimal therapy.

In enteroviral and other viral meningitides, children usually recover completely. Some patients complain of fatigue, irritability, decreased ability to concentrate, muscle pain, muscle weakness and spasm, and incoordination for several weeks after an acute illness. Although the outcome of enteroviral meningitis most often is without residual, some infants who have enteroviral meningitis in the first few months of life have an increased risk for altered language development.[23,298] Formally evaluating such children at age 3 to 6 years is important.

PREVENTION

The universal use of polio and mumps vaccines in children clearly is effective in controlling these two diseases. Control of insect vectors by suitable spraying methods and eradication of insect breeding sites is important in the control of many arboviruses. The control of animal vectors such as mice and rats alters the incidence of infections with LCM and encephalomyocarditis viruses.

CHAPTER 42

Encephalitis and Meningoencephalitis

James D. Cherry ✪ W. Donald Shields ✪ David E. Bronstein

Encephalitis is an inflammation of the brain, and meningoencephalitis is a similar inflammatory illness in which the brain and the meninges are involved. The diagnosis of encephalitis can be established with absolute certainty only by the microscopic examination of brain tissue, and, similarly, the etiology is established only by the recovery from or the demonstration in brain tissue of an infectious agent. In clinical practice, the diagnosis frequently is based on neurologic manifestations, the recovery of infectious agents from other sites in the body, the serologic evidence of a specific infection, and relevant epidemiologic findings.

Encephalitis frequently is classified as primary or as postinfectious or parainfectious. Primary encephalitis is an illness in which encephalitis is the major manifestation. Symptoms are caused by direct invasion and replication of an infectious agent in the central nervous system (CNS), resulting in objective clinical evidence of cerebral or cerebellar dysfunction. Postinfectious or parainfectious encephalitis occurs after or in combination with other illnesses that are not CNS illnesses, or after a vaccine or other product has been administered. Manifestations may be mediated immunologically.

When neurologic clinical findings suggest encephalitis but inflammation of the brain has not occurred (e.g., in Reye syndrome), the condition is identified by the less specific term *encephalopathy*. Frequently, when encephalitis or meningoencephalitis occurs, other areas of the nervous system, such as the spinal cord (myelitis), nerve roots (radiculitis), and nerves (neuritis), also are involved.

HISTORY

Rabies encephalitis was recognized in ancient times in Europe and Asia.[169] In 100 CE, Celsus noted the relationship of animal rabies to human disease. "Sleeping sickness" associated with epidemic influenza was noted early in the 18th century.[345] For the past 100 years, epizootics of encephalitis in equine animals have been observed in the United States, and in 1933, St. Louis encephalitis virus was isolated from the brains of humans dying from epidemic encephalitis.[230,251] Meningoencephalitis was recognized at the beginning of the 20th century as a complication of mumps.[103] Nonpolio enteroviruses have been known for the past 55 years to be a cause of encephalitis; during the same period, more than 400 zoonotic arthropod-borne viruses have been discovered, and of these, 100 or more cause encephalitis in humans.[26]

ETIOLOGY

Table 42–1 presents etiologic agents in acute encephalitis, meningoencephalitis, and acute illnesses with an encephalitic component. All of the infectious agents or diseases are presented more fully and are referenced more completely elsewhere in this book (see Index).

Despite extensive testing and evaluation, the etiology of most cases of encephalitis remained unexplained in more recent prospective studies.[121,193] During the first 2.5 years of the California Encephalitis Project, 334 immunocompetent patients older than 6 months of age were identified who met the case definition of encephalopathy requiring hospitalization and having at least one other sign or symptom, including fever, seizure, focal neurological findings, cerebrospinal fluid (CSF) pleocytosis, or electroencephalography (EEG) or neuroimaging findings consistent with encephalitis.[121] Of these cases, a confirmed or probable viral agent was identified in only 9 percent of cases, and bacterial and parasitic agents were found in only 3 percent and 1 percent, respectively; an etiology was not discovered for 62 percent of the cases. A possible etiology was noted in 12 percent, a noninfectious cause was identified in 10 percent, and a nonencephalitis infection was identified in 3 percent.

VIRUSES

As a group, the herpesviruses are the most frequently identified agents responsible for viral encephalitis. Herpes simplex encephalitis is the most common cause of sporadic fatal encephalitis in the United States, with approximately one third of cases occurring in patients younger than age 20 years but older than 6 months and approximately half occurring in patients older than 50 years.[230,281,335,351] Molecular analyses of paired oral or labial and brain sites have indicated that herpes simplex encephalitis can be the result of a primary infection, a reactivation of latent herpes simplex virus (HSV), or a reinfection by a second HSV.[348] Although in neonates HSV type 2 (HSV-2) is a leading cause of severe and frequently fatal encephalitis,[352] in older children, the usual cause is HSV-1.[71,164,183,219,231,263,273,337] Recurrent genital infection with HSV-2 occasionally is associated with an aseptic meningitis, but this type 2 virus rarely causes encephalitis outside the newborn period except in immunocompromised individuals.

Encephalitis can occur in association with primary infection with varicella-zoster virus (VZV) (chickenpox) and with endogenous recurrent disease (herpes zoster).* In a study in Finland of more than 3000 patients with acute CNS infections of suspected viral origin, VZV constituted 29 percent of all confirmed or probable etiologic agents.[187] In chickenpox, the rate of encephalitis is approximately 0.3/1000 cases,[49] and the case-fatality rate is approximately 17 percent.[265] Of patients with herpes zoster, 0.5 to 5 percent have encephalitis.[168] This complication occurs more commonly in immunocompromised patients.

In infectious mononucleosis, encephalitis occurs in less than 1 percent of cases. Most patients with Epstein-Barr virus encephalitis are adolescents and young adults, and although patients typically present 1 to 3 weeks after the onset of mononucleosis syndrome, encephalitis may be the presenting complaint in Epstein-Barr virus infection.[79,82,96,153,207,335] Caruso and associates[45] reported five children with subacute and chronic neurologic deficits associated with apparent primary Epstein-Barr virus infections. Severe chronic involvement of the brain is a common finding in congenital cytomegalovirus (CMV) infection.[143] Encephalitis caused by acquired CMV infection is uncommon

TABLE 42–1 Etiologic Agents in Acute Encephalitis and Acute Meningoencephalitis

Etiologic Agents	Frequency*
Viruses	
Spread person-to-person only	
Herpes simplex types 1 and 2	+++
Varicella zoster	++
Epstein-Barr	+
Cytomegalovirus	++
Human herpesvirus type 6	++
Human herpesvirus type 7	+
Enteroviruses	++
Reoviruses	+
Influenza A and B	++
Respiratory syncytial	+
Parainfluenza 1-3	+
Adenovirus	+
Rubella	++
Human Coronavirus	+
Mumps	+++
Measles	++
Variola	+
Hepatitis A, B, C	+
Human parvovirus	+
Rotavirus	+
BK and JC	+
Spread to humans by mosquitoes or ticks	++
Arboviruses†—those that occur in the United States are the following: St. Louis, West Nile, Eastern equine, Western equine, Venezuelan equine, California, Powassan, and Colorado tick fever	
Spread by warm-blooded mammals	
Rabies	+++
Simian herpesvirus (herpesvirus B)	+
Lymphocytic choriomeningitis	++
Encephalomyocarditis	+
Vesicular stomatitis	+
Equine Morbillivirus (Hendra virus)	+
Nipah	+
Monkeypox	+
Bacteria	
Haemophilus influenzae, *Neisseria meningitidis*, *Streptococcus pneumoniae*, *Mycobacterium tuberculosis*, and other bacterial meningitides often have an encephalitic component	+++
Spirochetal infections: *Treponema pallidum*, *Leptospira*, *Borrelia burgdorferi*, and other *Borrelia* spp. infections	+++
Brucella spp.	+
Actinomyces and *Nocardia*	+
Bartonella henselae	+
Listeria monocytogenes	+
Other	
Chlamydia psittaci, *Chlamydia pneumoniae*	+
Rickettsial infections: Rocky Mountain spotted fever, ehrlichiosis, Q fever, and typhus	+++
Mycoplasma infections: *Mycoplasma pneumoniae* and *Mycoplasma hominis*	++
Fungal: *Coccidioides immitis*, *Cryptococcus neoformans*, and other fungal meningitides often have an encephalitic component	++
Protozoal: *Plasmodium* spp., *Trypanosoma* spp., *Naegleria* spp., *Acanthamoeba* spp., *Balamuthia mandrillaris*, and *Toxoplasma gondii*	+++
Helminths: *Trichinella spiralis*, *Schistosoma* spp., *Strongyloides stercoralis*, *Baylisascaris procyonis*	++
Drug: trimethoprim	+

*Frequency refers to the rate of occurrence of encephalitis or encephalitis component in the particular disease cited and not its relative overall occurrence; +++ = frequent, ++ = infrequent; + = rare.

†See Chapters 184, 187, 188, 202 and 203 for viral diseases in other countries transmitted by arthropods.

and usually occurs in immunocompromised children.[135,153,304] Several cases have been described in previously healthy patients, however.

Human herpesvirus type 6 (HHV-6) is an important cause of acute febrile illness and roseola infantum in young children, commonly associated with febrile convulsions.[100] Encephalitis is a rare complication of HHV-6 infection in children with and without roseola.[8,46,164-166,221,247,361] HHV-6 increasingly has become recognized as an important cause of encephalitis in immunocompromised, post-transplantation patients, occasionally manifesting as severe amnesia after they have undergone bone marrow transplantation.[35,70,76,115,213,290,306,338] HHV-7 also they have undergone has been implicated as a causative agent in encephalitis.[263,328,344]

Enteroviruses now are the leading viral cause of neurologic disease in children in the United States, and they are a major cause of encephalitis.* The following viral types have been associated with encephalitis: coxsackieviruses A2, 4 to 7, 9, 10, 16, and B1-5; echoviruses 1 to 9, 11 to 25, 27, 30, and 33; and enterovirus 71. In 1998, an extensive epidemic of enterovirus 71 disease occurred in Taiwan.[64,154,157,208,211,342,357,358] Manifestations of illness in this epidemic varied, and many children had severe neurologic events, including meningitis, meningoencephalitis, encephalitis, cerebellitis, and polio-like syndrome. In particular, numerous children had brain stem encephalitis, with many fatalities occurring. A variety of neurologic illnesses, including encephalitis, have occurred rarely in reoviral infections.[102,173,188,190,364]

Encephalitis occurs with some regularity as a manifestation of influenza viral infection,† more often described in children than in adults. Although particularly notable during 1997 to 2001 influenza A epidemics in Japan, cases of influenza-associated encephalitis and encephalopathy also have been described in North America and Europe, and influenza B has been implicated as well.[237,240,318,326,360] Numerous other clinical CNS manifestations have been shown to occur during the course of influenza infection, including Reye syndrome (see Chapter 56), acute necrotizing encephalopathy, and myelitis.[160,250,289,317] Rarely, encephalitis occurs during the course of respiratory infections with respiratory syncytial virus, human coronavirus, and parainfluenza virus infections.‡

Adenoviruses are uncommon, but not rare, causes of encephalitis and meningoencephalitis.[50,88,89,97,186,244,252] Adenoviral types 1 to 3, 5 to 7, 11, 12, and 32 have been recovered from either the brain or the CSF in affected patients. More recently, a syndrome of transient encephalopathy associated with adenovirus type 3 has been described.[316]

Neurologic involvement is a common manifestation of congenital rubella virus infection,[144] and encephalitis is a rare complication of noncongenital disease.[63,201,232] Some data suggest a rate of encephalitis in rubella between 1/5000 and 1/10,000 cases.[50] In the pre-vaccine era, the encephalitis rate in one epidemic in 1964 was 1/5000 cases, and in another epidemic in 1942, it was 1/6000 cases.[217,301]

Before the use of mumps vaccine became widespread, this virus was the leading cause of meningoencephalitis in the United States. Today, mumps is rare, although extensive mumps outbreaks with associated cases of encephalitis occurred in 2006.[60] The incidence of encephalitis among individuals with mumps is approximately three episodes per 1000 cases, and the case-fatality rate is 1.4 percent.[53] In the pre-vaccine era, measles was an important cause of severe encephalitis in children.[49,51] Measles is a rare occurrence in the United States, and encephalitis occurs uncommonly, at a rate of 0.74/1000 cases of measles; the case-fatality rate is 14 percent. Smallpox (variola virus infection), before its worldwide eradication, was a rare cause of encephalitis.

Hepatitis B virus and potentially hepatitis C virus are rare causes of encephalitis, and encephalitis has been reported as a complication of erythema infectiosum (human parvovirus infection).[16,17,34,141,246,315] Encephalitis and cerebellitis have been noted in association with rotavirus gastroenteritis,[126,212,242] and BK and JC viruses have been detected in the CSF of patients with suspected encephalitis.[23,24,340] A case of encephalitis in a 3-year-old boy caused by vesicular stomatitis virus has been described.[270] This virus can be spread by direct contact with infected animals or by insects.

Arboviruses are the most important worldwide cause of severe encephalitis. The occurrence of specific arboviruses is seasonal and highly geographic. More than 400 different arboviruses exist, and detailed information about illnesses caused by specific types in various areas of the world is provided in Chapters 184, 187, 188, 202 and 203.[26,153,176] In the United States, eight arboviruses (eastern equine, western equine, Venezuelan equine, St. Louis, Powassan, West Nile, California, and Colorado tick fever) that cause encephalitis have been isolated.

First detected in the Western Hemisphere in 1999 in New York City, West Nile virus subsequently spread across North America from the Atlantic to the Pacific coasts, and into Canada and Mexico.[39,55,104,216,162,239,261] Between 1999 and 2005, greater than 18,000 cases were reported in the United States, with more than 700 deaths.[57,150] An estimated 1 in 150 infections results in severe neurologic illness, and, although the incidence of neuroinvasive disease increases with age, West Nile virus has been responsible for encephalitis in young children and adolescents, occurring in approximately one fifth of the 150 pediatric cases diagnosed in the United States in 2002.[73,113,149] Before the introduction of West Nile virus, La Crosse encephalitis virus was the most common cause of pediatric arboviral encephalitis in the United States.[225,294] Of all North American causes of arboviral encephalitis, eastern equine encephalitis virus results in the most severe disease and has the highest case-fatality rate, particularly among infants and children.[280]

Human rabies is uncommon in the United States, but more than 20,000 cases and deaths occur worldwide every year.[356] Since the early 1970s, approximately two cases of rabies have occurred per year in the United States, and approximately 50 percent of the cases have occurred in children and teenagers.[6,52] Although rabies previously was considered to be universally fatal, a 15-year-old girl with clinical rabies survived after induction of coma and administration of antiviral therapy.[353] Encephalitis caused by herpesvirus B is rare; it occurs predominantly in monkey handlers and usually after monkey bites.[163] Except in outbreak situations, lymphocytic choriomeningitis virus rarely is recognized as a cause of encephalitis.[28] Serologic surveys have indicated, however, that neurologic disease caused by this virus is not rare in the United States,[89-91,170,230] and clusters of lymphocytic choriomeningitis virus cases were identified among recipients of solid organ transplants in 2003 and 2005.[108] Rare cases of encephalitis are caused by encephalomyocarditis virus; infection of humans with this virus is common, but most infections go unrecognized.[324]

Since its emergence in Japan in the 1870s, Japanese encephalitis virus, a mosquito-borne flavivirus, has spread across Asia to become the most important cause of epidemic encephalitis worldwide, with an estimated 35,000 to 50,000 cases and 10,000 deaths annually.[309,310,332] Nipah virus, a new paramyxovirus, is the first wide-scale epizoonotic encephalitis with direct animal-to-human, rather than vectorial, transmission.[66] The initial outbreak of Nipah virus encephalitis occurred among pig farmers in Malaysia and Singapore in 1999, and subsequently outbreaks have been identified in Bangladesh and India.[25,62,124,145,156,195,204,321,322] A fatal case of encephalitis caused by Hendra virus (equine morbillivirus), another novel paramyxovirus, was reported in an adult[253];

*See references 22, 50, 58, 59, 71, 88, 89, 91, 97, 136, 153, 175, 179, 186, 198, 230, 234, 236, 244.

†See references 22, 50, 74, 88, 89, 91, 109, 122, 123, 188, 244, 255, 271, 317, 343, 366.

‡See references 16, 29, 49, 88, 91, 188, 241, 319, 341, 359.

previously, this virus had been noted in association with fatal respiratory infections in horses and humans.

In 2003, another emerging pathogen, Chandipura virus, was responsible for a large outbreak of acute encephalitis in 329 children in southern India, with a case-fatality rate of 56 percent.[272] This rhabdovirus transmitted to humans by sandflies was responsible for a second outbreak in western India in 2004, with an even higher case-fatality rate of 78 percent.[61] During the 2003 monkeypox outbreak in the midwestern United States, one child developed severe acute encephalitis and seizures; no additional encephalitis cases were identified.[295]

BACTERIA

Signs and symptoms of acute encephalitis (drowsiness, coma, convulsions, mental confusion) commonly occur in *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae* bacterial meningitides, but the true etiology usually is established easily by the examination of the CSF. Spirochetal infections are a more common cause of nervous system disease, specifically encephalitis, than generally is appreciated. Encephalitis is a recognized complication of leptospirosis, Lyme disease, and relapsing fever.[29,38,95,257,260,311] *Brucella* spp. are infrequent causes of meningoencephalitis, and *Bartonella henselae* encephalitis is an uncommon complication of cat-scratch disease.[43,120,227,228,245,314,362] Infection with *Listeria monocytogenes* has been shown to mimic herpetic and West Nile virus encephalitis.[81,266]

Neurologic disease is a common complication of pertussis. A 10-year study in the United States indicated a rate of neurologic disease in infants of approximately 9 per 1000 cases.[105] An extensive review by Miller and associates[232] suggested that the neurologic disease occurring with pertussis rarely, if ever, is inflammatory, and it is better classified as an encephalopathy.

OTHER AGENTS

Encephalitis is an uncommon occurrence in psittacosis, occurring in 1 to 3 percent of cases.[44,114] It can be caused by *Chlamydia psittaci* and *Chlamydia pneumoniae*. Neurologic involvement commonly occurs in Rocky Mountain spotted fever.[151,178] In one study, two thirds of the ill children had evidence of encephalitis. Neurologic sequelae are common.[127] Neurologic involvement also occurs in nonspotted fever rickettsial infections.[98,125,191,210,258,273,299] *Coxiella burnetii*, *Ehrlichia canis*, *Rickettsia typhi*, *Rickettsia canada*, and *Rickettsia conorii* all have been implicated.

Mycoplasma pneumoniae is an important cause of encephalitis.* Pönkä[264] noted that 4.8 percent of hospitalized patients with *M. pneumoniae* infections had CNS manifestations, and most of them had encephalitis or meningoencephalitis. *Mycoplasma hominis* is a rare cause of neonatal meningoencephalitis.[215]

Numerous fungi cause neurologic illness.[287] These illnesses occur most commonly in immunocompromised patients, but some infections occur in apparently normal individuals. Meningitis and brain abscess are the most common pathologic events, but encephalitis is associated commonly with meningitis. The following fungal agents are the most common causes of meningoencephalitis in children and adults with normal immunologic status: *Blastomyces dermatitidis*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Cladosporium* spp., *Histoplasma capsulatum*, and *Paracoccidioides brasiliensis*.

Involvement of the brain in parasitic infections is common, and the reader is referred to Section XXII for a complete review. Cerebral malaria is a common complication of *Plasmodium falciparum* infection. Meningoencephalitis and enlarging cerebral mass lesions rarely occur in acute acquired toxoplasmosis.[330] The free-living ameba *Naegleria fowleri* is a rare cause of encephalitis, but infection with this agent usually is fatal.[293,325] Most cases occur in children and young adults and are caused by swimming or playing in contaminated water. Fatal encephalitis also has resulted from infection with *Balamuthia mandrillaris*, a soil ameba formerly thought to be innocuous.[132,339] *Baylisascaris procyonis*, a raccoon roundworm, has been associated with severe and often fatal encephalitis in children.[56,117,118,354] A recurrent encephalitis caused by administration of trimethoprim has been reported.[152]

POSTIMMUNIZATION

Neurologic disease, including encephalitis and meningoencephalitis, has occurred after immunization with a variety of prophylactic and therapeutic preparations. Depending on the type of immunizing agent, the encephalitis can be the result of an immunologic reaction, a CNS infection with the vaccine virus, or a combination of infection and immunologic reaction. Historically, many of the observed neurologic reactions occurred after the administration of antisera prepared in animals in the treatment of specific diseases. Antisera to the following diseases or infectious agents have been noted in association with neurologic illness: tetanus, diphtheria, scarlet fever, tuberculosis, gas gangrene, pneumococcus, gonococcus, meningococcus, and streptococci.[3,161,180,231,279] Of 100 neurologic syndromes complicating administration of serum reviewed by Miller and Stanton,[231] only 10 percent were of a cerebral or meningeal type.

Neurologic disease was a common complication of rabies vaccine derived from animal nervous tissue.[231] The incidence of complication was between 3/1000 and 1/6000 cases.[32,231] Approximately 10 percent of the neurologic disease attributed to this rabies vaccine was meningoencephalitic or encephalomyelitic. Five cases of CNS disease (Guillain-Barré syndrome, demyelination, meningoradiculitis) have been reported in temporal association with the administration of human diploid cell rabies vaccine.[262] This occurrence is so rare that a causal relationship with vaccine is uncertain.

Encephalitis was an important complication of smallpox vaccination.[7,37,110,130,175,199,238,312] The rate of encephalitis varied markedly from one study to another, from 1 in 4000 primary vaccinations in the Netherlands[238] to approximately 1 in 80,000 primary vaccinations in the United States.[200] After reinstatement of the vaccination among military personnel and selected civilian groups in the United States, three cases of suspected encephalitis or myelitis were identified among 665,000 individuals vaccinated from 2002 to 2004.[296]

Neurologic disease, including encephalitis, occurs rarely after the administration of typhoid-paratyphoid vaccine.[231] Neurologic disease also rarely has been attributed to administration of tetanus toxoid and diphtheria toxoid, but the manifestations seldom are central.

Encephalitis and encephalopathy have been observed after the administration of influenza immunization.[119,131,282,355] In the extensive surveillance that occurred in the United States during the period October 1, 1976, to December 16, 1976, when 45,651,113 people received the A/New Jersey/76 influenza vaccine, no epidemiologic evidence of an association between vaccine and encephalitis was noted.[139] Two children who developed acute disseminated encephalomyelitis after receiving Japanese B encephalitis vaccination have been reported.[248]

Neurologic disease developing after administration of a whole-cell pertussis vaccine is a well-known event.[67-69] Pathologic evidence in fatal cases suggests encephalopathy rather than encephalitis.[80] Because neurologic illness similar to that which

*See references 30, 31, 47, 77, 85, 86, 140, 185, 209, 264, 302, 308, 331.

occurs after the administration of pertussis vaccination is a frequent development in infants who have not been vaccinated, establishing a true rate of pertussis vaccine encephalopathy, or that such an entity exists at all, has been difficult. The analysis of studies suggests that encephalopathy caused by pertussis vaccine does not occur.[68,69,134,280]

Neurologic disease, including encephalitis, is a rare complication of measles immunization.[48,51,111,197] The rate in vaccinees in the United States is less than 1/1 million. In contrast, the finding in the National Childhood Encephalopathy Study in England, Scotland, and Wales indicated a rate of 1/87,000 immunizations.[2] This high rate of encephalopathy may be an artifact due to the misclassification of complicated febrile convulsions as encephalopathy. Meningoencephalitis has been shown to be a rare complication of mumps immunization with some vaccine virus strains,[222] although it has not been a problem in the United States. More recent studies in the United States and Finland have failed to show an association between measles-mumps-rubella vaccination and encephalitis or encephalopathy.[214,275] A fatal encephalitis occurred in a 3-year-old child after receiving 17D yellow fever vaccine.[268]

POSTINFECTIOUS ENCEPHALITIS

Postinfectious or parainfectious encephalitis occurs after a demonstrated or presumed viral infection and is thought to be immune-mediated rather than due to a direct effect of the virus in nerve cells.[133,170-172,285] This theory has been studied extensively by Johnson[171,172] and Griffin[133] in encephalitis associated with measles. They have described a periventricular demyelinating disease and have not been able to isolate measles virus or identify measles antigens in nervous tissue. Other investigators, including one of us (J. D. C.), have recovered measles virus, however, from the CSF and brain of affected patients.[111,226,229,269,298] We suggest that immune mechanisms play a role in the pathogenesis of measles and perhaps other postinfectious neurologic illnesses, but the process is stimulated by the direct presence of the antigen in the nervous system. The mechanism of disease is important regarding possible treatment: steroids might be useful in immune-mediated disease but could be detrimental in an acute viral infection.

In contrast to measles, other apparent postinfectious encephalitides that usually have a subacute onset are immune mediated and have multifocal white-matter lesions.* Specifically, acute demyelinating encephalomyelitis (ADEM) usually is subacute in onset and is characterized by optic neuritis, myelitis, ataxia, hemiparesis, cranial nerve palsies, and multifocal white-matter lesions that are easily confused with multiple sclerosis. Subtle features help distinguish between the two disorders, however.[307] If solitary or unilateral lesions are present, it most likely is ADEM, whereas lesions in the corpus callosum are much more common in multiple sclerosis. Lesions greater than 4 cm diameter suggest ADEM, and ADEM lesions generally have indistinct borders compared with multiple sclerosis lesions, which generally have sharp borders. Patients with ADEM may respond dramatically to treatment with steroids and perhaps intravenous immunoglobulin or plasmapheresis.

CHRONIC ENCEPHALITIC OR ENCEPHALOPATHIC ILLNESSES

"Slow infections" that cause encephalitic and encephalopathic illness in humans have been recognized for many years. Many of these illnesses now are recognized as viral infections or caused by prions. Viral illnesses include progressive multifocal leukoencephalopathy (JC, SV40, and BK viruses), subacute sclerosing panencephalitis (measles virus), and acquired immunodeficiency syndrome (AIDS) (human immunodeficiency virus [HIV] type 1 [HIV-1] and HIV-2). Prion diseases, termed *transmissible spongiform encephalopathies*, include kuru, Jakob-Creutzfeldt disease, and Gerstmann-Sträussler-Scheinker disease.[267] Prion diseases are related to scrapie of sheep and bovine spongiform encephalopathy (mad cow disease), which are prion diseases of animals. These chronic illnesses are discussed in Chapter 205.

EPIDEMIOLOGY

Because encephalitis has many different causes, no unified epidemiologic pattern exists. The specific epidemiology of each infectious agent or disease is presented in detail in the respective chapters of this book; only a brief overview is presented here. Most cases occur in the summer and fall, reflecting arboviral and enteroviral etiologies. Encephalitis caused by arboviruses occurs in localized outbreaks and epidemics, with boundaries determined by the range of particular mosquito vectors and the prevalence of natural reservoir animals.

Arboviruses are zoonoses in which humans are infected accidentally by an arthropod vector, humans not being essential in the life cycle of arboviruses. Most commonly, mosquitoes or other insects acquire arboviruses by biting infected birds, which often have prolonged viremia without illness. The insect vectors, although preferring birds, bite other vertebrates, including humans and horses. Encephalitis in horses and mules may be the first indication of incipient trouble in an area; veterinarians often are the first to detect an impending epidemic. Rural exposure is not a sine qua non; urban and suburban outbreaks are frequent.

Although enteroviral disease, including aseptic meningitis, occurs in epidemics, severe encephalitis caused by these agents usually is a sporadic event. Sporadic cases of encephalitis occur in any season; epidemiologic considerations that must be reviewed in a search for the causative agent include geographic area; climatic conditions; animal, water, food, soil, and personal exposures; and host factors.

PATHOGENESIS

Because encephalitis and meningoencephalitis have multiple causes, the lack of a unified pathogenesis is not surprising.* Clinical manifestations of encephalitis can result from a direct or an indirect effect of an infectious agent on the brain. Rabies, arbovirus, herpes simplex, and enteroviral encephalitides are examples in which the viral infections directly involve tissue cells within the brain. In contrast, encephalitic symptoms in bacterial meningitides and in rickettsial infections may be caused by the vasculitis and liberated toxins of the surrounding infection. In addition, in many postinfectious or parainfectious encephalitides, immunologic events clearly are important in the pathogenesis. Measles and *M. pneumoniae* infections are in this category.

Postinfectious or parainfectious encephalitis is an acute demyelinating disease of the brain in which the findings suggest an autoimmune process. Usually, little evidence of an active infectious process is present when symptoms occur. Viral or other agents probably invaded the CNS initially and then were cleared but were a trigger for the subsequent development of disease. An immune (T-cell) response to myelin basic protein occurs.

*See references 4, 11, 15, 36, 83, 138, 181, 202, 224, 227, 238, 323, 359.

*See references 7, 27, 47, 77, 99, 107, 111, 127, 133, 137, 144, 153, 168, 170, 230-232, 235, 349.

In most encephalitides, such as those caused by arboviruses, mumps, and enteroviruses, the CNS infection is secondary to a primary viral infection elsewhere in the body. Generally, the infectious agents, whether from ingestion, as in enteroviral infections, or from the bite of a mosquito, as in an arboviral infection, enter the lymphatic system. In the lymphatics, viral multiplication occurs, which results in seeding of the bloodstream and infection of other organs in the body. Viral multiplication occurs at these secondary infection sites, extensive secondary viremia occurs, and then the CNS becomes infected. Actual involvement of nervous tissue may result from growth across or passive diffusion through brain capillaries or centripetal axonal transport of virus from the olfactory neuroepithelium to the olfactory bulb.[235]

Infection of the brain also may occur through the peripheral nerves. This retrograde spread of virus is important in rabies and HSV encephalitis.

PATHOLOGY

Determining the etiology of encephalitis at autopsy is difficult, although morphologic identification of falciparum malaria, trypanosomiasis, and fungal encephalitis is possible.[80,170,231,232,312] In viral encephalitides, the histopathologist may recognize rabies (Negri bodies) or an agent of the herpesvirus group (intranuclear inclusion bodies).

Tissue sections of the brain generally reveal meningeal congestion and mononuclear infiltration, perivascular cuffs of lymphocytes and plasma cells, some perivascular tissue necrosis with myelin breakdown, neuronal disruption in various stages (including ultimately neuronophagia), and endothelial proliferation or necrosis. A marked degree of demyelination with preservation of neurons and their axons is considered to be predominantly postinfectious or parainfectious (autoimmune) encephalitis. The severity and the extent of observed lesions vary with the infectious agent and with the degree of reaction of the host. The cerebral cortex, especially the temporal lobe, often is affected severely by HSV; the arboviruses tend to affect the entire brain; and rabies has a predilection for the basal structures. Involvement of the spinal cord, nerve roots, and peripheral nerves varies.

CLINICAL MANIFESTATIONS

The clinical findings in encephalitis are determined by the severity of involvement and anatomic localization of the affected portions of the nervous system, the inherent pathogenicity of the offending agent, and the immune and other reactive mechanisms of the patient ("host factors"). A wide range of severity of clinical manifestations exists even with the same etiologic agent. Evidence of brain parenchymal involvement is the hallmark of encephalitis. Children with encephalitis may show evidence of diffuse disease, such as behavioral or personality changes; decreased consciousness; and generalized seizures or localized changes, such as focal seizures, hemiparesis, movement disorders, cranial nerve defects, and ataxia. Some children may seem to be mildly affected initially only to lapse into coma and sudden death. In others, the illness is ushered in by high fever, violent convulsions interspersed with bizarre movements, and hallucinations alternating with brief periods of clarity, and the children emerge with relatively few sequelae.

Most commonly, the initial manifestations resemble an undifferentiated acute systemic illness with fever, headache, or, in infants, screaming spells, abdominal distress, nausea, and vomiting. Signs of an associated mild nasopharyngitis may suggest a respiratory infection. As the temperature increases, new findings direct attention to the nervous system: mental dullness eventuating in stupor; bizarre movements; convulsions; nuchal rigidity, often not as pronounced as in purely meningitic illness; and focal neurologic signs, which may be stationary, progress, or fluctuate. Loss of bowel and bladder control and unprovoked emotional outbursts may occur.

SPECIFIC FORMS OF ENCEPHALITIS

Specific forms of encephalitis or complicating manifestations of encephalitis include Guillain-Barré syndrome and related syndromes, acute transverse myelitis, acute hemiplegia, brain stem encephalitis, and acute cerebellar ataxia. Acute cerebellar ataxia is characterized by an abrupt onset of truncal ataxia resulting in varying degrees of gait disturbance and balance abnormalities. Children with this illness have tremulousness of the head and trunk when in the upright position and of the extremities when attempting to move them against gravity. The duration of illness varies from 3 to 4 days to several weeks. Acute cerebellar ataxia often follows chickenpox or other viral illnesses. In one study, 3 percent were related to immunization.[78] Approximately 90 percent of patients recovered completely from the ataxia, but 20 percent had transient behavioral or intellectual disturbances. Five percent had persistent learning problems.

Brain stem encephalitis (Bickerstaff encephalitis) is a rare disorder, but it is important because clinical signs appear similar to those of a brain stem glioma. The differentiation is important because treatment is radically different. The differentiation is made by the time of onset of symptoms and by the course. Brain stem glioma usually has slowly progressive symptoms developing over the course of several weeks or months. Brain stem encephalitis evolves over 1 to 7 days. Both disorders may be associated with radiographic evidence of brain stem enlargement. Brain stem encephalitis resolves after 1 to 4 weeks, whereas a tumor continues to progress until radiation therapy is given.

Most cases of brain stem encephalitis seem to be postinfectious and are similar to postinfectious cerebellar ataxia, Miller-Fisher syndrome, or Guillain-Barré syndrome. The conditions often overlap.[12] In postinfectious cases, the onset of brain stem encephalitis begins 1 to 3 weeks after a nonspecific viral infection. Brain stem encephalitis has been reported to occur, however, as a result of specific, identifiable, and possibly treatable infectious agents, including HSV,[278,292] VZV,[283,320] CMV,[116,174] and enterovirus 71[157,159] and *M. pneumoniae*,[196,313] *L. monocytogenes*,[5,9,10,13,19] *Propionibacterium acnes*,[41] and *Campylobacter jejuni*.[363]

Some patients with a typical clinical picture of brain stem encephalitis have had anti-GQ1b antibodies in the serum,[65] which may represent a subgroup of postinfectious brain stem encephalitis. Brain stem encephalitis may arise in HIV-infected patients and may be due to a treatable cause, such as herpes simplex encephalitis.[116,143,282] Brain stem encephalitis caused by viral infections may resolve similar to the typical postinfectious type, but some viral infections may lead to permanent neurologic sequelae. In an enterovirus outbreak in Taiwan, the most common neurologic complication was rhombencephalitis, and a 14 percent mortality rate was reported.[157,159] More recent reports suggest that intravenous immunoglobulin may be an effective therapy in some patients.[112] In a Cochrane review, this therapy remains unproven, however.[254]

DIFFERENTIAL DIAGNOSIS

The evaluation of a patient with an acute CNS illness (encephalopathy) must be considered carefully, and the sequence of tests should be dictated by the specific circumstances of the individual patient. Several disease processes may have a presentation similar

to that of encephalitis or meningoencephalitis. The differential diagnosis of acute encephalopathy includes the following:

1. Metabolic diseases, such as hypoglycemia, uremic encephalopathy, hepatic encephalopathy, and rare genetic inborn errors of metabolism, including disorders of glucose or ammonia metabolism
2. Toxic disorders, such as drug ingestion or Reye syndrome
3. Mass lesions, such as tumor or abscess
4. Subarachnoid hemorrhage from arteriovenous malformation or aneurysm
5. Embolic lesions caused by bacterial endocarditis
6. Acute demyelinating disorders, including acute multiple sclerosis, ADEM, and acute hemorrhagic leukoencephalitis
7. Status epilepticus, especially nonconvulsive status epilepticus, such as complex-partial status or absence status
8. Infectious diseases, including viral, bacterial, fungal, chlamydial, mycoplasmal, and parasitic
9. Postinfectious diseases, including Guillain-Barré syndrome, brain stem encephalitis, Miller-Fisher syndrome, and acute cerebellar ataxia
10. Acute confusional migraine

EVALUATION OF A PATIENT WITH ENCEPHALOPATHY OR POSSIBLE ENCEPHALITIS

Obtaining a careful history and performing a physical and neurologic examination are essential in all patients who present with a history consistent with encephalitis. The differential diagnosis previously presented indicates that encephalitis is only one of many disorders that can manifest with an acute or subacute picture of encephalopathy. Although the diagnosis of encephalitis may be determined best with a lumbar puncture and evaluation of the CSF, lumbar puncture may be contraindicated in some disorders and, if performed inappropriately, may lead to serious complications and even death. A child who has a cerebellar tumor with acute obstruction of the fourth ventricle may present with a decreasing level of consciousness caused by the rapidly increasing intracranial pressure (ICP). Nuchal rigidity may be present. The family may not have recognized the more subtle changes in cerebellar functions for the months before the acute obstruction developed and may give a history of acute encephalopathy. In that case, a lumbar puncture could result in herniation through the foramen magnum. It is essential that the patient be assessed for the possibility of increased ICP and the potential for herniation.

The history should be reviewed carefully, questioning specifically for symptoms of neurologic problems that manifested in the days or weeks before the acute disorder occurred. The physical examination must be performed with special attention given to focal neurologic abnormalities, cerebellar signs, and evidence of increased ICP. Conducting a careful funduscopic examination is important but may be impossible in an agitated patient or young child. The presence of papilledema indicates that neuroimaging should be performed before doing the lumbar puncture. If spontaneous venous pulsations are noted on funduscopic examination, ICP is not increased, and the lumbar puncture can be done without imaging the patient.

In addition to lumbar puncture, neuroimaging and EEG can help in determining the cause of the encephalopathy and in determining the most appropriate course of therapy. The history and physical examination are a guide to the most appropriate first test to perform, but generally neuroimaging is the most likely to be helpful. The exception would be a child in nonconvulsive status epilepticus. The history may suggest encephalitis as the most likely diagnosis, but in some patients, nonconvulsive status epilepticus may be clinically indistinguishable from encephalitis.

NEUROIMAGING

Most patients with encephalopathy should undergo neuroimaging to aid diagnosis of treatable conditions, such as HSV encephalitis. Computed tomography (CT) is helpful in the acute setting to identify abnormalities such as tumor or abscess and to decide whether performing a lumbar puncture is safe. CT is not as helpful, however, as is magnetic resonance imaging (MRI) in detecting the subtle changes associated with encephalitis.[40,206,300] In many cases of viral encephalitis, CT and MRI yield normal results or only nonspecific changes, such as swelling[347] or edema.[206] An important exception is herpes simplex encephalitis.

As previously noted, MRI is more sensitive than is CT. In one study, CT initially was positive in only 42 percent of cases, whereas MRI was positive in all cases.[182] MRI in HSV characteristically shows abnormalities in the medial temporal lobes, inferior frontal cortex, and insula.[205,350] The likelihood of finding the abnormalities may be increased by using T2-weighted imaging and fluid attenuated inversion recovery (FLAIR) sequences[14,177] or diffusion-weighted imaging.[297,327] Diffusion-weighted MRI seems to be more sensitive than is FLAIR or T2-weighted sequences in the detection of HSV or other encephalitides.[334] The localization of abnormalities may differ, however, from the classic pattern in young children. In neonatal herpes encephalitis, widespread changes occur in the periventricular white matter, often sparing the medial temporal and inferior frontal lobes. Another pattern has been described in children aged 4 to 13 months in whom the cortex and adjacent white matter of the hemispheres were abnormal.[205]

In addition to herpes, other encephalitides may yield abnormal neuroimaging. CT and MRI results often are abnormal with disorders caused by arbovirus or enterovirus infections. When imaging is abnormal, it usually is nonspecific, showing areas of decreased density (with CT) or increased signal intensity (with MRI) in the gray or white matter. A variety of MRI abnormalities with certain viral encephalitides have been reported. The basal ganglia, brain stem, and thalami have been reported to be abnormal on MRI of patients with eastern equine encephalitis,[93] Japanese encephalitis,[158,192] and enterovirus 71.[157,159] These differences help to distinguish HSV from other, nontreatable causes of viral encephalitis.

Postinfectious disorders most often are associated with selective oligodendrocyte involvement.[21] Imaging shows increased signal in white matter with T2-weighted MRI or low-density white matter with CT.[18,35,147,181,249] Patients with acute hemorrhagic leukoencephalitis, a rare disease that is rapidly progressive and often fatal, may present with a clinical picture similar to that of herpes simplex encephalitis. In contrast to HSV infection, the CT results often are abnormal within the first 1 or 2 days.[284,346] If a patient with suspected herpes simplex encephalitis has abnormal CT results early in the course, acute hemorrhagic leukoencephalitis should be considered.

Another imaging technique that has been reported to be helpful in establishing the diagnosis of encephalitis is single photon emission computed tomography (SPECT). Initial reports suggest that SPECT is more sensitive than is CT. Ackerman and colleagues[2] found that SPECT showed greater sensitivity and more precise localization than did conventional radionuclide scanning and CT. Launes and associates[202] studied 14 encephalitis patients and found that SPECT detected temporal lobe abnormalities in all six of the patients with HSV encephalitis and

yielded normal results in the remaining eight who had other etiologies. A few cases of normal MRI scans but abnormal SPECT in patients with herpes simplex encephalitis have been reported[146,218]; this is less likely to occur with newer MRI sequences such as diffusion weighted imaging. If SPECT is performed, Tc 99 m hexamethylpropyleneamine oxime seems to be superior to Tc 99 m ethyl cysteinate dimer.[87,106] Generally, SPECT should be reserved for cases with normal MRI and a nondiagnostic EEG in which herpes simplex encephalitis is still strongly suspected. Intracranial ultrasonography in neonates has been shown to be helpful in establishing the diagnosis and in follow-up of infants with HSV or CMV infections.[219]

ELECTROENCEPHALOGRAM

Generally, an EEG should be performed in most patients with encephalitis. EEG results of patients with encephalitis generally are normal or nonspecifically abnormal, showing diffuse slowing. Crucial exceptions to the general rule exist, however.

In acute encephalopathy, comatose patients may be in nonconvulsive status epilepticus,[328] which requires immediate and appropriate intervention. The presence of periodic lateralized epileptiform discharges (PLEDs) on EEG strongly suggests the possibility of herpes simplex encephalitis but also may be an indication of seizures.[20] Early in the course of herpes encephalitis, generalized slowing of the background frequencies and focal slowing over the affected temporal lobe may occur. Within a few days, the characteristic PLEDs pattern develops in most cases. Later in the course, the background activity between the bursts of PLEDs gradually may flatten. Occasionally, other areas of the brain seem to be involved, primarily with HSV. PLEDs, although strongly suggestive of HSV encephalitis, are not diagnostic. PLEDs have been reported with stroke and infectious mononucleosis encephalitis,[129] and periodic complexes are characteristic of the slow virus and prion disorders, including Jakob-Creutzfeldt disease and subacute sclerosing panencephalitis.

The EEG abnormalities in neonatal herpes encephalitis are similar. The characteristic EEG results yield periodic or pseudoperiodic complexes, usually triangular or sharp waves, occurring in a multifocal pattern.[233] In one study of 34 infants with herpes encephalitis, 21 underwent EEG; the results of 19 of the 21 were abnormal. The results of three showed only focal slowing, but the other 16 showed the characteristic periodic or pseudoperiodic complexes.[286] The authors reviewed 500 other neonatal EEG records and found 20 with similar complexes; 11 patients had meningoencephalitis of unknown etiology, 3 had hemorrhage, and 2 had asphyxia. Four were placed in a miscellaneous category. Periodic or pseudoperiodic complexes in neonatal EEG results strongly suggest HSV encephalitis, but they are not diagnostic.

SPECIFIC DIAGNOSIS

A meticulous history is essential and must evaluate exposure in the previous 2 to 3 weeks to illness in contacts; exposure to mosquitoes, ticks, and animals during recent vacations or picnics or other outdoor activities; awareness of illness in animals, especially horses and other Equidae, in the patient's environment; recent travel from the home area; recent injections of any kind; and the possibility of accidental exposure to heavy metals, pesticides, or other questionable substances. The CSF must be examined carefully to exclude other disorders that respond to specific therapy. Smears for bacteria, appropriate rapid antigen-identification tests, and cultures of the CSF are mandatory; the history and clinical findings may indicate the need for acid-fast stain and culture of the sediment for mycobacteria. Other circumstances may indicate the need for excluding fungal or protozoal infection; atypical cells may require cytopathologic study to exclude neural neoplasms that may manifest acutely.

The availability of polymerase chain reaction has allowed the definitive and rapid diagnosis of HSV encephalitis to be established, eliminating the need for brain biopsy.[94,194,291,337,352] HSV DNA was detected in the CSF of 53 of 54 patients with biopsy-proven herpes simplex encephalitis.[194] The etiology of encephalitis caused by other herpesviruses also has been determined by polymerase chain reaction assay of CSF.[84,221,335] In addition to its use in herpesvirus infections, polymerase chain reaction is useful in neurologic illnesses caused by enteroviruses and *M. pneumoniae* and in the future is likely to be useful in other encephalitides.[31,184,256,276]

In viral encephalitis, the CSF frequently is clear; the leukocyte count ranges from none to several thousand, often with a significant percentage of polymorphonuclear cells initially, moderate or no elevation of protein, and an initially normal level of glucose relative to the simultaneously determined blood glucose level. In any patient suspected to have viral meningoencephalitis, spinal fluid, blood, feces, and throat swabs should be collected and sent to a laboratory offering viral diagnostic services. An additional serum specimen should be collected 10 to 21 days later. Although these studies may not provide an immediate diagnosis, they may give early warning of a specific epidemic, and the use of specific antiviral chemotherapy may be indicated by the preliminary culture results.

Inquiry regarding recent illness, recent injections, and, especially, recent exposures away from the home environment sometimes is helpful. The incubation periods of some arboviruses are such that mosquito bites acquired at least 1 week earlier or insect bites now healed may give a clue. Occasionally, patients who have traveled to Africa or Asia in preceding weeks present with encephalitis caused by viruses, trypanosomiasis, or falciparum malaria with bizarre systemic and CNS signs and symptoms.

TREATMENT

Acyclovir should be used to treat herpes simplex and VZV encephalitis and perhaps encephalitis caused by Epstein-Barr virus. CMV encephalitis should be treated with ganciclovir. Pleconaril (if it becomes available) should be considered for treatment of enteroviral encephalitis, and oseltamivir should be considered for treatment of encephalitis caused by influenzaviruses A or B. Specific antimicrobial treatment should be used for infections caused by spirochetes, *Chlamydia*, *Mycoplasma*, fungi, and parasites.

General treatment is nonspecific and empiric, aimed at maintaining life and supporting each involved organ system. The effectiveness of various recommended regimens in most instances has not been evaluated objectively. Until a bacterial etiology and, in particular, a brain abscess are excluded substantially, parenteral antibiotic therapy should be administered.

Anticipating and being prepared for convulsions, cerebral edema, hyperpyrexia, inadequate respiratory exchange, disturbed fluid and electrolyte balance, aspiration and asphyxia, abrupt cardiac and respiratory arrest of central origin, cardiac decompensation, and gastrointestinal bleeding are crucial. The syndrome of disseminated intravascular coagulation may be an additional complication.

For these reasons, all patients with severe encephalitis should receive care in intensive care units. Cardiac monitoring should be maintained. Repeat CT and MRI scans are helpful in following comatose patients and often show signs of brain swelling before the patient has the typical clinical indicators of

ICP, such as Cushing triad (systolic hypertension, bradycardia, and slowing of respirations), dilated pupils, and decorticate or decerebrate posturing. The Cushing triad is an unreliable indicator of increased ICP, and, when the other signs of increased ICP occur, they often do so late in the course, when the patient's cerebral perfusion already is at risk.[223] If brain swelling becomes a problem, placing an ICP monitor may be necessary. The ICP should be maintained at less than 15 mm Hg if possible using the standard techniques for reduction of ICP, including hyperventilation, osmotic diuretics, and removal of CSF. As a last resort, inducing a barbiturate coma may be necessary. A related consequence of ICP is the syndrome of inappropriate antidiuretic hormone secretion. Careful monitoring of the fluid and electrolyte balance is essential in all seriously ill patients with encephalitis.

All fluids, electrolytes, and medications initially are given parenterally. In patients with prolonged coma, parenteral hyperalimentation is indicated. Normal blood levels of glucose, magnesium, and calcium must be maintained to minimize the threat of convulsions.

Status epilepticus caused by encephalitis should be treated vigorously using a structured protocol to ensure optimal control.[303,331] The current standard initial therapy is intravenous lorazepam, 0.1 to 0.2 mg/kg, up to 4 mg maximum. Seizures associated with encephalitis may be refractory to the usual therapy, and other anticonvulsants may be required to achieve and maintain control of seizures. In patients who fail initial therapy and are in medically refractory status epilepticus, continuous EEG monitoring usually is recommended to monitor the efficacy of the therapy, especially when the patient is in nonconvulsive status epilepticus.[92,329]

If after a second attempt, lorazepam fails to control the seizures, intravenous phenytoin (preferably phosphenytoin in children) is the next drug of choice. The dose is 18 to 20 mg/kg, maximum 1000 mg, given over 20 minutes. Phosphenytoin is preferred because it can be administered faster and does not cause sclerosis of the veins as does phenytoin and is not as likely to cause cardiac arrhythmias. Virtually all patients who require therapy beyond lorazepam need to be intubated to prevent respiratory embarrassment. If phosphenytoin is unsuccessful, or as an alternative to phosphenytoin, intravenous midazolam has gained favor in recent years.[75,258] The initial dose is 0.1 to 0.2 mg/kg over 5 minutes, with a maintenance infusion starting at 0.05 mg/kg/hr up to a maximum of 0.4 mg/kg/hr. Another alternative therapy is propofol, which generally is administered by an anesthesiologist.

Many methods have been proposed to minimize cerebral edema and to diminish the consequences of cerebral anoxia. The following measures are difficult to evaluate and generally are reserved for patients with severe illness whose condition apparently is desperate.

1. Dexamethasone, 0.1 to 0.2 mg/kg intravenously in an initial dose followed by 0.05 to 0.1 mg/kg intravenously every 4 to 6 hours, is given. This large dose should be reduced gradually after a few days if recovery or improvement is evident. Dexamethasone probably should not be used in acute viral diseases because steroids may potentiate the viral infection.
2. Other substances employed in an effort to reduce elevated ICP include (a) mannitol, given intravenously, as a 20 percent solution in a dose of 0.25 to 1 g/kg over a 30- to 60-minute period (this may be repeated every 8 to 12 hours), and (b) glycerol, by nasogastric tube, using 0.5 to 1 mL/kg diluted with twice that volume of orange juice. This regimen is nontoxic and may be repeated every 6 hours for an extended period.

For more than 40 years, steroids and adrenocorticotropic hormone frequently have been used as empiric therapy for encephalitis. No controlled studies have shown any efficacy, however. In two comparative studies of measles encephalitis, steroids were found to offer no benefit, and in both studies, the steroid recipients seemed to have had worse outcomes.[33,365] More recently, in a carefully controlled study, no benefit of high-dose dexamethasone was found in the treatment of acute encephalitis caused by Japanese encephalitis virus.[155]

In contrast to these investigations are more recent clinical experiences in the treatment of acute disseminated encephalomyelitis, in which MRI studies have indicated multifocal white-matter lesions.[36,138,181,224] Patients treated with steroids often have responded dramatically, with clinical improvement and resolution of the lesions as shown by MRI. Steroids, along with specific antibiotic therapy, also may be beneficial in the treatment of encephalitis caused by *M. pneumoniae* infection.[185,302]

In our opinion, steroids should not be used to treat encephalitis if the patient has an active infection, unless the infection can be treated concomitantly with an effective antimicrobial agent. Plasmapheresis and intravenous immunoglobulin have been used empirically to treat brain stem encephalitis and other encephalitides, but no studies have been done that indicate such therapies are helpful.[243]

Equipment and personnel for handling emergencies such as cardiac and respiratory arrest must be on hand constantly. Early consultation with an anesthesiologist or intensive care specialist is useful in anticipating the need for artificially assisted respiration.

Supportive and rehabilitative efforts are important after the patient recovers. Motor incoordination, convulsive disorders, squint, total or partial deafness, or behavioral disturbances may appear only after some time. Visual disturbances caused by chorioretinopathy and perceptual amblyopia also may make a delayed appearance. Special facilities and sometimes institutional placement may become necessary.

PROGNOSIS

The prognosis in all encephalitides is guarded with respect to immediate outcome and sequelae. Sequelae involving the CNS may be intellectual, motor, psychiatric, epileptic, visual, or auditory. Cardiovascular, intraocular, pulmonary, hepatic, and other systems sometimes are affected permanently. The short-term and long-term prognoses depend to some extent on etiology and age. Young infants usually have severe disease and sequelae. Generally, HSV carries a worse prognosis for survival and residual disability than do the enteroviruses.

Rautonen and associates[274] examined prognostic factors in childhood acute encephalitis at the Children's Hospital, University of Helsinki, during a 20-year period from 1968 to 1987. This study comprised 462 cases with the following etiologies: mumps virus, measles virus, rubella virus, VZV, HSV, enteroviruses, respiratory viruses, *M. pneumoniae*, other agents, and cause undetermined. The investigators found that mortality was fivefold greater in infants compared with older children. Children who were disorientated or unconscious before admission had 4-fold and 25-fold greater risks for death and severe damage than did children whose level of consciousness had been normal. Patients with HSV or *M. pneumoniae* infection had the greatest risks for death or serious residual damage compared with children with encephalitis of other etiologies.

California encephalitis has a low mortality rate but occurs most frequently in the pediatric age group. Of patients who experience seizures in the acute phase of their disease, 25 percent have a permanent seizure disorder.[128] Psychological sequelae were present in 15 percent in one series but were not found to be significant in several series if the children were evaluated several years after their illnesses.[72,220,277]

Prognosis in encephalitis caused by western equine virus is guarded; 56 percent of infants younger than 1 month of age have had recurring seizures with marked motor and behavioral changes. After they reach 1 year of age, the sequelae appear to diminish; only 5 percent of adults have neurologic sequelae. Fifty-seven percent of infants who survived western equine virus infection and who were younger than 1 year of age at the time of infection had major neurologic sequelae requiring either a special school or institutionalization late in life. Severe retardation, paralysis, spasticity, recurrent convulsions, hearing deficits, and speech difficulties all were reported as complications.[100,107]

Eastern equine encephalitis has a high mortality rate. Infants and children younger than 5 years of age who survive usually have severe sequelae consisting of mental retardation, convulsions, and paralysis. These consequences are in contrast to adults older than 40 years of age who survive, who recover completely or have only slight damage.

St. Louis encephalitis has a low mortality rate. Although neurologic sequelae are reported, their incidence is low in the pediatric age group.

PREVENTION

The widespread use of effective attenuated viral vaccines for measles, mumps, and rubella almost has eliminated CNS complications from these diseases in the United States. The control of encephalitis caused by arboviruses has been less successful because specific vaccines for the arbovirus diseases that occur in North America are unavailable. Control of insect vectors by suitable spraying methods and eradication of insect breeding sites is useful.

CHAPTER 43

Parainfectious and Postinfectious Disorders of the Nervous System

CHAPTER 43a

Parainfectious and Postinfectious Demyelinating Disorders of the Central Nervous System

Timothy Edward Lotze

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is a monophasic demyelinating disease of the central nervous system (CNS) that results in acute, polysymptomatic neurologic disability. It also has been termed *postinfectious encephalomyelitis*. It is related to other central inflammatory demyelinating conditions of childhood, including optic neuritis, transverse myelitis, neuromyelitis optica (Devic disease), and multiple sclerosis. Although no single diagnostic test can be used to distinguish among these conditions at the initial presentation, certain clinical features, laboratory results, and imaging findings can be used to ensure a correct diagnosis. Most of these conditions are thought to be caused by autoimmune dysregulation triggered by an infectious agent in a genetically susceptible host.

DIAGNOSTIC CRITERIA

The term *acute disseminated encephalomyelitis* has been used variably in the literature in describing clinical characteristics of this disease. Discrepancies exist among descriptive studies regarding (1) the occurrence of encephalopathy, (2) the association with preceding infection, (3) symptoms that are monofocal or multifocal, and (4) the possibility for recurrence. Lack of standardized diagnostic criteria for ADEM has impeded the ability to understand this distinct disease better as part of the spectrum of demyelinating conditions occurring in childhood.

More recently, the International Pediatric Multiple Sclerosis Study Group developed diagnostic criteria for ADEM.[32] The group created working definitions for monophasic ADEM and for recurrent forms of the disease. Table 43–1 lists the diagnostic criteria. An absolute criterion for a diagnosis of ADEM is the presence of encephalopathy. This criterion is defined to include either behavioral changes, such as lethargy or irritability, or more severe alterations in level of consciousness, such as coma. The onset of the encephalopathy must correspond with the occurrence of the disease state. Premorbid cognitive difficulties, such as learning difficulties or mental retardation, would not be included in this definition. Magnetic resonance imaging (MRI) shows multiple lesions in both hemispheres distributed throughout the white matter (Fig. 43–1). A distinguishing characteristic of ADEM is prominent involvement of the cortical gray matter and deep gray nuclei (basal ganglia and thalamus). Such involvement is atypical for multiple sclerosis and other demyelinating conditions. The lesions of ADEM are asymmetric, showing variable size, shape, and distribution between the hemispheres. MRI showing symmetric and confluent lesions should prompt the clinician to consider other diagnoses, such as leukodystrophies and inborn errors of metabolism. If MRI shows evidence of previous demyelination, the clinician should query the history further for previous attacks, which would suggest either a recurrent form of the disease or a chronic demyelinating condition. Cerebrospinal fluid (CSF) analysis may show a pleocytosis of greater than 50 cells, in contrast to pediatric multiple sclerosis, in which only a slight pleocytosis (<50 cells) is observed.

The International Pediatric Multiple Sclerosis Study Group has defined criteria to distinguish between an evolving pattern for the initial event and for recurrent forms of ADEM. Any new and fluctuating symptoms occurring within 3 months of the initial event are considered to be part of the same inciting event. In addition, symptoms that occur during steroid taper or within 1 month of the patient's completing a steroid taper are considered to be part of the same inciting event. Relapsing ADEM and multiphasic ADEM are the two recurrent forms of the disease. Both forms are defined to occur more than 3 months after the initial event and more than 1 month after completion of steroids. By definition for ADEM, both forms must include a clinical

TABLE 43–1 Diagnostic Criteria of Acute Disseminated Encephalomyelitis

Clinical Features
First clinical attack of demyelinating disease in CNS
Acute or subacute onset
Polysymptomatic presentation
Must include encephalopathy
Acute behavioral change (e.g., irritability, lethargy)
Alteration in consciousness (e.g., somnolence, coma)
Attack should be followed by improvement
Lesion Characteristics on MRI FLAIR and T2-Weighted Images
Multifocal, hyperintense, bilateral, asymmetric lesions in the white matter
At least one or more lesions >1-2 cm
Gray matter, especially basal ganglia and thalamus, may be involved
Spinal cord MRI may show confluent intramedullary lesions
No radiologic evidence of previous destructive white matter changes
Cerebrospinal Fluid
Pleocytosis ≥50 WBCs can be observed
Other
No other etiologies can explain the event
New or fluctuating symptoms and signs occurring within 3 mo of the inciting ADEM event are part of the same acute event

Note: *Symptoms that vary during periods of steroid taper within 3 mo of the inciting event or occur <30 days after discontinuation of all steroids are considered part of the initial inciting event.*

ADEM, acute disseminated encephalomyelitis; CNS, central nervous system; FLAIR, fluid-attenuated inversion recovery; MRI, magnetic resonance imaging; WBCs, white blood cells.

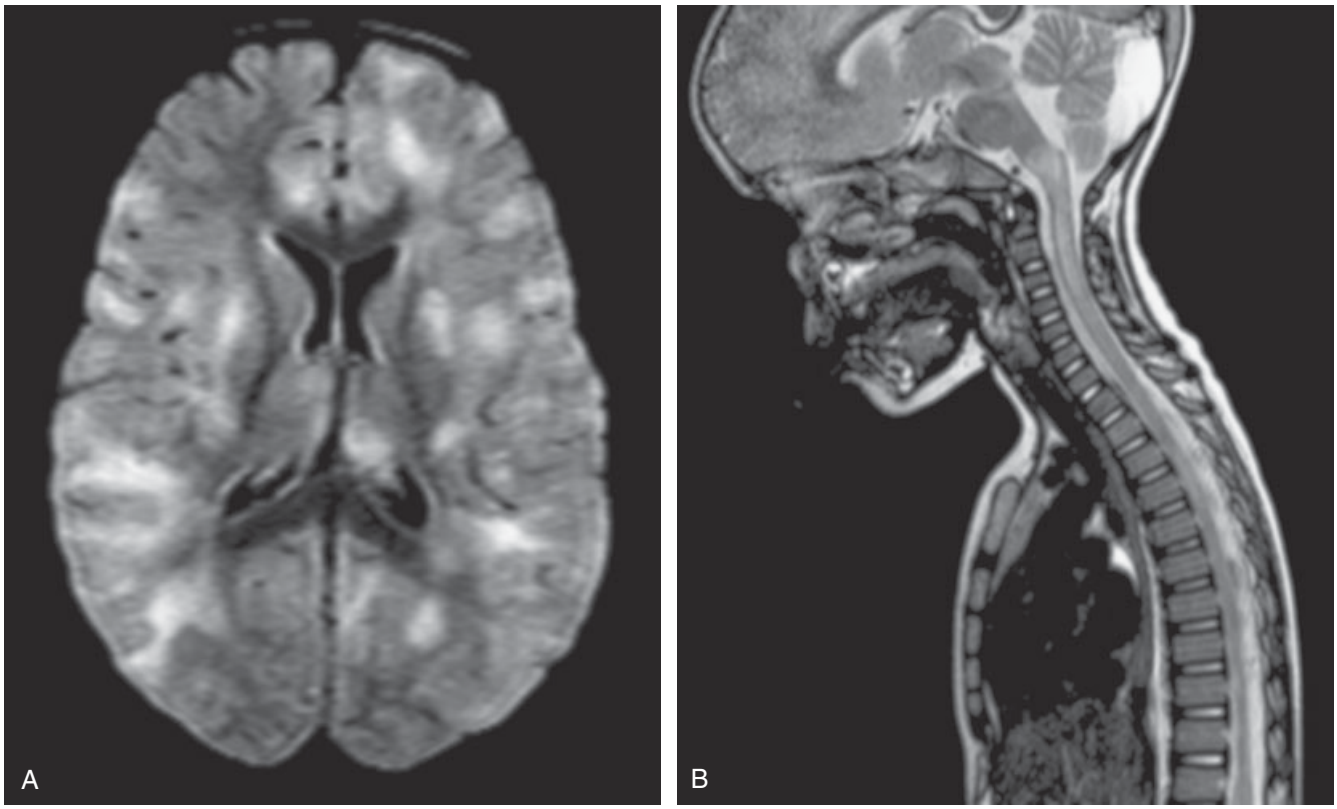

Figure 43–1 **A,** Axial fluid-attenuated inversion recovery (FLAIR) image showing multifocal areas of hyperintensity in both cerebral hemispheres involving cortical gray matter, centrum semiovale, and deep gray nuclei. **B,** Sagittal T2-weighted spine image with increased intrinsic signal consistent with longitudinally extensive transverse myelitis in the same patient. (*Courtesy of Tim Lotze, M.D.*)

presentation with encephalopathy. Relapsing ADEM describes the recurrence of the same symptoms that occurred at the time of the initial presentation. The MRI findings also are similar to the initial event, although they may show enlargement of the previous lesions. Multiphasic ADEM describes children with recurrent disease characterized by symptoms that differ from the initial event. MRI likewise shows development of new lesions different from those seen with the first attack.

CLINICAL MANIFESTATIONS

A febrile illness occurs in 50 to 75 percent of children in the 4 weeks before the onset of typical neurologic symptoms.[38] Preceding vaccinations have been associated with the occurrence of ADEM, but this is less common.[13,47] Fever, headache, vomiting, and meningismus often are present at the time of initial presentation and may persist during the hospitalization.[8,23] Neurologic symptoms typically appear 4 to 13 days after the infection develops or vaccination is administered.[13,23,40,47] New clinical symptoms may continue during hospitalization, and they may alter the treatment for the patient. As per current diagnostic criteria, all children with ADEM have an encephalopathy at the time of presentation.[32] The degree of altered mental status varies, ranging from irritability to somnolence to coma. Encephalopathy may be the initial symptom that brings the child to medical attention. Although alteration in mental state often raises concern for the possibility of seizures, they occur in only one third of patients.[15,47] In addition to having encephalopathy, patients exhibit various other neurologic features. The most common of these are long tract signs, acute hemiparesis, cerebellar ataxia, and cranial neuropathy.[8,15,23,40,47] Aphasia, movement disorders, and sensory deficits occur less commonly.

Demyelination of the optic nerves (optic neuritis) or spinal cord (transverse myelitis) may occur. Symptoms of optic neuritis include vision loss, pain with eye movement, and an afferent papillary defect. Inflammation of the optic disk may be seen on direct funduscopic examination if there is extensive involvement of the optic nerve. Patients with retrobulbar optic neuritis typically have a normal funduscopic examination. Optic neuritis may occur in one or both eyes, with differing degrees of involvement. Symptoms of transverse myelitis include flaccid paralysis of the legs, with a sensory level on examination. The arms can be involved as well if the demyelinating lesion is in the cervical cord. Respiratory failure may occur with high cervical lesions that extend into the brain stem. Bowel and bladder involvement secondary to spinal cord disease results in constipation and urinary retention.

The extent of demyelination in the CNS may not be recognized fully at the time of initial presentation, particularly if the patient has a severe encephalopathy. Imaging of the entire CNS to include the brain, orbits, and spinal cord should be done in all patients meeting diagnostic criteria for ADEM because co-occurrence of transverse myelitis or optic neuritis can have a significant impact on rehabilitation needs and long-term outcome.

CLINICAL VARIANTS

Relapsing ADEM and multiphasic ADEM are the two recurrent forms of the disease. Both forms are defined by reoccurrence of neurologic symptoms more than 3 months after the initial event and more than 1 month after completion of steroids. Most often, recurrence of disease is singular. Repeated events are unusual and should prompt assessment for a different underlying disease

process, including metabolic disorders or primary inflammatory diseases such as multiple sclerosis.

Acute hemorrhagic leukoencephalitis is considered to be a severe variant of ADEM. It accounts for 2 percent of patients with ADEM.[47] Clinical presentation is similar to that of ADEM, including an acute onset of neurologic deficits 1 to 3 weeks after an upper respiratory infection or vaccination. Seizures and coma ensue within hours. The mortality rate is extremely high with fulminant disease. Survivors often have severe residual neurologic deficits. The clinical presentation and imaging features mimic those typically seen in herpes simplex virus encephalitis. Evidence of inflammatory changes and hemorrhage on MRI often is not present for the first few days in herpes simplex virus encephalitis, which may help to distinguish the two conditions.[18] Early recognition with prompt institution of steroids or other immunosuppressive agents can be lifesaving.

Historically, site-restricted forms of demyelination, such as optic neuritis or transverse myelitis, have been included as part of the spectrum of ADEM. Although these conditions share similar underlying pathology, clinical presentations and prognosis are different, and they should be considered to be separate entities. They are considered to be clinically isolated syndromes by the current consensus definitions for demyelinating disease.[32] Clinically isolated syndromes may carry a greater risk for the development of multiple sclerosis or other recurrent forms of demyelinating disease.[49] *Neuromyelitis optica*, also known as *Devic disease*, describes coincident or sequential optic neuritis and longitudinally extensive myelitis. It is not always perinfectious in onset and is associated with antibodies directed against aquaporin-4 water channels in the CNS.[50]

Multiple sclerosis is the second most common cause of acquired neurologic disability in adults. It is an uncommon finding in pediatric patients. Five percent of adults with multiple sclerosis had onset of disease before reaching 18 years of age.[4] Clinical phenotypes consistent with ADEM, relapsing ADEM, and multiphasic ADEM should not be confused with multiple sclerosis. Although they may share some of the same initiating pathologic mechanisms, they are different diseases.[10] The diagnosis of multiple sclerosis requires clinical or radiographic evidence for demyelinating events separated in space and time in the CNS. Patients typically follow a relapsing course of neurologic attacks with resolution or remission of disability between attacks. Evolution into a course of progressive disability occurs in 50 percent of patients who have had the disease for more than 15 years.[7] Treatment consists of medications that modulate the immune response by decreasing migration into the CNS, altering cytokine profiles, and interrupting antigen presentation.

EPIDEMIOLOGY

The estimated incidence of ADEM is 0.8 per 100,000 population per year.[34] ADEM occurs just as frequently in children as it does in adults.[10] It has no specific gender predilection or ethnic distribution.[13,14] In contrast to multiple sclerosis, which generally has a higher incidence at more northern latitudes, ADEM has no appreciable geographic distribution.

PATHOLOGY AND PATHOGENESIS

ROLE OF INFECTION

ADEM is preceded by a viral or bacterial infection in 75 percent of the cases. This infection usually is in the form of a nonspecific upper respiratory infection. Many different pathogens have been identified in association with the illness (Table 43–2). No well-defined latency period has been identified in which an infection can be related to ADEM. Generally, patients present within 1 month of their illness. Correlation between ADEM and an infection occurring more than 30 days prior is more difficult because children are diagnosed with a viral infection four to six times per year, resulting in a positive infectious history in 33 to 50 percent of patients.[38]

The phenotypic presentation for ADEM varies depending on the infectious agent. Some organisms have been associated with typical clinical features. Measles virus infection is associated with ADEM in 1 in 1000 cases. The clinical course often is fulminating, with severe neurological sequelae or death in most patients. Introduction of vaccination has reduced markedly the occurrence of measles in developed countries, although vaccine-associated ADEM is described in 2 cases per 1 million.[6]

Post-varicella ADEM is characterized by ataxia in more than 90 percent of patients, occasionally with an explosive onset.[24] Headache and meningismus are typical constitutional signs. Pyramidal symptoms include bilateral symmetric upper motor neuron weakness. Patients also may have mood disturbances with a depressed affect or irritability.

ADEM that develops after a rubella infection is similar to measles, with an explosive onset in most children.[24] There is often profound lethargy and coma and generalized seizures. Most patients with explosive onset of disease have pyramidal signs and myelitis, whereas a milder phenotype is more likely to have ataxia. Both forms also have been associated with brain stem signs.

Group A beta-hemolytic streptococcal infection has been associated with a dystonic extrapyramidal syndrome. Abnormal movements include dystonia, tremor, and parkinsonism. Tics and chorea have not been associated with this condition. Similar to Sydenham chorea and pediatric autoimmune neuropsychiatric disorders associated with streptoccocal infection (PANDAS), behavioral disturbances, such as emotional lability, obsessive-compulsive tendencies, and inappropriate speech, can occur. Changes in mental status can vary from irritability to coma. MRI shows a predilection for demyelination within the basal ganglia, which includes the caudate, putamen, and globus pallidus. Other

deep gray structures, including the thalamus, subthalamus, and substantia nigra, may be affected as well. This finding is distinct from Sydenham chorea and PANDAS, in which imaging is unremarkable. It has been associated with anti–basal ganglia antibodies that cross-react with certain strains of streptococcus.[14]

ROLE OF IMMUNIZATION

Vaccine-associated ADEM has been described with nearly every immunization (Table 43–3). The Collaborating Center for Reference and Research on Viral Hepatitis of the World Health Organization has suggested a maximal period of 3 months to diagnose vaccination-associated ADEM. Post-vaccination ADEM accounts for less than 5 percent of ADEM cases.

Historically, Pasteur rabies vaccination was associated with prototypic ADEM in approximately one in 1000 individuals.[6] The inoculum was derived from rabbit spinal cord injected with fixed rabies virus. The disease was thought to result principally from the neural tissue contaminating the vaccine, rather than the virus itself. This suggestion is supported further by the continued higher incidence of vaccine-associated encephalomyelitis in patients receiving the Semple or duck embryo vaccinations, both of which contain neural tissue. These forms of the vaccination usually are found in developing countries. Experimental allergic encephalomyelitis, the animal model of demyelinating disease, is induced by inoculating myelin or myelin antigens into a suitable experimental animal, further supporting a role of CNS tissue as the causal agent.

Currently, measles, mumps, and rubella vaccination is associated most often with post-vaccination encephalomyelitis. There is a significant difference between the incidence of live-measles vaccination associated ADEM (1 to 2 per 1 million) and the incidence of ADEM previously associated with the measles virus infection (1 in 1000).

Smallpox was eradicated in 1980 following a successful vaccination program that was discontinued in the United States in 1971.[11] The World Health Organization has allowed retention of the variola virus at a designated laboratory in the United States and Russia for the purpose of creating a safer vaccination than the presently available live vaccinia virus. More recent concerns for bioterrorism have resulted in the reinstitution of smallpox vaccination to certain identified groups within the United States that might come into contact with the virus as first responders to a possible smallpox outbreak. The previously reported incidence of ADEM associated with smallpox vaccination was 10 to 300 cases for every 1 million vaccinations. It is estimated, based on these figures, that vaccination of the entire British population would result in approximately 600 cases of vaccine-associated ADEM. Administration of anti-vaccinia gamma-globulin at the time of vaccination can help to prevent this complication.[44]

IMMUNOLOGIC FACTORS

A review of the normal process of immune system regulation and surveillance of the CNS is useful when discussing immune dysfunction in the pathogenesis of ADEM. Similar to other disorders of immune dysfunction, activated $CD4^+$ T cells play a principal role in the disease process. T cells reactive against self-antigens, including myelin components, are present in the normal immune system. Several regulatory mechanisms are thought to prevent activation of these lymphocytes, and failure of such processes results in autoimmune conditions. The thymus plays a crucial role in normal T-cell development by deleting many autoreactive lymphocytes from the immune system. Other peripheral mechanisms also are needed because this thymic depletion often is incomplete. Clonal anergy describes the unresponsive state of T cells that have encountered their antigen without costimulatory factors.[41] A risk for failure of this mechanism exists through release of nonspecific, costimulatory factors from damaged tissue. Another peripheral process is immunologic ignorance, in which no productive reaction exists between the T cell and its corresponding peptide/MHC complex on an antigen-presenting cell. Changes in antigen availability, such as through increased antigen presentation by an invading microorganism, can disrupt this safeguard.[26]

Active regulation is a third process by which regulatory T cells prevent expansion of self-reactive lymphocytes.[31] Regulatory T cells exert their suppressive effects through direct cell-to-cell contact with membrane-bound molecules (CTLA-4) or indirectly through soluble suppressive cytokines, such as interleukin-10 and transforming growth factor-β.[25] Natural killer cells expressing a T-cell receptor also can regulate autoimmune diseases.[37] The presence of such cells within demyelinating regions suggests that some of the inflammation associated with ADEM may have a protective effect.

Although failure of these mechanisms may result in the activation of T cells reactive against myelin antigens, migration of lymphocytes into the CNS is required to produce disease. The CNS has been considered to be a site of limited immunologic surveillance because of the blood-brain barrier and lack of classic lymph vessels. The blood-brain barrier is principally a mechanical diffusion barrier, however, for hydrophilic molecules formed by specialized endothelial cells at the level of the capillaries. Leukocytes readily cross through endothelial cells in post-capillary venules to occupy the perivenular spaces or move on to the neuropil.[21] In addition, antigens and antigen-presenting cells drain from the brain into cervical lymph nodes via the cribriform plate and perineural sheath of the cranial nerves.[12,28] As discussed later, these factors allow for the presentation of antigen in the systemic immune compartment and passage of leukocytes into the CNS for production of disease.

Children with demyelinating disease of the CNS are thought to have a genetic predisposition for such conditions. The strongest data relate to susceptibility genes on chromosome 6p21 in the area of the histocompatibility leukocyte antigen (HLA). Much of the research into these genetic determinants has been related to adult-onset multiple sclerosis.[46] Limited research is available for pediatric demyelinating diseases. Some of the findings show similarities, however, among age groups and various demyelinating diseases. Linkage studies in Russian children found an association between ADEM and HLA-DRB1*01 and HLA-DRB1*017(03) alleles.[24] Korean children with ADEM were found to have higher frequencies of HLA-DRB4*0101 and HLA-DRB1*1501 compared with controls. In adults with multiple sclerosis, the specific genes that confer the highest risk include HLA-DRB1*1501 and HLA-DRB5*0101 among others. In multiple sclerosis, these genes have been linked to earlier disease onset, female gender, a relapsing remitting course, and optic neuritis or spinal involvement as the initial symptom. In addition,

genes associated with this haplotype include transforming growth factor-β family members, CTLA-4, the tumor necrosis factor cluster, interleukin-1 receptor antagonist, interleukin-1, and estrogen receptor. Polymorphisms in these genes also have been associated with increased risk for development of demyelinating disease.[16]

The precise mechanism by which these HLA class II genes confer risk for development of demyelinating disease is unclear. Possibilities include (1) preferential binding of self-antigens by these peptides, (2) preferential linkage of autoreactive T cells to the antigen-presenting cell expressing these peptides, (3) abnormal antigen presentation by certain DR molecules, and (4) engagement of HLA class II molecules leading to intracellular signaling events.[46]

Humoral factors also play a role in the production of demyelinating disease. This finding is based on disease-associated laboratory findings and treatment responses. Analysis of CSF in one third of patients with ADEM shows production of oligoclonal bands, which are not found to be present in the serum.[13] In addition, some patients with post-rabies inoculation ADEM have been found to have positive serum antibodies against myelin basic protein and galactocerebroside.[33]

PATHOGENESIS

ADEM is considered to occur in genetically susceptible individuals prone to immune system dysregulation after an encounter with an appropriate environmental stimulus. Mechanisms of disease production are based principally on two animal models that closely resemble the disease. The first is experimental autoimmune encephalomyelitis.[43] In this model, animals develop monophasic neurologic disease similar to ADEM after receiving immunization with CNS homogenate or encephalitogenic myelin peptides emulsified in Freund complete adjuvant. The second model is Theiler murine encephalomyelitis, in which susceptible mouse strains develop disease after receiving direct injection of Theiler murine encephalomyelitis virus into the cerebrum.[22] In both of these models, increased exposure of the immune system to myelin proteins produces disease.

By comparing these models with ADEM in humans, two pathogenetic concepts have been developed. The inflammatory cascade concept implies a direct CNS infection with a neurotropic pathogen, which results in CNS tissue damage and systemic leakage of CNS-confined autoantigens through a damaged blood-brain barrier into the systemic circulation. Presentation of these antigens within systemic lymphatic organs leads to tolerance breakdown and a self-reactive encephalitogenic T-cell response. The molecular mimicry concept suggests structural amino acid homology between the invading pathogen and myelin basic protein in the host.[17] Although similar to myelin peptides, the amino acid sequence contains subtle differences that fail to prevent immune tolerance and result in activation of myelin-reactive T cells against similar "self" myelin antigens. Epstein-Barr virus provides an example of this. The virus contains a pentapeptide sequence in its nuclear antigen (EBNA) that shares sequence homology with an epitope of myelin basic protein, a major protein of the myelin sheath.[9] Epstein-Barr virus has been implicated in the pathogenesis of multiple sclerosis partly based on this concept of molecular mimicry.[1]

The immunopathologic events leading to ADEM can be divided into two major phases: (1) initial T-cell priming and activation and (2) subsequent recruitment and effector phase.[5] The priming phase occurs in systemic secondary lymphoid organs, where the antigen-presenting cell presents myelin protein antigen and peptides to neuroantigen-reactive T cells. The activated T cells expand and then migrate to the CNS via the postcapillary venules into the perivascular space. In the Virchow-Robin space, the T cells re-encounter their cognate antigen, in the context of HLA class II molecules expressed by dendritic cells.[19] This reactivation allows the T cells to migrate through the glial limitans and enter the brain parenchyma.

Further recruitment occurs through the production of cytokines and chemokines by antigen-presenting cells and activated T cells, promoting migration into the CNS of additional T cells and other leukocytes, such as polymorphonuclear and monomorphonuclear phagocytes.[46] Breakdown of the blood-brain barrier occurs by release of proteases from recruited mast cells, T cells, and monocytes. In addition, production of reactive oxygen radicals occurs, causing further endothelial injury, which leads to the effector phase in which T cells have more of a secondary role to other inflammatory processes that cause demyelination and axonal injury. These inflammatory processes include oxygen and nitrogen radicals, tumor necrosis factor-α, direct and indirect complement activation, antibody-dependent cellular toxicity, myelin phagocytosis, direct axonal injury by $CD8^+$ cytotoxic T lymphocytes, protease secretion, and oligodendrocyte apoptosis.[46] Glutamate-mediated excitotoxic injury of the oligodendrocytes also occurs.[42] The inflammatory process continues for a few days to 2 weeks, resulting in stretches of demyelinated axons, some of which may be transected.

The repair process begins with activation and proliferation of astrocytes. Clearing of debris by macrophages and increased production of anti-inflammatory cytokines and various growth factors by resident cells and T cells occur. Oligodendrocyte precursors become activated and, along with surviving oligodendrocytes, begin the process of remyelination. The clinical and imaging outcome of ADEM most often shows complete recovery. Subtle differences in repaired myelin, including altered thickness and redistribution of sodium channels, may occur, however. In addition, the relative composition of myelin peptides is altered to forms that may have increased vulnerability to further damage[48] and may explain recurrent forms of ADEM.

CLINICAL EVALUATION

ADEM should be considered in a child presenting several days after a febrile illness with subacute onset of encephalopathy and polysymptomatic neurologic deficits. The clinical features require ruling out other possible diagnoses, however, through additional diagnostic tests.

Diagnostic imaging is the most useful tool in establishing the diagnosis. Computed tomography (CT) scans usually are done on an emergent basis for encephalopathic patients. Areas of demyelination may appear as darker areas of hypodensity, with any hemorrhagic component being hyperdense. CT does not adequately show the full burden of disease, however, and may be completely normal. MRI is the most sensitive means for showing the widespread demyelination typical of the disease (see Fig. 43–1). T2-weighted sequences provide the best assessment of the disease, with demyelinating areas being hyperintense and accompanied by surrounding edema. Administration of gadolinium contrast material may show breakdown of the blood-brain barrier with areas of enhancement. This enhancement may appear homogeneous throughout the lesion or show a "broken ring" appearance, with the open edge pointing toward the cortex. Lesions may be large, measuring more than 1 cm in diameter. They typically are rounded with poorly defined margins.

Of most common concern in children presenting with a febrile encephalopathy is the possibility of an underlying CNS infection. A lumbar puncture often is done to investigate this possibility. A lymphocytic pleocytosis may occur (commonly >50 cells). Elevated albumin levels also may be present. Findings of neutrophils and elevated red blood cells alternatively would raise concern for the possibility of herpes encephalitis.

Intrathecal oligoclonal bands may be positive, and IgG synthesis may be increased in 30 percent of patients with ADEM. These abnormalities usually are associated with multiple sclerosis. In ADEM, convalescent testing for both should normalize, whereas tests remain positive in multiple sclerosis. Their relationship to the underlying disease pathophysiology is unclear but is thought to represent a response of B cells within the CNS to the inflammatory process.[3] Serologic studies of the CSF may be useful to uncover the causal agent, although results should be interpreted with caution because many neurotropic viruses have a high prevalence in the general population.

Rarely, patients may present with very large demyelinating lesions, characteristically described as *tumefactive*. In such circumstances, a biopsy may be needed to determine the underlying etiology. Findings typical of demyelination help to rule out a CNS malignancy. Before a biopsy is done, the clinician should investigate for other evidence of demyelinating disease, including imaging of the spinal cord. A comorbid transverse myelitis would provide more evidence of a demyelinating condition and reduce the need for a biopsy. In addition, normal CSF cytology helps to discount an underlying malignancy.

Either a primary or a secondary CNS vasculitis associated with collagen vascular diseases, such as systemic lupus erythematosus or antiphospholipid antibody syndrome, may manifest with a similar clinical and radiologic picture. These diseases are typified by recurrent ischemic strokes. Distinguishing features for antiphospholipid antibody syndrome include a family history of strokes or other thromboses at a young age and fetal loss. Testing for antiphospholipid antibody and lupus anticoagulant is positive. A primary CNS vasculitis with strokes is best investigated through conventional angiography showing an irregular vessel lumen. Leptomeningeal biopsy is considered the gold standard to confirm the diagnosis.

A severe course that principally affects the optic nerves and spinal cord should raise concern for neuromyelitis optica. Serum or CSF testing for the aquaporin-4 water channel antibody that is associated with this disease is clinically available. The test is greater than 90 percent specific for neuromyelitis optica.[50]

Neurophysiologic studies can be useful to evaluate comorbidities and burden of disease. An electroencephalogram should be obtained in patients with seizures and severe encephalopathy to characterize the seizure focus and to investigate for subclinical seizures. Findings often are consistent with a diffuse disturbance in brain function noting slowing of the normal electric rhythms. Visual evoked potentials can evaluate for demyelination of the optic nerves, which may not be appreciated on imaging. The examination measures the time for an electric impulse to travel from the retina to the occipital lobe, with delays suggesting a demyelinating lesion. The patient needs to be attentive to a flashing light stimulus, rendering this test difficult to perform in patients with severe encephalopathy.

TREATMENT

To date, no controlled clinical trials have been conducted regarding the optimal treatment for ADEM. Based on empiric evidence, intravenous high-dose corticosteroids are accepted as first-line treatment.[45] Methylprednisolone is given at 30 mg/kg per dose (maximum 1000 mg) for a total of five doses. Alternatively, dexamethasone, 1 mg/kg per dose for five doses, may be used. A prednisone taper typically is instituted on completion of this regimen with an initial dosing of 1 mg/kg/day and tapering by 5 mg every 5 days. Alternative anti-inflammatory and immunosuppressive therapies may be used depending on the response to the initial steroid treatment. Intravenous immunoglobulin (IVIG) has been found to be beneficial in some patients.[45] IVIG is given 2 g/kg divided over 2 to 5 days.

Plasmapheresis also may be used.[29,30] The patient receives a total of seven treatments consisting of 1.1 to 1.4 plasma volume exchanges over a 14-day course. IVIG and plasmapheresis typically are not considered as first-line treatment for ADEM, partly related to availability of IVIG or pheresis units, cost of treatment compared with steroids, prolonged hospitalization, and need for adequate venous access. Nonetheless, they should be considered as secondary treatment options, especially in the occasional patient who continues to deteriorate during steroid treatment or who fails to show adequate recovery 7 days after completing intravenous steroids. The choice between the two agents is arbitrary. Particular consideration for plasmapheresis might be given in the setting of a comorbid myelopathy because this has been noted to be beneficial in patients presenting with transverse myelitis.[27] Severe cases failing to respond to any of these measures may require immunosuppressive agents, such as cyclophosphamide.[36]

Additional treatment that may be needed for patients depends on the nature of their neurologic deficits. Anticonvulsants should be given for management of seizures. Attention given to bowel and bladder care is important to avoid secondary complications of retention. Impaired swallowing requires adequate nutrition to be provided by gavage feedings. Transverse myelopathy can be associated with autonomic dysfunction, including orthostatic hypotension, necessitating the use of an abdominal binder. Rehabilitation should begin at the time of admission with the assistance of physical medicine and rehabilitation specialists. During the long-term recovery period, modifications to the home and school environment may be needed depending on residual deficits.

OUTCOME AND PROGNOSIS

Historically, ADEM was associated with high morbidity and mortality rates principally related to disease associated with the measles virus. Measles-associated ADEM was associated with death in 25 percent of affected patients, with an additional 30 percent of patients having severe neurologic sequelae.[35] This dismal outcome has improved dramatically with institution of measles vaccination. The introduction of high-dose steroid treatment in modifying the disease course also may have improved the current outcome findings. A 5 percent mortality rate remains associated with this disease.

Currently, 80 to 90 percent of patients show excellent recovery of functional and cognitive deficits.[2,13,24,47] Mild neurologic disabilities, weakness and fine motor difficulties being the most common ones, may be present in some patients. Epilepsy may occur in 6 percent of patients after an episode of ADEM.[13] Neurocognitive testing of children recovering from ADEM has shown mild impairments in attention and executive function and reduced visuospatial and visuomotor skills.[20] The greatest risk for development of neurologic sequelae may be in older patients with sudden onset of severe neurologic symptoms.

Recurrent forms of the disease often raise concern for pediatric multiple sclerosis. The exact relationship between ADEM and multiple sclerosis remains to be better defined. The conditions are distinct, however, based on the clinical presentations, imaging, and clinical courses. Studies investigating risk for disease recurrence or evolution into multiple sclerosis have been limited and do not adequately define ADEM in the context of the current definition, and they do not distinguish between recurrent forms of the disease and multiple sclerosis. Disease recurrence occurs in 30 percent of patients.[38] Most patients have their second attack within the first year after their initial event.[2,39] It often occurs soon after discontinuation of steroid taper, or after an infection or vaccination encountered shortly after the initial event. Treatment and outcome for recurrences are not different from those described for the initial event.

CHAPTER 43b

INFECTION-ASSOCIATED MYELITIS AND MYELOPATHIES OF THE SPINAL CORD

Mark P. Gorman ● Scott L. Pomeroy

ACUTE TRANSVERSE MYELITIS

The rapid onset of paraplegia and bowel and bladder dysfunction that characterizes acute transverse myelitis (ATM) terrifies affected children and their families. Successful management requires prompt diagnosis and treatment. Because of the association of ATM with numerous infections, specialists in infectious diseases frequently participate in the care of children with ATM. The clinical presentation, radiologic features, differential diagnosis, pathophysiology, treatment, and prognosis of pediatric ATM are reviewed here.

TERMINOLOGY

ATM is a clinical syndrome consisting of progressive symptoms and signs reflecting bilateral sensory, motor, or autonomic dysfunction attributable to the spinal cord. This constellation of symptoms and signs can be caused by a heterogeneous group of disorders, including ATM. Several disorders, including direct infections of the spinal cord, can mimic ATM.
