Many appropriate topical antimicrobial agents for treatment of bacterial conjunctivitis are readily available and include topical moxifloxacin, gatifloxacin, ciprofloxacin, ofloxacin, norfloxacin, tobramycin, gentamicin, erythromycin, sulfacetamide, and combination antibiotics. Aminoglycoside-containing compounds such as neomycin occasionally can cause a dramatic allergic blepharoconjunctivitis that can be worse than the original problem. The choice of using either drops or ointment is best left to the person who will be instilling the medication because neither has any proven therapeutic advantage. With the emergence of multidrug-resistant organisms in many parts of the country, the choice of antibiotic should be modified accordingly. Newer agents, such as the fourth-generation fluoroquinolones (moxifloxacin and gatifloxacin), have many advantages over older drugs, including broad-spectrum coverage, ease of dosing, and pH neutrality. A typical regimen for treatment of mild conjunctivitis is 1 drop or a 0.25-inch bead of ointment placed into the inferior conjunctival fornix three to six times daily for 5 to 7 days, depending on the actual medication. Persistent infection should prompt a return to the physician for reconsideration of the diagnosis. Mild bacterial conjunctivitis generally resolves spontaneously in 7 to 14 days without treatment.[82,83]

Severe Bacterial Conjunctivitis

Severe bacterial conjunctivitis, characterized by pronounced conjunctival infection and copious purulent discharge, usually is caused by *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *S. aureus*, *S. pneumoniae*, and, in children younger than 5 years, *H. influenzae*. A hyperpurulent state in which the copious purulent discharge reaccumulates in a matter of minutes is characteristic of infection with *N. gonorrhoeae*.[96,194]

Severe conjunctivitis demands a comprehensive microbiologic evaluation consisting of stains and cultures. Samples from both eyes should be cultured separately, even if only one eye is involved, to allow the uninvolved eye to serve as a useful control.[205] Gram stains of conjunctival scrapings should be done at the time of culture. A useful culture technique includes the use of a cotton or calcium alginate swab (Calgiswab, Spectrum, Houston) gently rubbed against the palpebral conjunctiva of the lower lid and inoculated onto blood and chocolate agar. If *N. gonorrhoeae* is suspected, culture for chlamydia also is indicated because concurrent infection with both organisms is a common occurrence.

Treatment of severe bacterial conjunctivitis is based initially on results of the stains and later modified according to culture

and sensitivities. If *Neisseria* is strongly suspected, the patient should be treated as though the disease is present, even if the laboratory results are not confirmatory. Ocular *N. gonorrhoeae* infection is a vision- and life-threatening disease. This organism can penetrate the intact cornea and cause microbial keratitis, corneal perforation, and endophthalmitis, in addition to conjunctivitis. *N. gonorrhoeae* conjunctivitis should be considered in three patient groups: neonates after passage through an infected birth canal, sexually active individuals, and victims of suspected sexual abuse. Pediatric infection with *N. gonorrhoeae* requires hospital admission and administration of a systemic antibiotic. Because of the prevalence of penicillin-resistant strains, a broad-spectrum (third-generation) cephalosporin, such as ceftriaxone, is the most appropriate choice of antibiotic.[92] Adjunctive treatment of *N. gonorrhoeae* conjunctivitis with topical moxifloxacin and simple saline irrigation for 5 days can be helpful, but topical agents should never be used as an isolated treatment.[96] Moxifloxacin is a particularly good antibiotic choice because it is effective against chlamydia as well.

Conjunctivitis caused by gram-positive cocci can be treated with topical moxifloxacin, gatifloxacin, ciprofloxacin, or erythromycin. Systemic nafcillin, a second- or third-generation cephalosporin, or both can be added as needed for more extensive infections. Gram-negative bacterial conjunctivitis can be treated with topical erythromycin ointment or an aminoglycoside drip such as gentamicin or tobramycin. Systemic antibiotics can be added if needed.[205]

VIRAL CONJUNCTIVITIS

Adenoviral Conjunctivitis

Viruses are another common cause of infectious conjunctivitis in children. Many pediatric cases of viral conjunctivitis are caused by adenovirus. Serotypes 1, 2, 3, 4, 7, and 10 produce an acute form of conjunctivitis with prominent conjunctival follicles. Serotypes 3 and 7 also may cause pharyngoconjunctival fever. This entity is characterized by conjunctivitis, fever, and pharyngitis.[21] Serotypes 8, 19, and 37 primarily cause epidemic keratoconjunctivitis.[205] The keratitis is characterized by a combination of a punctate epithelial keratitis and an immune response that results in subepithelial infiltrates. Photophobia is a prominent feature, and vision may be decreased markedly with this entity. Epidemic keratoconjunctivitis commonly is associated with pharyngitis and rhinitis, which may precede or coexist with the conjunctivitis.

Adenoviral conjunctivitis is highly contagious. It is transmitted easily from an infected individual to others at home or school. The incubation period is 5 to 10 days but may be as long as 21 days. The virus is shed from the infected conjunctiva for 7 to 12 days after the onset of infection. Frequently, a prodromal upper respiratory infection consisting of fever, pharyngitis, or otitis media occurs.[205] Ocular signs and symptoms include photophobia (with corneal involvement), foreign body sensation, epiphora, bulbar and palpebral conjunctival injection and chemosis (edema), and subconjunctival hemorrhage.[100] Formation of grayish pink friable membranes on the palpebral conjunctiva is a hallmark of the disease and may result in bleeding when removed. Preauricular lymphadenopathy is a common feature in older children and adults. Keratitis may be prolonged, with mild to moderate reduction of vision lasting weeks to months.[100,136]

The diagnosis of adenoviral conjunctivitis usually is clinical. Rarely is laboratory confirmation necessary. Viral cultures are possible when indicated, and a rapid enzyme immunoassay test is available.[228] Treatment of adenoviral conjunctivitis is supportive, aimed at decreasing symptoms. Cool compresses and acetaminophen are helpful, and removal of conjunctival membranes with a cotton swab may relieve the foreign-body sensation. A small amount of bleeding often occurs after removal of these membranes, and the membranes can recur after several days. If corneal subepithelial infiltrates cause significant discomfort or an unacceptable decrease in vision, treatment with a short course of topical steroids may provide symptomatic relief and speed resolution. The use of steroid preparations requires careful monitoring,[135,205] and they should be prescribed only by an ophthalmologist.

The clinician should wear gloves when examining patients with suspected adenovirus infection. Careful handwashing is essential after direct contact. Instruments or equipment used in examining an infected patient should be cleaned with 10 percent sodium hypochlorite solution or other solutions known to eradicate adenovirus. Mini-epidemics have originated in physicians' offices.[113] At home, families should exercise caution and separate the towels and bed clothes of the patient from those of others in the household. Children of school age should be kept home for approximately 7 days or longer to reduce the risk of transmitting the infection to classmates.[205]

Herpes Simplex Virus Conjunctivitis and Complex Forms

HSV conjunctivitis may occur as a primary or as a secondary infection. Ocular infection usually is caused by HSV-1, except in newborns, in whom HSV-2 predominates.[42] Typical initial signs of HSV conjunctivitis include a serous discharge, scant conjunctival follicle formation on the inferior palpebral conjunctiva, and preauricular lymphadenopathy. Eighty percent of cases are unilateral. Eyelid vesicles often occur in primary infections. Bulbar conjunctival ulceration is an unusual occurrence, but when present, it is virtually pathognomonic of primary HSV-1 infection. Keratitis occurs in as many as 50 percent of primary cases and is characterized by mild epithelial irregularities. Dendrites can occur in primary infections. Reactivated HSV keratitis has the characteristic dendritic pattern of epithelial disease. Lid vesicles usually do not develop in reactivated HSV infection.[117]

Primary HSV dermatoblepharitis is seen most commonly in children younger than 6 years old, but it may occur at any age. The initial episode may be associated with an upper respiratory infection, and recurrences are common. Clinical signs include an eyelid vesicular reaction, mild follicular conjunctivitis, preauricular lymphadenopathy, and, occasionally, atypical epithelial keratitis. Secondary bacterial infection can occur. Systemic acyclovir is a safe and effective treatment, although the disease itself typically is self-limited and does not require treatment.[117]

The diagnosis of HSV keratoconjunctivitis usually is made on the basis of the clinical appearance alone. Antigen detection tests or viral cultures can be used when the diagnosis is in question.[113] Viral cultures, when necessary, require special handling.[205] In primary HSV infection, after the skin surface has been swabbed with an alcohol sponge, a tuberculin syringe with a 30-gauge needle is used to aspirate fluid from an intact vesicle. If no vesicles are present, a Dacron swab is wiped on the palpebral conjunctiva of the lower lid. In either case, the viral transport medium is inoculated and taken to the laboratory for special handling.

Treatment of HSV conjunctivitis alone (in the absence of corneal epithelial disease) is somewhat controversial. Oral acyclovir may be used for severe cases of primary HSV infection.[189,201] Three topical antiviral agents are available: iododeoxyuridine, vidarabine, and trifluridine.

When epithelial HSV keratitis is reactivated and the typical dendritic (branched) epithelial lesions are seen, the cornea usually is hypoesthetic. Iritis commonly is associated with HSV keratitis and is characterized by miosis, photophobia, ocular pain, and a foreign-body sensation. Vision may be decreased if the epithelial disease involves the visual axis.[205] Epithelial HSV may be atypical,

more severe, or more complicated in patients receiving topical steroids and in immunocompromised patients.

Treatment with topical trifluridine or vidarabine is indicated in all cases of HSV keratitis. Topical steroid is effective in decreasing corneal scarring caused by HSV stromal keratitis. When using a topical steroid, coverage with a topical antiviral agent such as vidarabine always should be included to reduce the risk for recurrent active viral proliferation during the course of steroid treatment. Oral acyclovir is not effective for treating active HSV keratitis, but it may be useful in treating HSV uveitis.[201] Ancillary treatments include cycloplegic eyedrops to dilate the pupil and pain medications.

Though not helpful in treating acute epithelial disease, chronic suppression with oral acyclovir is effective in reducing the number of recurrences of HSV epithelial and stromal keratitis, especially in patients with stromal keratitis.[201,205] Interferon also significantly adds to the efficacy of topical antiviral therapy, but the adverse side effects of interferon must be weighed against its potential benefits.[201]

External Ocular Infections with Varicella-Zoster Virus

Childhood varicella infection (chickenpox) commonly is accompanied by conjunctivitis. Vesicles, ulcers, or both occur occasionally on the bulbar or palpebral conjunctiva. Conjunctivitis associated with varicella infection does not result in permanent visual sequelae. Corneal involvement rarely occurs and typically heals without sequelae. Occasionally, it may result in stromal scarring and produce irregular astigmatism and reduced vision.

After primary varicella infection occurs, the virus may persist in latent form in the trigeminal nerve ganglia. Herpes zoster ophthalmicus occurs when the ophthalmic division of the trigeminal nerve is affected by reactivation of the virus. The condition occurs more commonly in immunocompromised patients, and recurrences occur infrequently except in these patients.

The diagnosis of herpes zoster ophthalmicus almost always is made on the basis of the characteristic clinical feature of a painful, tender vesicular eruption in the V1 dermatome. Ocular involvement may include keratitis and uveitis. Corneal epithelial lesions may appear dendritiform, with or without subepithelial infiltrates. Uveitis may occur with or without associated keratitis. Usually it is mild, but occasionally it may be severe, with the formation of a hypopyon or hyphema. Immunofluorescence testing of vesicular base scrapings or viral cultures may be helpful if the manifestation is atypical or the diagnosis is in doubt.[125]

Treatment of herpes zoster ophthalmicus involves the administration of oral or intravenous acyclovir. Treatment is most effective when initiated within 72 hours of the appearance of vesicles. Keratitis and uveitis do not respond to topical antiviral therapy.[201] Sometimes topical steroids can be helpful in treating varicella keratitis and uveitis, but such treatment should be administered under the direction of an ophthalmologist.[135]

Chlamydial Conjunctivitis and Trachoma

Chlamydia spp. can cause conjunctivitis and trachoma. *Chlamydia psittaci* rarely causes ocular disease in humans. *Chlamydia trachomatis*, however, has numerous serotypes that affect the eye. Serotypes A, B, Ba, and C cause trachoma, and serotypes B, C, D, Da, D–, E, F, G, H, I, Ia, J, and K cause inclusion conjunctivitis, including neonatal inclusion conjunctivitis. Neonatal chlamydial conjunctivitis is discussed in the section "Neonatal Conjunctivitis."

Inclusion conjunctivitis in older children and adults is manifested as subacute or chronic inflammation of the conjunctiva. The condition may be unilateral or bilateral. A mucopurulent discharge typically occurs, as do follicles on the bulbar and perilimbal conjunctiva. Preauricular lymphadenopathy is a common finding. Punctate epithelial keratitis with subepithelial infiltrates and a superior micropannus (i.e., vascular growth on the cornea) may develop.[52]

The differential diagnosis of inclusion conjunctivitis is sizable and includes viral and bacterial conjunctivitis, molluscum contagiosum, and toxic keratoconjunctivitis from chronic administration of topical agents. Laboratory testing may be necessary to confirm the diagnosis. Giemsa staining of conjunctival scrapings may demonstrate the classic intracytoplasmic inclusions. A fluorescent antibody detection test or enzyme immunoassay is used to make a rapid diagnosis.[205] Rarely are chlamydial cultures needed except when the diagnosis remains in doubt.

Treatment consists of oral erythromycin or doxycycline if systemic infection is suspected. Topical erythromycin or tetracycline alone four times each day for 7 days is effective treatment of infection limited to the conjunctiva.[52,205] Moxifloxacin recently has been shown to be effective against chlamydia as well but is not yet the recommended treatment of choice.

Trachoma remains a leading cause of blindness worldwide, ranking second or third, depending on the region studied. It is a disease of impoverished populations that is exacerbated by inadequate supplies of water and by poor hygiene. Trachoma seldom is seen in developed countries. In the United States, it is encountered on Native American reservations in the Southwest and in individuals arriving in endemic areas of the United States. Eye-seeking flies play an important role in transmission of *Chlamydia* from one person to another.[205]

Trachoma causes blindness by producing chronic inflammation of the palpebral conjunctiva of the upper eyelid with secondary scar formation. Contracture of the palpebral conjunctiva scar causes entropion of the eyelid and trichiasis. Eventually, this situation leads to corneal opacification and vision loss.[204,205] Less commonly, the cornea may be infected directly. The complete course of the disease from initial infection to blindness generally takes decades.

The diagnosis of trachoma usually is made on the basis of clinical findings alone. The disease passes through characteristic stages, from simple inflammation to scarring, entropion, and trichiasis. Multiple stages may coexist in various parts of the eyelids. The World Health Organization classifies the stages of trachoma as follows: TF, trachomatous follicular response; TI, diffuse trachomatous conjunctival inflammation; TS, trachomatous scarring of the palpebral conjunctiva; TT, trachomatous trichiasis; and TO, trachomatous corneal opacification. In the pediatric population, physicians usually encounter only stages TI and TF.[214] The scars on the palpebral conjunctiva, referred to as *Arlt lines*, are linear and multidirectional. Slit-lamp examination may reveal a superior limbal micropannus and Herbert pits (i.e., hollowed-out areas in the superior limbus), which represent sites of resolved follicles.

Treatment of trachoma consists of topical tetracycline or erythromycin ointment instilled twice daily for 2 months and, more importantly, improved sanitation and hygiene to prevent recurrence.[205] Trachoma can be self-limited if hygiene alone is improved.[204] In patients who do not respond promptly to topical treatment or in those with severe disease, systemic antimicrobial agents should be instituted. For those older than 8 years, doxycycline should be administered orally daily for 40 days. Erythromycin can be substituted in younger children or in patients intolerant of doxycycline.

NEONATAL CONJUNCTIVITIS

Neonatal conjunctivitis, or ophthalmia neonatorum, is a common vision-threatening disorder throughout the world, although it has been relegated to a position of secondary importance in the industrialized world, where screening and prophylactic measures

are widespread. It remains a significant cause of childhood ocular morbidity in developing countries.

Dilute topical silver nitrate solution instilled just after birth for prophylaxis against ophthalmia neonatorum was the first treatment used. It was responsible for reducing the prevalence of gonococcal ophthalmia neonatorum from 10 to 0.17 percent of live births in Europe.[205] A mild, self-limited chemical conjunctivitis is associated with the use of silver nitrate,[154] but it lasts 2 to 4 days and resolves with no treatment. Topical erythromycin largely has replaced silver nitrate in developed countries because it is effective without producing a chemical conjunctivitis.[94] In the developing world, regional conflicts, political instability, and burgeoning refugee populations often result in underuse of these simple prophylactic measures.[78,94]

Causes of neonatal conjunctivitis are highly variable among populations. In areas that use silver nitrate drops for prophylaxis, chemical conjunctivitis is the most common cause of neonatal conjunctivitis.[154] Infectious conjunctivitis occurs in 0.5 to 6.0 percent of live births in the United States. The leading infection is *C. trachomatis*.[15,99,185,205] Neonatal infection is caused by ocular exposure to contaminated maternal discharge during normal birth, although it may occur in infants born by cesarean section, especially if the membranes rupture prematurely. Other important infectious agents that may cause ophthalmia neonatorum are *N. gonorrhoeae* and *S. aureus*.[77,194] Bacteria that normally reside in the vaginal or gastrointestinal tract occasionally are implicated in ophthalmia neonatorum. Such bacteria include *Streptococcus* spp., *Haemophilus* spp., *Pseudomonas aeruginosa*, *Moraxella* spp., *Moraxella catarrhalis*, *N. meningitidis*, *E. coli*, and *Enterobacter cloacae*.[185,200]

Viruses occasionally produce neonatal conjunctivitis. Rarely, HSV may cause keratoconjunctivitis.[78] It is associated with distinctive vesicular skin changes and systemic signs, and the diagnosis seldom is in doubt.[9] Life-threatening HSV meningoencephalitis is a serious potential complication of HSV ophthalmia neonatorum.[152] Other viruses occasionally implicated include adenovirus, coxsackievirus A9, cytomegalovirus (CMV), and echovirus.[199]

Certain clinical features may help establish the specific etiologic diagnosis in cases of ophthalmia neonatorum (Table 68–1), but considerable overlap in findings exists, and physicians cannot rely on the history and physical examination alone to make a definitive diagnosis. Even when all appropriate investigative modalities are used, the cause may remain unknown in some cases.

Variations in the time of onset after birth, severity of inflammation, and character of the ocular discharge are common, and none is considered pathognomonic of a specific infectious process, but general considerations are worth reviewing.[185] Silver nitrate conjunctivitis typically begins during the first 48 hours of life and produces a watery discharge with mild inflammation. It is self-limited and resolves within 48 to 72 hours of its appearance.[154] *C. trachomatis* conjunctivitis generally begins 1 to 21 days after birth and usually is apparent by day 7. A moderately copious mucopurulent discharge may be present but can be variable.[99,149] *S. aureus* conjunctivitis also begins during the first 3 weeks of life and can produce a moderately profuse mucopurulent discharge. Many other bacterial agents produce an overlapping clinical picture. Conjunctivitis caused by *N. gonorrhoeae* ordinarily begins somewhat earlier, usually by the third day of life, but it may appear as late as 3 weeks after birth. The hallmark is a copious, hyperpurulent discharge that can reaccumulate in a matter of minutes after it is removed. *N. gonorrhoeae* can penetrate an initially intact cornea and result in perforation of the eye and endophthalmitis.[96,187,199] Conjunctivitis caused by gastrointestinal flora often begins within a few days of birth and can produce a copious purulent discharge.

TABLE 68–1 Clinical Characteristics of Neonatal Conjunctivitis Caused by Various Agents

Agent	Day of Life at Onset	Discharge
Silver nitrate	1 (0-2)	Serous
Chlamydia trachomatis	7 (1-21)	Mucopurulent
Staphylococcus aureus	5 (1-21)	Mucopurulent
Neisseria gonorrhoeae	3 (0-21)	Purulent
Other bacteria	7 (1-21)	Mucopurulent
Herpes simplex virus	5 (0-21)	Serosanguineous
Other viruses	Not established	Probably serous

Viral neonatal conjunctivitis is a rare occurrence. HSV infection may begin during the first 3 weeks of life and usually produces a serous or serosanguineous discharge.[78,152] Other viruses have highly variable characteristics, but a serous discharge is a common finding.

The differential diagnosis of neonatal conjunctivitis includes congenital glaucoma, dacryostenosis with or without dacryocystitis, keratitis, and uveitis. Dacryostenosis is manifested as epiphora and a watery or purulent discharge. Occasionally, conjunctivitis may develop. Because epiphora caused by congenital dacryostenosis ordinarily is not seen until the second or third week of life, it rarely is a serious consideration. Newborns with congenital glaucoma often are photophobic and irritable.[222] They may exhibit increased tearing, conjunctival injection, and corneal edema. Both keratitis and uveitis most often are accompanied by photophobia and pain. The discharge with keratitis can vary but with bacterial causes is purulent. The discharge with uveitis, if present, is watery.

Laboratory testing is important in establishing a specific diagnosis and should include Gram and Giemsa stains, a chlamydial immunoassay, and cultures for aerobic and anaerobic bacteria. Cotton-tipped swabs should be used to obtain material for culture from the conjunctival fornices. Viral and chlamydial cultures and immunoassays can be considered but usually are unnecessary.[14,207] Gonococcal immunoassay and HSV immunochemical tests are available but not in widespread use.

The initial treatment of neonatal conjunctivitis depends on the suspected infectious agent. Broad-spectrum treatment should be considered if the diagnostic possibilities cannot be narrowed. Silver nitrate–induced conjunctivitis is self-limited and does not require treatment. *C. trachomatis* conjunctivitis is treated with tetracycline (1%) or erythromycin (0.5%) ointment four times daily for 3 weeks and with systemic erythromycin for 2 to 3 weeks to prevent or to treat chlamydial pneumonia. Sulfonamides can be used to treat chlamydial conjunctivitis if erythromycin is not tolerated. Topical antibiotics alone are insufficient for the treatment of neonatal *Chlamydia* infection.[87,95,99] Staphylococcal conjunctivitis can be treated with erythromycin ointment or a variety of other topical antimicrobial agents every 4 to 6 hours for 3 to 7 days. Appropriate systemic antibiotic treatment should be considered if the infection is particularly severe.[205]

N. gonorrhoeae infection requires systemic treatment in all cases. Aqueous penicillin G can be considered if resistant strains are unlikely. However, one dose of intramuscular ceftriaxone is the treatment of choice in the United States because it is effective against all *N. gonorrhoeae* strains.[92,171] Eyes should be irrigated with saline every hour until the discharge clears and then in reduced frequency as necessary to reduce the risk for development of corneal infection. This interval usually is 24 to 48 hours after the initiation of systemic treatment. Penicillin G drops are recommended by some ophthalmologists, but such drops do not appear to improve the overall prognosis or speed of recovery.

HSV neonatal conjunctivitis is treated with systemic acyclovir in appropriate doses for as long as 3 weeks.[78] Treatment should be instituted on an emergency basis because of the potential for

development of serious permanent neurologic sequelae and death if treatment is delayed. Topical ophthalmic vidarabine or trifluridine also should be applied to the eyes four times daily for 2 to 3 weeks.

Prevention of ophthalmia neonatorum is simple and requires only instillation of an antibiotic or antiseptic agent within the first hour after birth. Silver nitrate drops (1%), erythromycin ointment (0.5%), and tetracycline ointment (1%) have been effective treatment against *N. gonorrhoeae* and *C. trachomatis*.[95,205] A 5 percent solution of povidone-iodine also has been effective and economical in prophylaxis against a variety of agents, including gonococcal neonatal conjunctivitis. It may be particularly useful in developing countries.[110] As with other sexually transmitted diseases, neonatal conjunctivitis caused by *N. gonorrhoeae*, *C. trachomatis*, or HSV should be addressed according to standard public health policies, with reporting, investigation, and case identification as required by local law.

KERATITIS: CORNEAL INFECTION

The cornea, with its overlying tear film, is the major refracting component of the human eye. Keratitis means inflammation of the cornea. Any irregularity of the corneal surface or an opacity involving the central visual axis of the cornea may impair vision.

The cornea is composed of five distinct layers: epithelium, Bowman membrane, stroma, Descemet membrane, and endothelium. The epithelium is several layers thick and, when healthy, can regenerate without scarring after an insult. The Bowman membrane lies beneath the epithelium. It does not regenerate and, when injured, heals with a scar. The stroma, approximately 0.5 mm in thickness, is the thickest part of the cornea. It is composed of regularly arranged collagen fibrils embedded in a matrix of mucoproteins and glycoproteins. The arrangement of the fibrils is more regular in the posterior aspect of the stroma. Like the Bowman membrane, the stroma heals with scarring. The Descemet membrane is the basement membrane of the corneal endothelium. It can regenerate after an insult and does not opacify. The innermost layer, the endothelium, is derived from neuroectoderm. It consists of a single layer of cells that do not have significant regenerative capacity. The cornea is an avascular structure that is kept clear by virtue of the regular arrangement of collagen fibers in the stroma and by the pumping action of the endothelium, which keeps the stroma relatively dehydrated. The cornea will become edematous and opacify if the endothelium is significantly damaged or diseased.

The external corneal surface is protected from injury and exposure by the eyelids. Reflex tearing in response to mechanical irritation provides further protection. The blink response to threat and the antimicrobial properties of the normal tear film further protect the cornea from injury and infection.

Keratitis is a potentially vision-threatening condition that refers to inflammatory reactions and infectious processes of the cornea. Persons with keratitis usually have erythema of the perilimbal bulbar conjunctiva and eye pain. Additional complaints may include decreased vision and photophobia. The diagnosis of keratitis depends on the presence of a corneal epithelial or stromal infiltrate. The infiltrate can be extremely difficult to see in uncooperative infants and young children. Ideally, the patient is examined with a slit lamp; sometimes sedation is required for adequate examination of uncooperative children. Stains and cultures often are required to establish the diagnosis, and an ophthalmologist should be consulted promptly. Rarely, biopsy of the cornea is needed to obtain material for culture, and corneal transplantation is required occasionally to halt progression of an infection or to treat corneal perforation. Etiologic diagnosis is based on clinical findings and examination of stains and cultures.

ISOLATED EPITHELIAL KERATITIS

Keratitis can be classified further according to the layer of cornea involved. Most infections involve the epithelium or stroma. Isolated epithelial keratitis usually is caused by one of several viruses: HSV, varicella-zoster virus (VZV), adenovirus, EBV, and measles virus (rubeola). The first three organisms are discussed in an earlier section.

EBV causes HSV-like dendritic corneal epithelial lesions. Stromal disease also may occur. The lesions are self-limited and do not respond to antiviral therapy.[136] When measles involves the cornea, it usually does so in the context of transient epithelial infiltrates, which resolve without permanent sequelae.[117] In malnourished children with vitamin A deficiency, however, measles represents a serious threat to life and vision. Deep corneal ulcers may develop during the first few days of measles infection. Rapid progression culminating in corneal perforation and ultimate loss of the eye may occur.[20,75] Whether the ulcers are caused by direct measles virus infection, by the keratomalacia of vitamin A deficiency, or by some combination of these factors has been debated for some time. Measles immunization programs and vitamin A administration programs can reduce the prevalence of childhood blindness in developing nations significantly.

STROMAL KERATITIS

Syphilis and unique parasitic and viral infections can cause a nonsuppurative keratitis isolated to the corneal stroma. Congenital syphilis produces interstitial (stromal) keratitis in children, although the condition usually does not become apparent until late in the first decade of life. An indolent, peripheral corneal haze develops and slowly progresses centrally. Ghost vessels devoid of blood flow are seen in the corneal stroma on slit-lamp examination.[206] The condition is manifested as a bilateral inactive stromal process[190] in 80 percent of cases and is accompanied by iritis, iridocyclitis, or scleritis at some point in the course of the disease. When ocular syphilis is diagnosed, systemic infection is present by definition. The systemic disease should be treated according to accepted guidelines.

BACTERIAL KERATITIS

Bacterial keratitis (i.e., corneal ulcer) most often occurs after trauma that disrupts the normal integrity of the corneal epithelium. The trauma can be mild and occult, such as that caused by lens wear. *S. aureus*, *S. pneumoniae*, *P. aeruginosa*, and *Moraxella* spp. are the most common bacterial causes of severe necrotizing bacterial keratitis.[8,127,217] Other organisms, such as *S. epidermidis*, *Actinomyces* spp., viridans streptococci, and a variety of others, have been implicated in less severe cases.

Accurate identification of the offending organism facilitates treatment. A specimen is obtained by scraping the edge of the ulcer with a sterile platinum spatula. Smears should be fixed in 70 percent methanol, not by heat, and Gram stain for bacteria and acridine orange stain for fungi and *Acanthamoeba* are recommended. The yield of culture-positive cases is higher in laboratories skilled in handling corneal cultures. Material for culture should be inoculated onto fresh media such as blood and chocolate agar (aerobes and facultative anaerobes), Sabouraud agar (fungi), and thioglycolate broth (anaerobic bacteria). Thayer-Martin agar should be plated if *N. gonorrhoeae* is suspected. Initial treatment is based on the resulting stains (Table 68–2) and modified pending cultures (Table 68–3).[17,126]

Medical treatment of bacterial keratitis includes fourth-generation fluoroquinolones, fortified topical antibiotics, and, occasionally, subconjunctival antibiotic injection (see Table

TABLE 68–2 Treatment of Keratitis Based on Smear Morphology

	Antibiotic

‡*Periocular use only.*
IM, intramuscularly; IV, intravenously.

68–2).[38,156,205] Antibiotics are administered as often as every 15 to 30 minutes initially. Systemic antibiotics are required only for gonococcal, chlamydial, and onchocercal keratitis, as well as for actual or threatened perforation of the cornea, extension of infection to the sclera, or worsening of the process during topical or periocular treatment (or both). Topical steroids are useful if the resulting inflammation threatens to destroy the mechanical or optical integrity of the cornea, but steroids never are used as isolated treatment.[205]

FUNGAL KERATITIS

The most common causes of fungal keratitis include *Candida*, *Aspergillus*, and *Fusarium*. Mycotic keratitis associated with the filamentous fungi *Aspergillus* and *Fusarium* is thought to occur with trauma, whereas keratitis caused by *Candida* is associated more commonly with a preexisting ocular (e.g., dry eye) or systemic (e.g., diabetes mellitus, immunosuppression) condition.[210] Fungal keratitis tends to be relatively indolent in comparison to bacterial keratitis. Typically, white stromal infiltrates with irregular and indistinct borders are detected. Satellite lesions, or those independent of the main lesion, may be evident. Mild concurrent iritis is a common finding. Severe iritis with hypopyon can occur but is an infrequent manifestation of fungal corneal disease.[157] Acridine orange stain is recommended, and culture on a Sabouraud agar plate is indicated. Hyphal fungi are treated with topical natamycin, topical fluconazole, systemic fluconazole, or some combination of these medications. Yeasts are treated with topical or systemic amphotericin B, fluconazole, or both agents.[76]

PROTOZOAN KERATITIS

Protozoan keratitis is a particularly serious vision-threatening process. It usually is caused by *Acanthamoeba* and occurs more

frequently in wearers of soft contact lenses. Use of homemade saline solution is a significant risk factor and should be discouraged.[31] Amebae are ubiquitous organisms in soil, water, and air. They have been identified in hot tubs and in the feces of domestic animals.[134] People living in rural areas may be at special risk. *Acanthamoeba* keratitis also has been reported in children without a history of contact lens use or trauma.[53]

Acanthamoeba corneal ulcers are pleomorphic.[109] Older lesions may exhibit a ringlike infiltrate around a central ulcer. Iritis or iridocyclitis may be intense, and severe pain is a hallmark of the disease. Acridine orange and calcofluor white stains aid in establishing an early diagnosis of the condition. Tandem scanning confocal microscopy of corneal specimens may increase diagnostic accuracy, and the organism may grow on blood and chocolate agar.[31,131,133,138,166]

Treatment of *Acanthamoeba* keratitis is complex and suboptimal. Topical application of polyhexamethylene biguanide (0.02%),[123] chlorhexidine (0.02%), paromomycin (0.1%), or propamidine isethionate (Brolene) drops may be effective. Oral itraconazole (Sporanox) has been used successfully in adults.[127,131,138] Cycloplegic agents are recommended to improve the patient's comfort, and pain medications often are required. Corneal transplantation is needed if the infection progresses despite treatment, if perforation occurs, or if significant corneal opacification remains after the disease is eradicated.

Onchocerca volvulus is a filarial parasite that causes river blindness (i.e., onchocerciasis). The disease is endemic in sub-Saharan West Africa and in areas of Central and South America. The organism is transmitted by the bite of a blackfly of the family Simuliidae.[179] Larvae migrate to subcutaneous tissue and pass through several molts to become adult worms, which encapsulate in nodules and produce microfilariae that pass into blood, skin, and other organs, including the eyes. The conjunctiva, cornea, aqueous humor, vitreous, retina, uveal tract, sclera, and optic nerve all may be infested. Corneal involvement can lead to vision loss caused by corneal opacification, but most severe vision loss is caused by choroidal, retinal, and optic nerve disease.[93] Although children often are infected, blindness usually does not occur until they reach the third or fourth decade of life.[213,220]

Current treatment of onchocercal infection is administration of ivermectin every 6 to 12 months to all individuals living in endemic areas. Ivermectin kills the microfilariae but not the adult worms, which remain until their death.[209] The adult worm may live 10 or more years. Because of the long life span, ivermectin should be taken every 6 months for at least 10 years to treat microfilariae as they develop.

Microsporidia are intracellular protozoa that represent a new emerging ocular pathogen. Interest in the organism has increased in the last decade because of its association with HIV and acquired immunodeficiency syndrome (AIDS). The ocular manifestation corresponds to both the immune status of the patient and the genus of microsporidia involved.[115] Typically, keratoconjunctivitis occurs in immunocompromised individuals, and stromal keratitis is seen in immunocompetent individuals. Keratoconjunctivitis is manifested as bilateral conjunctival inflammation and epithelial keratopathy, which may lead to decreased vision. Stromal keratitis is manifested as an insidious diskiform keratitis with uveitis similar to that seen in HSV stromal keratitis and may require penetrating keratoplasty because of perforation or scarring.

Potassium hydroxide plus calcofluor white and acid-fast stains are thought to be the most efficient means of establishing the diagnosis of microsporidial keratitis.[114] Transmission electron microscopy provides specificity in identification of the genus and possibly the species, but it may lack sensitivity and is laborious.[115] Knowledge of the genus and species may help guide management. Albendazole, fumagillin, itraconazole, metronidazole, and topical propamidine isethionate have been used as therapeutic agents.[43,115]

INFECTIONS PRIMARILY INVOLVING THE UVEA

The uveal tract is the vascular middle coat of the eye. It is situated between the sclera and the retina. Its major function is to provide nourishment for intraocular tissues, including the retina, lens, and cornea. The uveal tract is composed of the iris, ciliary body, and choroid.

Uveitis is a nonspecific term for inflammation of the uvea. If the inflammatory process primarily affects the iris, it is called *iritis*. If the ciliary body is involved, the process is called *cyclitis*. If these two structures together are involved, the process is called *iridocyclitis* (i.e., anterior uveitis). The term *intermediate uveitis* (i.e., pars planitis) applies to inflammation in the region of the ciliary body and peripheral retina. The term *posterior uveitis* usually applies to combined inflammation of the retina and choroids, also called *chorioretinitis*. If the choroid alone is involved, it is called *choroiditis*; inflammation of the retina alone is called *retinitis*. Because of the thinness and close apposition of these two tissue layers, inflammation in one layer frequently "spills over" into the other. The vitreous body occupies the central area of the eye behind the lens. It is composed of water, mucopolysaccharides, and collagen. Though transparent in a normal, healthy eye, the vitreous is subject to inflammation or vitritis, usually as a result of inflammation in adjacent retinal tissue or in the pars plana.

Causes of uveitis are numerous but can be categorized into two main groups: infectious and noninfectious. Infectious causes are discussed in this chapter. Uveitis in any area of the eye may result in pain, conjunctival or episcleral hyperemia, photophobia, lacrimation, and decreased vision, although these symptoms vary relative to the site and the aggressiveness of the inflammation.

With slit-lamp examination, the hallmark of anterior uveitis is the finding of hazy, proteinaceous aqueous humor, called *flare*, and the presence of leukocytes in the anterior chamber. The cell and flare components are graded independently on a 1+ to 4+ scale. If present in sufficiently great numbers, leukocytes can precipitate in the anterior chamber (with location dependent on gravity) and form a mass called a *hypopyon*. The cells can aggregate on the back of the cornea and create fine, medium, and large lesions known as *keratic precipitates*. The conjunctiva usually is injected or hyperemic. With chronic inflammation, the border of the pupil often adheres to the anterior surface of the lens. Such adhesions are called *posterior synechiae* and may cause the pupil to have an irregular shape and size, as well as poor reactivity to light. Chronic or recurrent anterior segment inflammation may lead to the formation of a cataract. Iris nodules or atrophy may develop with long-standing inflammation. Anterior vitreous cells may occur as a spillover phenomenon in the setting of a prolonged or vigorous anterior chamber reaction. Although inflammatory effects on the ciliary body generally compromise its production of aqueous humor and thereby reduce intraocular pressure, cellular and proteinaceous debris can occlude aqueous humor outflow channels and lead to elevated intraocular pressure.

Inflammation primarily involving the posterior segment of the eye usually leads to decreased vision, which may be the symptom for which treatment initially is sought. Pain may be minimal or absent. Inflammatory lesions of the retina and choroid also may lead to the development of cellular debris in the vitreous and cause the patient to perceive "floaters." Initially, the borders of the retinal or choroidal inflammatory foci often are indistinct and cream-colored. In the healing phase, the borders of these lesions increasingly become distinct, and a defined, partially pigmented scar results. Inflammatory perivascular sheathing of the retinal vessels may occur as well. Involvement of the macula with edema or exudates may result from inflammation of the posterior segment, and long-standing edema may evolve into a cystic configuration and cause loss of central visual acuity. The optic nerve may exhibit an inflammatory response; if the optic disk is so

involved, the response is called *papillitis*. Inflammatory debris also may be found in the vitreous.[4,159,233]

Under normal circumstances, the amount of immune traffic within the eye, especially in the anterior chamber, is held to a minimum by a group of immunomodulatory pathways that together form anterior chamber–associated immune deviation (ACAID). Chief among these deviations is active suppression of delayed hypersensitivity; distinctive ocular antigen-presenting cells migrate to the spleen, where they generate an immune response deficient in $CD4^+$ cells but high in $CD8^+$ cells. These regulatory T cells return to the eye to suppress the $CD4^+$ populace, thereby minimizing the arm of inflammation most likely to impair visual clarity.[74,200]

EPIDEMIOLOGY

In the United States, most uveitis cases have noninfectious causes. Large samples demonstrate a predominance of anterior rather than posterior uveitis. The most common category of anterior uveitis is idiopathic; the most common infectious cause of anterior uveitis is herpetic kerato-uveitis (simplex and zoster). Posterior uveitis is caused most frequently by *Toxoplasma gondii*. In developing nations, infectious uveitis plays a larger role. In West Africa, *T. gondii* probably accounts for most cases of intraocular inflammation.[177,178]

VIRAL UVEITIS

Herpes Simplex Virus

Most of the uveal inflammation associated with HSV (typically iridocyclitis) results from the corneal disease. Occasionally, a patient will have iritis as an isolated finding, but most patients with ocular HSV demonstrate conjunctivitis, keratitis, chorioretinitis, or retinal vasculitis. The iritis may require treatment with topical steroids and topical antivirals as prophylaxis against the development of corneal epithelial disease.[216,233]

Varicella-Zoster Virus

Occasionally, varicella infection (i.e., chickenpox) may be associated with a transient iritis that requires no treatment. Though rare, cases of unifocal choroiditis causing visual loss but responsive to acyclovir in children with primary varicella have been reported.[146]

Herpes zoster virus may cause iridocyclitis during the acute stage of the disease; the anterior chamber reaction can persist or recur long after resolution of the cutaneous component of the condition. Herpes zoster always should be considered in the differential diagnosis of chronic unilateral iridocyclitis. Topical steroids are indicated for iritis, with the addition of oral or intravenous acyclovir for severe cases. Segmental iris atrophy is a characteristic sequela of herpes zoster uveitis. Glaucoma, hyphema, retinitis, vasculitis, and extraocular muscle palsy occasionally occur in patients with herpes zoster ophthalmicus. In a profoundly immunosuppressed patient, VZV can cause a devastating retinitis known as *progressive outer retinal necrosis*.[125]

VZV and HSV-2 have been implicated as causes of acute retinal necrosis syndrome. Patients in whom this syndrome is diagnosed range from 13 to 71 years of age, with an average age of 43 years. The syndrome typically occurs in healthy patients. The virus causes a triad of acute vitritis, retinal vasculitis, and peripheral necrotizing retinitis and is bilateral in 33 percent of patients. Treatment consists of intravenous acyclovir. Prophylactic laser photocoagulation may prevent retinal detachment. The visual prognosis is guarded.[22,125]

Epstein-Barr Virus

Ocular EBV involvement has been reported primarily in patients with infectious mononucleosis. Follicular conjunctivitis may be diagnosed in 2 to 40 percent of patients. Corneal stromal inflammation, iritis, episcleritis, optic neuritis, and chorioretinitis occur less commonly. Systemic corticosteroids and acyclovir may be useful in treating sight-threatening complications of chronic intraocular inflammation from EBV infection.[135] Postinfectious uveitis also has been described and is discussed later.

Enteroviruses

Coxsackievirus A24 and enterovirus 70 may cause a painful follicular conjunctivitis called acute hemorrhagic conjunctivitis. Rarely, chorioretinitis may be diagnosed. Treatment of these infections primarily is supportive.[159]

Rubella Virus

Rubella virus can cause congenital and acquired infections. Ocular manifestations of acquired rubella include conjunctivitis in 70 percent of patients, superficial keratitis, and iritis. Rarely, retinitis has been reported.

Congenital rubella syndrome can be manifested as cataracts, glaucoma, microphthalmos, and retinitis. Cataracts occur in 15 percent of patients and glaucoma in 10 percent. Retinal examination reveals a "salt-and-pepper fundus" caused by the alternating pattern of hypopigmentation and hyperpigmentation of the retinal pigment epithelium. The prognosis for patients with retinitis alone usually is good, with vision between 20/20 and 20/40. Glaucoma resulting from rubella commonly requires surgery, as do the cataracts. Iritis is reported less commonly.[23,135]

Mumps Virus

Ocular manifestations of mumps virus includes dacryoadenitis, conjunctivitis, iritis, optic neuritis, and keratitis. Retinitis also has been reported. The prognosis for visual recovery from the retinitis is good, and sequelae of the iritis are rare occurrences.[76,135]

Measles Virus

Measles virus can cause congenital and acquired infections. In congenital infections, a "salt-and-pepper" retinopathy and cataract formation may occur, similar to that found in rubella. Ocular manifestations in acquired measles include conjunctivitis and, much less commonly, retinitis, retinal vasculitis, and optic nerve edema.[12,159]

Subacute Sclerosing Panencephalitis

Between 30 and 75 percent of patients with subacute sclerosing panencephalitis (SSPE or Dawson inclusion body encephalitis) have ocular findings. SSPE is caused by a variant of the measles virus; it differs from the wild-type virus by alteration or absence of viral M protein. Optic nerve edema, inflammation, and subsequent optic atrophy have been reported. Macular retinitis is a common finding, and the contiguous non-neural tissues (vitreous and choroid) almost never are involved. The visual prognosis of survivors is poor.[155,159]

Creutzfeldt-Jakob Disease

The most common ocular manifestation of Creutzfeldt-Jakob disease is cortical blindness. Optic atrophy may result from degeneration of the neurons of the optic nerve.[159]

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

As many as 75 percent of patients with advanced AIDS have ocular findings. Cotton-wool spots occur in more than 50 percent of patients and are bilateral in more than 80 percent. Cotton-wool patches represent focal infarctions of the neural layer of the retina and are the most common ocular finding in patients with AIDS. They generally produce no symptoms and do not decrease vision. These spots are white and fluffy and occur most commonly in the macular portion of the retina. They resolve in 4 to 6 weeks with no residual scars. Occasionally, flame-shaped hemorrhages are detected as well. The retina and choroid in these patients may become infected with HSV, CMV, VZV, syphilis, tuberculosis, ocular histoplasmosis, *Candida*, toxoplasmosis and *Pneumocystis*, although in the highly active antiretroviral therapy (HAART) era, the incidence of CMV retinitis has declined and its advance in existing cases has been slowed or halted. Symptomatic anterior uveitis in the absence of the aforementioned pathogens occurs rarely in patients with AIDS and may be caused by HIV itself.[111]

Cytomegalovirus Infection

CMV infections may occur in preterm neonates and immunosuppressed patients, especially those with AIDS. In neonates with symptoms of CMV infection (i.e., low birth weight, microcephaly, jaundice, thrombocytopenia, hepatosplenomegaly, or petechial rash), congenital CMV infection[18] (i.e., prenatal transmission) may be manifested in the fundus as chorioretinal scars (21%) and optic atrophy (7%).[41]

CMV retinitis develops in approximately 30 percent of adult patients with AIDS, usually those with $CD4^+$ counts less than $50/mm^3$.[63] In the pediatric AIDS population, $CD4^+$ counts of less than $20/mm^3$ may be required for appearance of the retinitis.[64] The disease is less common in pediatric patients with AIDS. Patients with CMV retinitis have no external ocular signs but may complain of loss of vision. Children may not complain of such loss, and the problem may become apparent only after bilateral severe vision loss has occurred.[64] The retinal lesions of CMV typically are yellow-white and often are associated with hemorrhage. The retinitis generally follows a perivascular distribution. The retina becomes necrotic and eventually atrophies, with a gliotic scar. CMV optic neuritis also may develop. Treatment consists of intravenous or intravitreal ganciclovir, intravenous or intravitreal cidofovir, or intravenous foscarnet[64,233] and can often be discontinued when the $CD4^+$ count rises above $100/mm^3$.[212]

Parvovirus Infection

Bilateral panuveitis has been reported to be associated with parvovirus B19 infection.[130]

Human T-Cell Lymphotrophic Virus Infection

Human T-cell lymphotrophic virus (HTLV) is endemic in several regions of the globe: Japan, the Caribbean islands, and parts of central Africa. It probably is responsible for several cases of self-limited, occasionally recurrent uveitis in these regions.[153]

Lymphocytic Choriomeningitis Virus Infection

Lymphocytic choriomeningitis virus (LCMV) is an arenavirus endemic in mice; it is reported in hamsters as well and occasionally is transmitted to humans by direct contact with the rodent or through aerosolization of its feces or urine. Postnatal exposure results in asymptomatic seroconversion or aseptic meningitis, but intrauterine infection can have devastating consequences. Spontaneous abortion, congenital hydrocephalus, psychomotor retardation, and chorioretinitis have been documented. Diffuse chorioretinal scarring identified postnatally may bode a grim visual prognosis. LCMV may be an underdiagnosed cause of unexplained congenital chorioretinitis. The diagnosis is confirmed by elevated LCMV antibody titers. A survey of severely retarded, visually disabled children revealed immunologic evidence pointing to LCMV as the cause of the visual loss in approximately half of those surveyed.[140,143]

BACTERIAL UVEITIS

Syphilis

Syphilis (*Treponema pallidum*) should be considered as a possible cause in all cases of intraocular inflammation. Any patient with confirmed syphilitic uveitis should undergo a lumbar puncture to rule out asymptomatic neurosyphilis.

Ocular manifestations of congenital syphilis include interstitial keratitis, a mottled "salt-and-pepper" fundus, and chorioretinal scarring. Acute interstitial keratitis occurs as a late manifestation of congenital syphilis (5-25 years of age) and is thought to be a hypersensitivity response to treponemal antigen in the cornea. Patients complain of pain and photophobia and have a diffusely opaque cornea and anterior uveitis. Blood vessels invade the inflamed cornea and eventually are obliterated, with ghost vessels left in the corneal stroma. Glaucoma may occur. A unilateral manifestation of interstitial keratitis suggests postnatally acquired lues.

Secondary syphilis may involve any layer of the eye. Episcleritis, scleritis, iridocyclitis (acute, chronic, or recurrent), iris capillary dilation (i.e., iris roseata), vascular papules of the iris (i.e., iris papulosa), inflammatory nodules (i.e., iris nodosa), choroiditis, chorioretinitis, and retinal vasculitis all have been reported, as have optic neuritis and subsequent atrophy.

Tertiary syphilis may have associated gummata of the iris and an Argyll Robertson pupil (i.e., miotic, irregularly shaped pupil with loss of response to light but preservation of the near response). Intraocular inflammation seldom occurs at this stage.

Ocular inflammation secondary to syphilis should be treated as neurosyphilis. With the appropriate doses of penicillin G, the inflammation typically resolves rapidly. Occasionally, topical regional steroids are required to control local inflammation. Treatment of ocular syphilis may lead, at least initially, to a vigorous local and systemic self-limited, febrile response, presumably caused by liberation of spirochetal antigens or toxins. Topical oral corticosteroids may be required to quell this response, which is also known as a *Jarisch-Herxheimer reaction*.[4,132,159]

Lyme Disease

A mild follicular conjunctivitis occurs in 11 percent of patients with stage 1 Lyme disease, caused by *Borrelia burgdorferi*. During the second and third stages, neuro-ophthalmic manifestations, including cranial neuropathy (most often cranial nerves III, IV, VI, and VII), optic neuritis, bilateral keratitis, bilateral iridocyclitis, diffuse choroiditis, vasculitis, intermediate uveitis, and Parinaud oculoglandular syndrome, may be seen. The most frequent manifestation of late Lyme disease is arthritis. Ocular inflammation occurs in approximately 4 percent of children with Lyme arthritis.[108] Early, localized Lyme disease may be treated with doxycycline (8 years and older) or amoxicillin. More advanced or persistent disease is treated best with intravenous ceftriaxone.[6] Antibiotic treatment early in the course of the disease carries a better prognosis than does therapy initiated at later stages.[19]

Leptospirosis

Leptospirosis may cause an anterior uveitis that occurs months after the acute infection. Leptospirosis is identified as an important cause of epidemic panuveitis in southern India; the most common posterior segment manifestations in this group are vasculitis and vitritis.[39]

Tuberculosis

Any structure of the eye may be affected by tuberculosis. Allergic and infectious processes have been implicated as important causes of tuberculous uveitis. Anterior uveitis with or without keratitis has been attributed to tuberculosis. Choroiditis, optic neuritis, and orbital infections have been detected in cases of miliary tuberculosis. The most frequent manifestations of ocular tuberculosis are choroidal nodules and scars; anterior uveitis is an uncommon occurrence.[26] Treatment should be undertaken with the appropriate antituberculous medications. Corticosteroids often are necessary in conjunction with antimicrobial therapy.

Leprosy

Because *Mycobacterium leprae*, the cause of leprosy, grows best at lower temperatures, corneal infections predominate. Corneal involvement is associated with prominence of the corneal nerves, interstitial keratitis, and corneal hypoesthesia, but corneal opacities are often peripheral and not visually significant.[49] Uveal involvement in leprosy frequently is silent and accounts for a large number of the ocular complications from the disease.[48,49]

Brucella Infection

Ocular manifestations of *Brucella* infection are rare but include iritis, focal nodular choroiditis, and panophthalmitis.[159]

Cat-Scratch Disease

Bartonella henselae is a gram-negative rod transmitted to humans by the bite or scratch of an infected animal, often a young cat or kitten. Regional lymphadenopathy is the predominant nonocular finding. A striking stellate neuroretinitis characterized by swelling of the optic nerves and lipid deposition in the retina is the most easily identifiable complication of ocular infection. Other manifestations include intermediate uveitis, optic disk swelling, multifocal choroiditis, and serous macular detachment. The discrete foci of multifocal choroiditis are the most common findings in the posterior segment. The role of antibiotics in this condition is debated.[119,195]

FUNGAL UVEITIS

Histoplasmosis

The diagnosis of presumed ocular histoplasmosis syndrome is based on the clinical picture of disseminated punched-out retinal "histo spots," atrophic retinal changes around the optic nerve, and a clear vitreous.[168] Later in the course of the disease, subretinal hemorrhage and retinal detachment may occur. Ocular histoplasmosis often is bilateral and can result in legal blindness from the loss of macular vision. Presumed ocular histoplasmosis syndrome may occur after an episode of benign systemic histoplasmosis during childhood. Active inflammation and vitreous cells usually are not seen in this syndrome, although case series have documented active chorioretinal inflammation as new-onset lesions and as reactivation of previously quiescent lesions.[36,116] The hallmark histoplasmosis spots appear as white, punched-out, well-demarcated chorioretinal scars and represent healed fungal lesions. Generally, they first appear during adolescence, do not reduce vision, and do not require treatment. Macular disease, which may reduce vision, does not develop until after the patient reaches the second decade of life. Subretinal neovascularization may develop at the site of a macular histoplasmosis spot, with fluid, blood, and lipid accumulating in the subretinal space. This process plus local scarring can result in a marked reduction in central vision.

Macular neovascularization may be treated suitably with laser photocoagulation in an attempt to salvage the remaining central vision. Antifungal drugs may play a role in the unusual setting of demonstrated active histoplasmosis choroiditis.[184]

Candidiasis

Candida spp., including *C. albicans*, are fungi with yeast and filamentous forms. Candidiasis is encountered in immunocompromised patients and in situations involving indwelling catheters, intravenous therapy, chronic antibiotic use, poorly controlled diabetes, and intravenous drug abuse. Candidal chorioretinitis can develop in approximately 9 percent of patients with blood cultures positive for the fungus,[60] although more recent studies have demonstrated that ocular involvement (either chorioretinitis or endophthalmitis) in children is a rare occurrence.[61]

In the eye, *Candida* infection usually begins in the choroid and eventually causes multifocal white chorioretinal lesions. If the fungus proliferates unchecked, it may break through the retina into the vitreous and produce the classic, white, snowball-like "fungus ball." Candidal infection that progresses to endophthalmitis is exceedingly rare if appropriate intravenous antifungals are started promptly on notice of a positive blood culture.

Intravenous amphotericin B is the drug of choice. Other antifungal agents such as fluconazole, flucytosine, and miconazole also may be effective, but none is dramatically so. Surgical treatment of intraocular *Candida* disease is discussed in the section on endophthalmitis.

Aspergillosis

Aspergillus spp. can infect the choroid, retina, and vitreous of immunocompromised individuals. One group of investigators found a high rate (7%) of these unusual infections on reviewing records of deceased liver transplant recipients.[107]

Coccidioidomycosis

Coccidioides spp. have yeast and filamentous forms. Ocular disease consists of a multifocal chorioretinitis that develops during the course of systemic coccidioidomycosis. The lesions initially appear similar to those seen in histoplasmosis; in severe cases, endophthalmitis results, and vitrectomy may need to be performed. In less severe cases, the lesions may respond to intravenous amphotericin B. Occasionally, an isolated granulomatous iridocyclitis may develop.[147]

Cryptococcosis

Cryptococcus neoformans is a yeast-like fungus that can cause multifocal chorioretinitis and endophthalmitis. Most patients with cryptococcosis are severely immunocompromised; many have AIDS. The CNS and eye are involved commonly, and elevated intracranial pressure may cause papilledema and sixth cranial nerve palsy. Intravenous amphotericin B in combination with oral flucytosine is the treatment regimen of choice.[6,120]

Sporotrichosis

The dimorphic fungus *Sporothrix schenckii* is encountered commonly in rotting vegetable matter, wood, and soil. The fungus gains access to the host by traumatic implantation or inhalation. It has been reported to be responsible for anterior uveitis in the setting of a suggestive lesion on a finger of the dominant hand, with presumed hand-to-eye transmission.[219]

PROTOZOAL UVEITIS

Leishmaniasis

Ocular leishmaniasis has been described. Manifestations include conjunctivitis, blepharitis, and anterior uveitis. This trio of findings responds to systemic treatment with sodium stibogluconate.[68]

HELMINTHIC UVEITIS

Toxocariasis

Toxocara canis causes visceral larva migrans, which is not associated with ocular disease. In the retina, larvae get trapped in small capillaries and burrow into surrounding tissue; the dead larvae incite an intense eosinophilic abscess. Ocular toxocariasis has three classic clinical manifestations, almost always involving one eye only. One form occurs in children 2 to 9 years of age and causes an indolent endophthalmitis and leukokoria (i.e., white pupil). Tractional retinal detachment may occur. The eye typically shows little or no external evidence of inflammation, and the patient experiences no pain.

A second form appears in children between 4 and 14 years of age. These patients have reduced vision but little or no external inflammation and no pain. The reduced vision may cause strabismus, which may be the first sign. An inflammatory granuloma is seen in the macula.

The third form of ocular toxocariasis occurs in patients between 6 and 40 years of age but may not be recognized until years later. Patients with this form of toxocariasis have good vision, but a peripheral retinal granuloma is seen on routine eye examination. Vision may be affected if a traction band from the granuloma distorts the macula.

Inactive *Toxocara* granulomata do not respond to medication. When active intraocular inflammation exists in such a magnitude that it poses a further threat to vision, administration of periocular or systemic steroids may be necessary. Anthelmintic agents eradicate migrating larvae, but their effect on "residing" larvae is questionable. When giving antihelmintics, one should combine them with a short course of corticosteroids because death of the larvae may incite vigorous inflammation. Cryotherapy and laser therapy may be useful when the *Toxocara* granuloma is located away from the macula and optic nerve. Vitrectomy may be helpful if significant traction on the retina occurs. Antihelmintic drugs should not be administered after the patient has undergone posterior segment surgery. Visual prognosis is poor if the macula is involved.[159,186,191,229]

Onchocerciasis

Onchocerciasis often causes a severe choroiditis with an overlying retinitis. The various ocular manifestations of infestation with *O. volvulus* are discussed in the section on keratitis.

Loiasis

The *Loa loa* worm can migrate through the tissues of the eye and cause conjunctivitis, iridocyclitis, vitritis, and chorioretinitis. The disease is transmitted by the bite of a mango fly. Vascular obstruction with intraretinal hemorrhage and retinal exudation may occur as well. Medical treatment with diethylcarbamazine can kill the adult worms and microfilariae. Adult worms also can be removed from the eye surgically.[159]

Cysticercosis

The tapeworm *Taenia solium* causes cysticercosis. When the larva gains access to the eye, cysts form in the vitreous or subretinal space in 13 to 46 percent of patients. The living worm may be seen undulating in these spaces. With death of the organism, severe panuveitis can occur. Orbital and subconjunctival involvement occurs less commonly. Surgical removal of the intraocular cysts may prevent the severe inflammation that occurs on death of the worm. Praziquantel can kill the organism, but the ensuing increase in inflammation may be dramatic.[159]

UVEITIS CAUSED BY INSECT-INDUCED DISEASE

Ophthalmomyiasis is the ocular disorder caused by infestation with fly larvae, most commonly the larval form of the sheep botfly *Oestrus ovis*. Maggots may be seen in the conjunctival fornix (cul-de-sac) or inside the eye. Internal ophthalmomyiasis can be diagnosed by noting a motile larva in the anterior chamber, vitreous, or subretinal space. The maggot may leave trails ("railroad tracks") behind throughout the retina. A mild inflammatory response in the anterior chamber (e.g., iritis, iridocyclitis) or vitreous may occur. Treatment is surgical removal of the larva. Corticosteroids may be used to treat the accompanying intraocular inflammation.[65,159]

POSTINFECTIOUS UVEITIS

Increasingly, attention is being given to the role of bacterial and viral systemic illness in the eventual development of sterile intraocular inflammation. This type of uveitis is thought to be caused by an autoimmune response that occurs between sensitized lymphocytes and host tissues that bear some antigenic similarity to the recently cleared pathogen. Disruption of the ACAID is probably a prerequisite for the development of these postinfectious syndromes. Several reports exist of nongranulomatous anterior uveitis occurring weeks or months after streptococcal infection. These uveitides may be associated with other poststreptococcal findings (e.g., arthritis, glomerulonephritis) or may be the sole manifestation. Treatment with cycloplegics and topical corticosteroids is sufficient for the ocular manifestations.[16,215,231]

Uveitis, predominantly of the anterior type, has been reported to occur after illnesses caused by gram-negative enteric bacteria such as *Klebsiella*, *Salmonella*, and *Yersinia*. These gram-negative–induced uveitides are much more likely to occur in the setting of HLA-B27 positivity. The ocular findings often parallel the development of arthritis, thus suggesting that parallel immunologic processes are occurring in both these mesenchymal cavities (i.e., the joint space and the anterior chamber). An association between recent EBV infection and acute tubulointerstitial nephritis and anterior uveitis has been described, with onset of the renal and ocular inflammation occurring several months after the characteristic acute EBV infection.[90]

INFECTIONS INVOLVING PRIMARILY THE RETINA

EYE MANIFESTATIONS OF INTRAUTERINE INFECTIONS (TORCHS COMPLEX)

The TORCHS complex is a group of congenital and perinatal infections that may cause severe systemic and ophthalmic abnormalities. The effect of infection with one of the TORCHS organisms—*T. gondii*, others (LCMV, EBV), rubella virus, CMV, herpesvirus, and syphilis—may be evident at birth or be manifest later in childhood or adulthood. Congenital EBV infection (infectious mononucleosis) has been reported to be associated, possibly, with congenital cataracts.[85] All these infections commonly cause either mild or no clinically evident disease in the mother.[141] The diagnosis cannot always be established on clinical grounds alone, and neonatal and maternal serologic tests must be performed to confirm the clinical suspicion.

Toxoplasmosis

T. gondii is an obligate intracellular parasite that has an affinity for the CNS and retina. The parasite has three forms: tachyzoite, bradyzoite, and sporozoite or oocyst. Human infection may be congenital or acquired. Acquired infection results from the ingestion of undercooked meat contaminated with oocysts or from exposure to the feces of an infected cat, the definitive host. The oocysts release tachyzoites, which multiply intracellularly and result in cell death. In adults, primary acquired infection usually is asymptomatic. The immune response then transforms the tachyzoite into a bradyzoite, which encysts and remains dormant in tissues for years. These cysts have the propensity to rupture sometime later and cause an inflammatory response resulting in recurrent infection.

Congenital infection is transmitted through the transplacental route. In the United States, the reported incidence of congenital toxoplasmosis is one case per 1000 to 10,000 births.[9,47] Seventy percent of the obstetric population is negative for antibodies and, therefore, at risk for infection and transplacental transmission to the fetus.[141] Congenital infection is most severe when acquired in the first trimester and can result in chorioretinitis, intracranial calcifications, microcephaly, mental retardation, and deafness.[47,71,73] Symptomatic neonates with disseminated disease have hepatosplenomegaly, lymphadenopathy, jaundice, fever, anemia, pneumonitis, and a poor prognosis. Other ocular manifestations include cataracts, strabismus, microcornea, vitritis, retinal detachment, optic atrophy, microphthalmos, nystagmus, and ptosis.[141] In a prospective study, 15 percent of infected newborns had chorioretinal scars, indicative of infection in utero; 4 percent had active chorioretinitis; and, in 10 percent, retinal lesions developed by the time that the children were 1 to 2 years of age. Long-term follow-up studies have found that chorioretinal lesions develop in 82 to 85 percent of children with subclinical *Toxoplasma* infection, some with severe visual loss. Infants with asymptomatic toxoplasmosis should undergo regular ophthalmologic examination because retinal involvement can occur later in childhood or adulthood.[27,71,121] Some researchers have suggested that all neonates with toxoplasmosis should receive drug therapy, even if they are asymptomatic.[71]

Toxoplasmosis is the leading cause of acquired necrotizing retinitis and, in many cases, represents reactivation of congenitally acquired infection. Clinically, an area of active retinochoroiditis is adjacent to the border of a chorioretinal scar.[73,174] Associated choroiditis and vitritis may be present. Primary acquired ocular toxoplasmosis manifested as retinochoroiditis is well-documented also, and reports suggest that this route of infection may be more common than originally thought.[27,105] Recurrent ocular disease with postnatally acquired toxoplasmosis has been reported.[25]

T. gondii causes a focal necrotizing retinitis with secondary choroiditis and vitritis. Patients may have floaters, blurred vision, and photophobia. Those with macular involvement can suffer significant visual loss. After the inflammation has resolved, a flat, pigmented chorioretinal scar develops. Visual loss depends on the location of the retinal lesion, with peripheral lesions resulting in little or no visual disturbance and macular lesions capable of producing profound visual loss.

Toxoplasma retinochoroiditis is an emerging problem in patients with AIDS and may be the initial manifestation of this syndrome.[225] The clinical appearance often is atypical.[193] Chronic suppressive therapy is necessary because infection recurs with discontinuation of treatment. A combination of pyrimethamine and clindamycin has been reported to be most effective as prophylaxis.[225]

The diagnosis of *Toxoplasma* retinochoroiditis usually is presumptive and is based on clinical appearance and serologic testing. Several serologic tests are available. The standard serologic diagnosis is based on the presence of anti-*Toxoplasma* IgM in any sample or demonstration of a significant rise in antibody titer in paired sera taken 4 to 6 weeks apart. However, in reactivated congenital infections, which many cases are, *Toxoplasma* IgM results are not positive. The antibody tests most commonly used are indirect immunofluorescent assay (IFA) and enzyme-linked immunosorbent assay (ELISA) for IgM and IgA.[85] False-positive results can occur with both tests in the presence of rheumatoid factor. If clinical infection is suspected and the initial testing results are negative, repeat testing or an alternative testing technique should be considered.

Standard treatment of *Toxoplasma* retinochoroiditis is triple therapy with sulfadiazine (100 to 200 mg/kg/day in four divided doses [maximum, 1.5 g]), pyrimethamine (2 mg/kg/day for 3 days, then 1 mg/kg/day [maximum, 25 mg/day]), and leucovorin (folinic acid) (10 to 25 mg given orally daily for 6 weeks). Folinic acid prevents the leukopenia and thrombocytopenia that may result from pyrimethamine therapy. Weekly complete blood counts and platelet counts are required to monitor toxicity from therapy. Alternative therapy with clindamycin (40 mg/kg/day in four divided doses [maximum, 2.4 g] for 6 weeks) rather than sulfadiazine also has been effective.[208] This therapy is less toxic than is triple therapy and, therefore, is better tolerated. In patients with severe intraocular inflammation, systemic corticosteroids can be used with concurrent antimicrobial therapy.

Preventive measures are twofold: first, avoidance of raw meat and cat feces during pregnancy, especially during the first trimester, and second, treatment of a mother known to have contracted the disease during pregnancy with spiramycin because it has no known teratogenic effects.[45,55,56] In utero pyrimethamine and sulfadiazine treatment of a fetus known to be infected may be effective.[45,47,102]

Lymphocytic Choriomeningitis Infection

LCMV, an arenavirus discovered in 1933, was recognized as a cause of intrauterine infection in 1955 (also see the earlier section "Viral Uveitis").[142] The common house mouse *Mus musculus* is the natural host and reservoir of the virus, but laboratory mice and pet hamsters also may be infected.[7,101] LCMV may be transmitted to humans by airborne means, rodent bites, or food contaminated by rodent urine, feces, or saliva; the fetus may be infected by transplacental transmission.[85] The diagnosis may be confirmed by LCMV titers.

Systemic manifestations, often devastating, include hydrocephaly, microcephaly, periventricular calcifications, neonatal meningitis, hepatosplenomegaly, cerebral palsy, mental retarda-

tion, and seizures.[85] Ocular findings include chorioretinitis, optic atrophy, nystagmus, microphthalmos, strabismus, and cataracts[142]; the chorioretinitis may mimic congenital toxoplasmosis.[28] The most common ocular findings are peripheral chorioretinal scars, although macular involvement is a common occurrence as well. At present there is no effective treatment. Prevention involves avoidance of mice and hamsters by pregnant women.[85,142]

Rubella Infection

The rubella virion is an RNA virus of the family *Togaviridae* that causes a febrile exanthem. Before the advent of rubella vaccine in 1969, rubella, or "German measles," epidemics occurred every 6 to 9 years. The last major outbreak in the United States took place in 1964.[11] With preschool immunization programs, most primary cases now reported occur in individuals between 15 and 24 years of age. Transmission occurs by inhalation of aerosolized droplets in the nasopharynx. Primary infection in adults results in a mild febrile illness associated with lymphadenopathy and a rash. The proportion of susceptible nonimmunized women of child-bearing age ranges from 10 to 25 percent. Fetal infection occurs transplacentally, and the likelihood of transmission from mother to fetus is highest (90%) in the first trimester; transmission at this stage can produce severe fetal damage and result in spontaneous abortion, stillbirth, or multiple congenital anomalies.

The classic congenital rubella syndrome, first described by Sir Norman McAlister in Australia in 1949,[142] is characterized by cardiac defects, ocular abnormalities, and hearing deficits. The incidence of ocular and cardiac defects is higher with exposure early in the first trimester; hearing deficits appear to be associated with exposure late in the first trimester. Givens and associates[84] reported that 88 percent had multiorgan involvement. Hearing loss is the most frequent nonocular manifestation.[142] The most common cardiac defects are patent ductus arteriosus, pulmonary artery stenosis, and pulmonary valve stenosis. Other features include microcephaly, thrombocytopenia, hepatosplenomegaly, and mental retardation.

Ocular involvement occurs in approximately 50 percent of infected infants.[81] Pigmentary retinopathy (i.e., "salt-and-pepper" retinopathy) affects 22 percent of infected infants. The retina has a mottled appearance, most frequently observed in the posterior pole; the optic nerve and vessels usually are normal unless the patient also has glaucoma.

Nuclear cataracts, which affect between 15 and 27 percent of patients, are the second most frequent ocular complication. Glaucoma is seen in approximately 10 percent of eyes; the combination of cataracts and glaucoma is an uncommon finding. Microphthalmos (which occurs in 10-63% of affected individuals), iris atrophy, and iritis also have been reported.[23] Live virus may persist for years in the lens, so appropriate precautions must be taken during cataract surgery to prevent transmission.[85]

The retinopathy associated with rubella usually is asymptomatic and does not necessitate treatment. In some cases, it can be complicated by subretinal neovascularization, which may require laser or macular surgery. Cataracts cause most visual morbidity. Visual rehabilitation depends on early cataract extraction to prevent deprivation amblyopia, correction of aphakia with spectacles or contact lenses, and careful follow-up. Glaucoma in infants and children can be temporized with topical medications, but most cases require glaucoma surgery.

Congenital rubella has long-term consequences for all organs involved. In nearly two thirds of infants with no manifestations at birth, hearing loss or psychomotor deficits subsequently develop. From an ophthalmic standpoint, individuals with congenital rubella need continued follow-up.[84]

Cytomegalovirus Infection

CMV is an enveloped DNA virus of the family *Herpesviridae*. An estimated 80 percent of adults are infected by the time that they reach 40 years of age.[196] In immunocompetent adults, infection is asymptomatic or can cause a mononucleosis syndrome. Individuals can shed virus in saliva, urine, and other body fluids for months to years after initial infection. Transmission occurs through exposure to body fluids, sexual contact, blood transfusion, or organ transplantation, or it can occur transplacentally. Primary infection acquired in the birth canal is not likely to result in serious disease.

Congenital CMV is the most common congenital infection in humans[197] and can result from exposure to the virus in utero or in the birth canal. In utero infection produces more serious disease. CMV infection occurs in 1 percent of all live births, and only 5 to 10 percent of infants with congenital CMV infection are symptomatic. Maternal infection may be primary or recurrent, but primary infection carries the greatest risk (30-40%) for transmission of symptomatic CMV disease to the newborn.[196] Blood transfusions from CMV antibody–positive donors also can result in severe CMV infection in the newborn. Systemic manifestations include intrauterine growth retardation (IUGR), thrombocytopenic purpura, microcephaly with periventricular calcifications, hepatosplenomegaly, pneumonia, and sensorineural deafness.[54]

In symptomatic congenital CMV infection, the retina is the primary site of ocular involvement. Cytomegalic inclusion bodies are seen in all layers of the retina. Patchy white areas of necrotic retina with hemorrhage and vascular sheathing are seen in the peripheral portion of the retina, although the posterior pole can be affected as well.[128] Nonhemorrhagic retinitis also may be seen, and most affected infants do not have active retinitis at birth, although scars may be visible as evidence of previous disease.[41] Resolution of the retinitis results in an atrophic scar with areas of hyperpigmentation. If retinitis involves the retinal periphery, vision may be normal. However, visual loss may occur if the posterior pole is involved or if optic atrophy or retinal detachment occurs. CMV retinopathy develops in 5 to 30 percent of infants with clinically apparent disease.[66] Microphthalmos, optic nerve hypoplasia, optic atrophy, optic nerve colobomata, anophthalmia, corneal opacities, and anterior segment dysgenesis also have been associated with congenital CMV infection.[103] In addition, cyclopia and anophthalmia have been reported.[33]

The diagnosis of CMV retinitis is based on the clinical appearance and the constellation of systemic symptoms and signs. Recovery of the virus from urine, maternal cervical secretions, saliva, or aqueous humor can confirm the diagnosis. Complement fixation can identify IgM antibodies to CMV that do not cross-react with other herpesviruses. Immunofluorescence techniques are more sensitive but less specific than is complement fixation.[128]

Treatment of neonatal or pediatric CMV retinitis is based on the results of treatment of adults with CMV retinitis. Ganciclovir has been shown to stabilize and prevent spread of the disease in infants. Maintenance therapy is not required, but continued follow-up is necessary to detect recurrence. Granulocytopenia and thrombocytopenia can result. Retinal detachment requires vitrectomy, membrane peel, and silicone oil to tamponade the detached retina.[104]

Herpes Simplex Virus Infection

HSV is a double-stranded enveloped DNA virus. Both subtypes, HSV-1 and HSV-2, can cause a vesicular skin eruption. HSV-1 typically is isolated from oral-facial infections; HSV-2 usually is isolated from genital infections. After primary infection occurs, HSV can maintain latency in neuronal ganglion cells and reactivate. Transmission occurs by exposure to infected body fluids

such as saliva, and the risk of transmission is higher when the individual is symptomatic.[152]

Maternal-fetal transmission occurs through infected genital secretions in the birth canal (HSV-2) or exposure to infected individuals with oral-facial herpetic disease (HSV-1) in the postnatal period. In mothers with active genital disease, the risk of transmission to the neonate is 50 percent with vaginal delivery. Most series report that between 70 and 80 percent of neonatal HSV infection is caused by HSV-2. Neonatal HSV infection is life-threatening, and the mortality rate without treatment is 80 percent.[227] The diagnosis is suspected by the clinical findings: lethargy, respiratory distress, anorexia, vomiting, cyanosis, low birth weight, IUGR, microcephaly, seizures, intracranial calcifications, pneumonia, hepatosplenomegaly, and skin vesicles. The virus may be isolated from skin vesicles or from nasal or conjunctival secretions, CSF, or blood. The mortality rate of untreated neonatal HSV is 49 percent.[85]

Ocular sequelae develop in less than 1 percent of immunocompetent adults with HSV infection. In contrast, 17 to 40 percent of infected neonates have ocular disease.[135,196] Thirteen percent of neonates with HSV have eye involvement. Ocular involvement can range from mild conjunctivitis to severe bilateral necrotizing retinitis and may be unilateral or bilateral. Conjunctivitis is the most common manifestation. Conjunctivitis, keratitis, and, occasionally, retinitis develop 2 to 14 days after birth. HSV retinitis causes punctate, white-yellow lesions in the periphery and the posterior pole accompanied by choroiditis, vascular sheathing, hemorrhage, and vitritis. Chorioretinal atrophic scars with variable amounts of pigmentation around the border result after resolution of acute infection.[106,173] Visual prognosis depends on the severity of disease, macular scarring, optic atrophy, or CNS involvement of the visual pathways. Severe chorioretinitis and cortical blindness are the usual sequelae of HSV infection acquired through transplantation, a rare mode of transmission.

El Azazi and colleagues[67] examined children with serologically proven HSV infection 1 to 15 years after neonatal exposure and found a higher prevalence of chorioretinal scars than noted in previous reports (28% versus 4%). This finding suggests that HSV remains dormant in the retina and reactivates later in childhood or adulthood. Chorioretinitis, cataracts, optic atrophy, and microphthalmos have been reported.[91] Acute retinal necrosis from reactivation of HSV-2 has occurred as well.[211]

Ocular HSV infection can be seen in conjunction with a vesicular rash or disseminated disease. The differential diagnosis of ophthalmic complications from HSV includes infection with any of the TORCHS organisms. Identification of neonatal IgM antibody to HSV confirms the diagnosis of in utero infection. Demonstration of intranuclear inclusions and multinucleated giant cells in skin, conjunctiva, and oral and genital lesions may be diagnostic.

The drug of choice to treat neonatal HSV infection is intravenous acyclovir, 30 to 60 mg/kg/day.[165] Conjunctival and corneal disease also can be treated by débridement and topical antivirals such as vidarabine. In neonatal HSV infection, systemic acyclovir should be given regardless of topical treatment. Early diagnosis and treatment can reduce ocular morbidity.

Varicella-Zoster Virus Infection

VZV is a DNA virus of the family *Herpesviridae*; enveloped virions are the infectious agents. Primary infection results in chickenpox, a highly communicable febrile illness with a vesicular rash that appears after 48 to 72 hours of incubation. VZV can remain dormant in sensory ganglion neurons and reactivate as herpes zoster, a painful rash in the dermatomal distribution of the sensory ganglion.

Congenital varicella syndrome is considered a rare entity. One prospective series reported a 24 percent incidence of congenital varicella with serologic or clinical confirmation of maternal infection during pregnancy. Mortality rates can be high if maternal infection develops 5 days before delivery to 2 days after delivery. Systemic complications of VZV infection include cranial nerve palsy, hemiparesis, cicatricial skin lesions, IUGR, developmental delay, seizures, neurogenic bladder, and learning difficulty.[122,162]

Ocular abnormalities in children with congenital VZV infection include chorioretinitis, cataracts, Horner syndrome, optic atrophy and optic nerve hypoplasia, retinal coloboma, and microphthalmos. The chorioretinal scars of VZV infection have a deeply pigmented center with depigmented borders or a gliotic white center with hyperpigmented edges. The neurotropic nature of VZV infection may explain the association of Horner syndrome. Ocular involvement can be unilateral or bilateral. VZV chorioretinitis affects the macula, periphery, or both.

Serologic testing for IgG and IgM antibodies to VZV, a history of maternal infection during pregnancy, and the constellation of systemic findings help establish the diagnosis. Because active infection may occur early in pregnancy, the neonate may have IgG but no detectable IgM antibodies to VZV by the time of delivery. The persistence of elevated IgG antibodies beyond 6 months, when passive immunity through maternal antibodies has waned, without evidence of primary VZV infection postnatally is a helpful indication of infection in utero.

Syphilis

Syphilis is caused by the spirochete *T. pallidum*. Acquired syphilis is a sexually transmitted chronic disease and has three stages of infection. Primary infection is characterized by painless, indurated chancres of the skin or mucous membranes at the site of inoculation. The secondary stage appears as a maculopapular rash, classically involving the palms and soles. Generalized lymphadenopathy, fever, malaise, sore throat, headache, and arthralgias can accompany the rash. Hypertrophic lesions (i.e., condyloma lata) occur in moist mucous membranes. Approximately a third of untreated cases progress to the tertiary stage, which occurs after a variable latent period that may have occasional recurrences of secondary syphilis. Transmission to the fetus can occur with any stage of maternal syphilis.[206]

Pigmentary retinopathy is the most common early ocular manifestation of congenital syphilis. Diffuse mottling in the periphery (i.e., salt-and-pepper retinopathy) is indicative of chorioretinitis in utero. Pigment clumping in the periphery usually has no effect on vision, but macular involvement can cause decreased vision. Retinal changes can appear later in adulthood, thus suggesting that inflammatory changes caused by congenital infection can occur after birth. Salt-and-pepper retinopathy is evidence of previous inflammation, and no treatment is required. Interstitial keratitis (see the section "Stromal Keratitis") is the hallmark of congenital syphilis and occurs in 75 percent of these patients.[206] It usually is not detected until late in the first decade of life. Other reported ocular manifestations include optic neuritis and iritis.

Testing the serum by nontreponemal and treponemal methods confirms the diagnosis of congenital infection. The American Academy of Pediatrics recommends physical examination, quantitative nontreponemal serologic testing, a CSF Venereal Disease Research Laboratory (VDRL) test, long bone radiographs, and antitreponemal IgM testing, as specified by the Centers for Disease Control and Prevention (CDC). The CDC states that congenital syphilis is presumptively diagnosed with a positive VDRL and at least one of the following: physical examination evidence of congenital syphilis, characteristic radiographic long bone findings, VDRL + CSF, an otherwise unexplained elevated CSF protein or cell count, quantitative nontreponemal serologic titer four times greater than the mother's, or a positive FTA-

ABS-19s-IgM test.[5] Treatment is with intravenous penicillin G for 10 to 14 days.[6,132]

ENDOPHTHALMITIS

Endophthalmitis is an infection within the eye that may arise endogenously during septicemia or exogenously from accidental or surgical trauma.[144,153] Sixty-two percent of cases occur after intraocular surgery, 20 percent after penetrating trauma, and 10 percent after glaucoma surgery; 8 percent result from metastatic infection.[60,169] The patient usually has severe ocular pain and visual loss at initial evaluation. Rarely, patients may be asymptomatic. Signs of endophthalmitis include conjunctival injection, vitritis, uveitis, hypopyon, and intraocular membrane formation.

Endophthalmitis is an ophthalmic emergency and necessitates immediate evaluation of aqueous and vitreous cultures and institution of intravitreal antibiotic therapy. Any significant delay in recognition and treatment of endophthalmitis can result in permanent vision loss.

Postsurgical endophthalmitis occurs in 0.086 percent of cataract operations.[2] The source of postsurgical infection may be from the eyelids, conjunctiva, contaminated instruments and irrigating solutions, or contamination by operating room personnel. The routine use of subconjunctival antibiotics after intraocular surgery does not prevent all cases of postoperative endophthalmitis. Vitreous loss, which may occur occasionally as a complication of cataract surgery, increases the risk of infection developing. Patients who have undergone glaucoma filtering surgery are particularly prone to endophthalmitis, primarily because sclerostomy is performed routinely as part of this procedure and the only remaining protection that the eye has from infective organisms is a thin layer of conjunctiva overlying the sclerostomy. Local antimetabolites, often used in conjunction with glaucoma filtering procedures, predispose the conjunctiva to bleb leaks that allow direct access of microorganisms to the eye.

Endogenous (metastatic) endophthalmitis should be suspected when ocular inflammation occurs in a septicemic patient, particularly if the patient is immunocompromised or has an underlying systemic illness such as diabetes or leukemia.[24,150,158]

Post-traumatic endophthalmitis should be considered in any patient with a history of injury and visual loss. A history of a high-velocity projectile presents great concern for a penetrating injury, and apparently minor accidental ocular trauma may result in perforation of the globe with or without a retained foreign body. The likelihood of post-traumatic endophthalmitis occurring increases directly with the extent of the injury and the degree of intraocular contamination.

After the diagnosis is suspected, immediate referral to an ophthalmologist is necessary. Once the patient has been examined, a vitreous and aqueous aspirate is obtained under general anesthesia and material is evaluated with Gram and Giemsa stains. Staining with calcofluor white or acridine orange is performed if fungal infection is a concern. The material is cultured on blood and chocolate agar, thioglycolate broth, and Sabouraud agar. Vancomycin (1 mg) to cover gram-positive organisms and ceftazidime (2.25 mg) to cover gram-negative organisms are injected into the vitreous cavity. If fungal infection is suspected, intravitreal amphotericin B is given. Occasionally, the ophthalmologist uses intravitreal dexamethasone to control associated, intense intraocular inflammation. Gram stain results often are inconsistent with cultures.

The role of vitrectomy in postoperative endophthalmitis has been addressed in the Endophthalmitis Vitrectomy Study (EVS).[69] In eyes with better than light perception vision at initial evaluation, outcome measurements were equal between the vitrectomy group and the vitreous tap or biopsy group. In eyes with light perception–only vision, the EVS found that patients who underwent immediate pars plana vitrectomy did significantly better than those who underwent vitreous tap or biopsy alone.

The most common infectious agents in endophthalmitis are *S. epidermidis*, *Bacillus* spp., *Streptococcus* spp., *S. aureus*, and various fungi. *Bacillus cereus* is isolated in 30 to 40 percent of cases and can cause severe ocular morbidity.[1,50,51,59,98] *S. epidermidis* is the predominant organism in postoperative cases, and *Streptococcus* spp. with filtering blebs and *B. cereus* are the organisms associated most frequently with penetrating trauma. Approximately 65 percent of cases are culture-positive.

Fungal endophthalmitis has become a relatively common form of endophthalmitis in childhood because of the prolonged hospital care required for severely ill immunocompromised children. The most common organism is *C. albicans*. Children with a central line catheter or receiving prolonged intravenous therapy of any type are particularly prone to infection. In patients with *Candida* endophthalmitis, the vitreous may be hazy, and small, white "snowball" localizations of infected material may appear in the vitreous or on the surface of the retina. Daily careful observation may be required during intravenous amphotericin B therapy. If the endophthalmitis clears, no ocular surgical intervention is indicated. If the infection is not adequately controlled with intravenous therapy, vitrectomy with injection of intravitreal amphotericin may be required.

SECTION XII

Systemic Infectious Diseases

CHAPTER 69

Bacteremia and Septic Shock

Sheldon L. Kaplan ✪ Jesus G. Vallejo

One of the most serious and potentially life-threatening infectious diseases in childhood is a bacteremic illness. Bacteremia may be caused by a wide variety of gram-positive or gram-negative microorganisms, and it may or may not be associated with a specific focus of infection, such as pneumonia or meningitis. Some bacteremias are transient and self-limited; they are not discussed in this chapter.

The incidence of bacteremia in children has been studied in hospital and ambulatory settings. In otherwise normal children, beyond the newborn age group, *Streptococcus pneumoniae*, *Escherichia coli*, *Staphylococcus aureus*, group A streptococcus, *Salmonella* spp., and *Neisseria meningitidis* are the most common microorganisms causing bacteremia.[99,234] Children with underlying illnesses that depress the host response to infection may develop bacteremia caused by these same microorganisms; however, in this population of children, especially when hospitalized, Enterobacteriaceae, *S. aureus*, coagulase-negative staphylococci, and fungi are the most important organisms commonly isolated from blood cultures.[6,170] Indwelling vascular lines, urinary catheters, endotracheal tubes, and other foreign material further predispose already compromised children to nosocomial infections. The incidence of diagnosed septicemia has increased over the years, partly owing to improved medical technology and the greater numbers of individuals with immunocompromising conditions who previously would not have survived.[160]

Gray and colleagues[91] reported that the incidence of bloodstream infections in a pediatric intensive care unit (ICU) during a 3-year period was 39 cases per 1000 admissions. Of the episodes, 64 percent were acquired in the ICU and 20.6 percent were community-acquired infections. Gram-positive and gram-negative organisms accounted for 62 percent and 31 percent of the isolates. Yeasts were isolated in 5.6 percent of episodes. Children with acquired immunodeficiency syndrome or severe immunosuppression caused by human immunodeficiency virus infection also are at increased risk for developing bacteremias caused by gram-negative bacilli, especially *Pseudomonas aeruginosa*.[189]

Using a seven-state hospital discharge database, Watson and associates[234] estimated that the U.S. age-adjusted and sex-adjusted annual incidence of severe sepsis was 0.56 cases per 1000 children, or more than 42,000 cases per year. The highest age-specific incidence occurred in infants (5.16 cases per 1000), with the incidence declining to 0.20 cases per 1000 for children 10 to 14 years old. Half of the children had underlying comorbidity, with neuromuscular, cardiovascular, and respiratory disorders being the most common.

One potential consequence of bacteremia is septic shock, a state characterized by inadequate tissue perfusion that is associated frequently with endotoxemia. Although most children with septic shock have infections caused by gram-negative enteric bacteria, *P. aeruginosa*, or *N. meningitidis*, organisms with endotoxin or lipopolysaccharide (LPS) within cell walls, septic shock also is associated with disease caused by gram-positive bacteria (especially *S. aureus*, *Streptococcus pyogenes*, and viridans streptococci), viruses, rickettsiae, and fungi. New clones of community-acquired methicillin-resistant *S. aureus* (MRSA) in particular have been associated with severe sepsis and septic shock in young children and adolescents.[87] In adults, the frequency of septic shock continues to increase as the population ages, new technology including more complicated surgery and immunosuppressive agents is developed, and antibiotic resistance grows.[194]

Dupont and Spink[64] reviewed the cases of 172 children, 30 days to 16 years of age, who were hospitalized at the University of Minnesota Medical Center with gram-negative bacteremia. Shock occurred in 25 percent of the children, and 98 percent of children with shock died. In meningococcal infections, 11 to 40 percent of children develop hypotension.[56,116,228] During a 10-month study period, Naqvi and colleagues[157] reported that shock occurred in 5 of 39 (13%) episodes of gram-negative bacillary sepsis, with three deaths. Jacobs and associates[107] reviewed the admissions of previously normal children to a pediatric ICU in a large children's hospital for a 30-month period. Hypotension or evidence of peripheral hypoperfusion occurred in 143 children with confirmed bacterial sepsis, mostly *Haemophilus influenzae* type b (Hib), or apparent meningococcemia. Among 1058 consecutive admissions of 916 children to a pediatric ICU in Canada from July 1, 1991, to July 31, 1992, 25 episodes (2%) of septic shock occurred.[178] During a 12-month period, 140 episodes of septicemia (135 bacterial and 5 fungal) were documented in 100 pediatric hematology-oncology patients.[5] Septic shock occurred in 19 percent.

The organisms and case-fatality rates in the study by Watson and colleagues[234] are outlined in Table 69–1. *N. meningitidis* and fungi were associated with the highest mortality rates. Early-onset group B streptococcal infections in neonates and overwhelming *S. pneumoniae* infections in children with splenic dysfunction or asplenia are associated with shock in a high percentage of cases. *S. aureus* or group A streptococcus may cause hypotension in a child with or without other manifestations of toxic shock syndrome.[202]

Advances in understanding of the pathogenesis and pathophysiology of septic shock with respect to the host response to infection have required that more precise clinical definitions of sepsis and expanded syndromes be developed. Much of the impetus for this effort is related to the ability to identify more readily patients with infections who may benefit from administration of newer (expensive) adjunctive measures. An American College of Chest Physicians and Society of Critical Care Medicine Consensus Conference in 1991 developed new terminology to define sepsis and its sequelae.[28] This terminology has been modified for use in children by an international consensus panel of 20 experts in sepsis and clinical research (Table 69–2).[84]

TABLE 69–1 Occurrence and Case-Fatality Rates of Selected Pathogens among Children with Severe Sepsis Based on Age*

	<1 Year (*N* = 4643)		1-10 Years (*N* = 2724)		11-19 Years (*N* = 2308)	
Organism	***Cases (%)***	***Case-Fatality (%)***	***Cases (%)***	***Case-Fatality (%)***	***Cases (%)***	***Case-Fatality (%)***
Neisseria meningitidis	0.3	20	8	10.4	2.3	15.1
Haemophilus influenzae	1.6	4.2	2.4	1.6	1.9	6.8
Pseudomonas	3.6	14.6	7.7	12.4	6.9	9.4
Staphylococcus aureus	2.3	5.7	2.9	0	3.5	3.8
Group A streptococcus	0.3	0	0.7	5	0.2	0
Group B streptococcus	3.1	7.6	0.1	50	0.8	5.6
Fungus	10	10.8	13.3	16.8	10.4	11.6

**Represents data from a seven-state hospital discharge database in 1995.*
Modified from Watson, R. S., Carcillo, J. A., Linde-Zwirble, W. T., et al.: The epidemiology of severe sepsis in children in the United States. Am. J. Respir. Care Med. 167:695-701, *2003.*

TABLE 69–2 Consensus Definitions of Systemic Inflammatory Response Syndrome (SIRS), Infection, Sepsis, Severe Sepsis, and Septic Shock

SIRS

The presence of ≥2 of the following 4 criteria, one of which must be abnormal temperature or white blood cell count:
- Core temperature (rectal, bladder, oral, or central catheter probe) >38.5°C or <36°C
- Tachycardia defined as >2 standard deviations above normal for age in the absence of external factors or drugs; *or* otherwise unexplained persistent elevation of a 0.5- to 4-hr time period; *or* for children <1 yr old, bradycardia defined as a mean heart rate <10th percentile for age in the absence of external factors or drugs or otherwise unexplained persistent depression over a 0.5-hr period
- Mean respiratory rate >2 standard deviations for age *or* mechanical ventilation for an acute process not related to an underlying neuromuscular disease or to general anesthesia
- Peripheral white blood cell count elevated or depressed for age unrelated to medications or >10% immature neutrophils

Infection

A suspected or proven (by culture, tissue stain, polymerase chain reaction assay) infection caused by any pathogen *or* a clinical syndrome associated with a high probability of infection

Sepsis

SIRS in the presence of or caused by suspected or proven infection

Severe Sepsis

Sepsis plus 1 of the following: cardiovascular organ dysfunction, acute respiratory distress syndrome *or* ≥2 other organ dysfunction as defined in the consensus statement

Septic Shock

Sepsis and cardiovascular organ dysfunction as defined in the consensus statement

Modified from Goldstein, B., Giroir, B., Randoph, A.; and the Members of the International Consensus Conference on Pediatric Sepsis: International pediatric sepsis conference: Definitions for sepsis and organ dysfunction in pediatrics. Pediatr. Crit. Care Med. 6:2-8, *2005.*

PATHOPHYSIOLOGY

The pathophysiology of bacteremia is highly variable and depends on the specific microorganism isolated, the immune status of the host, and other factors such as the locations of indwelling catheters. Highly encapsulated organisms, such as *S. pneumoniae*, *N. meningitidis*, and Hib, normally may reside in the nasopharynx and, for reasons that are poorly understood, are capable of invading beyond mucosal barriers into the bloodstream. A preceding viral upper respiratory tract infection may play some role in alterations in local host defense mechanisms that result in bacteremia.[117,143]

Using human columnar nasopharyngeal tissue in organ cultures, Stephens and colleagues[208] showed that *N. meningitidis* organisms were ingested by the columnar cells, then found within phagocytic vacuoles, and later observed within subepithelial tissues, suggesting that the meningococci had penetrated the epithelial layer. In this same model, Hib organisms attach to nonciliated columnar epithelial cells and subsequently are found in the intercellular spaces in association with a preceding disruption of the tight junctions of epithelial cells.[66] After passing the mucosal barriers, Hib may enter the bloodstream directly through pharyngeal blood vessels.[192] Pneumococci adhere to specific ligands on respiratory cells. The inflammatory mediators generated during viral infections up-regulate platelet-activating factor receptor on respiratory cells to which the pneumococci adhere more avidly and subsequently invade.[223] Pili or adhesins of gram-negative enteric organisms seem to be important in attachment and adherence of these microorganisms to specific receptors expressed on epithelial surfaces. Pili also have been shown to be important in the pathogenesis of some gram-positive infections, such as *S. pyogenes*, group B streptococcus, and *S. pneumoniae*.[18,152]

The placement of an endotracheal tube unmasks a greater number of these receptors, presumably through increased protease activity of secretions and decreased cell-bound fibronectin, and leads to colonization of the upper respiratory tract with gram-negative organisms, which are ubiquitous in the environment of an ICU.[244] Altered host defense mechanisms allow these organisms to move beyond epithelial surfaces and cause bacteremia.

The gastrointestinal and genitourinary tracts are major sources of gram-negative organisms responsible for bacteremia. These organisms first may cause localized abscesses or peritonitis if intestinal perforation occurs, or they may translocate the intestinal mucosa, particularly when the mucosa is affected by antineoplastic agents. Viridans streptococci can cause bacteremia in a neutropenic patient with severe mucositis that develops after the patient undergoes chemotherapy.[204] Microorganisms within the bladder may ascend the genitourinary tract and presumably enter the bloodstream through the kidneys. *S. aureus* and *S. pyogenes* are common inhabitants of the skin and skin structures. Any skin wound or foreign matter within the skin tissue renders the skin more susceptible to bacterial invasion. Staphylococci have a unique capability of adhering to solid surfaces, such as catheters, which may be an important prerequisite to colonization and subsequent catheter-related bacteremia.[173]

The pathophysiology of septic shock is very complex. Septic shock associated with gram-negative organisms has been studied most extensively, especially with respect to endotoxin or bacterial LPS, which has multiple biologic effects. Bacterial LPS has three basic components, as follows:

1. Terminal side chains consist of repeating oligosaccharides that differ from strain to strain and are responsible for the antigenic specificity of the O antigens.

2. A core LPS also consists of oligosaccharides but has less diversity in structure among strains than do the terminal side chains.

3. Lipid A is very similar among the different strains and is responsible for most of the biologic activity of endotoxin.

Endotoxin shock has been the subject of intensive animal research, and much of what is known about the pathogenesis of endotoxin shock has been derived from animal models. Although septic shock in humans is not simulated precisely in these animal models because the animals do not have underlying host defense defects, much of what has been learned about endotoxin shock in animals has been corroborated in the human host.

ENDOTOXIN SHOCK IN ANIMALS

Most animal models of endotoxin shock employ infusions of live gram-negative bacteria, usually *Escherichia coli*, or purified endotoxin, after which observations are made. The effects of purified endotoxin depend partly on the species of animal being studied. The effects of endotoxin in animal models are summarized in Table 69–3.

Numerous mediators induced by endotoxin play pivotal roles in the pathogenesis of endotoxin shock. Tumor necrosis factor (TNF) or cachectin, a polypeptide hormone, is a key cytokine mediating septic shock.[219] The tissue injury induced by TNF largely is a result of other mediators that are induced by TNF, including interleukin-1β (IL-1β), IL-6, eicosanoids, and platelet-activating factor.[62,103,217,220] TNF is synthesized by a wide variety of cells (including monocytes/macrophages, natural killer cells, microglial cells, hepatic Kupffer cells) after stimulation by LPS, C5a, viruses, and enterotoxins, among other agents. TNF initiates a cascade of events that leads to endothelial cell injury, an enhanced inflammatory response, and, ultimately, the characteristic findings of endotoxic shock.

Nitric oxide (i.e., endothelium-derived relaxing factor) is the final pathway by which endogenous vasodilators stimulated by endotoxin result in hypotension from altered control of microcirculation. LPS through the release of cytokines induces a form of the enzyme nitric oxide synthase II, which leads to increased production of nitric oxide.[150] Inhibitors of nitric oxide synthase, such as N^G-monomethyl-l-arginine, can reverse or prevent hypotension in animals challenged with LPS.[142]

The pathophysiology of septic shock caused by gram-positive bacteria is similar to that described for gram-negative organisms.[206] Cell wall components, such as peptidoglycan and teichoic acid, promote proinflammatory activity, but are less potent than endotoxin.

TABLE 69–3 Endotoxin Shock in Animal Models

Effects	Mediators
Cardiovascular Effects	
Decreased peripheral vascular resistance[158]	Histamine, bradykinin,[145] serotonin, complement activation, prostaglandins, anaphylatoxins
Decreased cardiac output[8,13,180]	
Depressed myocardial function[140]	
Decreased systemic blood pressure[48]	
Metabolic Effects[180]	
Hyperglycemia[54]	Hypoinsulinemia
Hypoglycemia[70]	
Increased adrenocorticotropic hormone, growth hormone, and antidiuretic hormone[241]	
Decreased calcium[213]	
Increased triglycerides[97]	
Decreased iron, transferrin, and zinc	
Pulmonary Effects	
Congestive atelectasis[29]	Polymorphonuclear leukocytes
Increased capillary permeability[32,101]	Polymorphonuclear leukocytes
Vasoconstriction	Thromboxane, prostacyclin
Bronchoconstriction[23]	Leukotrienes
Central Nervous System Effects	
Decreased regional and total cerebral blood flow[158]	
Increased cerebral oxygen consumption[179]	

ENDOTOXIN SHOCK IN HUMANS

The pathophysiology of septic shock is highly complex and is related predominantly to actions of endogenous mediators released as part of the systemic inflammatory response to an infection. The cascade of events is intertwining, with production of one cytokine stimulating the synthesis of others; synergistic, in that the activities of certain cytokines act in concert; and sometimes antagonistic, with the production of other molecules to inhibit or compete with various cytokines. This complicated response to an infectious stimulus has been studied best for LPS, but a similar series of events occurs in response to gram-positive infections. Although the best understood system is the one that recognizes bacterial LPS, others exist for sensing the presence of bacterial peptidoglycan, DNA, lipopeptides, flagella, viral double-stranded RNA, and other conserved microbial molecules.

The first host protein involved in the recognition of LPS is LPS-binding protein. LPS-binding protein is an acute-phase protein; its role is to bring LPS to the cell surface by binding to LPS and forming a ternary complex with the LPS receptor molecule, CD14.[235,245] Formation of the complex between LPS and CD14 facilitates the transfer of LPS to the LPS receptor complex, which is composed of toll-like receptor 4 (TLR4) and MD2. Studies over the course of several years led to the discovery of the TLR4/MD2 receptor complex as the signaling entity for LPS (Fig. 69–1).[23,24] MD2 is a secreted glycoprotein that functions as an indispensable extracellular adapter molecule for LPS-initiated signaling events, perhaps by aiding in ligand recognition. The resulting signal promotes mononuclear phagocytes to produce reactive oxygen molecules, cytokines, and arachidonic acid metabolites, including prostaglandin and leukotrienes. A counterregulatory protein is a bactericidal, permeability-increasing protein that is stored in the granules of polymorphonuclear leukocytes and inhibits the effects of LPS.[77]

TNF is largely responsible for the biologic effects, including fever, shock, myocardial suppression, capillary leak (i.e., endothelial damage), coagulation alterations, and metabolic changes,[39,40,144,177,218] of LPS in humans. In children, including neonates, the role of cytokines in sepsis caused by a variety of organisms, but especially *N. meningitidis*, is well-documented.[34,56,81,213,228] LPS and TNF each can induce the synthesis of other proinflammatory cytokines, such as IL-1β and IL-6.[63] IL-6 levels in plasma correlate with mortality. IL-8 plasma concentrations also are increased after infusion of LPS or IL-1β.[63,93]

The anti-inflammatory cytokine IL-10 is produced after LPS is injected and inhibits the production of TNF, IL-1β, and IL-6.[138] Naturally occurring inhibitors of TNF or IL-1β are present in serum samples of patients with the sepsis syndrome.[59,60,83] IL-1 receptor antagonist (IL-1a) binds competitively to the IL-1

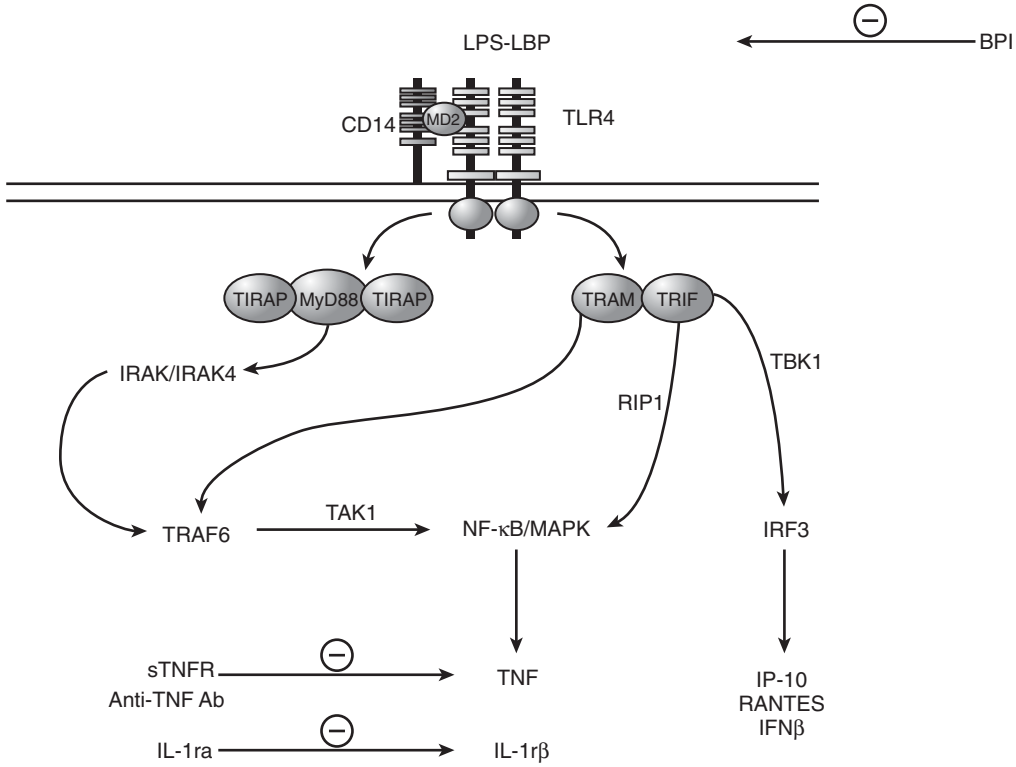

Figure 69–1 Activation of the cytokine network by lipopolysaccharide (LPS). Circulating lipopolysaccharide-binding protein (LBP) recognizes LPS in the plasma and brings it to CD14. This aids the loading of LPS onto the LPS receptor complex, which is composed of dimerized toll-like receptor 4 (TLR4) receptors and two molecules of the extracellular adapter MD-2. Signals activated by TLR4 can be subdivided into signals dependent on MyD88 (and Mal), which occur early (represented by the events illustrated on the left-hand side of the diagram), and signals independent of MyD88, which occur later and use the adapters TRIF and TRAM (depicted on the right). IL-1ra, interleukin-1 receptor antagonist; sTNFr, soluble tumor necrosis factor receptor.

receptor to block the action of IL-1. Soluble TNF receptors bind to circulating TNF, which prevents its proinflammatory actions (see Fig. 69–1).

In humans, gram-negative bacteremia is followed by a decrease in systemic vascular resistance and mean blood pressure and an increase in cardiac output.[24,237] Decreased systemic vascular resistance may be accompanied by activation of the complement and kinin systems.[145] After this early phase, the blood pressure decreases further without change in the central venous pressure. Certain patients, especially children, are able to maintain their cardiac output and cardiac index, and this ability may be associated with increased rates of survival. When peripheral resistance is measured within 12 to 24 hours of the onset of shock, its decrease is significant in patients who survive compared with patients who die.[162] In contrast, cardiac output is reduced significantly in other patients; this decrease is associated with increased concentration of blood lactate, decreased arterial blood pH, and decreased rates of survival.

Depression of myocardial function has been shown in adult and pediatric patients in septic shock.[69] These patients have a reduced ejection fraction, left ventricular dilation, and significantly altered ventricular performance in response to infusion of volume.[164] This depression of myocardial function is transient in survivors, however, reverting to normal within 1 to 4 days.[167] Parker and colleagues[168] found that patients who did not survive septic shock did not have left ventricular dilation or reduction in the ejection fraction. When the systemic vascular resistance index was averaged over the course of time, nonsurvivors had a significantly ($p < 0.05$) lower index than that of survivors of septic shock. This study included three children who were 9 to 17 years of age. Abraham and associates[1] sequentially monitored hemodynamic and oxygen transport measurements in 33 patients with septic shock. In the 24-hour period before the onset of hypotension, the survivors showed significantly greater cardiac index, left cardiac work index, oxygen delivery, and oxygen consumption than the nonsurvivors.

A circulating myocardial depressant factor in patients with septic shock was proposed more than 50 years ago, but myocardial dysfunction was not quantitatively linked to a serum factor until the late 1980s.[140,169,181] Kumar and colleagues[121] later reported that the myocardial depressant activity of sera obtained from patients with septic shock could be eliminated by the immunoprecipitation of TNF and IL-1β. Several investigators also have shown that TNF and IL-1β synergistically depress myocardial function in vitro, and that this effect can be abolished by an inhibitor of nitric oxide.[38,166] Germane to this discussion is the observation that LPS-induced biosynthesis of TNF mRNA and protein is not strictly confined to peripheral mononuclear cells but also may occur within many different tissue compartments. Experimental studies have shown that the cardiac compartment can be a significant source of TNF during septic shock. Kapadia and colleagues[111] showed that administration of LPS leads to intramyocardial production of TNF mRNA and protein in vivo.

These observations raise the possibility that the myocardial depression occurring in sepsis may develop directly in response to the compartmentalized production of TNF and other cytokines within the heart, as opposed to systemic production of these mediators by circulating mononuclear cells. TLR4 is expressed in the heart, and investigators have suggested that it is involved in signaling the cytokine production induced by LPS within the heart.[20]

In children, the most comprehensive investigation of myocardial dysfunction has been in meningococcal septic shock. Thiru and coworkers[214] measured serum concentrations of the cardiac muscle–specific protein cardiac troponin I, which is released from injured cardiac myocytes, in 101 children with meningococcal septicemia. Minimum left ventricular ejection fraction was inversely related to peak cardiac troponin I levels. The degree of myocardial dysfunction, as determined by inotrope measurement, was related directly to peak cardiac troponin I concentrations. Their results suggested that myocardial cell death might contribute, at least in part, to the cardiac dysfunction associated with meningococcal septic shock.

Hematologic changes, such as leukocytosis, leukopenia, and thrombocytopenia, have been observed in human volunteers after receiving an infusion of endotoxin. Thrombocytopenia commonly occurs in association with sepsis of any cause.[50] Septic shock is one of the most common causes of disseminated intravascular coagulation in children. Hageman factor (i.e., factor XII), which initiates the coagulation cascade, can be activated directly by LPS or through endothelial damage induced by bacteria.[134] In septic shock, concentrations of Hageman factor, prekallikrein, high-molecular-weight kininogen, and factor VII are decreased partly as a result of consumption.[53,110] Similarly, levels of inactivators of clotting factors, such as C1 esterase inhibitor, α_2-macroglobulin, and antithrombin III, also are diminished. Corrigan and Jordan[53] diagnosed disseminated intravascular coagulation in 24 of 26 children with septic shock and found that improvement in coagulation parameters seemed to be related most to restoration of blood pressure. Gram-negative bacteremia may be associated with a coagulopathy that is not disseminated intravascular coagulation but is characterized by prolongation of the prothrombin and partial thromboplastin times caused by a reduction in the vitamin K–dependent coagulation factors.[52]

LPS or cell wall components of gram-positive organisms, through cytokine production, activate blood coagulation predominantly through the extrinsic pathway. The procoagulant state is enhanced further by decreased protein C activity, which is an important inhibitor of coagulation factors Va and VIIIa. The fibrinolytic system also is altered by endotoxemia and is mediated by plasminogen activator inhibitor 1–induced suppression. The coagulopathy associated with septic shock is characterized by a procoagulant state and inhibition of fibrinolysis.[125,130] Protein C has anti-inflammatory properties. The antithrombotic, profibrinolytic, and anti-inflammatory actions of activated protein C counteract the effects of cytokine activation, but a deficiency of protein C may be acquired during severe sepsis. Low levels of protein C have been associated with increased morbidity and mortality rates in patients with severe sepsis and septic shock.[73] For meningococcal disease in particular, dysfunction of the protein C activation pathway is a key factor in the development of the thrombosis associated with purpura fulminans. Down-regulation of the endothelial thrombomodulin–endothelial protein C receptor pathway seems to be the mechanism for impaired activation of protein C during severe meningococcal sepsis.[67]

LPS can activate the complement cascade by the classic or the alternate pathway. Significantly depressed concentrations of C3 occur in patients with bacteremia and hypotension compared with normal individuals or with patients with uncomplicated bacteremia, and C3 is activated primarily by the alternate pathway.[68,110,136] In patients with bacteremia and hypotension, C1, C4, and C2 levels were not depressed significantly from values found in normal controls or in normotensive patients with bacteremia. In contrast, C3, C5, C6, C9, properdin, and factor B levels were decreased significantly ($p < 0.05$) in bacteremic patients with shock. In children with meningococcal disease, Tubbs[222] found a mean C3 concentration (as a percentage of normal values) of 132 ± 21 percent for survivors versus 91 ± 21 percent for nonsurvivors. The C3 levels did not correlate with endotoxin levels in sera.

Many metabolic alterations have been documented in the human host during endotoxin shock. Hyperglycemia followed by hypoglycemia can complicate the shock state induced by sepsis.[70,146] Whole-body use of glucose is increased during sepsis, which probably is cytokine-mediated.[147] Glycolysis and gluconeogenesis are increased, but insulin resistance occurs in skeletal muscle. Children with underlying liver disease or with reduced glycogen stores are most likely to develop hypoglycemia during septic shock. Lactic acidosis develops as a result of poor tissue perfusion and cellular hypoxia. Lactic acid concentrations are increased in nonsurvivors and patients with poor or low-flow cardiac output during sepsis.

In clinical studies, Clowes and associates[47] identified a subgroup of patients with low-flow septic shock in whom concentrations of serum insulin were lower than concentrations in a control population. In children with meningococcal sepsis, van Waardenburg and colleagues[225] found higher blood glucose concentrations and significantly lower insulin levels on day 2 or 3 of hospitalization in children with shock compared with children without shock. Levels of plasma insulin and soluble TNF receptor 75 were inversely correlated in these children. Their findings were consistent with the inflammatory response inhibiting insulin secretion.

Hypocalcemia and decreased serum ionized calcium concentrations occur frequently during bacterial sepsis. In one study, 12 (20%) of 60 critically ill adults with bacterial sepsis had hypocalcemia.[247] The mortality rate in the hypocalcemic patients was 50 percent compared with 30 percent in the patients who were normocalcemic. Cardenas-Rivero and associates[42] studied calcium homeostasis in 145 children admitted to an ICU. Of eight children with confirmed sepsis or meningitis (or both) not caused by Hib, seven had hypocalcemia, and six of seven had ionized hypocalcemia. Five of the six children with ionized hypocalcemia had inappropriately normal concentrations of parathyroid hormone, which suggests that transient hypoparathyroidism occurs in some children with sepsis. Hypocalcemia also occurs commonly in patients with toxic shock syndrome.[240] In women with toxic shock syndrome and hypocalcemia, serum concentrations of calcitonin are elevated by unknown mechanisms.[45] Hypocalcemia and elevated calcitonin concentrations also have been documented in children with fulminant meningococcemia.[131]

Procalcitonin levels are elevated in several conditions associated with systemic inflammatory response syndrome, including sepsis, and have been proposed as adjunctive laboratory tests for the early detection of, and indicators for prognosis of, meningococcal disease.[43,96,122] These changes in calcium levels are especially critical because the level of ionized calcium and cardiac output in septic shock can be correlated.[243] Other metabolic changes may occur during septic shock in humans, as follows:

1. Increased concentrations of cortisol and growth hormone (including in neonates[215])[229]
2. Depression of triiodothyronine and thyroxine levels related to poor nutrition[186]
3. Elevations in total concentrations of amino acid in plasma and the preferential use of branched-chain amino acids as an energy source for skeletal muscle[147]
4. Muscle proteolysis, possibly induced by one or more circulating agents in the plasma of patients with serious infections[46]
5. Elevations in concentrations of plasma thromboxane, which are observed in nonsurvivors of septic shock[183]
6. Elevations in concentrations of triglycerides and free fatty acid during gram-negative bacteremia[78,118]

Liver dysfunction is an important aspect of endotoxin shock in adults. Banks and colleagues[16] found that clinical jaundice was apparent in 63 percent of their patients with septic shock, that it was found more commonly in nonsurvivors than in survivors, and that the degree of biochemical liver abnormalities was related to the duration of shock. Postmortem findings included focal liver necrosis, Kupffer cell hyperplasia, portal tract inflammation, venous congestion, and intrahepatic cholestasis.

Adult respiratory distress syndrome (ARDS), or shock lung, is a major complication of septic shock in children.[104,175] The lungs of children with ARDS have characteristic changes consisting of increased lung weight reflecting congestion and atelectasis, alveoli lined with hyaline membranes, microthrombi, hemorrhage, and interstitial edema.[104] Increased capillary permeability and intrapulmonary shunts have been documented in patients with ARDS.[4,55] C5a, a potent chemotactic factor, causes aggregation of polymorphonuclear neutrophils, is elevated in the sera of patients who ultimately develop ARDS, and is found in increased concentrations in bronchoalveolar lavage fluid obtained from patients with ARDS.[94,187] Leukocyte aggregates are thought to be trapped in lung tissue and may cause damage to the endothelium of the pulmonary microvasculature through the release of oxygen radicals, lysosomal enzymes, and products of arachidonic acid metabolism. Although neutrophils play a critical role in the pathogenesis of ARDS, other factors also are important, considering that ARDS can develop in patients who are neutropenic.[163,238] Thromboxane, platelet-activating factor, fibrin, and other substances contribute to the lung injury in ARDS.[190]

The effects of endotoxin shock on the central nervous system have not been studied carefully in humans.[90] The encephalopathy associated with sepsis seems to be caused partly by altered phenylalanine metabolism; concentrations of phenylalanine and its metabolite, phenylacetic acid, are increased in the sera and cerebrospinal fluid of septic adults who are stuporous or comatose.[148]

Endotoxin has been implicated in the pathogenesis of acute renal failure associated with sepsis. Wardle[231,232] showed that 12 of 16 patients with acute tubular necrosis had endotoxemia. Renal arterial blood flow and renal vascular resistance are decreased significantly in baboons 2 to 4 hours after infusion of endotoxin. Inadequate perfusion pressure was associated with renal ischemia and negligible urine output in these animals shortly after administration of endotoxin.[197] Pathologic examination of the kidneys revealed focal necrosis of the proximal tubular epithelium, eosinophilic casts within proximal and distal tubules, and microthrombi in the glomerular capillaries. Endothelin, a potent vasoconstrictor peptide produced by endothelial cells, is elevated in concentration in the plasma of patients with septic shock. Because endothelin contributes to the regulation of regional blood flow, elevated levels suggest that it may relate to renal vasoconstriction and dysfunction.[227]

Endotoxin can be measured in the plasma of patients with gram-negative bacteremia. The presence of circulating endotoxin does not mean that bacteremia is present or ever has occurred because endotoxin presumably may be "absorbed or leak" into the circulation from the gastrointestinal tract.[126,211,221] Endotoxemia may be a valid indicator, however, of impending gram-negative septicemia in febrile patients.[61] Preformed antibody to LPS or lipid A is associated with protection against shock and death caused by gram-negative bacteremia in adults. McCartney and colleagues[138] detected endotoxin in the blood (after chloroform extraction) of patients with gram-negative septic shock; all 18 patients with persistently positive endotoxin assays died. In contrast, nine patients who initially had endotoxemia but subsequently had negative assays survived. Other studies confirm the association between endotoxemia and outcome.[123] Evidence exists that human endotoxin is cleared from the circulation by the liver and can be detoxified by neutrophil enzymes (i.e., acyloxacyl hydrolases).[135,153]

The sequence of events in the evolution of endotoxin shock has been outlined by several investigators.[159] Bacteria, endotoxin, or other bacterial products stimulate the production of TNF and other cytokines, which in concert with endotoxin set off a whole series of events. Potent mediators, including C3a, C5a, eicosanoids, platelet-activating factor, histamine, and myocardial depressant substance, are released. Potent vasodilators cause peripheral vasodilation, and decreased systemic peripheral resistance leads to pooling of blood and decreased venous return to the heart. Mean blood pressure may be low, or it may be normal if cardiac output increases sufficiently to compensate for these alterations despite depression of ventricular function. The central venous pressure, which partially depends on myocardial performance, may be low or in the normal range.

If intravascular volume is increased by the administration of sufficient fluids, shock may be prevented or corrected. Continued hypotension and diminished perfusion pressure may lead, however, to cellular hypoxia and increased production of lactic acid from pyruvate. The microcirculation is altered by local tissue acidosis. Capillary beds become congested, and intravascular fluid may leak into the interstitial spaces. Increased secretion of catecholamine leads to arteriolar and venular constriction and increased peripheral resistance. Pooling of blood is enhanced, which leads to a further diminution in venous return and a reduction of cardiac output. Oliguria, coagulation abnormalities, and additional metabolic alterations indicate multiple organ system failure and presage the death of the patient.

CLINICAL PRESENTATION AND DIAGNOSIS

The signs and symptoms of bacteremia vary, greatly depending on the age and underlying disease of the patient, the duration of illness, and the specific microorganisms. Young, otherwise healthy children aged 3 months to 3 years may present with fever and evidence of an upper or lower respiratory tract infection or no focus of infection and yet have unsuspected bacteremia. Most studies indicated that the risk of developing bacteremia increases as the body temperature increases and that after the temperature exceeds 41°C, almost 25 percent of these children may be bacteremic.[19] In a previously healthy child, the persistence of irritability and the inability to console the child despite optimal environmental conditions have been proposed as key points in the physical examination that should alert the clinician to the possibility of a serious infection, such as bacteremia or meningitis.[137,203]

Underlying illnesses with splenic dysfunction place a child at increased risk for acquisition of infections caused by encapsulated organisms, whereas children with leukemia or other immunosuppressive diseases or children in the ICU are more likely to be infected with gram-negative bacilli or *S. aureus.* A history of diarrhea may suggest *Salmonella* spp. as a possible cause of illness. Preceding skin infections or wounds are important clues to infection caused by *S. aureus* or group A streptococcus. An indwelling vascular catheter may precipitate overlying erythema in a patient with evidence of phlebitis proximally. Gram-positive cocci and gram-negative bacilli can be associated with catheter-related sepsis.[199] Toxic shock syndrome should be considered in a hypotensive girl or woman with a recent menstrual period and history of tampon use, although toxic shock also is associated with *S. aureus* sepsis in males and nonmenstruating females.[87,202] Evidence of osteomyelitis, with or without venous thrombosis, is a very common finding in staphylococcal sepsis.[88] Intra-abdominal sources of infection increase the likelihood of developing anaerobic bacteremia.

Petechiae may be associated with many microorganisms, especially invasive disease caused by *N. meningitidis*.[161] Purpura is an ominous finding and frequently is associated with overwhelming infection caused by *N. meningitidis*, *S. pneumoniae*, and Hib. *P. aeruginosa* is associated specifically with erythema gangrenosum. Almost half of children presenting with erythroderma (diffuse erythema) either had shock at presentation or developed shock in one study.[37] Other skin and soft tissue manifestations of gram-negative sepsis include bullous lesions, cellulitis, fasciitis, thrombophlebitis, and symmetrical peripheral gangrene with disseminated intravascular coagulation.[154] Signs of meningeal irritation or increased intracranial pressure are important because they may modify the approach to management of fluids in a child in shock.

The onset of bacteremia may be heralded by chills, fever, nausea, vomiting, diarrhea, rashes, and petechiae. Initially, the skin feels warm and appears flushed. A change or impairment in mental status may be the first clue to the presence of shock. Hyperventilation also may develop before the onset of clinical shock occurs, which can alert the physician to impending circulatory insufficiency.[25] In time, cold, clammy extremities; a weak pulse; tachycardia; tachypnea; hypotension; and oliguria may occur. The skin over the extremities, the tip of the nose, and the earlobes especially are prone to cyanosis. Auscultation of the lungs may reveal rales, indicating pneumonia or pulmonary edema. Abnormal distention or tenderness to palpation and guarding may be evidence of peritonitis. Costovertebral angle tenderness suggests acute pyelonephritis as a source of bacteremias.

The physician must distinguish among the following three main types of shock in children:

1. *Hypovolemic shock*, such as occurs with blood loss, fluid and electrolyte loss, adrenal insufficiency, or other causes
2. *Cardiogenic shock*, which is associated with drug intoxication, cardiac surgery, arrhythmias, and pericardial tamponade, among other causes
3. *Distributive shock*, which indicates abnormal distribution of blood flow leading to inadequate tissue perfusion (e.g., septic shock, anaphylaxis)

The laboratory evaluation of a child with bacteremia, septic shock, or both conditions should provide information concerning the cause and the data required for optimal supportive management. Several studies showed that a total white blood cell (WBC) count exceeding 15,000 cells/mm^3 in a 3- to 36-month-old child with a temperature greater than 39°C to 40°C and without a focus of infection is an indication that the child is at increased risk for having bacteremia, especially pneumococcal bacteremia.[17] Since the introduction of the pneumococcal conjugate vaccine, pneumococcal bacteremia in this scenario has been greatly reduced.[99,196,210] An erythrocyte sedimentation rate greater than 30 mm/hr and C-reactive protein levels also have been suggested as useful screening tools for detecting serious bacterial infections. A low peripheral WBC count also may suggest septicemia and commonly is observed during episodes of overwhelming bacteremic illnesses.

Procalcitonin levels are elevated in bacteremic children and are related to the severity of illness, such as organ failure and even mortality.[96,122] Commercial kits for the rapid measurement of concentrations of procalcitonin are available in some countries. Hemoglobin and hematocrit results should help differentiate between septic and hemorrhagic shock. Examination of the peripheral smear may disclose evidence of splenic dysfunction (i.e., Howell-Jolly bodies) or fragmented red blood cells, as seen in disseminated intravascular coagulation. Thrombocytopenia, prolongation of prothrombin time and partial prothrombin time, and the presence of fibrin split products are consistent with disseminated intravascular coagulation.[42]

Hyponatremia is a common finding. Concentrations of serum bicarbonate may be depressed, which may signify a state of metabolic acidosis. Elevated lactic acid concentrations result from inadequate tissue perfusion, and in some reports have been significantly greater in nonsurvivors or patients with low-flow states than in survivors or patients with high-flow shock.[47] In pediatric studies, serial lactate levels showing normalization are associated with recovery.[30] Hyperglycemia or hypoglycemia may be encountered. In one study, serum glucose levels greater than 178 mg/dL were associated with a greater risk of death caused by septic shock.[31] Transaminase levels may be elevated and presumably reflect cellular injury. Serum calcium concentrations (preferably ionized calcium levels) should be checked periodically because hypocalcemia may interfere with optimal myocardial function.

A chest radiograph may reveal a pulmonary source of infection or show a secondary pulmonary manifestation of an invasive infection such as pneumonia or septic emboli in children with staphylococcal sepsis.[86] Arterial blood gases obtained early in endotoxin shock usually reveal hypocapnia and normal to elevated pH.[25,26] At this point, the patient has a mixed metabolic acidosis and respiratory alkalosis. If the shock state progresses, the metabolic acidosis becomes so severe that respiratory compensation is ineffective, and the patient becomes acidotic. In some patients, respiratory acidosis accompanies metabolic acidosis. In either case, decompensated metabolic acidosis in a patient with septic shock is associated with a grave prognosis. A major consequence of ARDS is hypoxemia. For patients with ARDS, the chest radiograph characteristically shows bilateral and diffuse hazy infiltrates; opacification of all lung fields usually is seen during the late phases of ARDS.

Concentrations of blood urea nitrogen and serum creatinine may be elevated. Jones and Weil[109] found that the ratio of urine to plasma osmolality was the most valuable indicator of renal impairment in adult patients with shock. When this ratio was greater than 1.5, the likelihood of developing progressive renal failure was remote. A urine osmolality value greater than 400 mOsm/kg also indicated adequate renal function. Many WBCs or WBC casts in the urine may suggest the genitourinary tract as the source of bacteremia. If one or more gram-negative rods are seen on the Gram stain of unspun urine, more than 10^5 colony-forming units/mL of bacteria are likely to be present.

Isolating the organism responsible for bacteremia or septic shock is important for documenting the infection and for providing optimal antimicrobial therapy. With instruments that continuously monitor growth in the blood culture bottles, growth can be detected sooner than if the bottles are inspected just once or twice daily. Before the use of the pneumococcal conjugate vaccine became routine, many authorities recommended that a blood culture be obtained in a 3- to 36-month-old child with temperature greater than 39°C to 40°C and a total WBC count greater than or equal to 15,000 cells/mm^3 and without a specific focus of infection. In this way, instances of "unsuspected" or "outpatient" bacteremia could be identified. In an outpatient setting, almost 90 percent of blood cultures growing true pathogens were positive within 24 hours of incubation using a continuously monitored system.[141] This approach is now less useful in the era of administration of pneumococcal conjugate vaccine to young infants.

In an infant who has received three or more doses of the conjugate pneumococcal vaccine, the likelihood of developing invasive pneumococcal infection is reduced approximately 90 percent. The proportion of children with high fever without localizing findings and a WBC count of 15,000/mm^3 or greater who might have occult pneumococcal bacteremia may be less than 1 percent, a level that no longer justifies this approach. Most organisms isolated from blood cultures in these patients are now more likely to be a contaminant than a true pathogen. Currently, the approach to a febrile child without a source has changed in

many emergency departments such that more selective criteria for obtaining blood cultures are being developed.

When appropriate, cerebrospinal fluid, urine, and other pertinent sites should be cultured before initiating antibiotic therapy, if possible. When an intra-abdominal source of infection is likely, blood and other cultures should be processed anaerobically. Gram stain or acridine orange stain of a buffy coat smear of peripheral blood may reveal evidence of the causative microorganism, especially in an overwhelming infection.[119] Gram stain of material obtained from petechial or purpuric lesions may show gram-negative diplococci suggestive of meningococcus. Polymerase chain reaction for detecting *N. meningitidis* is available in selected laboratories and may be the only method by which infection is documented when cultures are sterile. Bacterial polysaccharide antigens can be detected rapidly in many body fluids by latex agglutination tests. Rapid diagnostic procedures for evaluating outpatients with suspected bacteremia are unreliable. Pneumococcal antigenuria is not detected readily when bacteremia occurs without a specific focus of infection. The value of assays for detecting circulating endotoxin is unclear.

TREATMENT

The initial selection of antibiotics for administration to a child with suspected bacteremia is based on the clinical situation (Table 69–4). If untreated initially, children with occult bacteremia are at risk of developing serious complications, such as meningitis or pneumonia.[133,155] Empiric antibiotic therapy for children who are selected carefully and followed seems reasonable.[17] Two prospective studies of empiric administration of penicillin or amoxicillin in this situation reached different conclusions, however.[44,108] Ceftriaxone has been compared with amoxicillin or amoxicillin-clavulanate in two large studies involving children 3 to 36 months old. Ceftriaxone was marginally superior at best to the oral agents with regard to efficacy.[19,74]

In children who have not received more than two doses of the pneumococcal conjugate vaccine, one approach may be to obtain a blood culture from children aged 3 to 36 months with a temperature of 39° C or greater who have no focal findings and whose peripheral WBC count is greater than or equal to 15,000/mm^3. In such patients, the decision to administer antibiotics expectantly may be based on several factors, especially the ability of the parents to observe the child and communicate this information back to the physician in a timely manner. Ceftriaxone given parenterally, an oral agent such as amoxicillin and amoxicillin-clavulanate, or other oral antibiotics can be administered. If treatment is initiated, a properly collected urine specimen for urinalysis or urine culture also should be obtained so that a urinary tract infection would not be treated inadvertently. Occult bacteremia caused by *S. pneumoniae* intermediate or resistant to penicillin or intermediate to ceftriaxone in an otherwise normal child should resolve with any of the options noted earlier.[115] This approach probably is less useful in an infant or child who has received three or more doses of the conjugate pneumococcal vaccine.

Children who subsequently are determined to have *S. pneumoniae* bacteremia and who have been treated with antibiotics expectantly need to be re-evaluated as soon as the results of the blood cultures are known. If the child appears well and has been afebrile for at least 24 hours and if the parents can observe the child carefully and are able to communicate frequently with the physician, outpatient management can be continued. For children who were not treated initially, who remain febrile, and who are called back to be re-evaluated for a positive blood culture, a parenteral dose of antibiotics is recommended.[15] Close contact with the parents and patient is mandatory no matter how these children are managed initially. Hospitalization for intravenous antibiotics is indicated if the child appears "toxic" or has other signs suggesting a serious infection.

For children with suspected bacteremia who are ill and require admission to the hospital, antibiotics are selected to cover the most serious organisms causing that infection. In normal children aged 3 months or older, a combination of nafcillin (150 to 200 mg/kg/day) or another semisynthetic antistaphylococcal penicillin plus cefotaxime (150 to 200 mg/kg/day) or ceftriaxone (75 to 100 mg/kg/day) covers most of the likely pathogens (e.g., *S. pneumoniae*, *S. aureus*, *S. pyogenes*, *N. meningitidis*, Hib). In areas of the United States where community-acquired MRSA is a problem, an agent effective against MRSA should be included in the initial empiric regimen.[98,113] Vancomycin (45 to 60 mg/kg/day) is the gold standard for treating infections caused by MRSA. Whether adding an aminoglycoside or rifampin to vancomycin is beneficial is unclear. For most community-acquired MRSA isolates, clindamycin (40 mg/kg/day in four divided doses) also is an effective antibiotic. Some experts recommend adding clindamycin to vancomycin or nafcillin theoretically to reduce toxin production. This reduction occurs in vitro, but no clinical data indicate that this approach leads to a decrease in the incidence of morbidity or mortality.[209]

Treatment of bacteremia associated with a genitourinary or gastrointestinal source requires antibiotics to which gram-negative enterics are susceptible. In such cases, initial therapy could consist of an aminoglycoside with an additional antibiotic active against anaerobes, such as clindamycin, metronidazole, ticarcillin-clavulanate, or piperacillin-tazobactam, for a gastrointestinal focus of infection. Extended-spectrum cephalosporins, such as cefotaxime or ceftriaxone, are possible alternative drugs for treating serious gram-negative enteric infections.[112] Optimal management of intra-abdominal or other abscesses usually requires surgical drainage, which should be undertaken as soon as the child's condition allows.

Immunosuppressed children or children with serious illnesses in the ICU require a different initial approach to suspected bacteremia. Gram-negative enterics, *P. aeruginosa*, *S. aureus*, and coagulase-negative staphylococcus are likely to be isolated from these patients.[6] Empiric therapy of nosocomial infection is based on the current antibiotic susceptibility pattern within the hospital.[216] *E. coli*, *Klebsiella* spp., and *Enterobacter* spp. are among the most common organisms causing bacteremia in patients in the pediatric ICU.[185] *E. coli* and *Klebsiella* spp. frequently produce β-lactamases that lead to resistance to ticarcillin or piperacillin. Generally, a combination of an antistaphylococcal semisynthetic

TABLE 69–4 Empiric Antibiotic Regimens for Septic Shock in Infants and Children under Selected Clinical Circumstances

Circumstances	Antibiotics
Normal Child	
Skin findings suggesting meningococcemia or preceding skin trauma or varicella	Cefotaxime or ceftriaxone + vancomycin ± nafcillin
Urinary tract source	Cefotaxime or ceftriaxone + aminoglycoside
Intra-abdominal source	Clindamycin + gentamicin + ampicillin or piperacillin or piperacillin-tazobactam
Immunocompromised Child	
Malignancy or immunodeficiency or neutropenia or central line	Vancomycin + aminoglycoside + ticarcillin-clavulanate piperacillin-tazobactam or ceftazidime
Asplenia or splenic dysfunction	Vancomycin + cefotaxime or ceftriaxone

penicillin or vancomycin (if a central line is present) or, if MRSA is a relatively common nosocomial pathogen, an aminoglycoside and an extended-spectrum penicillin (e.g., ticarcillin-clavulanate, piperacillin-tazobactam) is administered initially until a specific pathogen is isolated.[105] Broad-spectrum penicillins and aminoglycosides frequently exhibit synergy in vitro against gram-negative organisms, especially against *P. aeruginosa*.[124,198] In critically ill patients, a synergistic combination of antibiotics may be beneficial for treating bacteremia caused by *P. aeruginosa* or *Klebsiella* spp., although this subject remains controversial.[100,120]

After a specific organism is identified and antibiotic susceptibilities are known, the most appropriate agent is selected. If *E. coli* or *Klebsiella* spp. are isolated, these organisms can produce extended-spectrum β-lactamases, and the isolates should be tested for this possibility.[172] An extended-spectrum, β-lactamase–producing organism may seem susceptible to the extended-spectrum cephalosporins with minimal inhibitory concentrations of 2 to 8 μg/mL, but treatment failures may occur. If an extended-spectrum, β-lactamase–producing organism is identified, treatment with an extended-spectrum cephalosporin (e.g., cefotaxime, ceftriaxone, ceftazidime) is not recommended.[171] In this case, a carbapenem, such as imipenem-cilastatin or meropenem, is suggested.[171]

Enterobacter spp. may hyperproduce β-lactamase enzymes or be induced to hyperproduce these enzymes and are resistant or can become resistant to the extended-spectrum cephalosporins.[174] In many institutions, more than 30 percent of *Enterobacter cloacae* isolates are resistant to ceftazidime.[35] Cefepime may be more active than is ceftazidime or cefotaxime against *Enterobacter* spp. and other Amp C, β-lactamase enzyme–producing, gram-negative bacilli.[195] A carbapenem with an aminoglycoside is the treatment regimen recommended for treating infections caused by *Enterobacter* spp. resistant to ceftazidime.

In these patients, rapidly achieving therapeutic aminoglycoside levels in the plasma is important.[151] Serum concentrations of the aminoglycoside should be measured within 24 hours of initiation of therapy to ensure that therapeutic concentrations have been reached.

Antibiotics should be administered as soon as the diagnosis of septic shock is suspected. The selection of antibiotics is the same as that for bacteremia. If *S. aureus* is suspected among the potential causes of septic shock, antibiotic therapy is complicated by two factors: MRSA may make up more than 50 percent of community-acquired isolates[114] and nafcillin or oxacillin is superior to vancomycin for the treatment of serious infections caused by MRSA.[89] Nafcillin or oxacillin plus an aminoglycoside may be synergistic against staphylococci, but adding an aminoglycoside increases the risk for nephrotoxicity to develop. Some authorities include nafcillin or oxacillin plus vancomycin plus gentamicin in the initial empiric therapy of patients with life-threatening infections possibly caused by *S. aureus*.[9]

The management of septic shock is directed toward three main objectives: (1) control of the infectious process, (2) restoration of adequate tissue perfusion, and (3) maintenance of efficient respiratory function. Details of management have been the subject of numerous reports.[36,41,194] The reader is referred to these reviews for expert detailed guidance in the fluid management, use of vasoactive agents, and respiratory treatments in children with septic shock.

The benefits of therapy with high doses of corticosteroids in the treatment of endotoxin shock remain unproved. Extensive experimental data document the salutary hemodynamic, metabolic, microcirculatory, and cellular effect of steroids in laboratory models of endotoxin shock.[102] High-dose steroids were never found to be efficacious, however, in randomized controlled trials conducted in adults with severe sepsis or septic shock.[30,205,213]

On the basis of these studies, the routine use of high-dose corticosteroids in patients with severe sepsis or septic shock is not recommended. Later, results of small studies enrolling adults suggested that lower stress doses of hydrocortisone might be beneficial in managing patients with septic shock.[27,33] In one of these trials, placebo was compared with a 100-mg loading dose of hydrocortisone followed by a continuous infusion of 0.18 mg/kg/hr with a reduction of the infusion after shock had been reversed. Twenty patients were randomly assigned to each treatment arm. Infusion of stress doses of hydrocortisone reduced the time to discontinuing the vasopressor therapy and was associated with a trend toward earlier resolution of sepsis-induced organ dysfunction. Overall reversal of shock and mortality rates was unchanged, however. The role of low-dose hydrocortisone in children with septic shock remains controversial.[12,224] Randomized studies are needed to clarify the role of stress doses of hydrocortisone in children with septic shock.

Every effort should be made to ensure an adequate airway, which may require periodic suctioning if the patient is unable to clear pooled secretions. Humidified oxygen in concentrations required to maintain an adequate partial pressure of oxygen should be provided early. The method of oxygen administration (e.g., mask, ventilator) depends on the clinical state of the patient. Intubation and assisted ventilation are indicated if the child shows evidence of impending respiratory failure.

ARDS, usually appearing within 2 days after the onset of shock, may complicate the respiratory and fluid management.[104] Pulmonary edema, atelectasis, decreased pulmonary compliance, and ventilation-perfusion abnormalities are some factors that can lead to inadequate oxygenation. Administration of excessive fluids may contribute to ARDS. The central venous pressure may remain normal, despite the presence of pulmonary edema. Positive end-expiratory pressure, oxygen, and careful attention to cardiovascular parameters are the mainstays of therapy for ARDS.[104,175,191] Steroids are not beneficial after ARDS has been diagnosed.

The general supportive care of a child with septic shock includes attention to nutritional and metabolic requirements.[182] Administration of fluids containing 10 percent glucose may be necessary to prevent development of hypoglycemia. Parenteral alimentation may be the only means by which to provide nutrition, although the optimal amount and composition of elemental nutrients for children with septic shock are unknown. Hypocalcemia should be corrected. Platelet transfusions or fresh-frozen plasma may be necessary to correct coagulopathies. Continuous venovenous hemofiltration with or without dialysis may be instituted for complications of renal failure, such as fluid overload with pulmonary edema or hyperkalemia. It is not surprising that children who have acute renal failure complicating severe septic shock have a significantly higher mortality rate than that of children without acute renal failure.[176]

INVESTIGATIVE THERAPIES

Based on the evolving understanding of the pathophysiology of septic shock, many large, randomized, double-blind, multicenter trials have been conducted to assess the efficacy of agents that neutralize or counteract toxins or cytokines that are important in the evolution of septic shock. These immunomodulating strategies have been used on the basis of experimental data from animal studies. The conditions seen in experimental animal models of sepsis do not reflect the pathophysiologic situation seen in patients with severe sepsis or septic shock, however, which has led to many negative clinical trials (Table 69–5).

Antibody to Lipopolysaccharide

Endotoxemia frequently can be documented in patients with gram-negative sepsis. Endotoxin is released when bacteria are

TNF, tumor necrosis factor.

killed by bactericidal antibiotics.[200,201] This release may help explain why some patients develop shock after parenteral antibiotics are administered. Because endotoxin is responsible directly or through mediators for many of the adverse effects of gram-negative bacteremia, attempts to neutralize endotoxin have been undertaken. One problem with this approach is that only patients with septic shock caused by endotoxin-producing organisms may benefit from this treatment, and distinguishing a gram-positive from a gram-negative infection is impossible on patient presentation.

Neither E-5[29,92,95] (XMMEN-OEJ; XOMA Corp., Berkeley, CA), a murine monoclonal antibody, nor HA-1A[139,248] (Centoxin; Centocor, Malvern, PA), a different human monoclonal antibody against lipid A, were found to be efficacious in randomized, multicenter trials of gram-negative sepsis in adults. Children were not included in either study, although the pharmacokinetics and safety of HA-1A were established in children.[188] In the one study performed, HA-1A did not reduce the mortality rate in children with meningococcal disease.[57]

Other Potential Adjunctive Therapies

Antibody to TNF, soluble TNF receptors, antiplatelet activating factor, recombinant IL-1 receptor antagonist, antibradykinin, nitric oxide synthase inhibitor, and other therapies have undergone evaluation in large clinical trials of adjunctive therapy for adults with sepsis syndrome. None has proved beneficial.[4,14,72] Some combination of therapies may provide significant benefit in humans with gram-negative septic shock, as has been shown in animals.[193] Using recombinant soluble CD14 is another approach for blocking the action of endotoxin.[97]

Recombinant bactericidal/permeability-increasing protein ($rBPI_{23}$), a human-derived recombinant protein that expresses the amino-terminal half of the whole bactericidal, permeability-increasing protein molecule, has been studied in children with severe meningococcal sepsis.[149] Preliminary evaluation of $rBPI_{23}$ in 26 children with severe meningococcal sepsis in an open-label phase I/II trial was associated with fewer cases of mortality than in historical control patients.[82] A subsequent large, multicenter, randomized, double-blind trial in which 395 children were enrolled was conducted in 22 centers throughout the United States and the United Kingdom.[127] Mortality rates (7.4%) were not diminished significantly in the $rBPI_{23}$ group because the mortality rate in the control group was only 9.9 percent, a rate much less than anticipated. Children receiving $rBPI_{23}$ did have fewer amputations and a better functional outcome than did children receiving placebo. $rBPI_{23}$ is not being developed further.

Based on the complex interaction of the inflammatory and procoagulation responses of the host to infection as outlined in the pathophysiology section, recombinant human activated protein C (drotrecogin alfa activated [rhAPC]) was evaluated for adjunctive treatment of severe sepsis in patients 18 years old and older. In a multicenter, double-blind, placebo-controlled study conducted in several countries, placebo or rhAPC was infused at a rate of 24 μg/kg/hr for 96 hours to patients with severe sepsis.[22] Selected demographic and clinical characteristics of the patients showed that the patients were matched well. The mortality rate at 28 days was 30.8 percent for the 840 patients in the placebo group and 24.7 percent for the patients receiving rhAPC (p = 0.005). The relative risk of mortality was reduced in the rhAPC group by 19.4 percent (95% confidence interval 6.6 to 30.5). The major difference in serious adverse effects was for serious bleeding, which occurred in 3.5 percent and 2 percent of the rhAPC and placebo patients. Recombinant human activated protein C has been approved for use in adults by the U.S. Food and Drug Administration.

Protein C concentrate has been administered to several children with fulminant meningococcemia and thought to be associated with enhanced survival and decreased amputations.[7,239] These findings supported the continued evaluation of rhAPC in the adjunctive treatment of septic shock in children. Phase I and II studies evaluated the pharmacokinetics and safety of rhAPC in children with severe sepsis.[129] An infusion rate of 24 μg/kg/hr resulted in mean serum concentrations of 67 ng/mL in 43 infants and children. (The mean concentration found in adults was 52 ng/mL.) rhAPC did not accumulate during a 96-hour infusion. The estimated half-life was 0.91 hours, and plasma clearance was 0.49 L/hr/kg. In 2005, however, the Food and Drug Administration and the manufacturer announced the discontinuation of a randomized, placebo-controlled trial of rhAPC in pediatric patients with severe sepsis (information available online at www.fda.gov/medwatch/SAFETY/2005/safety05.htm#Xigris2). An interim analysis showed that rhAPC was highly unlikely to show a benefit over placebo in the primary end-point (time to complete organ failure resolution over 14 days). rhAPC was associated with a significantly higher risk for central nervous system bleeding. The risk for intracranial hemorrhage was particularly elevated in patients younger than 60 days. The use of rhAPC is not indicated for use in pediatric severe sepsis.[156]

Intravenous immunoglobulin is recommended for adjunctive therapy for patients with toxic shock syndrome caused by either group A streptococcus or *S. aureus* that is not responding to aggressive therapy after several hours or after appropriate drainage of focal infections.[10] The value of intravenous immunoglobulin in the treatment of septic shock caused by *S. aureus* infection but not associated with toxic shock syndrome has not been established.[80] Tefibazumab is a monoclonal antibody directed against clumping factor A, an adhesin on the surface of *S. aureus*, that is being investigated to determine if it improves the outcome of adults with *S. aureus* bacteremia.[236]

Polymyxin B is an antibiotic that can neutralize endotoxin possibly through a detergent-like action. In experimental models, polymyxin B moderates some of the cardiovascular, metabolic, and lethal consequences of *E. coli* sepsis in rabbits and overwhelming Hib disease in infant rats.[75,230] Clinical studies of polymyxin B have not been conducted in humans with sepsis or septic shock.

Pentoxifylline is a phosphodiesterase inhibitor that has anti-inflammatory properties, including the ability to suppress endotoxin-induced mononuclear cell production of TNF. Pentoxifylline decreases endotoxin or TNF-induced lung injury and increases survival in animals infected with *E. coli* or infused with endotoxin.[128] In a study of human volunteers, a 500-mg dose of pentoxifylline infused 30 minutes before a 100-ng injection of endotoxin from *Salmonella abortus equi* blunted the TNF response but did not affect IL-6 serum levels after administration of endotoxin.[246] Clinical effects, such as fever, myalgia, and headache, were not affected by pentoxifylline. In one small study of 51 patients, a continuous infusion of pentoxifylline was associated with improvement in organ dysfunction scores, Pao_2/Fio_2 ratio, and the pressure-adjusted heart rate compared with placebo-treated patients.[207] Larger clinical studies of pentoxifylline or similar agents are warranted for the adjunctive treatment of sepsis and septic shock.

Plasmapheresis, exchange transfusions, and extracorporeal membrane oxygenation are heroic measures that seem to be beneficial in selected patients not responding to standard management.[21,58,79] These procedures may be considered for such patients when, in the opinion of experienced clinicians, their use is justified and they are the last hope for a successful outcome.[76]

PROGNOSIS

The morbidity and mortality rates for septic shock in children vary with age, the presence or absence of underlying diseases, and the specific microorganisms responsible for the septicemic state. Dupont and Spink[64] reported a 98 percent mortality rate in their series of children with septic shock and gram-negative bacteremia. Jacobs and colleagues[107] reported a 9.8 percent case-fatality rate for otherwise normal children with septic shock. In the pediatric HA-1A study, the overall mortality rate for severe sepsis or septic shock was 31 percent.[188] The overall mortality rate for children with meningococcal infection was 8 percent in a 10-center surveillance study.[116] For the seven-state sepsis cohort, the overall mortality rate was approximately 10 percent.[234] Much progress has been made in the treatment of sepsis and septic shock since the report of Dupont and Spink was published.[64] As with many infections, prevention is more desirable than is treatment. Careful attention given to sterile techniques for insertion and maintenance of intravascular or other lines and other procedures is crucial and may prevent some episodes of bacteremia and septic shock.

CHAPTER 70

Fever without Source and Fever of Unknown Origin

Debra L. Palazzi ✪ Ralph D. Feigin

Petersdorf and Beeson[76] in 1961 proposed that the term *fever of unknown origin* (FUO) be reserved for persons with an illness persisting for 3 or more weeks and accompanied by temperatures higher than 38.4° C (101.2° F) on at least several occasions. They further specified that the cause of the fever should remain undetermined after at least 1 week of investigation in the hospital. Although this definition was arbitrary, it was useful at that time, when many of the diagnostic tests now in routine use were unknown. The purpose of their precise definition was to explore the cause of fever in this select group of adult patients and to permit comparison of data from different investigations. This exacting definition probably never was applied rigorously in pediatric practice. In children, the term FUO should be reserved for fever of at least 8 days' duration and for which no diagnosis is apparent after the initial work-up in the hospital or as an outpatient.

Many investigators prefer using the term *fever without source* (FWS) for fever of recent onset with no adequate explanation determined by the history or physical examination. The distinction between FUO and FWS is of more than academic interest for several reasons. First, although overlap exists, the differential diagnoses of these clinical conditions are distinct, and the most frequent causes of one are different from the most frequent causes of the other. Second, a child with fever of recent onset generally warrants more immediate evaluation than does a child with FUO. The latter usually does not occur as an emergency and requires timely, but not urgent, diagnostic or therapeutic intervention. Third, although expectant antibiotic treatment of children with FUO generally is not indicated, expectant treatment of infants with FWS is recommended in most cases.

FEVER WITHOUT SOURCE

A convenient definition of FWS *is the occurrence of fever for 1 week or less in a child in whom a careful history and physical*

examination fail to reveal a probable cause of the fever. An estimated 14 to 40 percent of children with fever have no localizing signs or symptoms.[7,12] Stein[89] found that the peak incidence occurs during the second year of life. On the basis of a review of private pediatric practices in upstate New York, Hoekelman and colleagues[43] predicted that every 4 to 5 days a practicing pediatrician would see one child between 1 and 24 months of age with FWS.

Most children with fever of recent onset have acute infectious diseases, the majority of which are self-limited.[100] A few of these patients have serious acute infectious diseases, including meningitis and bacteremia, and a very few have acute noninfectious diseases or chronic disorders. For example, an occasional patient with FWS is discovered to have a disorder such as heat illness, drug poisoning, Kawasaki disease, malignancy, or connective tissue disease. However, these disorders occur infrequently. A physician faced with a child with FWS should consider the possibility of a noninfectious cause or the onset of a chronic disease, but unless a clinical clue suggests one of these entities, investigation in this direction is not warranted.

Many children with FWS are in the prodromal stages of an acute infectious illness, and evidence of a specific infection, such as pharyngitis, otitis media, or pneumonia, develops within hours to days of first being evaluated by a physician. Fever can precede the appearance of specific signs and symptoms by as long as 3 days, as in measles, Rocky Mountain spotted fever, and leptospirosis. In some infections, such as roseola, viral hepatitis, infectious mononucleosis, typhus, and typhoid fever, the interval between the onset of fever and the appearance of specific findings often is more than 3 days.

OCCULT BACTEREMIA

One major concern regarding a young child with FWS is the possibility that the child has occult bacteremia. The patient does not appear ill, is judged clinically well enough to be managed as an outpatient, and does not have an infection commonly associated with bacteremia such as pneumonia, but the blood culture yields pathogenic bacteria such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae*, *Escherichia coli*, *Salmonella*, or *Staphylococcus aureus*. Before introduction of the pneumococcal conjugate vaccine, the incidence of occult bacteremia in children with FWS was approximately 3 to 5 percent.[14,25,60,70,93,100] More recent data report an incidence of 0.2 to 3 percent, although this figure can vary depending on vaccine coverage rates in the population studied.[2,3,42,74,85,91] Few prospective, large studies have been performed to further investigate the impact of the pneumococcal conjugate vaccine on the incidence of occult bacteremia in children.[79] Historically, occult bacteremia has been found to occur more commonly in children with FWS than in febrile children of the same age with infections such as pharyngitis, otitis media, or upper respiratory tract infection. In the 1970s, investigators[60] reported the incidence of bacteremia in febrile children without an obvious source of infection to be 9.9 percent, as opposed to 3.3 percent in children with otitis media, upper respiratory tract infection, or a flu-like syndrome. During the same era, Teele and colleagues[93] found a 3.9 percent incidence of bacteremia in children with FWS and a 1.5 percent incidence in comparably febrile children with otitis media or pharyngitis.

The risk of occult bacteremia developing in a child with FWS is age-related, with most cases occurring in children younger than 24 months old. Numerous studies have demonstrated a higher risk for bacteremia or other serious bacterial infections (SBIs) in febrile infants younger than 3 months old.[58,60,84,93] In a group of children with clinically unsuspected meningococcemia, all 12 patients who initially looked well enough to be treated as outpatients were younger than 24 months of age.[31] Bonadio and colleagues[20] found the incidence of positive bacterial cultures to be 12 percent in febrile infants younger than 4 weeks and 6 percent in those between 4 and 8 weeks of age.

The risk of having occult bacteremia and other SBIs increases with the severity of fever. In a prospective study of bacteremia in children seen in the outpatient department, McCarthy and colleagues[61] identified a small, but statistically significant, difference in the incidence of bacteremia between children with temperatures of 40° C (104° F) or higher and those with temperatures of 40.5° C (104.9° F) or higher. In a prospective study in which blood was obtained for culture from all febrile children younger than 2 years old seen in a walk-in clinic, no positive blood cultures were found in 44 children with FWS and rectal temperatures lower than 38.9° C (102° F), whereas five (3.9%) positive blood cultures were found in 129 children with FWS and rectal temperatures of 38.9° C (102° F) or higher.[93] Other studies have reported similar findings.[14,58,85] Several series of children with fevers of 41° C (105.8° F) or higher found a relatively high prevalence of bacteremia and other SBIs, especially meningitis and pneumonia.[19,58,81] However, even in this group of children with very high fever, most of those older than 2 or 3 months of age who looked well did not have an SBI.

The white blood cell (WBC) count has been studied extensively as a potential tool in the diagnosis of occult bacteremia. On the basis of a study of hospitalized children, Todd[94] reported that the absolute number of polymorphonuclear leukocytes and the absolute number of nonsegmented polymorphonuclear leukocytes were more sensitive than was the total WBC count, the percentage of polymorphonuclear leukocytes, or the percentage of nonsegmented polymorphonuclear leukocytes. However, whether information based on hospitalized children—presumably all of whom had serious localized infections or looked ill enough to warrant hospitalization—can be applied to children with FWS who look well enough to be treated on an ambulatory basis is questionable.

Considerable debate continues over the usefulness of the WBC count in febrile children evaluated in the outpatient setting. McCarthy and associates[61] concluded that a WBC count of 15,000/mm^3 or greater was helpful in identifying patients at greatest risk for the development of bacteremia. Dershewitz[32] found a direct relationship between the total leukocyte count and the prevalence of bacteremia and stated that "knowledge of the count was a helpful but limited predictor of patients with positive blood cultures." Other investigators reported that the incidence of bacteremia increased with an increased WBC count[85] and that bacteremia most commonly occurred in patients with counts of 20,000/mm^3 or higher.[66]

Other studies have examined the utility of the WBC count specifically in children with FWS who look well enough to be treated on an outpatient basis. One such study found a sensitivity of 1.0 and a positive predictive value of 0.11 for a total WBC count of 15,000/mm^3.[93] Using a WBC count of 20,000/mm^3 would have decreased the sensitivity to 0.4 while increasing the positive predictive value to only 0.13. In another series, the sensitivity for a WBC count of 15,000/mm^3 was 0.87, with a specificity of 0.73.[14] Kline and coworkers[50] found that a WBC count of 15,000/mm^3 was more sensitive for *S. pneumoniae* bacteremia than for *H. influenzae* bacteremia. Although a total WBC count of 15,000/mm^3 does not accurately predict which child is or is not bacteremic, it is helpful in dividing the population of children with FWS into high- and low-risk groups.

Some investigators have found the erythrocyte sedimentation rate to be no more useful than the WBC count in predicting bacteremia in ambulatory febrile patients.[61] Others have reported that the serum concentration of C-reactive protein (CRP) may be more accurate than is the complete blood count or erythrocyte sedimentation rate in distinguishing bacterial from viral infec-

tions.[59,75] However, recent studies reported conflicting data regarding the utility of the CRP test in screening children aged 3 to 36 months old for occult bacteremia.[44,82] An elevated serum procalcitonin level has been found by some investigators to be at least as sensitive and specific as is CRP in predicting SBI in children with fever and no localizing signs.[51,80]

Other hematologic findings that suggest bacteremia include thrombocytopenia,[29] Döhle inclusion bodies, toxic granulations, and vacuolization of neutrophils. In one study, peripheral blood smears of children younger than 24 months old with acute febrile illnesses were reviewed the following day by a single investigator to determine whether vacuolization and toxic granulations were present; when both abnormalities were present, the positive predictive value for bacteremia was 0.76.[53] The presence of these findings should be considered when estimating the risk for bacteremia.[1,29,69]

Several studies have examined the response to acetaminophen and found no difference in the rate of reduction of temperature or improvement in clinical appearance between bacteremic and nonbacteremic children.[9,95,102] Mazur and associates,[57] however, found that febrile children aged 2 months to 6 years old who did not respond to a dose of acetaminophen by a reduction in temperature of at least 0.8° C in 2 hours had a statistically significant increased risk of developing occult bacteremia in comparison to those who did respond.

The most important aspects of assessment of a febrile child are a careful history and physical examination. Laboratory data are secondary and should be ordered on the basis of the clinical assessment. By definition, a child with FWS has no localizing signs to explain the fever or indicate a site of infection. Many physicians suggest that a general impression can indicate whether the child has occult bacteremia. Some physicians have suggested that careful clinical judgment, based on extensive experience, can identify most, if not all, children with serious illnesses.[18] McCarthy and colleagues,[62-64] in a series of carefully designed studies, elucidated the variables of history and observation that were most useful in assessing febrile children. They found that observation of the variable *playfulness* had the strongest correlation with overall assessment.[63] However, they observed that even an experienced attending pediatrician could identify only 57 percent of seriously ill children by initial impression before performing a full physical examination. Dershewitz[32] found that private pediatricians were no more accurate than were pediatric residents in identifying children with occult bacteremia and that in the private office, pediatricians were no better at predicting bacteremia in familiar patients than in first-time patients.

In a study of 292 consecutive febrile children seen in an emergency department, Waskerwitz and Berkelhammer[97] identified a subgroup of patients who had no localizing signs and who looked so well that they were predicted not to have bacteremia. The physicians were assisted in their assessment by a functional scale that gave 0 to 2 points for the child's eating, drinking, sleeping, and play activities, with a best possible score of 8. The group of patients who had functional scores of 5 or greater, with no localized infection and predicted clinically not to have bacteremia, were free of bacteremia, whereas 14 of 202 patients with functional scores of 4 or less were bacteremic. In this study, the physicians were not able to identify which patients had bacteremia and which did not; rather, they were able to identify one subgroup at high risk for having bacteremia and another at very low risk. Teach and Fleisher[92] found that although Yale Observation Scale scores were higher in patients with bacteremia than in those without, the difference was not clinically useful in detecting bacteremia in well-looking febrile children without a discernible focus of infection. The clinician's overall assessment of the degree of illness of the child appears to be a valuable, but not infallible, tool in estimating the risk of occult bacteremia in children with FWS.

CLINICAL MANAGEMENT OF FEVER WITHOUT SOURCE

As many as 3 percent of children with FWS are bacteremic. Numerous studies (all performed before institution of the routine use of *H. influenzae* vaccine) have shown that if these children were not treated with antibiotics at the time of the initial clinical encounter, 5 to 10 percent would return with bacterial meningitis, 10 percent with localized bacterial infection, and another 30 percent with continued fever and persistent bacteremia.[14,21,43,56,60,61,66,93] In all of these retrospective studies, patients treated initially with antibiotics fared better than those not treated initially, although the decision regarding treatment always was at the discretion of the physician and was not randomized.

In a prospective, randomized investigation, Carroll and associates[25] studied 96 children between the ages of 6 and 24 months who had FWS and a temperature higher than 40° C (104° F). Of 10 patients who were bacteremic, 5 were treated initially with antibiotics on an outpatient basis and 5 were not treated. The difference in outcome between the two groups was statistically significant in favor of the treatment group; four of the five treated patients were improved clinically, as opposed to none of the five untreated patients. Bacterial meningitis did not develop in any of the treated patients, whereas it did develop in two of the five untreated patients. In a prospective, randomized, placebo-controlled study of empiric treatment with amoxicillin in children at risk for developing occult bacteremia, Jaffee and colleagues[46] showed no difference existed between treatment and nontreatment groups. However, the power of this study was low, and a true difference in outcome easily could have been missed.[5] The dosage of amoxicillin used was 125 mg three times daily for children who weighed 10 kg or less and 250 mg three times daily for those weighing more than 10 kg, so some children may have received as little as 37.5 mg/kg/day. Although this dosage is close to the usual recommended dosage of 40 mg/kg/day for infections such as otitis media, Baron and coworkers[15] suggested that considerably higher doses might be required to treat occult bacteremia. In a retrospective study of a private pediatric practice, these investigators found that no complications developed in 11 infants with FWS and bacteremia who initially received 150 mg/kg/day or more of amoxicillin ($p = 0.03$). In contrast, in 5 of 12 such infants not treated or treated with less than 100 mg/kg/day of amoxicillin, complications did develop. A study of the outcome of outpatient management of febrile children who proved to have pneumococcal bacteremia found that those not treated with antibiotics and those still febrile on re-evaluation were most likely to have persistent bacteremia.[6]

One should not be dogmatic about the management of children with FWS. One reasonable approach, based on a careful history, thorough physical examination, and overall clinical impression, is to classify these children as being at low or high risk for the development of occult bacteremia and other SBIs. For the low-risk group, no laboratory investigation is required routinely. For the high-risk group, a complete blood count and blood culture should be obtained. Lumbar puncture, chest radiography, urinalysis, and urine culture are considered on an individual basis. If the patient appears ill, admission to the hospital may be justified, even if all test results are negative. When high-risk children look well enough to be sent home, they are reasonable candidates for expectant antibiotic therapy, pending the outcome of blood culture. For patients clinically considered to be at moderate risk (not clearly high or low risk), the physician has the option of obtaining a WBC count and using the results to decide whether to draw blood for culture and prescribe antibiotics expectantly.

Table 70–1 lists risk factors for the development of occult bacteremia. Current information is not sufficient to warrant the use of scoring systems except as part of investigational series. In the final analysis, the clinician's judgment, taking into account all

TABLE 70–1 Risk Factors for Occult Bacteremia

Factor	High Risk	Low Risk
Age	≤24 mo	>36 mo
Magnitude of fever	≥40°C (104°F)	≤39.4°C (103°F)
White blood cell count	≥15,000/mm^3	<15,000/mm^3
Peripheral blood smear	Toxic granulation or vacuolization of polymorphonuclear leukocytes, thrombocytopenia	Unremarkable
Underlying chronic disorder	Sickle-cell disease, immunodeficiency, malnutrition	None
History of contact with bacterial disease	Contact with *Neisseria meningitidis* or *Haemophilus influenzae*	None
Clinical appearance	Appears ill, "toxic," or unhappy; inconsolable; irritable or lethargic; not eating or drinking enough	Looks well, playful, eating normally, not irritable

available clinical and laboratory data about each patient, is the guide to selecting which children require a diagnostic work-up and expectant therapy with antibiotics.

If the physician elects to prescribe antibiotics while awaiting the results of blood culture, such antibiotic therapy should provide adequate coverage for *S. pneumoniae*, *N. meningitidis*, and *H. influenzae*, although the frequency of *H. influenzae* has decreased dramatically with current immunization practice. A single injection of 50 to 75 mg/kg of ceftriaxone given while awaiting the results of blood culture has been successful in resolving fever, clearing bacteremia, and preventing meningitis and was found to be superior to oral regimens in several series.[13,16,38] Children with a positive blood culture should be recalled for re-evaluation, even if they are afebrile.

Because *S. pneumoniae* is a dominant cause of occult bacteremia, routine use of pneumococcal vaccine is expected to diminish the occurrence of occult bacteremia significantly. Children who have been immunized against both *H. influenzae* and *S. pneumoniae* should be considered to be at relatively low risk for the development of occult bacteremia and may require less work-up, unless they appear ill or have a very high fever.

Infants younger than 90 days old pose a special problem because they have an increased risk for developing SBI, clinical evaluation is more difficult, and a broader spectrum of invading organisms (e.g., group B *Streptococcus*, *E. coli*, *Listeria monocytogenes*) exists. Baker and coworkers[8] showed the safety of managing selected low-risk infants (i.e., normal WBC count, urinalysis, lumbar puncture, and chest roentgenogram and, if diarrhea was present, negative smear for fecal leukocytes) 30 to 90 days of age on an outpatient basis without antibiotics. Jaskiewicz and coworkers[48] found the Rochester criteria (WBC count of 5000 to 15,000/mm^3, band count <1500/mm^3, spun urine specimen <10 WBCs/high-power field, stool specimen [if diarrhea] <5 WBCs/high-power field) to have a 98.9 percent negative predictive value in well-appearing, previously healthy infants younger than 90 days old with no focal infections. One reasonable practice guideline for managing infants with FWS is to hospitalize and treat all who appear toxic and all younger than 28 days. Those between 28 and 90 days of age can be managed as outpatients if they look well and the blood count, urinalysis, and cerebrospinal fluid analysis are within normal limits.[10,11]

FEVER OF UNKNOWN ORIGIN

The exact definition of FUO is a subject of considerable disagreement, and series in the pediatric literature differ in their criteria for inclusion. Brewis[22] defined FUO in children as a temperature of 38.3°C (101°F) or higher for 5 to 7 consecutive days without localizing signs or symptoms. In sharp contrast, McClung[65] and Lohr and Hendley[54] considered children with fever for at least 3 weeks on an outpatient basis or 1 week in the hospital to have FUO. Pizzo and associates,[78] however, required only that the fever be present for 2 weeks, with no distinction made between outpatient or in-hospital status. A reasonable working definition of FUO for clinical purposes is the presence of fever for 8 or more days in a child for whom a careful and thorough history and physical examination and preliminary laboratory data fail to reveal a probable cause of the fever.

Most cases of FUO in children are caused by relatively common diseases. In four series of FUO totaling 418 children, only 5 patients would be considered to have rare disorders (i.e., Behçet syndrome, ichthyosis, variant of "blue diaper" syndrome, diencephalic seizure disorder, and "possible chronic lead and/or arsenic intoxication").[22,54,65,78] The adage that FUO is more likely to be caused by an unusual manifestation of a common disorder than by a common manifestation of a rare disorder certainly is true in pediatrics. The three most common discernible causes of FUO in children, in order of decreasing frequency, are infectious diseases, connective tissue diseases, and neoplasms. In approximately 10 to 20 percent of cases, a definitive diagnosis never is established.

In the United States, the systemic infectious diseases diagnosed most frequently in children with FUO include tuberculosis, brucellosis, tularemia, salmonellosis, and infections caused by rickettsia, spirochetes (e.g., leptospirosis), Epstein-Barr virus, cytomegalic inclusion virus, human immunodeficiency virus, hepatitis viruses, and other viruses. The most common causes of localized infection are upper respiratory tract infections (e.g., sinusitis, otitis, tonsillitis), urinary tract infection, osteomyelitis, and occult abscesses, including hepatic and pelvic abscesses.

The connective tissue disease most commonly manifested as FUO in children is juvenile rheumatoid arthritis, which accounts for more than 90 percent of connective tissue diseases in most series, followed by systemic lupus erythematosus and then by undefined vasculitis.[54,65,68,78] Frequently, a definitive diagnosis of juvenile rheumatoid arthritis can be made only after an extended period of observation because physical examination may yield no findings and the results of specific serologic studies generally are normal or negative.

Malignancy is a less frequent cause of FUO in children than in adults and usually is the third-largest group, after infectious diseases and connective tissue diseases. Malignancy accounted for 7 percent of FUO cases in the series reported by Pizzo and associates[78] and for 13 percent in the Lohr and Hendley[54] series. Leukemia and lymphoma are responsible for most cases of cancer manifested as FUO in children. Other tumors less commonly reported as causing FUO include neuroblastoma, hepatoma, sarcoma, and atrial myxoma.

Although the prognosis for children with FUO is better than that for adults and even though most children with FUO have treatable or self-limited disease, the overall prognosis is far from benign. Mortality rates were 9 percent in the series reported by Pizzo and associates[78] and 6 percent in Lohr and Hendley's series.[54] The prognosis for children in whom a definitive diagnosis is not established during the initial hospitalization is mixed. In most cases, the fever eventually resolves.[36] In some patients, a specific diagnosis is established, whereas other patients continue to have fever without a definitive diagnosis. McClung[65] described 11 such patients, most of whom appeared to do well despite having recurrent episodes of fever.

DIAGNOSTIC APPROACH TO A CHILD WITH FEVER OF UNKNOWN ORIGIN

A child with FUO is admitted to the hospital for more than simply laboratory investigation. Hospitalization provides an opportunity to observe the child, repeat the history and physical examination, analyze all available data, and investigate every potential diagnostic lead. In the Lohr and Hendley[54] series of 54 children with FUO, an incomplete history delayed establishing the diagnosis in 9 cases, and physical findings that were ignored delayed rendering the diagnosis in 4 cases. In McClung's report[65] of 99 pediatric cases of FUO, errors in the history or physical examination obscured the correct diagnosis for at least 10 patients. Failure to use existing laboratory data correctly is another common factor preventing early determination of the diagnosis in children with FUO.[54,78]

Clinical Evaluation

The first and most important step in the diagnostic work-up of a child with FUO is obtaining a complete and detailed history and conducting a physical examination. The clinical evaluation must be thorough and careful, and it must be repeated frequently. Often, a patient or parent eventually recalls information that was omitted or forgotten when the initial history was obtained. Physical findings change, and abnormalities not originally present can appear subsequently. Lohr and Hendley[54] noted that in more than 25 percent of children admitted to the hospital with FUO, significant physical findings developed that were not present at the time of admission.

A detailed history should be obtained regarding contact with infected or otherwise ill persons and any exposure to animals, including pets and wild animals. The number of children with zoonotic infections is increasing each year. Immunization of domestic animals such as the dog against leptospirosis can prevent canine disease, but it does not prevent carriage, excretion, and transmission of this infection. A history of travel extending back to birth must be elicited. Re-emergence of histoplasmosis, coccidioidomycosis, blastomycosis, or malaria years after visiting or living in an endemic area can occur. Inquiring about prophylactic immunizations, precautions taken against the ingestion of contaminated food or water, and malarial prophylaxis is important. Questioning should include the possibility that rocks, soil, or artifacts from geographically distant regions may have been brought into the home, as well as the possibility that contact with persons who have visited distant countries has occurred. Even contact with insects can be important. Tick bites can be a clue to Rocky Mountain spotted fever or tick-borne relapsing fever. North American mosquitoes and some ticks carry a variety of arboviruses.

The physician should determine whether the patient has eaten game meat, raw meat, or raw shellfish. A history of pica should be sought routinely. Ingestion of dirt can suggest a diagnosis of visceral larva migrans, toxoplasmosis, or other infectious diseases. A detailed history regarding all medications, including topical agents and nonprescription items, must be elicited carefully. Any history of surgical procedures should be explored.

Questions designed to determine the genetic or ethnic background of the patient can reveal information that specifically suggests or largely excludes diagnoses such as nephrogenic diabetes insipidus (found in Ulster Scots), familial Mediterranean fever (found in Armenians, Arabs, and Sephardic Jews), familial dysautonomia (found in Jews), and Kikuchi-Fujimoto disease, a benign and self-limited histiocytic necrotizing lymphadenitis (found mostly in young Asian females and characterized by fever, lymphadenopathy, and malaise).

The history should be exacting regarding the duration, height, and pattern of the fever, as well as the circumstances under which temperature elevation occurs, whether the child appears ill or any signs or symptoms develop, and how well the fever responds to antipyretic drugs. A history of "fever" occurring only after exercise or late in the afternoon can indicate parental concern about normal variations in body temperature. A history of high fever occurring in the absence of malaise or other generalized signs can be a clue to factitious fever. The physician also should obtain a careful history regarding how well the fever has been documented. Has a thermometer been used, by whom, and in whose presence? A history of sweating and heat intolerance can indicate hyperthyroidism, whereas a history of heat intolerance with the absence of sweating can be a clue to ectodermal dysplasia.

Several investigators have found that neither the pattern of fever nor its duration was useful in pointing to or establishing a diagnosis in children with FUO.[54,78] However, occasionally the character of the fever can be helpful. *Intermittent fever* is characterized by a return of temperature to normal at least once daily. If the peak of fever is high and the rate of defervescence quick, this pattern often is referred to as *hectic* or *spiking*. Intermittent fevers suggest pyogenic infections but also occur with tuberculosis, lymphoma, and juvenile rheumatoid arthritis. In *remittent fever*, the temperature fluctuates but does not return to normal. A *sustained fever* pattern is characterized by persistent fever with little or no fluctuation and can occur in typhoid fever or typhus. Antipyretic agents can make a remittent or sustained fever appear intermittent. *Relapsing fever* refers to a pattern in which the patient is afebrile for 1 or more days between episodes of fever and can be seen with malaria, rat-bite fever, infection with *Borrelia*, and lymphoma. Recurrent episodes of fever of more than a year's duration can suggest metabolic defects, central nervous system abnormalities in temperature control, and immunodeficient states.

The general activity and appearance of the patient should be observed, vital signs checked, and growth parameters measured. Weight loss is an important, though nonspecific, finding. Impairment of linear growth or short stature can be a clue to inflammatory bowel disease, an intracranial lesion involving the pituitary gland, or a long-standing chronic disease. Examining the patient during an episode of fever to observe the presence or absence of sweating, the effect of the fever on the heart and respiratory rate, the presence or absence of malaise or other symptoms, and the appearance of "toxicity" is helpful. The rash of juvenile rheumatoid arthritis characteristically is evanescent and may be present only during periods of temperature elevation.

Some special aspects of the physical examination merit mention. Hypohidrosis, anomalous dentition, and sparse hair, particularly involving the eyebrows and eyelashes, suggest anhidrotic ectodermal dysplasia. Palpebral conjunctivitis can be a clue to the presence of infectious mononucleosis, Newcastle disease, or lupus erythematosus, whereas predominantly bulbar conjunctivitis can suggest leptospirosis or Kawasaki disease. Phlyctenular conjunctivitis can signal tuberculosis.

Absence of the pupillary constrictor response can be caused by a deficiency of the constrictor sphincter muscle of the eye. This muscle, derived from ectoderm rather than mesoderm, develops embryologically at the same time that hypothalamic structures and function are undergoing differentiation. Absence of this muscle can suggest that the elevation in temperature is the result of hypothalamic or autonomic dysfunction. Careful funduscopic examination can disclose evidence of miliary tuberculosis, vasculitis, or toxoplasmosis. Lack of tears, absence of corneal reflexes, and a smooth tongue with absence of the fungiform papillae suggest familial dysautonomia.

Purulent or persistent nasal discharge can be a sign of sinusitis. The physician should palpate for tenderness over the sinuses.

Hyperemia of the pharynx, even in the absence of exudate or specific symptoms, can be a clue to the diagnosis of infectious mononucleosis, cytomegalic inclusion disease, toxoplasmosis,

tularemia, or leptospirosis. Gingival hypertrophy or inflammation and loosening or loss of teeth can indicate leukemia or Langerhans cell histiocytosis.

The bones and muscles should be palpated carefully. Tenderness over a bone can be found in cases of osteomyelitis or marrow invasion by neoplastic disease. Muscle tenderness can be associated with trichinosis, dermatomyositis, polyarteritis, or various arboviral infections.

The search for skin lesions and rash must be careful, extensive, and repeated. Petechiae can indicate endocarditis or other sources of bacteremia but also can occur with viral and rickettsial infections. A seborrheic rash can be a sign of histiocytosis.

A careful rectal examination is imperative for patients of all ages and can reveal pararectal tenderness or a mass indicative of a pelvic abscess or tumor. A test for occult blood should be performed on any stool found on the examining finger. Examination of the external genitalia should be completed on patients of all ages, and sexually active adolescent females should undergo a pelvic examination.

Laboratory Evaluation

The extent of laboratory investigation depends on the age of the patient, duration of the fever, and history and physical examination findings. Laboratory studies should be directed, as much as possible, toward the most likely diagnostic possibilities. The tempo of the diagnostic evaluation should be adjusted to the severity of the illness. In a critically ill child, speedy evaluation is important. If the patient is less severely ill, however, the evaluation can proceed more slowly; sometimes the fever can disappear without apparent explanation before a definitive diagnosis can be established and any invasive diagnostic procedures have been undertaken.

A complete blood count and careful examination of the peripheral smear are indicated for all patients. Anemia, thrombocytosis, and thrombocytopenia should be noted. Although mild or moderate changes in the total WBC or differential count usually are of no help, in some series, children with more than 10,000 polymorphonuclear leukocytes or 500 nonsegmented neutrophils/mm^3 were found to have a greater likelihood of having SBI.[89,94] Atypical lymphocytes generally indicate viral infection, whereas bizarre or immature forms can suggest leukemia. Although the erythrocyte sedimentation rate is of no specific diagnostic value, it is a general indicator of inflammation and can help in ruling out factitious fever, determining the need for further evaluation, and monitoring the progress of the disease process.

Blood should be obtained from all patients for aerobic and anaerobic culture. In select cases, media appropriate for the isolation of *Francisella* organisms, *Leptospira*, and *Spirillum* also should be used.

Urine analysis and culture should be completed for all patients. In one series of FUO in children, failure to perform urinalysis and failure to investigate pyuria adequately were the most common laboratory errors.[65] Radiographic study of the urinary tract, however, should be performed only when indicated.

All patients should undergo radiographic examination of the chest. Diagnostic imaging of the nasal sinuses, mastoids, and gastrointestinal tract is performed initially only for specific indications but should be done eventually in all children whose fever persists without explanation for a long period. Persistent fever and elevation of the erythrocyte sedimentation rate, with or without anemia, abdominal complaints, anorexia, and weight loss, are sufficient indications for radiographic study to rule out inflammatory bowel disease.

All patients should have an intradermal tuberculin skin test. Control skin tests with antigens such as *Candida* are of limited value because the anergy may be specific for tuberculosis rather than universal for all skin-testing materials.[55,67,71,72] A positive control test result and negative tuberculin test result do not rule out tuberculosis.

Bone marrow examination is most useful in diagnosing cancer (especially leukemia), histiocytic disorders, and hemophagocytic disease. It is less useful in determining infection. Hayani and associates[41] reviewed the results of 414 bone marrow examinations for FUO in children. In only one case was an organism (*Salmonella* group D) recovered from the marrow that also was not recovered from blood or another source. Noninfectious causes of FUO were found in 8 percent of specimens: malignancy (6.7%), hemophagocytic syndrome (HPS, 0.7%), histiocytosis (0.5%), and hypoplastic anemia (0.2%). In most of these cases, the diagnosis had been suspected clinically before the bone marrow was examined.

All patients should undergo a serum test for human immunodeficiency virus infection. Other appropriate serologic tests can help establish a diagnosis of cat-scratch disease, brucellosis, tularemia, Epstein-Barr virus infection, cytomegalic inclusion virus infection, other viral infections, toxoplasmosis, and certain fungal infections.

Hepatic enzymes and serum chemistry, including electrolytes, urea nitrogen, and creatinine, should be determined in all patients. Serum antinuclear antibody should be measured in those older than 5 years. Serum hepatitis antigens, electrocardiography, electroencephalography, echocardiography, and stool culture and examination for ova and parasites generally should be performed in selected cases. Other tests to be considered for individual patients include ophthalmologic examination by slit lamp, radiographic bone survey, technetium bone scan, liver-spleen scan, and abdominal imaging by ultrasonography or computed tomography.[24,77] Computed tomographic scanning, gallium scanning, and indium 111 scanning[37] can detect inflammatory lesions and tumors. Such scanning procedures offer a relatively noninvasive technique for screening patients with FUO for a variety of disorders. Although Steele and associates[88] found that radionucleotide scans seldom led to unsuspected diagnoses in children and suggested that they not be used indiscriminately, gallium scanning has been helpful in diagnosing adult patients with FUO,[40] and it may be a reasonable test for selected children. Lymph node biopsy, liver biopsy, and exploratory laparoscopy are reserved for patients with evidence of involvement of these organs.

In general, antibiotics or other medications should not be administered empirically as a diagnostic measure in children with FUO. Exceptions include the use of nonsteroidal agents in children with presumed juvenile rheumatoid arthritis and the use of antituberculous drugs in critically ill children thought to have disseminated tuberculosis. Empiric trials of broad-spectrum antibiotics generally do more to obscure than illuminate the etiology of FUO and can mask or delay establishing the diagnosis of infections such as meningitis, parameningeal infection, endocarditis, or osteomyelitis.

Examples of disorders that can be manifested as FUO in children are listed in Table 70–2. A few of these disorders are discussed briefly in the following sections.

INFECTIOUS CAUSES OF FEVER OF UNKNOWN ORIGIN

Infectious causes of FUO can be divided into systemic and localized. Immunodeficient states may be considered under the general classification of infections.

Generalized Infections

BRUCELLOSIS

The manifestation of this disease as FUO is explained by the nonspecific symptoms that it engenders and by the chronicity of

untreated infection. Many physicians, particularly in urban areas, tend to ignore the possibility of this disease and neglect to inquire about a history of exposure to animals or animal products, especially the consumption of unpasteurized goat's milk cheese (see Chapter 139).

CAT-SCRATCH DISEASE

During recent years, many children with FUO have proved to be infected with *Bartonella henselae*. Cat-scratch disease is one of the most common causes of FUO in patients seen at the infectious disease service at Texas Children's Hospital in Houston.[4] Most of the children with this manifestation of cat-scratch disease have hepatosplenic involvement. Jacobs and Schutze[45] reported that *B. henselae* infection was the cause of 4.8 percent of all cases of FUO at the Arkansas Children's Hospital and 10.9 percent of the cases of FUO caused by infection. *B. henselae* infection is best diagnosed by serologic evaluation (i.e., immunofluorescence assay that detects serum antibody to *B. henselae*). Biopsy of lesions (e.g., lymph nodes, liver, bone marrow) may allow visualization of bacilli with the Warthin-Starry silver stain; however, this finding is not specific for *B. henselae*. Management of patients with cat-scratch disease is primarily symptomatic because the disease usually is self-limited. Antimicrobial therapy can be helpful in acutely or severely ill patients, especially those with hepatosplenic disease. Several oral antimicrobial regimens (rifampin, trimethoprim-sulfamethoxazole, azithromycin) and parenteral gentamicin have been used successfully for the treatment of this disease. In particular, rifampin at a dose of 20 mg/kg/day in two divided doses for 14 days has been particularly efficacious.[4] However, the optimal duration of therapy is not known.

LEPTOSPIROSIS

Leptospirosis is caused by a single family of organisms composed of multiple serotypes; it is one of the most widespread zoonoses in the world. Transmission of infection from animal to human can occur by direct contact with the blood, tissue, organs, or urine of infected animals or indirectly by exposure to an environment that has been contaminated by leptospires. The organism also can be acquired from soil or from fresh water after ingestion. Reports indicate that leptospirosis is not a rare disease, that many infections are not associated with occupational exposure, and that urban and suburban cases are becoming more prevalent.[26] Clinical manifestations of leptospirosis usually are not specific. A variety of laboratory aids are available, but specimens must be collected and handled properly. In some cases, establishing a definitive diagnosis may be impossible; negative cultures or failure to demonstrate a rise in antibody titer does not exclude the possibility that the patient has active infection because the organism may not be present in the specimens that have been cultured, the antibody titer may have peaked before an acute-phase specimen was collected, and antibiotic therapy may suppress the development of positive titers or delay their appearance (see Chapter 154).

TOXOPLASMOSIS

Toxoplasmosis should be considered in any child with persistent fever. Cervical or supraclavicular adenopathy is present in most cases, but occasionally fever is the only manifestation. The diagnosis is established by demonstration of a rising serologic titer; antibody to *Toxoplasma gondii* is so prevalent that demonstration of a high titer alone is not diagnostic of acute infection. Demonstration of *Toxoplasma* in tissue sections or body fluid is highly suggestive, although the organism can persist in tissue for years. Isolation of the parasite is not absolutely diagnostic of recent infection (see Chapter 235).

MALARIA

Malaria also should be considered in children with FUO. In addition to fever, splenomegaly usually is present. A history of travel to endemic areas should be sought, although malaria has occurred

in patients who never traveled outside the United States. Disease can occur even in persons who have taken antimalarial drugs when they visited the endemic region. A hiatus of several months can occur between the development of infection and the onset of symptoms. The infection can be transmitted from a person who has visited an endemic area to one who has not when an appropriate mosquito vector is present. Malaria also can be acquired by blood transfusion or by the use of needles and syringes contaminated by the parasite. Demonstration of malarial organisms on appropriately stained thin or thick smears of blood is diagnostic (see Chapter 231).

SALMONELLOSIS

Salmonella organisms are contaminants in many food products. In view of the nonspecific signs and symptoms with which salmonellosis can occur, its association with FUO in children is not surprising. Repetitive blood and stool cultures are most helpful in establishing a diagnosis (see Chapter 121).

TUBERCULOSIS

Tuberculosis is an important cause of FUO in children, as well as in adults. Nonpulmonary tuberculosis is manifested as FUO more frequently than pulmonary tuberculosis is, which usually is evident on routine chest radiographs. FUO occurs most commonly with disseminated tuberculosis or infection of the liver, peritoneum, pericardium, or genitourinary tract. Active disseminated tuberculosis has been well documented in children with negative results on chest radiography and tuberculin skin tests.[72,90] A high index of suspicion and a careful history of possible contacts can be the best diagnostic tools. Funduscopic examination can reveal choroid tubercles. Liver and bone marrow frequently are involved in children with miliary tuberculosis; liver biopsy specimens and bone marrow aspirates should be obtained and processed for morphologic evaluation and culture. If the chest radiograph yields abnormal results, cultures of gastric aspirates, sputum, or both should be obtained. Because nontuberculous mycobacteria (i.e., atypical organisms) are present in the gastric contents of normal individuals, demonstration of acid-fast organisms on smears of gastric secretion does not indicate disease necessarily. Rarely, a patient with tuberculous pericarditis has fever, weight loss, and weakness but no precordial pain or other specific cardiac complaints. Disseminated infection with atypical mycobacteria generally is seen in patients infected with human immunodeficiency virus (see Chapter 107).

TULAREMIA

Generally, failure to consider tularemia in children with FUO may be attributed to a lack of appreciation of the many sources of infection and the various routes of inoculation. The organism can be acquired from contact with a variety of animal species, as well as from ticks, mosquitoes, lice, fleas, flies, and contaminated water. The organism can penetrate mucous membranes and broken or unbroken skin, or it can be inhaled or swallowed. Patients and parents should be questioned about animal contact and the ingestion of rabbit or squirrel meat (see Chapter 144).

VIRAL INFECTIONS

Infection by most viruses produces an illness that is relatively brief. Exceptions to this rule include infections by cytomegalovirus, Epstein-Barr virus, hepatitis viruses, and certain arboviruses. In all of these diseases, symptoms are extremely variable and signs and symptoms frequently are nonspecific. The diagnosis can be established by appropriate cultures and serologic studies (see Section 17 and Chapter 264).

IMMUNODEFICIENCY

A variety of congenital and acquired immunodeficiency states can be manifested as FUO. Patients with immunoglobulin deficiencies (e.g., Bruton agammaglobulinemia) may have a long history of recurrent fever, with or without evident infection, whereas patients with abnormalities in lymphocyte function are more likely to have prolonged fever caused by persistent viral or parasitic infection.

Localized Infections

BACTERIAL ENDOCARDITIS

Infective endocarditis is an infrequent cause of FUO in children. Acute bacterial endocarditis tends to be fulminant in nature, but the subacute form begins insidiously, generally at the site of a preexisting cardiac lesion. Subacute bacterial endocarditis is a rare occurrence in infants and increases in frequency with advancing age. The organisms most commonly encountered are viridans streptococci, enterococci, *S. aureus*, and *Staphylococcus epidermidis*. The absence of a cardiac murmur does not exclude the possibility of endocarditis, especially when the infection is limited to the right side of the heart. Endocarditis also can occur in the absence of positive blood cultures, particularly in association with the following factors: use of antibiotics for an undefined febrile illness, right-sided cardiac lesions, prolonged duration of disease, infection by unusual organisms such as *Brucella* or *Coxiella burnetii*, and inadequate culture methods for the detection of infection with anaerobic organisms. Frequently associated laboratory findings include anemia, leukocytosis, and an elevated erythrocyte sedimentation rate. Several blood cultures (aerobic and anaerobic) should be obtained before starting antibiotics. Echocardiography and gallium scanning can reveal vegetations, but negative results do not rule out endocarditis (see Chapter 32).

BONE AND JOINT INFECTIONS

Infections of bones and joints usually can be diagnosed clinically but occasionally are manifested as FUO. This manifestation occurs commonly in young children who cannot explain where they hurt and is more likely to occur with osteomyelitis than with septic arthritis. Infection of the pelvic bones is implicated most often in this regard. Radioisotopic bone scan and magnetic resonance imaging are more sensitive than are plain radiographs of the bones (see Chapters 61 and 62).

INTRA-ABDOMINAL ABSCESSES

Subphrenic, perinephric, and pelvic abscesses may be manifested as FUO. A history of previous intra-abdominal disease or abdominal surgery or a history of vague abdominal complaints should heighten suspicion of an intra-abdominal collection of pus. The organisms involved most commonly are *S. aureus*, streptococci, *E. coli*, and anaerobic flora. Fever may be the only sign of a pelvic, perinephric, or psoas abscess. Urinalysis generally yields normal results, but the mass can be demonstrated by ultrasound examination, gallium scan, or computed tomography.

LIVER ABSCESS AND OTHER HEPATIC INFECTIONS

Pyogenic liver abscesses are encountered most frequently in immunocompromised pediatric patients but can be seen in otherwise normal children.[49] In some patients, persistent fever is the only finding. Blood cultures usually are sterile, and serum levels of liver enzymes generally are close to or within normal limits. Many patients have hepatomegaly and right upper quadrant abdominal tenderness. The diagnosis can be established by examination of the liver by ultrasonography, radioisotope scanning,

computed tomography, or magnetic resonance imaging; a body gallium scan also can yield positive results. Bacterial hepatitis and bacterial cholangitis can occur in the absence of jaundice and other specific signs of liver dysfunction.[98,101] Granulomatous hepatitis is not a specific disease but rather a syndrome characterized by granuloma formation within the liver. A specific cause cannot be determined in every case. Although most reported cases have been in adults,[86] pediatric cases do occur, particularly with Epstein-Barr virus infection and with cat-scratch disease. The diagnosis can be made by ultrasound or other diagnostic imaging (see Chapter 55).

UPPER RESPIRATORY TRACT INFECTIONS

Frequently, infections of the upper respiratory tract and related organs are manifested as FUO.[54,65,78] Although obvious signs or symptoms would be expected, the complaints often appear trivial and may be ignored. Reported cases of FUO have occurred in children with mastoiditis, sinusitis, chronic or recurrent otitis media, chronic or recurrent pharyngitis, tonsillitis, peritonsillar abscess, and nonspecific upper respiratory tract infection. A parapharyngeal inflammatory pseudotumor manifested as FUO has been reported in a 3-year-old girl in whom anemia and weight loss also developed. The cause never was discerned, but the symptoms resolved after surgical removal of the inflammatory mass.[27]

A syndrome of periodic fever has been associated with recurrent aphthous stomatitis, pharyngitis, and cervical adenitis. Symptoms recur at 4- to 6-week intervals, generally beginning abruptly and resolving spontaneously in 4 to 5 days. The cause of this syndrome remains unknown.[35]

NONINFECTIOUS CAUSES OF FEVER OF UNKNOWN ORIGIN

Central Nervous System Dysfunction

Children with severe brain damage can have dysfunctional thermoregulation, and body temperature in some of these patients can remain elevated for months. Cases of otherwise neurologically normal children who have had fever as a result of central dysfunction also have been reported. Berger[17] discussed a 16-year-old child with recurrent episodes of fever that were thought to represent a form of epilepsy but disappeared when treatment with phenytoin was begun. Wolff and associates[99] reported a 14-year-old child with cyclic episodes of fever, nausea, vomiting, and emotional disturbance caused by a central nervous system lesion.

Diabetes Insipidus

Central and nephrogenic diabetes insipidus can cause FUO in infants and young children. Polyuria and polydipsia may not be appreciated during infancy. Hyperthermia, weight loss, and peripheral vascular collapse can ensue. Signs of dehydration or an increased serum concentration of sodium suggests the diagnosis. The diagnosis is established by simultaneous measurements of urine and serum electrolytes and osmolality during periods of normal hydration and after carefully controlled periods of water deprivation. Serum levels of antidiuretic hormone also can be measured by radioimmunoassay.

Drug Fever

Nearly any medication can be associated with an allergic reaction, including fever. The offending agent may be a prescribed drug, an over-the-counter preparation, or a street drug such as amphetamine or PCP (1-[1-phenylcyclohexyl]piperidine, phencyclidine). Atropine, whether taken systemically or used topically in the form of eyedrops, can cause elevation of temperature. Phenothiazines and anticholinergic drugs can inhibit sweating and impair regulation of temperature. Epinephrine and related compounds can affect thermoregulatory control mechanisms and produce fever. Drug fever can be low-grade or high and spiking. Fever can be continuous or intermittent. Discontinuation of the drug generally is followed by disappearance of the fever within 48 hours, but it sometimes persists for as long as a month as a result of slow excretion of the offending agent.

Factitious Fever

A parent or patient may report the presence of fever that does not exist. The reading of the thermometer can be increased by immersing the bulb in hot liquid or by rinsing the mouth with hot liquid immediately before inserting the thermometer. Clues to factitious fever include absence of tachycardia, malaise, or discomfort despite a markedly elevated temperature; apparent rapid defervescence unaccompanied by diaphoresis; failure of the temperature curve to follow the normal diurnal variation of body temperature; hyperpyrexia; and normal temperature reading when the temperature is obtained rectally by someone who remains in attendance during the procedure. The presence of fever also can be confirmed or excluded by measuring the temperature of a freshly voided urine specimen. The current use of electronic thermometers in most hospitals decreases the possibility of factitious fever in that setting because the nurse or aide usually brings in the thermometer and stays in attendance during the relatively brief period of insertion. In more unusual cases, the patient or parent can induce fever by the injection of infective or foreign materials.

Familial Dysautonomia

Familial dysautonomia (Riley-Day syndrome), an autosomal recessive disorder, is characterized by autonomic and peripheral sensory nerve dysfunction. Eighty percent of patients are children of Jewish parentage, particularly Ashkenazi Jews. Defective regulation of temperature can result in hypothermia or hyperthermia.[30]

A careful history and physical examination can reveal the following: poorly coordinated swallowing movements that lead to recurrent aspiration and pneumonia; recurrent episodes of vomiting; excessive salivation; excessive or diminished sweating; diminished formation of tears; periods of hypotension, hypertension, or both; and erythema or blanching of the skin. The fungiform papillae of the tongue are absent or diminished in number, and the sensation of taste is deficient.[87] Self-mutilation or multiple sites of skin trauma can reflect diminished or absent pain sensation peripherally. Deep tendon reflexes are diminished; corneal reflexes are impaired; and mental deficiency, dysarthria, and emotional lability are common findings.

Excretion of vanillylmandelic acid in urine can be diminished, and excretion of homovanillic acid can be increased. Administration of histamine intradermally can produce a wheal but no flare or pain at the site of injection. Placement of methacholine (2.5%) into the conjunctival sac produces pupillary constriction in children with familial dysautonomia but no response in a normal child. Intravenous infusion of norepinephrine is followed by an exaggerated pressor response, and the hypotensive response to infusion of methacholine is increased.

Hemophagocytic Syndrome

HPS is characterized by prolonged fever, hepatosplenomegaly, cytopenia, and hemophagocytosis in the bone marrow, liver, spleen, or lymph nodes.[47,73] It is a life-threatening and unusual disorder in which uncontrolled proliferation of activated lympho-

cytes and histiocytes results in unregulated hypersecretion of inflammatory cytokines. HPS can be primarily a familial disease or can be manifested as a reactive process triggered by infection, malignancy, immunologic disease, or drugs.

The diagnosis of HPS is suggested by fever, hepatosplenomegaly, cytopenia in at least two cell lines, hypertriglyceridemia or hypofibrinogenemia, and an elevated ferritin level. Because HPS can be manifested initially as FUO and progress to masquerade as overwhelming sepsis, a high index of suspicion is required for establishing the diagnosis. Further investigation should include evaluation of bone marrow, cerebrospinal fluid, or lymph nodes for the presence of hemophagocytosis. Therapy should include treatment of the underlying infection or trigger, if one exists, in addition to appropriate immune modulation therapies. A substantial proportion of HPS cases progress rapidly to death despite administration of appropriate chemotherapy.[47,73]

Inflammatory Bowel Disease

Fever is a prominent feature in many children with inflammatory bowel disease.[28,52,96] A greater percentage of children than adults with regional enteritis have fever. Appropriate contrast-enhanced radiographic studies of the intestines should be undertaken in children with prolonged FUO, even in the absence of findings specifically referable to the gastrointestinal tract, especially if the erythrocyte sedimentation rate is elevated and if the patient has anemia, weight loss, failure of linear growth, or a positive stool guaiac test.

Ulcerative colitis can be manifested as FUO, though less commonly than with regional enteritis. In patients with ulcerative colitis, symptoms referable to the gastrointestinal tract generally are present at the time that the patient is febrile.

Infantile Cortical Hyperostosis

The cause of infantile cortical hyperostosis (i.e., Caffey disease) is unknown. The decreased incidence in recent years suggests an infectious, possibly a viral, cause. Spontaneous hyperplasia of subperiosteal bone begins during infancy and is associated with swelling of the overlying tissues. The skull, mandible, clavicles, scapula, and ribs are affected most frequently, but in some children the long bones and even the metatarsal bones can be involved. Most patients have persistent fever, sometimes as high as 40° C (104° F). Tenderness over the affected regions, irritability, elevated erythrocyte sedimentation rate, and leukocytosis are common findings. The diagnosis is established by the clinical picture in conjunction with radiographically demonstrated periosteal involvement.

Juvenile Rheumatoid Arthritis

Juvenile rheumatoid arthritis is a chronic inflammatory disorder that usually is manifested as one of three distinct syndromes: the systemic form, characterized by high, spiking temperatures (generally once or twice each day), evanescent rash, and lymphadenopathy; a polyarticular form; and a monarticular or pauciarticular form. Fever is associated with all three manifestations but occurs most commonly in the systemic form, in which case it is present in nearly 100 percent of patients. This form also is the one most likely to be manifested as FUO.[23] Arthritis may not develop for months to years after onset of the fever. The diagnosis often needs to be made by exclusion because serologic tests generally are negative.

Periodic Fevers

Familial Mediterranean fever is characterized by episodic fever and abdominal pain.[34] This disease, found in persons of Mediterranean ancestry, is inherited as an autosomal recessive trait. The pattern of recurrent fever, however, is irregular, with varying periods of normality between episodes of fever.

Reimann[83] called attention to a group of patients with recurrent episodes of fever at regular intervals, usually 7 to 21 days. Some of the patients had leukopenia and abdominal or thoracic pain. Reasons for the fever and its periodicity remain unknown. Patients with cyclic neutropenia frequently have fever during acute episodes, but not all the patients reported by Reimann had neutropenia. Cases of children with periodic fever and hyperimmunoglobulinemia D, with or without chills, cervical lymphadenopathy, and occasionally abdominal pain, have been reported,[33,39] primarily from Europe. The cause of the syndrome remains unknown.

CHAPTER 71

Toxic Shock Syndrome

Jeffrey Suen ✪ P. Joan Chesney ✪ Jeffrey P. Davis

Much has been learned about the pathogenesis and pathophysiology of toxic shock syndrome (TSS) since its initial description in 1978 by Dr. James K. Todd and colleagues.[305] The clinical illness is defined by the criteria listed in the case definition formulated for epidemiologic studies (Table 71–1). Though often confused with septic shock, TSS has unique clinical manifestations not generally noted in septic shock, including diffuse erythroderma, delayed desquamation of the palms and soles, conjunctival and pharyngeal hyperemia, muscle injury, rapidly accelerated renal failure, and gastrointestinal symptoms. The capillary leak syndrome, or rapid and massive loss of fluid from capillaries into the interstitial space, loss of peripheral vascular resistance, and subsequent multisystem end-organ failure further characterize this entity. The histopathologic findings are minimal and nonspecific, with extensive interstitial edema of all tissues and minimal perivascular mononuclear cellular infiltrates. TSS can recur after both menstrual and nonmenstrual cases. The highest recurrence rate of 65 percent was reported in a subset of untreated women with menstrual TSS who continued to use tampons during menses.

TABLE 71–1 Clinical Case Definition of Toxic Shock Syndrome

Clinical Findings
Fever: Temperature ≥38.9°C
Rash: Diffuse macular erythroderma
Desquamation: 1-2 wk after onset of illness, particularly on palms, soles, fingers, and toes
Hypotension: Systolic blood pressure ≤90 mm Hg for adults; <5th percentile by age for children <16 yr old; orthostatic drop in diastolic blood pressure ≥15 mm Hg from lying to sitting; orthostatic syncope or orthostatic dizziness
Involvement of three or more of the following organ systems:
Gastrointestinal: Vomiting or diarrhea at onset of illness
Muscular: Severe myalgia or creatinine phosphokinase level greater than twice the upper limit of normal for the laboratory
Mucous membrane: Vaginal, oropharyngeal, or conjunctival hyperemia
Renal: BUN or serum creatinine greater than twice the upper limit of normal or ≥5 white blood cells per high-power field in the absence of a urinary tract infection
Hepatic: Total bilirubin, AST, or ALT greater than twice the upper limit of normal for the laboratory
Hematologic: platelets <100,000/mm^3
Central nervous system: disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent
Negative results on the following tests, if obtained:
Blood, throat, or cerebrospinal fluid cultures; blood culture may be positive for *Staphylococcus aureus*
Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles
Case Classification
Probable: A case with 5 of the 6 clinical findings described above
Confirmed: A case with all 6 of the clinical findings described above, including desquamation, unless the patient dies before desquamation could occur

ALT, alanine transaminase; AST, aspartate transaminase; BUN, blood urea nitrogen.
From Wharton, M., Chorba, T. L., Vogt, R. L., et al.: Case definitions for public health surveillance. M. M. W. R. Recomm. Rep. 39(RR-13): 1-43, 1990.

When first described, TSS had unique geographic, age, sex, and racial characteristics. It was associated with menses, particularly tampon use, as well as with a phenotypically distinctive type of *Staphylococcus aureus*. In 1994, at least 42 percent of reported cases of TSS were nonmenstrual. *S. aureus* exotoxins now are recognized to be "superantigens," and the endogenous mediators produced by these exotoxins appear to mediate manifestations of the disease.

TSS toxin I (TSST-I) and the staphylococcal enterotoxins are extremely potent stimuli of the in vitro macrophage production of interleukin-1 (IL-1) and tumor necrosis factor-α (TNF-α) and the T-lymphocyte production of IL-2, lymphotoxin (TNF-β), and interferon-γ. These staphylococcal exotoxins are functionally bivalent mitogens that highly selectively bind to major histocompatibility complex (MHC) class II receptors on antigen-processing cells and to selected V_β elements of the T-cell receptor (TCR) specific for each toxin. They now are known as superantigens. Besides *S. aureus*, other bacteria, particularly *Streptococcus pyogenes*, also can produce exotoxins that function as superantigens and produce a toxic shock–like syndrome.

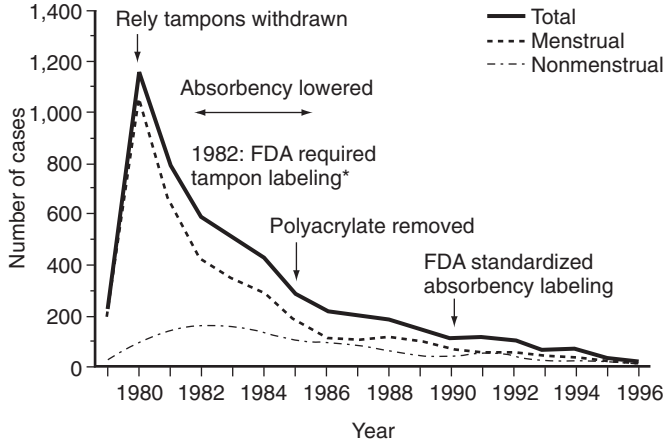
HISTORY

Illnesses resembling TSS and associated with *S. aureus* have been reported since 1927,[7,95,108,293,325] but the initial description of the illness as a disease of children was published in 1978.[305] A Kawasaki-like syndrome described in adults subsequently was recognized to be TSS.[201] The first 12 cases of TSS identified in Wisconsin and Minnesota between July 1979 and January 1980 were reported by state epidemiologists to the Centers for Disease Control and Prevention (CDC) in January 1980.[75,277,315] All 12 cases had occurred in women, and a possible association with

menses was noted. The probable recurrent nature of the illness also was reported.[75,315] In May 1980, the CDC reported findings of the first 55 nationally reported cases,[315] 95 percent of which occurred in women. Of 40 patients for whom a menstrual history was obtained, 38 (95%) had onset during menstruation. Thirteen patients had experienced recurrent episodes of TSS.

By June 1980, case-control studies statistically linking the occurrence of menstrual TSS with tampons had been completed by the Wisconsin Division of Health[75] and the CDC,[277] and similar trends had been noted by the Utah Department of Health.[162] In September 1980, the CDC reported that although TSS had been associated with many tampon brands, women using one particular brand of tampon, Rely (Procter & Gamble), were at greatest risk. This brand was withdrawn immediately and voluntarily from the market by the manufacturer.[24,120,264] Subsequent frequent updates by the CDC documented a decrease in reported cases.[316,317,320]

Microbiologic studies have established that most patients with menses-associated TSS (menstrual TSS) have evidence of vaginal or cervical colonization with *S. aureus*.[22] These strains of *S. aureus* made a characteristic toxin initially called *staphylococcal enterotoxin F*[23] and *pyrogenic exotoxin C*[270] and now known as *TSST-1*.



*FDA, Food and Drug Administration, including definite and probable toxic shock syndrome cases

Figure 71–1 Menstrual and nonmenstrual toxic shock syndrome cases reported to the Centers for Disease Control and Prevention by year, 1979 to 1996. *(From Hajjeh, R. A., Reingold, A., Weil, A., et al.: Toxic-shock syndrome in the United States: Surveillance update, 1979-1996. Emerg. Infect. Dis. 5:807-810, 1999.)*

EPIDEMIOLOGY

SURVEILLANCE AND INCIDENCE

Statewide surveillance for cases of TSS began in Wisconsin[77] and Minnesota[229] in January 1980, in Utah in February 1980,[175] and in other states after the national communications about TSS in spring 1980. In 1982, TSS became a nationally notifiable disease. Between 1983 and 1994, the CDC received reports of 4192 cases of TSS through the National Electronic Telecommunications System for Surveillance (NETSS).[296] The National Center for Infectious Diseases at the CDC maintains a database of TSS cases, including those reported before 1983. In addition, in January 1981, the National Center for Health Statistics recommended use of the International Classification of Diseases (ICD) code 040.89 for TSS, and a study involving reviews of records in 97 percent of Wisconsin general hospitals demonstrated that by 1983 the sensitivity and specificity of using this code in this review of discharge coding was 85 and 95 percent, respectively.[137] Since 1983, a continued downward trend in passively reported cases has been noted (Fig. 71–1).[330]

Of 2509 confirmed cases reported to the CDC through April 1984, 95 percent occurred in females.[249] Among the 2295 women with known menstrual histories, 89 percent had an onset of TSS associated with menstruation. Of 1716 menses-associated cases for which information related to tampon use was available, 99 percent occurred in tampon users and 1 percent in women using napkins or minipads.

The results of an active surveillance study conducted by the CDC in 1986 and 1987 in five states and Los Angeles County confirmed the trends previously noted in the CDC passive surveillance system.[127] The incidence of menstrual TSS was found to be 1 case per 100,000 women aged 15 to 44 years. This rate is a substantial reduction from the reported rates of 2.4 to 12.3 cases per 100,000 women of menstruating age in 1980.[75,175,229,241] Only 55 percent of the cases detected in the 1986-1987 study occurred in women, and 45 percent of all cases were menstrually associated.[38,127] The nationally reported TSS-related mortality rate for menstrual cases decreased from 5.5 percent in 1979 and 1980 to 2.8 percent in 1981 to 1986, then to 1.8 percent in 1987 to 1996 (chi-square for linear trend, $p = 0.0001$).[133]

The striking reduction in the incidence of menstrual TSS was attributed to a decrease in tampon absorbency, changes in composition of tampons and patterns of use, and the impact of publicity on early recognition of symptoms.[77,78,111,228,248,274] Since the 1980s, there has been a paucity of active surveillance data on TSS. Passive reporting during 2000 to 2003 in Minneapolis–St. Paul, Minnesota, suggested an increasing incidence of menstrual TSS cases from 0.8 per 100,000 to 3.4 per 100,000 women of menstrual age.[271] Subsequently, a medical record search for illnesses during 2000 to 2003 that had TSS-based, ICD-9 discharge codes (040.82 or 040.89) and a 20 percent random sample of five other shock or sepsis codes with review of cases was conducted in 25 Minneapolis–St. Paul metropolitan area hospitals. The incidence was not calculated, but the number of menstrual TSS cases (n = 23) was similar to the number of nonmenstrual cases (n = 21), and the gradual increase in total cases from 2000 (n = 9) to 2003 (n = 13) was not significant. Cases associated with methicillin-resistant *S. aureus* (MRSA) and new sites of staphylococcal infection (lung, urinary tract) were noted.[86]

In 1986 and 1987, the incidence of nonmenstrual TSS in women (0.25 case per 100,000 women) and TSS in men (0.16 case per 100,000 men) had changed little since 1980. However, with the declining trend in menstrual TSS, nonmenstrual TSS has accounted for a greater proportion of overall TSS cases. In 1994, only 192 cases of TSS were reported to the CDC through the NETSS (0.1 case per 100,000 population). Among confirmed cases, 42 percent were nonmenstrual.[296] The proportion of nonmenstrual cases reported after surgical procedures increased from 14 percent during 1979 to 1986 to 27 percent during 1987 to 1996.[133] Overall, no significant change in the case-fatality ratio for nonmenstrual cases has occurred: 8.5 percent for 1979 and 1980, 5.3 percent for 1981 to 1986, and 6 percent for 1987 to 1996.[38,133]

Although cases in the United States have been reported in all 50 states and the District of Columbia, significant differences in incidence were noted among the states through 1983.[249] Through mid-1983, the five states of Wisconsin, Minnesota, Colorado, Utah, and California accounted for 44 percent of the total reported cases but represented only 16 percent of the U.S. population.[309] Although intensified surveillance may have been a factor, regional differences in the degree of immunity to TSS-associated *S. aureus* toxins and in the distribution of toxin-producing organisms may have been important factors.[322]

Geographic differences in the occurrence of TSS continued even with the increase in the relative proportion of nonmenstrual cases.[38]

RISK FACTORS FOR MENSTRUAL TOXIC SHOCK SYNDROME

From early 1980 through 1990, most reported cases of TSS occurred in previously healthy, young white menstruating women who were using tampons at the time of onset of the illness. The explanation for this combination of risk factors is complex.

Age

The median age of patients with confirmed menstrual TSS (median age: 21 years, 1979 to 1980; 20 years, 1981 to 1986; 25 years, 1987 to 1996) has varied little since 1980.[127,133,249] Roughly a third of cases occur in adolescents 15 to 19 years of age[249] (Fig. 71–2). The mean age of patients with nonmenstrual TSS (27 years through 1982, 30 years in 1986) is significantly higher than that for menses-associated cases.[127,250] The precise reason for the increased incidence of TSS in adolescent girls is not known, but a lower prevalence of antibody to TSST-I may increase susceptibility in this age group.[324]

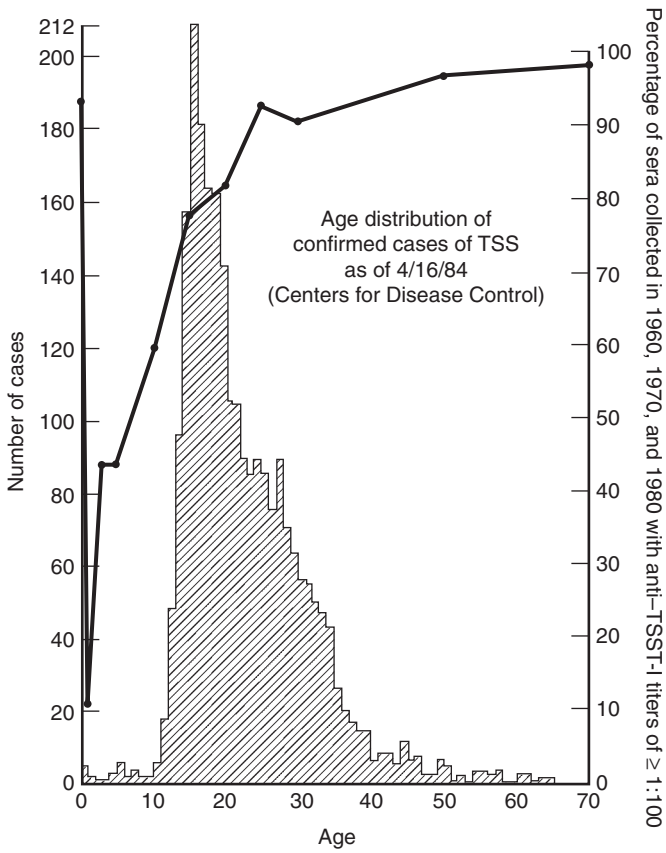


Figure 71–2 Age distribution of patients with confirmed toxic shock syndrome (TSS) reported to the Centers for Disease Control and Prevention before April 16, 1984. The age-specific prevalence of antibodies to toxic shock syndrome toxin I (TSST-I) in a normal population in Wisconsin in the years 1960, 1970, and 1980 is indicated by the *solid connected line*. *(Data from Vergeront, J. M., Stolz, S. J., Crass, B. A., et al.: Prevalence of serum antibody to staphylococcal enterotoxin F among Wisconsin residents: Implications for toxic shock syndrome. J. Infect. Dis.* 148*:692-698, 1983.)*

Race

A striking race-ethnicity distribution is present for menstrual TSS; 97 percent of such cases have occurred in whites, who make up 83 percent of the U.S. population. This distribution is not as striking for nonmenstrual TSS in that 87 percent of nonmenstrual cases have occurred in whites. The reasons for racial differences are not clear and only partially explained by differences in menses-related practices.[111,249,250] Racial differences in antibody to TSST-I may explain to some degree the differences in the distribution of cases.[322]

Menstruation and Tampon Use

The initial observations in 1980 that a high proportion of patients with TSS had an onset during menses is well documented now. The use of tampons as a significant risk factor for the development of TSS was established clearly in six case-control studies conducted in 1980[75,138,162,227,264,277] and one conducted in 1987.[127] Even though these studies varied in design and methodologic technique, all demonstrated that in at least 97 percent of affected individuals, use of tampons during menstrual periods was associated with disease onset. Although 76 to 89 percent of matched control individuals used tampons during temporally comparable menstrual periods, the use of tampons was associated with menstrual TSS in each of these studies, with odds ratios ranging from 11 to 18.[38]

Despite the fact that TSS has occurred and continues to occur with the use of all brands of tampons, the second CDC case-control study demonstrated a greater relative risk for menstrual TSS with the use of one tampon brand, Rely.[120,264] The Tri-State (Minnesota, Wisconsin, and Iowa) TSS Study established that tampons of increasing absorbency were associated with an increasing relative risk for the development of menstrual TSS and that the risk of development of menstrual TSS associated with Rely tampons was greater than that predicted by absorbency alone.[227]

Reasons listed earlier for the striking reduction in incidence of menstrual TSS may be the decrease in absorbency of tampons and changes in composition of tampons.[248] In 1980, products very high in absorbency were used by 42 percent of tampon users.[229] By 1983, this proportion had decreased to 18 percent and, by 1986, to 1 percent.[248] Overall, the absorbency of available tampon brand styles, as measured by the Syngina test,[217] ranged from 10.3 to 20.5 g in 1980 to less than 6 to 15 g in 1990, indicative of an industry-wide decrease in tampon absorbency. The composition of tampons also has changed since 1980. Tampons currently available are composed of cotton or cotton and rayon combinations. In 1980, additives included polyacrylate, polyester foam, cross-linked carboxymethylcellulose, and several surfactants, including Pluronic L-92.[267] Whether these additives enhanced the risk for development of TSS independently or in combination with their increasing absorbency is unclear.[24,227,264]

Two subsequent case-control studies conducted by the CDC and involving patients with an onset of TSS in 1983 and 1984 (CDC III) and 1986 and 1987 (CDC IV) confirmed the Tri-State TSS Study results of a linearly increasing risk for TSS related to increasing tampon absorbency; for each 1-g increase in absorbency, the risk for TSS increased by 34 to 37 percent.[24,116] In addition, the Tri-State TSS Study and the CDC III study both suggested that the effects of absorbency and chemical composition of tampons on TSS risk were independent.[24,38,227]

Continuous use of tampons was associated with a greater risk for the development of TSS than noncontinuous use was in one case-control study[277]; however, this finding was not confirmed in a subsequent investigation.[227] No association between TSS and the frequency of changing tampons has been demonstrated.

As a result of these studies demonstrating the importance of tampons in menses-associated TSS, as well as the voluntary

withdrawal of Rely, several other changes in the manufacture, labeling, and distribution of tampons have occurred. After a request by the Food and Drug Administration (FDA) in November 1980 that tampon manufacturers place warnings on tampon packages, on June 22, 1982, an FDA regulation required that information on TSS and tampon-associated risks appear on tampon packages.[90] In April 1985, two additional tampon manufacturers withdrew their superabsorbent tampons containing polyacrylate from the market on the basis of an in vitro study[208] and a judicial decision.[222] In 1990, the FDA published the in vitro rating system to be used by manufacturers to inform the public about tampon absorbency.[182,217,301]

RISK FACTORS FOR NONMENSTRUAL TOXIC SHOCK SYNDROME

Before 1986, less than 20 percent of confirmed cases of TSS reported to the CDC were nonmenstrual. In the 1986 and 1987 multistate active surveillance study (CDC IV), 54 percent of cases were found to be nonmenstrual.[127] Although the mean age of nonmenstrual cases is higher than that of menstrual cases and the ratio of males to females with nonmenstrual TSS is closer to that in the general population, the clinical findings and complications of nonmenstrual TSS are the same as those occurring in menstrual TSS. The number of confirmed cases of TSS reported in children younger than 10 years of age is surprisingly low, particularly in light of their demonstrated low antibody titers to TSST-I and the increased prevalence of nasal colonization (10%) with TSST-I–positive strains.[38,153,324,334]

Data on risk factors (Table 71–2) were obtained for 559 nonmenstrual TSS cases reported to the CDC through 1986.[38] Associated infections or procedures included nonsurgical cutaneous and subcutaneous infections, 22 percent; childbirth or abortion, 15 percent; infections after a wide variety of surgical procedures, 15 percent; vaginal infections occurring at times other than during menses, 6 percent; vaginal contraceptive sponge use, 5 percent[73]; diaphragm use, 6 percent; and other or unknown sources of infection, 31 percent. The proportion of all nonmenstrual cases reported after surgical procedures increased from 14 percent during 1979 to 1986 to 27 percent during 1987 to 1996. The proportion of female nonmenstrual case patients using barrier contraceptives was significantly less in 1987 to 1996 (6%) than in 1979 to 1986 (14%).[133]

In 1994, nonmenstrual cases accounted for at least 42 percent of all cases of TSS reported to the CDC through the passive surveillance system.[296] The three risk factors necessary for the acquisition of nonmenstrual disease include colonization (or acquisition) of a toxin-producing strain of *S. aureus*, absence of protective antitoxin antibody, and an infected site. TSS has been reported in association with *S. aureus* infections of almost every type, including primary staphylococcal infections and those occurring after surgery, infections associated with disruption of skin or a mucous membrane, and infections occurring after placement of a foreign body[22] (see Table 71–2). Numerous patients with TSS have been reported for whom no obvious focus of infection was found.[38,250] Trauma or surgery in areas of the body frequently colonized with *S. aureus* (nose, skin, vagina) places individuals at enhanced risk for infection and subsequent TSS.

TABLE 71–2 Risk Factors for Nonmenstrual Toxic Shock Syndrome

I.	Colonization with toxin-producing *Staphylococcus aureus*
II.	Absence of protective antitoxin antibody
III.	Infected site
	A. Primary *S. aureus* infection
	Carbuncle
	Cellulitis
	Dental abscess
	Empyema
	Endocarditis
	Folliculitis
	Mastitis
	Osteomyelitis
	Peritonitis
	Peritonsillar abscess
	Pneumonia
	Pyarthrosis
	Pyomyositis
	Sinusitis
	Tracheitis
	B. After surgery: wound infection
	Abdominal
	Breast
	Cesarean section
	Dermatologic
	Ear, nose, and throat
	Genitourinary
	Neurosurgery
	Orthopedic
	C. Skin or mucous membrane disruption
	Burns (chemical, scald, etc.)
	Dermatitis
	Influenza
	Pharyngitis
	Postpartum (vaginal delivery)
	Superficial/penetrating trauma (insect bite, needle-stick)
	Viral infection
	Varicella
	D. After surgical or nonsurgical foreign body placement
	Augmentation mammoplasty
	Catheters
	Diaphragm
	Sponge (contraceptive)
	Surgical prostheses/stents/packing material/sutures
	E. No obvious focus of infection (vaginal or pharyngeal colonization)

HOST RISK FACTORS: GENERAL

Colonization with Exotoxin-Producing *Staphylococcus aureus*

For TSS to develop, an individual must be colonized with or acquire a strain of *S. aureus* that produces TSST-I or one of the staphylococcal enterotoxins. Evidence that staphylococcal enterotoxin B (SEB) alone and, uncommonly, staphylococcal enterotoxin A (SEA) or staphylococcal enterotoxin C (SEC) alone, as well as TSST-I, may be responsible for the manifestations of TSS is compelling. Although many genotypically different strains of *S. aureus* possess the *tst*H gene, one clone has been isolated from 88 percent of menstrual cases and 54 percent of nonmenstrual cases.[214] Colonization with this clone, particularly in menstruating women, clearly provides a significant risk factor. Future work may identify other clones with unique adherence properties to other mucosal or skin sites.

Absence of Protective Antibody Levels

A necessary factor for the development of TSS is the absence of protective antibody levels for the toxin (TSST-I or enterotoxin) produced by the isolate associated with TSS. Thus, more than 90 percent of women with menstrual TSS associated with TSST-I–positive strains have antibody titers of 1 : 10 or lower, whereas a titer of 1 : 100 or higher is considered protective.[22] Because most

adults acquire these antibodies without the development of disease, absent antibody levels may be the result of lack of exposure to a toxin-producing organism or a lacunar inability to respond to the toxin. The failure of most patients, menstrual and nonmenstrual, to form antibody during convalescence may reflect this lacunar nonrecognition of staphylococcal protein antigen, or it may be a reflection of the superantigenic nature of these proteins and failure of the toxin proteins to be presented to the TCR as conventional antigens. In mice and one patient with TSS, in vivo TSST-I–induced proliferation was followed by hyporesponsiveness of TSST-I–responsive $V_\beta 2^+$ T cells.[181]

Interruption of a Mucosal or Skin Surface

Primary deep-tissue staphylococcal infections (e.g., osteomyelitis, pyarthrosis, pyomyositis,[4] endocarditis,[242,331] renal carbuncles, bacteremia) rarely are associated with TSS. Most nonmenstrual cases occur in patients with an altered skin or mucosal surface. Examples of skin disruption associated with TSS include burns, insect bites, needle-sticks, surgical incisions, and varicella. Cases of disruption of mucous membranes can be divided into those associated with respiratory and those associated with genital mucosae. Damage to respiratory mucosa may occur after nasal or other surgery, particularly with placement of stents or packing, in association with a viral respiratory infection such as influenza, or as a result of primary sinusitis, tracheitis, or a parapharyngeal abscess. Heavy colonization of the pharynx also has been associated with TSS. The vaginal mucosa may be damaged in numerous ways, including during placement of tampons or barrier contraceptives,[105,275,313] postpartum,[22,233] or after genital surgery or genital mucosal damage.[106,231,257] Heavy colonization of the vagina without any other apparent risk factor likewise has been associated with TSS.[250] These mucosal infections may provide the right conditions for production of TSST-I, including an aerobic environment, high carbon dioxide concentration, neutral pH, high protein and low glucose concentrations, and low to normal magnesium concentration.[296]

Presence of a Foreign Body

Tampons create an aerobic environment in the vagina, which normally is anaerobic. Tampons of three different types have been shown in humans to change the partial pressure of oxygen of the vaginal wall from an anaerobic environment to that of atmospheric air throughout the 90-minute interval after insertion.[326] Because oxygen is required for the production of TSST-I, researchers have suggested that tampons with enhanced absorbency allow the introduction of increasing concentrations of oxygen to enhance production of toxin.

Several alternative explanations for the role of tampons have been proposed. Tampons may remove vaginal substrates that normally inhibit the growth of *S. aureus.*[22] Another suggested role for tampons is that of inducing cervicovaginal ulceration. Such ulcers have been suggested to enhance bacterial growth or toxin absorption and expose submucosal fibronectin for binding of *S. aureus*.[68,70,329] Tampons can induce chronic cervicovaginal ulcers after long-term continuous use or superficial micro-ulcerations after a brief insertion in otherwise healthy women. However, vaginal ulcerations of the type typically seen in TSS have been found during postmortem examination in women who had never used tampons. This finding suggests that vaginal ulceration, such as that seen in the esophagus and bladder in TSS, may be induced by TSST-I.[174]

Investigations to determine whether individual tampon components can induce or amplify the production of TSST-I in vitro have provided conflicting data, in part because no consensus exists on how best to test tampons and their components to determine their potential to increase risk for the development of TSS. In one setting, although bacterial growth was unaffected, production of TSST-I varied from undetectable levels to 300 μg/mL, depending on the particular brand and style of tampon studied.[22] Other investigators have found that most tampons tested were inhibitory to both bacterial growth and production of TSST-I and that none consistently increased the production of TSST-I.[22]

Two studies clearly demonstrated enhanced production of TSST-I in vitro by the Rely tampon, which is composed of cross-linked carboxymethylcellulose and polyester foam.[238,268] The polyacrylate rayon included in two tampons now removed from the market increased the production of TSST-I under certain conditions,[208] as did the surfactant Pluronic L-92 used in at least one tampon.[268] Neither cotton nor rayon amplifies the production of TSST-I in vitro, nor do cotton tampons adsorb TSST-I or prevent its production.[238,268] Thus, cotton tampons cannot be claimed to be safer than cotton/rayon combinations, although this contention has been disputed.[303] The role of magnesium in controlling the production of TSST-I in the presence of tampons is unclear.[208]

Implanted foreign material such as sutures, central venous lines, and metallic or polymeric implants have been documented repeatedly to enhance the risk of acquiring bacterial infection.[22,155] These infections are characterized by limited spread beyond the tissues in immediate contact with the implants, poor response to antibiotics, and poor healing without removal of the foreign material. Two important differences between TSS and other *S. aureus* infections related to foreign material are the added ability of the organism to produce a toxin that readily disseminates and the limited ability of these strains to produce inflammation.[107] Researchers have suggested that the increased number of surgically associated TSS cases may be related to the number of implanted materials.[133]

The enhanced risk of acquiring infection by *S. aureus* in the presence of foreign material has been defined experimentally in animals. Rats remained asymptomatic after the subcutaneous injection of more than 1×10^6 colony-forming units of *S. aureus*, whereas 3×10^2 colony-forming units invariably led to infection in the presence of a suture. In addition, the ability of sutured tissue to resist infection varies with the kind of material implanted, particularly its physical or chemical configuration. For example, bacterial adherence is eightfold higher for braided sutures of silk, silicone-heated blue polyester, and absorbable polyglycolic acid than for monofilament nylon.[155]

In addition to sutures, other foreign materials associated with TSS-related wound infection are Teflon splints, gauze packing, and mammary implants.[22]

OTHER POTENTIAL HOST RISK FACTORS

Other factors have been examined in an attempt to identify individuals who may be at increased risk for the development of TSS.[80] Some of these factors have included HLA typing,[22] neutrophil function,[140] adherence of *S. aureus* to vaginal epithelial cells,[20] alteration of the cervicovaginal flora,[22] hormonal factors, and personal hygiene practices.[80] Of all these factors, those of potential importance included cervicovaginal flora and hormonal factors.

Vaginal co-colonization with *S. aureus* and one of the Enterobacteriaceae has been postulated to enhance the risk of development of TSS.[55] Prospective examination of 495 healthy women revealed a 7 percent vaginal colonization rate for *S. aureus* TSST-I–positive strains. Women who were colonized with toxin-producing *S. aureus* also were colonized with *Escherichia coli* or other Enterobacteriaceae statistically significantly more often than were women colonized with non–toxin-producing or no *S. aureus*. *E. coli* isolation rates were 54 percent in women with

TSST-I–positive isolates, 15 percent in women with TSST-I–negative isolates, and 11 percent in women with no *S. aureus*. Co-isolation of *E. coli* was the only identified factor associated with vaginal carriage of TSST-I–positive *S. aureus*. Additionally, among the 14 patients with TSS monitored in this study, 9 had *E. coli* as well as TSST-I–positive *S. aureus* co-isolated during the acute TSS episode. The significance of these observations and their relationship to postulated roles for endotoxin in TSS are not clear.

The results of early case-control studies suggested that oral contraceptive steroids may have an effect on vaginal *S. aureus* organisms that may produce or release TSS-associated toxins[75,227] and that this effect was protective. However, one case-control study found no protective effect or enhanced risk associated with oral contraceptive use.[127] Hormonal control is known to be responsible for numerous cyclic changes in vaginal pH and flora, but the role of hormonal factors in the pathogenesis of TSS has not been examined well.

HISTOPATHOLOGY

The histopathologic findings on postmortem examination support the concept that TSS is a toxin-mediated disease.[1,28,36,174,230,333] Striking histopathologic similarities exist between patients with TSS and those with "scarlet fever" reported in 1936.[36] Typically, a total absence of tissue invasion by bacteria and minimal evidence of an inflammatory reaction in most organs are noted. Findings thought to be due to a direct effect of the toxin or mediators (or both) and unrelated to hypoperfusion have included subepidermal ulcerations in the cervix, vagina, esophagus, and bladder; depletion of lymphocytes in lymph nodes; a subepidermal cleavage plane in the skin; and mild inflammatory changes in the kidney, liver, heart, and muscle.

Cervicovaginal ulcerations are the only characteristic lesions noted in the genital tract of patients with fatal menstrual TSS, and such ulcers have been found in a patient with menstrual TSS who had never used tampons.[174,233] The ulcerations are superficial. Capillary vasodilation and thrombosis with inflammation of the mucosa are present, but no deep-tissue bacterial invasion is seen. The layer of vacuolization and separation in the ulcers occurs beneath the basal layer. The same type of ulcer also has been found in the bladder and esophagus, which suggests that these ulcerations may be caused by the toxins or mediators and not by the use of tampons.

Although the myocardium was described as normal in one postmortem series of TSS, in another series of eight fatal cases, all patients had evidence of focal round-cell infiltration with variable degrees of congestion, edema, and hemorrhage.[174,230] Myxoid degeneration was found in all heart valves from four patients in one series. Sections of skeletal muscle have demonstrated only congestion, edema, focal hemorrhage or fiber necrosis, and a mild acute inflammatory infiltrate.

Varying degrees of triaditis or periportal lymphocytic inflammation have been the most consistent findings in the liver; centrilobular congestion with necrosis and mild cellular degeneration also has been described.[150] In the kidney, toxin-mediated mononuclear interstitial nephritis may result from perivasculitis of the adventitia of the renal venules, lesions that probably precede the development of hypotension-induced acute tubular necrosis. The most characteristic findings in the spleen and lymph nodes have been lymphocyte depletion; inactive hypocellular, hypoplastic lymphoid follicles with edema; marked histiocytosis in the interfollicular areas; and hemophagocytosis.

Perivascular lymphocytic infiltrates and bullae that separate at the basement membrane are characteristic of the early skin changes in TSS.[8,10,140] No evidence of vasculitis has been reported.

CLINICAL SPECTRUM

ACUTE PHASE: MODERATE TO SEVERE DISEASE*

Multisystem end-organ damage secondary to loss of peripheral vascular resistance, loss of intravascular volume as a result of endothelial damage and the capillary leak syndrome, and interstitial edema constitute the most important mediator-induced changes of TSS. Prolonged hypotension, interstitial edema, and vascular congestion additionally may result in ischemic organ damage.

The onset of illness in patients with moderate to severe disease is abrupt, with symptoms and signs including fever, chills, malaise, headache, sore throat, myalgia, muscle tenderness, fatigue, vomiting, diarrhea, abdominal pain, and orthostatic dizziness or syncope (Figs. 71–3 and 71–4).

During the first 24 to 48 hours, diffuse erythroderma, severe watery diarrhea (often with incontinence), decreased urine output, cyanosis, and edema of the extremities may be noted. Some patients may have purpura fulminans.[168] Cerebral ischemia and edema rapidly result in somnolence, confusion, irritability, agitation, and occasionally hallucinations, even in individuals without hypotension. Patients with TSS have had signs and symptoms of encephalopathy, cerebral infarction, meningismus,[15,27,135,179,283] and the cauda equina syndrome.[8]

During initial physical examination of a moderately to severely ill patient, fever, tachycardia, tachypnea, a low or unobtainable blood pressure, erythroderma (generally not seen in patients with severe hypotension or in those without T cells)[159] (see Fig. 71–4A), and muscle tenderness are noted in conjunction with peripheral cyanosis and edema, conjunctival hyperemia, subconjunctival hemorrhages (see Fig. 71–4B), beefy red edematous mucous membranes, somnolence, disorientation, and agitation. In menstrual TSS, edema and erythema of the inner aspect of the thighs and the perineum may be noted in conjunction with normal findings on uterine and adnexal examination. In nonmenstrual cases, vaginitis or another focus of infection will be present. In most postoperative cases, the surgical wound is not inflamed. If erythroderma is present, it will be most intense surrounding the infected focus.

Surgical wounds and some abscesses colonized or infected with *S. aureus* and responsible for postoperative or nonmenstrual TSS may have minimal or no signs of inflammation.[6,17,93,250] The production of TNF-α by macrophages in response to TSST-I inhibits neutrophil mobilization in vitro,[107] which may provide an explanation for the absence of signs of inflammation. The incubation period for postoperative or postpartum TSS may be as short as 12 to 48 hours. Relatively few cases have been associated with deep-tissue infection.[22]

Laboratory Changes

Abnormalities in clinical laboratory tests will reflect the endogenous cytokine release, shock, and organ failure associated with TSS. Leukocytosis may not be present, but the total proportion of mature and immature neutrophils generally exceeds 90 percent. The proportion of immature neutrophils usually is 25 to 50 percent of the total number of neutrophils and is associated with a profound and absolute lymphopenia. Thrombocytopenia and anemia are present during the first few days and frequently are accompanied by prolonged prothrombin and partial thromboplastin times. Disseminated intravascular coagulation may be present. Sterile pyuria and cerebrospinal fluid pleocytosis are indicative of generalized involvement of the mucous membranes and serosal surfaces. Elevated blood urea nitrogen and creatinine

TABLE 71–3 Therapeutic Principles for Management of Toxic Shock Syndrome

1. Identify the focus of infection: débride and irrigate extensively and remove any foreign material
2. Isolate the organism for antimicrobial susceptibility studies
3. Administer parenteral antimicrobial therapy
   Stop enzyme/toxin production with a protein synthesis inhibitor (e.g., clindamycin, erythromycin, gentamicin)
   and
   Eradicate the organism with a bacterial cell wall inhibitor (e.g., β-lactamase–resistant antistaphylococcal antimicrobial agent)
   Consider intravenous immunoglobulin to provide antitoxin antibodies for a subset of patients, including those with the following:
   - Disease refractory to initial fluid replacement and several hours of vasopressor support
   - A focus of infection that cannot be drained
   - Persistent oliguria despite massive fluid replacement and in the presence of pulmonary edema

   Consider additional measures, such as the following:
   - Methylprednisolone to suppress cytokine production and the inflammatory response
   - Fluid therapy to maintain adequate venous return and cardiac filling pressure and to prevent end-organ damage
4. Anticipate the management of multisystem organ failure

levels reflect kidney damage,[50] abnormalities in tests of liver function reflect liver damage and acute cholestasis,[130,150] and the profound hypocalcemia may reflect both hypoproteinemia and high serum levels of a calcitonin-like material.[51,286] Muscle involvement is noted by an elevated creatine phosphokinase level, and the hypophosphatemia that occurs despite impaired renal function is unexplained.[14,51,319] Most of these test results will return to normal within 7 to 10 days of disease onset. *S. aureus* will be cultured from the cervix or vagina in more than 85 percent of patients with menstrual TSS and from the focus of infection in patients with nonmenstrual TSS. Positive blood culture results are rare findings.[69] Antibody to TSST-I or to the staphylococcal enterotoxins will be absent at the onset of disease in more than 85 percent of patients.[23,33,66,259,281,332]

Treatment

The four general principles of treatment of TSS (Table 71–3) are (1) identification and drainage of the focus of toxin production, (2) identification and susceptibility testing of the organism, (3) administration of antimicrobial therapy to block synthesis of the toxin and to kill *S. aureus*, and (4) management of the systemic multiorgan actions of the toxins or mediators.*

LOCATION AND DRAINAGE OF THE INFECTED SITE

The focus of infection should be identified rapidly, any foreign bodies should be removed, and the site should be drained or irrigated completely, even if it does not appear to be inflamed. Performing this procedure is of utmost importance because perpetuation of even a small, undrained focus of infection may result in serious clinical consequences. If TSS occurs in the immediate postoperative period, the wound should be assumed to be the source of infection, regardless of its benign appearance.

IDENTIFICATION AND SUSCEPTIBILITY TESTING OF THE ORGANISM

The incidence of community-acquired MRSA infections has increased dramatically in incidence during the past 10 years.[129] These MRSA strains differ from the long-standing hospital-acquired MRSA strains in that they are acquired in the community by well individuals with no risk factors and are not multiresistant. Most strains are susceptible to clindamycin. Because MRSA strains are fully capable of producing TSST-I,[89,272] community-acquired menstrual and nonmenstrual cases of TSS may be caused by either community or multiresistant hospital-acquired strains of MRSA.[96] To date, vancomycin-resistant strains of *S. aureus* are rare findings.[143,288] Thus, every effort should be made to obtain the organism for susceptibility testing.

ADMINISTRATION OF ANTIMICROBIAL AGENTS

Administration of antistaphylococcal antibiotics is indicated to eradicate organisms and prevent recurrence.[75,76] The infection may be a superficial or deep-tissue infection and may be associated with *S. aureus* bacteremia or bacteriuria. Antistaphylococcal antimicrobial agents should be administered intravenously at maximal doses for age and should be initiated as soon as possible.

Once the patient is stable, no longer vomiting or having diarrhea, and able to take food by mouth, high doses of an oral antimicrobial agent to which the organism is susceptible can be given to complete a total course of 10 to 14 days.

Subinhibitory concentrations of the protein synthesis inhibitors clindamycin, lincomycin, erythromycin, clarithromycin, kanamycin, gentamicin, tetracycline, and linezolid have been shown to suppress TSST-I production in vitro.[88,237,269,291] In one study, clindamycin concentrations $^1/_{64}$ the minimal inhibitory concentration (MIC) were effective in totally blocking TSST-I production.[237] In a mouse model of myositis caused by *S. pyogenes*, another superantigen-producing organism, clindamycin and erythromycin were more efficacious than penicillin.[97,289,292]

Data suggest that subinhibitory concentrations of β-lactam antibiotics actually may *increase* TSST-I production by *S. aureus.* At a concentration of half the MIC, nafcillin can *increase* toxin production 10-fold more than do control conditions.[5] A similar effect has been described for nafcillin and the staphylococcal alpha-toxin.[163] The effect is not seen with vancomycin, another cell-wall-active drug, thus suggesting specificity beyond merely a cell wall effect. Co-administration of a protein synthesis inhibitor with a β-lactam antibiotic blocks the effect.[5]

The choice of initial empiric antimicrobial therapy has become more complex as a result of an increase in the number of community-acquired MRSA infections and the spread of multiresistant MRSA strains in hospitals.[161] The severity of TSS warrants initiating maximally effective therapy. Once the results of susceptibility testing of the organism are available, therapy can be adjusted appropriately. In the past, the most effective initial empiric therapy was a combination of a β-lactamase–resistant penicillin and clindamycin. If there is concern for MRSA strains causing TSS, consideration should be given to initiating therapy with vancomycin and clindamycin. This situation clearly is difficult because most patients with TSS have a degree of renal failure. In addition, if the organism is susceptible to methicillin, the β-lactamase–resistant penicillins generally are more efficacious than is vancomycin. As an option to vancomycin, linezolid has been used successfully for the treatment of staphylococcal TSS.[291] An infectious disease consultation should be considered to help in the management of these patients.

MANAGEMENT OF SYSTEMIC MULTIORGAN ACTIONS OF THE TOXINS OR MEDIATORS

Intravenous Immunoglobulin

Not surprisingly, given the high prevalence of antibodies to TSST-I in adults,[324] high levels of antibody to TSST-I are

*See references 47, 56, 75, 76, 114, 116, 139, 192, 264, 289, 311.

present in IVIG preparations.[46,52,196,233,300] In animal models of TSS, human IVIG given at the time of inoculation of TSST-I–positive *S. aureus* prevented the development of TSS. When IVIG was administered 8 hours later, it decreased the mortality rate from 90 percent in control rabbits to 16 percent. When IVIG was given 29 hours after administration of TSST-I, the increase in survival rates in the IVIG-treated animals still was significant. No adverse reactions were noted in the treated animals, and no evidence was found of disease mediated by the formation of antigen-antibody complexes.[196,197,199,200] Monoclonal antibodies to TSST-I can prevent the development of manifestations of TSS in the rabbit model completely.[34,235,276]

High concentrations of antibodies to TSST-I and the staphylococcal enterotoxins (SEA; SEB; SEC types 1, 2, and 3; SED; and SEE) have been demonstrated in pooled IVIG.[46,52,233,300] These antibodies may inhibit the binding of toxins to MHC class II antigen-processing cells or interfere with presentation of toxin by these cells to the TCR. As a result, production of TNF-α and TNF-β is inhibited by these antibodies in vitro in an apparent toxin-specific manner.[300] Down-regulation of the production of lymphokine induced by streptococcal pyrogenic exotoxin A by IVIG also has been demonstrated in vitro.[215,281]

The results of these in vitro studies have supported the use of IVIG for both streptococcal and staphylococcal TSS.[253] Anecdotal case reports have indicated a beneficial effect on both streptococcal[16,215,338] and staphylococcal[2,52,61,221,233] TSS in humans. The efficacy of IVIG as adjunctive therapy for streptococcal TSS was evaluated in a multicenter, randomized, double-blind, placebo-controlled trial.[72] Although the trial was prematurely terminated because of slow patient recruitment, results from 21 enrolled patients (10 IVIG recipients and 11 placebo recipients) showed 3.6-fold higher mortality in the placebo group. Even though statistical significance was not reached, the trial provides support for IVIG as adjunctive therapy for streptococcal TSS.

Because IVIG is expensive and most patients respond rapidly once standard therapeutic measures are initiated, some authors would reserve IVIG for patients with an inaccessible focus of infection or for those who continue to deteriorate after receiving fluid and vasopressor support for several hours (see Table 71–3). The dose most often used has been 400 mg/kg given as a single dose over the course of several hours. This dose results in a serum antibody titer of greater than 1:100, much higher than that appearing to provide immunity to TSST-I.[233] Some studies have used IVIG doses of up to 2 g/kg.[72] Because early administration of IVIG possibly could blunt the immune response to TSST-I or other toxins and increase the possibility of a recurrent episode, the potential risks and benefits of this form of therapy must be considered for each patient.

The role of endotoxin in the pathogenesis of TSS is unclear. The failure of polymyxin B and anti-J5 antiserum to alter the course of TSST-I–positive TSS in a rabbit model suggests that endotoxin may not be an important mediator of TSS in humans.[198]

Early and sporadic case reports of TSS have suggested therapeutic benefit with naloxone,[59] calcium,[233] and exchange transfusion in severely ill patients unresponsive to the usual forms of therapy.

Corticosteroids

Short courses of methylprednisolone or dexamethasone, if given early in the course of the disease, have been associated with a reduction in the duration of fever and the severity of illness but no reduction in mortality rates.[307] In vitro, dexamethasone has been shown to down-regulate TSST-I–induced cytokine production.[167] Because no controlled prospective study has demonstrated efficacy, the use of steroids probably should be restricted to hypotensive patients unresponsive to fluid resuscitation, antimicrobial agents, and intravenous immunoglobulin (IVIG).

Fluid Replacement

The most important aspect of the nonspecific treatment of symptomatic patients is fluid replacement.[304] Intravascular volume and cardiac filling pressure must be restored rapidly to achieve adequate tissue perfusion. Because of the ongoing capillary leakage, this fluid replacement may far exceed the estimated fluid requirements based on calculated maintenance and fluid deficit volumes. Some adults have required vasopressors and as much as 12 L of fluid during the first 24 hours to stabilize the circulating blood pressure. Pleural, pericardial, and peritoneal effusions and interstitial edema inevitably occur as a result of the continued vascular capillary fluid leak. Close monitoring in an intensive care unit will facilitate determining when the correct intravascular volume has been achieved, as well as detecting and appropriately monitoring and treating myocardial dysfunction, hemodynamic derangements, pulmonary edema, adult respiratory distress syndrome, acute renal failure, encephalopathy, and disseminated intravascular coagulation.

SUBACUTE PHASE: AFTER TREATMENT IS INITIATED

Once treatment is initiated, response usually is rapid. Temperature returns to normal within 48 hours. The hemodynamic changes are observed initially as tachycardia, decreased systemic vascular resistance, decreased central venous pressure, hypovolemia, normal pulmonary artery wedge pressure, and an increased cardiac index.[13,41,67,114,117] Once aggressive fluid therapy has been initiated, myocardial edema and potential failure, along with pulmonary and cerebral edema in the face of renal failure, become the most critical management issues. The reasons for myocardial failure are unclear but probably are related to perivascular inflammation of the coronary vessels, edema, and postulated myocardial depressant factors.[174,230] TSST-I has been shown to inhibit systolic function in isolated rabbit atria, though at higher than usual circulating concentrations.[224] Arrhythmias may result from myocardial damage or electrolyte abnormalities.[193,255] Endomyocardial biopsy in one patient with severe global hypokinesis of the left ventricle revealed no substantial inflammatory infiltrate but a mild to moderate number of T cells scattered diffusely throughout the biopsy specimen.[67]

During the decompensated stage of myocardial dysfunction, the cardiac index falls and pulmonary wedge pressure increases, with both left atrial and ventricular and diastolic diameters being at the upper limits of normal.[114] Reversible electrocardiographic findings include sinus tachycardia, diffuse loss of voltage, flattened T waves, and diffuse nonspecific ST-T wave changes. If fatal arrhythmia does not occur during the decompensated stage, the toxic cardiomyopathy is reversible and rarely results in permanent changes. This process is similar to "stunned myocardium," a transient, postischemic myocardial dysfunctional state.[67]

Pulmonary edema and adult respiratory distress syndrome occur commonly in patients with severe disease when massive fluid replacement is necessary and the capillary leak syndrome continues in the lungs. Pulmonary edema appears rapidly once fluid replacement is initiated and often necessitates intubation and respirator management for several days.[304]

Forms of TSS-associated acute renal failure include prerenal azotemia and both nonoliguric and oliguric renal failure.[50] The type of renal failure manifested may be dependent on the degree of intravascular volume depletion. Unless severe acute tubular necrosis necessitates temporary hemodialysis, repletion of intravascular volume usually results in rapid restoration of renal function and, ultimately, diuresis. Permanent renal damage is an extremely rare event.[46]

The gastrointestinal, musculoskeletal, and hepatic changes resolve rapidly. Sequelae associated with these changes are rare, except for prolonged muscle weakness.[46,79] Joint manifestations generally are self-limited.[22,119]

Management of fluids, electrolytes, and metabolic acidosis in patients with TSS is complex. Although tetany is a rare occurrence, this common severe hypocalcemia may be life-threatening and should be corrected.[51,233,286] Most patients require potassium replacement and management of metabolic acidosis. The use of colloid for fluid replacement and removal of the toxin stimulus for capillary leak syndrome ultimately correct the hypoproteinemia.

The typical dermatologic manifestations follow a predictable sequence (see Fig. 71–3). A dandruff-like flaky desquamation begins on the trunk and extremities 5 to 7 days after the onset of symptoms. From days 10 to 12 and for as long as a month, the characteristic full-thickness desquamation of the fingers, toes, palms, and soles takes place (Fig. 71–5). A variety of atypical dermatologic manifestations, including petechiae and subepidermal bullae, have been described.[10,101,146]

Early in the acute phase, many patients exhibit desquamation of the mucous membranes, which is particularly painful when the oral mucous membranes are involved.[47] In addition, a small number of patients will have reactivated herpes simplex virus type 1 or 2 lesions with the acute illness.[47] A late-onset pruritic maculopapular rash with edema and low-grade fever probably unrelated to antimicrobial therapy occurs in more than 50 percent of menses-associated cases within 7 to 14 days of disease onset.[47,84] The cause of this late-onset rash is unknown.

Telogen effluvium, a common sequela, is a nonspecific response to severe trauma, sepsis, or stress that results in disturbed metabolism and keratinization of the hair follicles and nails. The hair follicles appear to transform prematurely from the growth, or anlagen, phase to the telogen, or resting, phase. Hair and nail loss occurs 4 to 16 weeks after onset of the illness, with restoration taking place in 5 to 6 months.[22,26,47]

The hematologic system seldom is involved with major complications in TSS. Although disseminated intravascular coagulation may be present, gastrointestinal, uterine, or cerebral bleeding rarely occurs. Thrombocytopenia may be present initially in patients with disseminated intravascular coagulation; thrombocytosis is characteristic of the recovery phase. Mild to moderate normocytic, normochromic anemia, which probably is dilutional and a result of suppressed red blood cell synthesis, develops in virtually all moderately to severely ill patients with TSS and resolves during convalescence.[47,49] Hypoferrinemia occurs commonly.[49]

The relatively common toxic or ischemic encephalopathy, rarely complicated by seizures, resolves slowly during the first 4 to 5 days of hospitalization.

Outcome and Sequelae

Death associated with TSS usually takes place within the first few days of hospitalization, but it may occur as late as 15 days after admission. Fatalities have been attributed to refractory cardiac arrhythmias, cardiomyopathy, irreversible respiratory failure, and, rarely, bleeding caused by coagulation defects.[174,230] The duration of circulation of toxins and mediators and the associated hypotension may be the best predictors of the severity of the end-organ damage.

After being discharged, more patients experience prolonged fatigue, muscle weakness, and pain.[46] Sequelae attributed to TSS that appear to be related to a prolonged period of hypotension have included chronic renal failure, gangrene, and telogen effluvium.[79,158,202,258,262] Other sequelae, such as neuropsychological abnormalities, prolonged myalgia and weakness, carpal tunnel syndrome, chronic dermatitis, Raynaud syndrome, new allergies, and recurrences, are explained less easily. Abnormalities such as impaired memory and poorly sustained concentration have been found in patients who did not require any therapy other than intravenous fluids to restore their blood pressure.[258] In one center, patients with nonmenstrual TSS had more serious short- and long-term neuropsychological complications than did patients with menstrual TSS.[158] Sequelae related primarily to the neuromuscular system have resulted in speculation that the TSS-associated toxin may have a direct effect on nerve or muscle tissue. In one patient with TSS, cauda equina syndrome with partial paralysis developed after lumbar laminectomy and staphylococcal meningitis, thus suggesting a neurotoxic effect of the intrathecally produced SEC.[8]

One study compared the sequelae and other long-term effects in 183 (174 menstrual cases) women with TSS and 366 control women hospitalized for appendicitis and appendectomy and matched for age, race, and duration of follow-up.[79] Each subject completed two comprehensive phone interviews. When compared with controls, women with TSS were significantly more likely to report sequelae involving fatigue, the integument (hair loss and nail changes), mental and cognitive skills (problems with concentration, reading difficulty, and memory loss), emotions (menses attitude and emotional changes), and multiple organ

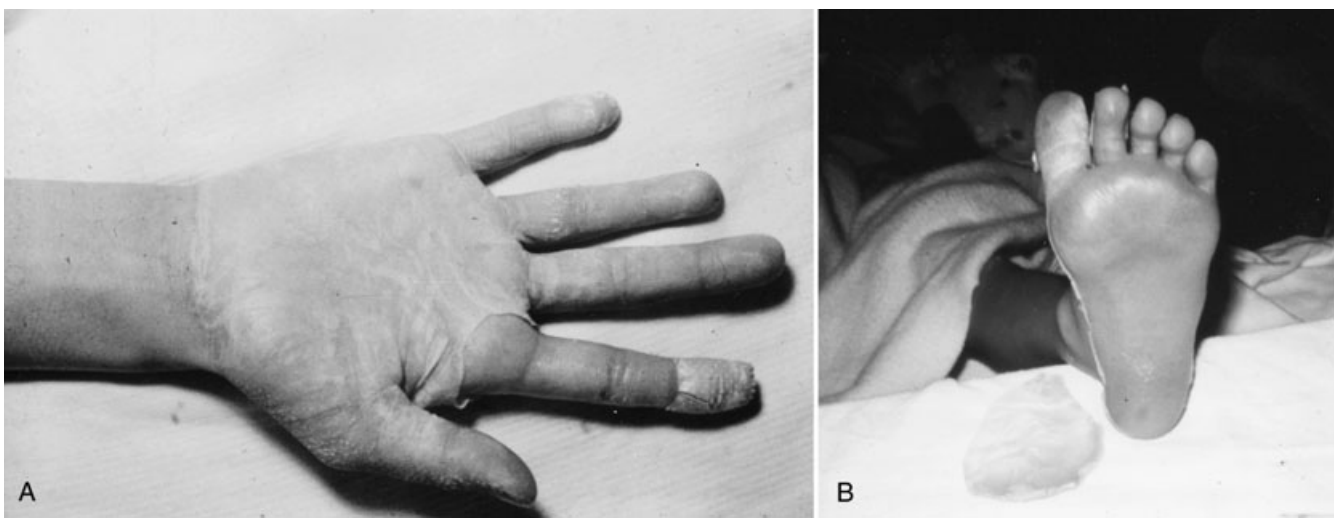

Figure 71–5 Universal full-thickness desquamation of the hands (**A**) and feet (**B**) first noted 7 to 14 days after disease onset and persisting for up to 30 days.

systems (conditions involving the joint, cardiac, muscle, and genitourinary systems). In addition, women with TSS were significantly more likely than controls to report persistence of symptoms. Fertility patterns and pregnancy outcomes were similar in controls and women with TSS, both before and after the index illness.[79]

Recurrences

One of the most puzzling aspects of the pathophysiology of TSS is the high rate of recurrence in patients with inadequately treated menstrual or nonmenstrual disease.[6,47,75,76,191,294] A small number of patients with menstrual disease and repeated tampon exposure have experienced as many as 6 to 12 recurrences. Recurrences associated with menstrual disease have no predictable pattern. In most patients the first episode is the most severe. However, asymptomatic menses may occur between symptomatic episodes, and the most severe episode may occur after one or more milder episodes.[76] The use of antistaphylococcal antimicrobial therapy to which the organism is susceptible in doses recommended for serious infections for 10 to 14 days and discontinuation of tampon use can be expected to reduce the rate of recurrence significantly.[76] Recurrences after nonmenstrual TSS are well described and usually are associated with inadequate initial therapy.[6,158,233] Cisplatin administration resulting in significant hypomagnesemia precipitated several recurrent episodes of TSS in an immunocompromised adult.[25]

The absent or delayed antibody response to TSST-I found in both menstrual and nonmenstrual TSS patients probably accounts for the continued susceptibility to TSS and for the high recurrence rate.[22,33,181,259,281,294,332] The fact that superantigenic toxins are not processed by antigen-processing cells and T lymphocytes as conventional antigens may provide an explanation for the poor convalescent antibody response to these antigens.[166]

Culture-negative, menses-associated, recurrent episodes of TSS continue to occur in a small number of patients despite discontinuation of tampon use and administration of appropriate antimicrobial therapy during the acute episode.[76] Administration of an oral β-lactamase–resistant antistaphylococcal antimicrobial agent during menses has been tried in an attempt to prevent these recurrences but is not always successful. In recurrent cases resistant to this form of prophylaxis, consideration could be given to the untested and empiric use of rifampin, clindamycin, erythromycin, or IVIG (if the patient has no antibody to TSST-I) or to the use of an oral contraceptive.[191]

ATYPICAL MANIFESTATIONS

Mild Disease

Recognition of mild episodes of TSS is particularly important in patients with menstrual TSS because repeated use of tampons and the risk for recurrence are episodic.[48,85,310] Patients with mild or severe menstrual TSS typically do not form antibody to TSST-I during convalescence[22,33,259,281,332] and, without appropriate therapy, may have one or more recurrences. Such recurrences may be mild or severe.[75,76,192] Patients with nonmenstrual TSS also do not form antibodies in convalescence. A mild episode may be recognized only in retrospect, after desquamation or a recurrent episode (or both) develop.[233]

The presence of any combination of fever, headache, sore throat, diarrhea, vomiting, orthostatic dizziness, syncope, and myalgia in a menstruating woman or an individual with a potential *S. aureus* infection, no matter how trivial, should raise suspicion of TSS. A specific laboratory test to confirm the clinical diagnosis is not available. A bacterial culture positive for *S. aureus* may be helpful but is not diagnostic of menstrual cases because *S. aureus* may be cultured from the cervix or vagina in as many as 33 percent of menstruating women.[186,239]

Other laboratory data usually do not reflect multisystem involvement in mild disease, and assays for TSST-I in body fluids are investigational.[195,323] Diagnostic support for the theory that the patient's signs and symptoms represent mild TSS often depends on the constellation of findings present, including subsequent typical desquamation of the palms, soles, toes, or fingers; demonstration that *S. aureus* isolates from the site of infection produce TSST-I or an enterotoxin; absence of antibody to TSST-I or enterotoxins in acute-phase serum; and recurrent disease, if it develops.

Nonmenstrual Disease

The incidence of postoperative cases of TSS after all types of surgery has been estimated to be 3 per 100,000 population.[131] For ear, nose, and throat surgery, the incidence is higher (16.5/100,000 population).[152] A striking feature of most postoperative cases with rapid onset is the absence of any signs of wound infection.[17,131,246,260] The mean time from surgery to the onset of symptoms is 2 to 4 days.[17] Nosocomial acquisition of TSST-I–positive organisms rarely has been documented for postoperative cases.[9,169,212] A wide variety of types of surgery have been associated with TSS.[22,43,211,223,252,278,282]

Burn wounds provide a particularly rich environment for growth of *S. aureus* and the production of toxins.* In burn centers, TSS occurs predominantly in young children with small burns.[98] In one large pediatric burn center, *S. aureus* normally was not cultured from any site on admission.[52] However, it was acquired within a few days of admission and became the most common wound pathogen. Of all wound isolates of *S. aureus*, just 16 percent produced TSST-I. Only 50 percent of the children had antibodies to TSST-I on admission, which reflects the low prevalence of antibodies in this population.[324] Of blood products administered, 76 percent had antibodies to TSST-I, and seroconversion occurred in children receiving these products. A toxic shock–like syndrome developed in 13 percent (7/53) of children, only one of whom had TSST-I–producing *S. aureus* isolated from the wound. SEA and SEB were produced by isolates from three patients. In burn patients, issues regarding the use of prophylactic antibiotics and occlusive dressings and enhancement of TSST-I production by topical antimicrobial agents are unsettled.[99] The mortality rate associated with TSS in children with burns may be as high as 57 percent.[122] Skin disrupted in any way, including disruption by varicella or a tattoo, also may be a focus for TSS.[22,37,65]

Patients whose anterior nares have been colonized by *S. aureus* are at particular risk for the development of TSS when the respiratory mucosa is disrupted by surgery, trauma, or a respiratory infection such as influenza.[22,63,180,312,314] TSS has been reported in association with sinusitis,[22,109] pharyngitis,[22,263] parapharyngeal abscesses,[263] tracheitis,[22,71,92,125,218] pneumonia,[22,74] rubeola,[297] and submandibular space abscesses. TSS occurring after ear, nose, and throat surgery has been associated with the use of nasal splints and packing materials and in part may be the result of interruption of the ciliary blanket.[3,22,121,207,339]

After orthopedic procedures or in association with bone and joint infections, the clinical manifestation of TSS may be confusing as a result of the intense and generalized myalgias associated with TSS, which may be misinterpreted as postoperative musculoskeletal symptoms. The wounds usually appear to be benign.[22,206,240,302,318] Infected abrasions under casts may be focal sites of TSST-I production.[285]

In one center, when cases of nonmenstrual TSS were compared with menstrual cases, patients with nonmenstrual disease

*See references 11, 52, 60, 98, 122, 124, 128, 142, 183, 188, 328.

were found to have a delayed onset of symptoms after the precipitating event, more frequent central nervous system manifestations, less frequent musculoskeletal involvement (myalgia and arthralgia), and a higher degree of anemia.[158] Recurrences occurred in both groups in untreated patients, and mortality rates were not different. Clinical differences between the two categories are suggested to be related to differences in the types of toxins produced. TSST-I was produced with comparable frequency in both groups. SEA was produced less often by nonmenstrual isolates, and menstrual isolates more often produced both TSST-I and SEA. SEB was produced more frequently by nonmenstrual isolates.

Several patients with TSS have been reported to be simultaneously infected with *S. aureus* and *S. pyogenes*.[100] Determining which infection primarily was responsible for the manifestations or whether an amplified effect of exotoxins from both organisms was present was not possible.

Recalcitrant Erythematous Desquamating Disorder

An atypical, subacute variant of TSS has been described in patients with acquired immunodeficiency syndrome (AIDS) and labeled recalcitrant erythematous desquamating disorder. *S. aureus* strains producing TSST-I, SEA, or SEB have been isolated from patients with AIDS and prolonged erythema, extensive cutaneous desquamation, hypotension, tachycardia, and multiple and variable organ involvement.[61,91,164] The illness is recalcitrant, prolonged, and characterized by multiple recurrences. In one patient, elevated levels of TNF and IL-6 were found during severe episodes. When antitoxin antibodies have been measured during recurrence, they have been undetectable. Two patients responded well to IVIG.[61,164] Patients with the combined cellular and humoral immunodeficiencies of AIDS may be at particular risk for the development of severe, frequent, and prolonged recurrent episodes of TSS.[61,91,112,164,284] TSST-I and the enterotoxins may activate human immunodeficiency virus type 1 (HIV-1) gene expression in vivo, as has been observed in vitro.[123]

Neonatal Toxic Shock Syndrome–like Exanthematous Disease

A toxic shock–like illness related to MRSA producing TSST-I, neonatal toxic shock syndrome–like exanthematous disease (NTED), was described initially in neonates in Japan[299] and subsequently recognized in France.[321] These infants are seen in the first week of life with the combination of a generalized erythematous macular rash, thrombocytopenia, elevated acute-phase reactants, and fever. Patients are colonized with MRSA belonging to a single clonal type that produces TSST-I and SEC.[147] Although no focus of infection is present and no exotoxins are detectable in serum, analysis of T cells shows selective expansion of $V_\beta 2$-positive T cells during the acute phase as a result of selective activation of TSST-I–reactive T cells.[298,299] Maternal IgG antibody to TSST-I plays a protective role in preventing NTED.[298] Although complications occur in premature neonates, term infants typically recover within 5 days without active treatment. The limited disease in comparison to TSS has been attributed to the minute amount of exotoxin from colonized sites and to the high susceptibility to induction of anergy in the immature T cells of neonates.[298,299]

Streptococcal and Other Toxic Shock Syndromes

An increase in the incidence and severity of invasive *S. pyogenes* infections was recognized in the 1980s. Manifestations of severe disease have included septicemia with or without a focus of infection; severe, painful cellulitis; necrotizing fasciitis; and in some cases, streptococcal TSS with or without a focus of infection. Streptococcal TSS is similar to staphylococcal TSS in that it appears to be mediated by superantigenic toxins and results in endothelial damage, hypotension, and multisystem organ involvement. In 1993, the Working Group on Severe Streptococcal Infections proposed a consensus definition for streptococcal TSS with clinical criteria, including isolation of group A streptococci from a normally sterile site, hypotension, and two or more of the following: renal impairment, coagulopathy, liver dysfunction, adult respiratory distress syndrome, erythematous macular rash, and soft tissue necrosis.[336]

Streptococcal toxic shock–like syndrome differs from staphylococcal TSS in numerous respects, including a slower onset over the course of several days; usual absence of vomiting, profuse diarrhea, and conjunctival infection; frequent absence of erythroderma or the presence of only a sandpaper-like rash; severe generalized hyperesthesia; extreme pain at the site of skin involvement; and a mortality rate of 40 to 50 percent.[62,290] Both cell-associated and soluble streptococcal virulence factors, including M protein and pyrogenic exotoxins A and B, have been implicated as superantigens mediating the systemic effects of streptococcal TSS.[39,103,141]

Clostridium sordellii has been reported to cause a toxic shock–like syndrome after medical abortion with mifepristone and intravaginal misoprostol.[58,113,279]

UNIQUE MANIFESTATIONS

Work with superantigens suggests that the pathophysiologic events observed in TSS are the result of release of endogenous mediators after monocyte and T-cell activation by TSST-I or the staphylococcal enterotoxins.

The physiologic changes induced by this dysregulation of the immune system are striking in their rapidity of onset and progression and the involvement of almost all body tissues and organs. The consequent functional disorders of many organs appear to be the result of extensive endothelial damage and loss of peripheral vascular resistance. The generalized decrease in vasomotor tone results in pooling of blood in the peripheral vasculature, vascular congestion, and probably relaxation of the microcirculation. Rapid, nonhydrostatic leakage of fluid from the intravascular to the interstitial space, or "second spacing," does occur and is manifested as extensive generalized anasarca-like, nonpitting edema. The universal hypoproteinemia and hypoalbuminemia in patients with TSS suggest that the fluid leaking from the vasculature is high in protein.

Unique clinical manifestations include profuse vomiting and diarrhea, often associated with incontinence; generalized erythroderma; intense erythema of the mucous membranes, including conjunctival injection and subconjunctival hemorrhages; absence of inflammation in surgical wounds and other focal sites of infection; absence of bacteremia; severe hypocalcemia and hypophosphatemia; rapidly accelerated renal dysfunction; universal desquamation of the palms, soles, fingers, and toes; and risk for recurrent disease and long-term cognitive sequelae.

DIAGNOSIS

Application of the case definition for a single episode[330] or recurrent episodes[76] to the patient's illness is currently the only way to confirm the diagnosis (see Table 71–1). Aggressive attempts to find the focus of *S. aureus* replication that always should be undertaken include culture of the cervix and vagina in patients with menses-associated illness and culture of other potentially infected sites that may not appear to be infected obviously in patients with nonmenstrual illness. *S. aureus* isolates could be

examined, when possible, for their ability to produce TSST-I, although such testing seldom is indicated. This test is of limited usefulness for nonmenstrual cases because TSST-I is produced by only 40 to 60 percent of *S. aureus* isolates from such patients.[126] Isolates from these patients could be examined for the presence of the other enterotoxins. Acute and convalescent sera can be tested for the presence of antibodies to TSST-I and the other enterotoxins.[144] Elevated levels of anti–TSST-I in the acute-phase serum of a patient with menstrual-associated TSS would be highly unusual.

In most instances, toxin detection tests are of value only for research or for the rare patient with chronic recurrent or otherwise puzzling disease. Genes for TSST-I and the enterotoxins have been detected in *S. aureus* strains by polymerase chain reaction[19,157,178,194,219,273] and hybridization techniques.[156,216,226] A noncompetitive enzyme-linked immunosorbent assay allows quantitation of TSST-I in clinical samples.[195,209] Reversed passive latex agglutination has been used in hospital laboratories to detect TSST-I and in research laboratories to detect enterotoxins.[83,104] Research laboratories also have developed techniques for detecting the selective expansion of $V_\beta 2$-positive T cells as evidence of host response to superantigenic toxins.[54,187]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of TSS includes clinical entities in which a rapid onset of fever, erythroderma-like rash, hypotension, and multisystem involvement are observed[42,110,210,233,241,243] (Table 71–4).

PREVENTION AND PROPHYLAXIS

To decrease the risk of development of menstrual TSS, in 1982 the Institute of Medicine Committee on TSS recommended that women, particularly adolescents, minimize their use of high-absorbency tampons.[244] The committee also recommended that women who have had TSS not use tampons because of the increased risk of recurrence and that postpartum women be informed that the use of tampons might increase their risk for the development of TSS.

Although the frequency of changing tampons during a menstrual period has not been associated with risk for the development of TSS, the use of an individual tampon for no more than 12 hours at a time might decrease the risk for menstrual TSS. Women using intravaginal contraceptive devices also should be informed of the potential increase in risk for development of TSS.[275]

Although postoperative TSS is a rare event, it generally occurs in healthy people. As a result of the unexpected and potentially severe consequences of TSS, issues regarding surgical antimicrobial prophylaxis for prevention have been raised. Perioperative systemic antistaphylococcal antibiotics did not prevent TSS in four patients[35,260] and do not eradicate nasal carriage of *S. aureus*.[154] TSS with onset after 48 hours of amoxicillin therapy was reported in two patients after they underwent endonasal sinus surgery.[2] Topical bacitracin ointment on nasal packing does not prevent the development of TSS.[35,87,152,154]

Most authors contend that the rare risk of development of postoperative TSS is comparable to the risk of having a severe antimicrobial reaction and that perioperative antimicrobial prophylaxis is not indicated for clean procedures of short duration.[131,246] Effort should be intensified to recognize postoperative cases early; to open, explore extensively, and irrigate wounds; and to provide immediate antimicrobial and supportive therapy for suspected TSS.

TABLE 71–4 Differential Diagnosis of Toxic Shock Syndrome Based on Clinical Manifestations

Diagnosis	Fever	Exanthem	Shock
Severe invasive *Streptococcus pyogenes* infection	+	+	+

CHARACTERISTICS OF TOXIC SHOCK SYNDROME–ASSOCIATED *STAPHYLOCOCCUS AUREUS* ISOLATES

The ability to produce TSST-I, a previously uncharacterized protein, is the single most distinguishing characteristic of TSS-associated *S. aureus* strains. More than 90 percent of *S. aureus* isolates from patients with menstrual TSS[23,270] and 40 to 60 percent of isolates from patients with nonmenstrual disease[126] produce TSST-I as compared with less than 20 percent of non-TSS strains.

S. aureus strains isolated from patients with TSS are phenotypically different from other strains of *S. aureus*.[22,306] They produce less beta-hemolysis on sheep blood agar and less frequently harbor plasmids than control strains do. An increase in protease production and proteolytic activity by TSS-associated strains has been noted.[306] Next to TSST-I production, production of protease is the most characteristic marker for these strains.

Unlike non-TSS *S. aureus* strains, most TSST-I–positive strains of *S. aureus* require tryptophan for growth and production.[57] In one study, 91 percent of 27 TSST-I–positive vaginal *S. aureus* isolates were tryptophan auxotrophs as compared with 6 percent of 32 TSST-I–negative vaginal *S. aureus* isolates. Eight of 22 TSST-I–producing tryptophan auxotrophs were blocked at the tryptophan synthetase B locus, thus suggesting that the TSST-I gene cluster may have been inserted into this locus and disrupted its function.

Additional differences between TSS and non-TSS strains of *S. aureus* include the resistance of TSS strains to cadmium, arsenate, and penicillin, characteristics that usually are plasmid mediated but, in TSS strains, are chromosomally mediated. As such, these traits must be the result of heterologous insertions. These characteristics are not co-transferred with and therefore presum-

ably not closely linked to the gene segment responsible for TSST-I production.[22,306] TSST-I production is unrelated to methicillin susceptibility or resistance.[272]

ROLE OF STAPHYLOCOCCAL EXOTOXIN TSST-I AND THE ENTEROTOXINS IN TOXIC SHOCK SYNDROME

ROLE OF TSST-I

TSST-I appears to be an important toxin in TSS. Factors supporting this statement include (1) the observation that more than 90 percent of isolates from patients with TSS produce TSST-I, (2) the absence of acute-phase antibody to TSST-I in more than 90 percent of patients with menstrual TSS, (3) the increase in anti–TSST-I antibody during recovery in nonmenstrual cases, (4) absent or low levels of antibody in patients with recurrent menstrual TSS, (5) comparable illness inducible with TSST-I in in vivo animal models, and (6) neutralization of IL-1 stimulation and response to TSST-I by antibody to TSST-I.

Most convincing are experiments in which the ability to cause TSS followed bacteriophage-mediated transfer of the TSST-I–positive chromosomal segment into a recipient *S. aureus* strain without the segment.[82,233] Experiments demonstrating the effectiveness of monoclonal antibodies to TSST-I in reversing the effects of TSST-I provide additional strong support.[171]

ROLE OF ENTEROTOXINS

Because 40 to 60 percent of nonmenstrual TSS *S. aureus* isolates and 5 to 10 percent of menstrual TSS isolates do not produce TSST-I, a role for other staphylococcal exotoxins, including the enterotoxins, has been proposed.[22,66,177,190,234,266,337] Patients with nonmenstrual disease infected with TSST-I–negative strains may have a higher mortality rate.[126] Significant increases in the titer of antibody to the staphylococcal enterotoxins during convalescence strongly suggest a role for these proteins in the pathogenesis of TSS.[12]

In rabbit models, the morbidity and mortality occurring after the injection of TSST-I–negative TSS isolates were comparable to those occurring after infection with TSST-I–positive strains and significantly greater than after inoculation with TSST-I–negative non-TSS isolates.[126] Administration of staphylococcal enterotoxins to animals results in many of the manifestations characteristic of TSS.[21,102]

When large numbers of isolates from patients with TSS have been examined, production of TSST-I alone is the toxin pattern identified most commonly.[22,66,184] Other patterns identified include production of TSST-I in combination with one or more of the identified enterotoxins, production of enterotoxins *only* (one or more), and nonproduction of TSST-I and enterotoxins. Of the TSS strains producing TSST-I, 60.6 percent also produce an enterotoxin.[66,184] SEA is co-expressed with TSST-I frequently, particularly in menstrual isolates. A clone producing both TSST-I and SEA is associated with 88 percent of menstrual TSS cases and may account for as many as 54 percent of isolates from nonmenstrual TSS cases.[44] Seroconversion to SEA occurs more commonly in TSS than in non-TSS *S. aureus* infection, thus further suggesting a role for SEA. TSST-I and SEA have a common MHC class II binding domain and share overlapping domains critical for superantigenic and lethal activities. A monoclonal antibody to TSST-I inhibits these SEA-induced activities.[172]

The third most common pattern of toxin production by TSS isolates is that of TSST-I plus SEC. These isolates have been associated with both menstrual and nonmenstrual cases and particularly with severe respiratory tract TSS-associated infections.[66] NTED also has been associated with MRSA isolates exhibiting a clonal pattern with TSST-1 and SEC production.[147]

The fourth most common pattern of toxin production is that of SEB alone. In one study, strains producing SEB alone accounted for 38 percent of all nonmenstrual TSS isolates.[177,266] This prevalence is significantly higher than that for isolates from non-TSS *S. aureus* infections (15%) or asymptomatic carriers (13%). SEB never is co-expressed with TSST-I. Even though all TSST-I–positive isolates contain the SEB genetic determinant, none produces SEB. SEB is produced only by isolates that have the SEB gene and no TSST-I gene. Given that production of both toxins is mutually exclusive and both genes are located close together on the chromosome, researchers have suggested that the TSST-I genetic determinant may have a preferred site of insertion within the SEB genetic element. Because the TSST-I gene is associated with a variable genetic element and such mobile genetic elements are known to be capable of gene disruption, the gene possibly was inserted within the SEB gene or in a position that interferes with its transcription.[83]

A TSS isolate producing TSST-I along with two other enterotoxins is the fifth most common combination, and an isolate producing no known toxins is the sixth. The identification of new enterotoxins[251,295] capable of producing TSS-like disease in rabbits may account for isolates previously identified as producing no toxins. Isolates producing a non-SEB enterotoxin alone are the least common.

PREVALENCE OF EXOTOXIN-PRODUCING *STAPHYLOCOCCUS AUREUS* STRAINS AND ANTIBODY TO THE EXOTOXINS

PREVALENCE OF EXOTOXIN-PRODUCING ORGANISMS

TSST-I–positive strains of *S. aureus* have been present since at least 1957, and antibody to TSST-I was as prevalent in the general population in 1960 as it was in 1999.[236,324] Thus, the increase in incidence of TSS from 1980 to 1985 is assumed to have been the result of newly introduced cofactors rather than an increase in the prevalence of TSST-I–positive organisms.

At any given time, *S. aureus* is present in 20 to 40 percent of cultures from the anterior nasal vestibule of adults and in as many as 33 percent of nasal cultures from children.[151] A study of 3012 menstruating women between 13 and 40 years of age in North America from 1998 to 1999 showed that 26 percent were colonized with *S. aureus* in at least one of three body sites (nose, vagina, or anus) and 9 percent were colonized vaginally.[236] In women, the prevalence of *S. aureus* in vaginal cultures is higher during menses than at midcycle.[186,225] Vaginal carriage rates vary from 7 percent in premenarcheal and nonmenstruating women to 33 percent in menstruating women.[236,239] TSST-I–positive *S. aureus* is present in 1 to 5 percent of vaginal cultures in women, 7 percent of nasal cultures in hospitalized patients, and 18 percent of nasal cultures in children. In prospective studies of *S. aureus* isolates from healthy individuals and from specimens received for other purposes, 14 to 39 percent of all isolates produced TSST-I and 7 to 14 percent produced SEB.[85,233,236] Overall, between 1 and 7 percent of healthy individuals at any given time are colonized at a mucosal site with TSST-I–positive *S. aureus*.

Of 60 *S. aureus* isolates from blood cultures of patients who did not have TSS, 28 percent produced TSST-I.[46] Presumably, these patients had circulating antibody to TSST-I that prevented the development of TSS despite *S. aureus* infection. Adults and children with persistent nasal carriage of a TSST-I–positive strain have high levels of antibody to TSST-I.[236,254]

Evidence suggests that a single clone of *S. aureus* causes most cases of TSS.[44,214] Multilocus enzyme electrophoresis has demonstrated that the TSST-I gene *tst*H is distributed widely over the whole spectrum of *S. aureus* genotypes. Of 315 *S. aureus* strains collected from around the world, 88 percent of menstrual TSS strains and 53 percent of nonmenstrual strains were indistinguishable by multilocus enzyme electrophoresis. The same clone also was found in 28 percent of vaginal isolates from asymptomatic women. This remarkable phenomenon may reflect the unique ability of this clone to colonize the urogenital epithelium or the unique capability of this clone to cause disease. Although TSS strains are similar in gene content, indicative of a common ancestor, their considerable heterogeneity indicates that the common ancestor was not recent in evolutionary time.[118] Thus, the TSS outbreak was the result of a change in the host environment and not geographic dissemination of a new "hypervirulent" strain.[118]

Even though TSST-I–positive strains may cluster within families, living units, and hospital settings, the occurrence of TSS clusters is a rare event.[169,212] Probable TSS has developed within 24 hours in a husband and wife[115] and in two mother-daughter pairs. Nosocomial acquisition and transmission of TSST-I–positive organisms have been described.[9,169,212]

PREVALENCE OF ANTIBODY TO EXOTOXINS

The prevalence of antibody to TSST-I in 689 Wisconsin residents was found to be 47 percent at 1 year of age, 58 percent at 5 years, 70 percent at 10 years, 88 percent at 20 years, and 96 percent for ages 30 to 50 during the years 1960 to 1983 (see Fig. 71–2).[315] The presence of transplacentally acquired antibody in more than 90 percent of infants also was demonstrated.[324] A study of 3012 menstruating women between 13 and 40 years of age across North America in 1998 and 1999 found similar results, with 85 percent overall and 81 percent of subjects aged 13 to 18 years having positive antibody to TSST-1.[236] Among carriers of toxigenic *S. aureus*, a significantly lower percentage of black women (89%) than white or Hispanic women (98% and 100%, respectively) had positive antibody titers. Mucosal colonization with TSST-I–positive *S. aureus* strains is assumed to result in antibody formation.[254] Coworkers of a nurse in whom recurrent TSS developed were demonstrated to be colonized by TSST-I–positive strains and to form antibody to TSST-I, but not to acquire TSS during a period of several months.[9] Subclinical and mild, unrecognized disease[48] may result in the formation of antibodies as well.

Acquisition of antibodies to the enterotoxins also is age related. By the time that children reach the age of 10 years, the proportion with antibody titers of 1:100 or higher is 15 percent for SEA, 65 percent for SEB, 30 percent for SEC, 5 percent for SED, and 20 percent for SEE. By 22 years of age, the numbers increase to 55 percent for SEA, 77 percent for SEB, and 98 percent for SEC.[22]

Former studies suggested that the prevalence of antibody varies from one area of the country to another. During 1982, of 1017 serum samples obtained from U.S. Air Force recruits between the ages of 17 and 26 years, 35 percent from the Mountain and Pacific states were serosusceptible to TSST-I versus 3 percent from the south Atlantic states and 5 percent from the east south central states. Because low titers appear to indicate susceptibility, the findings in this study suggest that differences in the incidence of TSS among states and regions were explained in part by differences in host susceptibility.[322] However, the 2005 multicenter study of 3012 women from Ohio, New Jersey, Florida, Arizona, and Manitoba, Canada, found no significant regional differences in rates of *S. aureus* colonization or prevalence of antibody.[236]

Sera randomly selected from 87 control women were seronegative more frequently for antibody to TSST-I (24%) than were those from 66 control men (9%), which led to the suggestion that women may be more susceptible than men to TSS.[259] Patients in whom TSS develops have significantly lower levels of antibody to SEB and SEC, as well as to TSST-I, than the general population does.[22,66]

As noted in the discussion on recurrence, acute-phase sera of patients with TSS uniformly demonstrate absent or low levels of antibody to TSST-I. The antibody response to TSST-I is absent or delayed in both menstrual and nonmenstrual TSS.[233,294]

PHYSICOCHEMICAL AND BIOLOGIC CHARACTERISTICS OF TSST-I

PHYSICOCHEMICAL PROPERTIES

The mature secreted TSST-I protein is a single polypeptide chain with a molecular weight of 22,000 daltons and an isoelectric point of 7.2. It is resistant to proteolytic digestion by trypsin but is hydrolyzed by pepsin at pH 4.5. In sterile solution at neutral pH, it is stable for months. When lyophilized, it is a white powder that easily dissolves in distilled water. No loss of serologic activity of the lyophilized powder occurs for at least a year. TSST-I can be heated to 100°C for longer than an hour without loss of biologic activity.[29]

Purification of TSST-I has yielded diffraction-quality crystals that have led to an understanding of its three-dimensional structure.[29] The molecule is folded into two closely associated domains that create two major grooves, the front and backside grooves. The backside groove is larger and more exposed to the external environment. The crystal structures of all the protein superantigens have striking similarity in the two-domain conformational architecture, even though the primary protein segments are different.[189]

REGULATION OF PRODUCTION

S. aureus is highly adaptable and able to live and grow in extremes of temperature, pH, and oxygen concentration. TSST-I production, however, is controlled tightly. TSST-I is not produced in unfavorable conditions, including an anaerobic environment, pH values lower than 6.0 and greater than 8.0, concentrations of clindamycin below the MIC of the organism, glucose concentrations greater than 3 percent, and temperatures lower than 37°C or greater than 40°C.[22,29,335] Conditions and factors that enhance production of TSST-I include uniform aeration of medium through shaking or a roller apparatus, complex medium containing animal protein and low glucose concentrations, a neutral pH, incubation in 5 percent carbon dioxide (under some in vitro conditions), and temperatures of 37°C to 40°C. The role of magnesium is unclear.[88] Twice as much toxin is produced at 40°C as at 37°C. The addition of blood to media does not increase production of TSST-I reliably. Depending on in vitro growth conditions, most strains of TSST-I–negative *S. aureus* produce 3 μg/mL of TSST-I, but some may produce up to 30 μg/mL.

Under optimal in vitro growth conditions, TSST-I production lags behind but parallels bacterial growth. Like other *S. aureus* exotoxins, TSST-I is made primarily during the postexponential phase of growth, when nutrients are scarce and cell density is great.[85] Levels of TSST-I remain stable throughout the stationary phase, even after the organisms begin to die. Under less than optimal conditions, synchronous production of TSST-I and growth of *S. aureus* do not occur. For example, bacterial growth

may be reduced only twofold in an anaerobic environment, whereas TSST-I production is inhibited. Likewise, clindamycin at concentrations below the MIC for the organism will inhibit the production of toxins without altering growth.[269]

Most strains of *S. aureus* do not have the genes for TSST-I or the enterotoxins. TSST-I thus is not necessary for bacterial homeostasis, and its production is a variable genetic trait.

The gene *tst*H is encoded by a transposon-like mobile genetic element.[57,83,148,170] The chromosomal fragment with the structural gene for production of TSST-I is a 10.6-kilobase (kb) unit that has been cloned in *E. coli*. *tst*H has been sequenced and encodes a 234–amino acid protein that is converted by the removal of a signal peptide of 40 amino acids to the mature exotoxin of 194 amino acids.[29,85,170] *tst*H has been inserted in the chromosome to disrupt both the tryptophan synthetase B and SEB genes, thereby preventing the production of both proteins.[57,83]

Production of TSST-I and other post–exponential-phase virulence factors is regulated by three separate genetic loci: the accessory gene regulator (*agr*), the staphylococcal accessory regulator (*sar*), and the extracellular protein regulator (*xpr*).[12,29,85] All three regulators affect gene expression primarily at the level of transcription. During the late log phase of bacterial growth, they activate the expression of TSST-I, alpha- and gamma-hemolysins, serine protease, and nuclease and downregulate the expression of cell wall–associated proteins, fibronectin-binding protein, protein A, and coagulase. Beta-hemolysin, SEB, SEC, and exfoliative toxin A are regulated less tightly by *agr* than TSST-I is. SEA appears to be independent of *agr* in some strains. This complex regulation of exoprotein synthesis probably is the result of a complex interaction between environmental factors and gene products.[29,85] These regulatory functions explain why the production of TSST-I is stimulated under some conditions without SEA or SEC stimulation.[335]

Glyceryl monolaurate is a mild surfactant and emulsifier commonly used in the food and cosmetic industries. It is capable of inhibiting the production of staphylococcal and streptococcal exotoxins at concentrations subinhibitory to growth.[40,245,267] As a lipophilic compound, the mechanism of action appears to be insertion into the cell membrane with resulting interruption of signal transduction. Other surfactants used in the tampon industry have been found to both inhibit and enhance[268] the production of TSST-I in vitro.

KINETICS OF DISTRIBUTION

Detecting TSST-I in body fluids is difficult. In humans, nanogram quantities have been detected by radioimmunoassay in the breast milk of a woman with TSS,[149,323] in serum early during illness in two of four patients,[195] in urine, and in vaginal washings in a small number of patients.[195] By means of the rabbit subcutaneous Wiffle ball abscess model, TSST-I can be detected first in abscess fluid 4 hours after *S. aureus* has been inoculated into the Wiffle ball and in urine 48 hours after inoculation.[195]

For further examination of in vivo target tissues for TSST-I activity, purified TSST-I radiolabeled with iodine 139 has been injected intravenously into rabbits. Measurement of plasma clearance demonstrated a half-life of 1.5 hours. Within 15 minutes of injection, TSST-I was concentrated fourfold in blood cells in comparison to plasma. Toxin persisted in the cellular compartment, and plasma concentrations fell. After 3 hours, most of the radiolabel was found in the spleen.

TSST-I, SEA, and SEB can cross epithelial membranes intact in a fully functional form.[134] In a cellular model of the blood-brain barrier, TSST-1 showed slow bidirectional movement consistent with restricted paracellular diffusion.[18]

CELLULAR INTERACTIONS

TSST-I has been shown to inhibit systolic function in isolated rabbit atria.[224] It also can bind directly to human and porcine endothelial cells and is cytotoxic to porcine endothelial cells because it permits leakage across endothelial cell monolayers.[173,176] However, concentrations of TSST-I needed to induce these and other diverse cytotoxic changes in vitro are higher than the usual tissue and serum levels. Interactions of TSST-I and the enterotoxins with T lymphocytes and antigen-processing cells are described in the next section.

BIOLOGIC FUNCTIONS

Animal Models

Much information regarding pathogenesis has been obtained from both the subcutaneous Wiffle ball and the vaginal tampon rabbit models and a primate model.[81] Rabbits, primates, and other species have been examined for sensitivity to TSST-I or TSS-associated strains of *S. aureus*.[232] Rabbits and baboons exhibit clinical and laboratory changes most consistent with the human syndrome, including pyrogenicity and lethality.* The signs and symptoms observed in these animals after the intravenous injection of purified TSST-I include skin erythema, conjunctivitis, diarrhea, lethargy, tachypnea, respiratory distress, central nervous system changes, and increased capillary permeability, as demonstrated by the skin bluing technique. A variety of laboratory abnormalities consistent with those described in human TSS have been reported for these models.

Immunoregulatory Activities

The absence of in vitro cytotoxicity of TSST-I[22,232] despite potent in vivo biologic effects has suggested an important role for endogenous mediators in TSS. The ability of SEB to induce dramatic T-cell proliferation was recognized a decade ago.[160,166,185] Subsequent work has shown it to be a feature of other bacterial exotoxins, including TSST-I, the staphylococcal enterotoxins, the streptococcal pyrogenic exotoxins A and C, a new streptococcal superantigen, and a streptococcal M surface protein.[166] Since the late 1980s, activation of T cells by these bacterial components or products has become an area of intense interest. The term *superantigen* was coined in 1989 to describe antigens that at concentrations lower than those of conventional antigens (picomolar concentrations) can stimulate proliferation of a large percentage of T cells bearing a TCR beta-chain variable (V_β) sequence or sequences specific for each superantigen. Such activation and proliferation of T cells result in profound alterations in immune system homeostasis by inducing the release of large quantities of monokines (IL-1, TNF-α) and lymphokines (IL-2, TNF-β).[166,280,341]

T cells are activated to produce lymphokines as a result of TCR-antigen binding and activation of signal transduction.[45,94,287] Antigens can bind to the TCR in one of two forms: as conventional antigens or as superantigens. Conventional antigens enter antigen-processing cells by endocytosis. They are broken into small peptides in the lysosomal compartments of the antigen-processing cell and targeted to small vesicles, where they form complexes with one of the allele-restricted MHC class II molecules (HLA-DQ, HLA-DP, and HLA-DR).[280] The complex then is transported to the cell surface, where it is bound in the groove on the heavy chain formed by the alpha and beta chains of the class II molecule. Certain amino acids in residues at critical points

*See references 31, 32, 81, 82, 196, 198, 200, 234, 247, 270, 276.

in the peptide's sequence anchor the peptides in the groove, and this interaction is moderately specific for each different allelic form of the MHC molecule.[280] This complex of peptide and MHC molecule of the same allelic type as the T cell is recognized by the TCR.

The TCR is composed of both alpha and beta glycoprotein chains, each of which is composed of variable (V) and joining (J) segments. The beta chain has an additional diversity (D) segment. As many as 50 V_β and 32 V_α segments are present on human T cells. The $V_{\alpha\beta\alpha\beta}$ segments each are encoded by different genes that undergo gene rearrangement to give more than 10,000 possible combinations to recognize conventional antigenic peptides presented by antigen-processing cells.[16,280] Conventional antigens presented as peptides must be recognized by a specific combination of these elements. Thus, one peptide will activate only 1 in 10^4 to 10^6 T cells, and only $CD4^+$ T cells respond to conventional antigens.

In contrast, superantigens are presented to T lymphocytes in a very different fashion. They bind first as intact proteins (small fragments are inactive) to most allelic forms of MHC class II molecules in an unrestricted fashion at a site outside the peptide-binding groove. They then react with the TCR only through the V_β element or elements specific for that molecule and will react with all T cells carrying that V_β element.[145] Because only 25 to 50 major families of V_β genes exist in humans, each superantigen can interact with 5 to 20 percent of resting T cells, depending on the frequency of T cells expressing that V_β family in each individual's repertoire. Both $CD4^+$ and $CD8^+$ T cells are activated. Features unique to the presentation of superantigens to the TCR V_β receptor thus include the requirement for initial binding of superantigen to the MHC class II molecule (even if unrestricted and not self) outside the antigen-presenting groove and the requirement for an intact superantigen protein.

Once the T cell has recognized the superantigen,[132] both antigen-processing cell and T-cell activation by signal transduction[45] results in release of cytokine by the antigen-processing cell (IL-1, TNF-α) and the lymphocyte (IL-2, TNF-β). In mice and possibly also in humans, the initial T-cell activation occurs in lymph nodes.[205] Within hours of T-cell activation by superantigens, cytokines are detected in vitro and in serum in vivo.

TSST-I binds only to the $V_\beta 2$ element.[256] In humans with TSS caused by TSST-I–secreting *S. aureus*, within 10 to 14 days 30 to 70 percent of the circulating T-cell population will be T cells bearing the $V_\beta 2$ element.[53,54,187] The number of circulating $V_\beta 2$ T cells does not return to normal for several months. In contrast, patients with TSS caused by *S. pyogenes* have a consistent pattern of depletion of certain V_β T-cell types after T-cell activation.[166,220,327] In mice, such depletion is thought to be the result of programmed cell death (apoptosis).[203,204]

Thus, activation of T cells by superantigens may result in massive cytokine release with subsequent selected V_β T-cell expansion, T-cell deletion, or apoptosis, depending on the superantigen and species. The fact that superantigens bind only to selected and specific V_β elements distinguishes them from the nondiscriminating mitogens.

Activation of monocytes and lymphocytes by superantigens involves signal transduction. Activation of both src protein tyrosine kinases and protein kinase C occurs in a manner common to that of other immunoglobulin supergene family members. MHC class II cells also are expressed on beta, endothelial, and dendritic cells. In some instances, superantigens may activate these cells uniquely.

Convincing evidence from the mouse model supports a central role for T-lymphocyte activation in superantigen-mediated disease. Mice that have received cyclosporine to block T-cell activation and lymphokine production or mice with severe combined immunodeficiency disease are protected against SEB-induced lethal shock. Repopulation with T cells results in susceptibility to SEB. The same mice are not protected against endotoxin-induced shock because lipopolysaccharide activates only monocytes.[203-205]

Mononuclear production of IL-1 and TNF-α is central to the shock induced by endotoxin. Production of these two cytokines in addition to production of the lymphokines IL-2, IFN-α, and TNF-β may explain the enhanced severity of superantigen-associated TSS.[30,132,166] These powerful effects on the immune system may account for the tenacity of shock in otherwise healthy individuals. If more than one superantigen is produced by an organism (e.g., TSST-I plus one or more enterotoxins), different V_β specificities would result in an even greater number of T cells being activated, with the potential for development of disease with enhanced severity and mortality.

Once superantigens have resulted in monokine and lymphokine release, the subsequent pathophysiologic events appear to be related to the many and complex interactions of these cytokines,[30,136,340] with the ultimate result being profound endothelial damage. TNF-α and TNF-β and the complex interaction of cytokines, leukotrienes, prostaglandins, adhesion molecules, nitric oxide, platelet-activating factor, complement components, neutrophils, platelets, and endothelium-derived factors appear to be responsible for the extensive endothelial damage and resulting capillary fluid leakage and the decrease in peripheral vascular resistance.[30,136,261,340] In a different setting of antineoplastic therapy, high doses of IL-2 and lymphokine-activated killer cells induce the capillary leak syndrome, which is characterized by rapid weight gain, anasarca, pulmonary edema, hypoalbuminemia, and multiple organ dysfunction in humans.[64,165]

Endotoxin Enhancement

A striking property of TSST-I is its marked ability to enhance the susceptibility of some animals to lethal endotoxic shock.[29,265,270] Intravenous administration of TSST-I to rabbits at less than $^1/_2$ the median lethal dose (LD_{50}) followed 2 hours later by endotoxin at less than $^1/_{500}$ the LD_{50} results in 50 to 100 percent mortality, a 10,000-fold enhancement. In vitro, endotoxin enhances IL-1 production by TSST-I–stimulated monocytes.[20] Whether enhanced endotoxin susceptibility plays any role in human disease is not clear.[55]

STRUCTURE-FUNCTION RELATIONSHIPS

Effort to understand the molecular actions of TSST-I has focused on separating regions that interact with the TCR from those required for lethality.[29,31,32,213] Through the use of TSST-I variants (TSST-ovine and TSST-bovine) and TSST-I molecules with single–amino acid mutations, the areas responsible for binding of TSST-I to both the TCR and the macrophage class II MHC molecule have been defined.[29] In animal models, lethality, induction of fever, and endotoxin susceptibility do not depend on T-cell proliferation as measured by superantigenic activity but must involve interaction of toxin with other host-cell receptors in the body.[29]

Most secreted bacterial superantigens are small, compact globular proteins of 20 to 30 kd.[29] They are protease-, heat-, and acid-resistant and share immunologic, biologic, and functional properties. However, they do not share sequence homology. Although they do not share obvious structural features that would predict their superantigen properties, they may share a common conformational structure.[166] The secreted exotoxins can be divided into two groups based on their amino acid sequence homology. In group 1, SEA, SED, and SEE share 54 to 90 percent homology. In group 2, streptococcal pyrogenic exotoxin A, SEB, and SEC-1, SEC-2, and SEC-3 share 46 to 68 percent homology. In group 3, TSST-I, the exfoliative toxins, and strep-

tococcal pyrogenic exotoxin show no significant homology to each other or to any of the members of group 1 or 2. However, all the secreted superantigens may share a three-dimensional conformation that allows them to interact simultaneously with two different receptors on two different cell types.[29,166]

The structure and binding sites of SEB to the MHC class II molecule have been determined by crystallographic conformation. Two different MHC class II binding sites for SEB exist. The amino-terminal domain forms most of the contact, but residues at the carboxy-terminal domain also contact the MHC class II molecule, as well as the TCR. Although TSST-I is very similar to SEB on the basis of their crystallographic structure, the two proteins do not compete with each other for the same MHC class II HLA-DR sites. Likewise, SEA and SEE have greater than 90 percent amino acid sequence homology but quite distinct patterns of V_β specificity. TSST-I and the exfoliative toxins A and B are unrelated structurally but have the same $V_\beta 2$ specificity.[166,185]

CHAPTER 72

Acute Respiratory Distress Syndrome in Children

Christopher M. Oermann ✪ Peter W. Hiatt

Ashbaugh and associates[11] first used the term *adult respiratory distress syndrome* in a case series that they reported in 1967. In it, they described a clinical syndrome of diverse etiology that was characterized by the development of fulminant respiratory failure associated with rapidly progressive bilateral pulmonary infiltrates in the absence of cardiac failure. Although the mortality rate in their patients was 67 percent, four individuals treated with continuous positive airway pressure and high positive end-expiratory pressure (PEEP) survived. Postmortem examination of the lungs from nonsurvivors revealed significant pulmonary edema and hyaline membrane formation. They assumed that the presence of hyaline membranes and the favorable response to positive pressure indicated an acquired surfactant deficiency. The term *adult respiratory distress syndrome* was used as an analogy to neonatal respiratory distress syndrome (hyaline membrane disease) caused by insufficient surfactant production and is now referred to as *acute respiratory distress syndrome* (ARDS).

ARDS now is recognized as a relatively common sequela of a variety of local or systemic diseases that result in damage to the vascular endothelium, alveolar epithelium, and alveolar-capillary membrane. Compromise of these structures leads to the final common pathway of ARDS: pulmonary vascular leak, noncardiogenic pulmonary edema, and respiratory failure. The clinical syndrome consists of tachypnea, dyspnea, and marked hypoxemia caused by edema and reduced total lung compliance. Radiographs demonstrate diffuse bilateral opacities. Although considerable research has been conducted in an attempt to identify factors predisposing individuals to ARDS and even more in therapeutic trials, ARDS remains poorly understood and therapy is primarily supportive. Even though mortality rates in adults and children

have decreased during the past 20 years, ARDS remains a life-threatening disease.[77,102,123]

ARDS initially was described in adults, but it has been recognized as a leading cause of mortality in pediatric patients in critical care units. More than 500 cases have been reported in children ranging in age from 2 weeks to 17 years.* The true incidence of pediatric ARDS is unknown but has been estimated to be between 8.5 and 10.4 cases per 100 pediatric intensive care unit (ICU) admissions.[107] The prevalence rate of ARDS in pediatric patients in ICUs has been reported to be 0.6 to 7.2 percent.[23,27] A recent population-based study of pediatric ARDS in Germany reported a prevalence of 5.5×10^{-5} cases per year and an incidence of 3.4×10^{-5} cases per year.[18] As in adults, ARDS in children can result from a variety of injuries that all lead to increased vascular permeability, pulmonary edema, and clinical respiratory failure. Also as in adults, ARDS develops in most children as a result of sepsis, pneumonia, and aspiration.[30,33,44,91,141] Advances in supportive therapy for ARDS have improved outcomes in adults, and the results of several adult clinical trials have been extrapolated for use in children. The overall mortality rates have decreased in both adults and children during the past decade, with recent pediatric studies reporting mortality rates of 22 to 31 percent.[30,33,35,44,141]

DEFINITION

Defining ARDS has been the source of much confusion and, at times, heated debate. Initially, ARDS signified a disease of adults, but the reporting of numerous cases in children prompted the use of *acute* rather than *adult* respiratory distress syndrome. Although both terms occasionally appear, *acute respiratory distress syndrome* currently is the preferred designation. Early attempts at defining ARDS resulted in the use of criteria proposed by the National Heart, Lung, and Blood Institute (NHLBI) that included (1) acute and rapidly progressing pulmonary disease of a noncardiac nature; (2) progressive, diffuse, bilateral pulmonary infiltrates on chest radiographs; and (3) hypoxemia, defined as a ratio of arterial oxygen tension to the fractional concentration of inspired oxygen (Pao_2/Fio_2) of less than 150 without PEEP or less than 200 with PEEP. Continued interest in the systematic study of ARDS from epidemiologic and therapeutic standpoints, combined with continued difficulty in comparing data because of differences in definition, led to the formation of an international discussion group. The European-American Consensus Committee on ARDS then published a unifying definition of ARDS that included (1) impaired oxygenation with a Pao_2/Fio_2 ratio less than 200, regardless of PEEP; (2) bilateral densities demonstrated on chest radiographs; and (3) pulmonary artery wedge pressure less than 18 mm Hg with no evidence of left atrial hypertension.[15] Although this definition of ARDS in pediatric populations is widely accepted, recent evaluation suggests that the Pao_2/Fio_2 ratio used may need to be modified in children.[103]

PATHOPHYSIOLOGY

The pathophysiologic abnormalities associated with ARDS, though studied extensively since the syndrome was originally described in 1967, remain incompletely understood. A host of seemingly unrelated systemic diseases and local insults to the respiratory tract have been reported to result in ARDS. Despite efforts to elucidate the precise chain of events that lead from these initial triggers to massive cellular injury and rapidly progressive respiratory failure, much of the process remains a mystery. Nonetheless, certain cellular and biochemical markers, as well as physiologic characteristics associated with ARDS, have been identified. In addition, the histologic findings seen in ARDS follow a characteristic pattern that has been well described. These pathophysiologic events and findings generally correlate with the clinical findings seen in ARDS.

As mentioned earlier, a wide variety of apparently unrelated disorders and injuries have been associated with the development of ARDS[22,26,33,35,70,91,107,135] and include a broad spectrum of infections (bacterial, viral, and other), inhalation/aspiration injuries, sepsis syndromes, trauma, drug reactions and metabolic disorders, transfusion and stem cell transplantation reactions, and malignancies, among other causes (Tables 72–1 and 72–2). Although the mechanism or mechanisms of injury that unite this group are unknown, underlying damage to the vascular endothelium, alveolar epithelium, or alveolar-capillary membrane (or any combination of such damage) clearly must be present. Several hypotheses have been proposed and are summarized in review articles.[105,111] These hypotheses include activation of the complement cascade, excessive neutrophil and macrophage activity, surfactant dysfunction, and others. A more recent review of ARDS summarizes the importance of disruption of the alveolar-capillary barrier and its constituents—the microvascular endothelium and the alveolar epithelium.[145]

Complement activation occurs after trauma, pancreatic damage, endothelial damage, exposure to endotoxin, and other systemic and respiratory injuries.[99] By-products of complement activation then cause recruitment and activation of neutrophils, which in turn escalate the inflammatory cycle and damage the

pulmonary parenchyma through the release of oxygen radicals, proteolytic enzymes, and eicosanoids. A strong association has been demonstrated between complement activation and the development of ARDS.[50] However, other investigators have reported that complement activation is nonspecific in predicting the development of ARDS.[40,64,83,150] Additional evidence suggests that the combination of circulating endotoxin and complement activation is potentially more important in the development of ARDS than is complement activation alone.[82] Complement activation further stimulates an inflammatory cascade involving tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), IL-6, IL-8, and other mediators.[14] Additional studies suggest possible roles for other proinflammatory elements, as well as genetic influences related to the inflammatory response.[31,48,89]

Significant, though again not conclusive, evidence suggests a key role for neutrophils in the genesis of ARDS.[14,129] Once activated, neutrophils can damage the lung parenchyma by the release of proteolytic enzymes, generation of toxic oxygen radicals, and initiation of arachidonic acid metabolism. Numerous studies have indicated potential roles for superoxide radicals in the development of ARDS or the presence of elevated concentrations of peroxide in the breath of ARDS patients.[54,124,125] Patients with ARDS similarly have elevated concentrations of elastase and collagenase and increased leukotriene B_4 in bronchoalveolar lavage fluid, findings consistent with neutrophil degranulation.[124,127] Although neutrophils are capable of causing widespread parenchymal lung damage, are characteristically found in ARDS, and probably play some role in the pathogenesis or propagation of ARDS (or both), the occurrence of ARDS in severely neutropenic individuals suggests that they are not essential or singly responsible for its development.[80,115]

Alveolar macrophages may play a critical role in the pathogenesis of ARDS. They are found in abundance in normal airways, and when stimulated by endotoxin or endogenous proinflammatory cytokines, alveolar macrophages synthesize and release TNF and IL-1.[111] Both products promote neutrophil chemotaxis, degranulation, and release of oxygen metabolites, thereby creating a cycle of inflammation within the pulmonary parenchyma. Administration of TNF to animals in experimental models produces pulmonary edema, decreased pulmonary compliance, increased cellularity, and increased lung water, the primary physiologic markers of ARDS.[121,138,139] Conversely, anti-TNF antibody offered protection from ARDS in a baboon septicemia model.[140]

In his review article, Royall[105] also discusses putative roles for oxygen radicals, platelet-derived eicosanoids, proteolytic enzymes, fibrin and its degradation products, and other processes that may be involved in the pathogenesis of ARDS. Likewise, secondary injuries, such as acquired surfactant deficiency, oxygen toxicity, and barotrauma, are thought to contribute to the pulmonary damage. As noted in the same article, a single mediator or mechanism probably is not responsible for all the findings seen in ARDS, and simultaneous activity on several fronts most likely occurs.

The physiologic hallmark of ARDS is damage to the capillary endothelium and alveolar epithelial barriers, leading to disruption of the alveolar-capillary membrane, increased permeability, and noncardiogenic pulmonary edema.[107] Increasing fluid within the alveoli and interstitial spaces leads to decreased total lung compliance, decreased functional residual capacity, increased airway resistance, and increased dead space. The resultant ventilation-perfusion mismatch creates the large intrapulmonary shunt responsible for the profound hypoxemia seen clinically.[63] Additional physiologic derangements seen in ARDS include alterations in peripheral oxygen delivery and consumption, pulmonary hypertension with right ventricular compromise, and end-organ damage (liver, kidney, intestine, bone marrow).[23,111,148]

The histologic findings seen at postmortem examination of patients dying as a result of ARDS are very consistent and have been well described.[12,60,95,137] Historically, three interrelated and overlapping phases are described. They correlate well with clinical progression of the syndrome and include the exudative, proliferative, and fibrotic phases.[14] The early exudative phase typically is recognized from 12 to 96 hours after the onset of respiratory failure.[107,111,137] It is characterized by increased fluid in the alveoli and interstitium and hemorrhagic alveolitis. Grossly, the lungs are rigid, dusky, red-blue, and very heavy.[137] The alveolar fluid is protein-rich, often hemorrhagic, and associated with hyaline membranes.[95] A combined neutrophilic and monocytic infiltrate is observed in the pulmonary capillaries, interstitium, and alveoli (Fig. 72–1A). Although capillaries also contain fibrin plugs and microthrombi, endothelial cells show only subtle abnormalities when compared with the alveolar surfaces, which undergo degeneration and sloughing.[107]

The proliferative phase occurs 3 to 10 days after the onset of ARDS and is characterized by organization of the alveolar and interstitial exudates acquired during the exudative phase.[137] Gross examination reveals the lungs to be solid, pale gray, and slippery because of the generation of connective tissue. The proliferation of type II cuboidal epithelial cells occurs as early as 3 days after onset, with fibrosis visible by 10 days. Type II pneumocytes are metabolically active and responsible for the production of surfactant, and they evolve into the type I epithelial cells that line the alveolar spaces (see Fig. 72–1B). Within the alveolar walls, fibro-

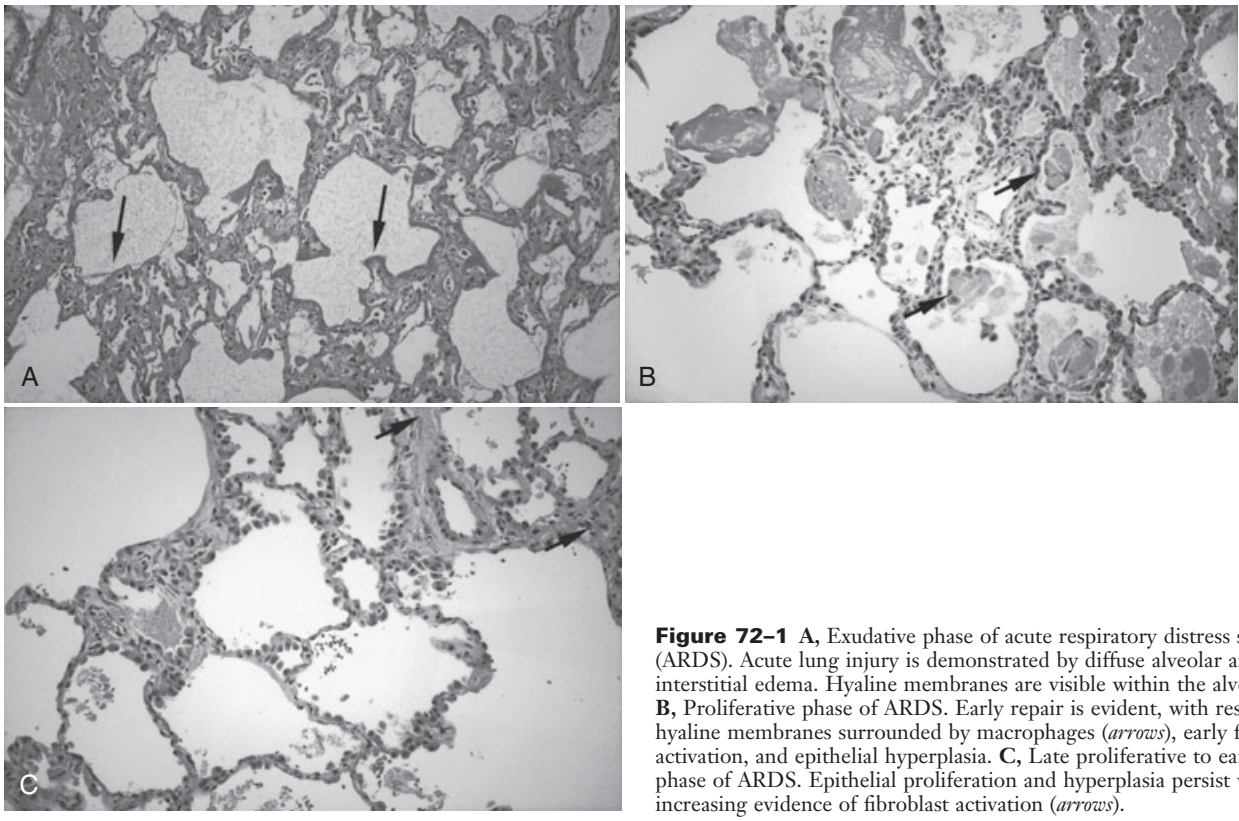

Figure 72–1 **A,** Exudative phase of acute respiratory distress syndrome (ARDS). Acute lung injury is demonstrated by diffuse alveolar and interstitial edema. Hyaline membranes are visible within the alveoli (*arrows*). **B,** Proliferative phase of ARDS. Early repair is evident, with residual hyaline membranes surrounded by macrophages (*arrows*), early fibroblast activation, and epithelial hyperplasia. **C,** Late proliferative to early fibrotic phase of ARDS. Epithelial proliferation and hyperplasia persist with increasing evidence of fibroblast activation (*arrows*).

blasts and myofibroblasts also proliferate and migrate through the basement membrane into the alveolar space. In addition, early resolution of the hyaline membranes and pulmonary edema begins. This phase is considered to be reparative in nature.

Phase III, the fibrotic stage, begins to develop 7 to 10 days after the onset of respiratory failure and is characterized by progressive fibrosis that distorts the primary acinar architecture of the lung. The lungs appear pale and spongy with a cobblestone surface. Cellularity is reduced, alveolar fluid organizes, and fibrosis develops in and around the terminal respiratory units (see Fig. 72–1C). Airspaces are irregularly enlarged and separated by thick bands of collagenous connective tissue. Extensive fibrosis appears to be related to irreversible respiratory failure.[12]

CLINICAL MANIFESTATIONS

The clinical features of ARDS are a reflection of the pathophysiologic changes previously discussed and generally follow a typical course regardless of the initiating event or injury. The syndrome progresses through four stages: the acute injury, a latent period, acute respiratory failure, and a period of severe physiologic derangement.[105,107,111] During the period of acute injury, the physical, laboratory, and radiographic findings associated with the causative disease or injury generally overshadow those associated with ARDS itself. Disorders associated with primary lung injury (e.g., aspiration pneumonitis or inhalation injury) may demonstrate significant physical or radiographic findings, whereas individuals with trauma or sepsis syndromes may have entirely normal auscultative or radiographic examinations of the chest.

The latent period is said to occur from 6 to 48 hours after the onset of ARDS and is characterized by cardiopulmonary stabilization or even improvement in the patient's condition. Subtle physical examination findings (mild tachypnea), radiographic findings (fine reticular infiltrates), and laboratory abnormalities (increased $Paco_2$, increased pulmonary vascular resistance, decreased tissue oxygen delivery, increased serum von Willebrand factor antigen) may suggest the development of ARDS during this phase.[1,108,114]

The diagnosis of ARDS generally is made during the period of acute respiratory failure and is based on appropriate clinical and laboratory findings supportive of the diagnosis combined with a preexisting condition known to be associated with ARDS. The physical examination is remarkable for tachypnea, tachycardia, dyspnea, and cyanosis. The chest is quiet generally, but fine crackles may be present. Hypoxemia refractory to supplemental oxygen therapy is one of the hallmarks of the syndrome. Chest radiographs demonstrate diffuse, bilateral infiltrates suggestive of both interstitial fluid and alveolar filling or atelectasis (Fig. 72–2). Computed tomography may be helpful in characterizing the nature of the pulmonary infiltrates or even distinguishing the cause of the ARDS.[38] Respiratory failure and profound hypoxemia require intubation. The hypoxemia often worsens rapidly despite assisted ventilation, and many patients progress to the phase of severe physiologic abnormalities. During this stage, hypoxemia and hypercapnia refractory to high levels of ventilatory support often denote an irreversible pulmonary process. Multiorgan system failure frequently ensues at this point. The clinical course thereafter depends on the severity and character of the initial illness and the development of complications such as sepsis, disseminated intravascular coagulation, and pulmonary air leak syndromes.

TREATMENT

Although tremendous energy and resources have been invested in research aimed at defining the mechanism of lung injury in

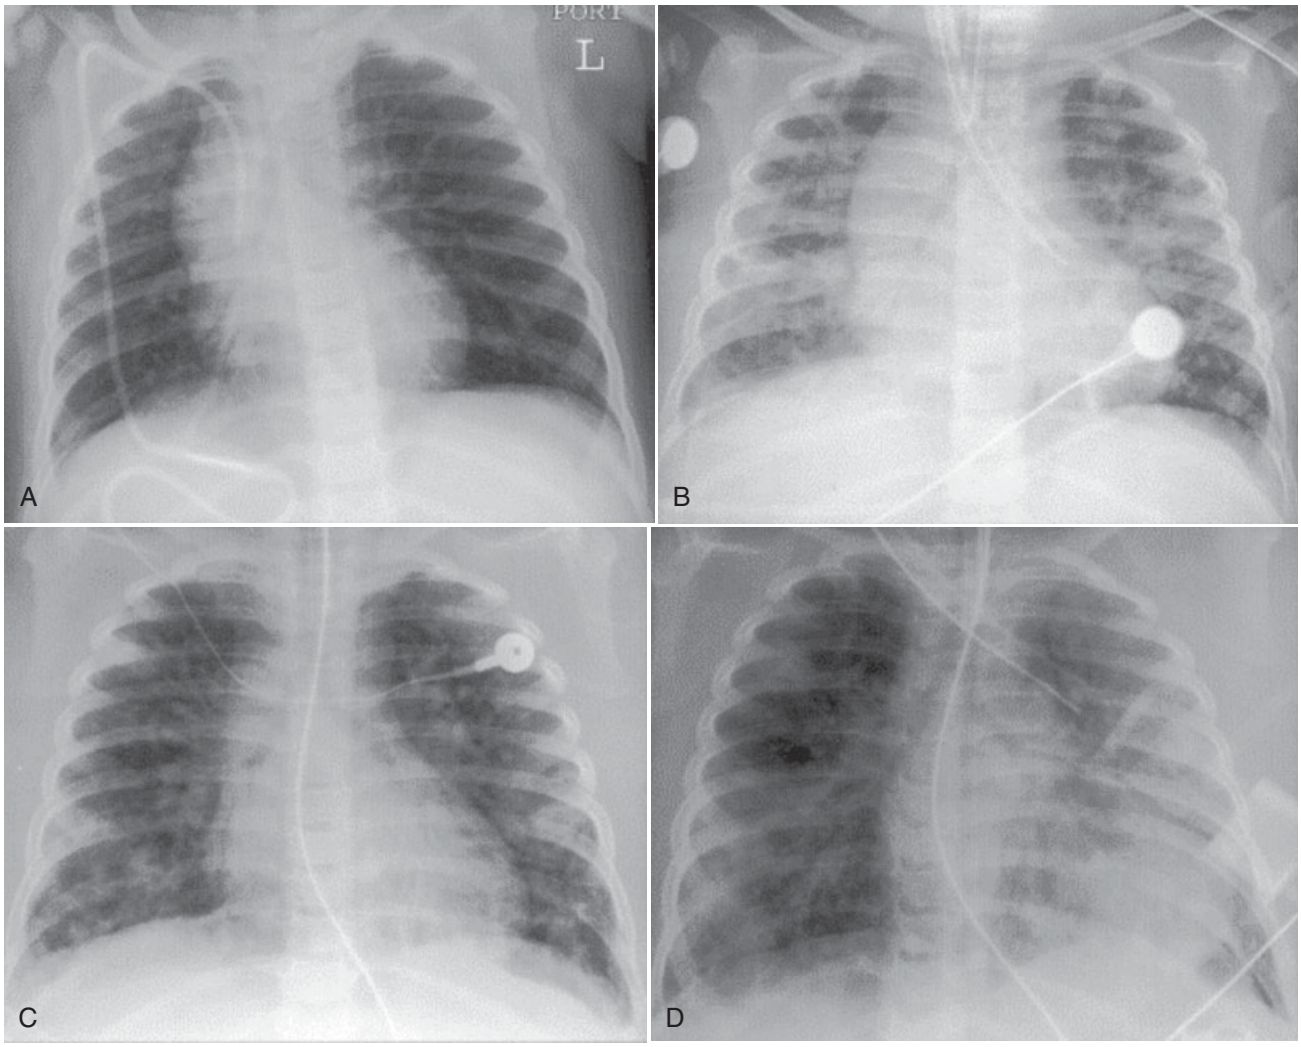

Figure 72–2 Chest radiographs of a 4-year-old child with central line sepsis and acute respiratory distress syndrome. Note the diffuse bilateral infiltrates suggestive of alveolar filling, interstitial fluid, and atelectasis. The time from **A** to **B** was 24 hours, but the intervals from **B** to **C** and from **C** to **D** were several days.

ARDS, a definitive answer and, thus, definitive therapeutic interventions have remained elusive. For this reason, management of ARDS historically has been primarily supportive. The traditional goals of therapy have been to treat the underlying or predisposing condition, maintain adequate end-organ oxygenation through the use of oxygen and supportive ventilation, and minimize complications of therapy or acute/chronic illness (oxygen toxicity, barotrauma, nosocomial infections, negative nitrogen balance, and multisystem organ dysfunction).[106,111] Only in the past decade have significant advances been made in improving supportive care and have attempts been made to treat some of the underlying pathologies encountered in ARDS.

Both Sarnaik and Lieh-Lai[111] and Royall[105] have stressed the importance of adequate monitoring of patients with ARDS. Invasive and noninvasive monitoring modalities allow the physician to assess pulmonary mechanics, the adequacy of peripheral oxygen delivery and consumption, cardiac function, and other critical physiologic parameters. Pulse oximetry, arterial catheters, and central venous pressure monitors are suggested as a minimum, with the use of pulmonary artery catheters as indicated by the patient's clinical status.

Positive-pressure ventilation is a major component of care for patients with ARDS. Several randomized trials have evaluated the usefulness of low–tidal volume ventilation as a method to improve survival and decrease complications. Experimental animal data suggested that high–tidal volume ventilation was associated with inflammation and increased release of inflammatory mediators from the lung into the systemic circulation (e.g., TNF-α, IL-6) when compared with low–tidal volume ventilation strategies.[62,142] Initial human trials with relatively small sample sizes yielded conflicting results.[5,20,21,122] A large multicenter trial sponsored by the NHLBI's ARDS Network (ARMA) enrolled 861 patients at ten sites to compare a ventilatory protocol consisting of tidal volumes of less than 6 mL/kg with conventional ventilation using higher tidal volumes. Plateau pressures were maintained at less than that of 30 cm H_2O.[132] The study reported that the group undergoing low–tidal volume ventilation had a lower rate of mortality than that of controls (31% versus 40%), more mean days free of mechanical ventilation, and more days free of nonpulmonary organ failure. Thus, high tidal volumes and high plateau pressures were associated with worse outcomes in patients treated for ARDS and should be avoided if possible in these patients. Other treatment parameters outlined in the publication suggest maintaining pH between 7.3 to 7.45 by changing the respiratory rate and adjusting the fraction of inspired oxygen and PEEP to achieve adequate oxygenation (Pao_2, 55 to 80 mm Hg, or Spo_2, 88%-95%).

High-frequency oscillation is a mode of ventilation that delivers small tidal volumes and has been proposed as a better method of ventilation for ARDS. Two randomized trials in adults and one in children demonstrated improved oxygenation in patients receiving high-frequency ventilation, but mortality rates were not significantly different from those of patients undergoing conventional ventilation.[10,19,37] These studies had considerably fewer patients than did the ARMA trial. Pediatric case series suggest that this mode of ventilation is safe and can be used as rescue therapy; however, large randomized trials in pediatrics are needed.[9,55,94] The role of high-frequency oscillation versus low–tidal volume ventilation in the routine treatment of ARDS remains to be determined and will require further investigation.

The historical approach to the respiratory management of ARDS has focused on the use of oxygen and PEEP. PEEP is a critical component of mechanical ventilation in the treatment of patients with ARDS. Hypoxemia is profound in patients with ARDS and is refractory to supplemental oxygen given by face mask. The vast majority of patients require intubation and supportive mechanical ventilation. Once the patient is intubated, high concentrations of supplemental oxygen and high levels of PEEP often are needed. PEEP improves pulmonary function in ARDS by reducing ventilation-perfusion mismatch and decreasing intrapulmonary shunting,[32,113] which is accomplished by increasing functional residual capacity by enlarging open alveoli and recruiting atelectatic airspaces. PEEP additionally reduces the repetitive expansion and collapse of terminal airways and redistributes alveolar fluid. The improved lung compliance and decreased ventilation-perfusion mismatch may allow a reduction in F_{IO_2}, thereby decreasing the potential for oxygen toxicity and possibly protecting the lung.[87,151]

Although PEEP is used to treat patients with ARDS, the optimal values have not been established. Several randomized trials have not demonstrated a significant change in mortality rates with increased levels of PEEP.[132,134,144] To determine the effect of high PEEP in the treatment of ARDS, the NHLBI sponsored a multicenter randomized trial comparing patients randomized to high PEEP (12-24 cm H_2O) with a comparable group randomized to low PEEP (5-24 cm H_2O).[134] No significant differences were observed between the two groups in mortality rates, yet the high-PEEP group had improved oxygenation. All patients in the trial were ventilated with low tidal volumes. Mean days of mechanical ventilation and the duration of nonpulmonary organ failure were comparable in both groups. Thus, PEEP should be used to maintain adequate oxygenation, yet the optimal pressure will vary, depending on the severity of the patient's disease.

PEEP significantly improves ventilation-perfusion mismatch, but it can affect cardiac output. Decreased venous return to the heart and a shift in the interventricular cardiac septum can occur with high pressure. These complications are treated by a reduction in left ventricular afterload. PEEP should be used to maximize oxygen delivery at the lowest pressure that achieves this goal. Additional methods of improving mechanical ventilation are prone positioning, inverse-ratio ventilation, partial liquid ventilation, and noninvasive ventilation. Randomized controlled trials of prone positioning have demonstrated that improved oxygenation is achieved with a change in positioning; however, mortality rates in these trials did not significantly decrease with its use.[28,46,49,71,98] For selected patients with an F_{IO_2} requirement of greater than 0.6 or refractory hypoxemia, use of the prone position may be helpful. Because extubation is a potential complication with repositioning, prone positioning should be used with caution at centers unfamiliar with this technique. Studies using perfluorocarbons for partial liquid ventilation have not shown improved outcomes over standard methods of ventilation.[52,56] Noninvasive positive-pressure ventilation is useful in selected patients with acute lung injury, such as pediatric cancer,[92] but it will not provide sufficient ventilatory support for the majority of patients with ARDS.

Many of the predisposing conditions associated with ARDS result in cardiovascular instability. Cardiovascular function should be monitored and maintained with additional therapies (e.g., inotropic agents, fluids) as needed. Patients seen in the early stages of septic shock often require vigorous fluid resuscitation to maintain adequate tissue perfusion.[101] Once the patient has been stabilized for a minimum of 12 hours, a conservative fluid strategy to maintain cardiovascular function and keep the patient's fluid balance stable with no net gain should be considered. A large randomized trial by the Acute Respiratory Distress Network reported more ventilator-free days and ICU-free days with a conservative fluid treatment approach than with a liberal fluid strategy; however, no significant differences were observed in mortality rates.[4] Furthermore, the need for renal dialysis and the prevalence of shock were not significantly different between the conservative and liberal fluid management groups. Patients in shock still should receive fluid resuscitation as needed and would not be candidates for the conservative fluid management strategy. Colloid or crystalloid is used for volume resuscitation.[24,152] A recent large randomized trial reported the equivalence of saline resuscitation and albumin volume resuscitation[43]; however, albumin with furosemide may be useful in patients with hypoproteinemia.[6] Once patients are hemodynamically stable, fluids are restricted to decrease vascular leak and subsequent pulmonary edema. Patients frequently are given diuretics to reduce fluid in the interstitium and alveoli. Positive inotropic support with dopamine or dobutamine may be required.

The overall goal of cardiopulmonary management of ARDS is to maintain good cardiac output and optimize oxygen delivery to the periphery. Other important aspects of the supportive care required for management of ARDS include maintenance of adequate nutrition, avoidance or treatment of complications related to therapy (barotrauma and oxygen toxicity) or prolonged illness (infection), and support of other organ systems.[106] Poor nutrition is a common problem in critically ill children and results in inadequate tissue repair, multiple organ system dysfunction, respiratory muscle weakness, and immune deficiency.[93,120] Hence, nutritional support is of paramount importance in ARDS and must be maintained.[97] The related issues of oxygen toxicity and barotrauma are considered later. Infection is both a common precipitating event in ARDS and an important factor in its course and outcome.[106] Infections typically take the form of bacteremia/sepsis or nosocomial pneumonia. Organisms frequently isolated from the lower respiratory tract are *Klebsiella* and *Pseudomonas*; however, *Escherichia coli*, *Candida albicans*, and *Staphylococcus epidermidis* are not uncommon isolates.[111] A high index of suspicion and a low threshold for initiating therapy should be maintained. Finally, prevention, detection, and treatment of multisystem organ dysfunction or its complications are critical in the overall management of children with ARDS.

As suggested earlier, many of the innovations in the supportive care of ARDS have come in the arena of ventilatory support. Pressure-limited ventilation with a reversed inspiratory-to-expiratory ratio, permissive hypercapnia, high-frequency ventilation (positive pressure, jet, and oscillating), prone positioning, and extracorporeal membrane oxygenation have been reported.* Patients unresponsive to conventional mechanical ventilation may benefit, in terms of improved oxygenation, from any of these methods. Additionally, patients may benefit from lower F_{IO_2} and peak airway pressure to decrease the potential oxygen toxicity and barotrauma. Although many of these newer forms of ventilation

*See references 5, 10, 47, 51, 57, 61, 65, 67, 84, 85.

show promise for children with ARDS, none has been demonstrated conclusively to be superior to another, and all will require more research and clinical experience. At present, many of them are considered "rescue therapy."

Numerous pharmacologic agents have been used for the treatment of ARDS during the past decade. Therapeutic trials with corticosteroids, vasodilators, and prostaglandin E_1 have been reported.[7,16,29,106,149] Improved outcomes have been achieved with short-course corticosteroid therapy for early-phase ARDS and moderate-dose therapy for prolonged ARDS, yet a 7-year multicenter trial did not find a change in mortality rates with moderate-dose methylprednisolone for 14 days in patients with persistent ARDS.[6,25,43,45,72,100,101,133,152] In addition, starting corticosteroid therapy more than 2 weeks after the onset of ARDS was associated with increased mortality rates at 60 and 180 days.[133] Few data exist on the benefits of steroid therapy in pediatrics. Therefore, the role of corticosteroid therapy in the routine treatment of ARDS remains unresolved at the present time. Small trials with a host of other agents have failed to identify universally effective therapies.[61,75] Among the many pharmacologic agents studied, corticosteroid therapy, exogenous surfactant, and inhaled nitric oxide (NO) have been evaluated in large, multicenter trials.

The relative or acquired surfactant deficiency seen in ARDS renders surfactant replacement therapy an attractive area of investigation. In 1993, Lewis and Jobe[66] presented a comprehensive review of the rationale behind surfactant use in ARDS. Theoretically, replacement of endogenous surfactant by exogenous material would increase total lung compliance, decrease atelectasis, and improve pulmonary mechanics, thereby leading to decreased ventilation-perfusion mismatch, improved oxygenation, and less potential oxygen toxicity and barotrauma. The results of several trials have been reported in recent years and appear to offer some hope of improving outcomes in children with ARDS.[41,68,73,117,126,154] Early phase I and II trials in adults were encouraging, but larger randomized trials with synthetic surfactant[8] and natural and recombinant surfactant[118,119] have not demonstrated improvement in the mortality rate. In contrast, a recent randomized trial in children reported a decrease in the mortality rate and improved oxygenation.[153] The randomized trial enrolled 153 infants, children, and adolescents with acute lung injury. Although the mortality rate was greater in the placebo group, no significant differences were observed in the number of ventilator-free days or the duration of respiratory failure. Problems with surfactant therapy include difficulty with delivery and inactivation by lung fluid proteins. As the aforementioned references suggest, solutions to these and other issues related to surfactant therapy for ARDS are being sought aggressively, and researchers hope that surfactant will prove to be a valuable therapy in the future.

Another area of active research for the treatment of ARDS is the use of inhaled NO. NO has been shown to be a potent vasodilator and has been used in numerous settings for infants and children with a variety of cardiopulmonary diseases.[3,58] Numerous clinical trials have suggested a potential role for NO in the treatment of ARDS.[2,34,36,39,76,78,81] However, several randomized trials have not reported a reduction in mortality rates with its use. Improved oxygenation is observed on initiation of therapy, but it often is transient, with the effect lasting just a few days.[36,69,76,104,130,143] NO should be considered rescue therapy pending further investigation.[116,131] Some authors have questioned its use altogether.[74,86] Additional study is required to answer questions regarding the best use of NO therapy for ARDS. Other pharmacologic agents being investigated for the treatment of ARDS include beta-agonists,[88] granulocyte-macrophage colony-stimulating factor (GM-CSF),[96] and activated protein C.[17,110,146,147]

PROGNOSIS

Despite the huge investments of time, money, energy, and talent that have gone into research on the basic pathophysiologic mechanisms involved in the development of ARDS and equal amounts into potential therapies, many questions remain unanswered. Mortality rates have decreased during the past decade since this disease first was described in children. Mortality rates have decreased from 40 to 70 percent (see Table 72–2) to 20 to 31 percent.[30,44,141] New supportive and therapeutic interventions have improved the care of children with ARDS. Most children who survive ARDS eventually have normal radiographic results, and pulmonary function improves gradually with only a mild reduction in forced vital capacity.[42] Long-term physiologic abnormalities show a strong correlation with the severity of the acute illness and the degree of support required in the acute phase of ARDS. The search for innovative therapies to decrease the acuity of illness during the acute phase of the disease and reduce the incidence of iatrogenic complications holds some hope for the future.

SECTION XIII

INFECTIONS OF THE FETUS AND NEWBORN

CHAPTER 73

VIRAL INFECTIONS OF THE FETUS AND NEONATE

Pablo J. Sánchez ❂ Gail J. Demmler-Harrison

GENERAL ASPECTS OF VIRAL INFECTIONS OF THE FETUS AND NEWBORN

The fetus and newborn infant are highly susceptible to many different viruses that in most instances cause little or no disease in older age groups. However, relatively few of the hundreds of viruses to which humans constantly are exposed are ever transmitted to the fetus or cause infection in newborn infants. Nonetheless, viral infections are an important cause of neonatal morbidity and mortality. The cumulative frequency of viral infections in the fetus or newborn infant may be as high as 6 to 8 percent of all live births, whereas systemic bacterial disease occurs in only 1 to 2 percent of neonates.[188,229]

Contributing to the frequency of viral infections in this age group is that the infection can be acquired at several different periods during intrauterine and neonatal life: in utero (congenital infection), at the time of birth (natal infection), or after birth but during the neonatal period (postnatal infection). In addition, numerous different outcomes of infection are possible. Congenital infections can result in resorption of the embryo; abortion; stillbirth; congenital malformation; prematurity; intrauterine growth restriction; acute disease apparent in utero, at birth, or shortly thereafter; asymptomatic infection in the neonatal period, but a persistent postnatal infection with neurologic sequelae later in life; or a normal infant with no apparent sequelae. Natal or postnatal infections can cause acute systemic illness leading to death, persistent infection with late sequelae, self-limited disease with no discernible damage, or asymptomatic infection.[188,229]

Recent developments in the fields of diagnostic virology, epidemiology, and viral immunology have expanded our knowledge tremendously and modified our understanding of fetal and neonatal viral infections and their contribution to disease, not only in the neonatal period but also later in life.[188,229] In addition, the development of rubella vaccine and antiviral drugs effective against a few of the agents offers hope for prevention or control of these infections. This chapter provides the physician with an approach to diagnosis and management of, as well as prognostic information about, viral infections that occur in the fetus and newborn infant. Human immunodeficiency virus (HIV), an important perinatal viral pathogen, is covered in another chapter.

PATHOGENESIS

Congenital Viral Infections

Congenital viral infections are secondary to exposure of the fetus during maternal viral infection. Evidence from both humans and experimental animals indicates that most fetal infections are preceded by a systemic viral infection in the mother, with hematogenous spread of the virus to the placenta and subsequently to the fetus (Fig. 73–1). Ascending infection through amniotic membranes also may occur while the fetus is still in utero. Viral infections that occur in the mother during pregnancy and that are limited to the respiratory or gastrointestinal tract may not pose a risk to the fetus but later may be transmitted perinatally to the newborn infant. Even if viremia does occur in the mother, maternal host defense mechanisms and the placenta appear to provide a protective barrier for the fetus. With most viruses known to cause fetal infection—cytomegalovirus (CMV), rubella virus, herpes simplex virus (HSV), varicella-zoster virus (VZV), and vaccinia virus–placental involvement by the virus also has been documented.[74,550] Viruses may reach the fetal circulation by (1) replication through the layers of the placenta, (2) production of virus-induced vascular lesions in the placenta resulting in abnormal communications between the maternal and fetal circulation, or (3) diapedesis of virus-infected maternal leukocytes through the layers of the placenta to the fetal circulation.[74,475,635] Damage to the fetus also may occur in the absence of actual fetal viral infection as a result of severe systemic illness in the mother or alteration of placental function (e.g., abortion or stillbirth in maternal measles, influenza). Viruses demonstrated to have caused congenital infection are listed in Table 73–1. Proof of congenital infection usually consists of the presence of infection or disease caused by the virus or demonstration of the pathogen in the fetus before birth or in the neonate at birth or shortly thereafter.

The effect that congenital infection with various viruses can have on the fetus is shown in Table 73–2.[581-583] Abortion or stillbirth usually occurs when the mother is infected very early in gestation (e.g., rubella) or when the systemic illness in the mother is severe (e.g., measles, influenza). The reasons that premature birth occurs in congenital viral infection are not well understood. Infants with congenital viral infection who are small for gestational age have intrauterine growth restriction, usually the result of decreased numbers of cells in organs.[444,445]

Developmental malformations result from infection of the fetus with the virus (see Table 73–2). Rubella virus is the classic known teratogen; that is, it causes disturbances in organogenesis. VZV has been shown to cause limb hypoplasia and developmental malformations of the eye.[243] Other viruses that result in congenital defects, such as CMV and HSV, cause inflammatory, destructive lesions of already developed organs. Type B coxsackieviruses have been associated with a variety of congenital malformations of the heart,[93-95] and mumps has been linked to endocardial fibroelastosis,[595] but these associations require further substantiation before a causative role can be assigned.

In Table 73–2, congenital disease refers to any manifestation of illness present at birth or shortly thereafter that is secondary to transplacental infection with the virus. Some of the viruses that result in congenital disease cause a chronic persistent infection (CMV, rubella, and hepatitis B virus [HBV]), whereas others cause acute, self-limited, or fatal infection (echovirus, coxsackie-

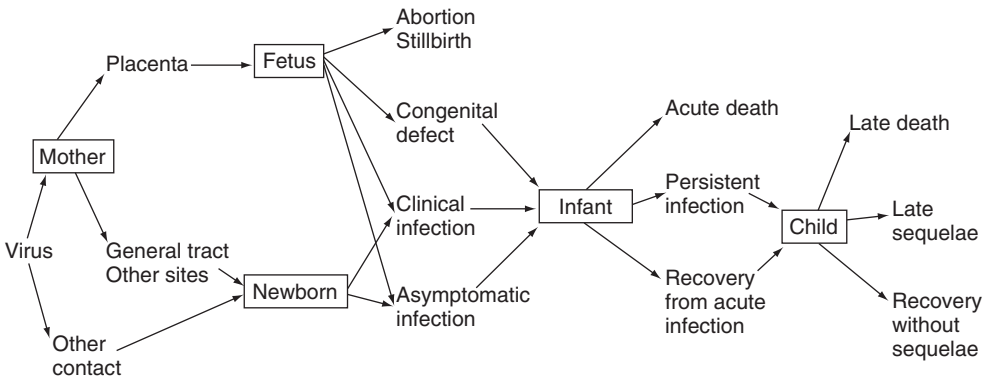

Figure 73–1 Pathogenesis of viral infections in the fetus and newborn.

TABLE 73–1 Period of Transmission of Selected Viruses to the Fetus or Newborn Infant

Viruses	Congenital	Natal	Postnatal
Adenovirus	+	+	+

Echoviruses	+	+	+
Epstein-Barr	+	–	–
Hepatitis A	–	++	+
Hepatitis B	+	++	+
Hepatitis C	+	++	–
Herpes simplex	+	++	+
Herpesvirus-6	+	–	+
Human immunodeficiency virus	+	++	+
Human parvovirus B19	+	–	–
Influenza	(+)	–	–
Lymphocytic choriomeningitis virus	++	–	–
Measles	+	–	–
Mumps	+	–	–
Parechovirus	–	–	+
Polioviruses	+	–	–
Rubella	++	–	–
Smallpox	+	–	–
St. Louis encephalitis virus	(+)	–	(+)
Type B coxsackieviruses	+	+	+
Vaccinia	+	–	–
Varicella-zoster	++	–	–
West Nile virus	+	–	+
Western equine encephalitis	+	–	–

++, major demonstrated route; +, minor demonstrated route; (+), suggested route, few supporting data; –, route not demonstrated.

virus B, poliovirus, measles, vaccinia, smallpox, western equine encephalitis, and human parvovirus B19). HSV and VZV can cause chronic persistent intrauterine infection, as well as acute transplacental infection at the time of delivery. Because HSV has a relatively short incubation period, ascending amniotic infection with HSV, in association with premature rupture of membranes and maternal genital herpes infection, may cause acute disease that is evident at birth or shortly thereafter. Other viruses, including adenoviruses, Epstein-Barr virus, and respiratory syncytial virus (RSV), also have been detected in the amniotic fluid of both normal fetuses and fetuses with structural abnormalities; however, the direct role these viruses play in fetal infection and disease is not currently known.[418]

Viruses and Congenital Malformation

The role of viruses as etiologic agents in congenital malformations merits special mention. After the recognition by Gregg[198,250] in 1941 that congenital cataracts and other defects occurred in the offspring of mothers with German measles, the concept of an infectious origin for congenital malformations was established firmly. Major malformations occur in 2 to 3 percent of all live births. Although great strides have been made in the diagnosis and management of these defects, their etiologic basis remains largely undefined. Approximately 10 percent are caused by environmental agents such as infections, drugs, or radiation. Another 10 percent have genetic origin and result from familial inheritance or demonstrable chromosomal abnormalities.[475] The remaining 80 percent are of unknown etiology. Most congenital defects may not be caused by environmental or genetic factors acting individually but rather in concert with one another. A genetically predisposed fetus is exposed to the appropriate environmental factor at a particular stage during organogenesis, which then leads to the development of malformations. Because control of the genetic factors contributing to fetal malformation is unlikely to be developed to the point of practical application in the near future, efforts to identify environmental factors that are amenable to control appear warranted.

For several reasons, viruses have been considered to be likely contributors to the 80 percent of malformations that are of unknown etiology. First, the precedent is established that rubella virus and VZV infections during pregnancy do cause congenital defects. Second, most women are expected to have one or more viral infections at some time during pregnancy,[570] so the potential exposure rate is high. Third, a viral infection could be unrecognized in the mother yet produce significant disease in the fetus, which could lead to the occurrence of a "congenital defect of unknown etiology." Fourth, viruses are known to multiply readily in rapidly dividing immature cells, with resultant cell destruction or altered cell function.[426] In the case of more destructive viruses (e.g., measles, vaccinia), fetal death with abortion or stillbirth may occur, whereas with less cytolytic agents (e.g., rubella, CMV), the fetus may survive but defects are produced. Finally, experimental animals provide numerous examples of infection with a virus resulting in little or no disease in the pregnant mother, yet the fetuses are aborted or the newborn offspring are deformed.[208] Therefore, physicians caring for newborn infants should not only be familiar with the patterns of congenital defects currently known to be caused by viruses (CMV, rubella, HSV, and VZV) but also be aware that additional viruses may be added to the list of causative agents in the future.

Natal Viral Infections

Natal viral infections are the result of exposure of the newborn to virus replicating in the genital tract (CMV, HSV, HBV) or to fecal virus contaminating genital secretions (enteroviruses) (see Fig. 73–1 and Table 73–1). Because the incubation periods of HSV and enteroviruses are short, acute postnatal disease may appear in the neonate within 5 to 7 days after natal infection with

these agents occurs (see Table 73–2). In contrast, the incubation periods of CMV and HBV are long, and clinically apparent disease, if it occurs, may not be observed for several weeks or even months after birth (see Table 73–2). Persistent postnatal infection can occur after natal infection with CMV, HSV, and HBV.

Postnatal Viral Infections

The source of exposure for postnatal infections of a newborn infant often is the mother, but other sources have been observed and include personnel or other infants in the nursery or newborn intensive care unit and family members (see Fig. 73–1). Neonatal infections, as well as hospital-associated outbreaks of enterovirus[34,526] and parechovirus,[429,654] RSV,[260] rotavirus, adenovirus, rhinovirus, parainfluenza virus, and influenza virus infection, have occurred in nurseries. In addition, health-care-associated HSV infections have occurred in neonates (see Table 73–1).[262,321,487,542,650] Although the maternal respiratory and gastrointestinal tracts are the most common sites from which virus can be transmitted to the neonate postnatally, other viruses, including HIV, human T-cell leukemia virus types 1 and 2 (HTLV I and II), CMV,[277] West Nile virus, rubella virus, hepatitis C virus (HCV), and HBV,[381] have been recovered from breast milk. HSV and VZV lesions on the breast of a mother also may be a source of transmission of virus for the breast-feeding neonate, even though these viruses probably are not present in the breast milk. Finally, HIV, CMV,[697] and HBV[201] have been transmitted to newborn infants by blood transfusion.[199,692] Although most postnatal infections are acute, self-limited processes, severe disease and fatalities have been reported, especially in preterm infants infected with enteroviruses, adenoviruses, or RSV, and persistent postnatal infection may occur with CMV and HBV (see Table 73–2).

EPIDEMIOLOGY

Factors Influencing the Frequency of Infection

Many factors can influence the frequency of infections in the fetus and newborn infant (Table 73–3). Because the mother is the source of the virus causing fetal and neonatal infection in most instances, factors influencing the frequency of maternal infection are of major importance. Except for CMV infection, most congenital infections of the fetus occur after primary viral infection has occurred in the mother. Congenital CMV infection may occur as frequently in mothers known to be seropositive before conception as in seronegative mothers.[603] Congenital rubella, on the other hand, occurs only rarely in immune mothers.[532] Transplacental HBV infection occurs much more often in mothers with acute, primary, symptomatic infection, whereas natal infection is the primary route of transmission in chronic carrier mothers.[470,559] Fetal parvovirus B19 infection and perinatal enteroviral and adenovirus infections acquired from the mother almost always are the result of primary maternal infection. In contrast, natal infections with CMV, HBV, and HSV may result from primary or persistent or recurrent infections in the mother.

The time during pregnancy when the mother is infected (the gestational age of the fetus) is a major factor influencing both the frequency of transmission and the severity of congenital rubella.

TABLE 73–3 Factors Influencing Frequency and Severity of Viral Infections in the Fetus and Newborn Infant

	Time of Fetal or Neonatal Infection

Season of year	++	+	++
Sexual promiscuity	+	++	–
Socioeconomic status	++	++	++

++, major influence; +, minor influence; –, little or no influence.

One hundred percent of infants who have congenital rubella infection during the first 11 weeks of pregnancy have malformations associated with congenital rubella syndrome, 30 percent who have congenital infection from 12 to 20 weeks have malformations, and no malformations develop with infections occurring after 20 weeks.[442] A similar phenomenon occurs with congenital parvovirus B19, CMV, and VZV infections.[282,488,598] In contrast, transplacental HBV and HSV infections appear to develop more frequently when the acute, symptomatic maternal infection occurs in the third trimester rather than the first or second.[704] With viruses such as polio, measles, vaccinia, and smallpox, early-gestation maternal disease results in abortion or stillbirth, whereas late-gestation infection results in congenital disease with acute symptoms in the early neonatal period (see Table 73–2).

Several social and environmental factors may influence the likelihood of development of maternal infection and thereby affect the frequency of infection in the fetus and neonate. The development of rubella vaccine and its licensure in 1969 reduced the incidence of congenital rubella syndrome significantly.[54,473] The successful eradication of smallpox worldwide and discontinuation of the need for smallpox vaccine (vaccinia virus) have eliminated fetal infection with these viruses. Although measles and mumps vaccines have reduced significantly the frequency of occurrence of these diseases in children, whether waning immunity in women of child-bearing age who were vaccinated as infants will predispose to reinfection in pregnant women and subsequent fetal or neonatal disease remains unclear. The presence of epidemics in the community, such as those caused by rubella or enteroviruses, certainly can influence the frequency of maternal and, therefore, congenital, natal, and postnatal infections. The incidence of infection with some viruses (e.g., rubella, primary VZV, enteroviruses, measles, mumps, influenza) clearly is higher during certain months of the year, so the season can influence maternal and neonatal infection rates. In contrast, other viruses causing congenital or natal infection, such as CMV, HBV, or HSV, do not occur in an epidemic or seasonal fashion. Geographic location also can be influential, probably because of differences in the ethnic (and, therefore, genetic) origin of populations in different locations. Rates of chronic carriage of hepatitis B surface antigen (HBsAg) in mothers and the frequency of congenital and natal HBV infection in neonates are much higher in Taiwanese than in U.S. residents.[704] The incidence of numerous maternal viral infections is known to be higher in populations with a lower socioeconomic status, thereby influencing the frequency of congenital, natal, and postnatal infections. Other social factors such as drug abuse, which is associated with higher rates of HBV infection, also can affect the frequency of congenital and natal infections. Because CMV, HBV, and HSV all have been shown to be transmitted venereally, sexual promiscuity in the mother can influence the frequency of these infections in the neonate.

Case identification is a major factor that can have some bearing on the frequency of recognized infection in the neonate. Because most neonates with congenital CMV, rubella virus, or HBV infection are asymptomatic, the use of clinical case-finding methods alone significantly underestimates the true frequency of these infections. Epidemiologic observations (e.g., rubella or enterovirus epidemic in the community), clinical or laboratory information about the mother (e.g., viral illness with a rash or the presence of HBsAg in serum), or screening tests in the newborn (e.g., elevated quantitative IgM in umbilical cord blood) often have been used to select a group of neonates at high risk of contracting congenital infection. The performance of additional laboratory tests in these high-risk neonates to identify potential specific causative agents often has led to the demonstration of infection rates much higher than previously suspected.

Frequency of Infection in the Mother and Neonate

Table 73–4 shows the approximate frequency of the most common viral infections in the mother during pregnancy and in the newborn infant. Although the figures have been obtained by a variety of laboratory methods and some are based on a relatively small or nonrepresentative population sample, they do provide an estimate of the relative frequency of the infections. In many studies, prospective screening of mothers for viral infection during pregnancy or screening of infants for elevated cord blood serum immunoglobulin M (IgM) levels was done to select a population of neonates at high risk of acquiring congenital infection for more detailed virologic investigation.

CMV clearly is the most common cause of viral infection, both in the mother and in the neonate.[105] Surveys in the United States indicate that 30 to 110 per 1000 women excrete virus in urine during pregnancy and that 60 per 1000 are excreters at the time of delivery.[225,284,341,435,452,528] Isolation from cervical swabs is even more common: 80 to 120 per 1000 women during pregnancy and 110 to 130 per 1000 at delivery.[130,341,435,528] Most maternal CMV infections occurring during pregnancy are recurrent rather than primary.[600] Extrapolation from data obtained at the same institution[528,600,605] suggests that two thirds to three quarters of CMV shedding in the cervix or urine during pregnancy is the result of recurrent rather than primary CMV infection in the mother. The frequency of primary CMV infection occurring during pregnancy averages 20 to 25 per 1000 (range, 10 to 40), with higher rates occurring in populations with a larger percentage of susceptible persons (seronegative at the beginning of pregnancy).[251,598] Several factors are known to be associated with increased rates of recurrent urine or cervical shedding: (1) sampling on several occasions rather than a single time; (2) collection of specimens during the third rather than the first trimester because shedding rates are known to increase as gestation progresses; (3) Asian, black, or Native American versus white populations; (4) younger maternal age; (5) lower socioeconomic status; (6) a greater number of lifetime sexual partners; and (7) a history of sexually transmitted diseases.[130,341,452,606] An even more important source for transmission of CMV to the neonate may be breast milk. Postpartum shedding from colostrum or breast milk, the cervix, urine, or saliva was demonstrated in 130 to 280 per 1000 unselected women, and breast milk was the most common site by far.[202,598,605,607]

Congenital CMV infection has been documented in 6 to 24 per 1000 live births, as determined by isolation of virus from the urine of the neonate within the first few days of life.[73,178,530,603] In contrast to rubella, congenital infection with CMV occurs in mothers with either primary or recurrent infections during pregnancy.[603] Congenital CMV infection rates are significantly higher

TABLE 73–4 Approximate Frequency of Infections in the Mother during Pregnancy and in the Newborn Infant

Viruses	Mother (No./1000 Pregnancies)	Neonate (No./1000 Live Births)
Cytomegalovirus		
During pregnancy, congenital	30-120	6-24
At delivery, natal	80-130	20-60
After delivery, postnatal	130-280	140-210
Rubella		
1964 epidemic	20-40	3-7
Interepidemic prevaccine	0.1-2.0	0.1-0.7
Postvaccine	0.15-0.3	0.03
Hepatitis B	1-160	0-61
Enteroviruses	90-600	2-38
Herpes simplex	1-7	0.1-0.6

in lower socioeconomic groups (1.6%) than in middle to upper ones (0.6%).[600] However, among low-income mothers, the status of immunity to CMV is high (82%), and most congenital infections (81%) are associated with recurrent CMV infection during pregnancy. In contrast, seroimmunity to CMV in middle- to upper-income women is lower (55%), and the frequency of congenital infection associated with recurrent maternal CMV also is lower (47%). Although the rate of total congenital CMV infection is lower in mid- to high-income mothers, the proportion of infants born after primary CMV infection is acquired during pregnancy is higher (53% versus 19%). Pooled data from several studies indicate that 30 to 40 percent (range, 20-52%) of mothers with primary CMV infection during pregnancy deliver congenitally infected infants.[12,13,251,364,598,600] Congenitally infected babies born to mothers with primary rather than recurrent CMV infection during pregnancy have a greater frequency of symptoms of CMV disease at birth, higher levels of IgM in cord serum, higher titers of virus in urine, and a greater likelihood of having neurologic sequelae at follow-up.[11,12,598,600] The time during gestation when maternal primary CMV infection occurs does not appear to influence the rate of fetal infection, but fetal damage seems to occur more frequently and to be more severe after the acquisition of maternal infection during the first half than during the second half of pregnancy.[11,251,509,598]

The frequency of natal and postnatal acquisition of CMV by newborn infants is far greater than that of congenital infection. Natally acquired CMV infection occurs at an incidence of 20 per 1000 live births.[528,604] Because approximately one half the infants born to mothers known to be cervical excreters at the time of delivery acquire natal infection[528] and because as many as 130 per 1000 mothers from a low socioeconomic group are excreting CMV at this time, the actual rate of natally acquired CMV infection may be as high as 60 per 1000 live births. A more frequent source for infection of the neonate with CMV is postnatal consumption of virus-infected colostrum or breast milk. In two studies, 58 to 69 percent of infants of nursing mothers who excreted CMV in milk acquired infection.[202,605] Shedding of virus occurred most frequently between 2 and 12 weeks postpartum, and the onset of infant viruria usually occurred when the infants were between 1 and 6 months of age. The aforementioned rates of postnatal infection would project to between 140 and 210 infections per 1000 live births in the United States. These rates, of course, would be affected by all the factors mentioned earlier that influence maternal CMV infection rates, as well as the frequency and duration of breast-feeding.

Yet another source for transmission of CMV to neonates is blood transfusion in infants in neonatal intensive care units. Risk factors include birth weight less than 1250 g, a CMV-seronegative mother, hospitalization for a period longer than 4 weeks, receipt of multiple blood transfusions or a total volume of more than 50 mL, and receipt of blood from a CMV-seropositive donor.[10,50,228,697] The infection rate in high-risk infants may be high: 24 to 31 percent. Morbidity and mortality rates with these infections also are high: clinical disease developed in 88 percent of 34 reported cases, and 24 percent died (CMV was thought to be causal or contributory).

In summary, several factors contribute to the high rates of fetal and neonatal CMV infection: (1) virus can be transmitted from both immune mothers (recurrent infection) and nonimmune mothers (primary infection); (2) virus may be shed or carried in many different sites in the mother's blood (for transplacental infection), urine, cervix, breast milk, and saliva; (3) infection may occur at different times—congenitally, natally, and postnatally; and (4) infection may come from sources other than the mother (e.g., hospital-acquired infection from blood transfusion).

The use of rubella vaccine has modified the epidemiologic patterns of this disease in the United States.[54,184,473] Vaccination has eliminated endemic rubella in the United States. Rates of maternal and congenital rubella during the 1964 epidemic were many times higher than in interepidemic periods. Nonetheless, a comparison of the incidence during the 1964 epidemic with the rates during prevaccine interepidemic periods and what may be happening currently provides useful information. The frequency of serologically proven clinical rubella among 30,000 pregnant women in the Collaborative Perinatal Research Study was approximately 1 per 1000 during the interepidemic years before vaccine licensure but rose to 22 per 1000 during the epidemic. The total figure for rubella during pregnancy is likely to be at least two times higher because as many as one half to two thirds of maternal rubella infections are subclinical or not diagnosed as rubella.[568] An incidence of congenital rubella of 0.7 per 1000 live births was demonstrated during the interepidemic period in a study screening cord blood sera for the presence of rubella-specific IgM antibody.[15] During the 1964 epidemic, an estimated 20,000 babies were born with congenital rubella syndrome in the United States among approximately 4 million live births, an incidence of 5 per 1000 live births.[454] During 1980 to 1982, an average of 11 cases of confirmed congenital rubella syndrome were reported to the Centers for Disease Control and Prevention (CDC) each year.[473] Correcting for under-reporting and missed cases yielded an annual estimate of 110 cases.[473] With an annual national birth rate of 3.5 million per year, this figure projects to 0.03 cases of congenital rubella syndrome per 1000 live births currently in the United States. Assuming a 10 to 20 percent rate of congenital rubella infection during pregnancy, the current estimate is thought to be 0.15 to 0.3 cases of maternal rubella per 1000 pregnancies. Importantly, however, a resurgence in acquired and congenital rubella, particularly in unvaccinated women in correctional institutions and unimmunized communities,[116,412] emphasizes the need for continued surveillance for rubella disease and proper use of the vaccine.

HBV infection during pregnancy may result in acute clinical disease in the mother or, more commonly, may result in an asymptomatic chronic carrier state.[560] The frequency of HBsAg in the serum of pregnant women varies highly and is influenced by geographic location, ethnic origin, socioeconomic status, and other social factors such as illicit drug use and sexual promiscuity. An incidence of 1 to 160 per 1000 pregnancies has been reported in several series.* Infection with HBV in the neonate is even more variable, for several reasons. First, transmission of the virus to the fetus or neonate may occur by several routes: (1) transplacental; (2) natal, from the genital tract; (3) postnatal, by intrafamilial spread through unknown mechanisms; and (4) postnatal, by blood transfusion. Second, infants born to mothers with hepatitis B may follow one of these courses: (1) serum from the infant remains negative for HBsAg, and hepatitis B never develops; (2) umbilical cord blood is positive for HBsAg, but the antigenemia clears and no disease is evident, presumably representing transplacental transmission of antigen only or insufficient virus to cause true infection in the neonate; (3) umbilical cord blood is HBsAg-positive, and clinical or subclinical infection develops with or without persistent hepatitis B antigenemia; or (4) cord blood is antigen-negative, but infection occurs, sometimes not until several months after birth, and persistent antigenemia may or may not develop. Third, because exposed infants may follow one of several courses and because HBV infection may be demonstrable at various times after birth, serial blood specimens must be obtained for evaluation of the true frequency of neonatal infection. Serial blood specimens are difficult to obtain in this age group, and published reports may have based their estimates of infection on one or two blood specimens per infant. Fourth, transplacental infection occurs much more commonly in mothers

*See references 31, 66, 183, 200, 347, 381, 469, 486, 560, 615, 687.

with acute, symptomatic hepatitis, particularly during the second or third trimester of pregnancy, than it does in mothers who are chronic carriers.[560] Finally, even in these mothers, true differences in the rates of transplacental transmission occur: Asians have a much higher incidence than whites do,[704] and mothers who are hepatitis B e antigen (HBeAg)-positive are much more likely to transmit infection than are mothers who have anti-HBe antibody or lack e-antigen markers.[469] Therefore, the incidence of HBV infection in the neonate varies from 0 to 61 per 1000 live births in different reports.*

Data from several studies indicate that perinatal enteroviral infections occur much more frequently than previously realized.[106,307,318,429,436,536,93-95,353,567] Serologic surveys indicate a surprisingly high rate of seroconversion to at least one enterovirus during pregnancy (first serum at the time of enrollment for obstetric care, second serum at delivery): 90 to 600 per 1000 pregnancies.[93-95,353,567] Several factors complicate arriving at an interpretation of the data concerning the frequency of occurrence of maternal enteroviral infections. First, only 2 to 13 of the almost 70 nonpolio enterovirus serotypes were used for antibody testing, thereby resulting in an underestimate of the true frequency for all enteroviruses. Second, the data are reported as the total number of enteroviral infections for a group of pregnant women rather than the percentage of pregnancies complicated by at least one enteroviral infection. Use of these data for calculating the number of pregnancies per 1000 complicated by enteroviral infection would result in an overestimation because more than 25 percent of women may have more than one enteroviral infection during the 9 months of pregnancy.[93]

Data concerning the actual frequency of neonatal enteroviral and parechoviral infection also are difficult to summarize because of differences in the study designs used in the various published results. Modlin and associates[432] reported four echovirus 11 infections among 158 consecutive neonates who had stool samples taken when they were 3 days and 2 weeks of age during the 3-week period of an outbreak of echovirus 11 in Boston. Assuming that live births are distributed evenly throughout the year and that no additional cases of enteroviral infection occurred during the remainder of the year, this incidence translates into two enteroviral infections per 1000 live births. These calculations probably underestimate the true frequency markedly because only echovirus 11 was sought in the diagnostic virology laboratory evaluation of these 158 infants, and, obviously, enteroviral infections occur for more than a 3-week period of the year. A prospective study of all enteroviral infections acquired during the patient's first month of life in Rochester, New York, during the peak enterovirus season (June to October) demonstrated 75 (12.8%) nonpolio enteroviral infections in 586 infants.[307] Fourteen (18.7%) of these 75 infected infants were hospitalized for "suspected sepsis." By using the estimated number of live births per year in the Rochester area and assuming that no additional cases of neonatal enteroviral infection occurred during the remaining 7 months of the year, the authors projected a rate of seven neonatal enteroviral infections serious enough to require hospitalization per 1000 live births. If one considered the total 75 enteroviral infections (14 hospitalized and 61 not hospitalized), the rate would be 38 per 1000 live births. A survey by Kaplan and associates[318] of 77 cases of coxsackievirus B infection occurring during the first 3 months of life in infants hospitalized at the Nassau County Medical Center between 1970 and 1979 yielded an estimated rate of 0.5 per 1000 live births. Because group B coxsackieviruses account for only 45 percent of all enteroviral infections during early infancy[351] and because only 18 to 19 percent of all enterovirus-infected infants may require hospitalization,[307] the actual rate for all enteroviral infections may be 6 per 1000 live births. Despite the variation in estimates, enteroviral infections are clearly a frequent cause of maternal and neonatal infection. Parechovirus infections are being diagnosed and described in the medical literature with increased frequency, but current knowledge of the epidemiology of this infection in neonates is still evolving.[654] The infected genital tract of the mother is the source of virus for most neonatal HSV infections. However, other sources, such as nongenital sites in the mother, family members, and even other infants or caretakers in the nursery, have been implicated. Both genital and neonatal herpes have increased in frequency in recent years.[67,623] Current estimates are that culture-positive genital herpes may occur at a rate of one to seven per 1000[75,77,97-102] during pregnancy and at a rate of one to four per 1000 at the time of delivery.[97,101,450,513,632] However, culture is not the most sensitive method to detect genital HSV-2 infection. Seroprevalence studies have demonstrated HSV-2–specific antibody in 32 percent of women in private obstetric practices,[362] and polymerase chain reaction (PCR) detected HSV DNA in 9 percent of asymptomatic women in labor.[149] Higher rates are associated with lower socioeconomic status, increased numbers of sexual partners, and occurrence of other sexually transmitted diseases. Rates of neonatal herpes have been estimated at 0.1 to 0.6 per 1000 live births.[97,623,669] The greatest risk of acquiring neonatal infection occurs when the mother has an initial genital infection at the time of vaginal delivery.

The frequency of infection with the other viruses listed in Tables 73–1 and 73–2 is so low that numeric estimates per 1000 pregnancies or live births cannot be made.

APPROACH TO DIAGNOSIS

Fetal viral infection may be suspected if the mother is exposed to or experiences an infection with a virus known to transmit to the fetus; or abnormalities detected on routine fetal ultrasound may suggest fetal infection. Fetal abnormalities detected during prenatal evaluation that may be caused by in utero virus infection include intrauterine growth retardation, microcephaly, cerebral ventriculomegaly or hydrocephalus, cataracts, hepatosplenomegaly, hepatic or intracranial calcifications, echogenic bowel, fetal ascites, cardiomegaly, congestive heart failure, fetal hydrops, or poly- or oligohydramnios.[173] Intrauterine cardiac abnormalities, myocarditis, and heart failure may be associated with HIV, parvovirus B19, mumps virus, or adenovirus, and cardiac structural defects may be associated with rubella virus. Limb deformities or dysplasias, especially if they are associated with eye or central nervous system (CNS) abnormalities, may be caused by intrauterine VZV or HSV infection. Consultation with a maternal-fetal medicine specialist is recommended if fetal viral infection is suspected because intervention strategies are now available for many of these infections, which may lessen the morbidity and mortality rates associated with viral infections in the fetus.[1,173,461]

The usual set of circumstances leading one to consider the diagnosis of viral infection in a newborn infant is the presence of clinical or laboratory features in the neonate that suggest this possibility (Table 73–5). Icterus, petechiae, or hepatosplenomegaly at the time of birth or shortly thereafter in a small-for-gestational-age infant suggests a chronic in utero viral infection. On the other hand, acute viral infection in a neonate with suspected sepsis may be present when cultures of blood, spinal fluid, and urine fail to yield a bacterial or fungal agent.

Evaluation of the Mother

Once the suspicion of a viral infection in a newborn infant has been raised, one should proceed with an evaluation of the mother for features that might add further evidence to this possibility.

*See references 31, 66, 183, 200, 347, 381, 469, 486, 560, 576, 615, 687.

TABLE 73–5 Common Manifestations of Viral Infections in the Newborn Infant

Asymptomatic Infection	
Chronic Infection (Early Gestation to Midgestation Congenital)	
General Characteristics	
Manifestations present at birth or shortly thereafter	
Presence of congenital defects	
Specific Features	
General	Small for gestational age
Central nervous system	Microcephaly, seizures, cerebral calcification, hypertonia or hypotonia, cerebrospinal fluid pleocytosis, encephalitis, hydrocephalus, hearing loss
Skin	Icterus, petechiae, purpura, vesicles, hypopigmentation
Eye	Chorioretinitis, cataracts, glaucoma, microphthalmos, optic atrophy
Heart	Patent ductus arteriosus, pulmonary artery stenosis
Abdomen	Hepatosplenomegaly, hepatitis
Lung	Pneumonitis
Musculoskeletal	Bone lesions, limb hypoplasia
Acute Infection (Late Gestation Congenital, Natal, or Postnatal)	
General Characteristics	
Manifestations usually appear several days to weeks after birth	
Absence of congenital defects	
Specific Features	
General	Hyperthermia or hypothermia, irritability, lethargy, jitters, poor feeding, vomiting
Central nervous system	Seizures, hypertonia or hypotonia, full fontanelle, meningitis, encephalitis, hearing loss
Skin	Icterus, petechiae, purpura, vesicles, maculopapular rash
Eye	Conjunctivitis, keratitis
Heart	Myocarditis
Abdomen	Hepatosplenomegaly, hepatitis
Lung	Pneumonitis, respiratory distress, cyanosis

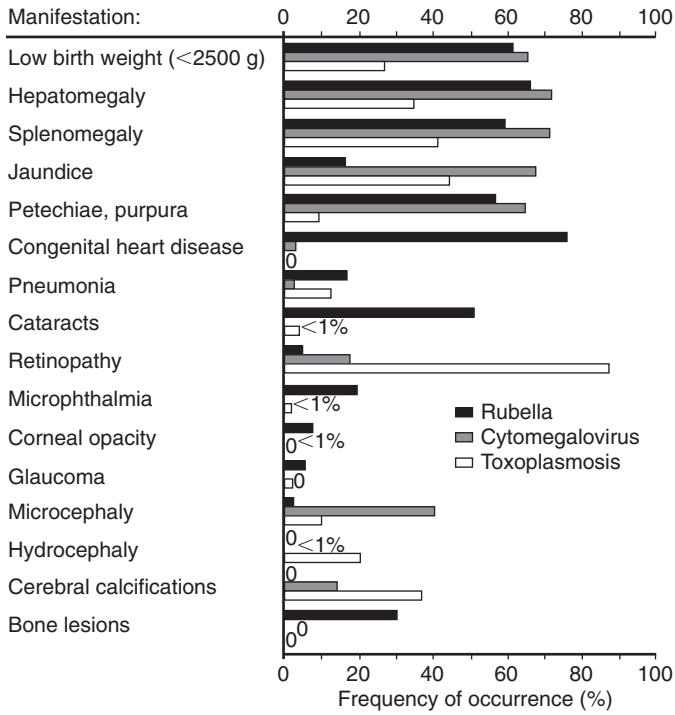

Figure 73–2 Manifestations of symptomatic congenital rubella virus and cytomegalovirus infections and toxoplamosis.

For example, the occurrence of maternal viral illness with an associated maculopapular rash suggests rubella or enterovirus infection in the neonate, whereas ulcerative genital lesions suggest HSV and heterophile-negative infectious mononucleosis is suggestive of CMV. Maternal rash with arthralgias may be caused by parvovirus B19. One should note, however, that most maternal viral infections that lead to fetal or neonatal infection (almost all cases of CMV and HBV infection[612,687] and one half to two thirds of rubella virus and HSV infections[450,568,669,675]) are asymptomatic in the mother. Therefore, the absence of a history of viral infection in the mother certainly does not rule out the possibility of a viral infection in her neonate.

Specimens from the mother for isolation or detection of the viral agent usually are not available. However, the presence of HBsAg- or CMV-specific IgM antibody in maternal serum or isolation of CMV or HSV from the genital tract or an enterovirus from the stool at the time of delivery certainly should lead one to consider these agents in her newborn infant. Serologic documentation of a specific viral illness in the mother during pregnancy requires serum specimens that bracket the illness. Unfortunately, these specimens rarely are available when the pediatrician is considering the possibility of a congenital or neonatal viral illness. Routine IgG antibody determinations on a single specimen obtained from the mother after the birth of a neonate with suspected congenital viral infection are not likely to yield useful information, except if the mother lacks IgG antibody to the pathogen in question. Such a finding in the face of a symptomatic infant would rule out that organism as the cause of the infant's disease. Although the presence of specific IgM antibody against CMV,[253,269,608] rubella virus,[246] parvovirus B19, or HSV[447] in a single maternal serum specimen is highly suggestive of recent infection, IgM tests are known to produce false-positive results and need to be interpreted accordingly. On the other hand, if the maternal viral infection occurs near the time of delivery (e.g., enterovirus meningitis, coxsackievirus B pleurodynia, initial genital herpes), acute and convalescent serum specimens may be obtained from the mother that do demonstrate the diagnostic fourfold or greater rise in antibody titer against a specific agent. Documentation of a particular causative agent in the mother does not constitute proof that the same agent is causing disease in the neonate, but it certainly does provide strong suggestive evidence. Definitive proof, therefore, must come from studies in the newborn infant.

Clinical Features in the Neonate

Certain clinical manifestations of viral disease in the neonate may provide helpful clues to the specific etiologic agent. However, most viral infections are asymptomatic in neonates: more than 95 percent of CMV, two thirds of rubella virus, and most HBV infections. In contrast, less than 1 percent of HSV infections in the neonate are subclinical. To complicate the effort to pinpoint the diagnosis further, the clinical and laboratory manifestations of symptomatic disease caused by numerous agents often have similar patterns (see Table 73–5; Figs. 73–2 and 73–3). However, infants whose congenital viral infections were incurred in early gestation to midgestation have manifestations of disease at birth or shortly thereafter, whereas infants with late-gestation congenital infections or natal or postnatal infections usually do not

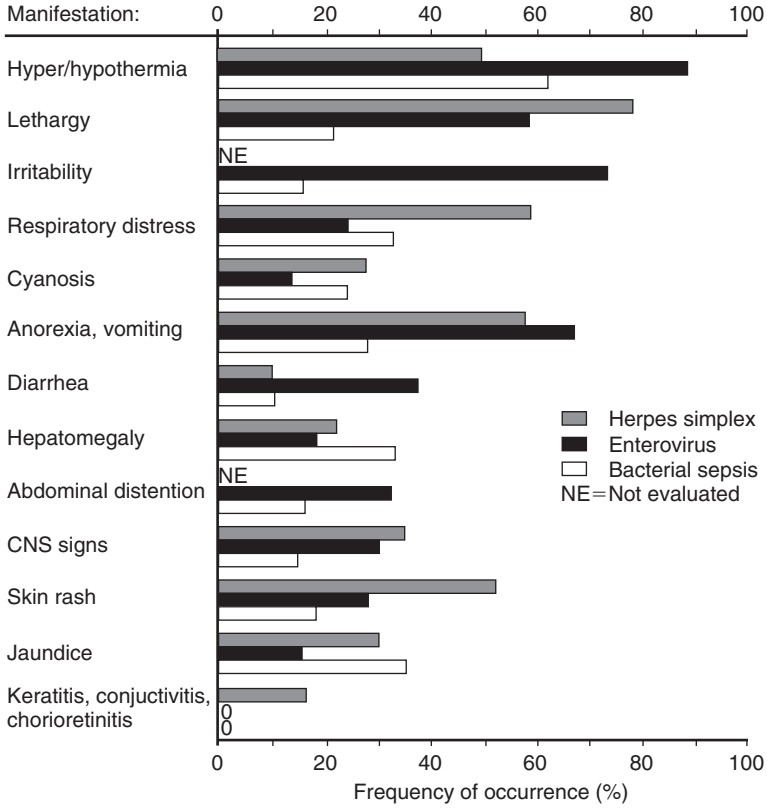

Figure 73–3 Manifestations of herpes simplex virus and enterovirus infections and bacterial sepsis in the neonate.

exhibit signs and symptoms for several days to several weeks after birth (see Table 73–5). In addition, newborn infants who acquire congenital infections in early gestation to midgestation exhibit congenital defects and intrauterine growth retardation, whereas neonates who acquire viral infections near the time of birth have acute disease resembling bacterial sepsis or the viral syndrome typically seen in older children (e.g., enterovirus exanthem, chickenpox) (see Table 73–5). Because the viral agents that commonly cause chronic intrauterine infections are different from those that result in acute neonatal diseases (see Tables 73–1 to 73–3), recognition of these two different patterns helps define a specific etiologic agent.

The most common manifestations of congenital CMV and rubella infection in symptomatic newborn infants are shown in Figure 73–2. Also shown in this figure are the features observed in infants with congenital toxoplasmosis because this infection is important to consider in the differential diagnosis. (Infection with *Toxoplasma gondii* is covered in another chapter.) Note that many nonspecific manifestations, such as low birth weight caused by intrauterine growth retardation, hepatomegaly, splenomegaly, jaundice, and petechiae/purpura, occur with a similar frequency in the three infections. However, certain specific findings may be helpful in the differential diagnosis. The presence of cataracts, congenital heart disease, bone lesions, or microphthalmos is highly suggestive of rubella, whereas chorioretinitis, cerebral calcifications, and hydrocephaly are findings against this diagnosis. In congenital CMV infection, microcephaly, cerebral calcifications, and sensorineural hearing loss are relatively common findings, but congenital heart disease, eye abnormalities, and bone lesions rarely occur. Chorioretinitis, cerebral calcifications, or hydrocephaly should suggest toxoplasmosis or lymphocytic choriomeningitis virus (LCMV). The cerebral calcifications in CMV infection tend to be periventricular, whereas those in toxoplasmosis are scattered through the parietal lobes of the cerebrum. An important note is that some manifestations may not be evident for several months after birth: congenital heart disease, chorioretinitis, microcephaly, hydrocephaly, and cerebral calcifications.

The most frequent findings in the common acute viral infections of the neonate—HSV and enterovirus infections—are shown in Figure 73–3. Because the features in infants with these two kinds of viral infection resemble those associated with bacterial sepsis, the manifestations in neonates with septicemia also are presented. Again, the more common nonspecific features, such as fever or hypothermia, respiratory distress, cyanosis, anorexia or vomiting, and hepatomegaly, occur at a relatively similar frequency in the three infections.[106,107] Lethargy, irritability, and CNS signs are found more commonly with HSV and enterovirus infections, probably because encephalitis and meningitis, respectively, occur more frequently with these two infections. Features that suggest a diagnosis of HSV infection are a vesicular rash and keratitis or conjunctivitis, whereas enterovirus infection usually is associated with diarrhea and abdominal distention. The rash in enterovirus infection usually is erythematous and maculopapular, but petechiae can occur with overwhelming infection. The skin lesions in bacterial sepsis generally are pustules, abscesses, cellulitis, or purpura.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis in a fetus or newborn infant with a suspected viral infection is extensive. In the fetus, noninfectious and genetic etiologies may cause signs and symptoms similar to congenital virus syndromes. Many of the neonatal manifestations shown in Figures 73–2 and 73–3, such as lethargy, irritability, respiratory distress, cyanosis, and anorexia, can be caused by the most common diseases occurring in sick newborn infants—hyaline membrane disease, prematurity, intraventricular hemorrhage, metabolic disturbances, and bacterial sepsis.[106,107,674] Infants

with low birth weight caused by intrauterine growth restriction (small for gestational age) may have congenital malformations, chromosomal abnormalities, placental insufficiency, and inborn errors of metabolism. Hepatosplenomegaly usually is caused by one of the infectious diseases of the neonate. In infants with jaundice, ABO and Rh hemolytic disease and physiologic jaundice should be considered. Noninfectious causes of petechiae/purpura include idiopathic or drug-induced (including transplacental passage) thrombocytopenia, erythroblastosis fetalis, and disseminated intravascular coagulation.

Little firm evidence indicates that infectious agents other than rubella can cause congenital heart disease. However, in utero mumps, adenovirus, CMV, and parvovirus B19 may produce myocarditis and congestive heart failure. Diffuse pulmonary infiltrates early in the neonatal period most commonly are caused by hyaline membrane disease, but in older neonates one should consider bronchopulmonary dysplasia and chlamydial infection. Causes of cataracts other than congenital rubella, HSV, and VZV infection include congenital galactosemia and the oculocerebrorenal (Lowe) syndrome. Chorioretinitis or retinopathy usually is caused by infection with *Taxoplasma gondii* or with viruses such as HSV, CMV, rubella, or LCMV. Microcephaly also can be caused by infection with HSV or VZV; noninfectious causes include Down syndrome, perinatal anoxia, phenylketonuria, and maternal irradiation. Hydrocephalus generally is caused by a congenital malformation of the ventricular aqueductal or subarachnoid space system. In a neonate with manifestations of an acute infection, major diagnostic considerations include serious bacterial infections such as sepsis, meningitis, urinary tract infection, or pneumonia. However, neonatal viral infections also are common causes of fever and sepsis syndrome in the neonate.[92,106-108,236,654,654a] After appropriate samples for bacterial and viral cultures have been obtained from the neonate, systemic antibiotics should be administered until a bacterial infection has been ruled out. Because of the frequency of neonatal HSV disease and its severe morbidity and mortality if untreated, and because results of recent studies have shown viral testing and antiviral treatment to be cost-effective as well as life-saving, some experts recommend administering intravenous acyclovir as well to selected neonates who present with fever or sepsis syndrome and appear to be at high risk for having neonatal HSV infection.[106-108]

LABORATORY DIAGNOSIS

Because the clinical manifestations in the various neonatal viral infections frequently overlap, establishing a specific etiologic diagnosis usually depends on the laboratory. General laboratory tests may show abnormalities suggestive of viral infection. For example, the peripheral white blood cell count may show neutropenia or lymphocytosis, with thrombocytopenia, and liver function tests may be elevated. The approach to the specific laboratory diagnosis of viral infection in a newborn infant is outlined in Table 73–6. Details of the various methods for each virus are covered in the respective chapters for these agents; only general comments relevant to the diagnosis of infection in the fetus or neonate are presented here.

Historically, histopathologic methods were used to attempt to establish a diagnosis of viral infection. For example, examination of stained cells from urine for CMV inclusions or examination of cells scraped from the base of a vesicle or from the conjunctivae for multinucleated giant cells with intranuclear inclusions characteristic of HSV or VZV (Tzanck-stained smear) were performed previously, but they are rarely performed currently. In addition, tissue obtained by biopsy or at postmortem examination may reveal intranuclear inclusions and multinucleated giant cells characteristic of the herpesviruses. Electron microscopy may reveal viral particles in vesicle fluid or tissue. Except for the propensity to involve certain organs (e.g., rubella virus, the heart; HBV, the liver), the pathologic changes induced by viruses other than the herpes group rarely are sufficiently specific to enable one to make an etiologic diagnosis. Even for the herpesviruses, the routine histopathologic methods are only one half to two thirds as sensitive as is isolation of the virus.

TABLE 73–6 Laboratory Diagnosis of Viral Infection in the Newborn Infant

Procedure	Details, Comments
Routine histopathologic methods	Urine cells stained for inclusions Scraping of vesicle base or conjunctiva for multinucleated giant cells Examination of biopsy or autopsy tissue
Isolation of detection of infectious agents	Isolation of infectious agent in cell culture or animals Detection of viral particles by electron microscopy Detection of viral antigen by immunologic methods Detection of viral nucleic acid by DNA probes, often after amplification by PCR
IgG antiviral antibody	Persistence of antibody in serum of infant beyond age of normal decline in maternal transplacental antibody—usually 4-6 mo Variety of methods available (CF, neut, HI, IHA, IFA, ELISA, etc.)—sensitivity of method varies according to specific virus
IgM-specific antiviral antibody	IgM not normally passed transplacentally, presence in cord blood or neonatal serum diagnostic IgM-specific antibodies not always present in neonate False-positive and false-negative results
Quantitative IgM level	Not a specific diagnostic test, suggests intrauterine infection

CF, complement fixation; ELISA, enzyme-linked immunosorbent assay; HI, hemagglutination inhibition; IFA, immunofluorescent assay; IHA, indirect hemagglutination; neut, neutralization; PCR, polymerase chain reaction. Modified from Hanshaw, J. R., Dudgeon, J. A., and Marshall, W. C.: Viral Disease of the Fetus and Newborn. 2nd ed. Philadelphia, W. B. Saunders, 1985.

The most direct, definitive, and preferred method of establishing the diagnosis is isolation of the agent from an appropriate site in the fetus or neonate. Prenatal diagnosis of fetal viral infection may be established by testing amniotic fluid for viral culture and PCR and fetal blood sample or viral-specific IgM and PCR.[310,628] The following sites generally are used in neonates: urine, saliva, and blood for CMV; throat, cataracts, and occasionally spinal fluid or urine for rubella; skin vesicles, buffy coat or whole blood, cerebrospinal fluid (CSF), conjunctivae, throat, stool, and urine for HSV; throat, stool, urine, CSF, or serum/buffy coat for enteroviruses; and skin vesicles for VZV. In addition, isolation of virus can be attempted from biopsy or autopsy specimens. Recovery of a virus from internal body fluids (buffy coat, CSF, urine), vesicle fluid, or tissue from organs is strong evidence of an etiologic association. Electron-microscopic examination of vesicle fluid can demonstrate typical herpesvirus particles in both HSV and VZV infection but cannot distinguish between the two. Immunofluorescence and immunoperoxidase methods are available for many of the viruses and can demonstrate and type viral antigen in cells scraped from lesions or in biopsy material. HBsAg is demonstrable in serum by radioimmunoassay or enzyme-linked immunosorbent assay (ELISA).

Methods for amplifying a particular segment of a viral genome, using methods such as traditional and real-time PCR, are now available in many hospital laboratories and most reference labo-

ratories. Most commonly, testing for CMV, HBV, HSV, VZV, parvovirus B19, adenovirus, and the enteroviruses and parechoviruses is performed in neonates.[479] However, almost any viral pathogen may now be detected using molecular techniques. In general, PCR and other molecular amplification methods are more rapid and sensitive than is virus isolation and are quite specific and may become the diagnostic test of choice for many viral infections. Molecular diagnostic tests also may be performed on any body fluid, but most commonly on blood and CSF. In addition, molecular methods also have been applied recently to diagnose congenital viral infections retrospectively from archived dried blood spots and used prospectively to develop newborn screening programs.[51,659]

Though not as sensitive, immediate, or direct as is isolation or detection of the viral agent using molecular methods, serologic studies are a readily available and traditional means for laboratory diagnosis of viral infection in a fetus or newborn infant. They should be used only when isolation or detection of the organism is not possible. The "TORCH" screen for antibodies *(Toxoplasma*, other, rubella, cytomegalovirus, and herpes simplex) was developed for this purpose. However, proper interpretation of serologic tests in newborn infants requires an understanding of the kinetics of the humoral immune response in the fetus and newborn infant, as well as an appreciation of the transplacental passage of antibodies from mother to fetus. Figure 73–4 illustrates the pattern of immunoglobulin concentrations in the serum of the fetus and newborn infant, as well as older infants and children. Maternal IgG, which contains antibody against viruses to which the mother has been exposed, passes transplacentally, beginning at midgestation. Peak levels are reached in fetal serum at the time of birth (umbilical cord blood); they decline to undetectable levels by the time that the infant reaches 6 to 12 months of age. However, the use of more sensitive assays for IgG antibody detection, such as immunoblotting, has demonstrated that maternal IgG antibody may persist for as long as 15 to 18 months.

In contrast, maternal IgM antibody normally is not passed transplacentally. Because the fetus is in a "protected" environment and usually does not receive an antigenic challenge in utero, fetal immunoglobulin levels remain low and do not begin to rise until after birth, when exposure to a variety of antigens occurs. However, the fetus is capable of mounting a humoral immune response when exposed to an antigen (a virus) in utero. Elevated levels of fetal immunoglobulins, therefore, can be detected at birth in umbilical cord blood. Because maternal IgG is present in such high concentration in cord blood serum, assays for IgM are performed. A fetus challenged in utero with a virus can have specific IgM antibodies against the viral agent, as well as elevated levels of the total IgM fraction. Often, a fetus with detectable virus-specific IgM will have severe in utero disease caused by the virus. Typically, three approaches can be used to make a serologic diagnosis of viral infection in a newborn infant: (1) assay of maternal serum and serum specimens from the infant at birth and at 5 to 6 months of age for antiviral antibody (predominantly IgG activity), (2) assay of neonatal serum for IgM antibody against a specific viral agent, and (3) assay of neonatal serum for quantitative IgM levels, a nonspecific indication of antigenic challenge in utero.

For purposes of illustration, the rubella hemagglutination-inhibition titers of two mother/infant pairs are shown in Table 73–7. Both mothers were exposed to someone with a rubella-like rash during pregnancy. The first mother was susceptible; subclinical rubella developed, and she delivered an infant with congenital rubella, whereas the second mother was immune and delivered an uninfected normal infant. The serum specimen obtained from the first mother at the time of exposure showed no detectable hemagglutination-inhibition titer, whereas the serum at delivery and 6 months postpartum showed high titers indicative of acute rubella virus infection during pregnancy. Serum specimens from her infant at birth and at 6 months of age demonstrated rubella virus hemagglutination-inhibition antibodies at approximately the same level, thus indicating the persistence of antibody formed by the infant and substantiating the occurrence of congenital infection. In the second mother, the rubella hemagglutination-inhibition titers remained unchanged in all three specimens. Her infant had evidence of transplacental maternal antibody in serum obtained at birth but no detectable antibody at 6 months of age. Similar results could be expected from serologic studies with the other viral agents listed in Tables 73–1 and 73–2, not only for congenital infections but also for natal and postnatal infections in which primary viral infection occurred in the mother. Even with natal infections in immune mothers and postnatal infections from nonmaternal sources, the serologic responses in the neonate would be similar to those shown in Table 73–7.

The presence of IgM antibodies in maternal, fetal, or neonatal serum against a specific virus usually is considered to be diagnostic of acute or recent infection with that agent. However, both false-positive and false-negative results can occur. False-positive findings can result from cross-reaction between viruses, espe-

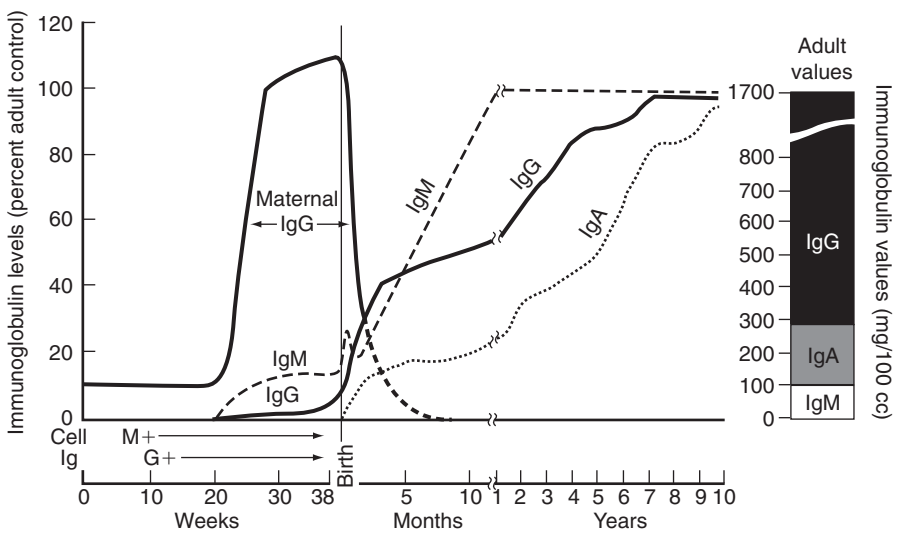

Figure 73–4 Kinetics of fetal and neonatal immunoglobulins. (*From Alford, C. A.: Immunoglobulin determinations in the diagnosis of fetal children. Pediatr. Clin. North Am.* 18:*99-113, 1971.*)

Comment	Congenital rubella		Passive transfer of antibody; no congential rubella	

cially the herpesviruses,[458] and the presence of rheumatoid factor (IgM antibody that binds to the Fc portion of IgG) in serum.[129] False-negative results can occur because of a poor or delayed humoral immune response in the fetus/neonate. For example, CMV IgM antibody was present in the serum of only 70 percent of congenitally infected infants, as demonstrated by isolation of virus from urine in the first few days of life.[608]

Determination of a quantitative IgM level in cord-blood serum often has been recommended as a screening test for congenital viral infection. Values above 20 mg/dL are considered to be abnormal, but the normal values in local laboratories should be used as a guide.[18] Unfortunately, contamination of cord-blood serum samples by maternal blood may occur in one half to two thirds of specimens.[15,425] Contamination is determined by demonstrating that the concentration of cord-blood serum IgA, which also is not passed transplacentally, is higher than the IgM level. If one excludes contaminated specimens, the incidence of congenital infection in infants with an elevated IgM level is many times higher than that in infants with normal levels. However, at least 50 percent of infants with a proven congenital infection, particularly those with asymptomatic infection, have a normal IgM level. In two thirds of infants with elevated IgM, infection with a specific etiologic agent could not be diagnosed.[15,18] Therefore, high rates of both false-positive and false-negative results occur. Finally, an elevated IgM level does not enable a specific etiologic diagnosis; it merely provides strong evidence for an intrauterine infection of some type.

The similarities in the clinical signs and physical findings associated with congenital and perinatal infection have led to the recommendation that for establishing appropriate diagnoses of these infections, submission of maternal and neonatal serum specimens for the "TORCH" screen or, in selected instances, a single neonatal specimen for specific IgM antibodies is best. The use of a "TORCH" battery of serologic tests, however, no longer can be recommended routinely because of poor diagnostic return; these tests are difficult to interpret because of transplacental passage of maternal IgG antibodies, and IgM assays may result in false-positive findings.[1] Instead, the laboratory test or tests that should be performed must be dictated by which congenital infection or infections one is trying to diagnose or rule out. As seen in Table 73–6, the variety of tests that are available for establishing the diagnosis of any of the multitude of different potential congenital pathogens renders a "TORCH" assay, and by inference the term "TORCH" itself, obsolete by current standards. Finally, if a congenital infection is suspected in the delivery room, the placenta should be sent for histopathologic studies.

CYTOMEGALOVIRUS

CMV is a ubiquitous agent that usually causes asymptomatic infection in a normal infant, child, or adult. CMV is the most common congenital infection in humans. Overall, the birth prevalence for congenital CMV infection has been estimated at 0.64 percent, with ranges between 0.4 and 1.2 percent reported. Congenital CMV infection occurs after both maternal primary and recurrent infections during pregnancy. It remains a worldwide public health problem for which interventions are critically necessary.[105,323,535] However, patients with immature or impaired host defenses, such as a fetus, newborn infant, or immunosuppressed patient, may exhibit a variety of clinical manifestations during the acute infection and have a greater potential for developing long-term neurologic sequelae.[17,178,228,267,451]

MICROBIOLOGY AND EPIDEMIOLOGY

CMV is a member of the herpesvirus group, which includes HSV, VZV, and Epstein-Barr virus, as well as human herpesvirus 6 (HHV6), HHV7, and HHV8. Several different genotypes or genetic strains of CMV differ, and an individual can have more than one CMV genotype or strain infection.[17,178,228] Different genotypes are associated with congenital CMV infection and disease; gB3 genotype appears to predominate in some studies, but no clear association between genotype and pathogenesis has been identified.[47,691]

Human CMV is limited to the human host and grows only in human cells in tissue culture. Its distribution is worldwide, and no predilection for either sex or a particular season of the year exists.* Studies of antibody prevalence and virus isolation have indicated two peak ages for acquisition of infection: (1) infancy and early childhood and (2) early adulthood (in the sexually active).[228,699] Infection rates are higher and exposure to the virus occurs earlier in life in developing countries, lower socioeconomic groups in industrial nations, and Asian populations.[228] The major source of infection of young infants is the mother, whereas transmission in the daycare setting is an important source for older infants and toddlers.[490,599] Approximately 50 percent of susceptible children between the ages of 1 to 3 years who are in group daycare acquire CMV, mostly by transfer of virus present in saliva on hands and toys. Within 3 to 7 months of their child's acquiring CMV infection in the daycare center, as many as 33 percent of the seronegative mothers become infected.[7] Transmission of CMV from a child in daycare to his mother and her fetus has been confirmed. Thus, CMV infection in young children in daycare has become an important source of maternal and fetal infection.[323,491] In young adults, intimate interpersonal contact appears to be necessary for transmission and an infected sexual partner also may be the source of infection for a pregnant woman and her fetus.

The usual sites for isolation of virus are the urine, cervix, and saliva,[228] but CMV also has been recovered from amniotic fluid,[171] semen,[375,376] breast milk,[202,277] feces,[159] and autopsy and biopsy tissue. Excretion of virus in urine, saliva, or the cervix may be prolonged after primary infection, particularly with congenital disease.[17,178,603,606] Intermittent, recurring shedding also may occur in a significant proportion of seropositive young adults.[528,604,606] Despite this prevalence of virus excretion, CMV seems to be of low communicability.[228] Beyond the neonatal period,

*See references 17, 52, 105, 170, 178, 228, 302, 305, 323, 535, 660.

infection appears to require prolonged or intimate contact and presumably is transmitted through contact with oropharyngeal or genital secretions.[105] Researchers have assumed that CMV may be transmitted sexually because of the frequency of isolation of virus from genital secretions and because the prevalence of antibody is higher in sexually active populations.[17,178] Finally, transmission of CMV by blood transfusion has been documented, particularly in the event of multiple seropositive blood donors.[10,228]

Prenatal transmission of CMV to the fetus presumably is associated with maternal viremia and transplacental passage of the virus, perhaps within virus-infected leukocytes.[17,178] An important observation is that congenital CMV infection occurs in the infants of mothers known to be immune to CMV, thus indicating that transplacental transmission is possible despite circulating antibody in maternal serum.[600,603] In addition, mothers have delivered more than one congenitally infected infant in successive pregnancies.[603,604] Analysis of CMV isolates obtained from the same mothers on repeated occasions are antigenically and genetically identical, whereas strains from different mothers are not.[297] In addition, strains obtained from pairs of mothers and their congenitally infected infant pairs, as well as congenitally infected siblings, usually, but not always, are identical. These results suggest that most CMV transmission from immune mothers to their fetuses or newborns is the result of reactivated latent infection. Recently, however, Boppana and colleagues[82] have documented that acquisition of a new strain of CMV by pregnant immune women can lead to symptomatic congenital CMV infection in their offspring. Fetal CMV infection also may occur in HIV-infected pregnant women.[194,443,558] Symptomatic congenital CMV infection has been documented in a preterm infant who died of disseminated CMV infection and was born to an HIV-infected, CMV-immune mother with acquired immunodeficiency syndrome (AIDS).[558] Among HIV-infected, CMV-immune women without advanced HIV disease, the rate of congenital CMV infection in their infants was similar to that of a comparison group of infants born to CMV-immune, HIV-uninfected mothers.[354,443] In another study, among a cohort of infants born to HIV-infected mothers, infants who were infected with HIV were significantly more likely to have congenital CMV infection than were non–HIV-infected infants, 21 versus 4 percent, respectively.[194] Importantly, HIV-infected infants who are co-infected with CMV appear to have greater immunosuppression and progression of disease than do those infected with HIV alone.[194,354,459]

Natal transmission of CMV results from exposure of the neonate to infected genital secretions at the time of delivery.[17,528,529] If the mother is excreting virus at the time of delivery, 40 to 50 percent of exposed infants become infected.[528] The level of maternal antibody did not influence the frequency or time of onset of infection in the neonate. The usual incubation period for natal infection is 5 to 6 weeks.[529]

The importance of breast milk and blood transfusion as sources for postnatal acquisition of CMV was mentioned earlier in the section "Frequency of Infection in the Mother and Neonate." Although nosocomial transmission of CMV from baby to baby via fomites or health care workers' hands in the neonatal intensive care unit has been documented,[593] it rarely occurs.[8,219]

PATHOGENESIS AND PATHOLOGY

Congenital infection results from transplacental transmission during maternal viremia.[17] However, CMV placentitis may occur without transplacental transmission of virus.[278] If transplacental transmission occurs, the virus spreads through the fetus by the hematogenous route.[400,550] The severity of congenital disease in the neonate usually, but not always, correlates with intrauterine infection at an earlier gestational age.[598] With the exception of blood transfusion-associated infection, natal and postnatal infection with CMV usually is acquired secondary to challenge of the nasopharynx or oropharynx of the infant with virus from infected maternal genital secretions or breast milk.[17,178] Replication of virus in the neonate occurs in the mucosa of the respiratory or gastrointestinal tract, with subsequent viremic spread to target organs. With blood transfusion-associated infection, virus is inoculated directly into the bloodstream. The major target organs are the CNS, eyes, lungs, liver, and kidneys.[17] Of interest is that overt disease in the neonate appears to be associated more commonly with the hematogenous route of inoculation: transplacental infection or infection secondary to blood transfusion.

CMV appears to have a particular affinity for epithelial cells, for ependymal cells lining the ventricles of the brain, and for the organ of Corti and neurons of the eighth nerve.[602] The characteristic pathologic features of CMV infection are cytolysis, focal necrosis and an inflammatory response, the formation of enlarged cells with intranuclear inclusions (cytomegalic cells), and the production of multinucleated giant cells. Healing results in fibrosis and often calcifications, which cause structural damage to the fetal developing organs. Damage may continue after birth because of persistent postnatal viral replication.[17] Replication of CMV in the epithelial cells of blood vessels may result in vascular damage and secondary structural defects. The intrauterine growth restriction associated with symptomatic congenital infection appears to be the result of a reduction in the numbers of cells in various organs rather than a diminution in cell size.[444] Abnormalities resulting from faulty organogenesis secondary to CMV infection are limited primarily to the brain and include microcephaly, optic atrophy, aplasia of various parts of the brain, and microphthalmos.[265] Although a variety of congenital malformations outside the CNS have been observed in infants with congenital CMV infection, they probably are coincidental rather than true teratogenic effects of the virus.[265] Such malformations include a variety of heart lesions, clubfoot deformities, indirect inguinal hernias, high arched palate, dental defects, and hypospadias.[17,265] Other than inguinal hernia in male infants and tooth enamel defects, the extraneural defects in infants with congenital CMV infection have been infrequent, sporadic, and diverse occurrences.

The fetus is capable of mounting a humoral immune response to CMV, as evidenced by the presence of elevated IgM levels and specific CMV IgM antibody in cord serum.[17,530,608] Excessive production of IgM and IgG in the presence of virus replication during the early postnatal course of congenital CMV has resulted in the formation of circulating immune complexes and rheumatoid factor, thereby providing a potential risk for tissue damage to occur by immune complexes.[609] The factors contributing to prolonged replication and excretion of CMV in involved infants are not understood fully, but it does not appear to be a matter of immunologic tolerance because infants do produce specific antibody against CMV.[17]

However, abnormalities in other aspects of the immune response of congenitally infected infants, including decreased lymphocyte blastogenesis and production of immune interferon in response to CMV antigen,[527,613] a decreased percentage of T cells in peripheral blood,[548] and a diminished interferon response in leukocytes challenged with Newcastle disease virus in vitro, have been observed.[210] The degree of suppression of these responses appears to correlate with the presence and amount of virus excretion and the severity of the disease.[529,613] Further investigations are necessary to determine the contribution of these immunologic aberrations to the pathogenesis of congenital CMV infection. The clinical relevance of these immunologic impairments is uncertain. Infants with congenital CMV infection do not have a higher incidence or severity of bacterial infections, although three fatal cases of overwhelming sepsis secondary to

Staphylococcus epidermidis have been described in CMV-infected, low-birth-weight infants.[365] Recently, *Pneumocystis carinii* pneumonia was reported in a 4-month-old infant who had congenital CMV infection; this infant was not infected with HIV but was severely malnourished.[386]

CLINICAL MANIFESTATIONS

From 90 to 95 percent of neonates with congenital CMV infection are asymptomatic in the neonatal period. Babies born to mothers with primary CMV infection during pregnancy are much more likely to be symptomatic as neonates than are newborns of mothers with recurrent infection.[11,17,23,178,510,600] The clinical manifestations present in those with overt disease in the neonatal period are shown in Figure 73–2. These features may occur singly or in combination. The constellation of findings seen in infants with multiorgan disease that primarily affects the reticuloendothelial system and CNS historically has been referred to as *cytomegalic inclusion disease*, a term that rarely, if ever, is used today.

Typical clinical features of symptomatic congenital CMV disease include small size for gestational age, hepatomegaly, splenomegaly, jaundice, petechiae or purpura, pneumonia, microcephaly, chorioretinitis, and cerebral calcifications.[589] The enlargement of the liver and spleen is caused by mild hepatitis, a reticuloendothelial response to chronic infection, and extramedullary hematopoiesis. Hepatitis is associated with direct- and indirect-reacting hyperbilirubinemia and mild elevation of liver enzymes. Liver biopsy specimens have revealed local infiltration and necrosis, multinucleated giant cells, large inclusion-bearing cells, cholangitis, fatty metamorphosis, interstitial fibrosis, and bile stasis.[17,178] Although hepatomegaly and mild alteration in liver function test results may persist for several months after birth, severe chronic liver disease with cirrhosis rarely occurs. Splenomegaly is a common event and may be the only abnormality present at birth. Petechiae and purpura are the result of thrombocytopenia, which usually resolves within a few weeks or months but may persist through the first year of life. Thrombocytopenia may be the only manifestation of CMV infection. "Blueberry muffin spots" are discrete, well-circumscribed lesions often mistaken for purpura; they represent dermal erythropoiesis in the more severely affected infants. A diffuse interstitial pneumonitis occurs in less than 1 percent of newborns with symptomatic disease. Congenital CMV infection also has been associated with defective enamelization of the deciduous teeth.[601]

Involvement of the CNS by CMV results in the most severe sequelae of the disease. CMV infection of the brain causes encephalitis and periependymitis, with resultant ventriculomegaly, gliosis, and calcification. The cerebral calcifications typically are periventricular, a pattern that may be distinguished from the more diffuse pattern observed in congenital toxoplasmosis. In addition, linear calcifications along the lenticulostriate vessels within the basal ganglia and thalamus have been associated with CMV infection. Intracranial calcifications are best visualized by unenhanced computed tomography (CT) scan of the brain; however, cranial ultrasound and brain magnetic resonance imaging (MRI) also have been applied to discern abnormalities.[128] As many as 70 percent of symptomatic infants have neurologic findings, with the most common being microcephaly. Microcephaly may not be present at birth but may become apparent when the child is 1 year of age or older, a period in which differences in growth rates between the brain and somatic tissues are observed. When associated with cerebral calcifications and chorioretinitis, microcephaly carries a high probability of developmental disabilities.[465] On occasion, microcephaly is associated with obstruction of the fourth ventricle, with subsequent development of hydrocephalus. As many as 37 percent of congenitally infected infants with neuroradiologic abnormalities will develop seizures.[623]

The most common ocular abnormalities are chorioretinitis, strabismus, and optic atrophy.[145] Central vision loss may occur in neonates with severe CNS involvement.[145] Although microphthalmos, cataracts, and other eye abnormalities have been observed in congenitally infected infants, they are rare occurrences and most likely are not caused by CMV, but rather represent a coincidental finding with another etiology.[145,265] Permanent vision loss may occur as long-term sequela.

Deafness is the most common sequela of congenital CMV infection. Sensorineural hearing loss occurs in approximately 50 to 75 percent of symptomatic infants and 7 to 15 percent of those with asymptomatic congenital infection. Hearing loss associated with symptomatic infection usually is severe and bilateral, whereas the hearing loss in asymptomatically infected infants usually is unilateral. Both forms of hearing loss are progressive.[230,678] Approximately 20 percent of infants with congenital CMV have late-onset hearing loss that will not manifest until after the child reaches 1 year of age.

Most naturally acquired natal and postnatal CMV infections in full-term newborn infants are asymptomatic and not associated with late neurologic sequelae such as hearing loss and psychomotor retardation. Most of these infections result from reactivation of latent maternal CMV, and infants are born with transplacentally acquired maternal IgG antibody that ameliorates the disease. However, mostly pneumonitis, but also hepatosplenomegaly and lymphadenopathy, has been noted in some infants.[366,597,670,698] Severe disease manifested also by neutropenia and thrombocytopenia has been reported predominantly in preterm infants and is associated with the development of chronic lung disease.[698] In addition, exacerbation of congenital CMV infection has been documented in premature infants receiving corticosteroid therapy for chronic lung disease of prematurity.[648] Similarly, postnatal acquisition of CMV through breast-feeding nearly always is an asymptomatic infection in full-term infants because of the presence of maternal antibodies. CMV infection acquired through breast milk by premature infants with a birth weight of 1000 g or less has been associated with a sepsis-like illness consisting of apnea and bradycardia, hepatosplenomegaly, a distended bowel, pallor, thrombocytopenia, and elevated liver function test results.[263,656]

Transfusion-acquired CMV infection is an important clinical syndrome associated with multiple blood transfusions from seropositive donors to very-low-birth-weight infants in neonatal intensive care units.[10,50,692,697] Eighty-eight percent of babies had hepatosplenomegaly, a "septic" appearance, deterioration in respiratory status, a peculiar gray pallor, and atypical lymphocytosis approximately 4 to 12 weeks after receiving transfusions.[10,50,697] The illness lasted 2 to 3 weeks in most infants, although 24 percent died.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Primary CMV infection occurring during pregnancy is documented by demonstration of IgG seroconversion with sera obtained before or during early pregnancy and at delivery. Detection of anti-CMV IgM in a single specimen is considered a presumptive primary infection.[12,13,253,364,452,509,608] Caution, however, must be exercised when analyzing the results of CMV IgM tests. Even with the best commercially available assays, at least 5 percent of positive serum IgM tests represent false-positive results. On the other hand, a negative CMV IgG antibody test in the mother of an infant in whom the diagnosis of CMV infection is in question would exclude congenital transmission as a possible source of CMV. CMV avidity tests can be helpful in distinguishing recent primary infections from past recurrent

CMV infections in CMV-seropositive women. The prenatal diagnosis of congenital CMV infection can be accomplished by amniocentesis, with detection of CMV in amniotic fluid by culture and PCR. Fetal blood sampling for CMV IgM determination, complete blood count (CBC) with platelet count, and serial fetal ultrasound examinations can help identify fetuses at high risk for developing disease and sequelae.[41,213,388]

Because the signs and symptoms of symptomatic CMV infection in newborns so often overlap with those in other diseases during this period of life, establishing a definitive diagnosis requires the use of laboratory tests. Isolation of virus from urine or saliva collected within the first 21 days of life is considered proof of congenital infection and is the most sensitive and recommended means of diagnosis.[17,178] The usual specimens for isolation of CMV are urine and saliva,[48] but virus may be recovered from CSF, buffy coat, nasopharynx, tears, and biopsy and postmortem tissue.[465] Congenitally infected infants are known to excrete virus for several years after birth. Isolation of virus in an infant beyond 3 weeks of age does not, by itself, differentiate between natal or postnatal infection and congenital infection, unless negative cultures have been obtained previously. Detection of CMV DNA by PCR in urine, saliva, blood,[235,311] or CSF also may confirm congenital infection, although the sensitivity and specificity of PCR performed on urine may be less than those for viral culture.[179,455] On the other hand, PCR is preferred for detection of CMV in CSF and blood because CMV culture usually is negative.[203,365,643] The presence of CMV DNA by PCR in the CSF of congenitally infected infants has correlated with abnormal neurologic outcome.[643] Similarly, the finding of a positive serum or whole blood CMV PCR in infants with congenital CMV infection has been associated with the development of hearing loss.[86] Quantitative CMV PCR assays also may be used to follow antiviral therapy.

Serologic tests, such as "TORCH" titers performed for specific antibody determination in neonates, rarely are helpful and are not recommended for establishing a diagnosis of congenital infection. If serologic tests that predominantly measure IgG are used, serial serum specimens from birth are required to differentiate congenital from natal or postnatal infection. One observes maintenance of a stable antibody titer during the first 6 months of life in infants with a congenital infection. In contrast, with natal and postnatal infection, a drop in antibody titer occurs during the first 2 to 3 months of life as maternal passive antibody declines, followed by a rise by the time the infant reaches 5 to 6 months of age.[529,607] If the infant is not evaluated until several months of age and serum specimens from earlier life are not available, determining whether the infection is congenital, natal, or postnatal in origin may not be possible.

Detection of CMV antigenemia in blood can be achieved by means of a commercial assay that uses monoclonal antibodies to pp65, a tegument protein of the virus that is present in infected polymorphonuclear leukocytes.[190] Its major use may be for evaluation of a symptomatic infant who has natally or postnatally acquired CMV infection, for which making a differentiation between congenital and acquired CMV infection is difficult at best and the finding of a positive urine CMV culture may be only incidental. The assay is quantitative, so it also may be used to follow antiviral treatment.

Examination for inclusion-bearing cells in urine carries historical significance, but this test yields positive results in only 20 to 50 percent of known virus-positive cases, and it is rarely, if ever, used today.[17,178] Typical intranuclear inclusions also may be seen in biopsy tissue or in megakaryocytes of bone marrow aspirates,[17,178] but virus may be isolated from tissue when these pathologic findings are absent.

The major diseases to consider in the differential diagnosis include congenital syphilis, congenital rubella, congenital toxoplasmosis, erythroblastosis fetalis, disseminated HSV infection, LCMV, neonatal sepsis, and enterovirus infection. Congenital syphilis is suggested by the presence of osteochondritis and periostitis on radiographs of the long bones in an infant born to a mother with reactive serologic tests for syphilis. Darkfield examination of spirochete-laden nasal secretions in infants with rhinitis confirms the diagnosis. The presence of congenital heart disease and cataracts suggests rubella, and chorioretinitis, hydrocephalus, and intracranial calcifications suggest toxoplasmosis, but a definitive diagnosis depends on the laboratory findings. In uncomplicated erythroblastosis, the direct bilirubin and liver function study results remain normal. Vesicular skin lesions suggest HSV or VZV infection. Positive blood cultures confirm the diagnosis of neonatal sepsis. Congenital CMV infection seldom is complicated by bacterial sepsis in a newborn. Neonatal enterovirus infections are seasonal; associated with maternal symptoms of enteroviral disease; and characterized by aseptic meningitis, hepatitis, myocarditis, or gastroenteritis. Biliary atresia, as well as noninfectious and genetic and metabolic disorders, also may mimic congenital CMV disease.

TREATMENT

Although treatment with idoxuridine,[148] floxuridine,[223] 5-fluorodeoxyuridine,[506] cytosine arabinoside,[357,405,506] adenine arabinoside,[58,138] interferon inducers,[506] human interferon,[38,211] and acyclovir[505] has been tried in infants with congenital CMV infection, the only effect was a transient alteration in viral excretion. Unfortunately, little or no effect on the clinical course of the disease was achieved with these early antiviral compounds. Foscarnet, cidofovir, ganciclovir, and valganciclovir are currently licensed for treatment of life- and sight-threatening CMV infections. Of these antivirals, only ganciclovir has been subjected to clinical trials that evaluated the pharmacokinetics and efficacy in treatment of newborns with virologically proven CMV disease.* Neither standard nor CMV hyperimmune intravenous immunoglobulin is recommended for the treatment of congenital CMV infection. However, in nonrandomized studies, maternal administration for in utero fetal treatment with CMV hyperimmune globulin has shown possible benefit in preventing transmission to the fetus and in ameliorating fetal disease.[440,462] Also, the extremely premature infant who develops CMV disease postnatally, after maternal IgG levels have declined and after administration of only CMV-seronegative blood products, may be devoid of virus-specific CMV antibody and, therefore, if CMV IgG levels are nil or negative, may possibly benefit from administration of IGIV or CMV hyperimmune globulin. However, there are no clinical trials published that evaluate the supportive role of immune globulin in the treatment of CMV disease in these special infants.

Clinical studies and experience support the use of ganciclovir in selected neonates. A phase II study of intravenous ganciclovir (4 or 6 mg/kg per dose every 12 hours for 6 weeks) in 47 neonates with congenital CMV infection involving the CNS found that the preferred dose was 12 mg/kg/day.[671] Adverse effects of ganciclovir included neutropenia in 16 (34%) infants, increases in aspartate aminotransferase in 6 (13%), and direct hyperbilirubinemia in 3 (6%). Hearing was improved or stabilized in 16 percent of infants at 6 months or longer of follow-up, thus suggesting efficacy.

Furthermore, a phase III, multicenter randomized study of ganciclovir therapy for infants with congenital CMV infection involving the CNS was performed by the Collaborative Antiviral Study Group (CASG) from 1991 to 1999.[335] This study evaluated

*See references 25, 180, 286, 330, 335, 411, 420, 421, 460, 462, 555, 590, 629, 646, 648.

the safety and efficacy of intravenous ganciclovir (6 mg/kg per dose every 12 hours for 6 weeks) versus no therapy in 100 enrolled CMV-infected neonates with neurologic involvement (≥32 weeks of gestation, birth weight ≥1200 g). Among 47 evaluable infants who completed all protocol follow-up evaluations, those who received ganciclovir were significantly more likely to have either improved or normal hearing at 6 months than were untreated infants, and none of the ganciclovir-treated infants had worse hearing. At 1 year or longer, those who received ganciclovir also were significantly less likely to have worse hearing than were those in the untreated group. Other beneficial effects of ganciclovir therapy included a significant decrease in the median time to normalization of alanine transaminase, as well as improved weight gain and head circumference after 6 weeks of therapy, but no change in mortality rates. Neutropenia developed in 63 percent of ganciclovir recipients, reversible with adjustment or discontinuation of medication. In addition, neurodevelopmental assessments in neonates at 6 to 12 months of age showed that treated neonates had fewer milestone delays and improved growth in head circumference compared with untreated neonates, suggesting another potential benefit of ganciclovir therapy.[335]

Currently, offering ganciclovir therapy to CMV-infected neonates with CNS disease seems reasonable because 90 to 95 percent of these infants will have significant neurologic and sensory sequelae. The decision to treat should be individualized and carefully considered.[25] Because 6 weeks of therapy may not be sufficient for optimal benefit, a phase I/II pharmacokinetic evaluation of oral valganciclovir in neonates with CMV infection of the CNS has been published recently, with the hope that studies evaluating the effects of long-term oral suppressive therapy will be soon conducted.[330,335] Ganciclovir also may be beneficial in treating critically ill neonates, especially preterm infants, with life-threatening CMV disease manifested by viral sepsis syndrome, persistent thrombocytopenia, recurrent or progressive sight threatening retinitis, persistent or severe pneumonitis, persistent hepatitis, or encephalitis.[179]

PROGNOSIS

The major long-term sequelae of neonatal CMV infection are neurodevelopmental, motor, and sensory disabilities.[231,269,367,530,541,602] The most guarded prognosis occurs in neonates born to mothers with primary CMV infection during pregnancy; in infants with symptoms at birth, particularly those of the CNS; in infants with the triad of microcephaly, intracranial calcifications, and chorioretinitis; and in neonates who have elevated quantitative IgM or in whom CMV-specific IgM is present.[17,81,178,231,252,367,465,466,678] The duration of CMV urinary excretion has not been associated with abnormalities in growth or neurodevelopmental deficits.[465] Overall, 25 percent of infants born to mothers with primary CMV infection during pregnancy will have at least one sequela, versus 8 percent of those born to mothers with recurrent infection.[231] Of symptomatic, congenitally infected neonates, approximately 8 percent die in the neonatal period.[82,589] Six percent of symptomatic infants die after the neonatal period, and death often is caused by progressive liver disease, failure to thrive, seizures, or intercurrent illnesses. Death beyond infancy is a result of malnutrition, aspiration pneumonia, or overwhelming infection. Of survivors with symptomatic congenital CMV disease, as many as 90 percent have some evidence of CNS abnormality, such as microcephaly, impaired intellect or development, neuromuscular disorders (seizures, cerebral palsy, spasticity, hemiparesis), sensorineural hearing loss, and ocular abnormalities (usually chorioretinitis).[147,231,492,596,679] Neurologic sequelae of congenital CMV disease, especially sensorineural hearing loss, may progress after the first year of life.[80] For this reason, the recommendation is that CMV-infected newborns have close audiologic and neurodevelopmental follow-up through childhood and adolescence. Cochlear transplantation performed in children as young as 11 months of age, accompanied by intensive speech language therapy, has been used successfully in infants who have profound bilateral hearing loss from congenital CMV disease.

Ninety to 95 percent of infants with congenital CMV infection are asymptomatic in the neonatal period. As many as 25 percent of these infants will have abnormal brain CT scans. Several long-term follow-up studies have indicated that as many as 15 percent will have progressive hearing loss, and at least 10 percent of these infants may have neurodevelopmental and auditory processing differences and disabilities, possibly caused by CMV. The following abnormalities were noted in infected infants when compared with matched control children: IQ less than 90 (32 vs. 16%), significant hearing loss (23 vs. 9%), predicted school failure (36 vs. 14%), and microcephaly (15 vs. 5%).[268,530] Auditory imperception problems also have been associated with congenital CMV infection in children with normal hearing. In addition, approximately 2 percent of infants with asymptomatic congenital infection may have silent, unrecognized chorioretinitis.[145]

As many as one third of neonates who acquire CMV natally from maternal cervical secretions may have acute disease associated with the onset of viruria, regardless of birth weight.[366,698] However, birth weight and age of onset of viral excretion appear to influence the development of neurologic sequelae significantly. Full-term neonates with natally acquired CMV do not have significantly altered behavioral, neurologic, audiologic, speech, and language examinations on long-term follow-up when compared with uninfected controls.[367] In contrast, infants with birth weight less than 2000 g and onset of CMV excretion before they reach 8 weeks of age have associated severe cardiopulmonary disease during the neonatal intensive care unit stay (perhaps because of CMV worsening the pulmonary disease) and a significantly greater percentage of severe handicaps on long-term follow-up than do matched controls.[489] The relationships among low birth weight, early onset of CMV excretion, lower levels of transplacental antibody, and more severe cardiopulmonary disease and their contribution to neurologic sequelae require further evaluation, but natal acquisition of CMV appears to contribute to the development of sequelae in selected situations. CMV disease acquired from blood transfusion in very-low-birth-weight infants also may contribute to neurologic sequelae.[10,17,697]

Infants with congenital CMV infection have many special needs. These infants and children require physical, occupational, and speech therapy, as well as audiologic follow-up to assess their need for hearing aids and cochlear implantation. Ophthalmologic follow-up also is necessary because strabismus, optic atrophy, and, rarely, late onset chorioretinitis may develop and affect visual acuity. Failure to thrive secondary to swallowing dysfunction, such as microaspiration and gastroesophageal reflux, often is present in the more severely affected infants, which renders the need for gastrostomy tube feeding essential for survival. This decision often becomes an ethical issue, as is establishment of resuscitation orders. Severely affected children also may have sleep disorders that may require the use of nighttime sedatives. In less severely affected children, school function must be assessed carefully. Finally, all these issues bring stress to the family unit, and the need for family support cannot be overemphasized.

PREVENTION

Routine serologic screening of pregnant women currently is not recommended routinely by all experts because no prophylactic or

therapeutic interventions, such as vaccines or antivirals, are available during pregnancy. However, many experts recommend that women of child-bearing years be aware of their CMV serostatus and also be aware of the most likely sources of CMV infection.[105] In addition, physicians caring for women who may become or are pregnant should counsel them about hygienic precautions that may reduce the risk of acquiring CMV infection during pregnancy, and educational materials are available to assist in counseling (*www.cdc.gov/cmv* or *www.bcm.edu/pedi/infect/cmv).* During pregnancy, meticulous adherence to standard precautions, especially handwashing after exposure to urine or saliva from young infants and toddlers and avoidance of kissing and sharing utensils with toddlers and young children who are likely to be shedding CMV, currently may be the most effective means of preventing transmission of CMV infection to susceptible pregnant women.[25,105,124,308] CMV often is transmitted within the family settings and in daycare centers caring for infants, toddlers, and young children. The rate of transmission of CMV in the hospital setting appears to be low[181,228] because prolonged or intimate contact seems to be necessary for spread to occur.[17,181,228,693] For this reason and because of the ubiquity of the virus, pregnant women are not excluded routinely from caring for patients infected with CMV.[25] Adherence to universal, standard precautions for all patients is adequate to prevent CMV transmission to patients and health care workers.[181]

Blood transfusion–associated CMV infection in low-birthweight infants in neonatal intensive care units virtually has been eliminated by the use of CMV-seronegative blood donors,[6,88,374,385] frozen deglycerolized red cells,[88,631] removal of the buffy coat by saline washing,[179] and filtration to remove white blood cells. Pasteurization of breast milk effectively kills CMV, although freezing at –20° C significantly reduces but does not eliminate infectivity. If donor breast milk is provided to premature infants or full-term infants born to nonimmune mothers, only that from a seronegative mother should be used.

Passive immunoprophylaxis with CMV hyperimmune globulin has been reported in uncontrolled studies to reduce transmission of CMV and morbidity in the fetus of women experiencing primary CMV infection while pregnant.[462] Randomized, controlled, multicenter trials should be performed, however, to determine if this approach can be beneficial enough to be routinely recommended.

Several vaccine candidates, including two live-attenuated CMV vaccines (AD-169 and Towne strains), have been evaluated in phase I and II clinical trials, and chimeric vaccines combining Towne and Toledo strains have been evaluated.[79,17,90,178] Currently, subunit vaccines using CMV glycoprotein gB, a principal target of the neutralizing antibody response, attached to an adjuvant, is a promising vaccine candidate that has been shown to be safe and immunogenic in phase I trials and currently awaits phase II and III trials. Development of a safe and effective CMV vaccine that can prevent severe congenital CMV disease remains a top priority and is a realistic and attainable goal.[36a,325,551]

RUBELLA

Rubella usually is a mild, often subclinical disease involving school-aged children and young adults. However, rubella virus also can cross the placenta, infect the fetus, and cause fetal death or congenital malformations. Since the original observations were made by the Australian ophthalmologist Norman McAlister were Gregg,[198,250] in which maternal rubella was associated with the birth of offspring with defects of the eye and heart, rubella has been the prototype for congenital viral infection.

MICROBIOLOGY AND EPIDEMIOLOGY

Rubella virus, an enveloped RNA virus in the family *Togaviridae*, has only a single antigenic type but has several newly characterized genotypes.[152,310,518] Genotyping is now used to track the molecular epidemiology of rubella strains associated with outbreaks.[310,518,628] Rubella virus grows in tissue culture from a variety of animal species, but commonly, a viral interference assay with African green monkey kidney cells is used for isolation in the diagnostic virology laboratory.[134] Several serologic tests, including complement fixation, hemagglutination inhibition, immunofluorescence, radioimmunoassay, and enzyme immunoassay (EIA), are available.[134,281] Although hemagglutination inhibition[619] has been the gold standard, many diagnostic virology laboratories now use more sensitive and practical methods such as ELISA, latex agglutination, or fluorescent assay kits.[134] In addition, traditional and real-time PCR assays can now detect and genotype rubella virus RNA in clinical samples.[310,518]

Rubella is worldwide in distribution. Human beings are the only host, and transmission occurs from person to person.[152,681] In the era before rubella vaccine was available, epidemics occurred at 6- to 9-year intervals, and pandemics occurred every 10 to 20 years.[681] Since the vaccine was licensed in 1969, this epidemic pattern has been interrupted; the last major outbreak in the United States was in 1964.[54,473] The peak seasonal incidence is in the spring.[681] In the prevaccine era, the peak age incidence was between 5 and 14 years of age,[681] but in the mid-1970s, the peak age was 15 to 19 years.[473] Currently, no peak age exists. Approximately 5 to 25 percent of women of child-bearing age lack rubella antibody and are susceptible to primary infection.[54,116] The attack rate for rubella in susceptible populations with prolonged intimate exposure is high—95 to 100 percent.[152,681] The frequency of transmission after brief exposure, however, is low.[152,681] The frequency of subclinical infections is much higher in adults than in children, although some serologically diagnosed infections in adults actually may be reinfections rather than primary disease.[293,294,566]

The incubation period for acquired rubella ranges from 14 to 23 days but usually is 16 to 18 days.[566] Virus may be isolated from the throat from 1 week before until 2 weeks after the onset of rash. Rubella virus infection may be subclinical in one third to a half of children and in half to two thirds of adults.[293,566] Rubella hemagglutination-inhibition antibody is detectable in serum within 2 to 3 days after the onset of rash, with peak titers being reached in 3 to 4 weeks.[134] Complement-fixation antibody rises more slowly, with peak titers noted at 4 to 6 weeks after the rash appears. Primary rubella virus infection is associated with an initial response in IgM-specific antibody, followed by an increase in IgG antibody. Reinfection with rubella virus is known to occur, and rates are higher in vaccine-immune than in naturally immune subjects.[293] The vast majority of congenital rubella virus infections occur after primary infection, but a few cases have been reported after reinfection.[131,206,532] If no evidence of rubella-specific IgM can be found in mothers with subclinical reinfection during pregnancy, the fetus is unlikely to be at risk.

PATHOGENESIS AND PATHOLOGY

Transplacental infection of the fetus with rubella virus occurs secondary to maternal viremia during the course of primary infection.[14,16,249] Fetal infection appears to result from embolization of pieces of necrotic placental vascular endothelium.[414] However, involvement of the placenta with rubella virus does not always result in fetal infection, particularly after the first trimester.[16] After maternal immunity, the next most critical factor determining the frequency of fetal infection and the severity of

disease in neonates is the time during gestation that rubella virus infection occurs. Studies of the frequency of fetal infection and congenital defects according to gestational age at the time of maternal infection have used more sensitive methods to detect maternal and neonatal infection and long-term follow-up to detect abnormalities that were not apparent during infancy.[422] These studies indicated higher fetal infection rates than previously realized: 90 percent during the first 11 weeks, 50 percent during weeks 11 to 20, 37 percent from 20 to 35 weeks, and 100 percent during the last month. The congenital defect rate was 100 percent for the first 11 weeks, 30 percent during weeks 11 to 20, and none thereafter. Neonatal purpura and cataracts or glaucoma are observed when maternal rubella occurs during the first 2 months of gestation; congenital heart disease, during the first 3 months; deafness and neurologic deficit, during the first 4 months; and retinopathy, during the first 5 months.[422,646]

Excretion of rubella virus from the throat of congenitally infected infants may continue for several months after birth; approximately 10 to 20 percent of infected infants shed virus in nasopharyngeal secretions at 6 months of age. A small number will continue to shed virus for 1 year or more, and the virus has been recovered from tissues up to several years later.[16,154] Persistence of viral replication after birth may result in continuing damage to involved tissues, especially in the CNS and the eye and lens. In fact, hearing loss and neurologic deficits may appear long after birth in children previously considered well, or the clinical severity of these sequelae actually may worsen as the child's condition is being monitored.[136,154,185]

Rubella virus is a proven teratogenic viral agent that may cause congenital malformations.[475] Knowledge of the mechanisms by which rubella virus causes deformities may lead to a basic understanding of the pathogenesis of these malformations. Rubella virus is noncytolytic in certain tissues in that it does not destroy the cells in which it replicates. This characteristic, if manifested in the fetus, would tend to allow survival but result in disordered function of cells, tissues, and organs. On the other hand, selective cell destruction also may occur in fetal tissues.

In studies of the pathology of therapeutically aborted, rubella-infected fetuses, scattered foci of necrotic cellular damage without inflammatory infiltrates were noted in the endothelial cells of blood vessels and in myocardial cells.[635] Rubella-induced defects could result in defective formation or function of developing tissues by direct cellular destruction or by hypoxic damage secondary to blood vessel obliteration. For example, alteration of the elastic or muscle fibers in the ductus arteriosus could result in failure of postnatal ductus closure. Studies of tissue obtained from infants with rubella syndrome and maintained in culture showed that the cells were infected with rubella virus persistently and had a decreased growth rate and shortened survival time.[521] Naeye and Blanc[445] noted that the growth retardation of infants with rubella syndrome was the result of decreased numbers of cells in organs. This impaired cellular growth, if it occurred during a crucial phase in cardiac development, for example, could result in such cardiac anomalies as septal defects.

Increased numbers of chromosome breaks have been noted in leukocyte cultures of children with congenital rubella.[467] Chromosomal injury possibly results in cell loss during rapid organ development and is, in part, responsible for the congenital anomalies. Persistence of virus possibly results in continuing cell destruction or immunopathologic damage to tissues. In addition, two studies have demonstrated circulating rubella antigen-antibody complexes in 10 infants with congenital rubella and late-onset manifestations such as interstitial pneumonia, hepatosplenomegaly, rash, lymphocytic meningitis, and rapid neurologic deterioration.[78,630] IgG levels were low and IgM levels were elevated, with a diminished number of T cells and an increased proportion of B cells. Delayed maturation of the immune response in congenital rubella was postulated to predispose possibly to persistent antigenemia complexed with IgM and deposition of circulating immune complexes in tissues. Finally, antibodies against thyroid microsomes or thyroglobulin were found in a much larger percentage of children with congenital rubella syndrome than in control subjects.[142] A significant number of the patients with congenital rubella and thyroid antibodies also had thyroid dysfunction. These observations suggest that autoimmunity, induced in some way by persistent infection with rubella virus, plays a role in the late-onset endocrine dysfunction that occurs in children and young adults with congenital rubella syndrome.

Specific pathologic lesions in infants with congenital rubella depend on the gestational age at the time of infection and the particular organs involved. One common finding is necrosis of vascular endothelium, which may be accompanied by damage to organs secondary to vascular obstruction.[416,635] Diffuse intimal changes have been observed in the pulmonary and systemic arteries, as well as the ductus arteriosus.[416] Focal inflammation and necrosis have been seen in the myocardium[352] and structures of the inner ear.

The fetus is capable of an immune response to rubella virus: specific IgM and, occasionally, IgA have been observed in fetal and cord-blood specimens. In fact, hypergammaglobulinemia may be observed during early life in some infants with congenital rubella.[264] On the other hand, hypogammaglobulinemia has been noted in a few infants.[264,504] In 10 to 20 percent of infants with congenital rubella, hemagglutination-inhibition antibody declines to undetectable levels when they reach 1 to 4 years of age.[154,270] Several of these infants failed to respond to immunization with rubella vaccine.[151] In fact, infants with congenital rubella have been reinfected with rubella virus later in life.[414] Several defects in cell-mediated immunity, including diminished responsiveness of peripheral blood leukocytes to phytohemagglutinin and diminished lymphocyte transformation, interferon production, and synthesis of leukocyte migration inhibitory factor in response to challenge with rubella virus antigen, have been observed in infants with congenital rubella.[104,472] Normal responses were observed in healthy, seropositive children and adults. Researchers have presumed, but have not proved, that these abnormalities in cell-mediated immunity play a role in persistent viral excretion in congenitally infected infants.

CLINICAL MANIFESTATIONS

Although the typical clinical features of rubella may occur in pregnant women, as many as one half to two thirds of these infections are subclinical.[568] Typical features that might occur in symptomatic postpubertal women include fever, rash, posterior auricular and postoccipital adenopathy, and arthralgia or arthritis.

As many as two thirds of infants with proven congenital rubella may be asymptomatic in the neonatal period.[549] However, evidence of long-term sequelae was noted in almost three quarters of such infants within the first 5 years of life.[549] The clinical manifestations of congenital rubella syndrome vary highly, not only with regard to specific features but also in relation to the age during which the specific feature occurs. The collected features may be divided into three broad categories: (1) transient—those that are present in the neonatal period and clear after a few months, such as thrombocytopenia and hepatitis; (2) permanent—major malformations that persist and may even worsen as the child grows older, such as congenital heart lesions, cataracts, or hearing loss; and (3) developmental—aspects that do not emerge until childhood or young adulthood, such as behavioral disorders or endocrine dysfunction.[151,569] This categorization of

abnormal features may be useful in determining the prognosis and management of these children.

The manifestations of congenital rubella that are symptomatic in the neonatal period, compiled from several series,[153,292,351,392,540] are illustrated in Figure 73–2. The low birth weight of infants with rubella syndrome results from intrauterine growth restriction; even when born prematurely, the infant often is small for gestational age. The frequency of purpura in most series ranges from 15 to 50 percent. Thrombocytopenia almost always was present in association with the purpura and usually resolved spontaneously in the first month of life. Neonatal thrombocytopenic purpura is a poor prognostic sign because it generally occurs in severely affected infants with multiple manifestations. Thirty-five percent of 58 patients with purpura in one series[153] died during the first year, in contrast to a mortality rate of only 13 percent during the first 18 months for patients from the entire series. Although the thrombocytopenia frequently was profound, death rarely was caused by hemorrhage.

Direct involvement of the liver by rubella virus results in neonatal hepatitis, as evidenced by hepatomegaly, predominantly direct-reacting hyperbilirubinemia, and elevation of liver enzymes.[217] Pathology studies usually demonstrate hepatocellular disease with necrosis, giant-cell formation, bile stasis, and fibrosis, but extrahepatic biliary obstruction also has been demonstrated.[620]

Congenital heart disease occurs frequently and generally is detectable in the neonatal period, although specific lesions may not be defined until later in life. The most common lesions in 87 catheterized patients with congenital rubella were patent ductus arteriosus in 78 percent, right pulmonary artery stenosis in 70 percent, left pulmonary artery stenosis in 56 percent, valvular pulmonic stenosis in 40 percent, mild aortic valvular stenosis in 14 percent, aberrant subclavian artery in 11 percent, and ventricular septal defect in 10 percent.[154] Evidence of active myocardial disease has been noted in some infants.[352]

Interstitial pneumonia with cough, tachypnea, and breathlessness as the major manifestation of congenital rubella has been reported.[498] Most patients with pneumonitis died in the first year of life as a result of their pulmonary disease. Cardiac abnormalities also were present but were thought not to be significant either clinically or from autopsy findings. Microscopic studies revealed acute to subacute chronic interstitial pneumonitis. Rubella virus was isolated from all of the four lung specimens cultured.

Although cataracts are the most characteristic ocular lesion in rubella syndrome, they may not be visualized until after the neonatal period. Worldwide, vision loss from cataracts associated with congenital rubella syndrome remains a global public health problem.[518,650] Retinopathy is described as widespread, with mottled or blotchy, black pigmentary deposits of variable size and location: the "salt and pepper" retinitis.[358] Retinal function usually is not affected adversely. The frequency of retinopathy in the combined data from six series of children monitored for several years was 36 percent.

Bone lesions are another finding in congenital rubella in the neonatal period. Radiographic studies reveal small linear areas of radiolucency and increased bone density in the longitudinal axis of the metaphyseal area of the long bones of the lower and upper extremities.[540] This abnormality results from disturbances in deposition and calcification of osteoid and usually resolves by the time the child is 2 to 3 months of age.

Involvement of the CNS frequently is evident in symptomatic infants. Lethargy, irritability, disturbances in tone, and a bulging fontanelle are common findings. One or more seizures developed in 27 of 100 infants in one series.[185,186] However, they usually occurred after the neonatal period. In most infants with CNS involvement, CSF protein is elevated, but increased cell counts are seen less frequently. Rubella virus may be isolated from the CSF; in one series, 25 percent of 99 CSF specimens obtained during the first 3 months of life from patients with CNS symptoms were positive.[185,186] The extent of impairment at 18 months of age was not readily predictable on the basis of clinical symptoms or isolation of virus in the first few weeks of life. However, severe involvement was found more frequently in infants with seizures and high levels of CSF protein in the first few months of life.[185,186] An important emphasis is the chronic nature of congenital rubella infection, and one should note that although most infants may be asymptomatic in the neonatal period, evidence of disease was seen on follow-up examination in up to 70 percent.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Because many maternal rubella cases are subclinical and other diseases may mimic symptomatic rubella, establishing a definitive diagnosis in the mother depends on the laboratory. Although rubella virus may be isolated from the throat during the acute phase of the illness, such culture frequently is not a practical means of establishing the diagnosis. The tissue culture cells required for isolation of rubella virus are not always available in routine virology laboratories. Widely used serologic tests include hemagglutination inhibition, ELISA, and fluorescent assay.[127,134] Susceptible individuals lack IgG antibody. Detectable antibody is present in the blood within a few days after onset of the rash, and peak titers are reached within 2 to 3 weeks. If serum specimens are not available until some time after the onset of illness, complement-fixation antibody titers may be useful because peak titers are not reached for 4 to 6 weeks after the rash is manifested. If only a single specimen is available, rubella-specific IgM antibody may be demonstrable by ELISA or immunofluorescence methods, peak 3 to 6 weeks after infection occurs, and persist for several months.[134,281] If maternal rubella infection is diagnosed, then prenatal diagnosis of congenital rubella infection can be made through amniocentesis to obtain amniotic fluid for viral rubella culture and rubella virus RNA detection by PCR and by fetal blood sampling for rubella IgM determination. Laboratory tests ideally should be combined with serial fetal ultrasound evaluations to determine the extent of fetal involvement if the fetus is identified as being infected with rubella.[308,627] Detection of viral RNA by PCR on chorionic villi samples obtained very early in gestation also has been used for prenatal diagnosis.

The most characteristic clinical features of congenital rubella are congenital heart disease, cataracts, microphthalmos, corneal opacity, glaucoma, and radiolucent bone lesions. In infants with these classic features, the clinical diagnosis correlates with laboratory confirmation of congenital rubella 80 percent of the time. However, many of the features, such as low birth weight, hepatosplenomegaly, icterus, and petechiae/purpura, overlap with those found in other infectious diseases of the newborn, and definitive diagnosis requires laboratory confirmation. The diagnosis of congenital rubella is confirmed by isolation of virus from the throat or urine; in addition, virus has been recovered from cataracts, conjunctivae, CSF, feces, bone marrow, and circulating leukocytes. The lens is an excellent site for recovery of virus, especially because cataracts are removed from these infants within the first few weeks of life. The diagnosis of congenital rubella also can be made by serologic means. Because rubella IgG antibody is passed transplacentally, serum levels determined early in the neonatal period mimic those of the mother. Stable or rising serum concentrations of rubella-specific IgG antibody in the serum of infants during their first 4 to 6 months of life can be considered diagnostic of congenital rubella when the clinical picture is compatible. The presence of specific IgM antibody in a single serum specimen obtained from an infant early in life also can be diagnostic, but false-positive test results have been reported. Whenever possible, isolation of virus should be per-

formed for definitive diagnosis. PCR performed on nasopharyngeal secretions ultimately may aid in establishing the diagnosis.[176,658]

The finding during pregnancy that a mother is immune to rubella is not sufficient to exclude the diagnosis because reinfection may have occurred or maternal infection may have developed before the screen was performed. If the diagnosis of congenital rubella is suspected clinically when the mother is thought to be immune, the infant should be screened with rubella-specific IgM ELISA and viral culture or PCR of appropriate clinical specimens. The diagnosis of congenital rubella infection can be eliminated if the mother is nonimmune when the infant manifests clinical signs of possible congenital infection.

The principal diseases to consider in the differential diagnosis include congenital CMV infection, congenital toxoplasmosis, erythroblastosis fetalis, disseminated herpes simplex, neonatal sepsis and congenital syphilis. Infants with congenital CMV infection more commonly have chorioretinitis and microcephaly, whereas congenital heart disease and eye malformations are unusual findings. Infants with symptomatic congenital toxoplasmosis have chorioretinitis, hydrocephaly, and cerebral calcifications but not congenital heart disease, cataracts, or glaucoma. In uncomplicated erythroblastosis, the direct bilirubin and liver function studies remain normal. Disseminated herpes simplex should be differentiated on the basis of the characteristic vesicular skin lesions or the presence of keratoconjunctivitis. Positive blood cultures identify neonatal sepsis. The bone lesions in congenital syphilis are associated with periosteal new bone formation; rhinitis and lesions of the skin and mucous membranes also are seen. Because of overlapping clinical features, however, definitive diagnosis requires laboratory confirmation.

TREATMENT

No specific antiviral therapy exists for congenital rubella. Although amantadine hydrochloride inhibits rubella virus in vitro, treatment with this drug was not shown to alter the clinical or virologic course of the disease.[504] Sensorineural hearing loss associated with congenital rubella syndrome now may be treated with cochlear implantation combined with speech language therapy, and vision loss associated with cataracts can be restored with ophthalmologic surgical procedures that remove the opaque lens and replace it.[317,518,651]

PROGNOSIS

The most common long-term sequelae of congenital rubella are listed in Table 73–8. Deafness is the most frequent finding and may not be apparent for several months to several years after birth. In 15 to 20 percent of children, it may be the only abnormality detectable.[154] Approximately one half of the children may have absent or hyporeactive responses to tests of vestibular function.[424] The hearing loss may be profound and, thus, a major contributor to speech impairment and learning disability. Cochlear implantation and speech language therapy, however, may restore hearing, improve receptive and expressive language abilities, and improve communication skills and school performance.[317] In approximately 50 percent of children with mental retardation, the deficiency is moderate to severe. Although retinopathy is present in a significant proportion of infants, it does not appear to interfere with vision. Cataracts, of course, certainly can interfere with the development of vision, and they should be removed surgically in the first few weeks of life. Most fatalities from congenital rubella occur in the first year of life and are associated with severe congenital heart disease and general debility from multiple defects.[154]

Long-term follow-up evaluation of children with congenital rubella syndrome is available.[136,185,186,414,569] Among 205 children examined at 8 to 9 years of age, 26 percent had severe mental retardation, 18 percent had reactive behavior disorder, 12 percent showed behavior disorder with neurologic damage, and 6 percent displayed autism. Of 29 children with neurologic manifestations of congenital rubella between birth and 18 months of age but with normal intelligence, 93 percent had hearing loss when examined at 9 to 12 years of age; 61 percent, poor balance; 54 percent, muscular weakness; 52 percent, learning deficits; 48 percent, behavioral disturbance; and 41 percent, deficits in tactile perception. Head circumference appears to correlate poorly with intellectual function in patients with congenital rubella.[398] Diabetes mellitus has been observed in 15 to 20 percent of adults with congenital rubella.[415] Onset usually occurs in the second or third decade of life. Other late manifestations[569] of congenital rubella syndrome include hyperIgM syndrome,[481] autoimmune disorders such as chronic lymphocytic thyroiditis,[706] thymic hypoplasia,[238] abnormal dermatoglyphics,[154] chromosomal abnormalities,[33] pancreatic insufficiency,[191] and progressive panencephalitis.[642,663] As one might expect, the severity of long-term sequelae appears to correlate with the number of defects observed in early life.[136,154]

TABLE 73–8 Frequency of Defects in Children with Congenital Rubella

Defect	Percentage of Cases
Deafness	67
Congenital heart disease	48
Psychomotor retardation	45
Retinopathy	39
Cataracts	29
Neonatal purpura	23
No defect	19
Deaths	16
Glaucoma	3

Data from 376 children studied in the New York Rubella Birth Defect Project. Modified from Cooper, L. Z., Ziring, P. R., Ockerse, A. B., et al.: Rubella: Clinical manifestations and management. Am. J. Dis. Child. 118:*18-29, 1969.*

PREVENTION

Active immunization with live, attenuated rubella virus vaccine is the most effective means of preventing congenital rubella syndrome.[539] It has led to the elimination of endemic rubella in the United States and progress toward elimination in Europe and other parts of the world.[117,377,503] The development and use of rubella vaccine in the United States clearly have reduced the frequency of congenital rubella.[54,285,473] Since 2001, fewer than 25 reported cases of congenital rubella syndrome have occurred each year, and genotype analysis showed all cases that have occurred originated in parts of the world other than the United States. However, outbreaks of rubella and congenital rubella syndrome have occurred in the United States, especially in South Texas near the Mexico border. In addition, Hispanic populations and foreign-born individuals from countries that do not have rubella vaccination programs appear to be the highest risk for rubella outbreaks.[377,705] The target population in the United States has been preschool- and school-aged children, whereas in Great Britain, selective vaccination of 11- to 14-year-olds and women immediately after delivery has been the goal. The strategy used in the United States is more effective in decreasing the incidence of congenital rubella syndrome. More recently, immunization programs in the United States have emphasized the need to vac-

cinate susceptible women of child-bearing age.[54,285,473] Moreover, routine prenatal screening for rubella immunity should be performed, and all nonimmune women should be vaccinated during the immediate postpartum period and before being discharged. Breast-feeding is not a contraindication to postpartum immunization. Although the vaccine virus may be transmitted in breast milk, the infection in the neonate is asymptomatic. Immunization with rubella vaccine, however, is contraindicated during pregnancy, and physicians recommend that a woman not conceive during the 3-month period after being immunized.[97,368] Data collected by the CDC from more than 500 pregnancies show that vaccine viruses can cross the placenta and infect the fetus but do not produce the defects associated with congenital rubella syndrome. The rate of isolation of vaccine virus from the products of conception is only 3 percent for the currently used RA 27/3 vaccine. Studies of fetal risk associated with inadvertent administration of rubella vaccine during pregnancy have confirmed rubella vaccine safety in pregnant women and their fetuses.[43] Thus, inadvertent administration of rubella vaccine during the first trimester of pregnancy is not an indication for termination of pregnancy.

Continuing concerns with regard to rubella include reinfection with wild rubella virus in vaccine-immune subjects,[293] failure of rubella herd immunity during an epidemic,[340] arthralgia and arthritis as side effects of the vaccine in children and particularly postpubertal women even though the risk of developing chronic arthropathy is not increased,[328,662] waning immunity that is more profound after immunization than after natural infection,[54,285,473] and, more recently, outbreaks of rubella among unvaccinated pregnant women in custodial institutions, immigration camps in border states, or selected communities, including Hispanic populations and groups of foreign-born individuals from countries with no rubella vaccine program.[16,114,412]

Although administration of gamma-globulin to women during pregnancy may reduce the frequency of symptomatic disease in the mother, it appears to have little effect on the frequency or severity of fetal and neonatal disease.[91,406] Infants with congenital rubella syndrome are considered to be contagious and are maintained with contact precautions until they are at least 1 year of age, unless repeated nasopharyngeal and urine cultures performed after they reach 3 months of age are negative for rubella virus. Health care workers are required to report all suspected and confirmed cases of congenital rubella to their local health department. Therefore, physicians who serve populations at high risk for rubella should be aware of the signs and symptoms of rubella and congenital rubella syndrome so that they may recognize the disease if it occurs in their patients.

MEASLES AND MUMPS

Measles during pregnancy may have severe complications, including maternal pneumonitis, hepatitis, and hemorrhagic sepsis syndrome. On rare instances, maternal measles during pregnancy may be fatal. The adverse fetal effects include spontaneous abortion or premature delivery, and neonates may be born with congenital measles syndrome.[39,136,204]

Mumps rarely if ever causes severe illness in pregnancy. However, mumps RNA has been detected in the myocardium of fetuses and neonates with myocarditis and endocardial fibroelastosis, providing molecular evidence for the long suspected role of mumps virus in these disease processes.[457]

HEPATITIS

Since the late 1970s, a veritable explosion of information concerning infection with hepatitis A virus (HAV), HBV, HCV, hepatitis D virus (HDV), and hepatitis E virus (HEV) has occurred.* HAV has been grown in cell cultures, and two purified viral glycoprotein vaccines have been licensed and recommended for use in high-risk individuals aged 2 years and older.[143,289,383,384] HBV and HCV are discussed later. HDV is a defective virus that infects only persons with acute or chronic HBV infection.[507] The major cause of enterically transmitted non-A, non-B (NANB) hepatitis, a problem confined largely to developing countries,[652] has been shown to be HEV, an RNA virus of the family *Calicivirus*.[355,634] Epidemic NANB hepatitis occurs more frequently during pregnancy and can result in fulminant hepatic failure in these women.

HAV and HDV rarely cause infection of the fetus and newborn.[614,704] Natal transmission of hepatitis A to the newborn can occur if the mother has jaundice or had acute hepatitis within the 2 weeks before and 1 week after delivery. Although most infants are asymptomatic, researchers have recommended that exposed infants receive 0.02 mL/kg of immunoglobulin intramuscularly as soon as possible after delivery. The infant should be maintained with contact precautions for 6 weeks, or for 1 week after the onset of symptoms. Preterm infants may excrete HAV antigen and RNA for several months after acquiring acute infection. Nosocomial transmission of hepatitis A within nurseries has been documented. A report from India indicated a relatively high rate of vertical transmission among eight women with third-trimester HEV infection[326]; more investigations are necessary to determine the true significance of maternal HEV infection for the fetus and newborn infant in the United States. The following section focuses on HBV and HCV.

MICROBIOLOGY AND EPIDEMIOLOGY

HBV, a double-stranded DNA virus with a DNA polymerase, is the prototype member of the family Hepadnaviridae.[296,346] Seroepidemiologic investigation of HBV infection has been enhanced by the identification and development of three major antigen systems, antibody systems, or both: surface antigen (HBsAg and anti-HBs), core antigen (total anti-HBc and IgM anti-HBc), and e antigen (HBeAg and anti-HBe).[296,346] Tests for HBsAg are used widely for establishing the diagnosis of acute or chronic infection with HBV. Anti-HBc is a marker of continuing viral replication in the liver, IgM anti-HBc is present during acute but not chronic HBV infection, and HBeAg is a more specific indicator of infectivity than HBsAg is.[120,288,296,346,572]

HBV accounts for 40 to 50 percent of all cases of hepatitis in the United States and 10 percent of those associated with blood transfusion.[120,572] Between 5 and 10 percent of patients infected with HBV become chronic carriers, and many of them have benign chronic persistent hepatitis or the more serious chronic active hepatitis.[296,346,396,572] A strong association has been noted, particularly in Asian males, between chronic carriage of HBsAg and death from cirrhosis or primary hepatocellular carcinoma.[24,62,409] The age at which HBV infection occurs has a significant effect on the occurrence of clinically overt hepatitis and the development of a chronic carrier state.[241] The vast majority of neonates who acquire HBV from their mothers have subclinical infection, but 60 to 95 percent of infected infants become chronic carriers, particularly when the mother is HBeAg-positive.[60,61,66,183,242,469,614,618,686]

In the United States, the frequency of HBsAg in the general population is 0.2 to 0.9 percent.[115] The highest prevalence of HBV antigenemia in the United States is in Asian immigrants/refugees (13%), Alaskan Natives/Pacific Islanders (5-15%), clients in institutions for the developmentally disabled (10-20%), users of illicit parenteral drugs (7%), sexually active homosexual

*See references 109, 111, 120, 164, 248, 291, 296, 346, 356, 361, 507, 572, 617, 649.

men (6%), household contacts of HBV chronic carriers (3-6%), and patients in hemodialysis units (3-10%).[115] Only 10 to 15 percent of persons reactive for HBsAg have a history of contracting hepatitis. In chronic carriers of HBsAg, antigen has been detected in saliva, feces, urine, wound exudates, vaginal secretions, breast milk, amniotic fluid, and semen.[296,346,572] The prevalence of anti-HBs in the general population is approximately 11 percent; this frequency increases with advancing age and is related inversely to socioeconomic status.[115]

Among children and adults, HBV is transmitted by the parenteral route (blood transfusion, needle-sticks), but infection by nonparenteral routes also occurs.[59,63,572,637] Hepatitis B is not transmitted by the fecal-oral route. In the United States, transmission by blood and blood products now is a rare event because of routine screening of blood donors and viral inactivation of certain blood products.

Clustering of HBV infections in families is known to occur; family members of a known antigen-positive index case have a 10-fold higher prevalence of HBsAg or anti-HBs than do control families of the same ethnic background.[627] Although this clustering within families initially was considered to have a genetic basis,[627] "vertical" transmission of HBV infection from the mother to the infant may be a source.[183,242,469] However, person-to-person spread clearly occurs, but the exact mechanism is not known.[59,637,704] It has been seen in household settings from child to child but not in daycare centers.

Moreover, transmission of HBV has occurred in children born to HBsAg-negative mothers who immigrated to the United States from countries where HBV infection is endemic.[59,637,704] The incubation period for the onset of HBV antigenemia after parenteral inoculation is 2 weeks to 2 months, depending on the dose of virus received. In nonparenteral exposure, the incubation period for antigenemia is 2 to 3 months. The onset of elevated liver enzymes and clinical symptoms follows the onset of antigenemia by 2 weeks to 2 months.[346]

In the fetus and neonate, transmission by the following routes has been suggested: transplacental, either during pregnancy or at the time of delivery secondary to placental leaks; natal, by exposure to HBsAg in amniotic fluid, cervical and vaginal secretions, or maternal blood; and postnatal, by contact with household members who are infected or are chronic carriers or, rarely, by transfusion of blood or blood products. Ninety-five percent of infections occur at the time of delivery, whereas only 5 percent occur in utero. The fetus or newborn infant, therefore, can be infected by hematogenous (transplacental, blood transfusion) or nonparenteral (contamination of the oropharynx or breaks in the skin) routes. Differences in the time of exposure (congenital, natal, postnatal) and in the route of viral inoculation (parenteral, nonparenteral) may account for the wide variation in time of onset of antigenemia in the neonate after birth. The usual age at onset of antigenemia in neonates born to chronic carrier mothers is 2 to 5 months,[31,183,200,381,470,576,615] which is consistent with exposure at the time of birth. Infections secondary to blood transfusion in the neonatal period also are associated with the onset of antigenemia at younger than 2 months of age.[201] Infants with an onset of antigenemia at younger than 2 months of age presumably were exposed to HBV in utero.[200,242,381,470,559,576] In general, infants of mothers with acute hepatitis near the time of birth have antigenemia at an earlier age (1-2 months), thus suggesting transplacental transmission of HBV.[242,559] Infants with an onset of antigenemia after they reach 6 months of age can be assumed to have had postnatal exposure,[559] but the exact source of virus in these infants is unclear.

In summary, evidence is good that infection with HBV can occur transplacentally, at the time of birth, and postnatally by blood transfusion or contamination of the oropharynx with infected secretions.[614] Several studies indicate that transmission by breast milk is a rare occurrence.[65,183,687] Further substantiation for the mother as the primary source of virus for the neonate comes from observations that the HBV serotype almost always is the same in infants and their carrier mothers.[242,470,615]

From 0.1 to 15.6 percent of pregnant women are asymptomatic chronic carriers of HBsAg. The lowest rates occur in the United States and in northern European populations,[183,200,588,687] and the highest rates occur in Chinese populations, regardless of geographic location.[31,66,185,381,615] Intermediate rates are observed in Japanese,[469,576] African,[183,687] South Asian,[183,687] and Mediterranean populations.[486] Rates of transmission of HBsAg from infected mothers to neonates vary highly and are influenced by the sensitivity of the HBsAg assay system used in the study, whether neonatal serum is examined for anti-HBs as well as for HBsAg, the frequency of bleeding and length of follow-up of infants, and the e antigen/antibody status of the mother. In general, HBsAg in a cord-blood specimen is not a reliable indicator of neonatal infection because of the possibility of contamination with antigen-positive maternal blood or vaginal secretions and because of the possibility of transient noninfectious antigenemia from the mother.[183,381,485,687] Demonstration of HBsAg in the serum of the infant during the first several months of life can be considered diagnostic of infection with HBV in the absence of immunization with hepatitis B vaccine. HBsAg may be detected for up to 1 week after the administration of a dose of vaccine. Most infants demonstrate antigenemia by the time they are 6 months of age, with peak acquisition occurring at 3 to 4 months of age.[31,242,381,576]

Factors known to be associated with higher rates of HBV transmission to neonates include the presence of HBeAg and the absence of anti-HBe in maternal serum—attack rates of 80 to 95 percent;[66,183,206,381,469,485,687] an Asian racial origin, particularly Chinese—attack rates of 40 to 70 percent;[31,183,381,576,615] maternal acute hepatitis in the third trimester of pregnancy or the immediate postpartum period—attack rates of 60 to 70 percent;[242,559,560] a higher titer of HBsAg in maternal serum—attack rates parallel the titer;[66,381,615] and the presence of antigenemia in older siblings.[31,469,615] Factors *not* related to transmission include the presence or absence of breast-feeding,[65,183,687] the particular HBV subtype in the mother,[242,470,615] the presence or absence of HBsAg in amniotic fluid,[381] and the presence or absence of anti-HBc in cord blood.[183,200,242] Data conflict regarding the significance of HBsAg in cord blood. Some studies have found no relationship between its presence or absence and subsequent infection of the neonate, whereas others have found a correlation. The reasons for this difference are not understood.[183,381,485,615,687]

From 75 to 100 percent of infants in whom HBsAg develops in serum within the first several months of life have persistent or chronic antigenemia.[31,183,242,469,470,576,615] In some infants, anti-HBs may develop after transient carriage of HBsAg, and in a few (usually those born to asymptomatic carrier mothers), anti-HBs may develop without the infant ever having detectable antigen.[485,576]

Transmission of HBV to infants in successive pregnancies of the same mother has been documented,[192,199] and such transmission has, on occasion, been associated with the development of fatal hepatitis.

PATHOGENESIS AND PATHOLOGY

HBV transmitted to the neonate by the hematogenous route probably seeds the liver directly, whereas nonparenteral exposure requires replication at the portal of entry before spread to the liver through the bloodstream occurs. Electron-microscopic studies of liver biopsy specimens from chronic carrier infants indicate that replication of HBV appears to occur in the nuclei of hepatocytes and that 50 to 100 percent of cells are involved.[197,559] Histopathologic examination demonstrates a diffuse hydropic appearance of the liver cells, with effacement of the normal cord

pattern and the creation of a "cobblestone appearance" in the liver lobule.[559] Only small foci of hepatocytolysis surrounded by macrophages and lymphocytes are present. Infants with symptomatic acute hepatitis have more widespread hepatic necrosis with surrounding inflammatory infiltrates, including giant cells.[199,319] In fulminant disease, massive necrosis with little or no inflammatory response is present.[199,319] In some infants with symptomatic hepatitis, the disease may progress to chronic persistent hepatitis, chronic active hepatitis, cirrhosis, or hepatocellular carcinoma.[184,201,319,399,636,647,690]

CLINICAL MANIFESTATIONS

Although clinically typical acute hepatitis may occur in mothers of infants in whom HBV infection develops, most are asymptomatic chronic carriers of HBsAg. Therefore, routine screening of serum for antigen in all pregnant women is necessary for the identification of infants at risk for development of HBV infection. Maternal HBV infection has not been associated with abortion, stillbirth, congenital malformations, or intrauterine growth retardation.[183,201,576] However, prematurity has been observed, particularly when the mother has acute hepatitis during pregnancy.[559]

A fetus or newborn infant exposed to HBV may follow one of several courses: (1) asymptomatic transient hepatitis B antigenemia, followed by the production of anti-Hbs[200,485]; (2) asymptomatic persistent antigenemia, variably associated with mild and fluctuating elevations in liver enzymes[31,200,242,576,599]; (3) symptomatic hepatitis with recovery and clearance of the antigen[201,222]; (4) symptomatic hepatitis that becomes chronically persistent or chronically active with continued presence of hepatitis B antigenemia[199,201,319,690]; (5) acute fulminant hepatitis with death[201,222]; and (6) asymptomatic neonatal/infant infection with progression to cirrhosis or liver cancer.[84,636,647] Most infants with HBsAg in their serum become asymptomatic chronic carriers. However, liver function studies may be abnormal in some of these infants, and liver biopsy specimens usually show evidence of mild, unresolved hepatitis.[183,201,242,559,576] The long-term significance of these persistent abnormalities in asymptomatic chronic carrier infants is unknown. The factors that determine which pattern of HBV infection occurs in a given newborn infant and the mechanisms responsible for chronic carriage of HBsAg in many infants are not understood.

The source of virus for 29 infants with symptomatic HBV infection in the first few months of life was blood transfusion in 15 (52%), a chronic carrier mother in 9 (31%), and unknown in 5 (17%).[201] The type of clinical disease in these infants was acute, self-limited hepatitis in 16 (55%), severe or fulminant hepatitis in 9 (31%), chronic persistent hepatitis in 2 (7%), chronic active hepatitis in one, and an asymptomatic chronic carrier state in 1. Most patients with fulminant hepatitis died.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

HBV infection in an infant generally is diagnosed by the demonstration of HBsAg in serum. If positive, infants also should be tested for HBeAg and anti-HBc IgM. In addition, PCR is available for detecting HBV DNA in blood. The major diseases to be considered in the differential diagnosis include biliary atresia and acute hepatitis caused by other viruses—HAV, CMV, rubella virus, enteroviruses, adenoviruses, and HSV.

TREATMENT

Treatment with human interferon has resulted in the termination or transient cessation of hepatitis B antigenemia in chronic hepatitis of adults,[249,291,497] but experience in neonates and children is limited.[320,370,453] Lamivudine also is licensed for the treatment of chronic infection in adults. Treatment of established disease in infants with hepatitis B immunoglobulin (HBIG) has not altered the course of illness.[199,222] Therefore, treatment of neonatal HBV infection primarily is supportive.

PROGNOSIS

The long-term outcome of asymptomatic infants with persistent antigenemia is guarded because chronic active and progressive hepatitis occur, as do death from cirrhosis, liver failure, and hepatocellular carcinoma. Death from fulminant HBV infection in neonates or young infants is a rare event but has occurred, particularly in successive children born to the same chronic carrier mother.[192,222]

PREVENTION

Remarkable advances have occurred in the prophylaxis of neonates born to mothers with HBV infection. Initial studies in infants born to HBeAg-positive, chronic carrier mothers demonstrated that administration of HBIG significantly reduced the development of a chronic carrier state.[61,64,192,309,347,523] The most successful regimens were those that began as soon as possible after birth and used multiple doses of HBIG. Anti-HBs developed in most infants who were protected against becoming chronic carriers, thus indicating that passive/active immunization had occurred. However, protection against persistent antigenemia was only 50 to 75 percent effective. Twenty to 30 percent of infants became infected during the second and third years after the protective effects of their passive immunoglobulin subsided.[61,64] This finding suggests that the risk of developing infection continues beyond the time of birth and that active immunization would be necessary to provide long-term protection.

Hepatitis B vaccine (Heptavax B; licensed but no longer produced in the United States) then was demonstrated to be both safe and effective in inducing protective levels of anti-HBs in 95 percent or more of infants receiving three doses of the vaccine.[53,382] Because passive/active immunization (HBIG plus three doses of HBV vaccine) in adults was shown to be safe and as effective in inducing long-term protective titers of anti-HBs as was a dosage of three doses of vaccine alone[702] this regimen was tried in infants. Several investigations have demonstrated 85 to 96 percent efficacy in preventing chronic antigenemia with the combined HBIG/vaccine regimen.[60,396,618,685] Persistent antibody against HBsAg developed in virtually all protected infants. Vaccine failures were thought to occur in babies who already were infected with HBV in utero and, hence, could not be protected by the HBIG/vaccine regimen initiated at birth. Subsequent studies using recombinant DNA vaccines (Recombivax HB, Engerix-B) showed them to be safe and highly immunogenic in neonates (>95%), with an efficacy of 90 to 95 percent.[508,616]

The concentration of HBsAg protein differs in the two vaccines; the pediatric formulation of Recombivax HB contains 10 μg/mL, whereas Engerix-B has 20 mg/mL. The two vaccines are interchangeable, and neither one contains thimerosal.

Because most chronic carrier mothers are asymptomatic, serologic screening during pregnancy would be required to identify neonates needing prophylaxis beginning at birth. Initial recommendations suggested screening during pregnancy in populations with high-risk factors: (1) Asian, Alaskan, or Pacific Island descent; (2) birth in Haiti, sub-Saharan Africa, Eastern Europe, the Middle East, the Caribbean, or Central or South America; (3) acute or chronic liver disease; (4) work or treatment in a dialysis unit; (5)

work or residence in an institution for the mentally retarded; (6) rejection as a blood donor; (7) blood transfusion on repeated occasions; (8) frequent occupational exposures to blood in medical or dental settings; (9) household contact with an HBV carrier or hemodialysis patient; (10) multiple episodes of sexually transmitted disease; or (11) percutaneous use of illicit drugs.[111,115,591] Because routine prenatal history to screen for these risk factors will miss one half to two thirds of asymptomatic chronic carrier mothers,[613,363] the current recommendation is to screen *all* pregnant women for HBsAg early in pregnancy.[35,36,112,119,617] Testing should be repeated late in pregnancy for women who are negative initially and at high risk for acquiring HBV infection or who have had clinical hepatitis since the screening was performed.[123]

Perinatal transmission is prevented in more than 90 percent of cases by the intramuscular administration of 0.5 mL of HBIG and hepatitis B vaccine to both term and preterm infants of HBsAg-positive mothers as soon as possible but within 12 hours of delivery.[115] HBIG efficacy decreases markedly if treatment is delayed beyond 48 hours. HBV vaccine is administered intramuscularly at a separate site at birth (preferably) or within 7 days, and in infants with a birth weight of 2 kg or more, administration is repeated at 1 to 2 months and 6 months after administration of the first dose. In infants with a birth weight less than 2 kg, the initial dose of hepatitis B vaccine does not count toward completion of the hepatitis B vaccine series, and administration of three additional doses of hepatitis B vaccine should commence when the infant is 1 month of age.[122] By the chronologic age of 1 month, all premature infants, regardless of initial birth weight or gestational age, are likely to respond as adequately as do older and larger infants.[329,365,397,494] Testing for HBsAg and anti-HBs is recommended at 1 to 3 months after completion of the vaccine series. The presence of anti-HBs along with the absence of HBsAg indicates successful prophylaxis and immunization. An HBsAg-positive result indicates failure of prophylaxis or in utero infection. Infants who are negative for anti-HBs and HBsAg should receive three additional doses of vaccine at a 0-, 1-, and 6-month schedule, followed by retesting for anti-HBs 1 month after the third dose. Alternatively, additional doses of vaccine (one to three) can be administered and the infant tested for anti-HBs 1 month after each dose has been administered to determine whether subsequent doses are necessary. Household members and sexual contacts of HBsAg-positive mothers should be screened, and if no evidence of previous HBV infection is noted, they also should be immunized.

Infants delivered by HBsAg-positive women are bathed as soon as possible after delivery to remove all maternal blood and secretions. Intramuscular injections should be delayed until bathing is completed; if such bathing is not possible, meticulous cleaning of the site with alcohol is necessary. These infants require standard precautions. Infants who have received both active and passive prophylaxis may be breast-fed.

In 1991, the Advisory Committee on Immunization Practices of the CDC[119] and, in 1992, the Committee on Infectious Diseases of the American Academy of Pediatrics[146] recommended the universal use of hepatitis B vaccine in all infants as the optimal strategy for prevention of HBV infection.[617] Current recommendations continue to support these opinions.[27] For infants with a birth weight of 2 kg or greater and born to mothers whose HBsAG status is negative, the first dose of HBV vaccine should be administered at or soon after birth, the second dose at 1 month or more after the first dose, and the third dose at 6 to 18 months of age. The minimal interval between the second and third doses is 2 months, and the third dose should not be given before 6 months. For infants who receive their first dose after they have reached 2 months of age, the minimal interval between the first and third doses is 4 months. An alternative schedule of the three doses administered at 2, 4, and 6 to 18 months of age concurrently with other routine vaccines may be used for HBsAg-negative infants not vaccinated at birth.

Seroconversion rates in premature infants who have a birth weight of less than 2 kg and are vaccinated shortly after birth are lower than those in larger preterm infants and full-term infants vaccinated at birth.[380] For this reason, for premature infants weighing less than 2 kg at birth and born to HBsAg-negative mothers, initiation of the vaccination series is delayed until they are 1 month of age.[122] The schedule for follow-up doses is the same as for other infants.

Infants with a birth weight of 2 kg or more and born to mothers whose HBsAg status is unknown should receive the first dose of vaccine within 12 hours of birth. Blood should be drawn from the mother at delivery to determine her HBsAg status. If it is positive, HBIG should be given as soon as possible, but no later than when the infant is 1 week of age. If the infant's birth weight is less than 2 kg, HBIG in addition to vaccine should be given within 12 hours of birth. This initial vaccine dose should not be counted as part of the three-dose schedule. The subsequent vaccine schedule is based on the mother's HBsAg status. If it remains unknown, the infant should be treated as though the mother were HBsAg-positive.

Because the rate of perinatal transmission is greatest in mothers who are HBeAg-positive or those who are negative for both HBeAg and anti-HBe, some researchers have suggested administering prophylaxis to neonates born only to this group of mothers.[534,577] However, the occurrence of several cases of hepatitis in babies born to mothers with anti-HBe[174,585] and the demonstration that measurements such as HBV DNA polymerase or HBV DNA by PCR may be more accurate indicators of infectivity than are measurements of HBe antigen or antibody[280,637] indicate that prophylaxis should be given to neonates of all chronic carrier mothers, regardless of their e antigen/antibody status.[27] Because the combined HBIG/vaccine regimen results in effective and long-term protection, breast-feeding is allowed and encouraged in chronic carrier mothers. These significant developments in prophylaxis against perinatal transmission of hepatitis B should reduce the frequency of chronic carriers strikingly and thereby decrease the number of cases of chronic active or progressive hepatitis and death from cirrhosis, liver failure, and hepatocellular carcinoma.

HEPATITIS C VIRUS INFECTION

The remarkable molecular biology effort to isolate and clone the gene of HCV[141] and to express a major nonstructural protein[368] led to the demonstration that HCV is the predominant cause of NANB hepatitis and a major contributor to chronic hepatitis in developed countries.[21-23,121,164,649] Rates of HCV seroprevalence are highest (60-90%) in those with repeated exposure to blood or blood products (e.g., injection drug users, hemophilia patients), intermediate (20%) in those with repeated or inapparent percutaneous exposure (e.g., hemodialysis patients), lower (1-10%) in those with high-risk sexual behavior or household contacts of infected persons, and lowest (0.5-1%) in blood donors.[22,164,649] Overall, an estimated 1.8 percent of the population, including pregnant women, in the United States is infected with HCV.[28]

Among studies of infants born to anti-HCV-positive women, an average of 5 percent (range, 0-25%) of infants were persistently positive for second-generation assay anti-HCV antibody or HCV RNA during a follow-up period of at least 10 months.* The risk of vertical transmission is correlated with higher concentrations of plasma HCV RNA[390,468]; with HIV-1 co-infection, especially in those with advanced stages of AIDS; with the specific genotype of HCV; and, possibly, with the vaginal route of deliv-

ery. HCV RNA has been detected in the breast milk of infected women, but transmission by breast milk has not been documented, and HCV infection is not a contraindication to breast-feeding.[391]

HCV infection can be diagnosed by antibody titers and molecular methods to detect and quantitate viral RNA. Antigen-detection tests and IgM assays are not available. Antibody titers in infants are confounded by maternal transplacental antibody; this effect presumably is gone by the time that the infant reaches 18 months of age.[27] Antibody testing involves a screening EIA, with repeat positive results confirmed by a recombinant immunoblot assay (RIBA), analogous to what is done for the serologic diagnosis of HIV infection. The second-generation EIA (EIA-2) and RIBA are 95 percent sensitive and 97 percent specific.[254] Infants born to HCV antibody-positive mothers should be screened for anti-HCV with the EIA-2 after they are 18 months of age. RIBA may be used as a supplemental test for specificity; both the EIA-2 and RIBA measure IgG antibody to recombinant HCV antigens. Detection of HCV RNA in infant blood is also available commercially and should be performed when the infant is between 1 and 2 months of age.[29,254] Infants who are infected perinatally should be referred to a hepatologist and have annual screening of liver enzymes, even if they remain asymptomatic.

Controlled trials of interferon therapy in children with chronic hepatitis C are limited.[144] Long-term prognosis for HCV infection in infants and children is not clear, but 85 percent of adults become chronically infected, and HCV is known to be associated with cirrhosis and hepatocellular carcinoma.[22,164,649]

The development of a successful vaccine for hepatitis C must overcome several obstacles, including multiple genotypes of the virus, lack of cross-protective immunity among the genotypes, lack of long-term protection with the same genotype, and lack of successful cultivation of the virus in cell culture.[22,164] In February 1994, the Advisory Committee on Immunization Practices reviewed the available data and concluded that no support was found for the use of immunoglobulin for postexposure prophylaxis. This recommendation is still the current opinion of experts.[28] Immunoglobulin is not protective because blood from anti-HCV-positive donors is excluded from the pool used for preparation and no neutralizing antibody for HCV has been identified as yet. Routine screening of all pregnant women and their newborns for HCV infection cannot be recommended at this time, but screening should be considered in those with known risk factors. For example, infants who received 1 U or more of blood or blood products before 1992 or who received Gammagard/Polygam (Baxter Healthcare Corporation, Glendale, CA) in 1993 or 1994 were screened with liver transaminase tests and for anti-HCV antibody.

HERPES SIMPLEX

HSV, the etiologic agent of cold sores, keratitis, encephalitis, and genital ulcers in older children and adults, causes serious disease in neonates, with high mortality rates and severe neurologic sequelae.

MICROBIOLOGY AND EPIDEMIOLOGY

The two types of HSV, type 1 and type 2, may be distinguished by antigenic, biochemical, molecular, and biologic differences.[156,667] HSV-1 (the "oral strain") usually causes mouth lesions, eye infections, and endemic encephalitis, whereas HSV-2 (the "genital strain") usually is associated with sexually transmitted genital infections.[156,667] However, 8 to 50 percent of genital herpes disease is now caused by HSV-1.[476] Most neonatal disease is caused by HSV-2, but HSV-1 neonatal disease appears in recent studies to be increasing in certain populations.[98]

Antiviral collaborative studies indicate that 4 percent of neonatal herpes cases are acquired in utero, 86 percent natally, and 10 percent postnatally. Three quarters of natal/postnatal cases of neonatal herpes are caused by HSV-2, and the remainder are caused by HSV-1 strains.[480] Virtually all neonatal HSV-2 infections probably are acquired from mothers having an active genital herpes infection at the time of delivery.[477,623,675,695] The majority of neonates with HSV appear to acquire the infection by contact with infected genital secretions at or during delivery from an asymptomatic mother who acquired her first episode of genital herpes infection in the third trimester or near the time of delivery.[96,97,100,102] Because 60 to 80 percent of these mothers have no signs or symptoms of genital herpes at the time of labor and delivery and have a negative past history of genital herpes or sexual contact with a partner who had a genital vesicular rash, some experts recommend routine serologic screening of pregnant women and their partners to identify potential at-risk mothers.[96-98,404,668,674] In a study of 140 pregnant women with cytologically diagnosed genital herpes, only 36 percent had clinically recognized herpetic lesions.[450] Twenty-one percent had nonspecific abnormal findings, and 43 percent were asymptomatic. In addition, 20 to 40 percent of nonpregnant women from whose genital secretions HSV is isolated are asymptomatic.[306,680] Use of more sensitive techniques, such as PCR, detects genital HSV shedding in asymptomatic women even more frequently.[149]

Neonates with HSV-1 infection can acquire the virus from several sources: maternal genital, oral, or breast lesions[97,98,196,389,622,695]; oral herpes in the father or other family members[193,623,695]; or health care–associated transmission from other infected babies or health care workers.[262,393] Although HSV-1 cold sores and asymptomatic oral shedding may be common findings in nursery personnel,[275,276] transmission to a neonate from this source appears to be rare.[414,533,650]

Because most fetal and neonatal HSV infections are transmitted from the mother, a summary of several aspects of herpes infection during pregnancy is appropriate. Fulminant or disseminated primary HSV disease may occur in pregnancy, but whether it develops more often than in nonpregnant women is not clear. A review[495] of seven such cases revealed (1) infection during the third trimester in all; (2) four beginning as a genital HSV infection and three as oral disease; (3) hepatitis in six, encephalitis in two, and pancreatitis in two; (4) maternal death in three (43%)—two from hepatitis and one from encephalitis; and (5) three instances of fetal death—each secondary to severe maternal systemic illness rather than direct infection with HSV. Evidence of visceral disease in a pregnant woman with either genital or oral HSV infection is an indication for providing systemic antiviral therapy.[369]

An increased rate of spontaneous abortion occurs in women with primary genital herpes during early pregnancy, regardless of socioeconomic status.[100,271,274,450,480] Premature delivery does not occur more commonly in prospectively monitored women with recurrent genital herpes,[274,480,657,682] but most reports of neonatal herpes cases find a greater preponderance of premature infants than in the general population.[480,668,675,695] This finding, however, may reflect a higher susceptibility of premature infants to HSV infection secondary to a lack of transplacentally acquired IgG neutralizing antibodies rather than being a cause of the prematurity. Recurrent genital herpes in middle-class pregnant women is no more severe or frequent than in nonpregnant ones,[271,657,682] but older studies demonstrated more frequent and longer episodes in women of lower socioeconomic groups.[450,456] Between 74 and 88 percent of middle-class pregnant women with a history of genital herpes had at least one clinical recurrence during an observed pregnancy.[271,657,682] A mean of 2.7 to 3.0 episodes occurred during gestation, and HSV was isolated from lesions in 56 to 75 percent of the recurrences and in 0.6 to 12

percent of concomitant cervical cultures obtained during the recurrence. Asymptomatic shedding of HSV from the cervix, either between clinical recurrences or in a history-positive woman with no episodes during the observed pregnancy, was detected in 0.5 to 2.3 percent of the cultures obtained. Importantly, the presence of HSV shedding during the latter weeks of pregnancy was not predictive of shedding at the time of delivery.[37,682]

The number of cases of neonatal herpes occurring in the United States each year is far less than one would expect from the probable number of pregnancies complicated by genital herpes. Of the 3.5 million annual pregnancies, 7000 to 200,000 of these women have genital herpes at some time during the pregnancy and 3500 to 14,000 have positive HSV cultures at the time of delivery.[75,255,274,632,657,673,682] The actual number of cases of neonatal herpes per year in Seattle and Atlanta (0.1 and 0.3 per 1000 live births, respectively) would project to a national estimate of 350 to 1050 per year in the United States.[623] Because asymptomatic HSV infection of the neonate rarely occurs, subclinical cases or missed diagnoses probably do not account for the differences between the estimated number of maternal and neonatal infections. More likely, neonatal infection rates in the babies of mothers with genital herpes are far lower than currently assumed, possibly because of the preventive measures used. The estimated infection rates quoted most often currently are: (1) a 33 to 50 percent rate for infants vaginally delivered by mothers with primary genital herpes, (2) a 3 to 5 percent rate for infants vaginally delivered by mothers with recurrent lesions, and (3) less than 3 percent for those delivered by mothers with recurrent asymptomatic shedding at the time of delivery.[75,97,155,480,682] In the early 1970s, Nahmias and associates[450] reported the following neonatal infection rates in babies born to mothers with genital herpes during pregnancy: (1) 33 percent in mothers with primary disease after the 32nd week of gestation, (2) 3 percent in mothers with recurrent episodes after 32 weeks, and (3) 42 percent in mothers with virus-positive lesions at the time of delivery (primary versus recurrent episodes not specified). More recent studies have determined a significant risk of neonatal herpes occurring in babies born to mothers with asymptomatic shedding at the time of vaginal delivery: 33 percent with subclinical first episodes[97] and 0 to 3 percent with recurrent shedding.[97,106-108,481,511] Accurate knowledge of the actual neonatal infection risk is important for making decisions about management (e.g., cesarean section, prophylactic antiviral therapy). However, because researchers have estimated that as many as 75 percent of neonates with HSV disease are born to mothers with no history or clinical findings suggestive of active HSV infection during pregnancy, labor, or delivery, not all neonatal HSV disease is preventable by management decisions made on the basis of current knowledge of known risk factors.[26,101,106-108]

Several factors influence the risk of acquiring neonatal herpes and the severity of neonatal disease once the infection develops. The greater risk of transmitting neonatal infection by mothers with primary, as opposed to recurrent, vesicular or ulcerative lesions at the time of delivery is well established. Also, a woman with virus-positive recurrent lesions at the time of delivery is likely to be a greater risk than is a woman who is asymptomatic and shedding virus identified by HSV surveillance cultures. Other aspects of the anatomic site and the severity of maternal genital herpes also may be associated with a greater risk of development of neonatal disease: (1) cervical as opposed to vulvar or buttock skin involvement—resulting in more virus being shed into vaginal secretions; (2) multiple as opposed to single vesicles or ulcers—again, more virus from multiple lesions; (3) higher titer of virus in vaginal secretions—cultures positive sooner or more intensely positive in the diagnostic virology laboratory; and (4) longer duration of fetal exposure to infected vaginal secretions because of prolonged rupture of membranes, or fetal scalp monitors.[155,478,480]

Investigations by Yeager and associates[695,696] indicate that no anti-HSV antibody or a low titer of such antibody in maternal and neonatal serum is associated with a greater risk of acquisition of neonatal infection and more serious disease and that high-titer antibody is associated with a lower risk. Studies of HSV antibody titers in neonates enrolled in the CASG trial do not show an association between antibody titer and outcome of disease.[676] More investigations are required, therefore, to determine the potential protective role of maternal transplacental anti-HSV antibody.

Premature infants have accounted for 40 to 50 percent of cases of neonatal herpes,[668,676] in contrast to the usual prematurity rates of 6 to 18 percent reported in the general maternal population. Whether the increased frequency of prematurity among neonates with herpes indicates a greater propensity of mothers with genital herpes to deliver prematurely or a greater susceptibility of premature infants to HSV infection is not known. Premature infants appear more likely to have a fatal outcome.[108,668,669]

Instrumentation of the neonate, particularly scalp electrodes for fetal monitoring, is known to increase the risk of acquiring neonatal HSV infection.[205,321,487] Mortality rates appear to be higher in neonates with HSV-2 than in those with HSV-1 infection, probably because of the greater proportion of HSV-2–infected babies with dissemination.[669] In neonatal herpes survivors, neurologic damage occurs much more frequently in infants with HSV-2 than in those with HSV-1 infection.[157,669] Finally, the body sites of involvement in the neonate clearly influence outcome. Babies with disseminated infection (liver, lungs, adrenals), with or without CNS involvement, have the highest mortality rates (70-80%); those with encephalitis have only intermediate rates (30-40%); and those with infection limited to the skin, eye, or mouth have the lowest rates (0%).[676] Babies delivered in a high-risk situation might be given anticipatory antiviral chemotherapy after appropriate cultures have been obtained, whereas those in low-risk situations might be cultured and observed closely for evidence of neonatal herpes.[480,481]

PATHOGENESIS AND PATHOLOGY

As mentioned previously, HSV may be transmitted to the neonate in utero either by a transplacental (congenital infection) or ascending route, at the time of birth (natal infection), or after birth (postnatal infection). Congenital infection probably results from transplacental transmission of virus secondary to leukocyte-associated viremia in a mother with genital herpes, but no direct evidence supports this hypothesis. HSV-2 viremia has been documented in two women with primary genital herpes.[160] A report of 13 neonates with intrauterine HSV infection indicated that primary genital herpes was present during pregnancy in four mothers, recurrent disease was present in one, and no history of genital herpes was elicited in the remaining eight.[301] In the fetus, HSV appears to be transmitted directly from the placenta through the bloodstream to target organs. Because of the known tropism of HSV for the CNS, one is not surprised that most infants with congenital infection have evidence of brain involvement at birth.[301] Intrauterine infection also may occur by an ascending route from an infected maternal genital tract, and such transmission is supported by the development of clinical signs of HSV infection in the first 5 days of life.

The natal infection presumably is acquired secondary to aspiration of infected vaginal secretions into the nares, oropharyngeal cavity, conjunctivae, and upper respiratory tract of the infant. Other portals of entry for natal infection include the scalp, skin, and umbilical cord.[480,668] In postnatal HSV infection, no evidence supports the genital tract as a source of virus. Most postnatally acquired infections appear to result from contact with saliva from persons with oral herpes or with virus carried on the hands of

TABLE 73–9 Congenital Herpes Simplex Virus Infection: Features in 30 Cases*

Feature	Number	Percentage
Culture-positive vesicles or bullae	28/30	93
HSV-2	24/27	89
Low birth weight	22/26	85
Microcephaly, seizures, diffuse brain damage, intracranial calcification	20/30	67
Chorioretinitis, microphthalmos	17/30	57
Small for gestational age	9/25	36

Other features: retinal dysplasia, scars on skin or digits, cataracts, pneumonitis, hepatomegaly.
**Features present at birth or shortly thereafter.*

personnel.[389,668,695] After natal or postnatal acquisition of HSV occurs, initial replication of the virus occurs at the portal of entry, with subsequent viremic dissemination to viscera. Involvement of the CNS occurs either from hematogenous spread to the brain in infants with disseminated disease, which results in multiple areas of cortical hemorrhagic necrosis, or from retrograde axonal transport of the virus to the CNS from superficial replication in the skin, eye, or mouth.[324,451,668]

CLINICAL MANIFESTATIONS

The clinical features of genital herpes in women have been discussed in detail elsewhere.[99,155,256,449,476] Women with initial or primary infections may have multiple, small, painful, and tender vesicles and ulcers involving the cervix, vagina, vulva, and skin of the perineal region. In addition, patients may complain of inguinal or pelvic pain that is caused by associated lymphadenopathy. Systemic symptoms consisting of fever, malaise, and myalgia usually are present. The total duration of pain is 10 days to 2 weeks, whereas the total duration of lesions may be 2 to 3 weeks. Peak lesion virus titers, from 10^4 to 10^5 plaque-forming units per milliliter, occur during the first week of illness.[99] The total duration of viral shedding lasts from 10 to 14 days.[99,155] Lesions on dry skin progress through the well-defined vesicle, ulcer, crust, and healed stages described for herpes simplex labialis.[594] On moist mucous membranes, vesicles quickly rupture to form shallow ulcers that persist for days and gradually heal from the periphery.[99]

Recurrent genital herpes in women usually is milder and of shorter duration than is primary infection, the vesicles and ulcers are more circumscribed and fewer in number, and the disease appears to be limited largely to the external genitals.[99] Peak virus titers occur during the first few days and are lower, 10^3 to 10^4 plaque-forming units per milliliter. The total duration of pain is 5 to 9 days, duration of vesicles and ulcers is 8 to 11 days, and the duration of viral shedding is 5 to 8 days.[99,155] Women with both primary or initial and recurrent genital herpes may be asymptomatic.[97]

The clinical spectrum in infants with congenital HSV infection is different from that observed in babies with natal or postnatal disease. The most prominent features summarized from 30 cases of congenital infection reported in the literature are shown in Table 73–9.* A vesicular rash, bullae, or cutaneous scars present at birth or within a few days of birth were noted in almost all infants. In some cases, the extent and severity of these lesions resulted in an initial diagnosis of epidermolysis bullosa. At least one case report of limb hypoplasia, similar to congenital varicella syndrome, has been shown to be caused by HSV-2.[312] Two thirds of infants demonstrate extensive involvement of the CNS at birth, either clinically or from autopsy findings: diffuse brain damage, microcephaly, or intracranial calcifications. In some infants, eye findings, including chorioretinitis, microphthalmos, retinal scars and retinal dysplasia, and cataracts, have been noted.[401]

As indicated in Figure 73–3, infants with natal or postnatal herpes commonly have a clinical picture resembling that of bacterial sepsis: alterations in temperature, lethargy, respiratory distress, anorexia or vomiting, and cyanosis.[106-108,266,674,675] The three general patterns of infection are categorized by the extent of disease: (1) disseminated infection with or without CNS involvement, present in 25 percent of cases; (2) infection localized to the CNS in 30 percent of cases; and (3) infection localized to the skin, eye, or mouth in 45 percent of cases.[106-108,334]

The frequency of disseminated disease has decreased after a high of 51 percent reported in the years 1973 to 1981; this decrease probably represents earlier diagnosis and treatment of localized infection before dissemination occurs.[672] The disseminated form of infection in the earlier years of recognition presented in infants between 9 and 11 days of age and usually involved the liver, where it caused fulminant hepatitis with disseminated intravascular coagulation, and the adrenal glands, and it most closely resembled the picture of bacterial sepsis.[279,640] Current reports show disseminated neonatal HSV may present as early as the first week of life, without cutaneous or localizing signs, similar to bacterial sepsis, and confirm that HSV remains an important cause of neonatal morbidity and mortality.[106-108,644] A disseminated infection can affect multiple organs, including the brain, larynx, trachea, lungs, esophagus, stomach, lower gastrointestinal tract, spleen, kidneys, pancreas, and heart. Pneumonia occurs in 37 percent of infants. Markedly elevated transaminase levels, direct hyperbilirubinemia, coagulopathy, and thrombocytopenia are common findings. Approximately 60 to 75 percent of infants with disseminated disease have hematogenously acquired CNS involvement, as manifested by irritability, a bulging fontanelle, localized or generalized seizures, flaccid or spastic paralysis, opisthotonos, decerebrate rigidity, or coma. Importantly, 39 percent of infants with disseminated disease do not have skin vesicles at initial evaluation, and vesicles do not develop during the acute HSV disease; only 56 percent initially have fever, and many are hypothermic on presentation.[106,107,334]

CNS disease from retrograde axonal transmission of virus presents later than does disseminated disease, usually when the infant is 11 to 17 days old but occasionally when the infant is as old as 4 to 6 weeks of age. Typically, these infants have focal seizures that subsequently generalize. Examination of CSF demonstrates mononuclear pleocytosis with a predominance of lymphocytes, a moderately low glucose concentration, and elevated protein levels. A normal cell count, glucose, and protein concentration, however, may be found on the initial lumbar puncture, if performed early in the disease process.[106,107,664] An elevated red blood cell count secondary to hemorrhagic brain involvement may be present but by itself is an unreliable sign. Fever is present at initial evaluation in only 44 percent of infants with HSV encephalitis, and 32 percent of infants do not have skin vesicles either initially or during the course of their illness.

Localized skin, eye, or mouth disease usually presents within the infant's first 7 to 10 days of life. Approximately 83 percent of these neonates have skin lesions: usually single vesicles, occasionally vesicle clusters, and rarely a zoster-like rash.[442] As many as 46 to 80 percent of neonates with skin lesions have 1 to 12 recurrences during the first 6 to 12 months of life.[295,337,669] Approximately 13 to 25 percent of infants have eye involvement; disease is limited to only the eye in one third of these cases. Common

manifestations include conjunctivitis, keratitis, and chorioretinitis.[258,448] As many as 83 percent of infants are afebrile initially.[106,107] One third of all infants have evidence of herpetic mouth lesions, but involvement of this site alone rarely occurs.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Up to 80 percent of infants have classic features that would suggest herpes simplex, such as skin vesicles, mouth ulcers, or keratoconjunctivitis. One half of the remaining 15 to 20 percent have either (1) focal or diffuse encephalitis or (2) a sepsis syndrome with pneumonitis, hepatitis, encephalitis, and frequently, disseminated intravascular coagulopathy.[106,107,480] A clinical picture of encephalitis certainly should suggest HSV infection; the combination of pneumonitis, hepatitis, and encephalitis seldom is seen in bacterial sepsis/meningitis and should alert the clinician that a neonatal viral infection is more likely. As many as 32 percent of all HSV-infected neonates do not have vesicular skin lesions that would prompt clinical suspicion and a more rapid diagnosis. Kimberlin and colleagues[334] with the CASG compared the clinical characteristics of neonates with HSV disease in two multicenter studies that they conducted, one from 1981 to 1988 and the other from 1989 to 1997. They found that no progress has been made in decreasing the time interval between the onset of HSV symptoms and the initiation of antiviral therapy; the mean time between the earliest manifestation of an HSV symptom and initiation of acyclovir therapy was between 5 and 7 days. Recent studies have shown neonatal HSV disease presents more commonly than previously appreciated and appears similar in incidence to bacterial meningitis.[106-108] Although acyclovir should not be part of routine antibiotic therapy for all neonates with presumed sepsis, intravenous acyclovir should be provided promptly, similar to the paradigm of bacterial sepsis, pending results of viral studies, if the diagnosis of neonatal HSV is in the differential diagnosis.

The most definitive means of establishing a diagnosis of HSV infection in a neonate is isolation or identification of the virus in clinical or autopsy specimens. Samples for isolation of virus in cell culture should be obtained prior to initiating antiviral therapy and may be obtained from the skin vesicles, nares, throat, nasopharynx, conjunctivae, stool, urine, peripheral blood buffy coat, CSF, brain tissue, and liver biopsy and autopsy material.[187] HSV has been isolated from CSF in up to 25 to 40 percent of cases of encephalitis. HSV also has been isolated from duodenal aspirates of infants with hepatitis. Ideally, specimens should be processed immediately or frozen at –70°C if testing cannot be performed until later. However, HSV is stable for 2 to 3 days at 4°C in commercial viral transport media or media containing trypticase soy broth or brain-heart infusion broth.[694] In cell culture, the typical HSV cytopathic effect often is evident within 1 to 2 days after inoculation. Studies using centrifugation of the specimen onto a cell monolayer at the bottom of a shell vial, followed by staining for HSV antigen the next day, yielded 99 percent sensitivity and 100 percent specificity.[479] Typing of HSV should be performed because recent evidence suggests that neurologic outcomes may be worse with neonatal infection caused by HSV-2 than with infection caused by HSV-1. Moreover, typing might help establish the mode of transmission and provide information useful for future counseling regarding preventive measures.

Direct immunofluorescence assays (DFAs) or immunoperoxidase techniques are available to demonstrate HSV-1 or HSV-2 antigens in cells scraped from the base of vesicles or the conjunctivae or in biopsy or autopsy material.[321,554] Scraping from the base of a vesicle reveals intranuclear inclusions and multinucleated giant cells by the Tzanck test or Wright stain in 60 to 70 percent of cases. Detection of specific HSV antigen from skin and mucocutaneous ulcers by immunofluorescence is preferred and can be accomplished in 70 to 80 percent of cases. Direct detection of HSV antigen by commercial EIA has variable reliability compared with that of traditional cell culture and DFA.[653]

The diagnosis of HSV encephalitis has been improved greatly by the development of PCR for detection of HSV DNA in CSF.[332,333,372,644] PCR has supplanted the need for biopsy testing of brain tissue for HSV diagnostic purposes. It has a sensitivity of 48 to 98 percent and a specificity of 94 to 100 percent. HSV DNA can be detected by PCR in most culture-positive CSF even after 1 week of acyclovir therapy. HSV DNA detection by PCR on infant serum and whole blood is a useful method to document HSV viremia and disseminated HSV infection.[106-108,333,610] Other tests that aid in the detection of CNS abnormalities and help establish CNS involvement with HSV include electroencephalography, enhanced brain CT, and MRI. The characteristic electroencephalographic abnormality is a periodic slow and sharp wave discharge; more commonly, multiple independent foci of periodic activity are present. CT scanning may be normal early in the course of the disease, with characteristic abnormalities appearing 3 to 5 days later. The findings most frequently observed in the acute phase are (1) patchy areas of low attenuation with brain edema in both cerebral hemispheres or (2) hemorrhage or calcification in the thalamus, insular cortex, and periventricular white matter and along the corticomedullary junction. Late findings include multicystic encephalomalacia and ventriculomegaly as a result of brain atrophy and destruction. MRI is sensitive in detecting early abnormalities in the periventricular white matter and in defining the extent of parenchymal lesions.

In most circumstances, serologic assays are not useful for establishing the diagnosis of maternal or neonatal herpes during the acute phase of the disease.[187] Antibody assays may be used for documenting initial or primary genital herpes infection in the mother, as well as for determining whether the mother has a past history of HSV-2 infection. New serologic assays are available that reliably detect serum HSV-2 IgG antibodies.[123] The persistent lack of HSV-2 antibody on repeated samples taken over time in a mother whose infant has clinical evidence of possible HSV infection would render HSV-2 unlikely. However, the possibility of the infection being caused by HSV-1 remains. Immunofluorescent techniques to quantify HSV-specific IgM antibodies have been developed, but these antibodies usually are not detected in serum for 2 or more weeks after onset of the infection in neonates.[447]

The major diseases to be considered in the differential diagnosis of neonatal HSV include bacterial sepsis and meningitis, adenovirus and enterovirus infection, and, to a lesser extent, congenital infection with CMV, rubella virus, and VZV. Inquiry about illness in the mother and other epidemiologic features may be helpful. For example, mothers of neonates with HSV infection may (but often do not) have a history of having had genital lesions or sexual contact with someone who has genital herpes. Infants with sepsis usually have associated factors known to predispose to bacterial infection, such as maternal peripartum infection, premature rupture of membranes, and procedures performed in the intensive care unit or nursery. Enterovirus infection of infants tends to occur in the summer and fall and is associated with signs and symptoms of enterovirus disease in the mother. Adenoviruses, however, occur year-round and may have slight increase in frequency during winter/spring months. Varicella in the neonate usually presents with a history of maternal varicella near the time of delivery or close contact with a caretaker with varicella.

TREATMENT

Studies conducted by the CASG of the National Institute of Allergy and Infectious Diseases (NIAID) have shown that antivi-

ral therapy for neonatal HSV disease significantly improves mortality rates and long-term outcomes of infected neonates. Vidarabine was the first commercially available drug for the treatment of neonatal HSV disease.[139] Placebo-controlled trials demonstrated that adenine arabinoside (vidarabine, ara-A) at doses of 15 or 30 mg/kg/day given as a 12-hour infusion significantly reduced the mortality rate from 62 percent in historic cases and placebo controls to 35 percent in treated cases and increased the percentage of normal survivors from 19 to 43 percent.[676] Results were best in infants with disseminated infection and disease localized to the CNS, with the mortality rate being reduced from 70 to 40 percent and the percentage of normal survivors increased from 10 to 30 percent. No difference was found between the 15-mg and the 30-mg dose in side effects, but the higher dose appeared to inhibit more effectively the progression of disease from skin-eye-mouth involvement to disseminated or CNS disease.[674] None of the 49 treated patients had significant adverse clinical reactions or laboratory abnormalities attributable to the drug. On the negative side, 21 percent of infants progressed to more serious disease while receiving therapy, and serious neurologic sequelae developed in 27 percent of the total. Fifteen percent of babies with disseminated or CNS disease continued to excrete HSV in the throat after 10 days of therapy.

The results of a vidarabine-acyclovir comparison trial in the treatment of neonatal herpes did not show any difference in efficacy and safety between the two drugs.[668] When the results with vidarabine and vidarabine-acyclovir were combined, the mortality rate was reduced from 49 percent in untreated historical controls to 17 percent in treated patients (Table 73–10). Normal survivors increased from 26 to 67 percent. Although the results in the total group of patients were encouraging, the outcome in the group of patients with disseminated disease was not: a mortality rate of 54 percent in treated patients versus 76 percent in untreated historical controls and normal development in 59 percent of treated survivors versus 54 percent of controls (see Table 73–10). Factors that predicted mortality and their relative risk were as follows: disseminated disease, 33; CNS disease, 5.8; semicoma or coma, 5.2; disseminated intravascular coagulation, 3.8; prematurity, 3.7; and pneumonitis, 3.6.[669] Factors significantly associated with neurologic sequelae in survivors and their relative risk in these studies were as follows: skin-eye-mouth disease with three or more recurrent skin lesions after completion of acute therapy, 21; skin-eye-mouth disease caused by HSV-2, 14; HSV-2 infection, regardless of disease category, 4.9; CNS disease, 4.4; and seizures, 3.0. In infants with HSV disease limited to the skin, eye, or mouth, neonates with HSV-1 infection were all normal developmentally at 1 year of age as compared with 86 percent of those with HSV-2 infection. Among the latter infants, those with impaired neurologic outcome were significantly more likely to have had three or more skin recurrences in the first 6 months of life.

Because of greater ease of administration, intravenous acyclovir has supplanted vidarabine as the drug of choice for the treatment of neonatal HSV infection. Vidarabine no longer is available commercially. Because mortality and morbidity in neonates with HSV infection remained high using standard (30 mg/kg/day) dosing of acyclovir for 10 days, the CASG evaluated intermediate-dose (45 mg/kg/day) and high-dose (60 mg/kg/day) intravenous acyclovir for 21 days in 79 neonates with neonatal HSV infection.[335] Data were compared with those of a previous CASG study in which all infants received standard doses of acyclovir (30 mg/kg/day) for 10 days. Overall, after stratification for disease category, the survival rate for patients treated with high-dose acyclovir was significantly higher than that for patients treated with the standard dose. Specifically, in neonates who received high-dose acyclovir, those with disseminated disease but not encephalitis had a significantly higher survival rate. The mortality rate at 24 months for patients with disseminated disease who received 21 days of high-dose acyclovir was 31 percent, compared with 57 percent for patients who received an intermediate dose for 21 days and 61 percent for those who received the standard dose for 10 days in the earlier CASG trial. For encephalitis, the mortality rate of infants at 24 months was 6 percent with high-dose acyclovir, 20 percent with the intermediate dose, and 19 percent with the standard dose. In addition, recipients of high-dose acyclovir had less morbidity than did historical control infants who received the standard dose of acyclovir. Patients treated with high-dose acyclovir were 6.6 times as likely to have normal development at 12 months of age. Among infants with encephalitis, however, 31 percent of high-dose acyclovir recipients were developing normally at 12 months as compared with 29 percent of patients treated with the standard dose. With respect to toxicity in the high-dose acyclovir recipients, 21 percent had a transient neutropenia that resolved either during continuation of high-dose acyclovir or after its cessation. Nephrotoxicity occurred in four (6%) infants who had disseminated disease. Because acyclovir is eliminated by the kidneys, the dose should be adjusted for renal disease.[216] High-dose acyclovir did not impede the development of an adequate antibody response to HSV in infected infants.

These studies have led to the current recommendation for the use of intravenous acyclovir at a dose of 60 mg/kg/day for 21 days to treat neonatal CNS and disseminated HSV disease and for 14 days for skin-eye-mouth disease.[26,331] In addition, infants with ocular involvement should receive a topical ophthalmic drug (1-2% trifluridine, 1% idoxuridine, or 3% vidarabine). Consultation with an ophthalmologist is also recommended to assist in the management of ocular HSV in the neonate. All patients with HSV CNS infection should have a repeat lumbar puncture performed at the completion of acyclovir therapy to determine

resolution of abnormal CSF parameters and to document whether the CSF specimen is HSV culture and PCR-negative. A positive CSF HSV PCR at this time is an indication for continuing intravenous acyclovir therapy and for performing repeat neuroimaging studies to evaluate the extent of CNS damage. Repeat samples of blood and CSF should be obtained weekly until HSV studies are negative and provide a guideline for duration of antiviral therapy.

Concern has been raised that some infants may have progressive neurologic injury after acquiring neonatal herpes encephalitis.[257] In addition, infants who have three or more skin recurrences with HSV-2 in the first 6 months of life have been shown to be at increased risk for having neurodevelopmental abnormalities at follow-up, whether as a consequence of previously undetected CNS infection or because of CNS dissemination during skin reactivation.[669] Suppression of HSV skin reactivation by the administration of acyclovir (300 mg/m^2 per dose given orally three times daily) for 6 months is recommended by some experts for selected patients. The infant's blood counts should be monitored while receiving oral acyclovir long term because Kimberlin and coworkers[336] documented suppressive therapy resulted in neutropenia in 50 percent of treated infants and emergence of an acyclovir-resistant HSV isolate in one infant. Acyclovir suppression should be considered after the initial recurrence of skin lesions in the first 2 to 3 months of age or after a recurrent episode of HSV encephalitis. Acyclovir suppression also has been used after development of HSV eye infection in which reactivation might imperil vision.

General supportive measures, such as maintenance of fluid and electrolyte balance, correction of hypoglycemia, management of disseminated intravascular coagulation and shock, control of seizures with anticonvulsants, mechanical support of the respiratory system, nutritional support, and antimicrobial therapy for complicating bacterial infections, also are critical in improving the outcome for neonates with HSV infection.

PROGNOSIS

As indicated in Table 73–10, the overall mortality rate from untreated neonatal HSV infection is 49 percent, and only 26 percent of survivors develop normally. The most guarded prognosis is natal infection that is disseminated, with pneumonitis, or presents as encephalitis localized to the CNS. Between 50 and 60 percent of infants with HSV infection limited to the skin, eye, and mouth who do not receive antiviral therapy progress to having CNS or disseminated disease. As shown in Table 73–10, neurologic sequelae develop in an appreciable proportion of survivors. All infants with neonatal herpes, therefore, require antiviral chemotherapy, regardless of the type or severity of disease at initial evaluation.

The major sequelae in infants surviving neonatal herpes involve the CNS. Diffuse brain damage, seizures, microcephaly, spasticity, paralysis, growth retardation, and chorioretinitis with visual loss all have been observed.[676] Serial CT or MRI of the head may be useful in these infants and can provide prognostic information.[674] Physical therapy and developmental interventions will help optimize the infant's abilities. Most infants with skin involvement have recurrent lesions, which can be managed with oral suppression therapy.

PREVENTION

The major approaches to the prevention of neonatal herpes involve interruption of transmission from sites of HSV infection and disease at the time of delivery and postnatally from a variety of potential sources. Because in utero transplacental congenital infection occurs so infrequently[668] and predicting the occurrence of congenital infection during pregnancy is not possible,[301] no standard recommendations for prophylaxis are available.

Cesarean delivery within 4 hours of rupture of fetal membranes in a mother with active genital herpes at the time of delivery is recommended to reduce the risk of natal infection. Because serial vaginal cultures taken during the latter stages of pregnancy have failed to predict shedding at the time of delivery,[37,71,682] such monitoring is not recommended. Cesarean delivery is recommended only for women with active vesicular or ulcerative lesions at the time of delivery.[45,244,274,485,511,561] Cesarean delivery is not always 100 percent protective, even if the membranes are intact.[274,480,511,561] Between 1.2 and 3 percent and, in one study, up to 33 percent of neonates with HSV infection are delivered by cesarean delivery.[102,673] The cost-effectiveness of performing a cesarean delivery in women with recurrent lesions at delivery has been questioned by some experts, but it remains the current recommendation in the United States.[519] Multiple clinical trials have shown that administration of prophylactic acyclovir and valacyclovir beginning at 36 weeks gestation reduces the risk of clinically apparent HSV genital vesicles and ulcers at delivery, reduces the risk of HSV viral shedding at delivery, and also reduces the incidence of cesarean delivery.[286,562,573,574,673] However, although the hope is that the risk of HSV disease in the neonate also would be reduced, in none of these studies was sufficient power or evidence available to determine the effect of peripartum prophylaxis on the incidence of neonatal HSV. No adverse effects have been seen in infants exposed to maternal acyclovir during pregnancy. Because fetal scalp electrode monitor, forceps, and maneuvers that might cause a break in the infant's skin during delivery appear to increase the risk for acquisition of neonatal HSV, they should be used only with clear indication and a careful assessment of the risk-to-benefit ratio.

The results of antenatal genital HSV cultures from pregnant women with a history of genital herpes do not predict the infant's risk of exposure to HSV at delivery. Because 60 to 80 percent of mothers of babies with neonatal herpes are asymptomatic or have unrecognized infection, the optimal approach may be to perform a screening test to identify women shedding or likely to shed HSV at the time of delivery. Although HSV rapid antigen-detection tests continue to be developed commercially,[479] their sensitivity in *asymptomatic* women still is only 60 to 75 percent. Screening of pregnant women for non–type-specific HSV antibody would be confounded by the presence of HSV-1 antibody, which is present in 60 to 80 percent of the population.[476] The presence of HSV-1 antibody probably represents oral herpes, which poses little risk to the neonate. Although type-specific antibody assays are available to identify pregnant women infected with HSV-2,[123,313] such an approach would miss women with genital HSV-1 infection[155,511] or those with asymptomatic primary HSV-2 infection near the time of delivery before antibody is detectable.[97,511] Its use has been recommended in identifying discordant couples, that is, women with no history of having genital HSV infection but whose sexual partner has had previous infection, so barrier precautions may be used before delivery to decrease the chance of development of a maternal primary infection that poses a greater risk to her infant.[123] Culturing the genital tract of women at the time of vaginal delivery would identify infants exposed to HSV and allow anticipatory management.[478,485,511] However, because genital HSV infection rates are only 0.1 to 0.4 percent,[97,450,513] this approach likely would not be practical or cost-effective for *all* women. Culturing of *selected* women at delivery could focus on (1) positive or partner-discordant HSV-2 serologic tests, (2) those women with a history of genital herpes in themselves or their sexual partners, (3) those women with a history of another sexually transmitted disease or multiple sexual partners, and (4) mothers with a history of maternal fever in labor. However, routine or selective serologic

screening, although recommended by some experts, is not currently a standard recommendation, and further investigation is required to determine whether screening of pregnant women to prevent neonatal herpes is beneficial, practical, and cost-effective.[26,106-108,169]

No studies have been conducted on the optimal management of asymptomatic infants exposed to maternal HSV infection at delivery, although some guidelines on obtaining viral cultures and prophylactic or anticipatory antiviral therapy are available.[26,478-480,511,561] In general, appropriate cultures for HSV should be performed for all infants born to mothers with active genital HSV infection at delivery. In asymptomatic infants, cultures of the conjunctiva, throat, rectum, and possibly urine should be done at 24 to 36 hours of age. Cultures obtained at birth may indicate only contaminating virus, whereas those obtained 1 to 2 days after birth probably represent HSV newly replicating in the mucous membranes. If the infant is delivered by cesarean section within 4 hours of rupture of membranes, no prophylactic antiviral therapy is indicated. If the infant is born vaginally or by cesarean section performed more than 4 hours after rupture of membranes, further management is dependent on the presence of other risk factors. If the mother has primary infection at delivery, a situation in which the neonatal infection rate may be as high as 30 to 50 percent, intravenous acyclovir (60 mg/kg/day) should be initiated. If the mother has recurrent infection, in which the risk of neonatal disease occurring after vaginal delivery is probably less than 3 percent, acyclovir may be withheld pending the results of culture or the development of clinical illness in the neonate that could be caused by HSV. Situations that increase the risk of neonatal transmission despite maternal recurrent disease include prematurity, the use of a scalp electrode monitor, or skin lacerations; prophylactic acyclovir should be considered in these instances if the infant has been delivered vaginally or by cesarean section more than 4 hours after rupture of membranes. In all instances, acyclovir can be discontinued when HSV cultures are negative at 48 to 72 hours and the infant has remained well. All infants should be monitored closely for any clinical evidence of HSV infection. Any positive culture or the occurrence of signs or symptoms suggesting HSV infection in the neonate suggests that a full virologic evaluation, including blood and CSF analysis for HSV by PCR, should be performed and antiviral therapy initiated. Antiviral therapy also should be administered to neonates with positive HSV cultures of mucosal sites, and these neonates should not be assessed as being merely colonized, as all require intravenous acyclovir therapy.[26] The duration of therapy, however, probably can be shortened to 7 or 10 days if no other site of infection is found and the infant remains asymptomatic. Breast-feeding is contraindicated only if the mother has a vesicular lesion on her breast. Physicians also have recommended that circumcision be delayed for 1 month in infants at highest risk of transmission.

Prevention of postnatally acquired neonatal infection needs to take into account the potential sources of HSV: (1) maternal oral herpes or breast lesions; (2) household member, such as father or sibling, or other close contact, such as grandparent or caretaker, with oral herpes or herpetic gingivostomatitis; and (3) health care–associated transmission from other infected babies or health care workers.[193,262,393,622,623,695] Transmission to the neonate from family members with oral herpes lesions can be interrupted by education, avoidance of kissing and nuzzling of the neonate if they have oral herpes ulcers, and avoidance of touching the neonate if they have a herpetic skin lesion or whitlow, as well as common sense personal hygiene, including handwashing. Health care–associated transmission can be reduced by contact isolation and hospital infection control measures, as well as universal precautions and good handwashing techniques.[327,339] Personnel with herpetic whitlow should not have direct patient care responsibilities until the lesion has healed. Infants with HSV infection should be placed in contact isolation for the duration of the illness.[26] The median duration of viral shedding from skin vesicles and mucosal sites in infants receiving acyclovir is approximately 5 to 8 days.[335] Asymptomatic but high-risk infants born to mothers with herpes at delivery also should be in contact isolation; alternatively, they may room-in with the mother in a private room.

ENTEROVIRUS AND PARECHOVIRUS

The enteroviruses and parechoviruses are small RNA viruses that are members of the virus family Picornaviridae. The enteroviruses currently include the polioviruses types 1, 2, and 3; the coxsackieviruses A and B; and the echoviruses. Currently, there are four known parechoviruses: PeV1 (formerly enterovirus 22), PeV2 (formerly enterovirus 23), PeV3, and PeV4.[654] Enteroviruses are common infections in neonates, children, and adults. Coxsackievirus and echovirus infections are fairly common events in young infants and, as with other viral agents, often result in more severe disease in neonates. Neonatal poliomyelitis, however, is a rare occurrence in the United States and is not covered in this section. All four known parechoviruses have caused disease in neonates.[76,654]

MICROBIOLOGY AND EPIDEMIOLOGY

Twenty-three types of type A coxsackieviruses, six types of type B coxsackieviruses, 30 types of echoviruses, three types of polioviruses, five types of other enteroviruses (68 to 72), and four types or parechoviruses are currently recognized.[76,413,653] Most strains grow in tissue culture, but some, particularly type A coxsackieviruses, require inoculation in suckling mice. Because no common or group antigens for the enteroviruses exist, separate antibody titration must be performed for each virus. Therefore, to make a laboratory diagnosis of enteroviral infection by serologic means alone is not recommended. However, antibody titers can be performed after a specific enterovirus has been isolated from the patient or when a concurrent epidemic with a known virus occurs in the community. Detection of enterovirus and parechovirus RNA by reverse transcriptase (RT)-PCR is now a common method of establishing a diagnosis.[158]

The attack rate for enteroviral infections is highest during infancy and early childhood.[109,165-167,359,403,429,436,684] In addition, severe disease occurs much more commonly in neonates than in older children or adults.[429,684] Sixty to 70 percent of neonates infected with enterovirus are males, whereas one study has shown females may predominate in parechovirus infections.[318,371,427,436,517,654] Enteroviruses are worldwide in distribution, and in temperate climates, infections occur predominantly during the summer and fall months, with peaks in July, August, and September.[109,307,413] Parechovirus infection also occurs during summer and fall months.[654] The incubation period for enteroviral infections in children and adults usually is 5 to 8 days, with a range of 2 to 12 days.[543,660] Of the cases reported to the CDC from 1970 to 1979, echoviruses accounted for 57 percent; type B coxsackieviruses, 25 percent; polioviruses, 9 percent; type A coxsackieviruses, 8 percent; and enterovirus types 68 to 71, 0.1 percent.[109] In infants younger than 2 months of age, echoviruses accounted for 51 percent of infections; type B coxsackieviruses, 45 percent; and type A coxsackieviruses, 4 percent.[394,436] In any given year in the United States, usually an epidemic occurs that is caused by a few enterovirus types: echovirus 11 and coxsackieviruses B2 and B4 in 1979, echoviruses 9 and 4 in 1978, echovirus 6 in 1977, coxsackievirus B4 in 1976, and echovirus 9 in 1975.[109]

Outbreaks of enteroviral disease have occurred in normal nurseries and in neonatal intensive care units.*

Acute enteroviral and parechoviral infections may be acquired congenitally, natally, or postnatally.[135,536] However, confusion concerning the incubation period and source of virus for neonatal infection often has ensued. Late-gestation congenital infection is presumed to occur in infants with an onset of illness at birth or within the first few days of life, when their mothers had symptoms of enteroviral disease just before or immediately after delivery.[5,107,133,172,371,429,499] Further evidence of congenital infection is the observation that viremia with echoviruses and coxsackieviruses is known to occur in pregnant women,[135] and virus has been isolated from the placenta of infants with an onset of disease early in life.[89,429] Infants with an onset of enteroviral disease between 3 and 8 to 10 days of age probably acquired the infection from their mothers at the time of birth (natal infection), whereas those with illness appearing after this time probably acquired it postnatally. At least one case of congenital parechovirus infection has been documented in a neonate who presented at 1 day of age.[654] The source of enterovirus for most cases in nurseries appears to be the mother because the age of the infants at the time that the first symptoms appear is usually less than 10 days.[5,107,133,172,371,429,499] However, in some cases and outbreaks, the infection clearly appears to be associated with health care, presumably through spread of virus from other infected neonates by the hands of personnel or from infected personnel themselves.[161,407,429]

Some investigations indicate that enteroviral infections acquired in the community are a common cause of hospitalization for a febrile illness in young infants.[107,165-167,307,359] Enteroviral infections were estimated to account for 20,000 to 40,000 hospitalizations per year in young infants in the United States. Viruses appear more frequently than do bacteria as a cause of fever in the neonate.[107] One study of 182 infants younger than 3 months of age and hospitalized for fever over the course of a year showed viral pathogens were isolated in 41 percent and bacteria in only 15 percent.[359] Enteroviruses accounted for 85 percent of the viral isolates. Among a cohort of 586 newborns prospectively monitored during the enteroviral season in Rochester, New York, 24 (4%) were hospitalized during the first month of life.[307] Two thirds of these 24 were infected with enteroviruses. Risk factors associated with development of infection and more severe enteroviral disease included a particular serotype of virus (e.g., echovirus 22, presumably a more virulent strain); lower socioeconomic status, probably with associated crowding and an increased rate of transmission; bottle feeding (absence of passive antibody in breast milk); and absence of antibody in cord serum.[166,307,429,432]

Evidence suggests that coxsackieviral infections in early pregnancy may cause congenital malformations in the fetus. Brown and colleagues[94,95] demonstrated a significant association between serologic evidence of coxsackievirus A9, B2, B3, or B4 infection in mothers during pregnancy and the birth of infants with anomalies of the cardiovascular, urogenital, and digestive systems. However, specific viral isolation and antibody studies were not performed on the involved infants, and no seasonal distribution was noted in their births. In addition, the observations of Brown and colleagues[94,95] have not been confirmed by others.[207,353,502] The association between maternal infection with coxsackieviruses and congenital malformations, therefore, remains suggestive but not proven. Moreover, no conclusive evidence supports any relationship between maternal infection with type B coxsackieviruses and congenital CNS malformations.[207] More studies are necessary to determine whether or not parechoviral infections are associated with congenital malformations.

PATHOGENESIS AND PATHOLOGY

Our knowledge of the pathogenesis of congenital enteroviral and parechoviral infections is incomplete because they are rare events. However, studies in gravid mice support the transplacental passage of enteroviruses with resultant fetal infection.[2,311,365,484] By inference from these studies and our understanding of congenital CMV and rubella virus infections, transplacental transmission secondary to maternal viremia probably occurs. Virus then is transmitted through fetal blood to target organs, principally the CNS, liver, heart, lungs, kidneys, and adrenal glands. In congenital infections that are fatal in the early neonatal period, type B coxsackieviruses involve primarily the heart, CNS, liver, and lungs,[239,318,371,684] and echoviruses involve the liver, adrenals, kidneys, CNS, and lungs.[133,299,259,360,428,429,499] Histopathologic findings have consisted of focal myocardial necrosis with type B coxsackieviruses[239,684]; massive hepatic necrosis with echoviruses[299,360,429,499]; and evidence of disseminated intravascular coagulation and adrenal, pulmonary, and renal hemorrhage with both virus groups.[133,239,299,360,371,429,499,684,684] Of interest is that the onset of illness in most neonates with fatal coxsackievirus B and echovirus infection occurred at birth or within the first few days of life, suggesting that transplacental infections carry a worse prognosis.[5,133,299,360,371,429,499] In addition, lack of transplacental transfer of maternal antibody before delivery could play a role.[426,427] Only a few isolated cases of congenital coxsackievirus A infection have been reported.[135]

Natal infection is secondary to aspiration and swallowing of enterovirus-contaminated vaginal secretions at the time of birth. Postnatal acquisition is the result of fecal-oropharyngeal spread of the virus on the hands of the mother, other family members, or hospital personnel.[135,429] Pathogenesis of natal and postnatal infection is similar to that observed in older infants and children. Because most infants with postnatal infection survive, the pathologic features are not well characterized.

CLINICAL MANIFESTATIONS

The clinical features in 134 neonates and very young infants with echoviral and coxsackieviral infections are shown in Figure 73–3. The most common findings, hyperthermia or hypothermia, anorexia or vomiting, and lethargy, are relatively nonspecific findings and are encountered with similar frequency in neonates with other viral infections or bacterial sepsis. Features that appear to be characteristic of enteroviral infection include signs and symptoms of aseptic meningitis and meningoencephalitis (irritability, CNS signs, including seizures); gastroenteritis (anorexia, vomiting, diarrhea, abdominal distention); and an erythematous, maculopapular exanthem. In addition, neonates may manifest a mild, nonspecific febrile illness, a severe sepsis-like disease, respiratory illness, hepatitis that may be fulminant with resultant hepatic necrosis and death, and cardiovascular manifestations secondary to myocarditis. Enteroviral DNA also has been detected by PCR in the respiratory tract of infants with sudden death.[245]

Infants with more serious disease may have a biphasic course that begins as a mild illness with slight elevation of temperature, coryza, anorexia, and diarrhea. After an apparent recovery period lasting 1 to 5 days, infants may have more severe symptoms of aseptic meningitis; myocarditis (tachycardia, tachypnea, respiratory distress, and cyanosis); hepatitis with elevated transaminases; or disseminated infection (abdominal distention, hepatomegaly, petechial rash, disseminated intravascular coagulation).

Milder forms of disease, such as pneumonitis, undifferentiated febrile illness, exanthematous illness, or gastroenteritis lasting only a few days, also occur.[303,371] In a survey of 338 infants younger than 2 months of age with enteroviral infections reported to the

TABLE 73–11 Characteristics Associated with Parechovirus and Enteroviral Infection in Neonates

Seasonal occurrence—summer and fall
Presence of known epidemic in the community
History of maternal viral illness near the time of delivery
Absence of factors predisposing to bacterial sepsis
Nursery outbreak of infectious illness with negative bacterial cultures
Development of culture-negative sepsis or aseptic meningitis in the neonate
Development of myocarditis, hepatitis, or erythematous maculopapular exanthem in the neonate

CDC, 74 percent had severe disease, and 26 percent had mild disease.[436] Five (1%) of these infants died, all in the group with severe disease. Asymptomatic infections in neonates have been detected during outbreaks in nurseries or when routine virologic surveillance was being performed in a nursery.[89] An outbreak of neonatal herpangina caused by coxsackievirus A5 was observed in Thailand.[132] Parechoviruses in neonates also may cause both mild and serious illnesses that cannot be differentiated clinically from enteroviruses and that include fever, seizures, rash, irritability, apnea, tachypnea, diarrhea, meningoencephalitis, hepatitis, and acute myocarditis.[653]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The major epidemiologic and clinical features that suggest a diagnosis of enteroviral or parechoviral infection in a neonate are listed in Table 73–11. Because the signs and symptoms in neonates with enteroviral and parechoviral disease often mimic those of bacterial sepsis and meningitis, antibiotic therapy generally should be initiated until a bacterial etiology is ruled out. In addition to sepsis and meningitis, the major diseases to be considered in the differential diagnosis include HSV infection, adenovirus, and, to a lesser extent, congenital infection with CMV and rubella virus. HSV infection is nonseasonal, endemic, and may be associated with genital ulcerative lesions in the mother. Symptomatic congenital CMV and rubella infections are associated with intrauterine growth retardation and a chronic rather than an acute infectious clinical picture in the infant.

The most direct means of establishing a diagnosis of enteroviral infection in neonates is isolation of the virus in tissue culture or suckling mice.[479] Virus may be recovered from throat swab, stool, CSF, serum or buffy coat, and biopsy and autopsy tissue. Ideally, specimens should be processed immediately, but enteroviruses may remain stable at 4° C for several days if testing cannot be performed until later. Isolation of virus from CSF, blood, or tissue can be considered diagnostic. A throat, urine, or stool isolate also can be considered etiologic in most neonatal illnesses. RT-PCR performed for detection of enterovirus or parechovirus RNA in CSF or blood samples is more sensitive and rapid than is isolation of virus[526] and is the preferred method for diagnosing meningitis or disseminated infection caused by these viruses in most circumstances.[547,552] Because of genetic differences, parechoviruses cannot be identified by primers used in enterovirus RT-PCR assays. Therefore, RT-PCR for both types of these viruses should be performed for optimal diagnostic sensitivity.[158,654]

TREATMENT

No licensed and effective antiviral chemotherapy exists for enteroviruses. Pleconaril administered orally on a compassionate basis to neonates with severe disseminated enteroviral disease has resulted in clinical recovery.[34,322,537] In adults, pleconaril has decreased the duration of clinical symptomatology in aseptic meningitis significantly and has resulted in cessation of viral shedding in immunocompromised individuals. Case reports and series on administration of pleconaril to neonates with enterovirus infection are published.[34,525,531] Clinical trials evaluating the benefits of pleconaril in neonatal enteroviral sepsis syndrome with liver or cardiac involvement are in progress through the NIAID CASG. Intravenous immunoglobulin often is recommended, especially if myocarditis is present, because it may improve survival.[4,168,261,314]

PROGNOSIS

The outcome is influenced by several factors: the enterovirus serotype causing the infection, the route of transmission of virus to the neonate, the age at acquisition of the infection, prematurity, and severity of the disease in the neonate. Mortality rates are highest for coxsackievirus B infections, intermediate for echovirus infections, and lowest for coxsackievirus A infections.[135,239,318,371] Most of the neonatal deaths caused by enteroviruses reported in recent years have occurred in infants whose onset of disease was at or within a few days of birth and who, therefore, had congenital disease.[133,299,365,371] Infection and mortality rates both appear to be higher for premature infants.[89,429] Death is most likely to occur in infants with acute myocarditis, encephalitis, or severe hepatitis.[135,429] Neurologic sequelae have been observed to occur after meningoencephalitis in the neonatal period,[135,565,677] although most infants who survive enteroviral meningitis appear to have an excellent long-term prognosis.[70] Long-term cardiac sequelae also do not appear to complicate most neonatal enteroviral myocarditis.[239] Long-term follow-up studies of neonates infected with parechovirus have not been performed.

PREVENTION

Polio vaccine has reduced maternal and neonatal poliomyelitis to an extremely rare occurrence, but poliovirus infections still occur in underdeveloped countries without polio vaccination programs. No prospects exist for vaccines for the echoviruses or coxsackieviruses or parechoviruses at this time. With the appearance of a case of enteroviral or parechoviral disease in a newborn nursery or intensive care unit, initiation of vigorous infection control measures involving contact precautions, including such measures for suspected cases and renewed emphasis on handwashing and exclusion of personnel with symptoms of enteroviral disease, is indicated. Of emphasis is that infection control measures applied in the nursery do not prevent congenital or natal transmission of virus from the mother to the infant. The continued appearance of cases in neonates younger than 8 to 10 days of age may reflect a persistent epidemic among pregnant women rather than a failure of nursery infection control measures and spread within the nursery.[626]

VARICELLA-ZOSTER VIRUS

VZV causes both varicella ("chickenpox"), the result of primary infection with the virus, and zoster, caused by reactivation of latent virus.[240,243,476] VZV infection of a pregnant woman results in three separate and distinct syndromes that become apparent in neonates and infants: (1) congenital varicella syndrome with congenital defects secondary to intrauterine VZV infection, (2) neonatal varicella, and (3) zoster in infants.[212,214,240,243,493] Transmission to the fetus occurs as a consequence of maternal viremia

and may result in congenital varicella syndrome, fetal hydrops, or fetal death.[240,243,273] Transmission to the neonate occurs through exposure to virus-infected secretions or lesions present in the mother or close contact and may result in neonatal varicella.

MATERNAL VARICELLA

Knowledge of several features of chickenpox in the mother is necessary to understand the pathogenesis of VZV infection in the fetus and neonate. Because antibody to VZV is present in approximately 90 percent of women of child-bearing age,[243] varicella occurring during pregnancy is a relatively uncommon event. Pregnant women with varicella may develop severe disease, with severe constitutional symptoms, and potentially fatal pneumonia.[272] Maternal chickenpox has been reported to occur in only 0.7 per 1000 pregnancies.[570] The incubation period for chickenpox (from exposure to the onset of rash) usually is between 14 and 16 days, with a range of 10 to 21 days.[240,243]

CONGENITAL VARICELLA SYNDROME

In several large prospective studies, no increase in anomalies was apparent in the offspring of women who had varicella during pregnancy.[87,581-583] However, a prospective study[410] of 43 pregnancies complicated by varicella indicated that (1) 21 percent of the women experienced appreciable morbidity, (2) 24 percent of 33 infants tested had clinical or immunologic evidence of intrauterine VZV infection, and (3) congenital varicella syndrome occurred in 9 percent of 11 women with first-trimester varicella. Pooling of results from several prospective studies indicates an approximate 2 percent risk of fetal malformations caused by maternal varicella during the first 20 weeks of pregnancy.[214,419,493] Of the reported cases of congenital varicella syndrome, 93 percent have occurred after maternal chickenpox and only 7 percent after maternal zoster. Seven percent of reported cases occurred after maternal varicella was acquired at less than the 20th week, with the latest being at 28 weeks of gestation.[19] In another recent prospective multicenter study of 347 pregnant women with varicella, the incidence of congenital varicella syndrome was 0.4 percent, with fetal death and fetal hydrops also observed.[273] One case of congenital varicella syndrome occurring after maternal varicella developed in the third trimester of pregnancy has been reported.[350]

The abnormalities present in 77 infants with congenital varicella syndrome are summarized in Table 73–12. The defects apparently are the result of VZV replication in and destruction of developing fetal ectodermal tissue: skin, peripheral nerves, cervical and lumbosacral spinal cord, brain, and eye.[41,44,233,463,482,545] Diagnosis of the syndrome usually is clinical: a history of varicella in the mother and recognition of the characteristic findings in the fetus or neonate. Prenatal diagnosis may be established by amniocentesis with demonstration of VZV in amniotic fluid by culture or PCR and by cordocentesis and demonstration of VZV-specific IgM in a fetal blood sample. Prenatal ultrasound and fetal MRI imaging may detect abnormalities and document the extent of involvement.[417,655] Virus has not been isolated from these infants, and serologic studies often have been inconclusive.[232,243] However, detection of varicella-zoster DNA by PCR has been used to confirm the syndrome in some cases.[438,461,514,544] Infants with varicella embryopathy do not require isolation. Severely affected neonates may die in infancy.[232,243] However, some children may survive and enjoy productive lives.[556] Children with congenital varicella syndrome also may experience apparent reactivation disease, involving skin and, rarely, brain or other organs.[85,545] Universal vaccination against varicella may decrease the importance of this virus in congenital and neonatal disease.

NEONATAL VARICELLA

Neonatal varicella refers to the onset of varicella ("chickenpox") within the first 28 days of life.[546] The incubation period, defined as the interval between the onset of rash in the mother and onset in the fetus or neonate, usually is 9 to 15 days, with a range between 1 and 16 days. Neonatal varicella occurs when a pregnant woman experiences varicella during the last 1 to 2 weeks of pregnancy or within the first few days postpartum. The attack rate is approximately 25 to 50 percent. As indicated in Table 73–13, the timing of the onset of disease in the mother and the neonate is a critical factor influencing the outcome in the infant. If disease onset occurs in the mother 5 or more days before delivery or in the neonate during the first 4 days of life, the infection is mild. In contrast, if disease onset in the mother is within 4 days before delivery or in the neonate between 5 and 10 days of age, the infection usually is disseminated and fulminant, and approximately one third of the infants die.[243,423] Other investigations have found that the risk period of the onset of maternal rash extends from 7 days before to 16 days after delivery.[28,512] The generally accepted explanation for this observation is that when

illness in the mother occurs more than 5 days before delivery or when illness in the baby occurs during the first 4 days of life, maternal antibody has time to pass transplacentally and provide passive protection for the infant. However, passive protection does not have time to occur when illness in the mother occurs within 4 days of delivery. Presumably, the immune responses of the neonate are insufficient to retard the growth and dissemination of VZV after intravenous inoculation via the placenta, and disseminated disease results.

The milder form of neonatal varicella resembles the disease in normal, older children, whereas the disseminated variety is similar to that seen in immunosuppressed, leukemic children. In the latter, diffuse pneumonia, severe hepatitis, and meningoencephalitis are the most common clinical manifestations. The diagnosis usually can be established clinically from the characteristic appearance of skin vesicles, and VZV antigen can be demonstrated by immunofluorescence testing of vesicular fluid. Less commonly, VZV may be isolated from vesicular fluid by tissue culture during the first 3 days of the rash, but VZV is difficult to isolate in commercial virology laboratories.[479] VZV DNA can be demonstrated in vesicular fluid by PCR.[300] The major disease to consider in the differential diagnosis is disseminated neonatal HSV infection. With HSV infection, a history of maternal genital herpes may be elicited; characteristic keratoconjunctivitis, mouth lesions, or both may be present in the infant, and growth of the virus in cell culture is markedly different.[476,479] Immunofluorescence testing of vesicular lesions with commercially available specific monoclonal antibodies will rapidly differentiate the two.

Varicella-zoster immunoglobulin (Vari-ZIG) should be administered as soon as possible after birth to a neonate born to a mother with an onset of chickenpox rash between 5 days before delivery and 2 days after delivery.[512] If Vari-ZIG is not available, some experts recommend IGIV, intravenous acyclovir, or both in combination, as an effective alternative.[297] Breakthrough varicella has occurred in neonates properly treated with Var-ZIG, however.[46] Therefore, these infants still must be considered potentially infective and isolated with airborne precautions in a negative-pressure room for 16 days after maternal onset of rash because the incubation period with in utero exposure is decreased. If the newborn is exposed to maternal varicella at delivery, airborne precautions are extended until 21 days after exposure (28 days when Vari-ZIG is given) if hospitalization is required. Exposed infants do not need to be separated from their mothers; on the contrary, rooming-in may be a preferable alternative. If breakthrough neonatal varicella occurs despite Vari-ZIG immunoprophylaxis and the neonatal varicella appears to be becoming severe (extensive skin lesions, high fever and toxicity, hepatitis, pneumonitis), treatment with intravenous acyclovir at 1500 mg/m^2/day or 45 mg/kg/day divided every 8 hours should be administered.[575]

Infants born to mothers with zoster do not require Vari-ZIG immunoprophylaxis because they already have high levels of transplacentally acquired maternal VZV IgG antibody. No special precautions are indicated except that the maternal lesions should be covered and good handwashing when handling the infant must be stressed.

ZOSTER IN INFANCY AND CHILDHOOD

Epidemiologic and serologic evidence indicates zoster is a reactivated infection with VZV.[240,476] Persons with zoster, therefore, have had a previous episode of chickenpox. The vast majority of zoster occurs in older adult patients. The occurrence of zoster in infants and children is somewhat of a paradox because many of these patients have a negative history of having had chickenpox.[103,243,408] However, with several of these cases of childhood zoster, particularly those occurring in infants and young children, the mother had a history of chickenpox during pregnancy.[103,214,240,390] The presumption is that fetal VZV infection occurred, with recovery and no evidence of disease in the neonate at birth. In a few other instances, an infant born to a VZV-immune mother may be exposed to chickenpox or zoster during early life at a time when maternal transplacental antibody still would be present. This passive antibody could provide protection against chickenpox and modify the disease to a subclinical or mild form that was not recognized.[224] Both situations could result in a patient with (1) an unrecognized episode of varicella and (2) the occurrence of zoster as the first overt manifestation of VZV infection.

The major disease in the differential diagnosis of neonatal varicella is HSV infection. Patients with neonatal herpes may have a clinical picture resembling that of zoster,[442] and laboratory evaluation is required to differentiate the two diseases.

HUMAN PARVOVIRUS B19 (*ERYTHROVIRUS*)

Human parvovirus B19 *(Erythrovirus)* is a small, single-stranded DNA virus with two viral capsid proteins, VP1 and VP2.[175] It is the cause of erythema infectiosum, or fifth disease, a mild exanthematous illness in school-aged children.[32] Parvovirus B19 infection in pregnant women is associated with spontaneous abortion, stillbirth, and nonimmune hydrops fetalis secondary to transplacental passage of the virus.[30,338,342,345,578,638,648,661,683] A summary of 22 published case reports of parvovirus fetal infection revealed that (1) only half the mothers had parvovirus-like clinical illness 4 to 13 weeks before fetal death; (2) all fetuses had hydrops fetalis and probable myocarditis; and (3) 19 died in utero at 16 to 26 weeks, and the remaining 3 died within 24 hours of delivery.[26] Laboratory evidence of parvovirus infection includes (1) maternal parvovirus IgM antibody, (2) elevated maternal alpha-fetoprotein, and (3) the presence of parvovirus DNA in amniotic fluid.[32,638,639] Maternal blood also may contain high titers of parvovirus DNA that is detectable by PCR assays. Persistent parvovirus B19 DNA-emia often occurs, and supplementary measurement of VP1 IgG avidity and VP2 IgG epitope-type specificity may be helpful in timing the infection in some cases.[214]

Hydrops fetalis occurs from replication of parvovirus in the fetal bone marrow and resultant profound fetal anemia, with myocarditis playing a potential secondary role.[32,174] Fortunately, not all pregnancies complicated by parvovirus infection result in fetal infection, and hydrops does not develop in all infected fetuses. A British study of 186 pregnant women who had parvovirus IgM antibody and were monitored to term demonstrated that fetal loss occurred in 16 percent (no data on fetal loss rates in a control population) and that 43 percent of 14 fetal tissues tested showed parvovirus DNA.[112,514] Extrapolation from these figures yielded a maximal parvovirus-associated adverse fetal outcome of 7 percent in pregnancies with laboratory-proven parvovirus infection. Extrapolation to the community level yielded the following estimates of fetal death in a pregnant woman exposed to active parvovirus infection: 1.8 percent with home exposure and 1.1 percent or less with school exposure.[112,514] Figures used in this estimate are 7 percent fetal death rate with documented maternal infection cited earlier. Furthermore, only approximately 50 percent of women of child-bearing age are seronegative and, therefore, susceptible, and infection rates after exposure to parvovirus infection are 50 percent in the home and 30 percent with a *widespread* school outbreak. More recent studies have indicated a total fetal infection rate of 25 to 50 percent, but an adverse fetal outcome rate of less than 1 to 2 percent.[247,343,-345,648] Overall, after an acute parvovirus B19 infection during pregnancy, the vertical transmission rate is

approximately 30 to 50 percent, the risk of fetal death is between 2 and 6 percent, and most infected newborns are asymptomatic. In addition, maternal parvovirus B19 infection during pregnancy has not been associated with congenital anomalies. CNS abnormalities, however, have been reported in a few infants with in utero infection.[150] Abnormalities consisted of cerebral atrophy, ventricular enlargement, basal ganglia and periventricular calcifications, and diffuse cortical dysplasia, with hypotonia and later development of cerebral palsy and developmental delay. These findings could be secondary to parvovirus infection of the fetal brain; alternatively, they could be a result of the profound anemia that can occur in the fetus.

Fetal infection is diagnosed best by demonstration of parvovirus B19 DNA in amniotic fluid or determination of parvovirus B19 IgM antibody and DNA levels in fetal blood obtained by cordocentesis. Presence and severity of fetal anemia and thrombocytopenia also can be determined and corrected by intrauterine fetal transfusions into the fetal vein.[162,552] Mild or asymptomatic fetal infections may be managed conservatively with weekly fetal ultrasound examinations because some cases resolve without fetal interventions.[316] Fetal hydrops is readily detectable and monitored by antenatal ultrasound.[661]

In the neonate, detection of virus in blood and CSF can document parvovirus B19 infection. Assays for detection of human parvovirus B19 IgG and IgM antibodies are available commercially. Many infected newborns lack specific parvovirus IgM antibody at birth but will demonstrate persistence of parvovirus B19 IgG antibody beyond infancy, thus documenting infection.

No specific therapy is available. Intravenous immunoglobulin therapy has suppressed or controlled parvovirus-associated chronic anemia in immunosuppressed patients,[233] although no evidence indicates that it would be beneficial in pregnant women with parvovirus infection. Intrauterine transfusions have been used in cases of fetal hydrops associated with severe anemia, although some cases of hydrops resolve spontaneously.

Recent studies on the long-term neurodevelopmental outcome of infants after fetal transfusions for non-immune hydrops associated with parvovirus B19 infection show normal or near normal development in most survivors, supporting the use of intrauterine transfusions for correction of severe anemia and hydrops associated with this intrauterine infection.[177,445] Because some infants have experienced neurodevelopmental disabilities, some experts suggest that parvovirus B19 possibly may invade the fetal and neonatal CNS and produce neurodevelopmental sequelae. However, further studies are necessary to investigate this hypothesis.

Prevention consists largely of the rational use of infection control measures, including handwashing and disposal of used facial tissues. To isolate or quarantine otherwise normal children who have the rash of erythema infectiosum makes no sense because viral shedding has ceased by the time that the rash appears.[32] On the other hand, hemoglobinopathy patients with parvovirus-induced aplastic crisis or immunosuppressed patients with parvovirus-associated chronic anemia are highly infectious,[69] so droplet precautions should be instituted.

LYMPHOCYTIC CHORIOMENINGITIS VIRUS

LCMV is an RNA virus and a member of the Arenaviridae family. It causes a chronic infection with virus excretion in rodents, but it also may infect humans worldwide, especially in Europe, Africa, and the Americas. LCMV most commonly causes a nonspecific febrile illness, aseptic meningitis, or encephalitis. In adults, it also has been associated with nonbacterial orchitis, parotitis, and sudden-onset deafness. On rare occasion, congenital infection and disease have been documented.[55] The incidence of congenital infection with this virus, however, has not been studied systematically, and some experts suggest that it may be under-recognized as a pathogen of the fetus and newborn.[55,79,417,689,700] Congenital infection with LCMV appears to be a common cause of ocular abnormalities such as chorioretinitis, chorioretinal scars, and optic atrophy. Rarely, microphthalmos and cataracts have been observed. Other neurologic abnormalities noted at birth include microcephaly, hydrocephalus, abnormal corpus callosum, cerebellar hypoplasia, porencephalic cysts, and periventricular calcifications. Sequelae such as cognitive delays, major motor disabilities, ataxia, seizures, and vision loss have been seen in these infants. In contrast to other congenital viral infections, signs such as hydrops, hepatosplenomegaly, skin lesions, thrombocytopenia, and hearing loss are uncommon findings in children born with congenital LCMV infection.

The diagnosis of congenital LCMV infection should be suspected in an infant who appears to have a congenital viral infection or congenital toxoplasmosis, but the routine laboratory evaluation for the usual "TORCH" agents does not identify one of these infections. Supporting evidence for congenital LCMV infection includes a mother with prenatal exposure to wild, pet, or laboratory rodents such as mice, hamsters, or gerbils. The laboratory diagnosis of LCMV most commonly is established serologically, and detection of LCMV-specific IgG and IgM antibodies in serum or CSF supports the diagnosis. Detection of the virus by culture or RT-PCR–based methods is also available in reference laboratories. The virus also has been isolated from the CSF of an infant with congenital LCMV.[555] Currently, management is supportive because antiviral therapy has not been evaluated in clinical trials. Prevention of congenital LCMV infection includes minimizing exposure of pregnant women to rodents in the home and workplace.

ADENOVIRUSES

Adenoviruses are DNA viruses and common respiratory and gastrointestinal pathogens of children and adults. Fetal infection with adenovirus has been diagnosed by detection of viral DNA by PCR in amniotic fluid and has been associated with intrauterine myocarditis, fetal tachyarrhythmia, and non-immune hydrops fetalis.[56,140,520,641] Echogenic liver lesions and CNS anomalies also have been described in association with detection of adenovirus DNA in amniotic fluid and fetal tissues. Postnatal adenovirus infections in both term and preterm neonates also occur and may cause keratoconjunctivitis, as well as severe multisystem disease involving the liver, lungs, and brain.[1,72,500] Fatalities are most often associated with prematurity and pneumonitis.[1,92,218,474,625] The virus is transmitted easily in the health care setting and by ophthalmologic instruments, and it can cause outbreaks in neonatal intensive and special care units.[218,226,500]

Diagnosis is established by isolation of adenovirus from blood, CSF, conjunctival swabs, stool or urine specimens, and oropharyngeal or respiratory secretions. Tissue obtained by biopsy or autopsy also may reveal adenoviruses by culture or adenovirus particles by electron microscopy.[474] Histopathology may show smudge cells in lung tissue, and virus-specific immunohistochemical staining may reveal adenovirus antigens in tissue. Direct detection of adenovirus antigen in clinical specimens using rapid immunochromatographic assays or direct immunofluorescence assays can support the diagnosis.[497] Detection and quantification of viral DNA using PCR assays also can provide laboratory diagnosis.[641] Treatment is primarily supportive, and neonates with severe necrotizing pneumonitis may require mechanical ventilation or extracorporeal membrane oxygenation. The antivirals cidofovir and ribavirin have activity against adenoviruses and both have been used to treat severe disseminated adenovirus disease. Neonates with suspected or proven adenovirus infection should be isolated and all ophthalmologic instruments thoroughly

disinfected to prevent health care–associated transmission of the virus.[72,226]

RESPIRATORY VIRUSES—RESPIRATORY SYNCYTIAL VIRUS, INFLUENZA VIRUSES, PARAINFLUENZA VIRUSES, CORONAVIRUSES, HUMAN METAPNEUMOVIRUS

The RNA viruses; influenza A and B viruses (Orthomyxoviridae family), as well as RSV; the parainfluenza viruses types 1, 2, 3, and 4 (Paramyxoviridae family); coronaviruses; and human metapneumovirus are common seasonal winter respiratory pathogens in children and adults. These viruses also may infect neonates, who present with upper or lower respiratory signs and symptoms, or sepsis syndrome. These viruses also may cause health care–associated outbreaks in special care units with cases of serious, even fatal, pneumonia in this special age group.[236,237,315,432,441,583,587,701] Coronavirus, RSV, and influenza A virus appear most frequently, followed by influenza B virus and parainfluenza virus type 3. Neonatal infections with human metapneumovirus and parainfluenza viruses 1, 2, and 4 are less well documented. An outbreak of parainfluenza virus type 3 in an intermediate care nursery was associated with upper respiratory symptoms (nasal discharge and cough), as well as lower respiratory illness, including pneumonia and oxygen requirement. No ventilatory support or fatalities, however, occurred. The outbreak was contained with institution of barrier isolation, reinforcement of hand washing, and temporary closure of the special care unit.[432] Influenza A virus also has been associated with an outbreak in a neonatal intensive care unit.[439] Rapid diagnostic techniques helped identify infected infants, and reinforcement of infection control measures limited the outbreak. Amantadine resistance also was documented in influenza virus isolated from one treated neonate. Term and preterm neonates, especially those infants with chronic lung disease or congenital heart disease, may experience severe or fatal disease with community or health care–acquired RSV infection.[584] More recently, coronaviruses and human metapneumoviruses have been identified as causes of acute illness in neonates, especially premature infants.[236,237,587] Outbreaks of coronavirus infection in neonatal intensive care units also have been documented. Symptoms and signs in infected neonates at presentation included fever, bradycardia, apnea, hypoxemia, and abdominal distension, and chest radiographics showed diffuse pneumonitis.[587] Respiratory viral pathogens should be considered in the differential diagnosis of neonates with fever, apnea, bradycardia, sepsis syndrome, or pneumonitis in whom bacterial and fungal cultures are negative. Rapid diagnostic techniques that detect viral antigens by immunochromatographic assays that provide results within minutes, DFAs that provide same-day diagnosis, and viral culture and viral RNA detection using PCR-based methods are now routinely available and should be used for laboratory diagnosis and confirmation of viral respiratory pathogens in high-risk neonates. Antiviral therapy may be considered in selected neonates with severe respiratory viral disease. The long-term impact on pulmonary function in neonates, both term and preterm, infected with any of these viral pathogens requires further study and investigation.

ARBOVIRUSES

West Nile virus, a single-stranded RNA flavivirus, has caused severe disease in pregnant women. West Nile virus infection in pregnancy has been associated with spontaneous abortion, as well as congenital and neonatal infection.[645] Transmission of West Nile virus appears to occur in less than 5 percent of neonates born to women with West Nile virus infection during pregnancy. Most of these neonatal infections appear asymptomatic. However, congenital abnormalities, including chorioretinitis and CNS abnormalities, have been described in neonates with laboratory evidence of congenital in utero infection with West Nile virus. Possible perinatal transmission of West Nile virus to a neonate through breast milk also has been reported. Neonates with West Nile virus infection may present with fever and encephalitis and may have severe or even fatal illness.[125,126] Neonatal infection with St. Louis encephalitis virus also has been documented in a 19-day-old neonate who presented with fever and seizures.[688] If arbovirus infection, especially West Nile virus infection, is documented during pregnancy, the fetus should be assessed with ultrasound imaging. Fetal infection may be documented by presence of virus-specific IgM in fetal blood obtained by cordocentesis. At delivery, the umbilical cord and placenta may be examined for evidence of virus infection. The infant should be followed for evidence of neurodevelopmental and sensory disabilities, and repeat serologic testing with virus specific IgG and IgM should be performed at 6 months of age, to confirm whether or not infection had occurred. No specific antiviral therapies are available at this time, and studies on the long-term neurodevelopmental outcome of these infants are necessary.

CHAPTER 74

Chlamydia trachomatis Infections in the Neonate

Margaret R. Hammerschlag

HISTORY

At the beginning of the 20th century, before expectant mothers began being screened for sexually transmitted diseases (STDs), the term *ophthalmia neonatorum* was, for all practical purposes, synonymous with gonococcal conjunctivitis. As neonatal conjunctivitis came under control with silver nitrate prophylaxis, the importance of another form of ophthalmia neonatorum, *inclusion blennorrhea*, was noted. The relationship between maternal genital infection and conjunctivitis of the newborn associated with inclusion bodies within epithelial cells was established by Lindner, Halberstader, Von Prowazek, and others.[10,29] Respiratory infection in infants caused by *Chlamydia trachomatis* probably was reported first in 1941 by Botsztejn,[5] who described an entity that he called *pertussoid eosinophilic pneumonia*.

EPIDEMIOLOGY

C. trachomatis is the most common sexually transmitted pathogen in the United States.[6] The rate of cervical infection with *C. trachomatis* during pregnancy varies from 1 to 37 percent, with the highest rates occurring in women aged 25 years and younger. *C. trachomatis* infection is acquired by the infant from the mother during parturition, as demonstrated in a number of well-controlled prospective studies conducted in the 1970s and 1980s of maternal-infant infection in which infection occurred only in infants born to infected mothers.[11,13,27] No convincing evidence demonstrates horizontal transmission from mother to infant, from other family members to the infant, or from infant to infant after delivery. Infection after cesarean delivery, usually associated with rupture of the membranes, or infection through intact membranes is a rare event but may occur.[3] The overall risk of an infant born to a mother with active chlamydial infection becoming infected at any anatomic site has been reported to be approximately 50 to 75 percent in various studies (Table 74–1).[11,13,27] Infants can be infected at more than one site, including the conjunctiva, nasopharynx, rectum, and vagina. The most frequent clinical manifestation of neonatal chlamydial infection, inclusion conjunctivitis, has been reported to occur in 15 to 37 percent of infants born to mothers with untreated cervical chlamydial infection.[11-13,27] The most frequent site of infection, however, is the nasopharynx, with 78 percent of infected infants having positive nasopharyngeal cultures in one study.[12] Approximately half of infants with inclusion conjunctivitis also will be infected in the nasopharynx. In only a minority of infants with nasopharyngeal

TABLE 74–1 Selected Studies of Perinatal Chlamydial Infection

	Prevalence of Maternal Genital Infection		Proportion of Infants with Chlamydial Infection Born to Infected Mothers				
Author, Year, City	Total	No. Infected (%)	Total	Conjunctivitis (%)	Pneumonia (%)	NP (%)	Rectum/Vagina (%)
Frommell et al., 1979, Denver[11]	340	30 (8.8)	67	39	11	6	NS
Schachter et al., 1986, San Francisco[27]	5531	262 (4.7)	131	17.6	16	11.5	14
Hammerschlag et al., 1989, Brooklyn[13]	4357	341 (7.8)	45	15	1	4	NS

NP, nasopharynx; NS, not studied.

infection does chlamydial pneumonia eventually develop; Hammerschlag and colleagues found that pneumonia subsequently developed in only 4 of 12 (33%) infants with isolated nasopharyngeal infection.[12] The overall risk of pneumonia developing in infants born to chlamydia-positive mothers has been reported to range from 1 to 22 percent.[11,13,27]

Data on the risk of acquiring rectal or vaginal infection are more limited. Bell and colleagues[4] demonstrated that perinatally acquired *C. trachomatis* infection may persist for months to years. Twenty-two infants born to women with culture-documented chlamydial infection were monitored, and positive cultures from the nasopharynx and oropharynx in the infants were detected as late as 28.5 months after birth. Rectal and vaginal infections were asymptomatic and persisted for at least 1 year, which can become an important confounding variable when young children are tested for the presence of *C. trachomatis* during evaluation for suspected sexual abuse.

CONJUNCTIVITIS

C. trachomatis was the most frequent identifiable infectious cause of neonatal conjunctivitis, and conjunctivitis was the major clinical manifestation of neonatal chlamydial infection in the United States in the 1990s.[11,13,27] The introduction of systematic screening and treatment of pregnant women has resulted in a dramatic decrease in the number of perinatal chlamydial infections. However, in countries in which pregnant women are not screened routinely, including many developing countries, *C. trachomatis* remains the most frequent cause of neonatal conjunctivitis.[10-12] The incubation period of *C. trachomatis* conjunctivitis is 5 to 14 days after delivery—or earlier if premature rupture of membranes has occurred. At least 50 percent of infants with chlamydial conjunctivitis also will have nasopharyngeal infection. The manifestation is extremely variable and ranges from mild conjunctivitis with scant mucoid discharge to severe conjunctivitis with copious purulent discharge, chemosis, and pseudomembrane formation. The conjunctiva can be very friable and may bleed when stroked with a swab. Eyelid erythema and edema frequently are present. A Gram-stained conjunctival smear initially may reveal a predominance of polymorphonuclear leukocytes. Chlamydial conjunctivitis needs to be differentiated from gonococcal ophthalmia in some infants, especially those born to mothers who did not receive any prenatal care, had gonorrhea during pregnancy, or abused drugs. An overlap in both incubation periods and clinical findings can occur. Bilateral infections are present in two thirds of cases. A follicular reaction is not seen because infants younger than 3 months old do not have the requisite lymphoid tissue present in the conjunctiva. Though an uncommon finding, chlamydial neonatal conjunctivitis has been noted to induce the long-term sequelae of corneal neovascularization and scarring. However, Hammerschlag and colleagues[12] did not detect micropannus at 1 year of age in seven infants who had culture-documented neonatal *C. trachomatis* conjunctivitis.

PNEUMONIA

As stated previously, approximately 70 percent of infected infants will have positive nasopharyngeal cultures, but the majority of these infections are asymptomatic. Chlamydial pneumonia develops in only approximately 30 percent of infants with nasopharyngeal infection.[12] In infants in whom pneumonia does develop, the manifestations and clinical findings are very characteristic.[1,17,30] The children usually are seen initially when they are between the ages of 4 and 12 weeks. A few cases have been reported in infants as young as 2 weeks of age, but no cases have been seen in infants older than 4 months. The infants frequently have a history of cough and congestion with an absence of fever. On physical examination, the infant is tachypneic, and rales are heard on auscultation of the chest; wheezing is a distinctly uncommon finding.[1,17,20] No specific radiographic findings except hyperinflation are found (Fig. 74–1). Significant laboratory findings include peripheral eosinophilia (>300 cells/cm^3) and elevated serum immunoglobulins. If cultures are performed, infants with *C. trachomatis* pneumonia may remain symptomatic and shed the organism from the nasopharynx for protracted periods.[4,12] Generally, infantile pneumonia caused by *C. trachomatis* appears to be self-limited. Most infants can be managed as outpatients, although a few cases of severe disease requiring hospitalization and assisted ventilation have been reported. *C. trachomatis* pneumonia in infants also appears to be associated with few sequelae, although data are limited. Rarely, infants with *C. trachomatis* pneumonia may have concomitant otitis media.[30]

Figure 74–1 Anteroposterior chest radiograph of a severely ill 1-month-old male infant with chlamydial pneumonitis. Diffuse interstitial infiltrates and hyperaeration with a flattened diaphragm are prominent.

DIAGNOSIS

The diagnosis of neonatal conjunctivitis cannot be made on clinical grounds alone. Significant overlap in both incubation period and clinical findings occurs with infections by other organisms, especially *Neisseria gonorrhoeae*. In a high-risk population, particularly infants born to women with no prenatal care, gonococcal ophthalmia must be considered seriously.[13] The incubation period for gonococcal conjunctivitis is usually 3 to 5 days, but it can be longer. The incubation period for chlamydial conjunctivitis is approximately 5 to 14 days. Most cases will be evident by the time that the infant is 2 weeks of age, which is after the infant leaves the hospital. Epidemiologic clues can help the physician decide whether gonococcal ophthalmia needs to be considered. Hammerschlag and colleagues[13] noted that seven of the eight infants with gonococcal conjunctivitis were born to mothers who had not received any prenatal care. Five of these women were

abusers of crack cocaine. Another epidemiologic clue is a history of gonorrhea or other STD during pregnancy.

The clinical manifestation of *C. trachomatis* pneumonitis in infants is fairly characteristic, and one may be able to establish a clinical diagnosis with a degree of certainty.

LABORATORY DIAGNOSIS OF *C. TRACHOMATIS* INFECTION IN INFANTS

The "gold standard" for diagnosis of *C. trachomatis* infection in infants and children remains isolation of *C. trachomatis* by culture from the conjunctiva, nasopharynx, vagina, or rectum. *C. trachomatis* culture has been defined further by the Centers for Disease Control and Prevention (CDC) as isolation of the organism in tissue culture and confirmation by microscopic identification of the characteristic inclusions, preferably by staining with a fluorescein-conjugated, species-specific monoclonal antibody.[6] Enzyme immunoassays (EIAs) have been used by some commercial laboratories as a "screen" for culture confirmation; however, use of EIAs for confirmation of culture results has been associated with a significant number of false-positive results, especially with rectal and vaginal specimens.[7] The CDC has stated strongly that the use of EIAs for this indication is not acceptable.[7] Several nonculture tests, specifically EIAs and direct fluorescent antibody (DFA) tests, have been approved for the diagnosis of chlamydial conjunctivitis in infants. The only EIA and DFA tests still available in the United States are the Pathfinder Chlamydia DFA and EIA Microplate (Bio-Rad Laboratories). These tests appear to perform well with conjunctival specimens, and sensitivities of 90 percent or greater and specificities of 95 percent or greater in comparison to culture have been achieved.[15,24] Unfortunately, their performance with nasopharyngeal specimens has not been as good, with sensitivities ranging from 33 to higher than 90 percent.[15,24] The DNA probe Pace II (GenProbe, San Diego, CA), which is still used in many laboratories, does not have approval for any site in children, including the conjunctiva.

There are currently three Food and Drug Administration (FDA)-approved, commercially available nucleic acid amplification tests (NAATs) for the diagnosis of *C. trachomatis* infection: polymerase chain reaction (PCR) (Amplicor; Roche Molecular Diagnostics, Nutley, NJ), strand displacement amplification (SDA) (ProbeTec; Becton Dickson, Sparks, MD), and transcription-mediated amplification (TMA) (GenProbe). These assays currently have FDA approval for cervical swabs from women, urethral swabs from men, and urine from men and women. Preliminary data suggest that PCR is equivalent to culture for detection of *C. trachomatis* in the conjunctiva and nasopharynx of infants with conjunctivitis.[16] Hammerschlag and associates evaluated Amplicor for the detection of *C. trachomatis* in ocular and nasopharyngeal specimens from 75 infants with suspected chlamydial conjunctivitis.[16] Amplicor was equivalent to culture for eye specimens, with a sensitivity and specificity of 92.3 and 100 percent, respectively. The sensitivity and specificity for nasopharyngeal specimens were 100 and 97.2 percent, respectively. PCR also detected *C. trachomatis* in the urine of 12 of 12 mothers of culture-positive infants.

TREATMENT OF CHLAMYDIAL CONJUNCTIVITIS AND PNEUMONIA IN INFANTS

Oral erythromycin suspension (ethylsuccinate or stearate) (50 mg/kg/day for 14 days) is the therapy of choice for the treatment of chlamydial conjunctivitis and pneumonia in infants.[2,7] It provides better and faster resolution of the conjunctivitis, in addition to treating any concurrent nasopharyngeal infection, which prevents the development of pneumonia. Additional topical therapy is not needed. The efficacy of this regimen has been reported to range from 80 to 90 percent; however, as many as 20 percent of infants may require another course of therapy.[7,12] Erythromycin given at the same dose for 2 weeks is the treatment of choice for pneumonia and does result in clinical improvement, as well as elimination of the organism from the respiratory tract.

Treatment with oral erythromycin has been associated with hypertrophic pyloric stenosis in infants younger than 6 weeks old who were given the drug for prophylaxis after nursery exposure to pertussis.[9,18] Erythromycin is a motilin receptor agonist. Data on the use of other macrolides, including azithromycin or clarithromycin, for the treatment of neonatal chlamydial infection are limited. No studies of clarithromycin have been published; only one small study evaluated azithromycin and found that a short course of azithromycin suspension (20 mg/kg/day orally, one dose daily for 3 days) was as effective as was 2 weeks of erythromycin for eradication of *C. trachomatis* from the conjunctivae and nasopharynx of infants with conjunctivitis.[14]

PREVENTION AND CONTROL STRATEGIES

Because *C. trachomatis* infections are transmitted vertically from mother to infant during delivery, several possible options for intervention exist. The results of several prospective studies of mother-to-infant transmission of *C. trachomatis* demonstrated that neonatal ocular prophylaxis with silver nitrate, erythromycin, and tetracycline ophthalmic ointment does not prevent the development of chlamydial conjunctivitis.[8,13,20] In 1989, Hammerschlag and colleagues[13] compared silver nitrate, erythromycin, and tetracycline as neonatal ocular prophylaxis in a large urban hospital in Brooklyn, New York. The prophylaxis preparations were given within 30 minutes of birth. Chlamydial conjunctivitis developed in 20 percent (15 of 76) of infants born to infected mothers who received silver nitrate drops, 14 percent (13 of 92) of those who received erythromycin, and 11 percent (7 of 62) of those who received tetracycline. There was no effect on the incidence of nasopharyngeal infection and pneumonia. A subsequent study from Taiwan compared silver nitrate, the two antibiotics, and no prophylaxis.[8] This study, in contrast to previous studies, did not specifically monitor infants born to women with culture-documented chlamydial infection but instead monitored all infants delivered during the period of the study—for 4 weeks or until conjunctivitis developed. Again, no difference occurred in the incidence of neonatal chlamydial conjunctivitis among the four groups. The incidence of chlamydial conjunctivitis in the tetracycline, erythromycin, silver nitrate, and no-prophylaxis groups was 1.3, 1.5, 1.7, and 1.6 percent, respectively. Diagnosis of *C. trachomatis* was by DFA rather than culture. No data were given on the prevalence of maternal infection with *C. trachomatis* or *N. gonorrhoeae*. Differences in the prevalence of maternal infection among the four groups could lead to different rates of *C. trachomatis* conjunctivitis in the infants that were unrelated to prophylaxis. Respiratory infection was not assessed. A similar study from a clinic in Kenya compared povidone-iodine, erythromycin ophthalmic ointment, and silver nitrate drops as neonatal ocular prophylaxis.[19] Povidone-iodine was selected because it has a broad antibacterial spectrum in vitro; it also is antiviral and very inexpensive in comparison to the other prophylaxis agents. As with the study from Taiwan, the pregnant women were not screened for *C. trachomatis* prenatally, and chlamydial conjunctivitis in the infants was diagnosed by DFA. Mothers were told to bring their infants back if conjunctivitis developed. Use of povidone-iodine appeared to result in a 50 percent reduction in *C. trachomatis* conjunctivitis in comparison to silver nitrate (5.5% versus 10.5% of infants) and an approximately 30 percent reduction in comparison to erythromycin

(7.4%). There was no difference in the proportions of infants in whom gonococcal ophthalmia developed. As a result of the structure of the study, one cannot be certain whether every infant in whom conjunctivitis developed returned to the clinic. Because the prevalence of chlamydial infection among the pregnant women in the population was unknown, the investigators did not know how many cases of chlamydial ophthalmia to expect. The CDC does not recommend the use of povidone-iodine because of subsequent data that suggest lower efficacy than antibiotics for prevention of gonococcal ophthalmia.[7] Silver nitrate drops no longer are manufactured in the United States. Another approach that has been considered is oral prophylaxis with erythromycin or azithromycin for infants born to mothers with untreated *C. trachomatis* infection.[25] However, several analyses have found this approach to be very expensive in comparison to watching and treating the infants when they become symptomatic. In addition, there is the issue of compliance, and no data exist on the efficacy of either oral erythromycin or azithromycin for prophylaxis.

The most effective method of control of perinatal *C. trachomatis* infection is screening and treatment of pregnant women. In the 1980s, McMillan and colleagues[22] and Schachter and coworkers[28] reported that treatment of pregnant women infected with *C. trachomatis* with erythromycin resulted in a dramatic decrease in chlamydial infection (conjunctivitis and nasopharyngeal infection) in their infants in comparison to infants born to untreated infected women. The introduction of NAATs for diagnosis and the use of well-tolerated antibiotic regimens, including amoxicillin and single-dose azithromycin, have increased the efficacy of prenatal screening and treatment. This approach has been validated by a dramatic decrease in perinatal chlamydial infection in the United States and persistence of these infections in countries in which screening and treatment of pregnant women are not standard practice, such as the Netherlands, India, and China.[21,23,26,31] Rours and colleagues[26] reported that from 1996 through 2001, *C. trachomatis* was responsible for 61 to 64 percent of cases of neonatal conjunctivitis seen in a large university-affiliated hospital in Rotterdam. Even though the rate of *C. trachomatis* infection among pregnant women in Rotterdam exceeded 5 percent, prenatal screening and treatment are not part of routine prenatal care in the Netherlands.

Reasons for failure of maternal treatment to prevent infantile chlamydial infection include poor compliance and reinfection from untreated or new sexual partners. Even with effective screening, some infected women will be missed, depending on the methods used. Additionally, some women do not seek prenatal care.

CHAPTER 75

Mycoplasma and *Ureaplasma* Infections of the Neonate

Vladana Milisavljevic ❂ James D. Cherry

Mycoplasmas are the smallest free-living microorganisms and are characterized by lack of a cell wall. *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *Ureaplasma parvum* are the genital mycoplasmas with clinical significance in neonatal disease.[26,62,164] The two *Ureaplasma* spp. were described previously as the two biovars of *Ureaplasma urealyticum*. Biovar 1 is now *U. parvum*, and biovar 2 is *U. urealyticum*.[70,91,92]

EPIDEMIOLOGY

M. hominis and *Ureaplasma* spp. are sexually transmitted organisms that colonize the urogenital tract of women at rates of 20 to 50 percent and 40 to 80 percent, respectively.[18,105,149] Colonization rates are similar in pregnant and nonpregnant women. High rates of colonization have been associated with younger age, lower socioeconomic status, sexual activity with multiple partners, black ethnicity, and use of oral contraceptives.

In general, cervicovaginal colonization with *Ureaplasma* spp. and *M. hominis* during pregnancy is not predictive of adverse outcomes such as premature delivery, low-birth-weight infants, and spontaneous abortion.[29,49,164] High-density genital ureaplasmal colonization, though, has been associated with chorioamnionitis and preterm delivery.[4] Both *Ureaplasma* spp. and *M. hominis* appear to be capable of invading the upper genital tract in a subpopulation of women, as evidenced by their isolation from the endometrium,[95] placenta,[47,94] and amniotic fluid.[21,25,28,51,65,76,152,173,174] *Ureaplasma* spp. have been associated strongly with histologic chorioamnionitis, postpartum fever, and endometritis.[10-12,23,28,29,143] *M. hominis* is a recognized cause of pelvic inflammatory disease, postpartum septicemia, and endometritis,[26,46,84,106,111] and it has been associated with surgical wound infection after cesarean delivery.[100,127] The role of these organisms in causing spontaneous abortion and premature birth, however, remains controversial and currently unproven.[48,164]

TRANSMISSION

Vertical transmission of *Ureaplasma* ssp. and *M. hominis* from a colonized mother to her newborn occurs in utero or during delivery.[6,8,63,132,164] The relative frequency of occurrence at each time point is not fully known. Acquisition of mycoplasmas by newborns can occur at the time of delivery through contact with a colonized birth canal, but they also have been found on the mucosal surfaces of newborns delivered by cesarean section performed before the onset of labor and rupture of amniotic membranes.[135,147] In utero transmission occurs either transplacentally by the hematogenous route or via an ascending intrauterine infection from a colonized maternal genital tract. Mycoplasmas have been isolated from maternal blood at the time of delivery and from umbilical cord blood, amniotic fluid, endometrium, chorioamnion, placenta, and aborted fetal tissue. Specific IgM antibody responses have been detected in neonatal serum. Postpartum or nosocomial transmission probably occurs, but definitive proof is lacking. The idea was suggested by the finding of ureaplasmal colonization in infants at 3 to 4 weeks of age who were not previously shown to be colonized with *Ureaplasma* spp. while in a neonatal intensive care unit (NICU).[135]

The rate of vertical transmission of *Ureaplasma* spp. ranges from 0.9 to 55 percent in full-term infants and 8.5 to 58 percent in preterm infants, depending on the number and type of mucosal surfaces sampled.[8,31,112,132,134,135,147] *M. hominis* has been isolated from the nasopharyngeal aspirates and gastric secretions of 30 to 42 percent[31,32] and 8 percent,[63] respectively, of infants born to colonized mothers. The rate of vertical transmission of *Ureaplasma* spp. is not affected by the method of delivery or the duration of time after rupture of membranes. Vertical transmission is increased significantly in the presence of chorioamnionitis and intraamniotic infection.[43,140] Colonization of newborn infants increases with decreasing gestational age and birth weight,[7] and it is highest in infants weighing less than 1000 g at birth.[135] Female newborns are more likely than are males to be colonized with *Ureaplasma* because the vagina is a common site of colonization.[52,134]

Colonization with *Ureaplasma* persists through early infancy; 68, 33, and 37 percent of full-term newborns colonized in the throat, eye, and vagina, respectively, are still colonized at 3 months of age.[147] However, most of them lose colonization by the time they reach 2 years of age.[52] Among preterm infants, 65 percent remain colonized at the time of discharge from the NICU or at 28 days of life.[135] Overall, the prevalence of ureaplasmal colonization varies from 2 to 86 percent among infants admitted to NICUs, and as many as 14 to 41 percent of infants have endotracheal aspirate cultures positive for *Ureaplasma* spp.[42,45,71,79,119,132]

CLINICAL MANIFESTATIONS

The roles of *Ureaplasma* spp. and *M. hominis* in neonatal disease continue to be investigated and defined. *M. hominis* and *Ureaplasma* spp. have been recovered from the lungs, brain, heart, and viscera of aborted fetuses and stillborn infants, with histologic findings of bronchopneumonia present in the lungs.[101,148] *Ureaplasma* spp. were isolated from blood in as many as 34 percent of infants younger than 34 weeks' gestational age.[117] Twenty-six percent of preterm infants had positive endotracheal aspirate cultures for *Ureaplasma* spp. in one study.[27] Genital mycoplasmas have been also isolated from the blood, urine, cerebrospinal fluid (CSF), and lung tissue of infants with clinical signs of infection. These organisms frequently colonize the mucosal surfaces of newborns,[88,134] and ascribing disease often is difficult. However, isolation from normally sterile body fluids in symptomatic infants has led to the recognition that these organisms are neonatal pathogens.

NEONATAL PNEUMONIA

Fatal neonatal pneumonia in a term infant was documented by isolation of *Ureaplasma* from lung tissue at autopsy, with demonstrated elevated serum IgG and IgM titers to the organism.[125] Afebrile pneumonitis was reported in infants younger than 3 months old.[144] Pneumonia and persistent pulmonary hypertension were documented in three infants from whom *Ureaplasma* spp. were isolated from blood, endotracheal aspirates, pleural fluid, or lung tissue (or any combination of these sites) at

autopsy.[161] Cultrera and colleagues[40] reported finding an association between colonization of the lower respiratory tract by *Ureaplasma* spp., particularly by *U. parvum* in preterm newborns, and respiratory distress syndrome. The potential role of *Ureaplasma* in neonatal pneumonia[19,54,60,120] has been strengthened by the demonstration of histologic evidence of pneumonia in the lungs of newborn mice and premature baboons; ureaplasmal isolates were obtained from the pleural fluid, lung biopsy specimens, and lung tissue of these experimental pneumonia models.[26,129,167] Crouse and associates[35] demonstrated that pneumonia is produced in newborn mice, but significantly less often in mice older than 14 days, and is potentiated by oxygen therapy. *Ureaplasma* spp. have been shown to induce ciliostasis and mucosal lesions in human fetal tracheal organ cultures.[26] In addition, *Ureaplasma* can induce the production of alveolar macrophage proinflammatory cytokines in vitro,[96] and both *Ureaplasma* spp. and *M. hominis* stimulate the production of tumor necrosis factor-α (TNF-α) and inducible nitric oxide synthase from murine macrophages.[36] Viscardi and colleagues[157] developed the first juvenile mouse model of *Ureaplasma* pneumonia. Their data suggest that *Ureaplasma* alone may cause limited inflammation and minimal tissue injury in the early phase of infection but may promote a mild chronic inflammatory response in the later phase of infection (days 14 to 28), similar to the process that occurs in human newborns. *M. hominis* also has been associated with pneumonia.[153]

CHRONIC LUNG DISEASE

Isolation of *Ureaplasma* spp. from endotracheal secretions, the nasopharynx, the throat, or gastric aspirates (or any combination of these sites) has been associated with chronic lung disease of prematurity. Development of chronic lung disease was described in low-birth-weight infants whose respiratory tracts were colonized with *Ureaplasma* spp. in the first week of life.*

The results from a meta-analysis performed by Wang and colleagues[172] involving 17 publications supported a significant association between ureaplasmal colonization and the subsequent development of chronic lung disease. Crouse and associates[37,38] noted that infants who weighed 1250 g or less at birth, had respiratory disease, and were colonized with *Ureaplasma* spp. in their tracheal secretions were more likely to have radiographic evidence of more severe pulmonary disease than were infants who were not colonized. These findings were not supported by studies of Cordero and colleagues,[33] who did not detect any specific radiographic abnormalities in 183 infants with a birth weight of 1250 g or less and who had endotracheal colonization with *Ureaplasma* spp., gram-negative cocci, or gram-negative bacilli. However, Ollikainen and associates[118] found that preterm infants colonized with *Ureaplasma* spp. had higher leukocyte counts on the first 2 days of life and that they required high-frequency oscillatory ventilation more often than did those not colonized. In addition, the isolation by Walsh and colleagues[168] of *Ureaplasma* spp. from the lungs of infants with chronic lung disease implies an invasive bacterial process as part of the pathogenesis of lung injury. In a retrospective study of 60 ventilated babies born at less than 30 weeks' gestation, 25 of whom were *Ureaplasma* culture–positive, Theilen and associates[151] found that the ventilated babies with *Ureaplasma* in their tracheal secretions had a different clinical and radiologic course than that of infants who were culture-negative. Specifically, they had less acute lung disease but an earlier onset of chronic lung disease.

In contrast to these studies, Heggie,[71] Da Silva,[42] and Couroucli[34] and their colleagues found no association between *Ureaplasma* and the development of bronchopulmonary dysplasia (BPD). Bowman and colleagues[16] used erythromycin to treat extremely-low-birth-weight infants colonized with *Ureaplasma* and found no association between the initial colonization and the development of chronic lung disease. They also called attention to the fact that in the study by Heggie and coworkers,[71] a substantial proportion of the colonized infants were treated with erythromycin, which might explain the lack of an association between colonization and subsequent chronic lung disease. In 1997, Van Waarde and associates[155] noted that preterm infants who were at the highest risk for the development of chronic lung disease (i.e., those with the lowest gestational age and birth weight) also were the ones most likely to be colonized with *Ureaplasma* spp. Castro-Alcaraz and coworkers[30] found that a persistently positive colonization pattern, which accounted for 45 percent of the *Ureaplasma*-positive infants, was associated with a significantly increased risk for the development of chronic lung disease.

One theory suggests that *Ureaplasma* is not the primary cause of BPD but that it might be the cause of undetected pneumonia.[24] This pneumonia results in an increased requirement for supplemental oxygen, and BPD is the result of oxygen toxicity caused by the supplemental oxygen therapy. Viscardi and associates,[156] using the preterm baboon model, suggested that a prolonged proinflammatory response initiated by intrauterine *Ureaplasma* infection contributed to the early development of fibrosis and altered developmental signaling in the immature lung.

The possibility that ureaplasmal colonization of the respiratory tract induces an inflammatory response without direct pulmonary invasion and infection cannot be excluded.[66,98] It has been supported by the finding of elevated levels of TNF-α, interleukin-6 (IL-6), IL-8, and monocyte chemoattractant protein-1 (MCP-1) in the tracheal secretions of colonized infants,[14,26,67,102,146] as well as by elevated white blood cell counts and eosinophilia in infants whose respiratory tract is colonized by *Ureaplasma* spp.[114,118,121] The contribution of *U. urealyticum* and *U. parvum* was evaluated by Heggie and colleagues.[71] Both species colonized preterm infants with a birth weight of less than 1500 g; however, no association was seen between endotracheal colonization with either species and the development of chronic lung disease. In a study performed by Katz and colleagues,[83] *U. parvum* was detected more often than was *U. urealyticum*, but they found no significant difference or trend in the prevalence of either species between infants with or without BPD.

In a meta-analysis, Schelonka and colleagues[137] reviewed 36 articles in which cohorts of neonates were screened for the presence of *Ureaplasma* by culture with or without polymerase chain reaction (PCR) and monitored prospectively for the development of BPD. They concluded that colonization with *Ureaplasma* was associated with higher reported rates of BPD. However, the greatest reported effect was seen in the small studies, and, therefore, reporting bias may be partially responsible for the higher rates of BPD in colonized infants.

NEONATAL CENTRAL NERVOUS SYSTEM INFECTIONS

Both *Ureaplasma* spp. and *M. hominis* have been isolated from the CSF of both full-term and preterm infants.* The repeated isolation of these organisms from the CSF of predominantly preterm infants with suspected meningitis and their association with a CSF pleocytosis consisting of polymorphonuclear or mononuclear cells, hypoglycorrhachia, and elevated protein content support their role in causing neonatal meningitis. Waites and

*See references 9, 56-58, 73, 74, 87, 103, 107, 109, 139, 141, 145, 154, 162, 165.

colleagues[165] noted hemiplegia, hydrocephalus, and developmental delay in survivors. Isolation of *Ureaplasma* spp. from the CSF of preterm infants also has been associated with severe intraventricular hemorrhage.[3,116,165] However, Likitnukul and associates[97] cultured the CSF and blood of 203 infants with suspected sepsis and failed to isolate *Ureaplasma* spp. Primarily in full-term infants, isolation of *Ureaplasma* spp. and *M. hominis* often has been associated with minimal if any CSF abnormalities, and these infants have done well without receiving specific antimicrobial therapy.[72,109,137,154,162] In such instances, the presence of these organisms remains of unclear clinical significance, and their role in producing disease is questionable.

SYSTEMIC INFECTIONS

Nonimmune hydrops fetalis was reported in a newborn at 32 weeks' gestation in whom *U. urealyticum* was isolated from bronchial secretions and lung and brain tissue at autopsy.[115] *M. hominis* has been associated with neonatal septicemia.[26,153]

OTHER INFECTIONS

Osteomyelitis of the femur was associated with isolation of *Ureaplasma* from the blood of a preterm infant.[59] *Ureaplasma* was recovered from a scalp abscess at the site of an internal fetal electrode monitor.[68] *M. hominis* infections have been noted in association with brain and scalp abscesses, ventriculitis, submandibular adenitis, abscesses of subcutaneous tissue, pericarditis, and conjuctivitis.[1,61,80,108,124,131] The clinical significance of isolation of genital mycoplasmas from urine obtained by suprapubic bladder aspiration in infants remains to be determined.[97] In such instances, analysis of urinary sediment has been normal.

DIAGNOSIS

Because of the frequent colonization of newborn infants with mycoplasmas, an etiologic role for these agents cannot be supported by detection of organisms on mucosal surfaces only. The diagnosis of mycoplasmal infection is made by isolating the organism from a normally sterile body fluid or suppurative focus. Genital mycoplasmas may be isolated on special broth and solid media that are available commercially. Shepard 10B broth and A8 agar have been used successfully for cultivation of both *Ureaplasma* spp. and *M. hominis*.[26] Cultures generally become positive within 2 to 5 days.

Cassell and colleagues[22,26] recommended that mucosal specimens be obtained with a Dacron or calcium alginate swab and be placed in a specific mycoplasmal transport medium such as Shepard 10B broth. Specimens should be refrigerated at 4°C until they are transported to the laboratory and be protected from drying. Alternatively, specimens in appropriate transport media can be frozen at –70°C because both *Ureaplasma* spp. and *M. hominis* are stable for long periods of time under these conditions. Specimens should be diluted serially in 10B broth to at least 10^{-3} (preferably to 10^{-5}) to overcome any potential inhibitory substances or metabolites, and an aliquot of the original sample and dilution should be plated directly onto A8 agar. Body fluids (e.g., blood, CSF, pleural fluid) should be inoculated into 10B broth in an approximate 1:10 ratio (usually 0.1 mL of fluid per 0.9 mL of 10B broth). Blood should be collected free of anticoagulants. Broth cultures and agar plates are incubated under 95 percent nitrogen and 5 percent carbon dioxide. The presence of mycoplasmal growth in 10B medium is indicated by a change in color from yellow to pink, which is caused by an alkaline shift in the media as a result of either the urease activity of ureaplasmas or arginine hydrolysis by *M. hominis*. Growth of mycoplasmas in broth culture as indicated by a change in color should be confirmed by inoculation of a broth specimen onto A8 agar. Characteristic colonies of *Ureaplasma* spp. and *M. hominis* can be identified readily on A8 agar after 24 to 72 hours of incubation.

Serologic tests have been used to measure antibody to genital mycoplasmas. Such tests include the metabolic inhibition assay, enzyme-linked immunosorbent assay, mycoplasmacidal test, indirect hemagglutination, indirect immunofluorescence, and IgG and IgM immunoblotting.[26,44,53,126] Use of these tests for establishing the diagnosis of mycoplasmal infection in infants remains problematic and is not well established. None is available commercially, and, therefore, diagnosis of newborns relies on culture results.

PCR assays involving the urease gene, 16S RNA genes, and the multiple-banded antigen genes have been used to detect *Ureaplasma* spp. in neonatal clinical specimens.* On endotracheal secretions, Blanchard and associates[15] reported finding a sensitivity of 100 percent and a specificity of 99 percent in comparison to culture. PCR assays using 16S rRNA and ribosomal DNA targets are available for *M. hominis*.[5,64,99] Ultimately, PCR may aid in identifying colonized or infected infants more readily (results available in 1 day) and reliably, given the fastidious nature of these organisms and the scarcity of microbiology laboratories that routinely perform mycoplasmal culture.

TREATMENT

The decision to treat an infant for possible mycoplasmal infection should be based on the clinical picture and culture results. In general, isolation of mycoplasmas from a normally sterile site in an ill neonate is an indication for consideration of treatment. However, no large randomized clinical trials have determined the efficacy of treatment in neonates. Experience on which to base treatment decisions, the choice of drug, and the duration of therapy is very limited.[171]

In a preterm infant with clinical evidence of sepsis or central nervous system disease in whom routine bacterial and viral cultures are sterile and the infant is not responding to antibacterial or antiviral therapy, the presence of mycoplasmal disease should be suspected and appropriate samples obtained for culture of mycoplasmas. Isolation of mycoplasmas from endotracheal secretions is not diagnostic of pneumonia, and most of these infants do not require any antimycoplasmal therapy. However, if pneumonia is suspected and the infant's clinical condition is deteriorating, a trial of therapy may be indicated despite the unknown efficacy of treatment.

Mycoplasmas are not susceptible to the antimicrobial agents routinely used to treat neonatal infections.[17,159,160,163] Because they lack a cell wall, mycoplasmas are insensitive to penicillins, cephalosporins, polymyxins, sulfonamides, and vancomycin. Although they may have moderate sensitivity to the aminoglycosides, the minimal inhibitory concentrations (MICs) of these agents for genital mycoplasmas usually are too high for therapeutic use. The drugs of choice for the treatment of infection caused by *M. hominis* are chloramphenicol, clindamycin, doxycycline, and tetracycline; for the treatment of ureaplasmal infections, erythromycin or other macrolides, doxycycline, tetracycline, and chloramphenicol are recommended.[89,104,159,166] When possible, antibiotic susceptibility testing should be performed on all clinically significant isolates because of the occurrence of multidrug resistance.

M. hominis is resistant to erythromycin, but in *Ureaplasma* spp., high-level resistance to erythromycin (MIC ≥ 32 mg/mL)

*See references 5, 6, 15, 41, 98, 99, 110, 128, 138, 150.

is found very infrequently. Cardiac toxicity consisting of acute cardiorespiratory deterioration possibly secondary to cardiac arrhythmias has been reported in neonates treated with intravenous erythromycin lactobionate for presumed ureaplasmal pneumonia.[50] Ototoxicity has been seen in adults but not in neonates.[39] Oral erythromycin has been associated with hypertrophic pyloric stenosis in infants younger than 6 weeks.[77] Although the exact duration of therapy is not known, a 10- to 14-day course seems reasonable when clinical improvement and microbiologic eradication are observed during that period.

Azithromycin and clarithromycin are active in vitro against *Ureaplasma* spp. but not *M. hominis*,[90,130,158] but their use in neonates has not been evaluated thoroughly. When given orally to very-low-birth-weight infants colonized with *Ureaplasma* spp., serum levels of clarithromycin at a dose of 7.5 mg/kg every 12 hours were subtherapeutic.[136] For this reason, a dose of 15 mg/kg every 12 hours is recommended.

PREVENTION

Erythromycin administered between 26 and 35 weeks' gestation to pregnant women colonized with *Ureaplasma* spp. was not effective in reducing adverse outcomes such as preterm delivery, low birth weight, or premature rupture of membranes.[49] In the ORACLE I study,[85] in which the use of broad-spectrum antibiotics was evaluated in mothers with premature rupture of membranes, use of erythromycin was associated with prolongation of pregnancy, reduction in neonatal treatment with surfactant, decrease in oxygen dependence at 28 days of age and older, fewer major cerebral abnormalities on ultrasonography before discharge, and fewer positive blood cultures. The ORACLE II study, which consisted of 6295 women with spontaneous preterm labor, intact membranes, and no evidence of clinical infection, showed that none of the trial antibiotics was associated with a lower rate of the composite primary outcome events than occurred in placebo recipients.[86] Because erythromycin therapy does not eliminate *Ureaplasma* spp. from the lower genital tract, it most likely also does not prevent neonatal ureaplasmal colonization.[113] Its effect on prevention of neonatal disease has not been evaluated fully.[13] Administration of erythromycin to preterm infants whose mothers had *Ureaplasma* spp. in their lower genital tract reduced respiratory tract colonization but did not decrease the duration of supplemental oxygen therapy[82] or chronic lung disease.[16,98] Treating very-low-birth-weight infants who have respiratory tract colonization with *Ureaplasma* spp. to prevent chronic lung disease cannot be recommended at present.[20]

CHAPTER 76

Yeast and Fungal Infections of the Fetus and Neonate

Gail J. Demmler-Harrison

The improved survival of preterm infants since the early 1980s has resulted in the emergence of yeasts and fungi as significant neonatal pathogens.* *Candida albicans* remains the most frequently isolated pathogenic yeast overall, but other *Candida* spp., especially *Candida parapsilosis* and *Candida tropicalis*, and less common pathogenic yeasts, such as *Malassezia*, *Trichosporon*, *Rhodotorula*, and *Pichia/Hansenula*, have increased in frequency. The incidence of invasive fungal disease, often with fatal outcomes, caused by *Aspergillus* and Zygomycetes (*Mucor*, *Rhizopus*, *Rhizomucor*, and *Absidia*) also has increased in neonates, especially infants who were born premature or with an inherited metabolic disorder or primary immunodeficiency.[309]

Reports about premature neonates with serious or fatal infection with rare, darkly pigmented fungi, such as *Phialemonium obovatum*, also have emerged more recently, perhaps heralding an increasing trend for unusual fungal infections in this special age group.[138] In addition, the rare vertical transmission of the endemic pathogenic yeast and fungi *Cryptococcus*, *Coccidioides*, and *Blastomyces* continues to be documented, especially in neonates born to mothers infected with human immunodeficiency virus (HIV).[67] Prompt recognition of pathogenic yeast or invasive fungal disease in neonates and institution of aggressive management that includes appropriate antifungal therapy and, when required, surgical intervention, are important to minimize rates of morbidity and mortality from these serious, often fatal, infections.

NEONATAL CANDIDIASIS

Candida spp. account for approximately 9 percent of all nosocomial infections in the neonatal intensive care unit (NICU). *Candida* spp. infect approximately 1 to 6 percent of infants with a birth weight less than 1500 g (very low birth weight [VLBW]) and 5 to 10 percent of infants with a birth weight less than 1000 g (extremely low birth weight [ELBW]).[177,292,295] The overall case-fatality rate is approximately 30 percent, with a range of 4 to 40 percent reported.[190,211,220,343,411] Neurodevelopmental disabilities also are more common findings in premature infants with invasive candidiasis.[98] In addition to excess mortality and disability rates, neonatal candidiasis is associated with increased length of hospitalizations and excess hospital costs.[343,411]

The species isolated most frequently is *C. albicans*,[27,28,37,41] which represents approximately 40 to 60 percent of isolates from neonates with systemic disease and is the most common *Candida* spp. associated with NICU outbreaks.[18,74,121,313] *Candida* spp. other than *C. albicans* have become increasingly more prevalent, however, and in some NICUs may be isolated more frequently than is *C. albicans*.[63,112,139,306] Among these organisms, *C. parapsilosis* is the most common,* followed by *C. tropicalis;*[124,303] both of them have caused outbreaks in NICUs. *Candida glabrata*,[26,112] *Candida guilliermondii*,[312,314,315] *Candida lusitaniae*,[316] and *Candida krusei*[133,304] also have caused invasive disease in neonates. Most recently, *Candida haemulonii*[193] has emerged as a neonatal pathogen and caused an outbreak in an NICU.[193] Manifestations of neonatal candidiasis range from commonly encountered benign oral and cutaneous candidiasis to systemic infection with candidemia to more severe and often fatal disseminated candidiasis.[27,28,31]

TRANSMISSION, PATHOGENESIS, AND RISK FACTORS

Candida transmitted to the fetus in utero by an ascending route from the colonized vagina of the mother results in

*See references 31, 37, 61, 149, 154, 161, 177, 332, 335, 341.

*See references 41, 85, 96, 113, 115, 166, 211, 218, 319, 373, 395, 405.

congenital candidiasis. Transplacental infection has not been described.[106,170,176,180,215,222] More frequently, vertical transmission to a newborn occurs during birth through the mother's colonized birth canal, which results in the development of oral candidiasis, or thrush, in an otherwise healthy infant.[10,27,65,76,306,382] *Candida* also may be acquired by the infant during breast-feeding if the mother's skin is colonized and from inadequate sterilization of feeding bottles and nipples.[113] Subsequent colonization of the gastrointestinal tract and the presence of *Candida* in stool lead to superficial cutaneous infection involving primarily the perineal area.[27]

Nosocomial transmission occurs and has resulted in nursery outbreaks. Even though *Candida* spp. have been detected on environmental surfaces and from the air samples of neonatal units, person-to-person transmission is the most important mode of transmission.[202,376,382] Horizontal transmission from health care worker to newborn with subsequent colonization of conjunctivae, mucosa, or skin and infant-to-infant transmission via the hands of health care workers have been documented in outbreak investigations that used molecular analysis of *Candida* isolates.* In addition, systemic candidiasis in ELBW infants has been linked to use of topical petrolatum ointment for skin care.[63]

Candidal colonization of the oropharynx of preterm neonates in NICUs is a common occurrence; it occurs in approximately 2.5 to 19 percent of infants in the first few days of life and increases with age and time in the NICU.[121,313] Subsequent colonization of the gastrointestinal tract and endotracheal tube in ventilated neonates seems to predispose them to development of invasive candidiasis.[27,310,314,315] Baley and colleagues[27] studied 146 infants with a birth weight less than 1500 g during an 11-month period. They performed fungal cultures of pharynx, rectum, and endotracheal aspirates within 24 hours of birth, and then weekly while the infants were in the NICU. The overall colonization rate was 27 percent; by 2 weeks of age, 85 percent of the infants were colonized with *Candida* spp. Mucocutaneous disease developed in 28 percent of the colonized infants, and systemic candidiasis was seen in 8 percent.

In high-risk neonates, gastrointestinal colonization also may lead to bloodstream dissemination, particularly if the integrity of the intestinal mucosal lining is disrupted by surgery, ischemia, or enterocolitis.[56,61,108,314,315] In addition, the immature skin of ELBW infants may predispose them to invasive candidal infection.[276,306] Gastrointestinal colonization with *Candida* occurs before the development of candidemia in most preterm infants.[314,315] In addition, Rowen and colleagues[310] showed that VLBW infants with endotracheal colonization by *Candida* had a sixfold increased risk for development of invasive disease.

The relationships among adhesion proteins, lymphocytes, and neutrophils may contribute to yeast pathogenicity in colonized neonates. The ability of *C. albicans* to invade oral and gastrointestinal mucosal tissues and enter the bloodstream may be a major determinant of virulence. In vitro studies of interaction of *C. albicans* with epithelial cells have shown that *C. albicans* invades mucosal tissues by promoting the proteolytic degradation of the junction adherin protein E-cadherin, allowing an increase in cell permeability.[129,160,379] Candidal dissemination in neonates is aided further by abnormal neonatal leukocyte function, as shown by an impaired ability of polymorphonuclear leukocytes to adhere to, ingest, and kill *Candida*, and a reduced capacity of lymphocytes to inhibit candidal growth.[331,357]

In addition, proteomic studies have begun decoding serologic responses to *Candida* cell wall proteins.[285,286] Antibodies made to *C. albicans* cell wall proteins, such as antiwall enolase antibodies, by survivors of systemic candidiasis may provide the basis for novel diagnostic and prognostic indicators and may be candidates for possible future vaccine development. More recently, *Candida* antigens identified by proteomic approaches were shown in murine models to induce protective responses, providing the basis for possible future human clinical vaccine trials.[286]

Risk factors for neonates colonized with *Candida* to progress to systemic infection include prematurity; VLBW and ELBW; prolonged endotracheal intubation with mechanical ventilation; bronchopulmonary dysplasia; indwelling intravenous catheters; prolonged administration of third-generation cephalosporin antibiotics, hyperalimentation solutions, H_2 blockers, and steroids; lack of enteral feedings; abdominal surgery; skin care practices; and early neutropenia.* Several risk factors consistently have been associated with systemic candidiasis, the most common being prematurity and VLBW and ELBW, with attendant impairment of host defense mechanisms; indwelling intravenous catheters; and prolonged use of broad-spectrum antimicrobial therapy, in particular, third-generation cephalosporins, which suppress normal gastrointestinal flora.[314,327,334] Although aminophylline is able to inhibit the activity of human granulocytes in vitro, its use has not been associated clinically with systemic candidiasis in neonates. Studies by Hostetter[37,160] suggested the use of heparin may be another predisposing factor; this in vitro finding also has not been confirmed in the clinical setting, however.

CLINICAL MANIFESTATIONS

ORAL CANDIDIASIS

Oral candidiasis is the most common form of infection with *Candida* spp.[242] Lesions on the mucous membranes of the mouth and oropharynx usually appear on the 7th to 10th day of life as whitish gray plaques that can be scraped easily from the mucosa to expose an erythematous base. Persistent or recurrent infection may be caused by the continued use of bottle nipples and pacifiers that harbor *Candida* on their surface. Primary and acquired immunodeficiency states, including infection with HIV, should be considered if oral thrush fails to clear with appropriate therapy.

CUTANEOUS CANDIDIASIS

Cutaneous candidiasis typically is manifested by erythematous, vesiculopustular lesions found primarily on the skin of the perineum, axilla, and intertriginous areas.[346] The periumbilical area also can be involved.[242] Benign diaper dermatitis with so-called satellite lesions is a frequent occurrence in an otherwise healthy infant, and the peak incidence occurs at 3 to 4 months of age. In VLBW and ELBW premature infants, seemingly benign mucocutaneous lesions, including lesions in the perineum or diaper area, may progress rapidly to invasive dermatitis, producing cutaneous scales, crusting, erosions, ulcerations, or extensive maceration of skin, and result in a potentially lethal systemic candidiasis (Fig. 76–1).[31,72,159,276,306] Scattered, faint, erythematous maculopapular lesions of the skin may be an expression of a serious disseminated candidiasis.[31,306,309] Chronic mucocutaneous candidiasis may be diagnosed in an otherwise well-appearing infant, if *Candida* infections of the skin, mucous membranes, and nails persist or recur, despite administration of antifungal therapy. These neonates have a congenital defect in T-lymphocyte function specific to *Candida* spp.

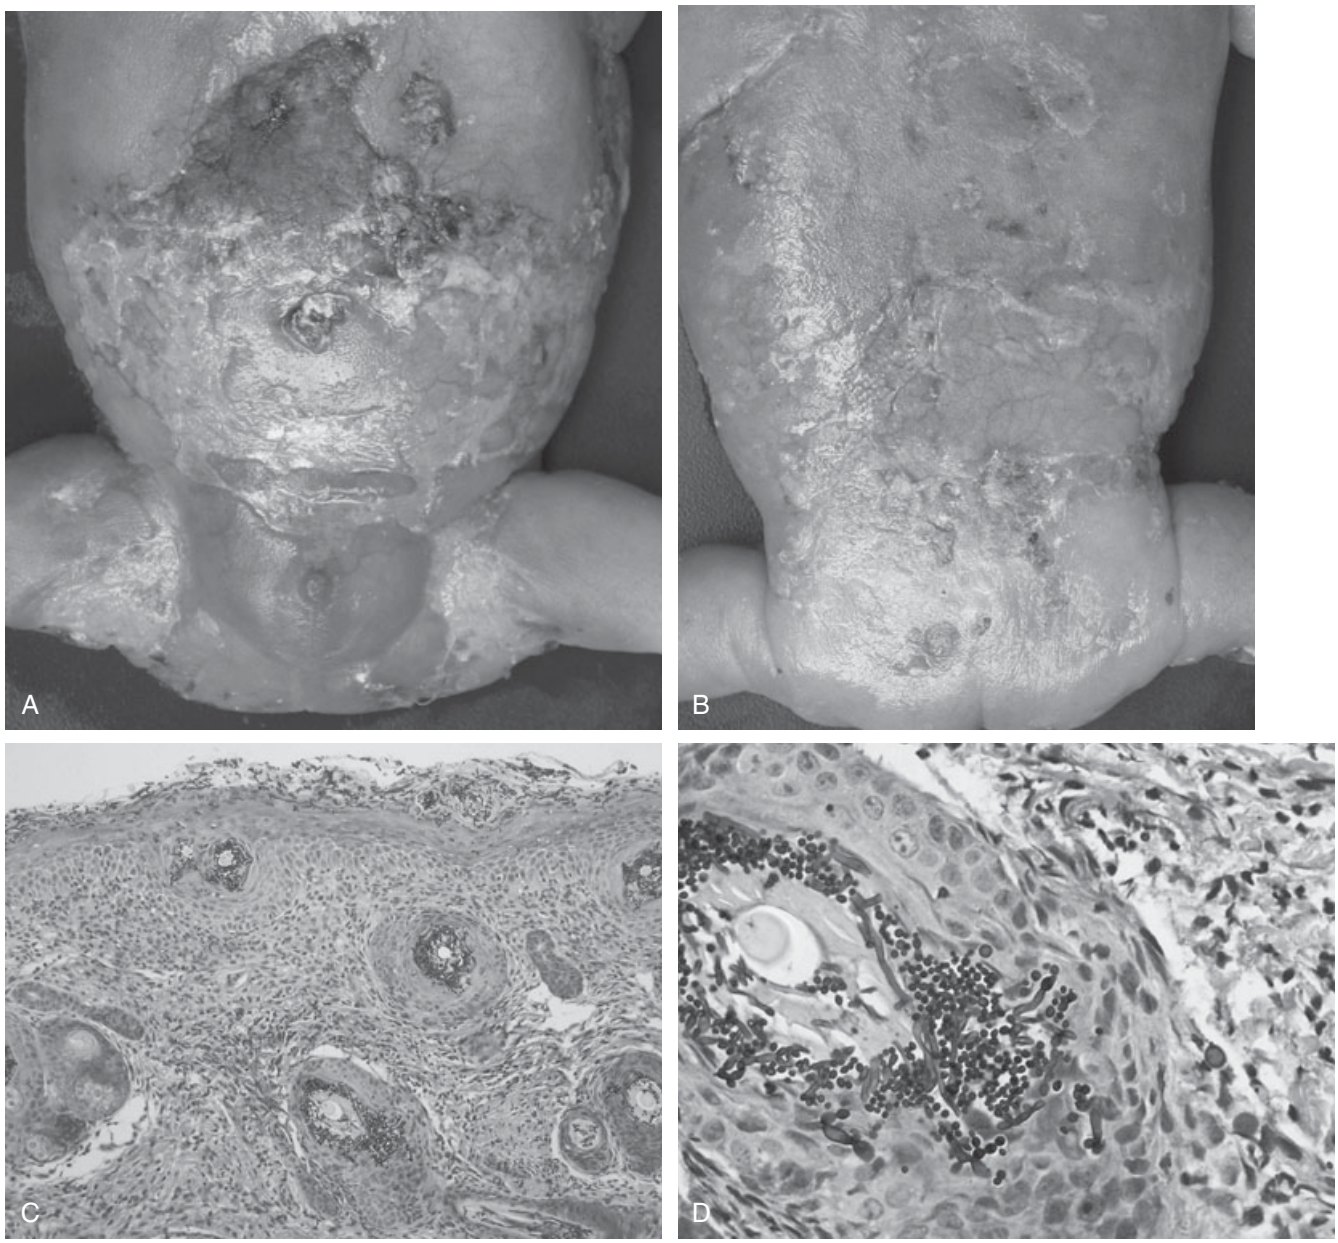

Figure 76–1 A-D, Invasive cutaneous candidiasis. A 3-week-old, former 24-2/7 weeks' gestation premature infant with fatal invasive candidiasis. The skin on the abdomen (**A**) and back (**B**) showed extensive cutaneous ulceration and exudates caused by *Candida* infection. Autopsy examination showed disseminated candidiasis with thromboemboli, infarction, and microabscesses involving the brain, lungs, and kidneys. Skin biopsy specimen showed numerous ovoid yeasts and pseudohyphae infiltrating the stratum corneum and within hair follicles (periodic acid–Schiff stain, 100× original magnification) (**C**) and infiltration of yeasts deep into the dermal connective tissue (periodic acid–Schiff stain, 400× original magnification) (**D**). (See companion Expert Consult web site for color version.) *(Courtesy of Dr. Megan K. Dishop, Department of Pathology, Baylor College of Medicine and Texas Children's Hospital, Houston, TX.)*

CONGENITAL CANDIDIASIS

Congenital candidiasis may cause fetal infection with onset of premature labor or intrauterine demise; it may be evident at birth, or it may appear within the first 24 to 48 hours of life.* Term and preterm neonates may be affected (Fig. 76–2).[348,349] Congenital candidiasis usually is caused by *C. albicans*, but other *Candida* spp., including *C. tropicalis* and *C. glabrata*, also have been reported to cause congenital candidiasis.[230,260]

Congenital cutaneous candidiasis most often manifests as a widespread, mucocutaneous infection, with erythematous maculopapular or vesiculopustular rash.[349,399] Congenital pneumonia also may be a part of the disease, with or without the mucocutaneous or systemic signs.[66,120,185] Congenital systemic candidiasis may manifest as life-threatening, early-onset sepsis syndrome, especially in premature neonates (see Fig. 76–2) with septic shock or meningitis; it also may be accompanied by leukocytosis or neutropenia, or it may mimic congenital leukemia.[66,268] Twins

*See references 32, 59, 60, 66, 106, 170, 173, 176, 180, 203, 237, 305, 306, 328.

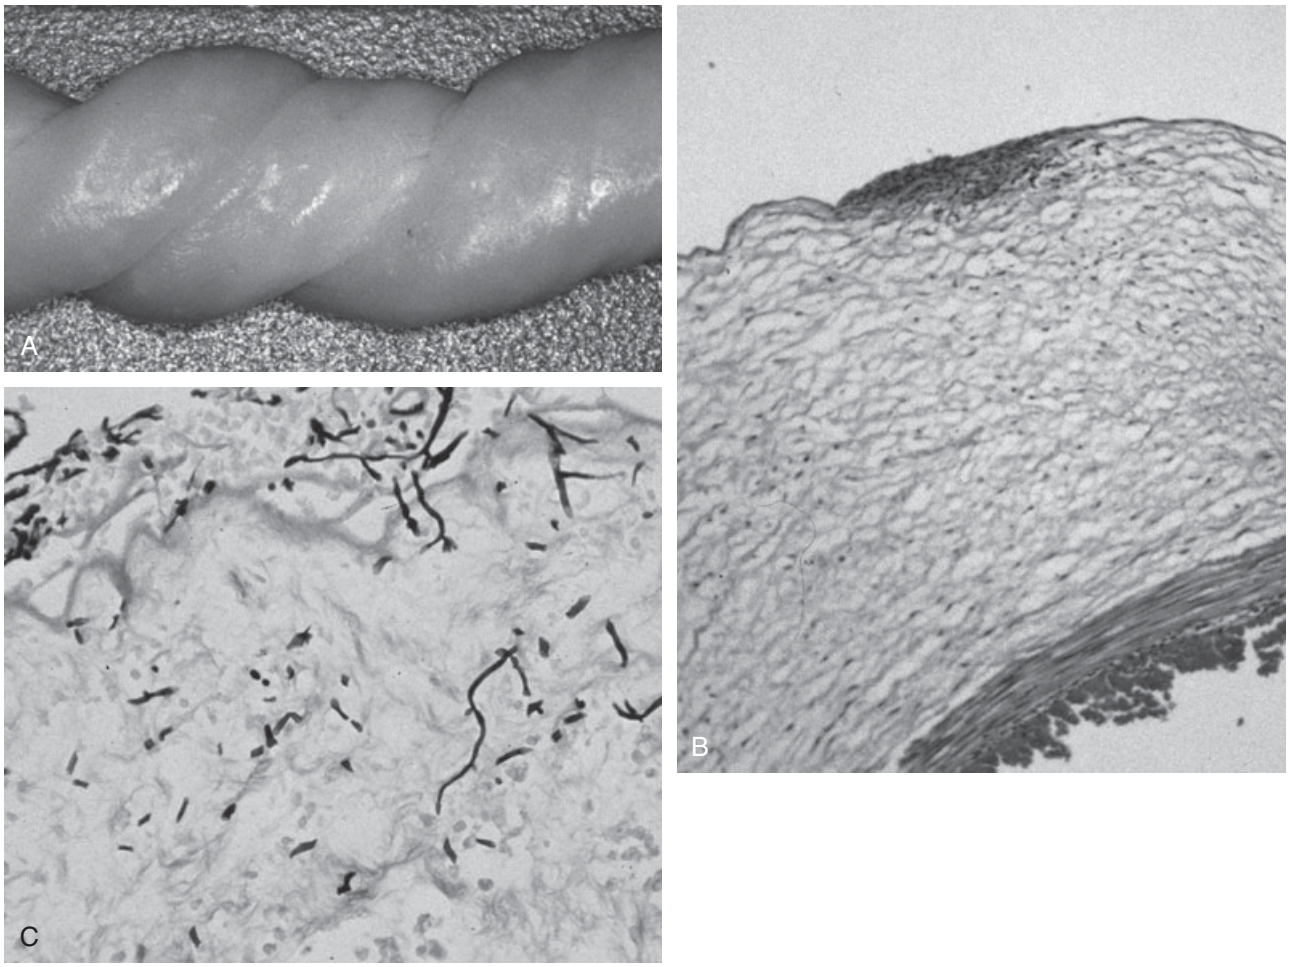

Figure 76–2 A-C, Umbilical cord funisitis in congenital candidiasis. **A,** Umbilical cord from a term infant born with congenital candidiasis (*C. albicans*). Gross examination showed cord edema with pinpoint yellow-white lesions on the surface. **B** and **C,** Umbilical cord from premature infant, born at 24 weeks' gestation with a birth weight of 610 g, to a mother with *Candida* vaginitis at the time of delivery. The infant presented at birth with septic shock associated with disseminated congenital candidiasis. Examination of the umbilical cord showed extensive funisitis with *Candida* microabscesses (hematoxylin and eosin stain, 40× original magnification) (**B**). Microscopic examination showed *Candida* funisitis with budding yeasts and invasive pseudohyphae (methenamine silver nitrate stain, 200× original magnification) (**C**). *(Courtesy of Dr. Edwina J. Popek, Department of Pathology, Baylor College of Medicine and Texas Children's Hospital, Houston, TX.)*

may be affected, sometimes with different *Candida* spp., manifestations, and outcomes for each twin.[203,326,350]

Prenatal diagnosis of intrauterine infection with *Candida* may be determined by amniocentesis.[49,237,305] A presumptive diagnosis in a neonate can be made by identifying budding yeast organisms on potassium hydroxide preparations or Gram-stained smears of the pustular or vesicular skin lesions, blood buffy coat, or gastric fluid aspirate.[294] Growth of *Candida* in culture provides confirmatory evidence. Term newborns with congenital candidiasis usually have infection limited to the skin, mucous membranes, lungs, or gastrointestinal tract; *Candida* rarely is isolated from blood or other sterile body sites. In contrast, premature neonates with congenital candidiasis often have more severe disease, with positive blood cultures and evidence of disseminated disease, including meningitis.[141,348,349] The umbilical cord from a fetus or newborn with congenital candidiasis may show *Candida* funisitis with yellow-white nodules and fungal microabscesses (see Fig. 76–2); the placenta also may have nodules and shows chorioamnionitis on histologic examination.[230,291,325]

Maternal risk factors include a history during pregnancy of *Candida* vaginitis, use of antibiotics, retained intrauterine contraceptive device, cervical cerclage, and prolonged rupture of fetal membranes, although none of these factors may be present in the history.[32,59,76,237,305,328] Poor prognostic factors for neonates include the presence of pneumonia or sepsis, prematurity, and early-onset neutropenia at presentation.[411]

SYSTEMIC CANDIDIASIS

Systemic candidiasis refers to the isolation of *Candida* or its histopathologic demonstration in a normally sterile body site. The most common forms of this clinical syndrome include (1) catheter-associated sepsis, in which *Candida* is isolated from the blood of infants who have central venous catheters, but no evidence of focal infection or disseminated disease; (2) disseminated candidiasis, in which *Candida* is isolated from the bloodstream in association with other foci of infection, such as skin or intestine, regardless of whether the infant has a central venous catheter[61]; and (3) focal disease of an organ or disseminated disease caused by *Candida* spp., without a positive blood culture. No significant differences in presentation of systemic candidiasis caused by different *Candida* spp. have been apparent.[41,43,112,116,163,165,166]

The clinical and laboratory signs of systemic candidiasis usually are nonspecific and resemble signs seen with bacterial sepsis.[37,41,43,220,221] Knowledge of prior colonization with *Candida*

spp. or presence of cutaneous crusting or erosions, dermatitis, or skin maceration provides clinical clues that a sepsis syndrome in a premature neonate may be caused by invasive *Candida* spp. (see Fig. 76–1A and B).[31,61,276,306,309] Signs and symptoms most commonly reported in neonates with systemic candidiasis include respiratory deterioration (74%), apnea and bradycardia (60%), carbohydrate intolerance (56%), skin manifestations (53%),[28,31,37] abdominal distention (49%), temperature instability (35%), guaiac-positive stools (26%), and hypotension (21%).[61,85]

The frequency of end-organ involvement in neonates with systemic candidiasis is difficult to determine precisely. Based on several retrospective, single-center medical literature reviews and one meta-analysis report, the sites most frequently involved in systemic neonatal candidiasis include blood (60-80%), the central nervous system (CNS) (meningoencephalitis, 25-60%),[113,114,123,199] the lungs (pneumonia, 70%),[28,74,185,277] the kidneys (renal candidiasis, 60%),[28,41,107,126,197,272,283,289] the liver and spleen (19%),[42,163,263] and the eyes (endophthalmitis, 30%).[24,25,263] End-organ disease is accompanied most often by positive blood or urine cultures, especially if cultures are persistently positive for more than 5 days.[39,73,263] Not all neonates with end-organ disease with *Candida* spp. have positive blood or urine cultures, however.

The organ involved most frequently in systemic candidiasis seems to be the kidney.[28,39,107,126,197,263] *Candida* may be isolated from the urine of 73 percent of neonates with systemic candidiasis with positive blood cultures, but only 5 to 15 percent of such neonates have documented *Candida* pyelonephritis with renal infiltration, mycetoma, or renal abscess.[7,22,41,153,192,198,206,368] The kidney seems to be particularly vulnerable to the formation of renal cortical abscesses and obstructive masses, which usually occur at the ureteropelvic junction. A neonate with persistently positive urine or blood cultures, hypertension, renal insufficiency or acute renal failure, or oliguria or anuria should undergo ultrasound imaging to determine the presence of a bezoar-associated obstructive uropathy, which requires immediate attention.[22,44,229,289,381,403,404] Urinary catheters or nephrostomy tubes may become colonized with *Candida* and result in secondary infections that may range from asymptomatic to invasive disease with obstruction.[44,229]

CNS involvement occurs in 3 to 23 percent of neonates with systemic candidiasis; percentages of 54 to 64 percent have been reported in a few series.[39,77,79,118,171] In addition to causing meningitis, *Candida* may invade the brain tissue, through hematogenous dissemination, producing focal nodular encephalitis, with minimal inflammation of the meninges (Fig. 76–3). The diagnosis of candidal meningoencephalitis requires a high index of suspicion, followed by thoughtful and careful evaluation.[113,114,123,199]

Candida meningitis may occur in the absence of positive blood cultures; cerebrospinal fluid (CSF) pleocytosis may be minimal or absent, and elevated protein or hypoglycorrhachia is an inconsistent finding. Gram-stained smears of CSF rarely reveal budding yeast, even when CSF cultures are positive for *Candida*.[40,90,123,169] More recent reviews determined that meningitis with *Candida* isolated from the CSF occurred in 8 percent of ELBW infants, but only 37 to 52 percent had *Candida*-positive blood cultures.[40,90,169] CSF findings in neonates diagnosed with *Candida* meningitis also may vary. Of neonates with *Candida* meningitis, 43 percent may have normal CSF.[90] Fernandez and associates,[123] in a 10-year review of candidal meningitis in 23 infants in an NICU, reported that pleocytosis occurred in only 39 percent of infants, and hypoglycorrhachia occurred in 25 percent, despite a positive CSF culture for *Candida* in 74 percent of infants. The remaining neonates are diagnosed when a positive blood culture occurs with an abnormal, but culture-negative, CSF.[98,114,208,254] *Candida* also may colonize and infect external ventricular drains placed for management of hydrocephalus.

Autopsy examination of a premature infant born at 25 weeks' gestation who died at 1 month of age of disseminated invasive candidiasis. **A,** Central nervous system involvement, with brain microglial nodules, was seen at autopsy examination (hematoxylin and eosin stain, 40× original magnification). **B,** Brain microglial nodules contained *Candida* yeasts and invasive ribbon-like *Candida* pseudohyphae (Gomori methenamine silver stain, 100× original magnification). *(Courtesy of Dr. Edwina J. Popek, Department of Pathology, Baylor College of Medicine and Texas Children's Hospital, Houston, TX.)*

Ventriculitis, brain abscesses, and brain calcifications are unusual complications of *Candida* meningitis that can be diagnosed with brain imaging procedures.[58,141,181,197,198] Mortality or neurodevelopmental disabilities in survivors may occur in 73 percent of neonates with *Candida* meningitis.[40,98,208,254]

Endocarditis is estimated to occur in 5 to 15 percent of neonates with systemic candidiasis.* It is a serious and potentially

*See references 39, 117, 128, 174, 216, 217, 263, 264, 284, 317, 414.

fatal complication of neonatal systemic candidiasis, with reported fatality rates of 25 to 73 percent.[216,217] *C. albicans* has been isolated most often, followed by *C. parapsilosis*. *Candida* endocarditis may occur in neonates with normal hearts and neonates with structural heart disease, and as a postoperative complication of cardiac surgery.[236,246] *Candida* endocarditis in neonates may differ in presentation from *Candida* endocarditis in older children and adults.[115,233] It usually occurs in premature neonates with persistent candidemia associated with an indwelling vascular catheter. Most neonates with *Candida* endocarditis have structurally normal hearts, however, and not all reported cases in neonates have been associated with vascular devices.[104,151,246]

The presentation of *Candida* endocarditis in neonates may be acute and associated with an episode of persistent candidemia, or late onset, often discovered weeks or months after a presumably silent or resolved episode of candidemia.[39,96,179,212,246,301] Cardiac murmurs may be absent. Early literature reports consisted mostly of autopsy diagnoses; however, more recently, echocardiography has proved to be a valuable tool in establishing the diagnosis of *Candida* endocarditis.[236,246,256] Intracardiac vegetations on the mitral, tricuspid, and aortic valves, or the presence of a right atrial mass, in association with persistently positive blood cultures for *Candida*, strongly supports the diagnosis of endocarditis.

Eye disease may occur in 3 to 11 percent of neonates with systemic candidiasis; figures as high as 45 percent have been reported.[77,246,263] Candidal eye disease may complicate systemic candidiasis in term, near-term, and preterm infants.[24-26] More recent reports suggest, however, that the prevalence of ophthalmologic complications in hospitalized infants and children, including premature VLBW infants who are treated aggressively and survive candidemia, may be decreasing.[100,127] Eye disease may occur on the first day of systemic candidiasis but more often is associated with prolonged candidemia.[25,99,263]

Advanced eye disease may be visible on routine examination; however, establishing the diagnosis of endophthalmitis early requires indirect ophthalmoscopy by an ophthalmologist.[77,248,269] Most lesions involve the retina and choroids; characteristic lesions include unilateral or bilateral yellow-white fluffy, retinal, or free-floating vitreal opacities or balls, often accompanied by hemorrhage or inflammatory vitreous haze.[12,24,25,269] The iris and lens of the eye also may be involved.[330,367] Lens abscesses manifesting as lens opacities or cataracts also may occur, and they may be a nidus of ongoing infection poorly reached by systemic antifungal therapy and a source for recurrent disease.[87,103,254,330,367] Untreated, *Candida* endophthalmitis also may progress and produce corneal thinning and perforation of the globe.[240] Rarely, *Candida* endophthalmitis may mimic retinoblastoma.[336] In addition, VLBW infants who experience candidemia may have concomitant endophthalmitis and retinopathy of prematurity, or they may develop more severe retinopathy of prematurity (stage 3 or beyond) or retinal detachment and require laser therapy.[49,136,145,184,245,262] Premature, high-risk, VLBW infants with candidemia should be monitored closely for *Candida* eye disease and for progression of retinopathy of prematurity.[262]

Osteoarthritis is a rare manifestation of systemic candidiasis in neonates.[2,146,162,199,361,387,390,393] It may occur temporarily associated with persistent candidemia or as a late complication, weeks to months later, after apparent resolution of an episode of candidemia.[146,162,390] In addition to premature infants, newborns with underlying inherited disorders of metabolism also may be at increased risk. Clinical features of candidal osteoarthritis in neonates are similar to the features of osteoarthritis caused by bacterial pathogens and include warmth, pain, tenderness, and swelling of the extremity and diminished range of motion. Imaging may show swelling of soft tissue and joint and cortical bone erosion. Culture of aspirated joint fluid or biopsy of bone tissue positive for *Candida* spp. confirms the diagnosis.[387,393]

Intra-abdominal infections, including enteritis, necrotizing enterocolitis (NEC), and peritonitis, and intra-abdominal and hepatosplenic abscesses are estimated to occur in 8 percent of neonates with invasive systemic candidiasis (Fig. 76–4).[39] *Candida* peritonitis and sepsis may complicate surgical procedures performed on the intestine for congenital bowel atresias or bowel perforation associated with NEC.[26,56,99,182,243] Distinct from NEC is idiopathic spontaneous focal intestinal perforation (SFIP), which occurs rarely in VLBW infants and has been associated with systemic candidiasis in half of cases.[1,88,243,290,299,307] SFIP is approximately 12-fold less common than is NEC in preterm neonates and has a distinct combination of clinical and laboratory features that help distinguish it from NEC. Prognosis and management differ, so it is important to understand the difference between these two clinical entities.

Neonates with SFIP are more likely than are neonates with NEC to be smaller at birth, have lower Apgar scores, experience early hypotension or hypothermia, and require more intensive

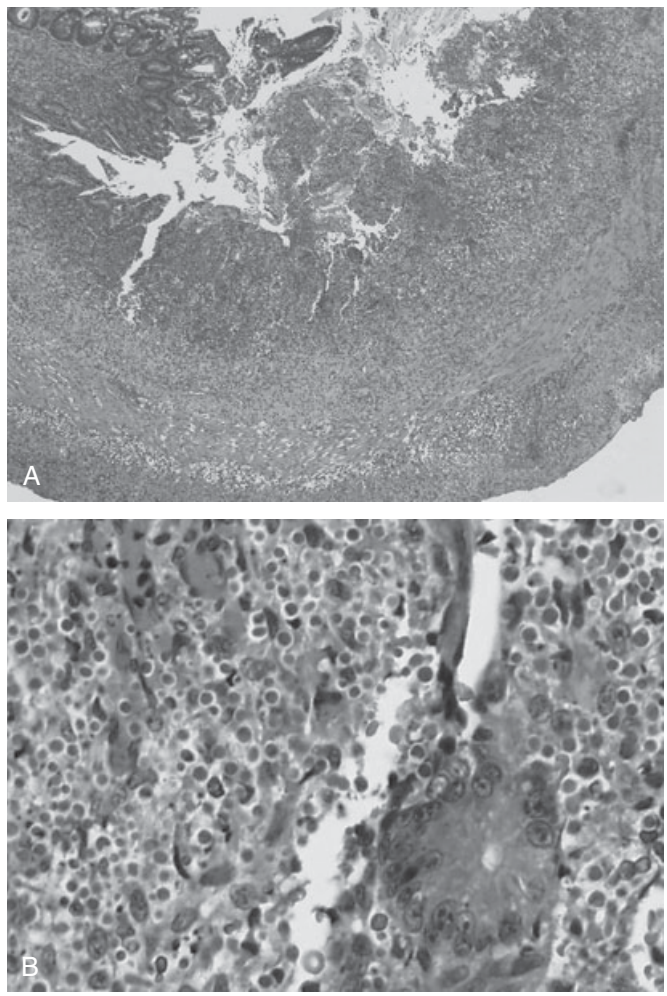

Figure 76–4 **A** and **B,** *Candida* infection complicating necrotizing enterocolitis. A 2-week-old extremely-low-birth-weight premature infant with invasive *Candida* infection associated with necrotizing enterocolitis with perforation. **A,** A large segment of resected bowel showed extensive mucosal erosion and hemorrhage with transmural inflammation (hematoxylin and eosin stain, 40× original magnification). **B,** Numerous yeast organisms infiltrated the eroded mucosa (hematoxylin and eosin stain, 400× original magnification). neonatal resuscitation.[182,307] Neonates with SFIP present acutely in the second or third week of life (mean, 16.7 days of life), with distention and a bluish discolored abdomen. Radiographs in SFIP reveal a gasless abdomen without pneumatosis intestinalis or portal venous gas commonly associated with NEC. SFIP frequently is an easily resectable focal area of necrosis associated with a single perforation less than 1 cm in size, often located in the terminal ileum, but also may involve the colon or stomach. The remaining bowel may be covered with serosal exudate, but otherwise it appears normal. In contrast, NEC often involves large areas of transmural bowel necrosis that are difficult to resect completely in many patients; *Candida* and other organisms may be seen in multiple sections of resected bowel (see Fig. 76–3B). Histologic findings in SFIP show focal hemorrhagic necrosis, often with *Candida* invading the bowel wall at the site of perforation only, and otherwise healthy bowel. *Candida* spp. and *Staphylococcus epidermidis* or coagulase-negative staphylococci are the predominant pathogens isolated in SFIP, whereas Enterobacteriaceae predominate in peritonitis caused by NEC-associated perforations, with *Candida* spp. isolated in approximately 10 percent of cases of NEC.[1,88,182,243,248,290] A peritoneal culture should be obtained in all neonates with intestinal perforation, regardless of cause, because results of cultures determine the most appropriate antimicrobial therapy for bacteria and *Candida* spp.

Pulmonary candidiasis is seen frequently in congenital candidiasis.[66,185] VLBW infants with endotracheal colonization with *Candida* spp. have an increased risk for development of systemic candidiasis.[132,310] Acquired pulmonary candidiasis with pneumonia may occur in 8 to 10 percent of ventilated premature neonates and must be differentiated clinically and radiographically from asymptomatic *Candida* colonization and pneumonia caused by other pathogens.[132,185,226,277,306,309]

DIAGNOSIS

Congenital or acquired cutaneous candidiasis may be diagnosed by the presence of budding yeast organisms in scrapings of skin lesions, and the species involved is established by culture. Invasive dermatitis caused by *Candida* can be differentiated from benign cutaneous dermatitis by skin biopsy. Histopathologic evidence of organisms beyond the stratum corneum is evidence of more serious invasive dermatitis that leads to potentially fatal systemic candidiasis (see Fig. 76–1C and D).[306,309]

The diagnosis of systemic candidiasis in a fetus or neonate is established by isolation of *Candida* spp. in culture from a normally sterile body fluid, such as amniotic fluid, urine, blood, or CSF, or from an involved site, such as joint or bone. Culture of *Candida* spp. from abscesses and intraoperative tissue specimens also establishes the diagnosis of invasive *Candida* disease. The presence of characteristic yeast or fungal elements in tissue specimens from the placenta, the umbilical cord, or the neonate provides supportive evidence for invasive *Candida* disease, but isolation of the organism from the tissue is required to establish the diagnosis. Methods of detection of *Candida* in blood or CSF by polymerase chain reaction amplification of *C. albicans* DNA or 18S rRNA and detection of *Candida* antigens, such as mannan, in blood or CSF have been developed by a variety of different laboratories; however, they have not been evaluated in neonates and should not replace culture as the definitive test to establish the diagnosis.[285,286,365,366,378] A high index of suspicion is the key to establishing an early and accurate diagnosis, which improves outcome. Systemic candidiasis has been diagnosed first in 20 to 50 percent of infants at autopsy, and a mean delay of 11 days has been reported between the onset of symptomatic disease and the initiation of antifungal therapy.[28]

The diagnosis often is made when a routine blood culture from an infant evaluated for possible bacterial sepsis yields a *Candida* organism. In as little as 4 hours, but usually within 48 to 72 hours, *Candida* grows in routine blood cultures processed in the automated systems used by most clinical laboratories. Yeast also may be detected in smears of blood or buffy coats in high-risk neonates.[287,294] In the evaluation of an infant for possible candidemia, blood for culture should be obtained from a peripheral vein or artery and through all intravascular catheters in place at the time.[311] In addition, at least one blood culture should be obtained after removal of a colonized catheter to determine if candidemia persists after the catheter is removed.

Culture of CSF should be performed if candidemia is documented, even if CSF indices are normal. A CSF specimen that grows *Candida* in a high-risk neonate should not be dismissed as a culture contaminant.

Urine obtained by suprapubic bladder aspiration, often facilitated by ultrasound guidance, is an excellent source for recovery of *Candida*.[283] If the urine grows *Candida*, renal or systemic infection is suggested. Bag specimens of urine are unreliable for establishing the diagnosis because of the high rate of perineal candidal colonization in infants. Catheterized urine specimens, although preferable to specimens obtained by bag, may be contaminated from contact with perineum and penis. Urine obtained from an indwelling urinary catheter may represent colonization of the catheter; a repeat specimen obtained using sterile technique, at least 24 hours after removal of the catheter, is recommended. Fungal culture of urine may yield candidal growth in a premature neonate with disseminated candidiasis, even when other body fluids, such as blood and CSF, do not. Microscopic analysis of urine, Gram-stained smear of urine, or potassium hydroxide preparation of freshly obtained urine may show evidence of yeast or fungi, providing evidence for a presumptive diagnosis and early initiation of antifungal therapy.

In addition to cultures of blood, CSF, and urine, cultures of all involved sites, such as joints, bones, and abscesses, should be performed. The peritoneal fluid from infants with NEC or SFIP who require surgical intervention should be stained and cultured, and resected bowel should be sent for histopathologic examination and culture. Endotracheal cultures positive for *Candida* spp. may represent colonization in an infant at risk for having invasive disease; however, if positive respiratory cultures for *Candida* are associated with pneumonia and respiratory deterioration, invasive pulmonary candidiasis may be present.[132,310]

In addition to culture and histopathology, routine laboratory evaluations may support the diagnosis of systemic or invasive candidiasis.[61] Persistent thrombocytopenia is a frequent early finding in infants with systemic candidiasis. Additional laboratory tests, such as a complete blood cell count, liver function tests, and determination of serum glucose, blood urea nitrogen, and creatinine, may be helpful in assessing the degree of systemic involvement.

Infants whose urine, blood, or CSF cultures yield *Candida*, especially if persistently positive, should have further evaluation done to detect any evidence of dissemination that would influence the prognosis and duration of antifungal therapy.[61,73,254,311] Ultrasound or enhanced computed tomography evaluation of the abdomen, kidneys, and bladder should be done to assess for possible liver or splenic abscesses and evidence of renal infiltration or obstructive lesions.[39,72,197,198,201] Cranial ultrasound may be a useful screen for CNS pathology, such as hydrocephalus. Infants with a positive CSF culture or who are otherwise suspected to have CNS involvement should undergo enhanced computed tomography or magnetic resonance imaging of the brain to detect abscesses, nodules, infarction, or parenchymal calcified granulomata.[141,181] Careful ophthalmologic examination also is recommended, especially if candidemia is persistent, to detect endophthalmitis or lens abscesses. Infants with persistent candidemia, structural or postoperative heart disease, or new-onset

heart murmur should have an echocardiogram done for possible valvular endocarditis or intracardiac mass.[317]

TREATMENT

MANAGEMENT STRATEGIES

Oral candidiasis or thrush in an otherwise healthy infant is treated with oral nystatin suspension or gentian violet. Superficial cutaneous candidiasis in an otherwise healthy neonate is treated with topical nystatin cream or powder. When the diaper area is extensively involved, oral nystatin therapy may be administered as well in an attempt to eliminate the yeast from the gastrointestinal tract. Cutaneous candidiasis that persists or evolves into invasive candidiasis requires systemic antifungal therapy, usually with amphotericin B or fluconazole.

Congenital candidiasis usually requires only topical antifungal therapy in an otherwise healthy newborn; neonates who have pulmonary involvement or who are preterm should receive systemic antifungal therapy because they are at greater risk for dissemination and a poor outcome.[61,66] In these instances, amphotericin B or fluconazole may be used for approximately 10 to 25 days, until clinical signs and symptoms have resolved.

Candidemia is now a common cause of late-onset sepsis in VLBW and ELBW neonates.[255,279] Because it is associated with significant morbidity and mortality rates, and potential risk factors for candidemia among high-risk neonates have been identified, some experts suggest that empiric antifungal therapy with amphotericin B or fluconazole should be administered along with antibiotics at the time that a blood culture is obtained for suspected sepsis in VLBW, extremely premature neonates with gestational ages of less than 28 weeks, especially if they have thrombocytopenia or a history of exposure to third-generation cephalosporin or carbapenem in the previous week.[38,63,220,221,335]

Although many antifungal medications are available, data from well-designed, randomized clinical trials in neonates, especially premature neonates, are insufficient to favor a recommendation of one antifungal agent or combination of agents for invasive or systemic candidiasis.* Most information published is derived from analyses of case series and retrospective reviews.[86,101,253] Published studies on pharmacokinetic profiles, studies evaluating optimal dose or duration of therapy, and studies with safety and toxicity data on neonates are difficult to find.† Recommendations for treatment are based on published experience in adults and older children and opinions of experts in neonatal medicine and pediatric infectious diseases. It is hoped that new data specific to neonates and premature neonates will emerge.

Most experts agree that evaluation for disseminated disease and prompt systemic antifungal therapy, usually with amphotericin B or fluconazole, is indicated if even a single blood culture from a neonate is positive for *Candida* spp.[72,311] Consensus seems to be lacking, however, on which antifungal compound or combination is preferred for treatment of complications such as meningitis, and for how long treatment should be administered.[72,79,123,169,178,253] The most appropriate management for an individual neonate should consider the *Candida* spp. prevalent in the nursery, the *Candida* spp. isolated from the patient, and the usual or known antifungal susceptibility patterns; the site of infection; the availability of pharmacokinetic, efficacy, and safety data; and the ability of the host to metabolize and eliminate the medication.[122,132,140,253,380,410,413]

Isolation of *Candida* from blood obtained through a vascular catheter means the device is colonized with the organism and must be removed promptly to eradicate the infection and reduce the risk of morbidity and mortality.[94,111,352] *Candida* is difficult to eradicate from catheters, and persistence of positive blood cultures from blood obtained through the catheter increases the rates of complications and mortality associated with candidemia.[73,111] In addition to removal of the catheter, systemic antifungal therapy should be administered for 10 to 14 days. If the peripheral blood culture also is positive for *Candida* spp., dissemination via the bloodstream may have occurred, and most experts recommend duration of antifungal therapy to be at least 25 to 30 days.[61,62,311]

Isolation of *Candida* spp. from urine obtained from an indwelling catheter suggests possible colonization of the catheter, requiring removal of the catheter if the infection is to be eradicated. Isolation of *Candida* spp. from a urine specimen obtained by sterile technique denotes invasive renal or systemic disease and requires further evaluation and systemic antifungal therapy. In some patients, medical therapy alone may eradicate the *Candida* infection, even if partial obstruction is present.[7,22,368] Some neonates may require an urgent surgical or endoscopic procedure, however, to relieve the obstruction and restore renal function.[44,51,153,229,289,381,403] Duration of antifungal therapy required for cure may range from 25 to 42 days or longer and should be guided by microbiologic cure and resolution of lesions by imaging studies.[51]

Treatment of meningoencephalitis caused by *Candida* spp. in a neonate usually requires systemic therapy for at least 30 days; longer courses of treatment may be required if ventriculitis or brain abscesses or nodules are present.[79,80,123,169,316] Repeat CSF examination and culture before discontinuing antifungal therapy is recommended to document sterilization and improved CSF parameters of white cells, glucose, and protein.[90] If *Candida* ventriculitis is associated with an indwelling ventricular drain or shunt, prompt removal of the device also is indicated. Repeat CSF examination and culture should be done every 24 to 48 hours until sterile, and treatment should be continued when, and for sometime after, the drain or shunt is replaced.

Treatment of endocarditis or septic thrombophlebitis caused by *Candida* spp. requires prolonged antifungal treatment, at least 30 days and usually 42 to 60 days, depending on clearance of candidemia, clinical progress, and resolution of intracardiac vegetations or lesions as documented by echocardiography.[115,128,233,263] Consultation with a cardiologist or cardiovascular surgeon is recommended.[96,104,246] If septic thrombophlebitis with vascular abscess is present, or an enlarging valvular mass obstructs blood flow, surgical intervention may be considered.[104,115,151,216,241] Reports of resolution of endocarditis with medical therapy alone suggest, however, that it may be a valid option to consider, especially for neonates who are hemodynamically stable, with right-sided, nonvalvular lesions.[115,117,128,151,183,212,317,414]

Treatment of eye disease, such as endophthalmitis, requires systemic antifungal therapy for 25 to 42 days, and consultation with an ophthalmologist is recommended to assess the extent of disease, presence or progression of comorbid retinopathy of prematurity, and response to therapy.[100,136,223,263,356] If an abscess of the lens is present, surgical drainage or lensectomy may be necessary.[25,87,103,330,356,367] Long-term follow-up of neonates with *Candida* endophthalmitis suggests that early medical therapy results in cure for most neonates who survive systemic candidiasis and that invasive procedures usually performed in adults with *Candida* eye disease, such as vitreous taps or intravitreal injections of medications, are unnecessary in most neonates.[12,25,127,136] Neonates with invasive candidiasis should be observed closely, however, for progression of retinopathy of prematurity.[49,145]

Renal disease caused by invasive *Candida* spp. usually responds to systemic antifungal therapy, the duration of which usually is

*See references 8, 29, 52, 62, 68, 86, 101, 102, 131, 140, 145, 172, 253, 265, 274, 321, 354, 410, 413.

†See references 30, 53, 78, 148, 157, 158, 255, 275, 320, 344, 347, 353, 363, 397.

at least 25 days.[7,41,44,153,263] Longer duration of therapy may be required to eradicate renal mycetomas, abscesses, or masses ("fungal balls"). If obstructive uropathy is present, urologic consultation is recommended to determine if nephrostomy or other diverting procedure is indicated to relieve the obstruction temporarily.*

Treatment of osteoarthritis caused by *Candida* spp. usually requires prolonged duration of systemic antifungal therapy (≥42 days).[361,387,393] Aspiration or surgical drainage by an orthopedic surgeon may be necessary if there is an infected joint or bone abscess.[2,146,162,199]

Peritonitis associated with NEC or SFIP usually requires at least 25 days of systemic antifungal therapy, but longer duration may be required if intra-abdominal abscesses develop.[39,88] Surgical management of SFIP also differs from that of NEC; simple surgical procedures, such as suturing or resection with primary anastomosis, may be all that is required for treatment of SFIP, whereas NEC may require extensive bowel resection.†

Duration of systemic antifungal treatment for pulmonary candidiasis is not well established. Treatment should be guided by clinical and radiographic improvement; however, 25 days is likely to be adequate for most patients.[39,132,310]

ANTIFUNGAL AGENTS

The choice of antifungal agents available to treat neonatal candidiasis has expanded beyond the traditional polyene antibiotics, nystatin and amphotericin B deoxycholate, and the pyrimidine analogue 5-flucytosine (5-FC). Lipid formulations of amphotericin B are safe and effective when administered to neonates.[3,51,68] The first antifungal azoles administered to neonates were imidazoles (miconazole and ketoconazole) with unpredictable absorption and toxicities.[83,359,369] First-generation triazoles (fluconazole and itraconazole), available now for almost 2 decades, seem to be effective and safe when administered to most neonates.[44,47,54,375] Rare reports of fetal malformations associated with fluconazole administered prenatally to pregnant women are of potential concern.[5] Newer compounds, including second-generation triazoles (posaconazole, ravuconazole, and voriconazole) and echinocandins (caspofungin, micafungin, and anidulafungin), have emerged as potentially valuable agents to treat resistant yeast and fungal infections in neonates.[8,72,150,158,253,337]

Amphotericin B

Amphotericin B deoxycholate, a polyene macrolide antibiotic, remains the drug of choice for most neonates with systemic candidiasis caused by susceptible *Candida* spp.‡ *Candida* spp. most commonly isolated, including *C. albicans*, usually are susceptible to amphotericin B; however, more recent reports suggest the incidence of amphotericin B resistance may be 20 to 25 percent in *C. albicans* and *C. parapsilosis* isolated from pediatric patients, including neonates.[18,405,410] In addition, resistance is a common finding in *C. lusitaniae* and *C. haemulonii*. Also, the compound seems to be less active in vitro against some species, including *C. parapsilosis*, *C. tropicalis*, and *C. guilliermondii*.[384]

The limited pharmacokinetic data available suggest neonates exhibit considerable interindividual variability in metabolism of the drug, and this variation is speculated to be due partly to genomic factors that affect drug metabolism.[8,353] The usual recommended dose is 1 mg/kg/day infused over the course of 2 to 4 hours; however, dosage ranges of 0.5 to 1.5 mg/kg/day have been used, depending on the diagnosis and organism isolated. Administration of a small initial test dose, slow escalation of doses, and premedication to prevent infusion-related reactions are unnecessary in neonates. The duration of therapy varies with the severity and type of *Candida* infection. For uncomplicated, catheter-associated candidemia in which prompt removal of the intravascular device results in rapid clinical and laboratory improvement, a cumulative dose of 7 to 10 mg/kg usually is sufficient.[62] For disseminated infection, cumulative doses of at least 25 mg/kg often are necessary.[62,311] For meningitis, a 30-mg/kg cumulative dose often is preferred,[79] whereas for endocarditis and osteoarthritis, cumulative doses of 40 to 50 mg/kg have been administered in some cases.[317]

Intrathecal amphotericin B deoxycholate has been used to treat refractory candidal meningitis, but it rarely is needed. The initial intrathecal dose is 0.01 mg, which is increased gradually over 5 to 7 days to 0.1 mg given every other or every third day.

Adverse effects of amphotericin B deoxycholate include nephrotoxicity in 15 percent of neonates, manifested by azotemia, hypokalemia, and hypomagnesemia, often with an elevated serum creatinine concentration and oliguria.[62,78,156,353] Hypokalemia occurs frequently and reflects tubular injury resulting in increased urinary excretion of potassium.[156] Nephrotoxicity may be minimized by avoiding concomitant use of other potentially nephrotoxic drugs during administration of amphotericin B. Animal and adult studies also have suggested higher sodium intake may prevent renal compromise during amphotericin B therapy. More recently, a study of the effects of fluid and electrolyte management on amphotericin B–induced nephrotoxicity in VLBW neonates suggested nephrotoxicity occurred more frequently in neonates with hyponatremia and suggested hydration and higher sodium intake may provide some protection against amphotericin B–induced nephrotoxicity in VLBW neonates.[156]

Hepatic enzyme abnormalities, hyperbilirubinemia,[172,267] anemia, and thrombocytopenia[69] also have been reported, but rarely occur in neonates. Similarly, neonates do not experience the fever, rigors, shaking, chills, or vomiting that are common infusion-related events in older children and adults.

Lipid preparations of amphotericin B, such as liposomal amphotericin B (L-AmB; AmBisome), amphotericin B lipid complex (ABLC; Abelcet), and amphotericin B colloidal dispersion (ABCD; Amphocil, Amphotec), in usual daily doses of 3 to 5 mg/kg (range 2.5 to 7.5 mg/kg), have been used safely and successfully in neonates with invasive candidiasis of many forms caused by a variety of *Candida* spp.* More recent pharmacokinetic and clinical information support their use in neonates, but optimal dosage with standardized duration of therapy has not been established in randomized controlled trials.[86,200,321]

Some reports suggest lipid preparations may eradicate *Candida* infection more rapidly than does amphotericin B deoxycholate when used as first-line therapy for some forms of invasive candidiasis and may benefit neonates who do not respond clinically and microbiologically to amphotericin B deoxycholate therapy.[179,183,200] Although experience with lipid formulations has increased dramatically in recent years, superior efficacy or safety for neonatal candidiasis has not been proven. In addition, lipid formulations are more costly than is amphotericin B deoxycholate, so they are not recommended universally for routine or first-line treatment in neonates.[134,142,152,171,206,386,402] In most centers, lipid preparations are reserved for clinical or microbiologic failure, or when toxicity, primarily renal, occurs during the course of conventional amphotericin B deoxycholate therapy.

Of the lipid preparations, liposomal amphotericin B may have improved CNS penetration; however, some preparations may not penetrate the kidney well.[142] Because these preparations prefer-

entially accumulate in organs of the reticuloendothelial system, they may be more useful for the treatment of hepatic or splenic candidal abscesses.[386] Toxicities associated with lipid preparations of amphotericin B are similar to the toxicities seen with amphotericin B deoxycholate and include hypokalemia, hypomagnesemia, renal insufficiency, and hepatic dysfunction; however, occurrence of toxicities may be less frequent or less severe than those of amphotericin B deoxycholate.[68,172,179,394]

5-Flucytosine

The compound 5-FC is a synthetic pyrimidine analogue that is administered orally in a dose of 50 to 150 mg/kg/day divided every 6 hours, in combination with amphotericin B formulations, when meningitis is present.[79,80,311] Some experts also consider using 5-FC if endophthalmitis, endocarditis, persistent candidemia, or osteoarthritis is present, whereas others prefer to use amphotericin B alone and monitor for clinical and microbiologic response.[61,62] Most *Candida* spp. are highly susceptible to 5-FC, and synergy of 5-FC with amphotericin B has been documented.[249] It also is well absorbed from the gastrointestinal tract and diffuses well into the CSF and eye.[53,80]

The dose of 5-FC should be decreased if renal insufficiency is present or suspected, and all neonates should have serum levels monitored frequently to ensure they have adequate levels and to avoid development of toxicity. Recommended therapeutic serum levels range from 25 to 100 mg/L. Some centers recommend steady-state serum levels of 40 to 60 mg/L, whereas others prefer predose and 2-hour postdose serum therapeutic ranges of 30 to 40 mg/L and 70 to 80 mg/L.[275,347] Levels greater than 100 mg/L are associated with toxicity and should be avoided. More recent studies on 5-FC therapeutic monitoring in pediatric patients, including neonates, have shown that the standard recommended daily dose of 100 mg/kg is associated with significantly higher serum concentrations in neonates, prompting recommendations for adjusted dosage schedules in this special age group.[275,336]

Approximately 4 to 8 percent of *C. albicans* isolates, and as many as 22 percent of non-*albicans* isolates, mostly *C. tropicalis* and *C. krusei*, are resistant to 5-FC.[366] The drug should never be used alone to treat candidiasis because resistance is likely to emerge even in susceptible *Candida* spp. if 5-FC is used as monotherapy. Side effects can be significant and include renal toxicity, hepatotoxicity, bone marrow suppression, gastrointestinal intolerance, and hemorrhagic enterocolitis.[53,186,317] These effects usually are associated with elevated serum levels greater than 100 μg/mL; nonetheless, it is prudent to monitor blood counts and liver and renal function tests in all neonates who receive 5-FC. Because of the potential for development of significant toxicity, the need for oral administration in premature neonates who may be unable to tolerate enteral feeds and recommended monitoring of drug levels, and the need for successful clinical experience with amphotericin B monotherapy, routine use of 5-FC requires thoughtful consideration.[62]

Triazoles (Fluconazole, Itraconazole, Voriconazole)

Fluconazole is a first-generation triazole antifungal agent with excellent antifungal activity against most isolates of *C. albicans*.[380] *C. krusei* and the more recently recognized *C. haemulonii* seem to be inherently resistant to fluconazole, and some strains of *C. glabrata*, *C. tropicalis*, *C. parapsilosis*, and *C. guilliermondii* may have reduced susceptibility.[164,193,311,380] Fluconazole resistance also has been detected more recently in *C. parapsilosis*, *C. albicans*, and *C. tropicalis* isolates from neonates.[50,139,319,380,410]

Fluconazole seems to be a safe and effective agent for treatment of neonatal systemic candidiasis and may be first-line therapy in some centers for uncomplicated, catheter-associated candidemia in neonates.* Breakthrough candidemia has been described, however, in neonates receiving fluconazole therapy.[204,246] Because it has excellent penetration of CSF, fluconazole also has been used occasionally to treat neonates with candidal meningitis.[169] Adverse effects associated with use of fluconazole in neonates are minimal and include elevated liver enzymes and skin rashes. Usual recommended doses for term neonates are 3 to 6 mg/kg/day for mucocutaneous disease and up to 6 to 12 mg/kg/day every 24 hours for systemic disease. In premature neonates, the dose interval should be adjusted to every 48 to 72 hours, depending on gestational and chronologic postnatal age. Duration of therapy should be at least 28 days for systemic candidiasis; shorter durations may be acceptable for isolated catheter colonization or mild, noninvasive mucocutaneous candidiasis.

Itraconazole, an oral first-generation triazole with activity against most *Candida* spp. except *C. krusei* is not approved for use in children or neonates. Nonetheless, it has been used rarely to treat systemic candidiasis in neonates.[47,375] Because it does not cross the blood-brain barrier well, itraconazole should not be used to treat neonates in whom *Candida* meningitis is suspected or proven. Clinical experience seems to be limited; similar to fluconazole, emergence of itraconazole resistance has been documented in *C. albicans* and *C. tropicalis* strains isolated from neonates.[140]

The second-generation triazole, voriconazole, has expanded antifungal activity that includes not only *Candida* spp., but also *Cryptococcus neoformans*, *Aspergillus*, *Fusarium*, and *Trichosporon beigelii*. Voriconazole displays nonlinear pharmacokinetics in adults, but it seems to have linear pharmacokinetics in children and neonates.[354] Higher doses in smaller patients may be needed to avoid treatment failures. Experience in neonates is very limited, and the drug is not approved for use in this age group. Nonetheless, isolated case reports of use of the drug in difficult cases appear in the literature. In one case report, the addition of intravenous voriconazole administered in the pediatric dose of 6 mg/kg/dose every 12 hours resulted in subtherapeutic levels; however, 6 mg/kg every 8 hours achieved acceptable serum concentrations and eliminated disseminated fluconazole-resistant *C. albicans* infection in a neonate with persistent infection while receiving liposomal amphotericin B alone.[255] In addition, voriconazole has been administered successfully to neonates with vertically transmitted cryptococcal meningitis and invasive dermatitis caused by *Aspergillus* spp.[130,189,318,333]

Currently, no data on neonates are available on the use of posaconazole, ravuconazole, isavuconazole, or albaconazole, which are antifungal azoles currently in preclinical and clinical development stages.[274]

Echinocandins (Caspofungin, Micafungin)

The echinocandins include caspofungin, micafungin, anidulafungin, and aminocandin and have activity against most *Candida* spp., including *C. krusei*.[64,239,282] Clinical trials showed caspofungin to be comparable to amphotericin B for treatment of candidemia in adult patients.[281] Caspofungin is not approved for use in children, however, and the appropriate dose and safety of this drug have not been established in neonates. Limited published experience using caspofungin to treat neonates with persistent candidemia or progressive invasive candidiasis caused by *C. albicans* or other *Candida* spp., resistant or unresponsive to amphotericin B or fluconazole, suggests that caspofungin may be a safe and effective alternative in selected neonates, alone or when added to amphotericin B.[55,150,224,257,265,334,405]

Caspofungin penetrates the kidneys well, and good levels are achieved in urine. It does not penetrate into CSF or the eye well,

*See references 54, 101, 102, 122, 169, 300, 311, 320, 324, 384, 397.

however, and it should not be used to treat neonates in whom *Candida* meningitis or endophthalmitis is suspected or proven.[137] It also may be less effective for *Candida* endocarditis. Available pharmacokinetic data suggest that caspofungin also requires higher doses in children and neonates, calculated using body surface area rather than body weight (70 mg/m^2 first day, then 50 mg/m^2 once daily).[274]

Micafungin, the newest echinocandin, is not approved for use in this age group. It has been administered to preterm neonates, however, in phase I clinical trials, and case reports of micafungin administered in combination with voriconazole and amphotericin B to treat severe cutaneous aspergillosis in preterm infants have been published.[157,158,318] Limited pharmacokinetic and safety data suggest that VLBW preterm infants tolerate doses up to 3 mg/kg daily, but may require a larger dose (8 to 15 mg/kg) or more frequent dosing compared with older children and adults.[157,363] Neonatal rabbit models suggest that micafungin does not reliably penetrate the CSF; studies administering micafungin to treat human neonates with *Candida* meningitis are unavailable.[157] Currently, no data or published experiences are available on administration of anidulafungin or aminocandin to neonates with invasive candidiasis.

Immunomodulators

Because antibody to fungal proteins is associated with recovery from invasive candidiasis, immunoglobulin and other immunomodulators may be evaluated eventually for treatment or prevention of invasive *Candida* infections. Currently, preclinical assessments of recombinant antibodies (hsp90, Mycograb, Efungumab) show antifungal activity against *Candida* spp. and *C. neoformans*, and synergy with antifungal chemotherapy agents.[155,231,261] No clinical trials evaluating specific antibody preparations for treatment or prevention of invasive yeast or fungal disease in neonates have been performed.

PREVENTION

FLUCONAZOLE PROPHYLAXIS

The high frequency and significant morbidity and mortality rates associated with *Candida* infections in VLBW neonates have been the impetus behind animal models and clinical studies of preventive strategies using antifungal agents.[187,338,377] In early studies evaluating prophylactic regimens, oral nystatin reduced fungal colonization and disease in preterm infants with a birth weight of less than 1250 g, and it has been used to control a nursery outbreak of *Candida* infection.[92,337] Miconazole oral gel decreased rectal fungal colonization, a predisposing factor for the development of systemic candidiasis, compared with placebo in infants with a birth weight of less than 1750 g.[383] Several single-center and cohort studies and a large, multicenter, randomized, double-blind, placebo-controlled trial have shown that fluconazole prophylaxis reduces *Candida* colonization, invasive candidiasis, or mortality rates in high-risk, VLBW premature neonates.*

These published studies presented slightly different methods of selection criteria for neonates for prophylaxis (universal for all infants weighing <1000 or <1500 g versus risk-based selection), doses (3 to 6 mg/kg/day), dosage schedules (daily versus every other day versus twice weekly), routes of administration (intravenous only versus intravenous followed by oral versus oral alone), and duration of prophylaxis (4 weeks versus 6 weeks), and slightly different outcome measures. Fluconazole administration was not associated with significant toxicity in any of the studies. Despite these encouraging findings, however, not all centers have adopted or advocate universal prophylaxis for VLBW infants with birth weight of less than 1500 to 1000 g. Some centers prefer a risk-based strategy, selecting only VLBW neonates with an additional risk factor, such as *Candida* surface colonization, central venous catheter in place, endotracheal intubation, or recent administration of third-generation cephalosporin.[234] Some centers advocate twice-weekly, rather than daily, prophylaxis to reduce health care costs and to minimize neonates' exposure to antifungals, with the speculation that lower and less frequent dosing may delay or prevent emergence of resistant *Candida* spp.[188]

Most studies of fluconazole prophylaxis in neonates did not report changes in patterns of colonization or rates of invasive disease caused by *Candida* spp. other than *C. albican*s, or emergence of resistance to fluconazole.[188,225,228] These studies may not have had sufficient duration of exposure or power, however, to determine a difference during the study period.[228] More recent reports have documented emergence of *Candida* spp. other than *C. albicans* as predominant pathogens[193,273,319] and emergence of resistance to fluconazole in *C. albicans* and other *Candida* spp.[140,380,410] One center with more than 10 years of experience using fluconazole prophylaxis documented emergence of a resistant strain of *C. parapsilosis* that caused invasive candidiasis in neonates.[319]

Similar to well-documented emergence of bacteria that become resistant to frequently used antibiotics, the emergence of *Candida* spp. resistant to antifungal agents is becoming an important consideration in clinical management of invasive candidiasis.[319,410,411] In addition, emergence of invasive yeasts other than *Candida* spp. may occur. An outbreak of *Rhodotorula mucilaginosa*, a fluconazole-resistant yeast, occurred more recently in an NICU that routinely administered prophylactic fluconazole.[280,371]

OTHER PREVENTIVE STRATEGIES

Preventive strategies other than administration of antifungal agents to reduce *Candida* infections in neonates, are important approaches to investigate. Oral supplementation of breast milk feedings with the probiotic *Lactobacillus casei* subspecies *rhamnosus* was shown more recently to reduce significantly the incidence and intensity of enteric colonization with *Candida* spp. in VLBW neonates.[227] Bloodstream infections with *Candida* spp. occurred in neonates enrolled in previous studies evaluating intravenous immunoglobulin for prevention of nosocomial infections in VLBW neonates; however, no studies have evaluated immunoprophylaxis strategies designed specifically for prevention of nosocomial *Candida* infections in VLBW neonates.[391]

The role of patient cohorting or single-room isolation of neonates with *Candida* colonization or infection also was reviewed more recently.[72,247] Published evidence shows that transmission of *Candida* in the NICU occurs by direct or indirect contact, and cross-infection by health care workers has been documented.[18,63,163,165,167,247,303] Guidelines for isolation procedures are unavailable, most likely because currently available information neither supports nor refutes the use of isolation measures to reduce transmission of *Candida* infections in high-risk neonates.[247]

INVASIVE YEASTS OTHER THAN *CANDIDA*

Disseminated candidiasis is the most common fungal infection in neonates. The dimorphic fungi may infect pregnant women and rarely may be transmitted to the fetus or newborn. More recent reports have suggested that unusual yeasts are becoming impor-

*See references 19, 46, 84, 187, 188, 194, 225, 234, 235, 273, 319.

tant causes of invasive disease in neonates and NICU outbreaks, often with high morbidity and mortality rates.[346] It is important to be aware of emerging pathogenic yeasts because a timely diagnosis and effective management may improve neonatal morbidity and mortality from these often challenging and difficult infections.

CRYPTOCOCCUS

Congenital and perinatal infections with the encapsulated yeast, *C. neoformans*, have been reported.[67,110,189,339,342] Fetal demise may occur, especially in pregnant women with untreated or severe disease.[110] Neonates also may aspirate the organism during delivery and present with fever and respiratory symptoms; meningitis, gastrointestinal involvement, and disseminated disease also may occur.[189] Neonates and young infants who present with disseminated *C. neoformans* also may have a congenital immune disorder, such as severe combined immunodeficiency.[342] Systemic antifungal treatment with amphotericin B is preferred, used in combination with 5-FC. Although *C. neoformans* seems to be susceptible to triazole agents, experience using these compounds to treat neonates with cryptococcosis is limited.[333]

MALASSEZIA

Malassezia genus of yeasts includes seven species. The six lipophilic species are *Malassezia furfur*, *Malassezia globosa*, *Malassezia obtuse*, *Malassezia restricta*, *Malassezia slooffiae*, and *Malassezia sympodialis*, and one species, *Malassezia pachydermatis*, is not strictly lipophilic.[17] *Malassezia* spp. frequently colonize the skin of neonates.[16,20,346] By the time they are 1 week old, 5 percent of neonates have positive skin cultures for *Malassezia* spp.; by 2 weeks of age, 37 to 51 percent of VLBW premature neonates have positive skin cultures. By the time they reach 3 to 6 months of age, healthy newborns have been observed to have colonization rates of 48 to 91 percent, as have preterm neonates in the NICU.[16,20,36] *Malassezia* spp. can be introduced into the NICU on the hands of health care workers and be transmitted to neonates; it also seems to persist on environmental surfaces such as incubators.[70,82,396] The species most frequently associated with neonatal infections and NICU outbreaks include *M. furfur*, *M. pachydermatis*, *M. sympodialis*, and *M. globosa*.

Skin infections with *M. furfur* and *M. sympodialis* have been associated with nonfollicular pustulosis skin conditions, such as neonatal cephalic pustulosis and neonatal acne, in neonates.[20,45,259,293] Skin scrapings of the pustules may show neutrophilic cells and fungal or yeast organisms when examined under the microscope, and fungal culture confirms the organism.[20,293] Neonatal cephalic pustulosis usually is a benign, self-limited condition of the skin and responds to topical antifungal therapy. It must be differentiated, however, from more invasive forms of yeast and fungal diseases. Skin infections with *M. globosa* and, to a lesser extent, *M. sympodialis* are associated with pityriasis versicolor.[17]

Intravascular catheters may become colonized with *M. furfur* or *M. pachydermatis* and cause bloodstream infections, often with serious complications in VLBW preterm neonates.[93,392] Risks for development of invasive disease include previous treatment with broad-spectrum antibiotics and prolonged use of intravascular catheters and intravenous fat emulsions or lipid infusions.[82,396] Neonates may present with systemic signs of sepsis, pulmonary decompensation, and thrombocytopenia.[360] Complications of catheter-associated bloodstream infections with *M. furfur* include peripheral thrombophlebitis, thromboembolism, catheter occlusion, adhesion of the vascular catheter to the vein wall, and endocarditis with intracardiac mass and thromboembolic phenomena.[21,95,191,195,323] Neonatal meningitis and urinary tract infections associated with *M. furfur* and *M. pachydermatis* also have been reported.[70]

Cultures of blood, catheter tip, urine, CSF, and involved tissue should be obtained. The organism also has been seen on peripheral blood smear.[48] Diagnosis may be elusive, however, because recovery of *Malassezia* spp. in routine cultures is rare; if the diagnosis is suspected, special fungal cultures on Sabouraud dextrose agar overlaid with sterile olive oil or media containing long-chain fatty acids may enhance recovery of lipophilic *Malassezia* spp. Treatment involves immediate removal of the catheter and discontinuation of lipid infusions. *Malassezia* spp. seem to be susceptible to most triazole agents and amphotericin B.[144,244] Administration of intravenous amphotericin B deoxycholate is recommended for treatment of neonates with invasive disease caused by *Malassezia* spp.

PICHIA

Pichia (*Hansenula*) *anomala* and *Pichia ohmeri* are emerging yeasts that may cause infection in preterm VLBW neonates and infants with severe combined immunodeficiency. In some NICUs, 17 percent of preterm neonates may be colonized, and single cases and NICU outbreaks associated with indwelling catheters, administration of total parenteral nutrition solutions, and abdominal surgery have been described.[13,23,219,256,278,338,364,401] Invasive diseases in preterm neonates include bloodstream infections, sepsis syndrome, abscesses, and meningitis with ventriculitis. Management includes removal of indwelling catheters and systemic antifungal therapy. Although *Pichia* spp. seem to be susceptible to amphotericin B and some antifungal triazoles, no standard treatment recommendations are available. Amphotericin B in combination with 5-FC usually has been administered as treatment for neonates with invasive *Pichia* spp. infections.[23,219,256,364,401]

TRICHOSPORON

Trichosporon spp. colonize the hair, skin, mucous membranes, and gastrointestinal tract. *T. beigelii* has caused invasive dermatitis, late-onset sepsis, pulmonary infiltrates, and urinary tract infections in VLBW preterm neonates with intravascular catheters.* It also may cause endophthalmitis and endocarditis. *Trichosporon asahii* infection in neonates has been reported more recently, suggesting that this species has emerged as a neonatal pathogen.[270,407]

Trichosporon spp. have been isolated from blood, urine, tracheal aspirates, skin lesions, and catheter tip cultures from neonates.[338] The organism may be identified preliminarily as a germ-tube negative yeast and be confused initially with *Candida* spp. Breakthrough *Trichosporon* infections in patients receiving antifungal agents for candidemia have been reported. The clinician may erroneously attribute persistently positive cultures to a resistant *Candida* spp. rather than *Trichosporon* spp.[35,298] *Trichosporon* spp. also share heat-stable antigens with *C. neoformans*, and produce false-positive cryptococcal antigen tests. A real-time polymerase chain reaction assay to detect *T. asahii* DNA in sera has been developed and may help facilitate rapid establishment of the diagnosis of this potentially fatal infection.[238]

*See references 15, 16, 20, 21, 36, 45, 70, 82, 95, 161, 191, 195, 259, 288, 293, 297, 323, 332, 360, 374, 396.

*See references 35, 125, 140, 147, 196, 270, 298, 338, 362, 385, 407, 408.

The organism has unpredictable susceptibility to antifungal agents, and there are no standardized recommendations for management of neonates with invasive *Trichosporon* infection. Most neonates have been treated with amphotericin B deoxycholate or liposomal amphotericin B.[338,407] The organism may be tolerant or resistant to amphotericin B, caspofungin, and posaconazole, and treatment failures with all of these agents may occur.[385] The organism seems to be susceptible to voriconazole, and isolated case reports of successful therapy in older patients using voriconazole, in combination with amphotericin B, have been published, but no published experience in neonates is available.[35,196,298]

RHODOTORULA

Rhodotorula spp. are another emerging opportunistic yeast that has caused catheter-associated bloodstream infections, endocarditis, peritonitis, meningitis, and endophthalmitis in immunocompromised patients and patients in intensive care units.[280,371] *R. mucilaginosa* and, less frequently, *Rhodotorula glutinis* have been documented to cause disease. *Rhodotorula* spp. usually are susceptible to amphotericin B, itraconazole, and voriconazole, but commonly are resistant to fluconazole. More recently, an outbreak of catheter-associated bloodstream infections with *R. mucilaginosa* in preterm neonates in an NICU administering routine fluconazole prophylaxis was reported.[280] Successful management of infected neonates included removal of the catheters and administration of systemic amphotericin B.

INVASIVE FUNGAL DISEASES

CONGENITAL AND PERINATAL TRANSMISSION

Fetal demise, congenital infection, and perinatal transmission associated with the endemic dimorphic fungi, *Coccidioides immitis* and *Blastomyces dermatiditis*, have been described.* Published case reports are very rare, however. Third-trimester acute infection with *C. immitis* seems to carry increased risk of developing severe illness for the mother and fetus. Perinatal transmission for both organisms likely occurs from neonatal aspiration of infected cervicovaginal secretions from a chronically infected maternal genitourinary tract. Cultures of urine, respiratory secretions, and lung tissue are most likely to yield the organisms. If coccidioidomycosis or blastomycosis is diagnosed in a neonate, treatment with systemic amphotericin B is recommended.

ACQUIRED INVASIVE FUNGAL DISEASE

Invasive fungal disease acquired by VLBW or ELBW premature neonates involves primarily the skin, lungs, or gastrointestinal tract. Because many of the invasive fungi that affect neonates also are angioinvasive, sepsis syndrome with hematogenous dissemination to lung, liver, spleen, CNS, and eye may occur rapidly.

ASPERGILLUS

Aspergillus spp. include *Aspergillus flavus*, *Aspergillus fumigatus*, *Aspergillus glaucus*, *Aspergillus nidulans*, *Aspergillus niger*, and *Aspergillus terreus*. *Aspergillus* spp. frequently are found in the environment and the hospital. Infection in neonates and outbreaks in NICUs have been associated with nearby construction or renovation.[9,11,143,271] Diseases associated with *Aspergillus* infection of the neonate include primary cutaneous aspergillosis or invasive dermatitis, pulmonary aspergillosis, and disseminated aspergillosis. Disseminated disease may involve the heart, liver, spleen, lungs, CNS, or eye.*

Neonatal aspergillosis usually manifests in the second week of life.[271,308,400] Risk factors include extreme prematurity and VLBW or ELBW, administration of steroids and broad-spectrum antibiotics, hyperglycemia, and trauma of the extremely vulnerable skin of the premature infant.[143,308] The delicate skin of VLBW infants can be macerated easily by adhesive tape, traumatized at the site of insertion of an indwelling intravascular catheter or by surgical procedures, or damaged by pressure sores, providing a portal of entry for the fungus. Invasive fungal dermatitis then occurs (Fig. 76–5). *Aspergillus* spp. also may gain entry through the lungs and cause invasive pulmonary aspergillosis.[143] Because the fungus has a predilection for invasion of blood vessels, it can disseminate quickly in the bloodstream and occlude vessels, causing thrombosis, infarction, and necrosis of tissue (see Fig. 76–5B and C).

Establishment of the diagnosis requires a high index of suspicion and documentation of the fungus by histopathologic examination and culture of the involved tissue or organ. Suspicious skin lesions may appear early as erythematous plaques, vesicles, scales, or persistent maceration; advanced disease may show dark, necrotic skin lesions; skin biopsy that shows invasion below the stratum corneum establishes the diagnosis of invasive fungal dermatitis (see Fig. 76–5A and B).[400] *Aspergillus* also may be recovered from tracheal aspirate cultures, ascites, and CSF.[135,143] No studies have evaluated the performance of galactomannan antigen tests for the early diagnosis of invasive aspergillosis in neonates.

Early diagnosis followed by prompt and aggressive treatment of a neonate with invasive aspergillosis is important to minimize the usually high morbidity and mortality rates associated with this disease. Traditional treatment has included prolonged, high-dose amphotericin B deoxycholate or lipid complex and surgical excision of accessible tissue, such as the skin and soft tissue, if local disease progresses despite administration of systemic antifungal therapy.[10,271,281] Treatment failures frequently occur.[130,135,143,149] More recently, case reports of premature neonates with primary cutaneous aspergillosis who were treated successfully with voriconazole alone or in combination with amphotericin B lipid complex and micafungin have been published.[130,318]

ZYGOMYCETES (*ABSIDIA, RHIZOPUS, MUCOR, RHIZOMUCOR*)

Zygomycosis, a term preferred now over mucormycosis, usually is caused by the following species of fungi: *Absidia* (*Absidia corymbifera*), *Rhizopus* (*Rhizopus arrhizus*, *Rhizopus microsporus*), *Mucor* (*Mucor amphibiorum*, *Mucor circinelloides*, *Mucor hiemalis*, *Mucor indicus*, *Mucor racemosus*, *Mucor ramsissimus*), or *Rhizomucor* (*Rhizomucor pusillus*, *Rhizomucor miehei*, *Rhizomucor variabilis*). Zygomycosis in a neonate usually manifests during the second and third weeks of life.[296,340,412] Health care–associated outbreaks have been linked to contaminated dressings, bandages, or armboards. Risk factors for acquisition of infection include VLBW, extreme prematurity, indwelling intravascular catheters, exposure to elastic bandages, adhesive dressings and tapes, and armboards or tongue depressors used to split extremities, and host factors such as congenital immunodeficiency or genetic disorders of metabolism that cause metabolic acidosis.[213,252,412]

The Zygomycetes are angiotrophic and aggressively invade blood vessels very early in the disease process (Fig. 76–6C). Invasion of blood vessels leads to thrombosis, infarction, and tissue

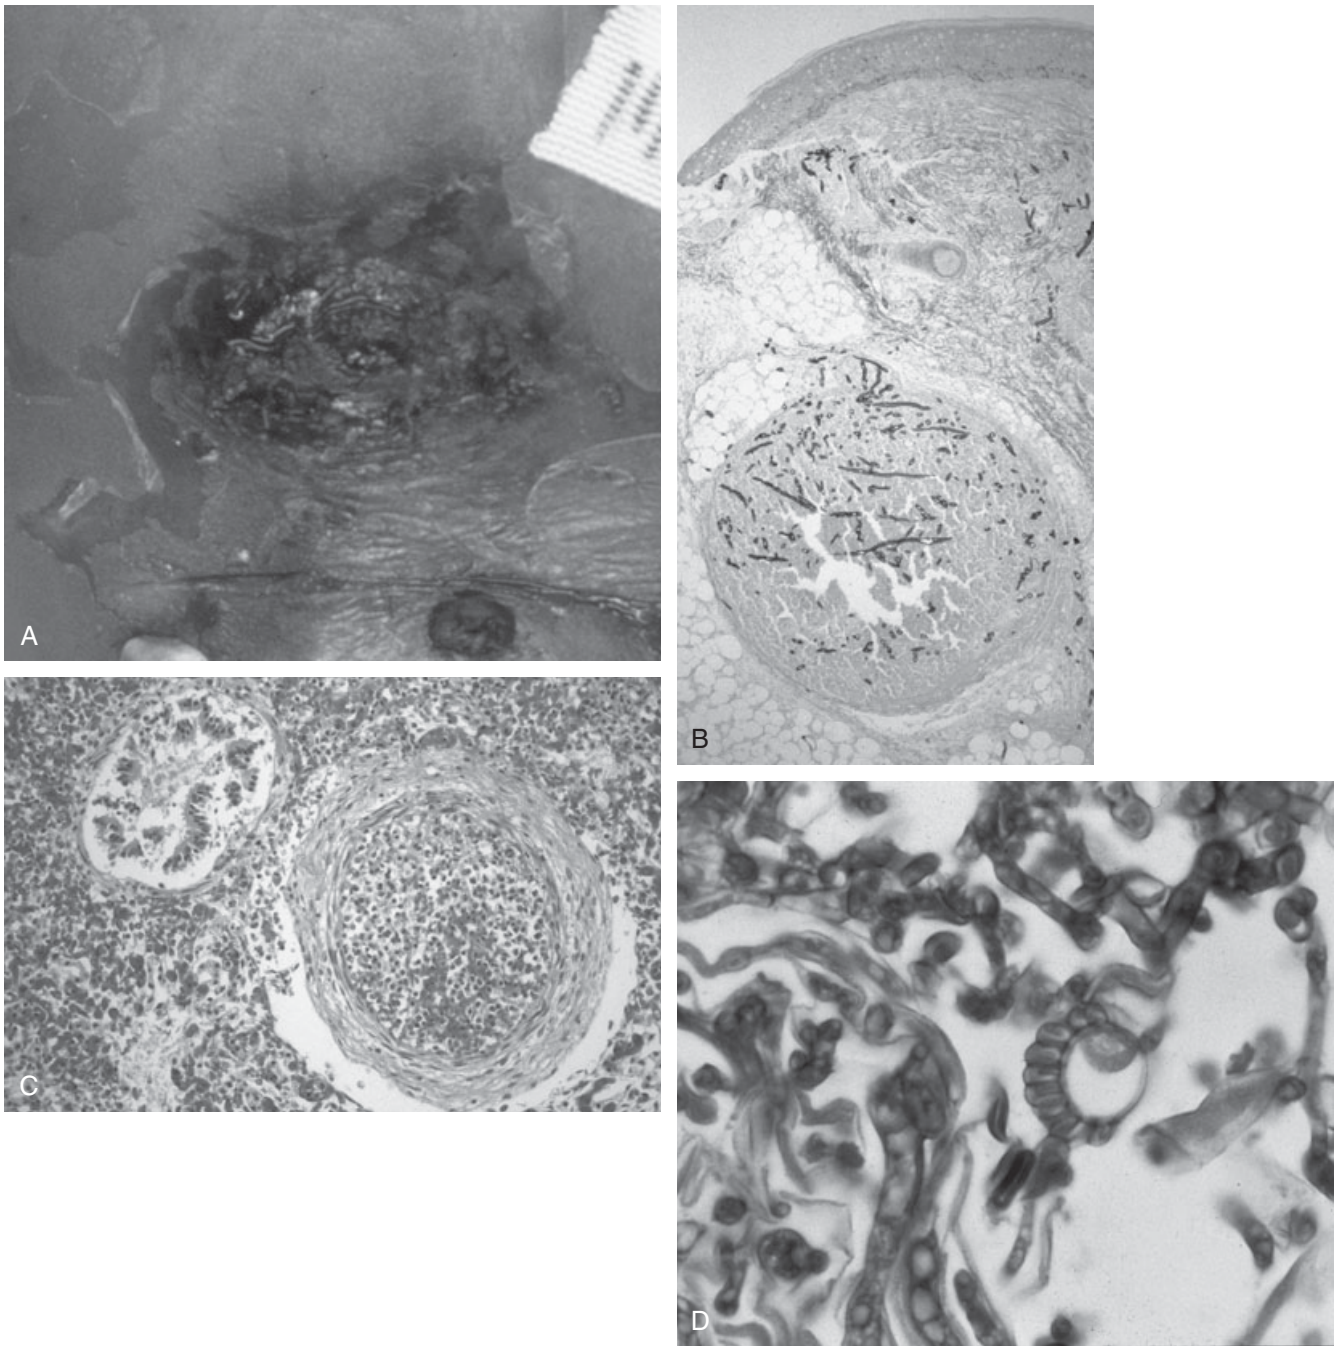

Figure 76–5 A-D, Invasive fungal dermatitis in a premature neonate caused by *Aspergillus flavus*. **A,** Fatal invasive fungal dermatitis with necrotizing fasciitis and disseminated fungal disease in a 23-day-old premature infant born at 26 weeks' gestation. **B-D,** Autopsy examination impressively showed angioinvasive nature of *A. flavus* with infected thrombus in skin (**B**) and lung (**C**) tissue. Uniformly broad, hyaline, septated, right angle branching hyphae with dramatic fungal fruiting body of *A. flavus* were seen in a lung lesion of this infant (**D**) (methenamine silver nitrate stain, 40×, 100×, and 400×, respectively, original magnification). *(Courtesy of Dr. Edwina J. Popek, Department of Pathology, Baylor College of Medicine and Texas Children's Hospital, Houston, TX.)*

necrosis; destruction of local tissue can be extensive, and the fungus may disseminate throughout the body and CNS. The most common presentation of invasive zygomycosis in neonates is primary cutaneous disease. Cutaneous zygomycosis usually begins at an area of minor skin trauma or at the site of intravenous catheter insertion that has come in contact with adhesive tape or bandages, first appearing as a cluster of necrotic vesicles or scales, which then rapidly progresses to extensive necrotizing cellulitis.[14,91,105,168,195,213,252,266,322] It usually involves the skin and soft tissues of the upper extremities, but the lower extremities, abdominal wall, or face also may be presenting sites.

Gastrointestinal zygomycosis in a premature neonate often mimics NEC clinically, but without the characteristic radiographic bowel patterns; rarely, it has presented as Hirschsprung disease.[6,412] Intestinal perforation, of small or large bowel or appendix, with secondary peritonitis, may occur (see Fig. 76–6).[4,6,81,91,97,296,340] Rhinocerebral zygomycosis classically manifests in diabetics with ketoacidosis, but it also may affect neonates with

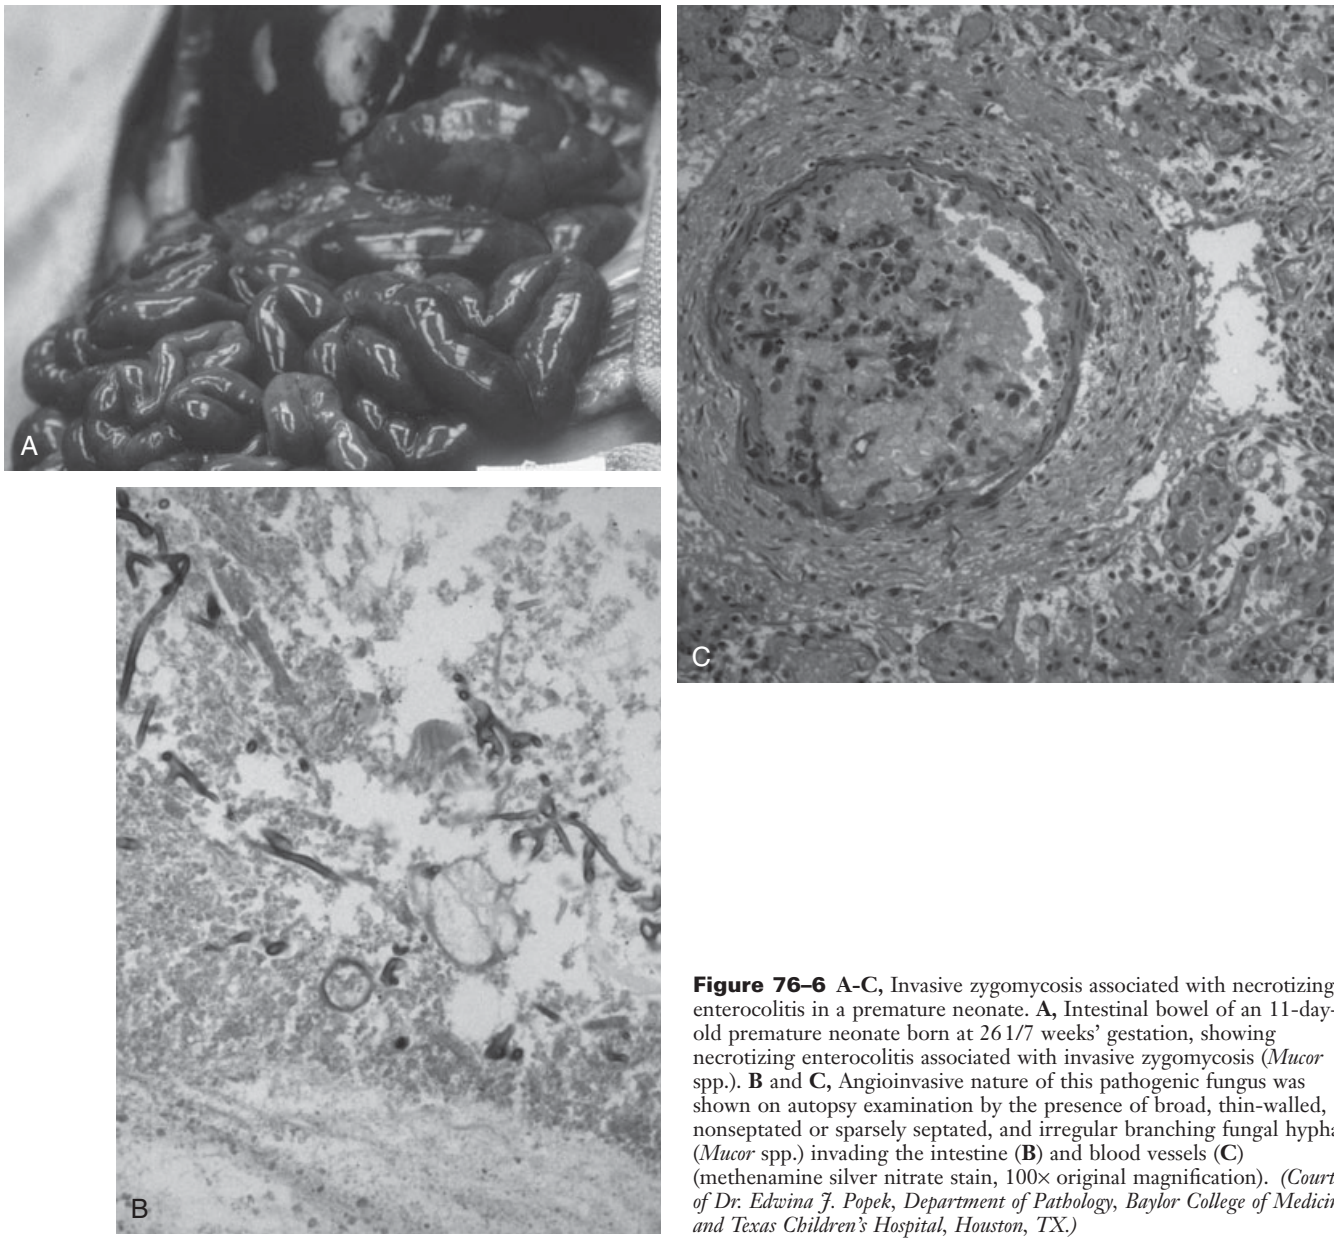

Figure 76–6 **A-C,** Invasive zygomycosis associated with necrotizing enterocolitis in a premature neonate. **A,** Intestinal bowel of an 11-day-old premature neonate born at 26 1/7 weeks' gestation, showing necrotizing enterocolitis associated with invasive zygomycosis (*Mucor* spp.). **B** and **C,** Angioinvasive nature of this pathogenic fungus was shown on autopsy examination by the presence of broad, thin-walled, nonseptated or sparsely septated, and irregular branching fungal hyphae (*Mucor* spp.) invading the intestine (**B**) and blood vessels (**C**) (methenamine silver nitrate stain, 100× original magnification). *(Courtesy of Dr. Edwina J. Popek, Department of Pathology, Baylor College of Medicine and Texas Children's Hospital, Houston, TX.)*

conditions associated with metabolic acidosis and premature infants. The fungus enters via the nasal passages and invades the sinus cavities and orbits, spreading to the CNS by fungal thrombosis of cavernous sinus and internal carotid artery.[413] Pulmonary zygomycosis also may occur, either as a primary pneumonia with consolidation and necrosis or secondary to vascular dissemination from a cutaneous or gastrointestinal source.[413] Disseminated zygomycosis is a fatal fungal sepsis syndrome, usually involving all major organ systems and the CNS.

Diagnosis is established by histopathologic examination of tissue, in which characteristic fungal elements invading the tissue and blood vessels can be seen. Fungal culture confirms the identification of the fungus. Successful management includes early diagnosis and aggressive surgical débridement and resection of involved tissues, to clear margins of resection.[252] Amputation or extensive skin grafts may be necessary in some patients.[205] Aggressive surgery is important because the fungus is resistant to most currently available antifungal agents, including the echinocandins and first-generation and second-generation triazoles. The fungus may be inhibited by amphotericin B given in high doses (1.5 mg/kg/day of amphotericin B deoxycholate or ≥5 mg/kg of lipid formulations), which should be administered as soon as the diagnosis is suspected. The newest triazole compound, posaconazole, seems to have activity against zygomycetes, but experience in administering this new agent to neonates is unavailable.[302]

RARE AND UNUSUAL PATHOGENIC FUNGI

Other unusual pathogenic fungi that have been reported to cause invasive, and often fatal, disease in neonates include *Curvularia* (especially *Curvularia lunata*), which caused invasive fungal dermatitis in a premature infant, caused sternal wound infection complicating cardiac surgery in another neonate, and complicated disseminated neonatal herpes simplex infection in a third neonate (unpublished data) (Fig. 76–7).[309,406] *Phialemonium obova-*

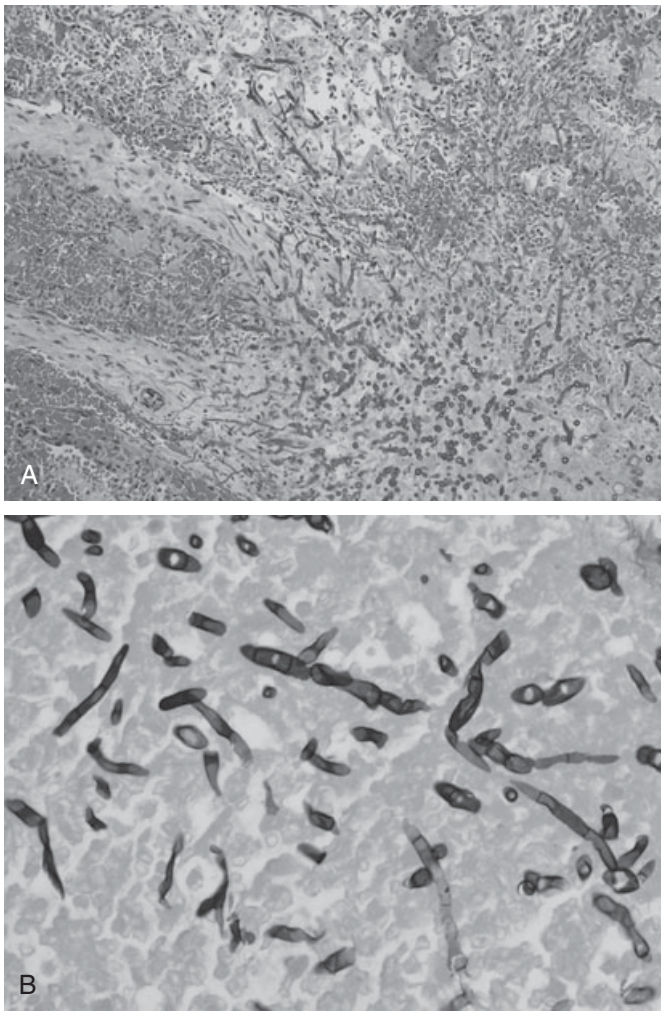

Figure 76–7 **A** and **B,** Disseminated *Curvularia* infection. Fatal invasive fungal infection with *Curvularia* in a 2-week-old term neonate with liver failure because of neonatal herpes simplex virus infection. **A,** The lungs showed angioinvasive fungal hyphae extending from the lumen of a thrombosed vessel into the adjacent alveolated lung parenchyma (hematoxylin and eosin stain, 100× original magnification). **B,** The fungal hyphae of *Curvularia* are narrow, frequently septated, with acute angle branching (methenamine silver nitrate stain, 400× original magnification). (See companion Expert Consult web site for color version.) *(Courtesy of Dr. Megan K. Dishop, Department of Pathology, Baylor College of Medicine and Texas Children's Hospital, Houston, TX.)*

tum reportedly has caused fatal endocarditis in a premature neonate.[138] *Bipolari spicifera* has caused invasive fungal dermatitis with dissemination in a preterm neonate.[250] Several cases of *Trichophyton* (*Trichophyton rubrum* and *Trichophyton violaceum*) causing localized scalp lesions, similar to tinea capitis, in neonates have been reported.[33,71,258,372]

CHAPTER 77

Congenital Toxoplasmosis

James B. McAuley ✪ Kenneth M. Boyer

Toxoplasma gondii is an obligate intracellular protozoan parasite (phylum Apicomplexa, class Sporozoasida, order Eucoccidiida).[126] The first report of human infection occurred in 1908.[18] In 1937, Wolf and Cowen[132] reported a case of congenital granulomatous encephalitis, which Sabin[103] later correctly attributed to *T. gondii* infection. Congenital toxoplasmosis results from placental infection that develops after primary maternal infection and subsequent hematogenous spread to the fetus.[95] *Toxoplasma* is ubiquitous in nature, with the cat family being the definitive host.[35,37]

The organism exists in three forms: (1) *oocyst*, which is excreted in cat feces and is infectious within 2 to 5 days after sporulation; (2) a proliferative stage called a *tachyzoite*; and (3) a tissue cystic stage called a *bradyzoite*. Mammals or birds ingest oocysts from contaminated plants and soil, or, if carnivorous, they may ingest

bradyzoites. When ingested, *Toxoplasma* replicate asexually, and tissue cysts accumulate in the organs and skeletal muscle of these animals. Possible routes of infection for humans are direct ingestion of sporulated oocysts from soil, water, fruits, or vegetables that have been contaminated by cat feces, or ingestion of undercooked meat containing bradyzoites.[6,8,26,95] Humans also have become infected after undergoing organ transplantation, after receiving blood product transfusions, and after having laboratory accidents.[95]

The prevalence of antibody to *T. gondii* in women of childbearing age in the United States varies from approximately 3 to 30 percent, depending on the region of the country.[57,58,111] The lowest seroprevalence rates have been found in the Mountain states, where a dry climate does not favor survival of oocysts in the soil. The highest rates have been noted in the northeastern and southeastern states. In contrast, the seropositivity rate for women in Paris may be 70 percent. These widely disparate seroprevalence rates in different adult populations throughout the world are explained by differences in eating and sanitation practices and conditions that affect survival of oocysts in the environment.[58,95] More recent studies have documented a declining prevalence of infection in the United States.[57] This decline likely is related to decreased rates of contamination of commercial meats with *Toxoplasma* and increased educational efforts aimed at informing the public about avoiding acquisition of infection.[27,58]

The prevalence of congenital infection in the United States has been documented to be 0.08 per 1000 births (1 in 12,000 births) by IgM screening of blood specimens collected on filter paper from newborns in Massachusetts and New Hampshire.[49] This figure compares with a rate of 3 to 10 per 1000 live births in Paris and Vienna. In Massachusetts, a case-control study involving 14 years of newborn screening for congenital toxoplasmosis found that birth of the mother outside the United States, particularly in Cambodia and Laos, and the educational level and higher gravidity of the mother were strongly predictive of congenital infection.[55]

TRANSMISSION

Infection of the fetus occurs during maternal parasitemia, with subsequent infection of the placenta caused by tachyzoites.[36,95] Placental infection represents an important intermediary step between maternal and fetal infection. A delay of 16 weeks between placental infection and subsequent infection of the fetus has been noted and is termed the *prenatal incubation period*.[95] Fetal infection occurs as a consequence of maternal primary infection acquired during pregnancy.[36,83,95] Rare instances of transmission have been reported in women with primary infection shortly before conception.[40,122] Reactivation of latent *Toxoplasma* infection during pregnancy does not lead to fetal infection except rarely in immunocompromised women, such as women infected with human immunodeficiency virus (HIV).[80,87,95,134] In these instances, congenital infection has been documented, although the risk is very low.[30] Maternal re-infection leading to congenital toxoplasmosis also has been reported rarely.[40,95] Congenital toxoplasmosis has occurred in twins and triplets.[13,95] Despite these occasional case reports, most congenital infections are the result of primary maternal infection during pregnancy.

The overall fetal infection rate from untreated maternal infection during pregnancy is approximately 40 percent, although the rate depends on when in pregnancy the mother becomes infected (Table 77–1).[31,95,134] Although the actual rate of fetal infection increases as pregnancy advances, the severity of clinical manifestations is greatest when maternal infection is acquired during the first trimester.[31,95,134] Transmission during breast-feeding in humans has not been shown, although the organism has been detected in human milk.

TABLE 77–1 Vertical Transmission and Severity of Disease for *Toxoplasma gondii* by the Timing of Maternal Infection during Pregnancy

	Trimester of Maternal Infection		
	First	*Second*	*Third*
Overall transmission rate (%)	15	30	60
Proportion of infected children with specific disease severity			
Stillborn/perinatal death (%)	35	7	0
Subclinical (asymptomatic) (%)	18	67	90
Mild disease (%)	6	18	10
Severe disease (%)	41	8	0

CLINICAL MANIFESTATIONS

Acute maternal infection acquired early in pregnancy may lead to fulminant fetal infection and result in stillbirth, nonimmune fetal hydrops, preterm birth, and perinatal death.[1,5,49,95] Chronic *Toxoplasma* infection has been associated only rarely with sporadic abortion.[95] Most infants born with congenital *Toxoplasma* infection are asymptomatic in the neonatal period, with clinical signs and symptoms being present in only approximately 25 percent of infants.[2,55,63,73] Long-term follow-up of these asymptomatically infected infants reveals eye or neurologic disease, or both, in 80 to 90 percent by the time they reach adulthood.[20,31,49,55,116,124] The clinical manifestations of congenital toxoplasmosis in newborns generally are indistinguishable from the manifestations associated with other agents of congenital infection, such as cytomegalovirus and *Treponema pallidum*. The most characteristic clinical findings, frequently referred to as the *classic triad of congenital toxoplasmosis*, are chorioretinitis, intracranial calcifications, and hydrocephalus.[32,95] They are seen in approximately 86 percent (chorioretinitis), 37 percent (intracranial calcifications), and 20 percent (hydrocephalus) of symptomatic infants. These conditions often are accompanied by a combination of signs and symptoms including anemia (59%), jaundice (43%), splenomegaly (41%), seizures (41%), fever (40%), hepatomegaly (34%), lymphadenopathy (32%), microcephaly (9%), and eosinophilia (9%).[32,95]

Involvement of the central nervous system is a hallmark of congenital *Toxoplasma* infection.[12a,13,20,32,72,95,100,111] Hydrocephalus usually is obstructive and often requires ventriculoperitoneal shunting.[95,111] It may be the only manifestation of disease. Abnormalities in cerebrospinal fluid (CSF) occur in approximately 63 percent of infected infants; characteristically, they consist of lymphocytic pleocytosis and an elevated protein level.[32,72,95] The markedly high protein concentrations in ventricular fluid, often exceeding 1 g/dL, and hydrocephalus are explained by periaqueductal and periventricular vasculitis with necrosis, which are associated specifically with toxoplasmosis.[95] Inflammation and necrosis involving the hypothalamus have resulted in hypothermia and hyperthermia. When microcephaly is present, it indicates severe brain damage. Intracranial calcifications may be single or multiple but typically are generalized and located in the caudate nucleus, choroid plexus, meninges, and subependyma.[25,88,95] Periventricular calcifications similar to those associated with cytomegalovirus also have been described. They are visualized best by computed tomography (CT),[72] although ultrasonography has been shown to have excellent correlation with CT findings.[10] The calcifications may resolve with appropriate antimicrobial therapy.[88]

Neurologic sequelae from untreated congenital toxoplasmosis include mental retardation (87%), seizures (82%), spasticity and palsies (71%), and deafness (15%).[32,72,95,111] *Toxoplasma* has been detected in the inner ear and mastoid, with the associated inflam-

mation resulting in deafness. An ascending flaccid paralysis with myelitis also has been reported.[95]

Chorioretinitis caused by *Toxoplasma* occurring at any age is likely to be a result of congenital infection, although acute acquired toxoplasmosis was reported to cause approximately 40 percent of childhood chorioretinitis in one study.[44,79,95] In infants, the most common manifestation is strabismus, whereas defects in visual acuity predominate in older children and adults. The characteristic lesion consists of a focal necrotizing retinitis that often is bilateral.[79] Organisms are present in the retina, and they have a predilection for the macula, with resultant loss of vision. Involvement of the optic nerve also may occur. Other complications include iridocyclitis and cataracts.[79]

Other manifestations of congenital toxoplasmosis include nonspecific maculopapular or petechial rash, myocarditis, pneumonitis, thrombocytopenia, nephrotic syndrome, and abnormalities in immunoglobulin production.[52,95] Bony abnormalities consisting of metaphyseal radiolucencies similar to those seen in congenital syphilis also have been reported. A variety of endocrine abnormalities, including hypothyroidism, diabetes insipidus,[72,95] precocious puberty, and growth hormone deficiency, may occur. All these abnormalities are related to the fact that the organism is capable of widespread dissemination throughout the brain and body, with involvement of virtually all organ systems.

DIAGNOSIS

The diagnosis of congenital toxoplasmosis can be established by isolating the organism from infected body fluids and tissues, such as the placenta, amniotic fluid, fetal blood obtained by cordocentesis, umbilical cord blood, infant blood, and CSF.[22,82,131] Such isolation involves inoculation of the specimen intraperitoneally into laboratory mice and requires approximately 4 to 6 weeks for confirmation. Testing is not widely available but can be done at the Toxoplasma Serology Laboratory, Palo Alto Medical Foundation (860 Bryant Street, Palo Alto, CA 94301; 415-326-8120). Alternatively, a diagnosis can be established by histopathologic examination of the placenta in which tachyzoites are revealed. Polymerase chain reaction (PCR) has been used successfully to detect *Toxoplasma* DNA in amniotic fluid, placenta, CSF, and fetal and infant blood.[22,48,50,82,101,102,131] PCR performed on amniotic fluid obtained by amniocentesis is the preferred method of confirming in utero infection. A negative amniotic fluid PCR result does not always rule out congenital infection, however.[82,131] In addition, interlaboratory variability in performance of PCR assays has been documented.

The most practical and widely used method of establishing the diagnosis is by testing maternal and newborn blood for serologic evidence of *Toxoplasma* infection. Major problems associated with serologic diagnosis include determining the acuity of the maternal infection and differentiating endogenous from transplacentally acquired antibodies in neonatal/fetal infection. In addition, many commercially available immunoglobulin M (IgM) assays have been associated with significant false-positive and false-negative results.[125,131] Table 77–2 is a brief overview of strategies for establishing the serologic diagnosis in maternal and fetal/neonatal sera, including when to send sera for testing in a reference laboratory.

Tests are available that detect *T. gondii*–specific IgG, and they include the Sabin-Feldman dye test,[104] which is considered to be the gold standard but requires live organisms/tachyzoites; the indirect immunofluorescent antibody test; IgG enzyme-linked immunosorbent assay (ELISA); and direct agglutination.[2,82,93,131,133] An AC/HS differential agglutination test has been developed as a confirmatory test to differentiate acute and chronic maternal infection.[16,24,68] This test compares the IgG serologic titer obtained with the use of formalin-fixed tachyzoites (HS antigen) with the titer obtained with acetone-fixed (or methanol-fixed) tachyzoites (AC antigen). The latter preparation contains stage-specific *Toxoplasma* antigens that are recognized by IgG antibodies only during early infection. The enzyme-linked immunofiltration assay compares the immunologic profile of the mother's antibody response and that of her child at delivery and allows discrimination between

TABLE 77–2 Guidelines for Interpretation of Serologic Tests for Toxoplasmosis in Newborns

Newborn Serology		
IgG	***IgM***	**Interpretation**
Positive	Negative	For newborns, 25% have false-negative IgM (competition with high maternal IgG or failure to produce adequate IgM). Repeat testing on second specimen. Consider using alternative assay (IgM ELISA if IFA was used first, IgM IFA if ELISA was used first) If clinically high suspicion (documented acute maternal primary infection in pregnancy *or* compatible illness in infant), specimen should be sent to a reference laboratory for further testing. Clinical evaluation may be initiated (see below) *Reference Laboratory*: 0.5 mL serum to Toxoplasma Serology Laboratory, Palo Alto Medical Foundation, 860 Bryant Street, Palo Alto, CA 94301, 415-326-8120
Positive	Positive	IgM ELISA can be false-positive in the presence of rheumatoid factor, and IgM IFA can be false-positive in the setting of antinuclear antibodies. Further testing needed (IgM ISAGA, IgA EIA, IgE EIA/ISAGA, AC/HS antigen, placental PCR) in reference laboratory (see above) If high likelihood of infection (known maternal primary infection *or* child with clinically compatible illness), begin work-up while reference laboratory tests are pending Initial clinical evaluation of the infant should include ophthalmologic examination, auditory brain stem response to 20 dB of sound, serum alanine aminotransferase, total and direct bilirubin, complete blood count, CSF examination (cell count, glucose, protein, and total IgG), and brain CT for calcifications (more recent data suggest excellent agreement between CT and ultrasound, which can be obtained more quickly and without the need for sedation)
Positive	Equivocal	Repeat testing on second specimen. Consider using alternative assay (IgM ELISA if IFA was used first, IgM IFA if ELISA was used first). If clinically high suspicion (documented acute maternal primary infection in pregnancy *or* compatible illness in infant), specimen should be sent to a reference laboratory (see above)
Negative	Negative	Newborn IgG reflects maternal antibody, so no evidence of maternal infection. Newborn not infected
Negative	Positive	Newborn IgG reflects maternal antibody, so no evidence of maternal infection. Newborn not likely to be infected; consider false-positive IgM. Repeat assay on second specimen (IgG and IgM). Consider using alternative assay (IgM ELISA if IFA was used first, IgM IFA if ELISA was used first)

AC/HS, differential agglutination acetone-fixed/formalin-fixed tachyzoites; CSF, cerebrospinal fluid; CT, computed tomography; EIA, enzyme immunoassay; ELISA, enzyme-linked immunosorbent assay; IFA, immunofluorescent assay; Ig, immunoglobulin; ISAGA, immunosorbent agglutination assay; PCR, polymerase chain reaction.

IgG antibodies of maternal origin and IgG synthesized by the fetus; it has a reported sensitivity of 94 percent and a specificity of 99 percent. The IgG avidity test may be more widely available than is the AC/HS test, which requires working with tachyzoites, and allows timing of the infection from a single maternal specimen.[10,131]

After primary infection occurs, the avidity of IgG antibody for *T. gondii* antigen is low. Urea dissociates low-avidity antibodies, and by determining the percentage of antibodies that resist elution by 6 mol/L urea, one can differentiate infection acquired within the past 12 weeks from an older infection. This test is useful in the first 12 weeks of gestation because the presence of high-avidity antibodies excludes the acquisition of infection in the previous 3 months.

Tests that detect *T. gondii*–specific IgM include (1) the double-sandwich IgM ELISA, which has a sensitivity of 75 percent and a specificity of 100 percent[23,94]; (2) the IgM immunosorbent agglutination assay, which is the most sensitive test but should not be performed on umbilical cord blood because even small quantities of maternal IgM antibodies contaminating the specimen would result in a false-positive test result[84-86]; and (3) the IgM immunofluorescent antibody test, which is not recommended as a first screening test for IgM antibodies because of lower sensitivity than that of either the IgM ELISA or the IgM immunosorbent agglutination assay but may be useful in conjunction with the IgM ELISA.[2,7,23,131] Other tests that can help differentiate acute infection further include a *T. gondii*–specific IgA ELISA and IgA immunofiltration assay; a *T. gondii*–specific IgE immuno-filtration assay; and IgG, IgM, and IgA immunoblotting tests.[19,22,82,92,93,113,131]

Evaluation of a pregnant woman and fetus typically is prompted initially either by detection of seroconversion in the context of a screening program or by serologic evaluation in the context of an acute illness compatible with toxoplasmosis. If the initial IgG is negative, a follow-up test needs to be performed to exclude seroconversion. If the initial test on a pregnant woman reveals IgG antibody, an attempt needs to be made to determine if the primary infection occurred during gestation. An IgM antibody test should be ordered, but the clinician must be aware of the potential for false-positive and false-negative results.[82,125,131] The IgG avidity test can be helpful if the pregnancy is within the first 12 weeks, with a high avidity test virtually excluding infection within the past 12 weeks. If the IgM is determined to be truly positive, and the IgG avidity test does not allow the clinician to exclude acute infection during pregnancy, the clinician needs to move to more sophisticated testing through a reference laboratory (see earlier) because IgM may persist for 12 to 18 months after acute infection.

If recent maternal infection is documented, the fetus should be evaluated and therapy should be started in the mother (see treatment section). The fetus is evaluated by ultrasound, and amniotic fluid should be tested for specific *Toxoplasma* DNA by PCR. PCR has supplanted the need for cordocentesis, and a positive result confirms fetal infection.[95] Postnatally, serologic testing of paired maternal and infant sera should be performed at a reliable laboratory that includes assays for IgG, IgM, IgA, and IgE antibodies. Subinoculation of placental tissue, amniotic fluid, and umbilical cord blood into mice should be considered. If the results of these tests suggest the possible presence of infection, the newborn should be evaluated fully by a complete blood cell count and platelet determination, liver function tests, CSF evaluation (including tests for IgG and IgM antibodies and PCR),[7,72,95] ophthalmologic examination, and CT scan or ultrasound of the head.

The presence of neonatal IgM antibody in serum or CSF or a positive PCR in serum or CSF indicates congenital infection. In addition, at-risk infants should have serologic follow-up to detect increasing serum IgG titers during the first year of life or persistent IgG antibody beyond 12 to 15 months of age, which would be indicative of congenital infection.[7,72] Uninfected infants have a continuous decline in *Toxoplasma* IgG titer, with no detectable IgM or IgA antibodies.

Low IgG titers and an AC/HS differential agglutination test that indicates remote maternal infection do not require further evaluation of the mother or infant, unless the mother is infected with HIV. Because fetal infection has occurred during chronic *Toxoplasma* infection in HIV-infected pregnant women, infants of co-infected mothers should be evaluated serologically at birth for evidence of congenital infection. Whether HIV-infected pregnant women who have low $CD4^+$ counts and who are seropositive for *Toxoplasma* antibody should receive empiric therapy to prevent fetal infection remains unclear. At present, available data are insufficient for routinely recommending such therapy.

TREATMENT

PREGNANT WOMEN

Treatment of an acutely infected woman during pregnancy with spiramycin may prevent transmission of the infection to the fetus.[14,33,127] A meta-analysis including 20 cohorts with 1721 infected mothers and 506 infected children suggested a reduction in transmission (odds ratio 0.48, 95% confidence interval 0.28 to 0.80) if therapy was started within 3 weeks of maternal seroconversion.[120] These results, considered along with the numerous women studied by individual investigators, strongly suggest that intrauterine treatment does reduce transmission of maternal infection to the fetus.[3,15,21,39,47,51] Contrary to the many individual studies, the meta-analysis failed to show that intrauterine treatment ameliorated the manifestations of congenital infection in the children who were born infected.

Spiramycin treatment of pregnant women with recently acquired primary infection should be instituted empirically while further testing is being done, in the hope of preventing spread of infection to the fetus. When fetal infection has occurred, however, maternal treatment with spiramycin does not seem to alter the evolution and severity of disease in the fetus, which is why evaluation of a potentially exposed fetus by PCR amplification of amniotic fluid permits informed decisions to be made concerning termination of pregnancy or treatment of the fetus in utero with pyrimethamine-sulfadiazine.

SEQUENTIAL FETAL AND POSTNATAL TREATMENT

Reports have described improved outcomes in patients treated in utero with continuing treatment during the first year of life compared with historical controls.[39,51] Pregnancies in which fetuses had obvious manifestations on ultrasound examination and most pregnancies with definite first-trimester infection were terminated, however.

Nonetheless, what is remarkable is that when this method of initiating aggressive treatment of fetuses in utero was applied, retinal disease was reported in only 3 of 50 such infants monitored until they reached 2 years of age. This finding contrasts with the presence of retinal or neurologic involvement in 50 percent of asymptomatic newborns detected by serologic screening in Massachusetts[49] and in 75 percent of children whose pediatricians referred them to our National Collaborative Treatment Trial for treatment in the perinatal period.[72] The outcome of pregnancies with infection acquired in the first trimester after in utero treatment also has been reported to be favorable in another study[5] in which only pregnancies in which the fetus had hydrocephalus were terminated.

TABLE 77–3 Treatment Guidelines for Congenital Toxoplasmosis

Condition	Medication	Dosage	Length of Therapy
Congenital infection	Pyrimethamine +	2 mg/kg/day for 2 days, then 1 mg/kg/day for 6 mo, then 3 times weekly (M-W-F) for 6 mo	1 year; monitor weekly complete blood counts and platelets
	Sulfadiazine +	100 mg/kg/day divided twice daily	
	Folinic acid +	5-10 mg 3 times weekly	Dose adjusted to maintain adequate complete blood count
	Prednisone	1 mg/kg/day divided twice daily	Until resolution of elevated CSF protein (<1 g/dL) or sight-threatening chorioretinitis resolves
Pregnant women—acute infection first 21 wk of gestation	Spiramycin—available on request from the Food and Drug Administration (301-827-2127)	1.5 g q12h without food	Until fetal infection documented or excluded (amniotic fluid PCR) at 21 wk gestation. If fetus infected, change to pyrimethamine + sulfadiazine + folinic acid until delivery
Pregnant women—fetal infection confirmed (amniotic fluid PCR positive)	Pyrimethamine +	100 mg/day divided twice daily for 2 days, then 50 mg/day	Until delivery
	Sulfadiazine +	100 mg/kg/day divided twice daily (maximum 3 g/day)	
	Folinic acid	5-20 mg/day	

CSF, cerebrospinal fluid; M-W-F, Monday, Wednesday, Friday; PCR, polymerase chain reaction.

CONGENITAL INFECTION

POSTNATAL TREATMENT

Data regarding the efficacy of postnatal treatment of infants with congenital *Toxoplasma* infection are becoming available.[45,46,49,72] The controlled National Collaborative Treatment Trial is in progress in Chicago.[72] This study seeks to define optimal therapeutic regimens. Physicians treating patients with congenital *Toxoplasma* infection who are younger than 2.5 months may wish to contact this multidisciplinary group regarding potential enrollment of their patients in that study (773-834-4152).

Outcomes to date from the National Collaborative Treatment Trial are substantially better for most, but not all, infants treated from the neonatal period for 12 months with pyrimethamine-sulfadiazine and leucovorin (Table 77–3) than for historical controls receiving no or short-course therapy.[72] Signs of active infection resolve within weeks of initiation of treatment. Overall, 18 of 66 (27%) children in the National Collaborative Treatment Trial have IQ results less than 70 compared to 86 of 101 (85%) in the reported literature.[32,72] No significant diminution in cognitive function occurs over the course of time, and most treated children are functioning well in regular school classrooms. No sensorineural hearing loss has been ascribable to congenital toxoplasmosis in treated children.[72,100,116] A subset of children with significant irreversible neurologic damage already present in the perinatal period have manifested profound developmental delay, motor impairment, and seizures. For the most part, these were children with hydrocephalus, high CSF protein, minimal improvement in brain CT scans after shunting, and often substantial delays in shunt placement or needed revision for shunt failure or other intercurrent medical problems.[116]

Although treatment during the first year of life arrests all signs of active disease, results in normal cognitive and motor outcome for most children and may result in resolution of seizures without recurrence for some treated children, the currently available drugs do not eradicate all cysts containing bradyzoites.[51] In most children, serologic titers of *T. gondii*–specific antibodies rebound 3 to 4 months after treatment is discontinued.[123] To date, new retinal lesions have occurred in 17 of 58 children in the National Collaborative Treatment Trial during 3 to 10 years of follow-up after the 1-year course of treatment.[72] Infected children undergo retinal examination each month for 3 months after discontinuing treatment around their first birthday, then every 3 months until they are old enough to describe visual symptoms accurately, and then every 6 months. In addition, an ophthalmologic evaluation should be performed promptly for any acute visual signs or symptoms that may be related to recrudescence of congenital ocular toxoplasmosis.[79]

Toxoplasmosis and coexistent HIV infection in children is increasingly rare since the advent of highly active antiretroviral therapy for HIV. Most children reported with toxoplasmosis and HIV have had congenital toxoplasmosis and have been symptomatic. For such children, therapy with pyrimethamine-sulfadiazine plus folinic acid is recommended in the doses presented in Table 77–3.

Indications for corticosteroid therapy with prednisone (0.5 mg/kg twice a day) are a CSF protein concentration of 1 g/dL or greater or chorioretinitis that threatens vision. Prednisone is continued until these findings are resolved.

PREVENTION

Routine serologic screening of women during pregnancy has been an effective means of prevention in France and Austria, and it has been advocated in other areas where the incidence of congenital toxoplasmosis remains high.[15] Such strategies have been criticized regarding the cost-effectiveness and feasibility of such strategies and the lack of randomized controlled trials definitively proving benefit.[44,121] Although such studies would be helpful, they are unlikely to be performed, given the current cohort data supporting the interventions. Neonatal screening for IgM antibody also has been advocated so that asymptomatic infants can be detected and treated before neurologic symptoms develop.[45,46,49,61,69,98] This strategy does not detect approximately 25 percent of infected infants who lack anti-*Toxoplasma* IgM antibody, but it allows postnatal treatment, which seems to ameliorate symptoms. The focus of prevention should be on educating women of child-bearing age to avoid ingesting oocysts in cat feces, fruits, or vegetables and encysted bradyzoites in raw meat.[8,11,12,33]

CHAPTER 78

Perinatal Bacterial Diseases

Dora Estripeaut ❂ Xavier Sáez-Llorens

In this chapter, we update relevant information on neonatal bacterial infections, with emphasis on epidemiology, pathogenesis, diagnosis, treatment, and prevention strategies. Aspects of the clinical manifestations, laboratory features, and management that are peculiar to the newborn infant are stressed. More complete descriptions of the bacterial pathogens, host-parasite relationships, and spectrum of diseases in older infants and children are presented elsewhere in the text.

ANTIBIOTIC DOSAGE SCHEDULES FOR NEONATES

Much has been written about the irrational use of antimicrobial agents in newborn infants. The "therapeutic misadventures" (i.e., the gray baby syndrome of chloramphenicol, kernicterus associated with sulfisoxazole, enamel hypoplasia after tetracycline therapy, and deafness from streptomycin and kanamycin) of past decades primarily resulted from lack of knowledge about pharmacologic concepts in neonates. Dosage recommendations for babies were calculated from simplified formulas that pared down the usual dosage for adults or from armchair reasoning based on information obtained from healthy men and women. In either case, the amount of antibiotic administered to neonates often was as subtherapeutic as it was toxic.

Physicians have come to realize that many of the physiologic and metabolic processes of the newborn constantly change during the first few days of life and that these alterations profoundly affect the pharmacokinetics of antibiotics. Since 1979, systematic investigations of these drugs have produced a clearer understanding of the factors influencing absorption, distribution, metabolism, and excretion of antimicrobials in newborn infants. As a result, the dosage and intervals of administration for the drugs most commonly used have been defined (Table 78–1).[312,420] These dosage schedules are offered as a guide to the safe and effective use of antibiotics in newborn infants. The suggested regimens must be modified in premature babies weighing less than 1200 g at birth, in patients with reduced renal or hepatic function, and in infants with altered metabolic or physiologic states (e.g., congestive heart failure, shock, hypothyroidism, during exchange transfusions and extracorporeal membrane oxygenation), in whom the volume of drug distribution in the body may be affected profoundly. Under such circumstances, the most effective means of prescribing antibiotics is to monitor serum concentrations and adjust the dosage accordingly.

EPIDEMIOLOGY AND PATHOGENESIS

Throughout pregnancy and until the membranes rupture, the infant's environment usually is sterile. Not until delivery and the immediate neonatal period is the infant exposed to many microorganisms. The human birth canal is host to large numbers of aerobic and anaerobic bacteria, *Mycoplasma*, *Ureaplasma*, *Chlamydia*, fungi, yeast, and viruses. *Staphylococcus epidermidis*, lactobacilli, diphtheroids, and alpha-hemolytic streptococci are found in 50 to 100 percent of vaginal cultures of pregnant women and constitute the predominant aerobic flora.[40,276,485] Significant but less common isolates include *Gardnerella vaginalis*, *Proteus* and *Klebsiella* spp., and group B and D streptococci; miscellaneous organisms, such as *Citrobacter*, *Acinetobacter*, and the *Campylobacter* group, are identified even less commonly.

Certain microorganisms are associated with the occurrence of stillbirths. Among these bacterial agents are *Escherichia coli*, group B streptococci, *Ureaplasma urealyticum*, *Listeria monocytogenes*, and *Treponema pallidum*. In countries with a high prevalence of syphilis, as many as half of all stillbirths are caused by this bacterium.[186,187] In the United States, stillbirths occur in nearly 7 per 1000 of all births, and 10 to 25 percent of them appear to be caused by a maternal/fetal infection. In developing countries, the relative contribution of infection may be even greater.[186]

Obligate anaerobes are present in most vaginal cultures of normal, healthy women.[189] Commonly, multiple anaerobic and aerobic species are present in the same host. Approximately 85

‡Not recommended for premature and/or hyperbilirubinemic neonates.

percent of women with genital colonization by anaerobes harbor *Bacteroides* spp., including *Bacteroides fragilis* in a third of cases. Anaerobic streptococci, *Peptostreptococcus* and *Peptococcus*, are found in approximately 40 percent of women, and *Clostridium* is present in 20 percent. Uncommon anaerobic isolates include *Veillonella*, *Bifidobacterium*, and *Eubacterium*. Vaginal cultures of pregnant women also yield mixed aerobic and anaerobic species, but the number of anaerobes decreases from early pregnancy to delivery.[276]

During the process of delivery, encounters with some of these bacteria initiate colonization of the infant's respiratory and gastrointestinal tracts. In most infants, the microbial flora is established without incident; however, disease caused by one of these organisms develops occasionally in an infant. Factors influencing conversion from colonization to disease are not understood well. Some women have asymptomatic bacterial vaginosis that has been associated with preterm labor and significant vaginal isolation of anaerobic flora.[193]

Worldwide, 1.6 million neonates die every year of infection. In the United States, the infant mortality rate is approximately 6.85 infant deaths per 1000 live births. Neonatal bacterial sepsis corresponds to the eighth leading cause of fatality.[31,233] The incidence of neonatal sepsis ranges from one to eight cases per 1000 live births, with the higher figures corresponding to developing countries. Low birth weight, male sex, and congenital malformation are important risk factors.[61] Extreme prematurity is the greatest risk factor for early-onset sepsis and is associated with an increased risk of having adverse outcomes, including respiratory distress syndrome, bronchopulmonary dysplasia, severe intraventricular hemorrhage, and periventricular leukomalacia.[477] Between 1962 and 1987, the overall incidence of neonatal sepsis in Panorama City, California, was 2.2 cases per 1000 live births; it was 18.6 for infants with birth weights less than 2500 g versus 1.2 for those with birth weights of 2500 g or greater.[263] In the same study, the incidence of meningitis was 0.3 case per 1000 live births and 2.8 and 0.07 for those with birth weights less than and greater than 2500 g, respectively. The highest age-specific incidence of bacterial meningitis occurs during the first month of life.[262]

Socioeconomic factors appear to be important in determining whether infants are at risk for infection. Premature infants and infants with low birth weight are born more frequently to mothers of low socioeconomic class than to those of average or high socioeconomic class.

Although no noticeable sex predilection has been observed for infants with intrauterine infections, a male preponderance is reported in almost all studies. The greater susceptibility of male infants is more evident in cases of sepsis caused by gram-negative enteric bacilli. The reasons behind this male preponderance are unknown but may be related to sex-linked factors in host susceptibility.

The bacterial cause of neonatal sepsis and meningitis varies from one geographic area to another. Although bacterial causes of neonatal sepsis in Western European countries are similar to those in the United States, a different pattern has been identified in Latin America, Asia, and Africa.[36,115] In the latter sites, gram-negative rods are the most frequent pathogens, followed by *Staphylococcus aureus* (Table 78–2).[25,530] Poor sterility standards in preparing intravenous solutions and performing invasive procedures might contribute to these etiologic patterns.[296]

The bacterial pathogens that cause infection in the nursery are different from those encountered when the infant arrives home. In the nursery, besides organisms acquired vertically from mothers, staphylococci (coagulase-positive and coagulase-negative) and gram-negative bacilli constitute the predominant etiologic agents causing nosocomial disease. At home, the infant is exposed to a different environment and to members and pets of the household, which provides opportunity for infection to

TABLE 78–2 Neonatal Pathogens of Sepsis in Hospitals in Different Geographic Areas (1990 to 2004)

	Latin America, Caribbean (%)	Africa	South Asia
All gram-positive	533 (41.7)	606 (38.8)	1857 (31.0)
Staphylococcus aureus	178 (13.9)	224 (14.3)	1206 (20.2)

Modified from Zaidi, A. K., Huskins, W. C., Thaver, D., et al.: Hospital-acquired neonatal infections in developing countries. Lancet 365:1175-1188, 2005.

develop in the newborn and probably in the household from the newborn.

The current most common bacterial pathogens of the neonatal period in very-low-birth-weight (VLBW) infants (401 to 1500 g) are *E. coli*, group B *Streptococcus* (GBS), and coagulase-negative staphylococci.[409,477] These three organisms account for approximately 65 percent of all bacterial sepsis cases in this population.[477] The bacteria usually are acquired from the mother during the intrapartum period, after the onset of labor or rupture of membranes.[444] The acute septicemic form of group B streptococcal disease can be caused by any of the group B types (B_I to B_{VIII}), and the specific B type causing disease in the infant usually is found in the maternal vaginal tract.[21,22] The gastrointestinal tract is the natural reservoir for GBS and the probable source of vaginal colonization.[79,135,444]

Epidemiologic studies have shown that approximately 10 to 30 percent of pregnant women are colonized vaginally, rectally, or both with GBS, with the highest percentage occurring in developed countries.[79,135,275,400] After routine implementation of maternal cultures and antibiotic prophylaxis guidelines, the incidence of invasive group B streptococcal infection among pregnant women in the United States has decreased dramatically in the past decade.[307]

In a report from Panama,[334] only 5 percent of poor pregnant women seen in a public hospital were colonized by GBS, and approximately 2 percent of documented neonatal sepsis cases were caused by these organisms; in contrast, almost 20 percent of "septic" neonates born to mothers with better socioeconomic status and higher vaginal colonization (seen in a hospital that is only 5 miles away) had group B streptococcal disease.[418] Possibly, better hygienic practices contribute to eradication of many microorganisms from vaginal sites, thereby allowing GBS to colonize the vagina without interference by other microbes. Currently, a sepsis group B streptococcal etiology is relatively common in our country (personal communication).

Vertical transmission from mother to infant occurs in 40 to 70 percent of women colonized with this organism.[1,35,157,528] Infants born to heavily colonized women are more likely to harbor the organism, frequently at multiple sites, than are those born to lightly colonized women.[12,245,370] Some mothers of infants who are infected with GBS are at high risk for having babies in the future who are infected similarly. A low titer of serum antibodies to the type of infecting GBS and persistence of the organism in the mother have been demonstrated.[90]

Although intrapartum mother-to-infant transfer is the initial mode of acquisition of GBS by the newborn, it is not the sole way in which the baby becomes colonized.[1,15,35,369] In a Houston nursery, infant colonization rates increased from 20 to 25 percent at 1 day of age to 60 to 65 percent at 3 to 5 days of age, without a concomitant increase in parturient colonization rates.[369] Nosocomial spread of organisms from the hands of nursery personnel to the infant probably explains the remarkable increase in colonization rates in this nursery. Analysis of the serotype distribution of GBS discloses no significant differences among parturients, 1-day-old infants, nursery personnel, and infants at hospital discharge.

The major sites of colonization in infants are the skin, nasopharynx, and rectum. GBS persists in the nasopharynx for weeks to months, whereas its cutaneous location usually is lost by the time that the infant reaches several weeks of age. For every 100 infants colonized with GBS, disease caused by this organism will develop in an estimated one or two infants.

Group B streptococcal meningitis is caused almost exclusively by the B_{III} organism.[22] These organisms may be acquired from nonmaternal sites. Clusters of three or four cases of group B streptococcal meningitis have occurred in nurseries during short intervals, thus suggesting nosocomial acquisition.[1,27,473]

E. coli is the other important agent implicated in neonatal bacterial disease, with an annual incidence of approximately 6.8 per 1000 live births, and it is the most common gram-negative bacterium causing meningitis during this period.[131,307,477] The *Escherichia* genus is antigenically complex, with at least 177 somatic (O), 103 capsular (K), and 53 flagellar (H) antigens.[56] The epidemiology of this agent in relation to newborn infection was defined more clearly with discovery of the association between the K1 capsular polysaccharide antigen and invasive disease.[403] Strains with K1 antigen are responsible for approximately 80 percent of neonatal meningitis cases caused by *E. coli* and 50 percent of sepsis cases.[20,335,430] K1 strains are associated with more severe disease than non-K1 strains are.[267,313]

Sepsis caused by *E. coli* is associated with greater morbidity and mortality rates than is early-onset group B streptococcal infection. This finding, however, may be confounded by the higher frequency of prematurity among the former infected group.[307]

The explanation for the association between *E. coli* K1 strains and neonatal meningitis is unknown. Animal studies have demonstrated that *E. coli* strains with K1 are highly virulent in mice and that this lethal effect can be prevented completely by pretreatment of mice with minute amounts of specific K1 antibody.[403] The proclivity of K1 strains for the meninges also has been demonstrated in infant rats, in which oral feeding of *E. coli* K1 strains resulted in septicemia and meningitis in approximately 20 percent of experimental animals.[182] Similar feeding experiments with *E. coli* K92 and K100 strains did not cause disease in this animal model. Recently, K1 strains have been categorized into two groups based on their profile for putative virulence factors, lipoproteins, proteases, and outer membrane proteins, which suggests that *E. coli* K1 may use different mechanisms to induce meningitis.[525]

Neonatal colonization with *E. coli* often results from maternal transmission during delivery.[430] Thus, vaginal colonization, observed in 3 to 20 percent of pregnant women, seems to be an important step in neonatal infection. Approximately half of all vaginal strains express the K1 antigen.[11,271] The *E. coli* strains responsible for invasive neonatal infections come from intestinal flora. Evidence suggests, however, that the vagina and amniotic fluid are two barriers that favor selection of a population of highly virulent *E. coli* strains. Most *E. coli* strains that cause neonatal meningitis and septicemia belong to the clone ECOR B2 group.[511]

The highest prevalence rates for rectal colonization with *E. coli* K1 strains are found in pregnant and nonpregnant women aged 16 to 31 years. Approximately 45 to 50 percent of this population have K1 organisms on rectal culture.[430] Studies of pediatric

populations have disclosed colonization rates of 20 to 30 percent for newborns on the second day of life, 40 percent for infants 4 weeks to 1 year of age, and 35 percent for children 1 year to 16 years of age. As expected, the organism is dispersed widely among hospital personnel, who have rectal carriage rates of approximately 40 percent.

Vertical (mother-to-infant) and horizontal (nursery staff–to-infant, infant-to-infant) modes of transmission have been documented for *E. coli* K1 infections.[55,430] Approximately 50 to 70 percent of infants born to culture-positive women acquire *E. coli* K1 strains during the first 48 hours of life; in these instances of vertical transmission, serologic concordance exists for the O and H types of the *E. coli* cultured from the mother and baby.[11] Approximately 10 to 15 percent of infants colonized with K1 strains are born to K1-negative mothers. For this group of babies, *E. coli* is acquired at a later age (3-4 days), presumably from horizontal transmission. Vertical acquisition of K1 organisms has been documented in approximately three fourths of neonates with *E. coli* K1 meningitis. Based on a colonization rate of approximately 200 to 300 infants per 1000 live births and an attack rate of 1 per 1000 live births, the colonization-to-disease ratio for *E. coli* is approximately 200:1 to 300:1.

E. coli containing the K1 antigen was isolated from women throughout their pregnancy and at delivery, and 50 percent of the babies were colonized if their mothers were positive for this organism at the time of delivery.

E. coli infection is highly associated with preterm delivery at less than 34 weeks' gestation and with VLBW neonates and occurs more frequently in infants of women who are heavily colonized.[271] Infants with early-onset *E. coli* sepsis had a poor outcome, with high mortality rates and neurodevelopmental sequelae in 30 percent of survivors. Although amoxicillin resistance is a common finding, a low prevalence of gentamicin resistance exists in coliform isolates.[14] Ampicillin-resistant *E. coli* infections tend to be severe and fatal and appear to be seen more frequently when ampicillin instead of penicillin is used for maternal group B streptococcal prophylaxis.[450] Characterization and comparison of virulence genotypes and phylogenetic analysis will help in understanding the origins and spread of virulence factors within the population of *E. coli* neonatal meningitis isolates.[60,66]

Listeria is a ubiquitous soil organism, and although the animal reservoir for this organism is large, transfer from animals to humans is a rare event and occurs in high-risk persons, such as farmers and veterinarians.[365,399,439] *L. monocytogenes* appears to be a common transient colonizer of the human gastrointestinal tract but with little propensity to cause invasive infection unless host risk factors are present or the gut inoculum is large enough to overwhelm local gastrointestinal preventive barriers. Host factors that increase the risk for *Listeria* infection include pregnancy, acquired immunosuppression associated with organ transplantation, cytotoxic chemotherapy, hemochromatosis, diabetes mellitus, and renal failure.[192,425,439]

The annual incidence of listeriosis in infants younger than 1 year old varies between 1.0 and 11.9 per 100,000, and it is seen more commonly in males. Rates in women of child-bearing age (15-39 years) are between 0.1 and 1.1 per 100,000, with the higher numbers being observed in the Hispanic population.[278,372] Perinatal infection constituted 34 percent (470 of 1378) of cases of listeriosis.[175,461]

Epidemiologic information implicating food as a vehicle for transmission of listeriosis from animals to humans now appears to be established firmly. Food-borne outbreaks have been traced to cabbage, dairy products, and vegetables. Undercooked chicken and hot dogs appear to be frequent sources of infection, as are delicatessen meats and unpasteurized cheese products, especially soft cheese.[367,439] In an outbreak in Canada,[440] *Listeria*-contaminated sheep manure was used to fertilize locally grown cabbage that was stored for the winter in the cold, where the organism is known to survive for long periods. Clinical disease occurred in pregnant women who consumed the processed cabbage months after its original contamination. In 1985, the first well-documented outbreak of listeriosis in humans through contaminated milk products was reported.[163] The milk, which came from a group of farms where listeriosis in dairy cattle was known to have occurred, was well pasteurized, which indicated that pasteurization might not be sufficient to eradicate a large inoculum of *L. monocytogenes*. Linnan and associates[292] reported a large outbreak of perinatal listeriosis in southern California that appeared to be caused by Mexican-style cheese contaminated with raw milk. In a report from Costa Rica, a nosocomial outbreak of listeriosis was associated with the use of contaminated mineral oil for bathing neonates.[448] In 2000, a small outbreak of listeriosis in two previously healthy adults occurred in Ontario, Canada, and was associated with the intake of imitation crab meat. In 2002, 47 cases of human listeriosis were related to ripening solutions used in a cheese-making process.[173,367]

Several large prospective epidemiologic studies have demonstrated that few women are colonized with *Listeria* strains during pregnancy and that the organism is cultured infrequently from healthy premature and term infants or from stillborn fetuses.[229,518] These studies suggest that human carriage of this bacterium does not appear to be of the same magnitude as that for GBS and *E. coli* K1, but asymptomatic colonization with *Listeria* does occur. *Listeria* has been found occasionally in the genitourinary tracts of pregnant women, in the throats of children, and in the noses of men.[197] *L. monocytogenes* rectal carriage rates of 1 to 30 percent of all pregnant or nonpregnant women have been reported.[283] The *Listeria* colonization rate in fecal surveys in the community is approximately 2 to 10 percent.[295,446] A possible venereal nature of listerial colonization has been suggested.[196]

Since the 1980s, epidemic and endemic colonization and disease of the newborn infant with methicillin-resistant *S. aureus* (MRSA) have been reported with increasing frequency in the United States and Europe. Table 78–4 demonstrates the relative frequency of infections caused by *S. aureus* versus those caused by other common neonatal pathogens in nurseries at Parkland Memorial Hospital in Dallas, Texas.

Epidemics of disease caused by MRSA have been reported in the United States and several other countries. Risk factors associated with the development of MRSA infection include lengthy hospitalization, previous antibiotic administration, overcrowding and understaffing, and the presence of predisposing factors such as indwelling central venous catheters, cerebrospinal shunts, mechanical ventilation, and prematurity.[264]

Potential reservoirs of MRSA in the hospital environment include colonized or infected neonates, hospital personnel, and the hospital inanimate environment. MRSA is spread by contact and by air and may circulate among patients, staff, and visitors for several months during an outbreak in hospitals, long-term care facilities, and the community.[64,272,284,327] Although chronic nasal carriage of MRSA by hospital personnel has been implicated in several hospital outbreaks, it generally is an uncommon event and is not necessary for initiation or propagation of hospital outbreaks.[489] Limited data suggest that the hospital inanimate environment may become contaminated with MRSA, thereby possibly sustaining outbreaks of infection.[64,489] Colonized patients without clinical disease contribute substantially to the inpatient reservoir of MRSA. In recent years, an increase in the incidence of community-acquired MRSA infections has occurred in healthy patients without obvious risk factors.[92,224,237]

Coagulase-negative staphylococci also have been found increasingly to be important neonatal pathogens. They are the most common species of the normal flora on the skin, nasal mucosa, and umbilicus of the newborn. With sensitive culture techniques, rates of colonization of the nose, umbilicus, gastrointestinal tract, and cutaneous areas of the neonate with coagu-

lase-negative staphylococci can be as high as 83 percent at 4 days of age.[463] The ubiquitous presence of the organisms and their tolerance to drying and temperature changes contribute to the increased presence of coagulase-negative staphylococci in neonates. Coagulase-negative staphylococci are the most common late-onset organisms isolated in neonatal intensive care units (48% of all infections and 68% of gram-positive infections).[80,239,477,478] In some neonatal intensive care units, disease caused by coagulase-negative staphylococci exceeds that of group B streptococci and *E. coli*.[387]

Prematurity, high rates of colonization, and aggressive treatment of newborn infants in intensive care units (e.g., placement of umbilical or central venous catheters, intravenous parenteral nutrition, and mechanical ventilation) account for coagulase-negative staphylococci becoming important invasive nosocomial pathogens.[478,482] Despite plausible evidence of an increasing prevalence of these organisms as neonatal pathogens, distinguishing between infection and contamination of blood cultures by them often is difficult.[80,208,478]

Most studies have shown that infections with coagulase-negative staphylococci are not associated with significant mortality rates or morbidity in infected infants.[239,251,320] Recently, however, an outbreak of coagulase-negative staphylococcal sepsis characterized by persistent bacteremia and severe thrombocytopenia was reported at the Children's and Women's Health Centre of British Columbia. Some experts suggest that this neonatal infection may not be as benign as has been perceived historically and recommend a large prospective evaluation.[256]

Group D streptococci are normal inhabitants of the gastrointestinal tract and can cause invasive disease. These bacteria are the third most frequent gram-positive organisms associated with late-onset sepsis.[103,422,478] Outbreaks of bacteremia and meningitis related to *Enterococcus faecium* were reported from neonatal intensive care units at the Medical College of Virginia and the Children's Hospital of Denver, Colorado.[119] These organisms have become resistant to ampicillin and vancomycin in many hospitals.[61] Disease caused by these multidrug-resistant enterococci often is difficult to treat. An outbreak of *E. faecium* resistant to vancomycin and teicoplanin was reported in South Korea, where all isolates are shown to have the vanA gene.[281]

Maternal, environmental, and host factors determine the infants in whom invasive bacterial infections will develop when exposed to a potentially pathogenic organism. The presence of any of the following factors can be associated with a 10-fold or greater increased risk for the development of systemic infection: premature onset of labor, prolonged rupture of fetal membranes, chorioamnionitis, and maternal fever. Twin pregnancy remains an independent risk factor for the acquisition of infection with GBS and other organisms after correction for low birth weight. The first-born twin is at a higher risk of contracting ascending intrauterine infection than the second-born is. Infection developed in 3 of 56 twin births, or 54 per 1000 live births, as compared with 7 infections in 603 single births, or 12 per 1000 live births.[371] The basis for the increased risk of acquisition of infection in twins includes the common features of virulent organisms, absence of protective antibody, and similar genetic heritage. Substance abuse by the mother (e.g., heroin) has been shown to alter T-cell activity significantly in the neonate, and such alterations persist through the first year of life.[121] Although numerous microorganisms have been documented to cause maternal bacteremia before delivery, infants born to mothers with bacteremia usually remain well. This phenomenon most likely is explained by a balance among the presence of maternal antibody, the virulence of the organism, and the effectiveness of the placenta in preventing transmission of the organism to the fetus.

Klebsiella pneumoniae is one of the most important neonatal pathogens in developing countries, with an incidence between 4.1 and 6.3 per 1000 live births and fatality rates of 18 to 68 percent. It is the second most frequent gram-negative organism associated with late-onset sepsis in developed nations.[478,530] Although *Klebsiella* strains are part of the normal gastrointestinal and vaginal flora, the resistant nature of the hospital isolates indicates their presence in contaminated environmental reservoirs.[102,296,349]

All arms of the defense system are relatively immature (i.e., lack of previous experience with microorganisms) in a healthy neonate and are impaired further by conditions such as prematurity, hypoxia, acidosis, jaundice, and metabolic derangements. Infants with galactosemia particularly are susceptible to the development of sepsis by gram-negative enteric bacilli.[287] *E. coli* is by far the organism most commonly encountered as a cause of sepsis and meningitis in these infants. The umbilical stump may serve as the portal of entry of microorganisms to the bloodstream. Closure of the umbilical vessels plus subsequent aseptic necrosis of the cord, which begins soon after birth, results in an ideal environment for microorganisms to multiply and invade deeper tissues, with resultant omphalitis. Complications of omphalitis include septic umbilical arteritis, suppurative thrombophlebitis of the umbilical or portal vein, peritonitis, liver abscess, endocarditis, superficial abscess, and necrotizing fasciitis.[10,299]

Of the various microbial virulence factors, the polysaccharide capsule has been studied most thoroughly. Bloodstream infections in infant rats and mice caused by *E. coli* K1 or any of the GBS serotypes can be prevented by pretreatment with type-specific capsular polysaccharide antibody. In infants, mortality and long-term sequelae were increased in cases of meningitis caused by *E. coli* K1 strains versus those caused by non-K1 strains.[217] K1 capsular polysaccharide has been detected in cerebrospinal fluid (CSF) by counterimmunoelectrophoresis in higher concentrations and for longer durations in patients who died or were impaired neurologically than in those who were normal survivors.[217] Concentrations and persistence of K1 capsular polysaccharide in the CSF of neonates with *E. coli* meningitis have been correlated with concentrations and persistence of endotoxin and interleukin-1β in CSF.[311] *E. coli* strains also have been found to resist phagocytosis by normal adult polymorphonuclear leukocytes, thereby resulting in delayed clearance of bacteria from the bloodstream. This delay allows the organism to multiply and achieve the concentration of 1000 colony-forming units per milliliter of blood or more, an inoculum that generally is considered essential for invasion of the meninges. The presence of K1 antigen alone, however, does not appear to account fully for an organism's virulence because nonpathogenic *E. coli* K12 strains that are transformed by plasmid containing the cloned K1 antigen gene do not become virulent on expression of the K1 antigen.[462]

E. coli causing neonatal meningitis usually belongs to the phylogenetic group B2 and to the main serotype O18:K1.[66,244,335] Virulence factors such as fimbrial adhesion S (sfaS), invasion IbeA (ibeA), and cytotoxic necrotizing factor (cnf1), in conjunction with the K1 antigen, facilitate penetration of the brain barrier. These extraintestinal pathogenicity genes of *E. coli* usually are clustered in chromosomal genomic structures known as pathogenicity islands.[66,235,258]

Detailed studies of type III GBS demonstrated that the quantity of sialic acid residues in the capsular polysaccharide and the spatial conformation of the antigenic molecule determine the antiphagocytic properties of this organism. A gene sequence that is specific for type III GBS has been identified and cloned. Strains with multiple copies of the gene sequence repeated within the chromosome have a lower lethal dose required to kill 50 percent of infected animals (LD_{50}) in the infant rat model of disease and are more resistant to opsonophagocytosis than are strains that do not contain the gene structure or have only one or two copies of that sequence.[413]

Studies in children and adults have demonstrated clearly that protection from disease caused by bacteria (i.e., *Haemophilus influenzae* type b, *Neisseria meningitidis*, and *Streptococcus pneumoniae*) possessing polysaccharide capsules is afforded by specific antibody directed against these structures.[331,441] Resistance to bloodstream clearance probably relates in part to relative resistance of the encapsulated organisms to complement. The capsule may protect the deep somatic antigen structures capable of activating the alternative complement pathway. Opsonization is essential for phagocytosis and intracellular killing of these organisms and depends primarily on anticapsular antibody. Studies indicate that levels of B_{III} antibody correlate with in vitro opsonic activity[13] and with in vivo protection in animals experimentally infected with GBS.[502] The lack of type-specific maternal opsonizing antibody is a significant risk factor for the development of systemic disease caused by GBS in the mother and infant.[27,222]

Most pregnant women colonized with group B_{III} organisms have increased concentrations of antibody in their circulation that pass transplacentally to the fetus. Both mother and baby in this instance are protected against disease by that specific B type. Conversely, infants born to mothers with undetectable concentrations of antibody are susceptible to invasion by the group B organisms. In one study, protective B_{III} antibody titers were detected in 73 percent of women whose newborns were well as compared with 17 percent of mothers whose newborn infants contracted group B streptococcal sepsis or meningitis.[26] The same study documented lower concentrations of B_{III} antibody in sick neonates than in healthy infants born to mothers with vaginal colonization. Other studies have shown that premature infants have lower concentrations of B_{Ia}, B_{II}, and B_{III} antibody than do term neonates.[74,107] This finding may explain in part the higher incidence and case-fatality rates of group B streptococcal disease observed in premature infants. Probably, a lack of K1 antibody in the sera of neonates predisposes them to *E. coli* K1 disease as well.[314] Mouse protection studies lend credence to this contention.[403]

Strong parallels exist between the host-parasite relationships found with GBS and with *E. coli*. Both organisms possess immunochemical structures as components of the surface polysaccharide capsule that appear to confer virulence. In both cases, neonatal immunity is mediated, at least in part, by maternally derived serum antibody. For both organisms, asymptomatic infection (i.e., colonization) occurs commonly and clinical disease rarely (i.e., colonization-to-disease ratios of 100:1 to 200:1). Questions concerning the precise role of the complement system in opsonization of these and other bacterial pathogens, the exact concentration of antibody that confers protection, and the feasibility of screening large populations for the absence of antibody need further investigation. The role of local immunity in determining invasion of these bacteria from their sites of colonization (i.e., respiratory and gastrointestinal tracts) needs clarification.

The meninges can be invaded directly from an adjacent infected site, such as skin lesions, meningomyelocele, or a skull fracture. Most cases of meningitis, however, result from bacteremia. After gaining access to the blood, bacteria probably enter the CSF space through the choroid plexus of the lateral ventricle and then spread to the subarachnoid space along normal paths of CSF flow. Because of the absence of antibody and complement in the subarachnoid space, bacteria multiply logarithmically, and as many as 10^8 colony-forming units/mL can be cultured from lumbar CSF. The larger the number of bacteria in CSF, the poorer the prognosis.

As a response to the interaction of bacteria or their cell wall components with central nervous system (CNS) tissues, the local production of inflammatory mediators, such as tumor necrosis factor and interleukin-1β, is an initial step in the cascade of events leading to inflammation and tissue destruction.[340,395,421] Experiments in animals demonstrated that interleukin-1β, tumor necrosis factor, and other mediators can act synergistically in altering the function of the cerebral capillary endothelium (i.e., blood-brain barrier) and in promoting attachment of leukocytes through the expression of adhesion receptors.[421,437] The net result is injury and increased permeability of the usually highly efficient blood-brain barrier that allows transendothelial passage of phagocytic cells and low-molecular-weight serum proteins, including complement. Despite this influx, the opsonic activity of CSF remains low; as a result, phagocytosis is inefficient, thereby allowing continued bacterial growth and meningeal inflammation.

Accumulation of inflammatory exudate and inflammation of the arachnoid villi can alter CSF flow, which coupled with loss of autoregulation of cerebral blood flow, can result in increased intracranial pressure. Hydrocephalus results from aqueductal obstruction by fibrinous debris or from reduced CSF outflow caused by inflammation of the arachnoid villi. The raised intracranial pressure, occlusion of blood vessels traversing the subarachnoid space, and edema of vascular endothelial cells can result in cerebral ischemia and possibly cerebral infarction. Anaerobic glycolysis by poorly perfused cerebral tissue results in increased CSF lactate concentrations and hypoglycorrhachia, which further potentiates swelling of glial and neuronal cells through failure of the adenosine triphosphate–dependent sodium pump; in turn, failure of the sodium pump results in accumulation of intracellular sodium. Inappropriate secretion of antidiuretic hormone also can contribute to cerebral edema.

SEPSIS NEONATORUM

Sepsis neonatorum is a bacterial disease of infants 30 days of age or younger. It involves primarily the bloodstream, although spread to the meninges or other organs occurs in a substantial portion of affected infants.[457] No obvious focus of infection of the bloodstream can be found in most cases. The presence of clinical and laboratory findings distinguishes this condition from the transient bacteremia observed in some healthy neonates. Terminology guidelines to classify infants and children with a systemic inflammatory response syndrome resulting from an infectious process are *sepsis*, *severe sepsis*, *septic shock*, and *multiple organ dysfunction syndrome*.[188,419,423]

Different opinions exist on the appropriate age for differentiating between early- and late-onset sepsis. Although the usual range is 2 to 7 days of age for the early-onset variety, more than 80 to 90 percent of infections in the first week of life have their onset in the infant's first 2 days of life.[476,478] Early-onset sepsis commonly is associated with vertical transmission and late-onset sepsis with the hospital environment or acquisition from human contact.

PREDISPOSING FACTORS

The skin is an important component of innate immunity. Preterm infants are particularly susceptible to the development of infections because the skin lacks the vernix (the naturally protective cutaneous biofilm[527]) and is developmentally immature, easily injured, and functionally compromised, thus becoming an additional risk factor for developing nosocomial sepsis.[116,126] This cutaneous barrier also is affected by malnutrition in developing countries.[125]

In a trial in Egypt consisting of topical application of sunflower seed oil to preterm infants, a substantial improvement in skin condition and a decrease in the risk for late-onset sepsis were observed. Nonetheless, a recent Cochrane review of four trials performed in developed countries using different emollient ointments with mineral oil found an increased risk for the development of coagulase-negative staphylococcal infection and fungal

nosocomial infections, so further clinical studies are warranted before recommending this practice.[116]

Many prepartum and intrapartum obstetric complications are associated with an increased risk for the acquisition of infection in newborn infants. Among these complications are premature onset of labor, prolonged rupture of fetal membranes, uterine inertia with high forceps extraction, and maternal pyrexia.[49,315,363]

Group B streptococcal disease is associated more frequently than are other causes of sepsis with frequent vaginal examinations and intrapartum fever.[450] Preterm delivery is identified consistently as a strong risk factor for the development of group B streptococcal infection. A multicenter study found that approximately 80 percent of group B streptococcal disease occurred in infants born at 37 weeks or fewer and that only 40 percent of cases of early-onset, non–group B streptococcal disease occurred in term infants.[450]

Sophisticated equipment for respiratory and nutritional support combined with invasive techniques provides life support to ill infants. Arterial and venous umbilical catheters, central venous catheters, peripheral arterial and venous cannulas, indwelling urinary catheters, and tracheal intubation provide enormous opportunity for relatively nonvirulent pathogens to establish infection and invade the host.[3,33,78,114,217,242,269,480] The frequency of these infections varies, and they usually are sporadic. Recognizing these opportunistic infections may be difficult because of the severe underlying illnesses requiring intensive therapy and the frequent use of antimicrobial agents in these infants.

CLINICAL MANIFESTATIONS

The newborn infant responds to many varieties of noxious stimuli (e.g., infectious, metabolic, respiratory, traumatic) with a limited repertoire of stereotyped reactions. As a result, many of the manifestations of sepsis have their counterparts in hypoglycemia, hypocalcemia, hypoxemia, hemolytic blood disorders, drug reactions, and surgical events. Most infectious problems in infants cannot be differentiated from other neonatal disorders on the basis of the initial clinical manifestations. The major signs and symptoms of sepsis relate to disturbances in thermoregulation, respiration, and gastrointestinal function.[140,315,354,465]

Abnormalities in temperature regulation frequently are observed as initial complaints. They may take the form of hypothermia (in 40% of cases) or, less commonly, hyperthermia.[61,122,147,503] With the introduction of isolette care of premature infants to maintain an optimal thermic environment, thermoregulatory disturbances commonly become obvious when the nurse reports the need to make frequent changes in the isolette's thermostat to accommodate the infant's loss of regulatory control. Fever can result from a variety of noninfectious causes, such as dehydration, elevation in ambient temperature, and hematomas, or from central origins secondary to neonatal conditions such as anoxia, CNS hemorrhage, and kernicterus.

Another frequent condition seen is respiratory distress manifested as tachypnea, grunting respirations, cyanosis, intercostal and substernal retractions, and apnea. A heart rate persistently in excess of 160 beats per minute can be a sensitive indicator of early-onset neonatal sepsis.[195] Although these findings are indicative of early-onset group B streptococcal disease in particular, they have been associated with infection caused by all of the pathogens commonly encountered in the neonatal period.

Approximately a third of infants have gastrointestinal findings, including poor feeding, regurgitation, vomiting, weak sucking, abdominal distention, diarrhea, and, rarely, gallbladder distention.[376] Although in most cases conditions other than sepsis can explain these findings, bacterial disease always must be considered. In most patients, ruling out sepsis on clinical grounds alone is impossible. Appropriate laboratory studies and therapeutic intervention frequently are necessary in the assessment of these nonspecific clinical manifestations.

Only a small percentage of infants have cutaneous findings (except for jaundice). Such findings include cellulitis, impetiginous lesions, furunculosis, papular lesions (i.e., listeriosis), vascular lesions (i.e., *Pseudomonas*), and exfoliative dermatitis (i.e., phage group II staphylococcal disease). Jaundice develops in approximately a third of infants with sepsis and can occur in infants with urinary tract infection. Occasionally, jaundice is the only sign of infection and occurs in septic infants, regardless of the type of bacterial pathogen.

In utero infection is identified by the presence of bacteria in blood obtained at delivery. Signs of fetal distress may be the first indication of infection in the newborn. Schiano and associates[438] suggested fetal tachycardia in the second stage of labor as a sign of intrauterine infection. Pneumonia or sepsis occurred in 3 of 8 infants with fetal heartbeats more rapid than than 180 per minute, in 7 of 32 infants with a rate of 160 to 179 beats per minute, and in 1 of 167 infants with lower heart rates.

One report suggests that infants with documented sepsis or a sepsis-like illness have abnormal heart rate characteristics for as long as 24 hours preceding their clinical signs. These abnormalities included reduced baseline variability and short-lived decelerations in heart rate. If these findings are confirmed, monitoring of these parameters in neonates at risk for sepsis may lead to earlier suspicion of disease and initiation of more effective and prompt therapy.[200]

ETIOLOGY

Since the middle of the 20th century, a shift has occurred in the microorganisms responsible for neonatal septicemia and meningitis.[140,168,183,315,354] In the 1930s and 1940s, the predominant organism was the group A beta-hemolytic *Streptococcus*. It was replaced in the 1950s by the phage group I *S. aureus* and by coliform organisms. In the last cohort of VLBW infants, gram-negative organisms accounted for 60 percent of infections, with 44 percent caused by *E. coli* and group B beta-hemolytic streptococci accounting for approximately 10 to 11 percent of all infections (Table 78–3).[477] *S. epidermidis* has emerged as an important

Modified from Stoll, B. J., Hansen, N., Fanaroff, A. A., et al.: Changes in pathogens causing early-onset sepsis in very-low-birth-weight infants. N. Engl. J. Med. 347:240-247, 2002.

pathogen in neonates and is responsible for a large proportion of cases of sepsis in newborn intensive care facilities.[39,91,336] A study of VLBW neonates (401 to 1500 g) born between 1998 and 2000 at 15 neonatal centers that belong to the Neonatal Research Network of the National Institute of Child Health and Human Development (NICHD) found a rate of early-onset sepsis of 15.4 per 1000 live births in this group, not a significant decline from the 19.3 per 1000 live births reported between 1991 and 1992. The important differences were a reduction in group B streptococcal sepsis from 5.9 to 1.7 per 1000 live births of VLBW infants and an increase in *E. coli* sepsis from 3.2 to 6.8 when compared with a previous cohort from 1991 to 1993.[477] In a survey of high-risk nurseries participating in the National Nosocomial Infection Surveillance System of the Centers for Disease Control and Prevention (CDC) conducted from October 1986 through September 1994, the pathogen most commonly reported as the cause of nosocomial bacteremia was coagulase-negative staphylococci, which accounted for 51 percent of isolates.[174] The apparent increased incidence of *S. epidermidis* sepsis has been associated with increased survival of very small premature infants and the introduction of invasive procedures.[208] MRSA also has emerged as a nosocomial pathogen of major importance in some nurseries. Prevalence rates for a specific bacterial pathogen vary from nursery to nursery and may change abruptly in any one unit.[38,41,168,183,222] Knowledge of the bacteria most commonly isolated in a nursery or intensive care unit, as well as the antimicrobial susceptibility of these organisms, is invaluable in treating infants with suspected sepsis neonatorum.

In 2004, a total of 308 cases of neonatal group B streptococcal disease, including 146 (47%) early-onset cases and 162 (53%) late-onset cases, were reported to the Emerging Infections Program. Between 1993 (pre-prophylaxis era) and 2003, the absolute difference in the incidence of early-onset disease between blacks and whites had declined by 68 percent. However, racial disparities in the incidence of both early- and late-onset group B streptococcal disease persist. In 2004, rates of early-onset disease per 1000 live births for black infants were 0.73, followed by 0.26 for white infants and 0.15 for those of other races.[95]

During 1999 to 2001, the incidence of early-onset disease in the United States was 0.47 case per 1000 live births; it declined to 0.32 and 0.34 in 2003 and 2004, respectively. In Parkland Memorial Hospital in Dallas, Texas, the incidence of cases has been diminished with the use of obstetric and neonatal chemoprophylaxis since 1995 (Fig. 78–1). Between 1995 and 1999, with implementation of the chemoprophylaxis protocol, no deaths as a result of GBS were reported in Parkland Memorial Hospital, as opposed to 8 percent from 1986 to 1994.[500] During the period from 1996 to 2004, late-onset disease occurred in 0.35 per 1000 live births (range, 0.29 to 0.39 per 1000). The rate of late-onset disease surpassed that of early-onset disease for the first time in 2003, a trend that continued in 2004 (Fig. 78–2).[95]

The etiologic agents of neonatal sepsis and meningitis at Parkland Memorial Hospital in Dallas, Texas, for 1987 through 1999 are shown in Table 78–4.

Coliform bacteria, including *E. coli*, *Klebsiella* spp., and *Enterobacter* spp., were recovered more frequently in Panama and Mal-

lorca than in Dallas.[225] *S. aureus* was recovered relatively commonly in the three nurseries; a large percentage of the strains isolated in the United States were methicillin-resistant, which underscores the importance of these organisms in some neonatal units. Coagulase-negative staphylococci also were recovered frequently from infants with neonatal sepsis. Anaerobes were responsible for a small percentage of cases of septicemia. Because special techniques for isolation of these relatively fastidious organisms were not used, the actual contribution of these bacteria to the development of sepsis may have been underestimated considerably.

H. influenzae, *S. pneumoniae*, and *N. meningitidis* are occasional causes of neonatal sepsis. Viridans streptococci are being isolated with increased frequency and, in one series, were the major pathogens in neonates with streptococcal septicemia. From 1987 to 1989, viridans streptococci were recovered from the blood of 20 of 273 infants with neonatal sepsis in nurseries at Parkland Memorial Hospital in Dallas, Texas.

The changing distribution of etiologic agents over the course of time has been demonstrated in both developed and developing countries.[294,359,467] In nurseries in the United States, gram-negative enteric organisms were the isolates most frequently recovered 2 decades ago; gram-positive bacteria (mostly GBS and staphylococci) constitute the predominant pathogens today. In the largest public hospital of Panama during an 18-year period (1975 to 1992), the proportional incidence of gram-negative infections also declined with time, whereas that of gram-positive infections increased.[334]

SPECIFIC CLINICAL SYNDROMES

Group B Beta-Hemolytic Streptococcal Infection

Group B streptococcal infection may become evident in a variety of ways, ranging from asymptomatic bacteremia to septicemia, pneumonia, and meningitis. Skin infections, such as impetigo, cellulitis, erythema nodosum–like lesions, adenitis, breast abscess, and scalp abscesses, also may occur.[20,231,345] Group B streptococcal infection may be manifested initially as conjunctivitis, orbital cellulitis, otitis media, or ethmoiditis. These organisms are responsible for an increasing proportion of suppurative arthritis and osteomyelitis cases during the newborn period and have been incriminated in unusual infections such as retropharyngeal cellulitis, pleural empyema, endocarditis, peritonitis, and adrenal abscess.[17,97,231,505,513]

Group B streptococcal colonization can be transient, chronic, or intermittent. Maternal intrapartum colonization is a major risk factor for early-onset disease in infants, and vertical transmission of this organism from mother to fetus occurs primarily after the onset of labor or rupture of membranes. However, colonization early in pregnancy is not predictive of neonatal sepsis.[401]

Culture screening of both the vagina and rectum for GBS late in gestation during prenatal care can detect women who are likely to be colonized at the time of delivery and thus are at higher risk for perinatal transmission of the organism.[72] Almost 21 percent of women are colonized vaginorectally with GBS, and the most frequent capsular serotypes are III and IA.[246]

The most important risk factors for the acquisition of group B streptococcal early-onset disease, in addition to colonization, include gestational age less than 37 weeks, prolonged rupture of membranes (≥18 hours), chorioamnionitis (intrapartum fever ≥38.0°C) , young maternal age, black race, Hispanic ethnicity, and low maternal levels of anticapsular antibody.[26,72,444,447,449,450,477] A multivariable analysis of a large multistate birth cohort in 1998 and 1999 found that intrapartum fever and a previous infant with GBS were associated with greater than a fivefold increase in risk.[444] Six or more vaginal examinations performed during delivery have been associated with a threefold risk for acquisition of group B streptococcal infection, and these factors were not associated with other organisms, probably because of differences in the route of transmission. GBS generally is acquired by vertical transmission, and non-GBS cases usually were seen after the first day of life and may be acquired during hospitalization or through contact.[450]

Universal administration of single-dose intramuscular penicillin to neonates at birth has been considered as an alternative strategy for prevention of early-onset group B streptococcal disease. Randomized trials have shown that this intervention alone[389,458,459] or in combination with a risk-based intrapartum

prophylaxis approach can result in significant prevention of early-onset invasive group B streptococcal disease.[374,500]

Animals studies that explore GBS based on a conserved surface protein that is expressed by all GBS serotypes found that it induced a strong systemic and mucosal antibody response in mice. This finding raises hope that a protein vaccine that would be effective against all serotypes also may prevent maternal colonization with this pathogen and protect neonates against invasive disease.[236] Phase I and II trials of candidates for capsular polysaccharide–protein conjugate group B streptococcal vaccines have been conducted in healthy, nonpregnant adults, and phase I safety and immunogenicity trials were conducted in pregnant women and yielded promising results.[14,31,253]

After implementation of the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics statements in 1992, the CDC chemoprophylaxis draft guidelines in 1994, and the official CDC guidelines in 1996 for prevention of group B streptococcal disease, a reduction in the prevalence of early-onset group B streptococcal sepsis has been documented, from 1.8 per 1000 live births in 1990[253,305,444,531] to 0.5 per 1000 live births in 1999 with an estimate of 4500 early-onset cases and 225 deaths being prevented per year. There was a plateau of tendencies during 1999 to 2002, but then the rates declined 34 percent in 2003 with an overall incidence of 0.32 (Fig. 78–2).[93,94,445] The efficacy of intrapartum prophylaxis adjusted for the presence of fever has been estimated to be 85 percent against early-onset group B streptococcal sepsis and 63 percent against early-onset sepsis attributable to other organisms.[450]

The previous guidelines for intrapartum antibiotic prophylaxis recommended a screen- and risk-based approach, and the modified 2002 guidelines recommend universal screening by vaginal and rectal GBS cultures for all pregnant women at 35 to 37 weeks of gestation.[253,444]

Intrapartum antibiotic prophylaxis is effective in preventing early-onset group B streptococcal sepsis, but the widespread use of antibiotics has led to concern about possible selection for other more virulent organisms and increased antibiotic resistance.[307,477]

Two clinically and epidemiologically distinct forms of illness have been described.[23,37,165,231] The early- or acute-onset form is seen in the first 3 days of life (usually within the first 6 to 12 hours) and is characterized by a high incidence of maternal complications. These infants usually are very ill within hours of delivery and exhibit unexplained apnea or tachypnea, respiratory distress, hypoxemia, and shock. Chest radiographs reveal a diffuse pulmonary infiltrate similar to that seen after aspiration or findings indistinguishable from those of hyaline membrane disease. One of the major diagnostic problems associated with the acute-onset syndrome is clinical differentiation of it from respiratory distress syndrome. Several features of early-onset group B streptococcal disease may be helpful in differentiating it from respiratory distress syndrome. Obstetric complications are encountered commonly in mothers of infants with group B streptococcal disease, whereas they seldom occur in mothers of infants with respiratory distress syndrome.[37,165] Evidence indicates that prenatal complications may protect the infant from respiratory distress syndrome because of increased corticosteroid secretion by the mother.

The proportion of infants with meningitis is higher in those with late-onset infections.[444] Intrauterine infection of the fetus results from ascending spread of GBS from the vagina of a colonized woman, who typically is asymptomatic. Fetal aspiration of infected amniotic fluid can lead to stillbirth, neonatal pneumonia, or sepsis. Infants also can become infected with GBS during passage through the birth canal, although the majority of infants who are exposed to the organism through this route become colonized on skin or mucous membranes but remain asymptomatic.[444]

When compared with infants who have respiratory distress syndrome, infants with streptococcal disease usually are sicker early in the course of illness, and apnea, shock, or both occur within 12 to 24 hours of the onset of infection. Infants with respiratory distress syndrome experience a more gradual evolution of events. In some infants with group B streptococcal disease, rapid progression to respiratory failure and death occurs within 12 hours. This situation is an unusual occurrence in infants with uncomplicated respiratory distress syndrome. The peak inspiratory pressures required to ventilate babies with streptococcal disease are said to be lower than those necessary for infants with respiratory distress syndrome.[2] In preterm infants, leukopenia with increased numbers of band forms occurs commonly in infected cases.[2,300]

The chest radiograph may be helpful in differentiating these two illnesses. Neonatal pneumonia is found in approximately 40 percent of infants with group B streptococcal disease. In the others, a diffuse reticulogranular pattern with air bronchograms is seen and cannot be distinguished from that observed in infants with respiratory distress syndrome. Hyaline membranes are seen pathologically in both illnesses.

The second major form of neonatal group B streptococcal disease is the late-onset syndrome. In contrast to the acute fulminant disease of the first day of life, the late-onset syndrome has an insidious onset after the infant reaches 5 to 7 days of age, although it occasionally may be fulminant.[23,238] The disease almost invariably involves the meninges. Most infants are initially seen in the second through fourth weeks of life, but documented cases have occurred at up to 12 weeks of age. A history of maternal obstetric complications usually is lacking, and the infant almost always has an unremarkable early neonatal history, although late-onset disease does occur occasionally in premature infants.[136] The case-fatality rate is low, on the order of 5 to 15 percent. Some cases of necrotizing fasciitis have been reported, with prematurity probably being the most important risk factor.[274]

GBS can be immunologically subclassified into nine different capsular serotypes (Ia, Ib, and II to VIII); Ia, II, III, and V uniformly are attributed as causes of early-onset disease, and the group B_{III} organism is responsible for approximately 90 percent of all late-onset cases[22,223] (irrespective of clinical manifestation) and cases of meningitis in infants (irrespective of the age at onset). This apparently virulent effect of type III strains, which account for two thirds of group B streptococcal infections in infants, appears to be restricted to young infants. In contrast, type II strains are predominant in isolates from adults with meningitis, but this serotype rarely is isolated from the CSF of infants with meningitis. All the capsular types, especially serotype III, are poorly immunogenic, which helps GBS avoid immune clearance by masking its surface proteins, and the capsular polysaccharide inhibits complement deposition and phagocytosis.[223,268]

The mode of acquisition of B_{III} is uncertain because this organism usually cannot be recovered from maternal sites at onset of the infant's illness. Horizontal transmission of the pathogen from nursery personnel, caregivers at home, and other individuals to the newborn has been proposed as the most reasonable mode of acquisition.[1,22,373]

The clinical features of illness are indistinguishable from those of other forms of purulent meningitis in this age group. An exception to the normal pattern of late-onset infection is the intensive care unit setting, where nosocomially acquired clusters of disease in low-birth-weight infants have been reported.[353,512] In such circumstances, the spectrum of clinical expression is similar to that of early-onset disease, although serotype III still predominates.[353]

The gastrointestinal tract serves as the natural reservoir for GBS and is the probable source of vaginal colonization. Vaginal

colonization is an unusual occurrence in children but becomes a more common finding in older adolescents.[210]

Resistance among group B streptococci has been limited to certain agents, such as macrolides and clindamycin, but not to penicillin. Resistance to erythromycin and clindamycin occurs in as many as 25 and 15 percent of clinical isolates, respectively.[14,221,443]

The impact of intrapartum antibiotic prophylaxis on neonatal infections caused by organisms other than GBS is not clear inasmuch as different studies have shown a range of results, including an increase, no change, and a decrease in frequency.[104,239,317,450,477] The incidence of ampicillin-resistant *E. coli* strains seems to be increasing, but the role of intrapartum prophylaxis in this trend remains unclear. Although the incidence of *E. coli* sepsis increased in VLBW infants in one report (from 3.2 to 6.8 cases per 1000 births), the occurrence of other types of gram-negative sepsis declined in the same report (from 5.1 to 2.6 per 1000 births).[477]

OTHER STREPTOCOCCAL DISEASE

Group A beta-hemolytic streptococcal disease does not occur as frequently now as in previous decades. Disease caused by this organism varies from low-grade chronic omphalitis to fulminant septicemia and meningitis. Because of the explosive nature of this organism in nursery settings, constant surveillance for colonized infants and prompt recognition of illness are mandatory to avert a nursery outbreak of group A streptococcal disease.[178]

Necrotizing fasciitis caused by group A streptococci is a rare event that occurs in approximately 0.018 percent of hospitalized neonates, with a mortality rate of 18 percent but with a long-term morbidity rate of 91 percent.[201] Maternal carriage is considered an important risk factor for neonatal infection, with an approximate rate of 0.03 percent for vaginal and rectal carriage.[319,328]

Group D and G streptococci have been reported to cause an illness indistinguishable from early-onset group B streptococcal sepsis.[141,456] Viridans streptococci are the second most frequent gram-positive organisms in early-onset sepsis, and they usually cause a less severe illness with a lower incidence of respiratory distress, shock, and white blood cell (WBC) count abnormalities.[450,468,477] Dobson and Baker,[138] in a review of 56 neonates with enterococcal septicemia from a single hospital in Houston, Texas, from 1977 through 1986, described two distinct clinical syndromes. Infants older than 7 days were more premature, had lower birth weights, and, in most cases, had infections characterized by a nosocomial origin. When compared with early-onset disease (5 days of age or younger), which was manifested as mild illness with respiratory distress or diarrhea without focal infection, late-onset enterococcal sepsis was heralded by severe apnea, bradycardia, circulatory collapse, and increased ventilation requirements. Focal infections, such as meningitis, pneumonia, scalp abscess, and catheter-related illnesses, were common occurrences.

Staphylococcus Infection

In the mid-1950s, phage group I *S. aureus* was the most common bacterial agent causing serious bacterial disease in newborn infants. Its unique invasive properties caused disseminated disease, including mastitis, furunculosis, suppurative arthritis, osteomyelitis, septicemia, and meningitis, with widespread manifestations. Because bloodstream infection usually occurs after local invasion, the primary focus must be searched for carefully in all septic babies. Changes in the epidemiologic characteristics of the organism, coupled with intensified microbial surveillance and infection control measures, have reduced colonization and disease rates attributable to phage group I *Staphylococcus*.

Coagulase-positive staphylococcal disease in nurseries also has been caused by phage group II organisms.[316] These organisms produce an exotoxin (i.e., exfoliatin) that results in intraepidermal cleavage through the granular cell layer because of disruption of desmosomes.[322] Clinical disease may take one of several forms, including bullous impetigo, toxic epidermal necrolysis (i.e., Ritter disease), and nonstreptococcal scarlatina. The initial finding in Ritter disease is intense, with painful erythema followed by the formation of bullae, which when ruptured leave a tender, weeping erythematous area. A characteristic desquamation of large epidermal sheets occurs approximately 3 to 5 days after onset of the disease. Fine desquamation is observed commonly in the perioral region. Bullous impetigo has been the disease associated most commonly with nursery outbreaks of group II staphylococcal infections.[6]

In premature infants, the risk of acquiring staphylococcal infection increases as a result of poorly developed host defense mechanisms; the presence of central venous, upper gastrointestinal tract, or endotracheal catheters; procedures causing interruption in skin integrity; prolonged total parenteral nutrition; and the use of steroids.[220] By the third day of life, *S. aureus* and coagulase-negative staphylococci colonize the nasopharyngeal compartment of nearly all infants with birth weights lower than 1750 g.[159]

In the 1980s, MRSA emerged as a nosocomial pathogen of considerable importance. MRSA demonstrates resistance to the penicillinase-resistant penicillin class of antibiotics, which includes methicillin, nafcillin, oxacillin, cloxacillin, and dicloxacillin. The mechanism of resistance involves, in part, alteration of penicillin-binding proteins in the periplasm of the bacterium, thereby resulting in a decrease in affinity for these antibiotics. The spectrum of clinical disease caused by MRSA is similar to that caused by methicillin-susceptible *S. aureus*, except that patients with MRSA bacteremia were reported to be less likely to have bone or joint infection.[479] Between 2000 and 2005, the incidence of MRSA infection in the Parkland nursery has varied between 0.12 to 0.45 per 1000 live births. There appears to be a more frequent colonization rate as well (P. Sanchez, personal communication, 2006).[426]

MRSA infection emerged in the late 1990s in healthy children and adults in the community setting. Community-acquired MRSA is associated more frequently with skin and soft tissue infections; however, some cases may progress to invasive infection and death.[169,246] In hospitalized neonates, different clinic characteristics, consisting of omphalitis, preseptal cellulites, otitis externa, pustulosis, mastitis, and bacteremia, can be present.[220]

Staphylococcal infections are a frequent and important cause of morbidity and mortality in nurseries.[19] Outbreaks of skin infections in neonates have been associated with colonized nurses.[54]

Coagulase-negative *Staphylococcus* is the most common organism associated with late-onset sepsis. However, determining which blood culture isolates represent an infection or contamination remains difficult.[330,478] Isolation of these organisms should be considered significant when they grow in aerobic and anaerobic blood culture bottles, when growth occurs within 72 hours, or when they are isolated from two or more sites or from the same site at different times.[39,336,352] *S. epidermidis* disease tends to occur as a late-onset infection (i.e., nosocomial acquisition) and is associated with the usual signs and symptoms of sepsis. WBC count abnormalities are found in approximately half of all infected infants. Major risk factors include prematurity, low birth weight, invasive procedures, central venous catheters, and total parenteral nutrition. Exposure to intravenous lipid emulsions was the major determinant of bacteremia caused by coagulase-negative staphylococci in VLBW infants in one case-control study.[167] These infections frequently are associated with colonization of central venous catheters and involvement of other sites, such as the CNS. Infected patients usually are not very ill and respond well to antimicrobial therapy, but frequently the central venous catheters must be removed to prevent further seeding of the

bloodstream. The mortality rate is low and ranges from 0 to 15 percent in different series.[39,162,336,352] In a cohort of 1313 VLBW infants with late-onset sepsis (Neonatal Research Network), infants with sepsis attributable to coagulase-negative staphylococci were not more likely to die than were infants who were not infected, but the results can be misleading because of the difficulty of determining which patients have true infections.[478]

Escherichia coli Infection

E. coli strains are the most common gram-negative bacteria that cause septicemia in neonates. Unlike illnesses caused by GBS and *L. monocytogenes*, *E. coli* infections do not fit into distinct clinical syndromes of early- and late-onset disease. Approximately 40 percent of *E. coli* strains causing septicemia possess K1 capsular antigen.[430] The clinical features of *E. coli* sepsis generally are similar to those observed in infants with disease caused by other pathogens. Localized *E. coli* infections have included breast abscess, cellulitis, meningitis, pneumonia, lung abscess, empyema, osteomyelitis, septic arthritis, urinary tract infection, ascending cholangitis, and otitis media.

In recent reviews of early-onset sepsis, *E. coli* isolates have shown an increase in resistance to ampicillin, with figures of higher than 80 percent reported in developed and developing countries. Women with ampicillin-resistant *E. coli* infections were more likely to have received intrapartum ampicillin than were those with susceptible strains.[477,530]

Klebsiella pneumoniae Infection

K. pneumoniae is the major pathogen responsible for neonatal sepsis in many developing countries. The incidence of infections varies from 4.1 to 6.3 per 1000 live births, with a fatality rate of 16 to 68 percent. A substantial number of infections occur as early-onset disease. Although species of *Klebsiella* can be normal flora in gastrointestinal and vaginal sites, isolation of resistant strains is more likely related to hospital acquisition in heavily contaminated environmental reservoirs, particularly in developing countries.[58,145,349,530]

Listeria monocytogenes Infection

The pathogenesis and clinical spectrum of diseases caused by *L. monocytogenes* are similar to those caused by GBS. Because the most common foci for neonatal infection are the lung and gut, the fetus probably is infected by the mother swallowing contaminated liquor and through the transplacental route. Infants acquire the infection in two ways, from mothers who are colonized in the gastrointestinal tract after eating contaminated food, with occult sepsis developing and resulting in chorioamnionitis, or from mothers carrying *Listeria* in the gastrointestinal or perianal regions that contaminates the skin and respiratory tract of their babies during birth.[439] Chorioamnionitis diagnosed by transabdominal amniocentesis in pregnant women with intact fetal membranes has been reported,[378] thus favoring the blood-borne route of infection. Early gestational *Listeria* can be associated with abortion or stillbirth. Premature labor in mothers with *Listeria* infection is a common occurrence; in approximately 70 percent of cases, delivery occurs before 35 weeks' gestation.

Evidence of preceding maternal illness often is described in infants with early-onset disease. Symptoms in mothers can be vague (i.e., malaise and myalgia) or distinctive (i.e., fever and chills) and may alert the physician to a risk for *Listeria* infection. Blood cultures often (35%) are positive for *Listeria* in such mothers.

In neonates, two types of illness have been described. "Early-onset" listeriosis can develop after maternal sepsis, and chorioamnionitis can cause abortion, stillbirth, or premature delivery of a severely infected infant. These patients can have pustular skin lesions (granulomatosis infantisepticum) and granulomatous hepatitis, findings often detected at autopsy. The associated mortality rate can reach up to 20 percent.[150,388] The pathogen is acquired transplacentally[499] or by aspiration at the time of vaginal delivery.[42] The infant frequently has hypothermia, is lethargic, and feeds poorly.[451] The organism can be found in the infant's blood, CSF, skin, and placenta; the primary clinical picture is severe sepsis with multiorgan involvement.

A characteristic rash consisting of small, salmon-colored papules scattered primarily on the trunk may be observed in some infants.

Listeria infection should be suspected in premature infants with early passage of meconium. Because meconium is an extremely unusual finding in premature infants younger than 32 weeks' gestational age, its presence should alert the physician to the possibility of *Listeria* infection. Chest radiographs show parenchymal infiltrates suggesting aspiration pneumonitis in most infants. A miliary type of bronchopneumonia also can be seen in some infants. No cases of acute-onset listeriosis mimicking the radiographic picture of hyaline membrane disease have been reported. *Listeria* serotypes Ia, Ib, and IVb produce the early-onset disease, whereas serotype IVb is the predominant type in late-onset meningitic disease.[7]

A delayed form of neonatal listeriosis (late-onset disease) occurs during the second through eighth weeks of life and involves the meninges in almost all cases.[318] Infected infants usually are the term products of an uncomplicated labor and delivery. The onset of symptoms and signs is relatively insidious, and they are indistinguishable from those observed with meningitis caused by other pathogens. Acute *Listeria* encephalitis, which usually is fatal within a few days, is a rare disease in humans. Other clinical forms of disease at this age include *Listeria*-induced colitis with associated diarrhea and sepsis but without meningitis. The bacteriology laboratory should be forewarned of the clinical suspicion of listerial meningitis because these microorganisms frequently are discarded as contaminants because of their tinctorial and morphologic similarities with diphtheroids. Overnight refrigeration of spinal fluid specimens frequently enhances growth of this organism.

The peripheral WBC count usually shows a brisk leukocytosis with a predominance of polymorphonuclear leukocytes in the differential count. A significant elevation in the number of monocytes to 7 to 21 percent of the total WBC count has been documented on admission laboratory evaluation of infected infants.[501] Likewise, a monocytosis of this magnitude can be demonstrated in most of the remaining infants on repetitive determination of the peripheral WBC count. In contrast, monocytes are not found typically in the spinal fluid of infants infected with *L. monocytogenes*. Polymorphonuclear leukocytes predominate in approximately 75 percent of cases, with a relative lymphocytosis detected in the remaining 25 percent. As with other pyogenic meningitides, hypoglycorrhachia and elevated protein concentrations are frequent findings. Examination of stained smears of spinal fluid has not been rewarding in more than 50 percent of cases, a reflection of the relatively low concentration of organisms in this fluid,[155] the atypical morphology, and the variable decoloration resulting from the Gram-staining procedure, which may result in organisms appearing as gram-negative rods or gram-positive cocci.

Pseudomonas aeruginosa Infection

Pseudomonas septicemia may be manifested as characteristic violaceous papular lesions in which central necrosis develops after several days (i.e., ecthyma gangrenosum). Noma (i.e., gangrenous lesions of the nose, lips, and mouth) has been associated with *P. aeruginosa* bacteremia. It is caused by a suppurative vasculitis, and

deep-seated abscess formation is a common finding.[398] A neonate treated with broad-spectrum antimicrobial agents while in an environment potentially contaminated by "water bugs" (e.g., respirators, moist oxygen) particularly is prone to acquisition of disease caused by *Pseudomonas* spp. or other fastidious commensals. The organism usually is a cause of late-onset disease.[282,478] Stevens and colleagues,[475] however, reported nine cases of *Pseudomonas* sepsis, four of which developed in the infants' first 72 hours of life. The clinical and radiologic findings in these four infants were similar to those of hyaline membrane disease.

DIAGNOSIS

The diagnosis of sepsis neonatorum relies heavily on the clinical judgment and diagnostic acumen of the physician. Signs and symptoms may be vague and frequently misleading. Bacterial infection may masquerade as metabolic disease, respiratory distress, environmental stress, and other noninfectious conditions. A physician evaluating an infant with possible sepsis must be guided by a complete perinatal history to elicit factors that place the infant at high risk, by a thorough physical examination with attention to signs suggestive of infection, and by clinical experience. When infection is likely, a laboratory work-up is indicated. When infection is unlikely and not substantiated by the history, physical examination, and clinical judgment, investigating for an infectious process usually is unnecessary. If doubt exists, as frequently is the case, good practice is to proceed with a laboratory work-up.

Recovery of an organism from a meaningful site, such as blood, CSF, urine, abscesses, pleural and peritoneal spaces, joints, bones, and middle ear cavities, substantiates the clinical impression of systemic bacterial disease. Isolation of an organism from mucocutaneous sites, such as the skin, ear canal, nasopharynx, gastric aspirate, and rectum, usually does not reflect the microbiologic status of normally sterile body fluids or tissues.[159] A point of emphasis is that the colonization-to-disease ratio for the major neonatal pathogens is approximately 100:1 to 200:1. For every infant with documented systemic bacterial disease, 100 or more infants are colonized superficially with this organism but are free of systemic bacterial disease.

Several sites to sample blood for culture give reliable results: peripheral vein, umbilical artery, and capillary blood. The preferred site is the peripheral vein. Venipuncture should be performed after the skin has been prepared properly by cleansing with an iodine-containing solution.[146] A two-phase antisepsis procedure using 70 percent isopropyl alcohol followed by chlorhexidine or povidone-iodine has been shown to be superior to one using chlorhexidine or povidone-iodine alone in reducing skin colonization by *S. epidermidis*.[100] The theoretical minimal amount of blood needed for detecting bacteremia is a function of the number of organisms circulating at any given time. Infants with *E. coli* sepsis have 5 to more than 1000 colony-forming units per milliliter of blood.[133] Culturing as little as 0.2 mL of blood should be sufficient for detecting *E. coli* bacteremia in these patients. On the basis of experimental *E. coli* sepsis in rabbits, a cultured volume of blood of 0.2 mL is as sensitive as is 1 mL in detecting bacteremia at a threshold level of five organisms per milliliter of circulating blood.[160] To improve culture sensitivity, a prudent procedure is to obtain at least 0.5 to 1 mL of blood for culture in infants aged birth to 2 months. Optimal results are obtained when the cultured volume of blood is 5 to 10 percent of the total amount of liquid growth medium to be inoculated.

Bacterial growth is seen in most blood cultures within 48 hours. With the use of conventional culture techniques and subcultures at 4 and 14 hours, only 4 percent of cultures that had positive results required more than 48 hours of incubation.[383] With the use of radiometric technique, 98 percent of cultures growing GBS and *E. coli* were identified within 24 hours.[412] We generally recommend obtaining one or two blood cultures before initiating antibiotic therapy. Urine and CSF should be obtained for examination and culture before starting therapy.

Many laboratory tests have been recommended for the evaluation of suspected bacterial disease in neonates. The WBC count is a simple, readily available test that can help in the early detection of sepsis.[46,300,301] Elevated total WBC counts, absolute neutrophils counts, and absolute band counts generally are not helpful singly as indicators of sepsis. Although neutropenia in neonates is caused by infection in most cases, it frequently is associated with other conditions, such as birth asphyxia and pregnancy-induced hypertension.[148]

The usefulness of abnormal WBC counts in the detection of sepsis is enhanced by measurement of the immature-to-total neutrophil ratio; a ratio of 0.2 or greater is a relatively sensitive indicator of neonatal sepsis.[108,379,380] Numerous studies that have evaluated the immature-to-total neutrophil ratio have shown that the ratio is too unreliable to achieve more than limited clinical usefulness. Sensitivities ranging from 90 to 60 percent or less have been reported.[52,53] Elevated ratios caused by a variety of perinatal conditions have been seen in 25 to 50 percent of noninfected, ill infants.[177,260] The ratio's greatest value is thought to be in its good negative predictive value; if the ratio is normal, the likelihood that infection is absent is very high.[177,260] An immature-to-total ratio of 0.8 or greater indicates depletion of bone marrow neutrophil reserves and is a poor prognostic indicator. A combination of all these laboratory findings (i.e., hematologic scoring system), rather than those of any test alone, increases the diagnostic specificity of a bacterial infection.[406] This scoring system is of limited value in late-onset, coagulase-negative staphylococcal infections.[128]

Determining the WBC count and immature-to-total ratio again 6 to 8 hours after the initial evaluation is important because studies in animals and human infants have demonstrated that the WBC count can be normal at the onset of group B streptococcal sepsis and abnormal 4 to 8 hours later. Morphologic changes in neutrophils, such as vacuolization and toxic granulation, suggest the presence of infection. The degree of these degenerative changes in the neutrophils of infected neonates provides no implication of the severity or potential outcome of the illness.[293] Identical morphologic findings can occur as artifacts in citrated blood samples stored for longer than 1 hour before smears are made.

A reduced platelet count associated with placental insufficiency is the most frequent cause of early-onset thrombocytopenia in neonates.[404] The presence of severe thrombocytopenia, or less than 50,000 cells/mL, within 72 hours of birth is an uncommon occurrence and more likely is related to perinatal asphyxia or early bacterial infection (e.g., group B streptococcal sepsis). Late-onset thrombocytopenia almost always is caused by bacterial sepsis or necrotizing enterocolitis. In these cases, platelets fall rapidly, with a nadir at 24 to 48 hours, to counts less than 50,000 cells/mL and tend to persist until the infection is controlled. Slow recovery of platelet counts over a period of 1 to 2 weeks is common.[98,337,404]

The erythrocyte sedimentation rate in infected patients generally is elevated above the normal range of 1 to 2 mm/hr at 12 hours of age to 17 to 20 mm/hr at 14 days of age.[4] Elevated rates usually are not observed until 24 to 48 hours after clinical signs of disease first occur. Other acute-phase reactants, such as C-reactive protein, haptoglobin, prealbumin, orosomucoid, and transferrin, may be useful in establishing the diagnosis of neonatal sepsis and in monitoring the course of the infection.[381] The most extensively studied of these acute-phase reactants is C-reactive protein. Concentrations of this protein increase significantly within a few hours of the onset of infection. In general, other perinatal events have little impact on neonatal C-reactive

protein values.[442] C-reactive protein concentrations decrease rapidly in infected neonates who respond to therapy and, conversely, are elevated persistently in neonates whose infections fail to respond to therapy.[241,429] Reliance on a single C-reactive protein determination as an early indicator of neonatal bacterial infection is not recommended. Serial determinations are helpful, especially in combination with other hematologic tests, when making a decision to stop antimicrobial therapy safely.[65,382]

Fibronectin is a glycoprotein that has been identified on cell surfaces and in extracellular fluids. The concentration of fibronectin in fetal plasma increases with gestational age to values at term of approximately half those found in healthy adults. Plasma concentrations fall significantly during an episode of sepsis[177] but may decrease in noninfectious neonatal conditions such as perinatal asphyxia and respiratory distress syndrome.[526] More data are needed to determine the value of fibronectin concentrations as an indicator of bacterial sepsis.

Detection of interleukin-6 in plasma samples of newborns has been suggested as a reliable early indicator of sepsis.[83,203,218] Interleukin-6 is a pleiotropic cytokine involved in many aspects of the immune system. It is synthesized and released in response to inflammatory stimuli by monocytes, endothelial cells, and fibroblasts after production of tumor necrosis factor and interleukin-1. Interleukin-6 is the major inducer for the synthesis of hepatic proteins, including C-reactive protein, fibrinogen, and other acute-phase reactants. Its sensitivity in the diagnosis of sepsis and necrotizing enterocolitis appears to be high.[218] One study suggests that measuring serum concentration of platelet-activating factor can identify septic infants at risk for necrotizing enterocolitis.[392] An analysis of all studies published indicates that the main diagnostic importance of measuring interleukin-6 in neonates appears to relate to its very high negative predictive value. An initial interleukin-6 value below 20 pg/mL excludes the possible presence of sepsis in more than 90 percent of infants; if it is still below this value when repeated several hours later, its usefulness as a negative predictor of sepsis is even stronger.[158,252,297] More studies are needed, however, to evaluate the precise role of interleukin-6 measurement in guiding physicians to a better diagnostic approach to systemic neonatal infections.

Procalcitonin

Procalcitonin (PCT) has been proposed as a sensitive and specific marker of bacterial infection.[105,176] Several recent studies have found that an elevated serum PCT concentration can be useful in diagnosing antenatal and early-onset infection because of its high positive and negative predictive values. Infants with viral infection, bacterial colonization, and sterile inflammatory stress have normal or slightly raised concentrations.[176] Some studies suggest that this test will be useful in evaluating the severity of the infection and monitoring the clinical course.[105] However, very high serum concentrations have been detected in patients with respiratory distress syndrome, acute lung and inhalation injuries, hemodynamic failure, and severe trauma.[351] Administration of antibiotics during the prenatal, intranatal, and postnatal periods also may alter the relationship between PCT and infection. Although cutoff values usually differ among studies, a concentration of 2 ng/mL is considered reliable in distinguishing between viral and bacterial infection.[498] More extense investigations are needed to determine whether PCT measurement, in a single or repeated sampling, would be of value in differentiating between bacterial infection and colonization and in reducing the number of patients treated unnecessarily with antibiotics.[248]

Other Diagnostic Tests

Detection of bacterial antigens in blood, urine, or CSF confirms the presence of systemic bacterial disease. Diagnostic techniques include countercurrent immunoelectrophoresis, latex particle agglutination, and coagglutination procedures. Countercurrent immunoelectrophoresis is specific but has low sensitivity and can be used to detect infections caused by *E. coli* K1 and GBS.[32,215] Latex particle agglutination and coagglutination tests are more sensitive than is countercurrent immunoelectrophoresis, but they have been associated with a small percentage of false-positive and false-negative reactions.[170,215] They can be used for the detection of disease caused by GBS, *N. meningitidis*, *S. pneumoniae*, and *H. influenzae* type b. The highest yield is achieved by testing concentrated heat-treated urine specimens and CSF. The sensitivity of this test is 90 to 98 percent, with an average false-positive rate of 2 to 6 percent. Perineal contamination may cause false-positive results in healthy colonized infants in the absence of invasive disease when the urine tested is obtained by bag collection.[427] The absence of antigen does not rule out infection. A positive result in the urine antigen test with negative results on blood culture can imply occult infection (e.g., osteomyelitis), partial treatment by intrapartum antibiotic therapy, or a false-positive result. The *E. coli* K1 antigen is identical immunologically to the *N. meningitidis* group B antigen and, therefore, can be detected by *N. meningitidis* group B kits. The usefulness of this test is much decreased, however, by its low sensitivity and the high contamination rate of urine collected by bag with *E. coli* from the gastrointestinal tract.

Direct examination of Gram- or methylene-stained blue buffy coat smears can help in the early detection of neonatal bacteremia if bacteria engulfed by neutrophils are visualized.[152] Some physicians consider only smears with intragranulocytic bacteria to be positive. Bacteria are seen more readily when acridine orange stain is used.[261] This technique requires a smaller volume of blood but cannot distinguish between gram-positive and gram-negative bacteria. Identification of bacteria on Gram-stained smears of tracheal secretions obtained in the first 12 hours of life from infants who require intubation is associated with bacteremia in approximately half of these cases.[452]

Endotoxin elaborated from gram-negative bacteria circulates in blood and is present in urine for considerable periods of time after these fluids have been sterilized. Detection of endotoxin by the *Limulus* amebocyte lysate assay may be helpful in the early identification of infected infants.[254,436] Endotoxin may be present in the blood of septic-appearing infants who have sterile blood cultures. Transient endotoxemia perhaps is responsible for "clinical sepsis" in these infants. The source of endotoxin may be the gram-negative bacterial flora of the bowel. Endotoxin possibly enters the circulation through injured and permeable gastrointestinal mucosa.

Several serologic tests for establishing the diagnosis of listeriosis have been described, but none has become an established routine method. Agglutination reactions, complement fixation, enzyme-linked immunosorbent assay, precipitin, indirect hemagglutination, and antigen fixation tests are available and may help occasionally. Caution is warranted, however, in attempts to use these tests for diagnostic purposes. Genetic studies have shown that an extracellular hemolysin, listeriolysin O, is essential for the intracellular multiplication of *Listeria*. Molecular tests, including DNA hybridization and polymerase chain reaction (PCR), also have been developed for rapid identification of *Listeria* spp. and for differentiating *L. monocytogenes* from other *Listeria* spp.[172]

In one study,[47] French investigators examined whether detection of specific anti-listeriolysin O could be used for the serodiagnosis of human listeriosis. Sera from 28 patients (13 were newborn) infected with *L. monocytogenes* and 101 controls were tested by dot-blot titration with purified listeriolysin O. Twenty-seven patients (96%) with *Listeria* infection produced specific anti-listeriolysin O, which was detected in low titer in 16 percent of healthy controls and in 12 percent of persons who had various bacterial, fungal, and viral infections. Anti-listeriolysin O could

be detected soon after infection and persisted for at least several months. Although this test might be useful for epidemiologic surveys and serodiagnosis of listeriosis, more data are needed before it can be used routinely for the serodiagnosis of human listeriosis.

TREATMENT

After the diagnosis of sepsis is suspected or established and the appropriate samples have been obtained for culture, antibiotic therapy should be instituted. When the infant's condition prompts an evaluation for sepsis, initiation of empiric parenteral antibiotic treatment usually is prudent, despite the fact that only 5 to 10 percent of blood cultures are positive. For practical purposes, we have summarized the recommended empiric antimicrobial treatment of the various bacterial infections occurring during the neonatal period based on the published etiologic organisms identified; therapeutic alternatives also are provided (Table 78–5).

Infants with suspected sepsis should be treated with a combination that includes a penicillin and an aminoglycoside. The choice of antibiotics must be based on the infectious history of the nursery, the antimicrobial susceptibilities of bacteria recently isolated from sick and healthy neonates, the probable etiologic agent, CSF penetration of antibiotics, and the infant's hepatic and renal function. Factors that determine the probable infecting organism include patient age and birth weight; environment (home versus hospital); previous antibiotic therapy; perinatal or nosocomial exposure to pathogens (e.g., MRSA); presence of central lines, drains, or endotracheal tube; and identification of specific infections, such as meningitis, necrotizing enterocolitis, peritonitis, thrombophlebitis, pneumonia, and soft tissue infections.

For treating early-onset sepsis neonatorum, we recommend ampicillin and gentamicin. Ampicillin is effective in vitro and clinically against GBS, *Listeria*, *Proteus*, most enterococci, and 15 to 30 percent of current *E. coli* strains.[450,477] The aminoglycosides have broader antimicrobial activity against many Enterobacteriaceae, including most *E. coli*, *Klebsiella-Enterobacter*, and *Proteus* strains, and, with the exception of kanamycin, against *P. aeruginosa*. Although gentamicin frequently is used, the choice of aminoglycoside (e.g., amikacin, tobramycin, netilmicin) should be based on the antimicrobial susceptibility of nosocomial bacteria within individual nurseries. For infections caused by gentamicin-resistant coliforms, amikacin or third-generation cephalosporins such as cefotaxime and ceftazidime should be used.[232,249,435,496]

Cephalosporins are not active against *Listeria* or enterococci and should not be used without concomitant administration of ampicillin. Moreover, when used with ampicillin, cephalosporins do not offer the advantage of synergism that aminoglycosides do against strains of enterococci. Staphylococci, nosocomial gram-negative organisms, and fungi rarely are encountered in early-onset sepsis neonatorum, and empiric coverage for them generally is not required. When the epidemiologic experience of the nursery suggests *Pseudomonas*, an extended-spectrum penicillin (i.e., ticarcillin or piperacillin) or ceftazidime combined with an aminoglycoside should be administered (see Table 78–1 for dosages). Therapeutic drug monitoring is recommended when aminoglycosides are used, especially in low-birth-weight neonates, and adjustment of the dosage is essential for infants with impaired renal function. Recent interest has focused on evaluating the use of extended intervals for aminoglycoside administration in the neonatal period,[358] and guidelines for drug monitoring in these circumstances need to be evaluated carefully.

Because late-onset sepsis neonatorum is more heterogeneous in its epidemiology than is early-onset disease and may reflect maternal, family, community, or nosocomial sources for the infecting pathogen, the organisms involved cover a broad taxonomic spectrum. As a result, empiric antimicrobial regimens vary. In a previously healthy infant who already has been discharged from the hospital, ampicillin and an aminoglycoside or cefotaxime are recommended unless staphylococcal infection is highly suspected, in which case an antistaphylococcal agent (e.g., oxacillin, nafcillin) should replace ampicillin. Selection of empiric antibiotic regimens can be more difficult for a septic premature infant who has had a prolonged hospitalization, previous antibiotic therapy, possible prolonged tracheal intubation, and placement of a central or peripheral intravascular catheter.

In these patients, major pathogens include coagulase-negative and coagulase-positive staphylococci (including MRSA), aminoglycoside-resistant coliforms, highly resistant opportunistic organisms (e.g., *Pseudomonas*, *Serratia*), fungi, and possibly enterococci. As a result, empiric regimens in this situation should be individualized. Examples include ampicillin, amikacin, and clindamycin for suspected necrotizing enterocolitis, vancomycin and an aminoglycoside or cefotaxime for patients with indwelling central vascular lines, and nafcillin and an aminoglycoside for babies with skin infection. Avoiding empiric vancomycin therapy seems to be a reasonable approach for treating late-onset sepsis because coagulase-negative staphylococci are common contaminants of blood cultures and are associated with a very low frequency of fulminant infection. In institutions with a high

TABLE 78–5 Recommended Empiric Antimicrobial Treatment of Several Neonatal Bacterial Infections on the Basis of Probable Etiologic Microorganisms

Bacterial Infection	Recommendation	Alternatives	Observations
Sepsis			
Early onset (<5 days)	AMPI + GENTA	AMPI + CEFO	
Late onset	AMPI + GENTA	AMPI + CEFO	Readmission of the neonate at term
Nosocomial	VAN ± OXA/NAF + GENTA or AMIK	VAN + CEFTA	Consider AMPHO
Meningitis	AMPI + CEFO	AMPI + GENTA	
Otitis media	AMOX/CLAV	CEFUROXIME	Given orally unless systemic signs present
Urinary infection	AMPI + GENTA	AMPI + CEFO	
Osteoarticular infection	VAN ± OXA/NAF + CEFO	VAN + CEFO	Consider AMPHO
Cellulitis/fasciitis/funisitis/omphalitis	VAN ± OXA/NAF or CLIN + GENTA or AMIK	VAN + CEFTA	Surgery
Pneumonia			
Early onset (<5 days)	AMPI + GENTA	AMPI + CEFO	
Nosocomial	VAN ± OXA/NAF + GENTA or AMIK	VAN + CEFTA	Consider macrolide

AMIK, amikacin; AMOX/CLAV, amoxicillin/clavulanate; AMPHO, amphotericin B; AMPI, ampicillin; CEFO, cefotaxime; CEFTA, ceftazidime; GENTA, gentamicin; NAF, nafcillin; OXA, oxacillin; VAN, vancomycin.

prevalence of MRSA infection, vancomycin generally is used as initial therapy for suspected staphylococcal disease.[251] For infants who fail antimicrobial therapy or have superficial cultures positive for *Candida albicans*, empiric use of amphotericin should be considered. Ceftazidime and cefotaxime should not be used routinely in neonatal units because of the potential for emergence of resistant *Enterobacter* and *Serratia* spp.

After culture and susceptibility studies are available, changes in therapy may be necessary. Ampicillin alone is preferred for enterococcal and *Listeria* infections, whereas ampicillin or penicillin can be used for group B streptococcal disease. Infants infected with these organisms usually receive a combination of ampicillin and an aminoglycoside for the first 3 to 5 days, followed by ampicillin for the balance of 7 to 10 days. The minimal inhibitory concentration (MIC) and minimal bactericidal concentration of ampicillin or penicillin against streptococci and that of nafcillin or oxacillin against *S. aureus* should be considered for the purpose of detecting tolerant strains of these organisms.[259,408,416,460] Tolerant strains are inhibited but not killed by concentrations of these antibiotics, which usually can be achieved in body fluids and are treated best by the addition of an aminoglycoside to ampicillin or nafcillin. The clinical significance of tolerance is uncertain. For *S. epidermidis* infection, vancomycin is the drug of choice unless the isolate demonstrates in vitro susceptibility to nafcillin or oxacillin; most are resistant to these latter drugs. In selected neonates, the addition of rifampin to vancomycin therapy may be beneficial in clearing persistent bacteremia caused by coagulase-negative staphylococci.[484]

Central venous catheters or other foreign bodies frequently must be removed to eliminate the source of these organisms. If a gram-negative enteric isolate is susceptible to ampicillin and aminoglycosides, treatment with either antibiotic alone can be adequate, but we prefer treatment with both drugs for at least a portion of the treatment period. For *Pseudomonas* infections, combined therapy with ticarcillin, piperacillin, or ceftazidime and an aminoglycoside should be used for the duration of therapy. In certain circumstances, antibiotics not approved for infants (i.e., cefepime, imipenem or meropenem, ciprofloxacin) need to be used to treat an infection caused by a multidrug-resistant gram-negative isolate. A few anecdotal reports have been published suggesting successful outcomes of treated neonates.[68,255,270,341]

Although the third-generation cephalosporins have attractive features for the treatment of sepsis neonatorum, such as excellent in vitro activity against GBS and gram-negative enteric bacilli, provision of high serum and CSF concentrations, and no dose-related toxicity, we do not recommend their routine use in the nursery. Clinical studies suggest that they are comparable but not superior to ampicillin and gentamicin and that gram-negative enteric bacilli can become resistant rapidly when third-generation cephalosporins are used for presumptive treatment of neonatal sepsis.

In a 1989 survey of directors of programs in pediatric infectious disease in the United States and Canada, most physicians favored the traditional regimen of ampicillin and gentamicin for initial empiric treatment of sepsis and meningitis.[524] Use of a cephalosporin (cefotaxime in most cases) in conjunction with ampicillin was considered to be appropriate alternative therapy when meningitis was diagnosed. Antibiotics that have the potential to displace bilirubin from albumin-binding sites, such as ceftriaxone and sulfonamides, should be avoided in the newborn period.[338] Currently, no rationale exists for the routine use of chloramphenicol in newborn infants because of individual variations in pharmacokinetics in neonates that are associated with increased risk for the development of toxicity and that necessitate monitoring of the serum drug concentration, its bacteriostatic action against most gram-negative enteric pathogens in vitro, its antagonism with ampicillin against enteric gram-negative rods and GBS, and the availability of equally potent, safer β-lactam antibiotics.

The duration of antimicrobial therapy for neonatal sepsis usually is 7 to 10 days or approximately 5 to 7 days after the clinical signs and symptoms of infection have disappeared. Delayed clinical improvement or persistently positive blood cultures during therapy may indicate that inappropriate antibiotics have been selected or that occult sites of infection (e.g., endocarditis, abscesses, infected foreign bodies) exist.

Blood cultures in bacteremic neonates become positive in 96 percent of infants by 48 hours and in 98 percent by 72 hours.[383] For infants whose initial bacterial cultures are sterile after 48 to 72 hours of incubation, antimicrobial therapy can be discontinued. If no pathogen has been isolated but bacterial sepsis cannot be excluded, a negative C-reactive protein test at 72 hours can help support the decision to discontinue antibiotics.[470] Because postmortem blood cultures can be negative in infants with unequivocal evidence of sepsis (in 18% of patients in one study[469]), blood cultures from septic infants probably are sterile in some at the time of initial evaluation.

A good outcome depends critically on giving careful attention to fluid and electrolyte balance; correcting hypoxia, acidosis, hypoglycemia, and other metabolic abnormalities; and providing nutritional support. The use of fresh-frozen plasma and exchange transfusion as adjunctive therapy in severe neonatal sepsis has not been studied adequately, and no recommendations for their use can be made.[510] Infusion of intravenous immunoglobulin with functional activity against GBS to neonates produces a significant increase in GBS-specific immunoglobulin G that is sustained for several days.[161] Potential therapeutic benefits of intravenous immunoglobulin include enhanced chemotaxis and opsonophagocytosis and improved bactericidal activity of neonatal sera for these organisms. In animal models, a therapeutic effect is achieved only when immunoglobulins are given early in the course of disease.[397]

Experience with human immunoglobulin for intravenous use in septic neonates is limited, but such use appears to be safe. In a double-blind, placebo-controlled study, Weisman and colleagues[516] evaluated the effect of intravenous immunoglobulin (500 mg/kg) on the outcome of 31 premature infants with early-onset sepsis. During the first 7 days after therapy, 5 (29%) of 17 albumin-treated patients and none of 14 patients treated with intravenous immunoglobulin died ($p < .05$). The survival rate at 56 days of age, however, was not improved significantly. Very large doses of intravenous immunoglobulin may induce a blockade of the neutrophil receptors that are necessary for opsonophagocytosis of GBS. Additional studies are required to demonstrate efficacy, safety, and optimal dosage before immunoglobulin therapy can be recommended confidently.

The efficacy of granulocyte transfusions in reducing mortality from severe neonatal sepsis has been reported by several researchers.[88,109,277] Christensen and associates[109] conducted a randomized, prospective, controlled trial of granulocyte transfusions in 16 septic neonates with depleted bone marrow reserves. None of seven infants receiving the transfusions died, whereas only one of nine neonates survived among those not receiving granulocyte transfusions. Cairo and coworkers[88] evaluated the early administration of granulocyte transfusions to neonates with clinical sepsis. Of 23 infants in their study, only 3 had depleted neutrophil storage pools. These researchers also found that the survival rate was improved in neonates with sepsis who received these transfusions as compared with control neonates. Only infants with granulocyte-depleted storage pools are likely to benefit from receiving transfusions. Neither clinical severity nor the degree of neutropenia predicted neutrophil storage pool depletion in septic infants; bone marrow aspiration is required for determining the status of the granulocyte storage pool.[34]

Although these studies are encouraging, they involve a small number of patients, and larger, carefully designed studies are needed. Currently, this strategy is used sporadically in a few

nurseries around the world. The granulocytes normally are obtained from healthy adult volunteers by leukapheresis and then irradiated for prevention of graft-versus-host disease. Approximately 0.5 to 1×10^9 granulocytes per kilogram of recipient body weight are transfused in 20 to 30 minutes.[510] These transfusions usually are tolerated well by neonates, but potential risks include blood group sensitization, graft-versus-host disease, transmission of cytomegalovirus and hepatitis viruses, and volume overload from hydroxyethyl starch.

A more practical and safer approach to reverse sepsis-associated neonatal neutropenia and potentially improve survival is the use of recombinant human granulocyte-macrophage colony-stimulating factor (rhGM-CSF). Several small studies have documented that subcutaneous administration of rhGM-CSF (5 to 10 μg/kg/day for 5 to 7 consecutive days) to septic infants with neutropenia significantly increases the number of various phagocytic cells and decreases mortality rates.[59,77,266,471] Large trials are needed to confirm these benefits before administration of hematopoietic factors can be recommended routinely.

Other nonconventional therapeutic approaches that are being evaluated include extracorporeal membrane oxygenation of neonates with early-onset GBS disease,[227] administration of colony-stimulating factors to neutropenic infants,[87] and immunomodulating strategies (e.g., anticytokine agents, steroids, pentoxifylline, nitric oxide inhibitors).[419] The precise role, if any, of these approaches for the management of newborns with systemic infection needs to be demonstrated in rigorous, carefully designed, double-blind clinical studies.

PREVENTION

Chemoprophylaxis

Studies on the prevention of neonatal infection have focused on those caused by GBS because of its greater prevalence and immunogenicity in comparison to other common neonatal pathogens. Methods proposed for the prevention of neonatal group B streptococcal disease are aimed either at decreasing the likelihood of exposure of the infant to GBS by the use of antibiotic chemoprophylaxis or at decreasing the susceptibility of the exposed infant through improved host defenses by passive or active immunoprophylaxis.

The efficacy of antepartum, intrapartum, or postpartum administration of ampicillin or penicillin has been evaluated in numerous studies. The results have established that selective intrapartum chemoprophylaxis can prevent colonization and disease caused by GBS in the first days of life and prevent postpartum maternal infection with this organism.

Many investigators have attempted to eradicate group B streptococcal colonization from pregnant women during the last trimester. In a prospective, randomized study of women known to be colonized with GBS, Hall and associates[207] demonstrated that treatment with ampicillin (500 mg four times daily for 1 week) briefly reduced maternal colonization, but no difference was found in maternal or infant colonization at the time of delivery. Reinfection from the untreated sexual partner or re-emergence of GBS from an undetectably low population of organisms remaining after antibiotic treatment probably explains failure of antepartum chemoprophylaxis. Gardner and associates[171] treated colonized women in the last trimester of pregnancy and their husbands simultaneously with oral penicillin for 12 to 14 days. Before therapy, 63 percent of husbands also were colonized with GBS in the genital tract, with concordance of isolated serotypes in 88 percent of colonized couples. Such treatment was found to have no effect on the colonization rate of the maternal genital tract at delivery. Other studies also demonstrated that antibiotic therapy had little effect on carriage of GBS.

In contrast, Merenstein and associates[324] demonstrated that treatment of colonized pregnant women with 500 mg of penicillin four times daily at 38 weeks' gestation until delivery resulted in a significant reduction in maternal and infant colonization. Such an approach may eliminate colonization in infants delivered after 38 weeks' gestation; however, because 30 percent of infants with early-onset disease are preterm, the timing of such treatment is inappropriate. The bulk of evidence indicates that antepartum oral antibiotic prophylaxis generally is unacceptable for prevention of early-onset GBS disease.

Parenteral administration of antibiotics during labor has been examined in an attempt to overcome the potential shortcomings of antibiotic administration during pregnancy. In the first published study of intrapartum therapy, 34 women with group B streptococcal genital colonization early in the third trimester were treated at term with intravenously administered ampicillin (500 mg every 6 hours until delivery) at hospital admission.[529] This approach uniformly interrupted vertical transmission of the organism to the infants of treated mothers, which would be expected in approximately 50 percent of infants born to genitally colonized women. Easmon and colleagues[142] conducted a prospective, controlled trial of 87 colonized parturient patients based on vaginal and anorectal cultures obtained at 36 weeks' gestation. Intrapartum prophylaxis with benzylpenicillin during labor significantly reduced the rate of transmission of GBS from mothers to their babies from 45 percent (untreated controls) to 3 percent ($p < .001$). Allerdice and associates[9] prospectively identified 57 women with prenatal group B streptococcal colonization and treated them intrapartum with ampicillin. Seven percent of infants born to treated women were found to have group B streptococcal colonization, and none had invasive disease; 46 percent of infants born to untreated women were colonized, and 7 percent had invasive disease.

Intrapartum chemoprophylaxis given to women with proven GBS reliably prevents colonization of the newborn in the postpartum period. Universal prophylaxis of all pregnant women with group B streptococcal colonization, however, would result in a large number of pregnant women being treated unnecessarily and clearly is unacceptable. Realizing this limitation, researchers started to investigate the feasibility of providing selective, rather than universal, intrapartum chemoprophylaxis.

Boyer and Gotoff[73] were the first to document the efficacy of maternal chemoprophylaxis in high-risk parturients for the prevention of neonatal sepsis. Infants born to women with prenatal cultures positive for GBS and gestation of less than 37 weeks, rupture of amniotic membranes more than 12 hours before delivery, or both, were studied. Eighty women were randomized to receive ampicillin (2 g intravenously and then 1 g every 4 hours until delivery) or no therapy. Infants whose mothers had received ampicillin also were given ampicillin (50 mg/kg body weight every 12 hours intramuscularly for 4 days). Only 1 (2%) of 43 infants born to treated mothers was colonized as compared with 13 (35%) of 37 born to untreated mothers. Boyer and associates,[70,73] in a randomized controlled trial of selective intrapartum chemoprophylaxis using the same selection criteria, demonstrated the efficacy of this approach for prevention of neonatal sepsis and postpartum maternal febrile morbidity.[71] In none of the 85 infants born to mothers in the treatment group versus 5 (6%) of 79 infants born to mothers in the untreated control group did group B streptococcal bacteremia develop ($p = .024$). Additionally, in none of the parturient women did an intrapartum temperature higher than 37.5°C develop in the ampicillin-treated group as compared with four in the control group ($p < .01$). The investigators estimated that their approach had the potential to eliminate more than 50 percent of cases of early-onset group B

streptococcal disease and 75 percent of associated deaths in the United States.

A prospective epidemiologic study of early-onset GBS disease for a 9-year period has provided additional data regarding risk factors for the development of early-onset disease.[70] In this study the relative risk of early-onset disease developing was 7.3 for infants whose birth weight was 2500 g or less (versus those weighing more than 2500 g), 7.2 for infants delivered more than 18 hours after rupture of membranes, and 4.0 for those born to women with intrapartum fever. Overall, 74 percent of the 61 infants had one of these perinatal risk factors at the time that the pregnant women were admitted to the hospital in labor. In Finland, Tupperainen and coworkers,[494] using a rapid latex agglutination test, selected patients solely on the basis of healthy intrapartum colonization. Early-onset group B streptococcal infection developed in 7 (12%) of 58 babies born to mothers who did not receive penicillin, whereas infection developed in only one (3%) of 36 infants whose mothers received penicillin. That infant had intrauterine pneumonia thought to be caused probably by GBS.

Morales and associates[333] selected patients in labor who had positive results on serial coagglutination tests performed on vaginal secretions obtained prenatally. Patients were stratified according to whether their test results were positive after 5 hours' preincubation, which indicated heavy colonization, or after 20 hours' preincubation, which indicated light colonization. None of the infants born to treated, highly colonized mothers was colonized at birth versus 35 percent of the control babies ($p < .001$). In no infant in either group did invasive group B streptococcal disease develop. None of the infants born to treated, heavily colonized mothers was colonized at birth or had early-onset disease; in contrast, 80 percent of the control babies whose mothers were untreated was colonized ($p < .001$), and early-onset group B strepococcal disease developed in three of these control infants ($p = .08$). In another study by the same group,[332] only preterm patients who had premature rupture of membranes were studied, again with use of the results of a rapid coagglutination test on vaginal secretions obtained at the time of hospital admission. Treatment of 36 women with ampicillin resulted in no cases of chorioamnionitis or neonatal sepsis, whereas chorioamnionitis developed in 23 percent of untreated mothers and early-onset group B streptococcal sepsis developed in 27 percent of the babies.

Together, these studies establish the efficacy of selective chemoprophylaxis to prevent early-onset group B streptococcal disease in neonates and postpartum infections in their mothers. Despite endorsement of this approach by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, many physicians involved in the management of mothers and their infants are not aware of or do not follow widely published guidelines to prevent acquisition of group B streptococcal disease.[240]

Chemoprophylaxis also has been targeted to neonates at birth. The observation in 1978 that early-onset group B streptococcal disease did not develop in infants born at Mount Sinai Hospital in New York who received intramuscular penicillin at birth for prevention of gonococcal ophthalmia prompted two prospective, randomized studies for evaluation of this regimen. Siegel and colleagues[458,459] studied preterm and term infants and demonstrated the efficacy of a single dose of penicillin administered at birth. The population in this study was characterized by group B streptococcal infection, mostly in term infants who acquired infection at the time of delivery, as evidenced by a delayed onset of symptoms. Because blood for culture was not obtained before penicillin was administered, whether some infections were suppressed inadvertently was unknown. The other investigation of chemoprophylaxis at birth was reported by Pyati and associates.[389] They studied only infants weighing 2000 g or less at birth and found no beneficial effect of penicillin administered at birth. These infants were infected in utero, as determined by the presence of positive blood cultures at the time of delivery in 21 of 24 infants with group B streptococcal disease. Infection had been established before the administration of penicillin at delivery. The population in each of these studies had unique characteristics, and, therefore, the results may not be broadly applicable to all nurseries.

Intrapartum ampicillin prophylaxis coupled with a dose of penicillin to the neonate immediately after birth has been used for years at Parkland Memorial Hospital in Dallas, Texas.[500] This policy has resulted in an approximately 75 percent reduction of group B streptococcal infection rates in neonates (see Table 78–4) without altering the incidence of infections caused by other pathogens. A substantial decline in neonatal early-onset group B streptococcal sepsis related to routine intrapartum prophylaxis also has been documented by the CDC and other U.S. institutions.[44,298] In our Dallas, Texas, series, the incidence of late-onset group B streptococcal sepsis also has declined.

Three special circumstances merit chemoprophylaxis. The first is an asymptomatic twin of an infant with group B streptococcal disease. This twin has an approximately 25-fold increased risk for the development of invasive group B streptococcal disease.[143] Cultures of blood and CSF should be obtained from the twin, and close observation in the hospital with or without treatment is indicated until cultures have been sterile for 72 hours. The second situation is chemoprophylaxis for a pregnant woman who previously has delivered an infant with invasive group B streptococcal disease. Starting at the end of the second trimester, rectal and vaginal cultures are recommended on three occasions at regular intervals for isolation of GBS. If cultures are negative and delivery occurs at term in the absence of maternal risk factors for neonatal infection, prophylaxis can be withheld. If one or more cultures are positive or delivery occurs before 37 weeks' gestation, intrapartum ampicillin should be administered intravenously. The condition of the newborn infant should be assessed; clinical findings and maternal obstetric factors may warrant further laboratory evaluation and antimicrobial therapy. Initiation of chemoprophylaxis in all women colonized with GBS who have two or more risk factors for invasive infection of the neonate seems prudent.[24,179,390]

Several studies[158,286,323,486,493] have indicated that routine administration of prophylactic ampicillin during labor to women with risk factors for GBS-associated infections has facilitated the proliferation of resistant gram-negative bacteria in the vaginal and rectal maternal mucosa and resulted in an increased incidence of neonatal sepsis caused by these organisms, particularly by *E. coli*. Based on these findings, switching to exclusive use of intrapartum penicillin for prevention of early group B streptococcal sepsis in neonates seems reasonable.

Prevention of early sepsis caused by gram-negative bacilli is important in areas of the world where these organisms are prevalent. Unfortunately, no evidence-based medical guidelines on the epidemiology, risk factors, and prophylactic approaches exist for making a clear recommendation. Empiric administration of aminoglycosides during labor frequently is used in Latin American countries, but no published reports have shown its usefulness. We demonstrated that a single, 1-g parenteral injection of ceftriaxone given to high-risk Panamanian pregnant women (i.e., gestation of less than 37 weeks, prolonged rupture of membranes of more than 12 hours, or both) during labor is associated with decreased bacterial colonization and early-onset infection caused by gram-negative enteric bacilli and possibly by GBS.[417] Although this prophylactic strategy seems to be safe and attractive, analysis of cost-effectiveness and careful evaluation for the potential emergence of ceftriaxone-resistant organisms must be done before recommending it for routine use in selected mothers.

Immunoprophylaxis

Effective immunoprophylaxis would be preferable to chemoprophylaxis because of the limitations of antibiotic prophylaxis and because an immunologic approach is more likely to prevent early- and late-onset group B streptococcal disease in neonates and postpartum febrile morbidity in the pregnant woman. The underlying principle is that IgG antibody directed against the type-specific polysaccharide antigen critical to protection against invasive group B streptococcal disease would be provided by passive or active immunization. GBS type-specific polysaccharide vaccines have been developed and found to be associated with low rates of side effects.[28] However, the immune response was unsatisfactory in as many as 40 percent of nonimmune pregnant women who received type III polysaccharide vaccine. These nonresponders did not develop specific antibody, even after repeated vaccine challenge.[28] Response to vaccine possibly is determined genetically, and some of the women in whom antibodies do not respond to vaginal colonization by GBS may be the same women in whom the vaccine will fail. Pregnant women with the highest risk may not benefit from vaccination. Studies of conjugated GBS vaccines using capsular polysaccharide are in progress. Candidate vaccines are immunogenic in adult women, but immune responses are poor even after protein conjugation. Thus, these vaccines are going to be limited for administration to pregnant women. Their use in pregnancy, however, is associated with many medicolegal difficulties.[25,31,181,368]

Maternal immunizations with type III GBS conjugate vaccines have demonstrated 77 percent placental transport of antibodies and persistence of titers in infants up to the age of 2 months. Infant sera uniformly promoted opsonization of type III GBS strains and killing by neutrophils in vitro, thus suggesting that this approach might be an option for the prevention of early- and late-onset disease.[25,31] A recent analysis published by Sinha and coworkers[464] showed that maternal immunization strategies are superior to all other prophylactic strategies, with prevention of 61 to 67 percent of early-onset and 70 to 72 percent of late onset neonatal disease versus a global 55 percent rate of prevention with the current practice of culture-based chemoprophylaxis. Maternal immunization, however, does not prevent disease in neonates who are born before 32 weeks' gestation because not enough antibody would pass transplacentally.

Prevention of late-onset infection, as opposed to early-onset disease, in neonates by the administration of intravenous immunoglobulin to preterm babies has undergone intense clinical scrutiny.[29,30,153,515,517] Premature babies, particularly those born before 32 weeks' gestation, are relatively hypogammaglobulinemic at birth and become more so during the first several weeks of life. Because these same infants are at high risk for the development of infection beyond the first week of life (late onset), intravenous immunoglobulin infusion may provide opsonizing antibody to prevent late-onset infections. Three of the five early clinical trials that examined the efficacy of intravenous immunoglobulin in preventing infection in neonates demonstrated significant favorable responses.[106,112,206,472] Problems with these studies included small sample size, definition of infection, and lack of a blind design.

A well-controlled multicenter study demonstrated the efficacy of intravenous immunoglobulin infusion in reducing late-onset infection rates.[30] Study infants received intravenous immunoglobulin (500 mg/kg) or placebo at 3 to 7 days of age, 1 week later, and every 2 weeks for a total of five infusions or until hospital discharge. Infusions were tolerated well. Although no significant differences in mortality rates or reduction of infections in infants weighing more than 1500 g occurred, the incidence of bacterial infections was reduced significantly in infants weighing less than 1500 g at birth, and the duration of hospitalization was significantly shorter in recipients of intravenous immunoglobulin. Most infections were bacterial in origin, and approximately 70 percent of them were caused by gram-positive organisms, primarily staphylococci. In contrast to the beneficial effect found in this study, two larger, multicenter, well-designed trials showed no significant differences in the rate of nosocomial infection or in the mortality rate between control and treated groups.[153,517] At this time, intravenous immunoglobulin cannot be recommended as routine prophylaxis for low-birth-weight infants. Investigations now are directed at evaluating the usefulness of pathogen-specific hyperimmunoglobulin for the prevention and treatment of sepsis caused by the most common etiologic agents.[515]

PURULENT MENINGITIS

As many as a fourth of neonates with bacterial sepsis have a simultaneous meningeal infection. The incidence of neonatal meningitis varies greatly among institutions in North America. Rates are approximately 0.2 to 0.4 case per 1000 live births but may be as high as 1 case per 1000 live births in some nurseries. In general, group B beta-hemolytic streptococci and *E. coli* strains account for two thirds of all cases of neonatal meningitis in North America. Gram-negative enteric bacilli predominate in many developing areas of the world (Table 78–6).

Information about the bacteria isolated from the CSF cultures of 257 neonates with meningitis treated at Children's Medical Center or Parkland Memorial Hospital in Dallas, Texas, from 1969 to 1989 is presented in Table 78–6. One hundred thirty-six (53%) of these 257 infants had disease caused by GBS. An additional 49 infants (19%) had meningitis caused by *E. coli* strains. *L. monocytogenes* added an additional 7 percent of cases. These three agents accounted for 79 percent of cases seen during the 20-year period. *E. coli* and *Klebsiella-Enterobacter* strains accounted for 77 percent of the gram-negative organisms causing meningitis. For an etiologic comparison, the distribution of meningeal pathogens in a developing setting[329] also is displayed in the same table.

PATHOLOGY

The pathologic findings are similar, regardless of the bacterial cause. Studies of the fulminant, early-onset form of group B streptococcal disease have shown primarily bronchopneumonia with or without hyaline membranes and usually no histologic

TABLE 78–6 Etiologic Agents of Neonatal Meningitis in Nurseries from a Developed and Developing Country

Organism	Isolation Rate in Dallas (1969-1989) *N* = 257	Isolation Rate in Panama (1975-1992) *N* = 105
Gram-negative bacteria	88 (35%)	68 (64%)
Escherichia coli	19%	16%
Klebsiella species	8%	25%
Other gram-negative rods	4%	16%
Pseudomonas aeruginosa	2%	5%
Haemophilus influenzae	1%	1%
Neisseria meningitidis	1%	1%
Gram-positive bacteria	169 (65%)	37 (36%)
Group B *Streptococcus*	53%	5%
Coagulase-negative *Staphylococcus*	<1%	18%
Staphylococcus aureus	2%	10%
Listeria monocytogenes	7%	1%
Enterococci	2%	1%
Streptococcus pneumoniae	1%	<1%

evidence of meningeal involvement. The most consistent finding at necropsy of meningitis cases is a purulent exudate of the meninges and ependymal surfaces of the ventricles.[52] The inflammatory response of neonates is similar to that observed in adults with meningitis, with the exception that babies have a scarcity of plasma cells and lymphocytes during the subacute stage of meningeal reactions. Some patients also have perivascular inflammation. Hydrocephalus and a noninfectious encephalopathy can be demonstrated in approximately 50 percent of infants dying of meningitis.

Subdural effusions occur rarely in neonates. In contrast, effusions are observed commonly (i.e., by computed tomography or magnetic resonance imaging) in infants with meningitis who are aged 3 to 12 months. Various degrees of phlebitis and arteritis of intracranial vessels can be found in all infants. Thrombophlebitis with occlusion of veins may occur in the subependymal zone. K1 antigen has been demonstrated in the brain tissue of infants succumbing to *E. coli* K1 infection.[430] High concentrations of interleukin-1β have been detected in the brain and meningeal tissue of infants succumbing to meningitis.[34]

CLINICAL MANIFESTATIONS

The early signs and symptoms of neonatal meningitis frequently are indistinguishable from those of septicemia and other disorders occurring in the neonatal period. The most frequent signs are temperature instability, respiratory distress, irritability, lethargy, and poor feeding or vomiting. GBS occasionally has been reported to be manifested as hydrocephalus without other signs of infection. Signs suggestive of meningeal involvement, such as a stiff neck, bulging fontanelle, convulsions, and opisthotonos, are the exception in neonates with meningitis. The frequency of these findings as culled from the literature is 17 percent for a bulging fontanelle, 33 percent for opisthotonos, 23 percent for a stiff neck, and 12 percent for convulsions.[52,315,363] The sensitivity of these findings in distinguishing infection of the pia-arachnoid is poor. All newborns being evaluated for sepsis should undergo examination of CSF, especially if antimicrobial therapy is to be instituted.

DIAGNOSIS

Interpretation of CSF values in newborn infants may be difficult. During the first several days of life, the mean WBC count is 15 ± 30 cells/mm^3 (95% confidence limit, 12 to 18 cells/mm^3) in the CSF of healthy or high-risk uninfected babies.[362,431] Approximately 60 percent of these cells are polymorphonuclear leukocytes. During the first week of life, the cell count slowly diminishes in term infants and increases in premature infants. Cell counts in the range of 0 to 10 cells/mm^3 (median, 4 cells/mm^3) are observed in infants at approximately 2 to 4 weeks of age. The WBC count is uncertain when bleeding occurs after the lumbar puncture has been performed. The fixed relationship between the number of WBCs in CSF and peripheral blood has been disputed. A repeat lumbar puncture may need to be performed in 12 to 24 hours to resolve the ambiguity of the traumatic lumbar puncture.

The mean cerebrospinal protein concentration in the first month of life is 64 ± 24 mg/dL, although individual values can be as great as 170 mg/dL, especially in low-birth-weight, premature infants. The ratio of cerebrospinal glucose to blood glucose is 60 to 70 percent and can be greater than 100 percent in term and preterm infants.[431] The upper limits of normal for cellular and chemistry values are higher in uninfected VLBW infants.[67]

These data indicate that CSF values must be interpreted in relation to these normal findings if a diagnosis of neonatal meningitis is to be made early. Comparison of the results of initial CSF evaluations obtained from newborns with proven bacterial meningitis with those from normal or high-risk infants revealed considerable overlap in the findings.[431] For example, approximately 30 percent of infants with group B streptococcal meningitis had normal spinal fluid leukocyte counts (<32 cells/mm^3), whereas only 4 percent of neonates with meningitis caused by gram-negative organisms had normal counts.[432] The ratio of CSF to blood glucose was normal in 45 percent and 15 percent of patients with streptococcal and coliform meningitis, respectively. However, when the total CSF evaluation (including Gram-stained smears) was considered, less than 1 percent of babies with bacteriologically proven meningitis had totally normal CSF on initial lumbar tap. The likelihood of suppurative meningitis is diminished greatly but not impossible if evaluation of CSF discloses no abnormalities. In some patients in whom the diagnosis is obscured, a repeat CSF examination performed 4 to 6 hours after the initial tap (regardless of whether therapy has been instituted in the interim) may help establish the diagnosis. In premature infants with meningitis caused by *S. epidermidis*, the CSF analysis may be only mildly abnormal despite compatible clinical findings.[204]

Careful examination of the stained smears of CSF from every infant with suspected meningitis is important. Grossly clear fluid may contain few WBCs and many bacteria. The stained smears from approximately 20 percent of neonates with proven meningitis are interpreted as showing no bacteria. Because of the low concentrations of organisms, most Gram-stained smears of CSF from infants with *L. monocytogenes* meningitis do not reveal bacteria. The CSF findings in an infant with a brain abscess may include a pleocytosis of up to a few hundred cells, a predominance of mononuclear cells, and an elevated protein concentration. Bacteria may not be seen on a Gram-stained smear of CSF if meningitis is not present. Ventriculitis is diagnosed on the basis of an elevated WBC count (>100 cells/mm^3), identification of an organism by culture, detection of antigen on a Gram-stained smear, increased intraventricular pressure, and dilated ventricles. A cranial computed tomogram with contrast material may show enhancement of the lining tissue of the ventricles.

Several techniques for establishing rapid diagnosis of bacterial meningitis have been described. The first, counterimmunoelectrophoresis, is used to detect bacterial capsular antigens in CSF and other body fluids. Depending on the source of antisera used in this method, meningitis can be diagnosed with counterimmunoelectrophoresis in almost all patients with *H. influenzae* type b and meningococcal groups B and C meningitis if spinal fluid, serum, and urine are tested.[154] Approximately 70 percent of infants with *E. coli* K1 meningitis have detectable K1 antigen in CSF, serum, or both.[301] Group B_{III} streptococcal antigen has been detected in the CSF, serum, and urine of approximately 90 percent of infected infants.[32] Quantitation of antigen is a helpful means of establishing the prognosis of infants with *E. coli* K1 and type III group B streptococcal meningitis.[32,313]

Latex particle agglutination and staphylococcal coagglutination tests have been developed for detection of bacterial antigens in body fluid. The latex particle agglutination method has been found useful in detecting antigen in the CSF of older infants and children with meningitis caused by *H. influenzae* type b; *N. meningitidis* groups A, B, and C; and *S. pneumoniae*.[350,519] This method is more sensitive than is counterimmunoelectrophoresis for measuring the capsular antigen of *H. influenzae*.[508] The staphylococcal coagglutination test has not been used extensively in pediatric patients, but the polyribose phosphate antigen of *H. influenzae* has been detected in body fluids by this method.[481] Both methods can be used for the detection of group B streptococcal infection.

The *Limulus* lysate test detects the presence of endotoxin, a soluble lipopolysaccharide constituent of the cell wall of gram-negative bacteria.[285] Endotoxin can be measured in the CSF of patients with meningitis caused by coliform bacteria, *H. influen-*

zae, and *N. meningitidis*.[304] Endotoxin has been detected in initial CSF specimens obtained from infants with meningitis caused by *E. coli* and other coliforms. Both counterimmunoelectrophoresis and the *Limulus* lysate technique require approximately 1 hour to run and can be performed in most hospital laboratories. If both methods are used, approximately 80 percent of neonates with coliform meningitis can be identified as having disease within an hour of the initial lumbar tap. However, these results are no better than those obtained from a carefully prepared and examined stained smear of CSF, in which bacteria can be identified in approximately 80 percent of patients with documented bacterial meningitis.[431]

TREATMENT

Selection of appropriate antibiotic therapy for meningitis is based in part on achievable CSF concentrations of these drugs in relation to the susceptibility of the pathogens causing disease. The highest concentrations of penicillin or ampicillin in CSF are at least 10 to 100 times greater than the susceptibilities (i.e., MICs) of GBS and *L. monocytogenes.* As a result, sufficient activity remains in CSF for at least 40 to 60 percent of the dosing interval, and most infants with meningitis caused by these two organisms respond promptly to ampicillin or penicillin therapy. CSF cultures usually are sterile within 24 to 36 hours of initiation of therapy. In contrast, concentrations of aminoglycosides (i.e., kanamycin, gentamicin, tobramycin, and amikacin) in CSF usually are equal to or several times greater than the MIC values for coliform organisms and *P. aeruginosa.* Because killing of bacteria by aminoglycosides is concentration-dependent and requires CSF drug concentrations at least fourfold to eightfold the minimal bactericidal concentration, cultures of CSF from infants with meningitis caused by these organisms often remain positive for 2 or 3 days or longer. Documenting bacteriologic cure in patients with meningitis is important because outcome is correlated with the time necessary to eradicate the bacterial pathogen.

Ampicillin and gentamicin or cefotaxime are recommended for initial empiric treatment of neonatal meningitis (for dosages, see Table 78–1). All infants should undergo repeat CSF examination and culture 24 to 36 hours after initiation of therapy. If organisms are observed on methylene blue– or Gram-stained smears of fluid, modification of the therapeutic regimen should be considered. For many years physicians have attempted to increase antibiotic concentrations in CSF by instilling drugs directly into the lumbar intrathecal space. The first Neonatal Meningitis Cooperative Study evaluated 117 prospectively enrolled, randomly treated infants to determine the role of intrathecal gentamicin therapy in the management of neonatal meningitis caused by coliform bacilli.[309] No statistically significant differences were seen in mortality rates, long-term morbidity, or days that CSF cultures remained positive in infants who received lumbar intrathecal gentamicin plus systemic therapy and those who were treated with systemic drugs only.

Data from the Neonatal Meningitis Cooperative Study and from adult neurosurgical patients with meningitis demonstrated that lumbar CSF concentrations of aminoglycoside drugs administered locally usually exceed the MIC values for coliform organisms by 10- to 50-fold.[309,393] However, lumbar instillation does not result consistently in diffusion of these drugs to the level of the cisterna or into ventricular fluid. In contrast, instillation of aminoglycosides into unobstructed ventricles results in rapid and uniform distribution of drug throughout the CSF space.

Data obtained from the second Neonatal Meningitis Cooperative Study demonstrated ventricular fluid gentamicin concentrations were 10 to 130 μg/mL at 1 to 6 hours after administration of a 2.5-mg intraventricular dose and were 1 to 24 μg/mL at 16 to 24 hours later.[308,310] Concentrations in lumbar CSF at comparable intervals after intraventricular administration were 8 to 85 μg/mL and 1.8 to 4.2 μg/mL, respectively. However, results of the intraventricular regimen were inferior to those obtained with systemic therapy alone. The mortality rate was significantly higher in infants who had meningitis and ventriculitis and received intraventricular gentamicin and systemic antibiotics (43%) than in those who were given systemic therapy only (12.5%). The duration of positive CSF cultures was 1 day shorter in those receiving intraventricular therapy. With the use of serial CSF samples from patients enrolled in this study, we demonstrated some years later that intraventricular gentamicin therapy, which resulted in higher gentamicin CSF concentrations, was associated with higher ventricular CSF endotoxin and interleukin-1β concentrations and greater CNS inflammation (i.e., higher CSF leukocyte count, higher protein concentration, and lower glucose concentration), most likely as a result of lysis of organisms.[339] This finding possibly could explain the poor outcomes in these patients versus infants who received parenteral antibiotic therapy only.[339]

On the basis of the findings from the second Neonatal Meningitis Cooperative Study, intraventricular therapy cannot be recommended for the routine management of neonatal meningitis caused by gram-negative enteric bacilli. A controlled study[316] found that ampicillin and moxalactam therapy (a broad-spectrum cephalosporin no longer available) for neonatal coliform meningitis was as effective as is a conventional regimen of ampicillin and amikacin. In that study, moxalactam achieved greater CSF and ventricular fluid concentrations, and bactericidal titers were considerably greater than those achieved with conventional therapy, but this increase did not translate into more rapid sterilization of the CSF, lower case-fatality rates, or improved neurologic outcome in survivors. Although no large controlled trials have evaluated the use of cefotaxime, clinical experience indicates that it can be used safely and effectively for the treatment of gram-negative meningitis in neonates. CSF examination and culture should be repeated 48 to 72 hours after initiation of therapy. If the results still are positive, computed tomography should be performed to rule out the possibility of subdural empyema, brain abscess, or ventriculitis. In all cases caused by *Citrobacter diversus*, cranial computed tomograms should be obtained early because of the frequent association with brain abscess. The duration of antibiotic therapy should be extended, depending on clinical evolution and resolution of the lesion based on repeated tomography. A neurosurgeon should be consulted early for needle aspiration or excision of the abscess. Aminoglycosides probably should not be used because of decreased activity in abscess cavities that have low pH and anaerobic conditions.

Third-generation cephalosporins possess attractive features, including lower MICs for gram-negative enteric bacilli than with aminoglycosides, good penetration into CSF in the presence of inflamed meninges, and a wide therapeutic index, for the treatment of bacterial meningitis in newborn infants. These agents are active against most streptococci but inactive against *L. monocytogenes* and enterococci. Only ceftazidime provides adequate activity against *P. aeruginosa*. Among these agents, cefotaxime is preferred for the treatment of neonatal meningitis because of extensive experience with this drug in the neonatal period and because it does not alter the bowel flora substantially. Cefotaxime can be used singly or in combination with an aminoglycoside. Ceftazidime has been shown to be effective in treating patients with *P. aeruginosa* meningitis. Because of high biliary excretion and marked alteration of the normal intestinal flora and because of potential concern for displacement of bilirubin, we do not recommend routine use of ceftriaxone during the neonatal period. A prospective study of neonatal bacterial meningitis conducted in England indicated that treatment with third-generation cephalosporins has been associated with a decrease in mortality rates from disease seen during the past decade, especially that related to gram-negative bacillary infection.[219]

For premature infants hospitalized in the nursery for prolonged periods, staphylococci, enterococci, and gentamicin-resistant gram-negative organisms are potential pathogens; an alternative antimicrobial regimen should be considered for initial empiric treatment. A combination of nafcillin or oxacillin and amikacin or ceftazidime or cefotaxime could be used as initial empiric therapy. When MRSA or *S. epidermidis* is a potential cause of infection, vancomycin and amikacin or cefotaxime can be used initially. Imipenem, meropenem, cefepime, and ciprofloxacin have been used to treat neonatal meningitis caused by multiresistant gram-negative bacteria. Greater experience is required before they can be recommended for routine use. For neonatal meningitis caused by *Flavobacterium meningosepticum* isolates, combined use of parenteral vancomycin and rifampin has been suggested as the best therapeutic option.[137]

After the pathogen has been identified and susceptibility studies are available, the single drug or combination of drugs that is most effective should be used. In general, penicillin G or ampicillin is preferred for group B streptococcal meningitis, ampicillin for *L. monocytogenes* and enterococci, ampicillin plus an aminoglycoside or cefotaxime for coliforms, and ceftazidime or ticarcillin and an aminoglycoside for *Pseudomonas* infections. The duration of systemic therapy in neonatal meningitis depends on the causative agent and the time necessary to sterilize CSF cultures. As a rule, therapy is given for approximately 2 weeks after bacteriologic cure has been achieved. For meningitis caused by GBS or *Listeria*, approximately 2 weeks of therapy usually is satisfactory. Because delayed sterilization is a common occurrence in infants with gram-negative enteric disease, systemic therapy is given for a minimum of 3 weeks and in some babies for many additional weeks. Final judgment about when to discontinue therapy must be based on the clinical course of the illness and on CSF findings at the time that this decision is to be made.

Despite the beneficial effects of dexamethasone achieved in several prospective, randomized, double-blind studies for the treatment of infants and children with bacterial meningitis,[415] especially that caused by *H. influenzae*,[434] no such data are available for its use in newborns; the use of steroids in neonatal meningitis cannot be recommended. A prospective trial performed in Jordan found lack of effectiveness of dexamethasone for neonatal meningitis in terms of mortality and sequelae rates when compared with the nonsteroid group.[124] Because this study was small (not sufficient statistical power), not blinded, and without a placebo group, additional studies are required to determine whether dexamethasone has a beneficial effect in neonates with meningitis.

PROGNOSIS

Acute complications of bacterial meningitis include communicating and noncommunicating hydrocephalus, subdural effusions (approximately 1% of patients), deafness, and blindness. Ventriculitis occurs in approximately 70 percent of neonates with coliform meningitis and usually is detected at the time of initial diagnosis. Brain abscess is an infrequent complication, except in infants with *C. diversus* meningitis, in whom abscess develops approximately 70 percent of the time.[194,309,310,316] A 30 to 50 percent incidence in neurologic sequelae has been reported in surviving infants.[202] Although gross retardation and neurologic deficits may be obvious in some infants at discharge, most babies appear "well" at this time. Only after prolonged and careful follow-up do the perceptual difficulties, behavioral problems, and other subtle neurologic signs become apparent. Within 4 to 6 weeks of recovering from meningitis, hearing should be evaluated by evoked response audiometry.

Case-fatality rates in neonates with meningitis range from 15 to greater than 30 percent.[131,315,363] A mortality rate of 30 percent was observed in 117 neonates with coliform meningitis enrolled in the first Neonatal Meningitis Cooperative Study.[309] In this project, term infants had a significantly lower rate (18%) than that observed in low-birth-weight (<2500 g) babies (45%) and in infants older than 30 days (48%). Poor outcome after gram-negative enteric meningitis is correlated directly with the presence of ventriculitis, the persistence of positive CSF cultures, the presence and persistence of elevated endotoxin and interleukin-1β concentrations in CSF, a CSF cell count of greater than 10,000/mm^3, and a CSF protein concentration higher than 500 mg/dL.[257] When meningitis is caused by *E. coli* K1, poor outcome is associated with persistence of large quantities of K1 capsular polysaccharide antigen in CSF.[311,313]

Long-term follow-up studies of babies with coliform meningitis enrolled in the Neonatal Meningitis Cooperative Study have revealed that approximately 65 percent of survivors were normal 3 to 7 years after illness. An additional 30 percent were classified as having mild to moderate neurologic sequelae. Many of these latter patients had only slightly abnormal neurologic or psychological evaluations and were considered normal on routine physical examination. About 5 to 10 percent of survivors had severe neurologic or mental impairment requiring custodial care. Approximately 15 to 20 percent of survivors of group B streptococcal meningitis have major sequelae, including spastic quadriplegia, profound mental retardation, hemiparesis, deafness, and blindness.[109] Hydrocephalus develops in 11 percent, and 13 percent have a seizure disorder. The survivors without major sequelae on physical examination, however, appear to function within normal limits and comparable to their siblings.

Edwards and associates[144] reported a 21 percent morbidity rate after group B streptococcal meningitis. Of the survivors, 29 percent had severe neurologic sequelae, 21 percent had minor deficits, and 50 percent were functioning normally. Factors at initial evaluation associated with death or severe disability included coma, decreased perfusion, CSF protein greater than 300 mg/dL, an absolute neutrophil count of less than 1000, and a total leukocyte count of less than 5000/mm^3. A report from Canada noted that duration of seizures longer than 72 hours, presence of coma, use of inotropes, and leukopenia were the most important predictors of an adverse outcome.[265] Our experience with gram-negative enteric bacillary meningitis in 98 identified neonates managed from 1969 through 1989 revealed a case-fatality rate of 17 percent; 61 percent of survivors had long-term sequelae that included seizure disorders, hydrocephalus, physical disability, developmental delay, and hearing loss.[497]

OTITIS MEDIA

Otitis media is diagnosed infrequently in neonates because of the paucity of clinical findings and the difficulty of examining an infant's tympanic membrane. The external canal is narrow and tortuous and often is filled with debris. Because a healthy baby's membrane may appear thickened and dull, mobility of the drum determined by pneumatoscopy should be used as the single most reliable indicator of middle ear abnormalities. The examiner must beware of mistaking movement of the distal interior canal wall for movement of the tympanic membrane. Movement of a normal membrane is seen best in the posterior portion. A reddish or reddish orange color of the tympanic membrane usually indicates infection, provided that the infant is not crying.

The exact incidence of disease is unknown, but a prospective study found that in 34 percent of 70 infants monitored from birth, the first episode of otitis media occurred before they reached 2 months of age.[302] Otitis media develops more commonly in premature than in term infants and occurs almost exclusively in bottle-fed babies. It is a frequent finding in neonates receiving intensive care, especially those with prolonged nasotra-

cheal intubation.[53] The ears of 127 infants with birth weights of less than 2300 g were examined by Warren and Stool[509] three times weekly until discharge from the nursery; in only three patients (2%) did otitis media develop. In contrast, in a study of 125 premature infants in a neonatal intensive care unit, Berman and associates[53] found that 38 infants (30%) had middle ear fluid compatible with the diagnosis of otitis media; this finding was confirmed by tympanocentesis in 13 patients in whom the procedure was performed. Development of otitis media was correlated significantly with nasotracheal intubation for longer than 7 days.

Meconium staining of amniotic fluid and prolonged rupture of membranes are two other risk factors for the subsequent development of middle ear disease.[377] Neonates with cleft palate, Down syndrome, or maxillofacial anomalies are at high risk for the development of chronic middle ear disease. The onset of illness is insidious, and the most common manifestations are rhinorrhea, irritability, and failure to thrive. Fever higher than 38°C is a rare finding. The presence of lethargy, hypotonia, hypothermia, high fever, or jaundice suggests septic complications such as bacteremia or meningitis.

The cause of neonatal otitis media is similar to that observed in older infants and children. *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis* account for more than 50 percent of cases.[62,63,455,487] The important difference from disease in older patients is that 10 to 15 percent of neonates have disease caused by coliforms, GBS, or *S. aureus*. In a review of 137 medical records of infants younger than 2 months with acute otitis media who underwent tympanocentesis in the emergency room of Soroka University Medical Center between January 1995 and May 1999, 20 percent of *S. pneumoniae* isolates were not susceptible to penicillin, thus indicating that antibiotic resistance already may be present at an early age. Pathogens isolated from the middle ear fluid of these infants were *S. pneumoniae* in 46 percent of cases, *H. influenzae* in 34 percent, group A *Streptococcus* in 10 percent, enteric gram-negative bacilli in 7 percent, *M. catarrhalis* in 2 percent, and *Streptococcus faecalis* in 1 percent. Mixed infections were recorded in 20 patients.[495] We occasionally have encountered neonates with otitis media associated with septicemia and pneumonia or meningitis. GBS or coliform organisms were the causative agents in these cases.

The importance of establishing the diagnosis and cause of otitis media in neonates and using appropriate therapy cannot be overemphasized. When otologic examination demonstrates middle ear disease, the infant should be examined carefully for other sites of infection. If none is found, which is the usual case, the infant can be treated on an outpatient basis. Because a small percentage of these cases are caused by coliform bacilli or *S. aureus*, drugs that include those organisms in their spectrum of activity (i.e., second-generation cephalosporin or amoxicillin-clavulanate) are preferable to the aminopenicillins. The patient's condition should be re-evaluated 8 to 72 hours after therapy is initiated to determine whether clinical improvement has occurred and whether the middle ear infection is resolving. In patients demonstrating no improvement, tympanocentesis should be performed for examination of stained smears of middle ear fluid and for culture of the contents. Changes in therapy should be based on the findings of these examinations. If gram-negative organisms or staphylococci are observed, the infant probably is managed best in the hospital by means of parenteral therapy, with administration of an aminoglycoside if coliforms are suspected or an antistaphylococcal penicillin for *S. aureus*. If organisms are not observed in infants with unresolving disease, nafcillin and gentamicin or cefuroxime can be used until the results of culture and susceptibility studies are available. CSF examination should be performed before parenteral therapy is initiated.

All infants with otitis media should be monitored carefully for many months after illness. Misdiagnosis or improper therapy may result in chronic middle ear disease and, occasionally, extension of infection to adjacent structures such as the mastoid or CNS. Infants in whom the first episode of otitis media develops before they reach 2 months of age may require 3 to 4 months to clear the effusions, and recurrent or chronic otitis media is reported to develop in a third of them.[302]

DIARRHEAL DISEASE

Although diarrheal disease during the neonatal period usually is brief and self-limited, it may cause significant morbidity in some infants and represents a potential danger to other infants in the nursery. The advent of modern sterilization practices and increased emphasis on hospital infection control measures has reduced the incidence of nosocomial diarrheal disease significantly.

Numerous factors, including underdevelopment of local and systemic immune responses; lack of fully developed aerobic and anaerobic enteric flora, which protects the gastrointestinal tract of older infants and children; a less effective gastric bactericidal barrier; less intestinal mucus; and less motility, contribute to increased susceptibility to neonatal enteric infections.[357] The infant may have been fed powdered formula that could have been mixed with contaminated water, or a critically ill newborn may have received a broad-spectrum antibiotic in intensive care, in which case highly resistant nosocomial flora pose a special risk.

The importance of breast-feeding in preventing diarrheal disease in infants cannot be overemphasized. The protective effects of breast-feeding have been confirmed in surveys of sporadic gastroenteritis, in community epidemics, and in outbreaks in newborn nurseries. Antibacterial and antiviral factors in breast milk, including lactoferrin, lysozyme, phagocytes, specific secretory immunoglobulins, and lymphocytes sensitive to organisms such as *E. coli*, *Salmonella*, *Shigella*, *Clostridium difficile* toxins A and B, and rotavirus, are well documented.[197,209,357,492] Breast-fed infants are less susceptible to diarrheal diseases than are bottle-fed infants.[205,357]

ETIOLOGY AND PATHOGENESIS

The most common cause of diarrhea in young infants is alteration of diet and feeding practices rather than specific bacterial or viral pathogens. Diarrhea can be a nonspecific symptom of sepsis or urinary tract infection in a newborn infant. Of the infectious causes, rotaviruses are important in infantile diarrheal disease.[326,415] They have been associated with nursery outbreaks of gastroenteritis and necrotizing enterocolitis.[111,410] Studies from France have shown that approximately a third of all neonates shed rotavirus in their stool; of these infants, only 29 percent have associated diarrhea.[101]

Transplacental transfer of rotaviral group-specific or type-specific maternal antibodies to neonates appears to have little effect on the incidence of infection or illness by rotaviruses.[135,136,355] The essential pathogenic feature of rotavirus infection is destruction of the absorptive cells lining the duodenum, jejunum, and possibly the ileum.[325] Lactase exists only in the brush borders of differentiated epithelial cells at these sites and has been suggested to act as a combined receptor and uncoating enzyme for the virus, which may explain why rotavirus infection occurs less commonly in infants of less than 32 weeks' gestation than in more mature infants.[89] In infants between 26 and 34 weeks' gestation, lactase activity is approximately 30 percent of that found in term infants.[280]

Enteropathogenic *E. coli* serotypes once were considered the most common bacterial agents responsible for diarrhea in young infants. Failure to demonstrate on rectal cultures specific sero-

types of *E. coli* designated as enteropathogenic does not rule out coliform disease. Enterotoxigenic strains of *E. coli* possessing nonenteropathogenic serotypes have been identified in nursery outbreaks of diarrheal disease.[75,360] These organisms inhabit the small bowel, where they attach to but do not invade the intestinal mucosa. The enterotoxin produced by these organisms stimulates cyclic adenosine monophosphate, which inhibits sodium and chloride transport across the intestinal wall. As a result, these salts are lost into the lumen of the upper bowel, followed passively by water, which causes a net loss of stools containing high concentrations of electrolytes. *Vibrio cholerae*, some *E. coli* serotypes (almost exclusively nonenteropathogenic strains), *Vibrio parahaemolyticus*, *Aeromonas*, and possibly some *Campylobacter* and *Yersinia* strains are examples of bacteria that cause diarrhea by this mechanism.

The importance of recognizing this form of diarrheal disease was emphasized in a nursery outbreak in the southwestern United States. Severe, watery diarrhea was observed in 59 infants during a 9-month period; in the 7 percent of infants who died, death resulted from altered hepatic function and a hemorrhagic diathesis.[75] An O142/K86/H6 *E. coli* strain was responsible for the outbreak. Because this organism is not a classic enteropathogenic serotype, it was not identified as a pathogen, which thereby delayed establishing the definitive diagnosis and institution of proper infection control techniques. Only by special laboratory techniques was this *E. coli* strain shown to produce labile enterotoxin.

A second mechanism involved in the development of bacterial diarrhea is invasion of the intestinal mucosa. *Shigella* dysentery is the classic example of this disease. Colonic invasion with subsequent destruction of the mucosa causes an outpouring of polymorphonuclear cells and mucus. The resultant diarrhea usually is bloody and contains mucus and pus. *Salmonella* spp. also invade the intestinal mucosa, but destruction is not extensive. The epithelial lining is left intact, and the organisms reach the lamina propria, where an inflammatory response is elicited.[483] *Campylobacter*, *Yersinia*, *Aeromonas* spp., and *C. difficile* also can cause bloody diarrhea.

Although serotyping of *E. coli* to identify the traditional enteropathogenic strains no longer is available routinely, the epidemiologic evidence is strong enough to support a pathogenic role for these strains, even though the mechanism of pathogenicity is unknown. When an index case of diarrhea caused by enteropathogenic *E. coli* or other pathogens is recognized in a nursery, secondary cases are likely to occur. In any nursery infant with diarrhea, a potentially communicable disease should be suspected. For all infants in proximity to the index case, rectal swabs should be tested by culture or by fluorescent antibody technique, which is more sensitive in identifying asymptomatic carriers of enteropathogenic *E. coli.* Ill and healthy colonized infants should be segregated and treated with orally administered neomycin (100 mg/kg/day in three or four divided doses) or with colistin sulfate (15 mg/kg/day in three or four divided doses) for 5 days. Neomycin causes rapid disappearance of the organism and abbreviates the duration diarrhea, but approximately 20 percent of infants revert to an asymptomatic carrier state (J. D. Nelson, personal communication, 1990). Repeated surveillance of infants is necessary until the pathogenic strain has been eliminated from the nursery. A report from Yugoslavia identified a multiresistant strain of enteroaggregative *E. coli* (O4 serogroup) associated with an outbreak of transient, self-limited diarrhea in a neonatal nursery ward.[113]

Campylobacter, a curved, gram-negative bacterium, has been recognized increasingly as a common cause of enteritis. Of the 14 known species, *Campylobacter fetus* and *Campylobacter jejuni* cause human disease most frequently. *C. fetus* causes prenatal and neonatal infections that result in abortion, premature delivery, bacteremia, and meningitis. Infections caused by *C. fetus* appear to be the most common type of *Campylobacter* infection in the first 3 weeks of life and are associated with a high incidence of fetal and neonatal morbidity.[205] In contrast, the most common syndrome produced by a *Campylobacter* species is enteritis caused by *C. jejuni*. Unlike the serious neonatal disease caused by *C. fetus*, infections with *C. jejuni* usually result in mild gastroenteritis, although meningitis occurs rarely. Nursery outbreaks of gastroenteritis caused by *C. jejuni* have been documented definitively.[205]

Although some diarrheal episodes in neonates probably can be caused by *C. difficile*, the diagnostic criteria used in older children and adults are inadequate to establish a definitive diagnosis in this age group. *C. difficile* is a gram-positive anaerobic bacillus that produces an enterotoxin (i.e., toxin A) that causes fluid secretion and a cytotoxin that damages cells (i.e., toxin B).[85,288] *C. difficile* colonic overgrowth and toxin production can result from the selective pressure of antibiotic therapy. A wide variety of antibiotic, antifungal, and antituberculous agents have been associated with *C. difficile* colitis.[205] Although healthy children older than 1 year and healthy adults rarely carry the organisms, as many as two thirds of neonates can be demonstrated to have both *C. difficile* and its cytotoxins in their stool.[205] This high frequency of colonization and the presence of cytotoxin have led to skepticism about the pathogenic potential of this organism in neonates.

CLINICAL MANIFESTATIONS

Although the cause of diarrhea in infants and children may be suspected on clinical grounds, usually this is not possible in newborn infants. As a general rule, diarrhea caused by enteropathogenic strains of *E. coli* is insidious in onset, is associated with 7 to 10 green watery stools daily, and generally is without blood or mucus. These infants do not appear to be acutely ill. Complications rarely occur and primarily are related to dehydration and electrolyte disturbances. *Shigella* infection seldom occurs, usually is episodic in neonates, and generally does not spread within nurseries.[211] Shigellosis in a newborn may occur as a diarrheic or dysenteric syndrome or may be evidenced only by a septic- or toxic-appearing infant. Suppurative complications are rare events, but dehydration and electrolyte disturbances are common and need immediate and constant attention. *C. jejuni* infection typically involves the gastrointestinal tract and produces watery diarrhea or a dysentery-like illness with fever and bloody mucoid stools. Extraintestinal infections related to *C. jejuni*, other than bacteremia, are rare occurrences but include cholecystitis, urinary tract infection, and meningitis.[205] The clinical manifestations in neonates with *C. fetus* infection are similar to those caused by the common neonatal pathogens.[205] *C. jejuni* has been reported to cause bloody diarrhea in otherwise asymptomatic neonates.[84]

A useful procedure for differentiating enteroinvasive from enterotoxigenic diarrhea is examination of fecal material for polymorphonuclear cells. Feces from many patients with dysentery show significant numbers of polymorphonuclear leukocytes, whereas those from patients with enterotoxigenic disease usually show few neutrophils.

TREATMENT

The most important aspect of therapy for diarrheal disease of newborn infants is maintenance of hydration and electrolyte balance. As a rule, parenteral solutions containing appropriate electrolytes should be administered during the time of active diarrhea, and the infant should be examined and weighed frequently to ensure that proper rehydration has been achieved and to prevent the development of complications. Estimates of fluid

loss from diarrhea and vomiting should be recorded carefully and used as a basis for replacement therapy.

Selection of appropriate antimicrobial therapy depends in part on the mechanism of diarrhea. In general, an orally administered, absorbable antibiotic such as ampicillin or trimethoprim-sulfamethoxazole is indicated for disease caused by invasive bacteria (e.g., shigellosis), whereas orally administered, nonabsorbable drugs such as neomycin and colistin sulfate are used for noninvasive organisms that produce enterotoxin (e.g., some *E. coli*).

Antimicrobial therapy for uncomplicated *Salmonella* gastroenteritis is controversial. We do not recommend antibiotics for most infants and children with uncomplicated *Salmonella* disease because such therapy does not shorten the course of illness and can be associated with an increased likelihood of prolonged asymptomatic excretion of the organism. However, neonates and infants younger than 3 or 4 months should be treated with a 7-day course of amoxicillin because of their propensity for the development of a protracted illness or bloodstream invasion with distant foci of infection.[130] Trimethoprim-sulfamethoxazole is a suitable alternative for ampicillin-resistant strains. The asymptomatic carrier state requires no therapy.

Ampicillin formerly was the antibiotic of choice for shigellosis, but in recent years significant resistance to this agent has been observed in many areas of the country. Some strains are susceptible to trimethoprim-sulfamethoxazole in a daily dosage of 10 mg of trimethoprim and 50 mg of sulfamethoxazole per kilogram per day in two divided doses. Sulfa drugs are contraindicated in newborns with jaundice. For multiresistant *Shigella* strains, some authorities recommend third-generation cephalosporins given parenterally (e.g., ceftriaxone) or orally (e.g., cefixime).

Erythromycin is the preferred drug for treating symptomatic *C. jejuni* enteritis. Frequently, if erythromycin therapy is initiated within the first 4 days of illness, excretion of the organism is reduced and symptoms resolve rapidly. An aminoglycoside is the drug of choice for treating *C. fetus* infections; chloramphenicol is an alternative.

Any infant with diarrhea must be isolated from other babies in the nursery. Surveillance of all infants in contact with the index case and institution of infection control measures are mandatory, as discussed earlier.

Probiotics (generally strains of *Bifidobacterium*, *Lactobacillus*, or *Saccharomyces*) have been used for the treatment of acute gastroenteritis with beneficial results. In murine experiments, however, administration of probiotic has shown the potential to causes sepsis in athymic mice, thus suggesting that the presence of immune deficiency in neonates may put them at risk for development of probiotic-induced sepsis. Accordingly, its use is not recommended at present.[76]

URINARY TRACT INFECTIONS

The incidence of bacteriuria in newborn infants ranges from 0.5 to 1 percent for term infants and is approximately 3 percent for premature infants.[348] Urinary tract infections occur more commonly in babies born to bacteriuric mothers and in boys during the neonatal period. The latter observation contrasts with the preponderance of infection in girls beyond the first months of life. The frequency of urinary tract infection and bacteremia is significantly higher in uncircumcised male neonates and young infants.[522] Circumcision reduces the frequency of urinary tract infection by approximately 90 percent. Bacterial colonization of both the prepuce and female perineum may occur because of the presence of maternal urinary tract infection. This prevalence was shown in a study in which 24 percent of infants were bacteriuric when delivered by mothers who had bacteriuria, whereas control infants whose mothers had not been bacteriuric had no bacteriuria. Clinical pyelonephritis occurred in 3 percent of these bacteriuric infants, but only 0.2 percent of 500 control infants of nonbacteriuric mothers had pyelonephritis.[375]

ETIOLOGY

E. coli is the most common etiologic agent of urinary tract infections and accounts for approximately 90 percent of acute infections and 70 to 80 percent of recurrent disease. Approximately 70 percent of *E. coli* strains belong to one of eight common somatic (O) antigen groups, similar to those found in older persons. Several capsular polysaccharide antigens (K1, K2, K12, and K13) are found more often in children with upper tract disease than in those with cystitis.[250,520] The association between K1 antigen and upper tract disease is found significantly more often in newborn and young infants than in older infants and children with *E. coli* urinary tract infection.[520] Fimbriated *E. coli* can attach to specific receptors or uroepithelial cells. Glycolipids of the P blood group constitute a specific receptor that is thought to be associated with pyelonephritis in patients who do not have reflux. When compared with asymptomatic bacteriuric infants, those with febrile urinary tract infections were found to have significantly increased inflammatory signs (e.g., C-reactive protein, microsedimentation rate) and attaching *E. coli*.[304] This finding suggests that bacterial properties determine not only the location of the urinary tract infection but also the severity of inflammation in individual patients.

Proteus, *Klebsiella*, and *Pseudomonas* spp. are encountered in patients with recurrent disease, particularly those receiving prolonged antimicrobial prophylaxis. Gram-positive bacteria, with the exception of enterococci, rarely are encountered as pathogens for the urinary tract. Only a few neonatal cases of renal abscess have been reported in the literature. *S. aureus* and coliforms were the predominant etiologic agents.[466]

CLINICAL MANIFESTATIONS

Most infants with significant bacteriuria are asymptomatic or have nonspecific signs and symptoms. The neonate may appear septic or may have decreased activity, feeding problems, and the other constitutional signs that are seen with infections of other organ systems. Jaundice, hepatomegaly, and thrombocytopenia may be observed in a few infants with urinary tract infection; these findings are associated with septicemia or cholestatic hepatitis in some babies.[50] Localizing signs suggesting urinary tract involvement are unusual findings. When present, they usually consist of a weak urinary stream on voiding or an abdominal tumor from bladder distention, hydronephrosis, or both.

DIAGNOSIS

The diagnosis of urinary tract infection is confirmed by examination and culture of urine. The results of these tests depend largely on the method of urine collection. Most pediatricians obtain urine with a sterile, plastic receptacle applied to the cleansed perineum. However, urine obtained by this method may have an elevated cell count because of recent circumcision, vaginal reflux of urine, or contamination from the perineum. Neonatal asphyxia also may increase the urine cell count. WBCs must be differentiated from round epithelial cells, which appear in the urine in significant numbers during the early days of life. Although pyuria commonly accompanies significant bacteriuria, cells can be few or absent. Direct microscopic examination of uncentrifuged, fresh urine is useful. If bacteria are seen readily in each high-power field, they generally number greater than 10^5 cells/mL.

Glitter cells are thought by many physicians to be diagnostic of urinary tract infection.

Quantitative urine cultures from infants with documented disease usually contain more than 100,000 colonies/mL of a single bacterial species. Any number of bacteria in a urine specimen obtained by percutaneous needle puncture of the bladder should be considered significant. This latter procedure is the single best source of urine for culture and is safe in most newborn infants.[343] The procedure should not be performed in infants who are dehydrated or have bleeding problems. Minor, transient hematuria is an uncommon occurrence, and serious problems from hemorrhage or perforation of the bowel have been rare events. If a "bagged urine specimen" contains fewer than 100,000 colonies/mL of a single species of bacteria or if the culture yields a mixed bacterial population, a repeat urine specimen should be obtained by suprapubic bladder aspiration or catheterization for culture.

Examination of the urinary sediment for antibody-coated bacteria has been found to be useful in differentiating upper tract disease from cystitis in adult patients.[247] Some reports have suggested, however, that this technique is not applicable to infants and children.[520] These studies have demonstrated false-positive and false-negative rates of approximately 30 percent. Because acute pyelonephritis is associated with enlargement of the kidneys secondary to edema and acute inflammatory infiltrate of the medulla and pelvis, ultrasound volume measurements of the kidneys provide a noninvasive method for identifying the probable site of urinary tract infection.[243] Fifteen of 18 children with upper urinary tract infection had increases in volume of 30 percent or greater in at least one kidney, whereas only 4 of 21 children with lower urinary tract infection had increases of greater than 30 percent ($p < .005$).

TREATMENT

Blood and urine should be obtained for culture from all newborn infants with suspected or proven urinary tract infection before antimicrobial therapy is initiated. Antibiotics initially are administered parenterally because sepsis is associated with urinary tract infection in 20 to 30 percent of infants[180] and absorption of antibiotics after oral administration is erratic in some babies. Therapy is initiated with an aminoglycoside and ampicillin to provide antibacterial coverage for the anticipated coliforms, enterococci, and GBS. If the patient has renal impairment, ampicillin and cefotaxime constitute an alternative empiric regimen. Because urine concentrations of these drugs exceed the MIC values of the urinary pathogens manyfold, the usual dosages may be reduced after septicemia has been ruled out.[312] Infants with renal or perirenal abscesses require percutaneous drainage under sonographic guidance or open surgical drainage if the former fails.

A repeat urine culture performed 48 to 72 hours after initiation of appropriate therapy should be sterile or show a substantial reduction in the bacterial count. Infants with persistent bacteriuria should be evaluated for the possibility of inappropriate therapy, obstruction, or perinephric abscess. In uncomplicated disease, therapy usually is continued for a period of 7 to 10 days. Approximately 1 week after discontinuance of therapy, a repeat urine culture is performed.

All infants with documented infection should undergo radiologic evaluation of the urinary tract. An intravenous pyelogram or renal sonograph is obtained during the course of therapy to rule out the possibility of gross congenital abnormalities of the urinary system. Renal sonography is preferred over intravenous pyelography in the acute phase of disease. Congenital malformations are unusual findings in the first week of life but may be present in a significant proportion of infants with urinary tract infections after this age. If obstruction is demonstrated, urologic procedures to ensure proper drainage are mandatory if therapy is to be successful. A voiding cystourethrogram or a radionuclide cystourethrogram should be obtained several weeks after therapy is discontinued. Radiologic abnormalities are found in approximately 45 percent of infants, especially in girls.[69,180]

Physicians have the responsibility of ascertaining that neonates with urinary tract infections do not have congenital abnormalities of the urinary system.[402] In these patients, recurrent urinary tract infections are common events, and physical growth may be retarded until definitive surgery has been performed. Every infant with urinary tract infection should undergo long-term follow-up studies for detection of recurrent infections, many of which are asymptomatic.

Infants found to have anatomic abnormalities (e.g., vesicoureteral reflux) must be protected from reinfection by prophylactic administration of trimethoprim-sulfamethoxazole or nitrofurantoin, and urine cultures or urinary nitrite tests should be performed soon thereafter for children. Although no absolute medical indication exists for routine circumcision of the newborn, cumulative data suggest that circumcision protects against urinary tract infections during early infancy.[523] When compared with the complications of urinary tract infections, short-term complications of circumcision are rare occurrences and mostly minor.[522]

SUPPURATIVE ARTHRITIS AND OSTEOMYELITIS

Osteomyelitis and suppurative arthritis rarely occur in the first 4 weeks of life. The incidence has not changed for many years and is estimated to be one to three cases of bone or joint infections per 1000 nursery admissions. A review of osteoarticular infections from Dallas, Texas, revealed 18 cases (3%) of neonatal arthritis and 18 cases (5%) of osteomyelitis out of 632 arthritis and 365 osteomyelitis cases in infants and children managed from 1959 to 1986.[343] Male infants are affected more often than female infants are (1.6:1), and the incidence is higher in premature than in term infants.

Bone and joint infections can be difficult to detect in neonates and young infants. Early establishment of the diagnosis and appropriate management are vital in preventing orthopedic abnormalities later in life.

ETIOLOGY AND PATHOGENESIS

The infecting organisms in osteomyelitis and septic arthritis vary, but the predominant ones are *S. aureus*, GBS, and gram-negative enteric organisms such as *Klebsiella*, *Proteus*, and *E. coli*. In a study of neonates in Dallas, Texas, *S. aureus* was the etiologic agent in 50 and 44 percent of cases of osteomyelitis and arthritis, respectively, whereas streptococci were responsible for 6 and 22 percent of such cases, respectively. GBS has become the single most common agent associated with arthritis in many areas of the United States.[164] Osteomyelitis and arthritis caused by gram-negative enteric bacilli have remained uncommon events despite the frequency of neonatal bacteremia caused by these organisms. Coliforms caused 11 percent of cases in Dallas and 5 percent in a children's hospital in Stockholm.[45] In Africa and Asia, rates as high as 45 percent have been described.[273] We reported that coliforms and *S. aureus* accounted for two thirds of isolates in neonates with osteoarticular infections in Panama.[424] Gonococcal arthritis and tenosynovitis were common occurrences in previous decades, but they are seen only occasionally today.[117] Other causative agents associated infrequently with newborn infection are *Salmonella*, *Pseudomonas*, *C. albicans*, and *U. urealyticum*.[123,385,386]

Osteomyelitis and arthritis have been reported in newborns after several invasive procedures, including heel puncture, femoral

venipuncture, exchange transfusions, fetal monitoring with electrodes, serial lumbar puncture, and umbilical artery catheterization.[18,48,290,342,364,386,391] Osteomyelitis of cranial bones has complicated infected cephalohematomas. The use of peripheral and central intravascular catheters in neonates has been associated with the development of bacterial and fungal osteomyelitis.[148] Septic embolization from catheter tip thrombi, together with local hypoxia from partial occlusion of the vessel by the catheter, may explain this association.[164,291] A very strong correlation exists between the site of the catheter and localization of infection in the limb; for example, the knees and hips are involved in most cases associated with aortic catheters.[291] Usually, the origin is unknown and presumed to be hematogenous.

During the infant's first month of life, the epiphyseal plate is traversed by multiple small transepiphyseal vessels that provide direct communication between the articular space and the metaphysis of the long bones.[356] As a result, infection of the metaphysis (i.e., osteomyelitis) can spread across the growth plate and penetrate the epiphysis or enter the joint space. Because the perforating vessels disappear when the child is approximately 1 year of age, septic arthritis usually is not associated with osteomyelitis in older infants and children. The two exceptions to this rule are osteomyelitis of the proximal ends of the femur and humerus. The capsule of the hip and shoulder attaches below the proximal metaphysis of the femur and humerus, respectively. Infection of the epiphyseal cartilage may rupture through the periosteum, enter the joint space, and produce purulent arthritis. Because the capsular articulation of the hip and shoulder is permanent, osteomyelitis and septic arthritis may coexist, thus rendering the origin of infection difficult to establish.

The large vascular spaces and thin spongy structure of the metaphyseal cortex in infants permit early decompression of the primary abscess into the subperiosteal space. The abscess then dissects rapidly between the loosely attached periosteum. As pressure increases from the accumulating pus, a subcutaneous abscess can develop that may point and drain spontaneously through the skin and form a sinus tract. Free communication between the original site of osteomyelitis and the subperiosteal space prevents the necrosis and extensive spread of infection within bone that occurs frequently in older children and adults.

CLINICAL MANIFESTATIONS

Two distinct clinical syndromes that may be associated with osteomyelitis in the newborn period have been described.[132,199,490] The first is a benign form in which the earliest sign of bone and joint infection in newborns is failure to move an extremity spontaneously or apparent pain on movement without systemic evidence of infection. Swelling, erythema, and heat localized to the affected part are late findings. Multiple bones or joints can be involved, especially when disease is caused by *S. aureus*. The striking feature of this form is the satisfactory general condition of the infant despite the intensity of the local process. The fatality rate is exceedingly low, and healing is prompt. The second syndrome, a severe form, is characterized by systemic manifestations of sepsis; only later are multiple sites of bone and visceral involvement noted.

Two other clinical entities unique to the newborn are maxillary bone involvement and osteomyelitis caused by GBS. Maxillitis or osteomyelitis of the superior maxilla is an unusual form of bone infection in newborn infants.[289,290] More than 85 percent of all maxillary infections in infants take place in the first 3 months of life, with the peak incidence occurring in the second to fourth weeks.[303] Swelling of the cheek, associated with unilateral nasal discharge of pus, and swelling of the alveolar ridge of the maxilla should alert the physician to this entity. Initially, dacryocystitis or orbital cellulitis may be suspected. The etiologic agent usually is *S. aureus*. Septicemia and death occur commonly in untreated cases.

Group B streptococcal osteomyelitis is manifested during the third and fourth weeks of life (i.e., late onset) and is caused predominantly by type III strains. It affects girls more often than boys, and the humerus is the most common site of involvement. In contrast to the fulminant onset and poor outcome that occur in some infants with late-onset meningitis, group B streptococcal bone and joint infection has an indolent nature and an almost uniformly good outcome. Occasionally, a diagnosis of Erb palsy may be entertained when inflammatory signs are minimal and diminished use of an arm is marked. Manipulations known to predispose neonates to bone and joint infections caused by other organisms have not been reported in infants with group B streptococcal arthritis or osteomyelitis.[299]

DIAGNOSIS

Conventional radiography remains the most useful means of establishing the diagnosis in patients with suspected suppurative arthritis; radiographs may be normal or show enlargement of the joint space. Later in the course of disease, subluxation and destruction of the joint are common findings. In early osteomyelitis, the normal radiographic water markings of tissues adjacent to the affected bone may be obliterated, an indication of deep-tissue inflammation and swelling. Lifting of the periosteum also may be observed, but cortical bone destruction seldom occurs before the second week of illness. A complete skeletal survey should be performed because of the frequent involvement of multiple sites.[164,329] In approximately 10 percent of patients, radiographic abnormalities are not seen during the course of disease. Although radionuclide bone scans are useful in establishing an early diagnosis of osteomyelitis in infants and children, they can be normal in newborn and young infants with confirmed infection. A report indicates a sensitivity of 90 percent for three-phase bone scintigraphy in the diagnosis of neonatal osteomyelitis.[5] Magnetic resonance imaging has been used successfully for establishing the diagnosis of osteomyelitis in the newborn period.

Blood should be obtained for culture from all infants with osteomyelitis or septic arthritis. In view of the varied etiologic bacteria, obtaining specimens of bone or a joint aspirate for culture is imperative, as is percutaneous needle aspiration of intra-articular pus in patients with suspected suppurative arthritis or aspiration of sequestrum in those with suspected osteomyelitis. If pus is obtained, the material should be Gram-stained and cultured.

TREATMENT

Selection of initial antimicrobial therapy is guided by preliminary identification of the pathogen from stained smears of material obtained by needle aspiration. If no microorganisms are seen, initiating treatment with two drugs, a penicillinase-resistant penicillin (e.g., nafcillin, oxacillin) and cefotaxime, is advisable. Vancomycin should be added if MRSA is a possibility. Use of an aminoglycoside with the antistaphylococcal penicillin does not provide adequate coverage for GBS. Definitive treatment is based on culture and susceptibility results. Direct instillation of an antibiotic into the joint space is unnecessary because most drugs penetrate the inflamed synovium and adequate concentrations are achieved in purulent material.[344] The same applies to treatment of osteomyelitis; direct instillation of antibiotics into acutely inflamed bone is unnecessary.[488]

Surgical removal of infected material is an integral part of treatment. Open drainage is essential for managing septic hip disease. The inflammation in osteomyelitis or septic arthritis can

occupy the epiphyseal and metaphyseal sides of the growth plate and result in ischemia and necrosis of the plate and permanent orthopedic damage. For other joints, repeated daily evacuation of fluid with a needle and syringe usually is adequate. In patients with osteomyelitis, the subperiosteal space and the metaphysis should be drained if pus is obtained during diagnostic aspiration. If only a small amount of bloody material is obtained at aspiration, surgery does not need to be performed immediately, and the patient generally can be managed with antibiotic therapy alone as long as the local and systemic signs resolve. If improvement is unsatisfactory, repeat aspiration or open surgical drainage may need to be performed.

Antimicrobial treatment of neonatal musculoskeletal infections caused by staphylococci or coliform organisms is continued for a minimum of 3 to 6 weeks. Group B streptococcal infection is treated with penicillin G or ampicillin for at least 2 weeks. Ten days of therapy usually is adequate for treating gonococcal infection. Use of oral antibiotics as a substitute for parenteral therapy during the second and third weeks of treatment is unwise unless compliance can be ensured and serum bactericidal activity or the antibiotic concentration is satisfactory, which indicates adequate absorption of the orally administered drug. Parenteral antibiotic therapy can be administered at home if the infant can be assessed routinely by a physician.

As a general rule, systemic symptoms disappear within several days of initiation of therapy and adequate surgical drainage, although such local signs as heat, erythema, and swelling may persist for 4 to 7 days. Full range of motion may not return to the involved limb for several months. The erythrocyte sedimentation rate is a useful guide for determining the duration of therapy. The rate usually returns to within the normal range within 2 to 4 weeks; in contrast, C-reactive protein becomes normal sooner. As reported for older infants and children, serial determinations of C-reactive protein may be valuable in assessing the clinical course, but experience is inadequate to use this test in guiding the duration of antimicrobial therapy for neonatal osteoarticular infections.[407] Complete resolution of the radiographic changes may take several months.

Physical therapy to ensure full range of motion should be started as soon as the pain has abated. Assessing residual joint abnormalities and abnormal bone growth patterns in infants frequently is difficult until many months or years have passed. Maintaining good long-term follow-up after treatment has concluded is important.

CONJUNCTIVITIS AND ORBITAL CELLULITIS

Infections of the eye of the newborn can be caused by a variety of microorganisms, including *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *S. aureus*, and *P. aeruginosa*. From a review of more than 300 eye infections in newborns at Grady Memorial Hospital in Atlanta, Georgia,[16] researchers determined that 29 percent were caused by *Chlamydia*, 14 percent by gonococci, 10 percent by staphylococci, 2 percent by chemical reactions, and 1 percent by mixed gonococcal and chlamydial infections. The remaining 44 percent were of uncertain cause. A prospective, controlled study found that the major microbial causes of neonatal conjunctivitis were *Haemophilus* spp. in 17 percent, *S. aureus* in 17 percent, *C. trachomatis* in 14 percent, *S. pneumoniae* in 11 percent, and enterococci in 8 percent.[428] Other less frequently encountered organisms included *M. catarrhalis*, *Pasteurella multocida*, *N. meningitidis*, and herpes simplex virus.

The incidence of ophthalmia neonatorum has not paralleled the large increase in gonococcal disease rates among adolescent and young adults, almost certainly a result of universal neonatal prophylaxis with 1 percent silver nitrate solution, antibiotic ointment, or systemic penicillin G. Today, we rarely see the invasive, destructive ophthalmitis described so vividly in the early literature.[151]

Numerous agents have been shown to be effective prophylactically against gonococci. The largest series was published by Greenberg and Vandow[198] and involved 250,000 infants treated with 1 percent silver nitrate. A failure rate of 6.6 per 100,000 infants treated with silver nitrate compared favorably with the rate of 22.5 per 100,000 in 86,000 infants who received no prophylaxis. Of the topical antimicrobial agents, tetracycline or erythromycin appears to be comparable in efficacy to silver nitrate and has the advantage of causing fewer cases of chemical conjunctivitis.[361] Penicillin applied topically or given intramuscularly also is effective, although the ointment no longer is available commercially. Bacitracin ointment is ineffective.[110,306] Ceftriaxone as a single dose of 50 mg/kg (for low-birth-weight infants, 25 to 50 mg/kg) can be useful for prophylaxis when the risk is high. Infants born to mothers with active gonorrhea should receive a single 125-mg dose of ceftriaxone intravenously or intramuscularly. Ceftriaxone should not be given to hyperbilirubinemic infants, especially premature ones.

A study by Hammerschlag and associates[211] showed that neonatal ocular prophylaxis with erythromycin or tetracycline ophthalmic ointment does not reduce the incidence of chlamydial conjunctivitis significantly in the offspring of mothers with *Chlamydia* infection when compared with silver nitrate. The investigators concluded that better management of maternal *Chlamydia* infection is required if the incidence of conjunctivitis caused by this organism is to be reduced. They suggested that a small but appreciable incidence of neonatal gonococcal ophthalmia could be prevented by performing better prenatal screening and treating maternal gonococcal infections.

DIAGNOSIS

Any infant with a conjunctival discharge should be evaluated carefully to determine the cause. Three tests should be performed: Gram and methylene blue stain of the exudate, culture of the exudate, and Giemsa stain and culture for *Chlamydia*, if available, of scrapings made from the lower palpebral conjunctiva after the exudate has been removed. The results of the stained smears determine the appropriate therapy. Direct detection of chlamydial antigens in eye scrapings now is possible by means of a commercially available enzyme-linked immunoassay (e.g., Chlamydiazyme). Limited experience in neonates suggests that it is a sensitive and specific test that can provide rapid and reliable results.[213]

DIFFERENTIAL DIAGNOSIS

Conjunctivitis occurring in the first days of life can be chemical or bacterial. Chemical irritants, such as silver nitrate, cause transient conjunctival hyperemia and a watery discharge that rarely turns purulent.

Gonococcal ophthalmia usually becomes apparent within the first 5 days of life and is characterized initially by a clear watery discharge. Conjunctival hyperemia and chemosis are associated with a copious discharge of thick, white purulent material. Both eyes generally are involved, though not necessarily to the same degree. Untreated gonococcal ophthalmia may extend to involve the cornea (i.e., keratitis) and the anterior chamber of the eye. Corneal perforation and blindness can result. Before adequate prophylactic measures were introduced, ophthalmia neonatorum was the most frequent cause of acquired blindness in the United States.

If gram-negative rods are seen in the stained exudate, the greatest concern is *P. aeruginosa* because of the virulent necrotiz-

ing endophthalmitis that can result. In this condition, a relatively mild conjunctivitis can progress to infection of the entire globe within 12 to 24 hours. Invasion of the cornea by small blood vessels (pannus) is characteristic of *Pseudomonas* conjunctivitis. Perforation of the cornea may occur, and blindness from corneal opacity occurs commonly. The ophthalmic disease occasionally can be followed by bacteremia and septic foci in other organs.[86] Prompt diagnosis and immediate institution of appropriate antimicrobial therapy are mandatory.[86]

Conjunctivitis during the second or third week of life can be caused by viral, bacterial, or chlamydial agents. Viral conjunctivitis frequently is associated with other symptoms of respiratory tract disease, such as rhinorrhea, cough, and rash, and several individuals in the family or nursery may have disease simultaneously. The discharge in viral conjunctivitis usually is watery or mucopurulent but rarely purulent. A hemorrhagic discharge can be seen with adenoviral infection. Preauricular adenopathy is a common finding. Staphylococci, streptococci, *Haemophilus*, and occasionally gonococci cause conjunctivitis in this age group. A smear of purulent material helps differentiate these bacterial agents. However, the presence of bacteria on a Gram-stained smear of exudate is not necessarily related etiologically to the conjunctivitis. The exudate may contain normal inhabitants of the skin and mucous membranes, such as staphylococci, diphtheroids, and *Neisseria* spp.

Chlamydial eye infection may begin on the first days of life but usually does not come to the attention of the physician until the second or third week. Conjunctivitis develops in approximately a third of infants exposed to *Chlamydia* during vaginal delivery.[127] Clinical manifestations of chlamydial infection (inclusion blennorrhea) vary from mild conjunctivitis to intense inflammation and swelling of the lids in conjunction with a copious purulent discharge.[190,411] Pseudomembrane formation and a diffuse "matte" injection of the tarsal conjunctiva are common findings. The cornea rarely is affected, and preauricular adenopathy is an unusual occurrence. In the early stages of disease, one eye may appear more swollen and infected than the other, but both eyes are involved almost invariably.

The diagnosis is established by scraping the tarsal conjunctiva and looking for typical cytoplasmic inclusions within epithelial cells (not in the exudate). Exudates are not sufficient for *Chlamydia* testing because specimens must contain epithelial cells that harbor the infecting organism. Newborns with conjunctivitis should have specimens obtained from both the conjunctiva and pharynx.[127]

Specially prepared tissue culture cells for *Chlamydia* are available in some centers, and immunoassays are available commercially for a rapid and specific diagnosis. The conjunctival material obtained is layered carefully onto a microscope slide and stained by the Giemsa method. Without treatment, the acute inflammation continues for several weeks and merges into a subacute phase of slight conjunctival infection with scant purulent material. Occasionally, chronicity develops; some cases persist for longer than a year. The PCR method is used comparably for detection of *C. trachomatis* in conjunctival and nasopharyngeal specimens from infants with conjunctivitis.[214]

TREATMENT

Initial therapy is based on the results of stained smears of exudate and epithelial cells. If gonococci are seen, parenteral penicillin or ceftriaxone therapy is administered. If staphylococci are detected, nafcillin or another penicillinase-resistant penicillin analogue is used. The necessity of using topical antibiotics in these two bacterial infections is dubious. In the presence of acute inflammation, ample antibiotic is present in eye secretions to inhibit bacteria.

Since the beginning of the 1980s, gonococci resistant to penicillin have appeared in the United States and other parts of the world.[139,396] These strains are susceptible to spectinomycin, erythromycin, and the new-generation cephalosporins (e.g., ceftriaxone, cefotaxime). Experience in treating gonococcal ophthalmia with these drugs is limited, as are pharmacologic data for spectinomycin in newborns. Infants with documented gonococcal infections at any site, including the eye, should be examined for disseminated gonococcal infection. This investigation should include a careful physical examination, especially of the joints, and evaluation of blood and CSF cultures. Term, nonhyperbilirubinemic infants with gonococcal ophthalmia should be treated for 4 to 7 days with ceftriaxone (50 mg/kg given intravenously or intramuscularly every 24 hours). Limited data suggest that uncomplicated gonococcal ophthalmia in infants can be cured with a single injection of ceftriaxone (50 mg/kg, up to 125 mg). If the gonococcal isolate is susceptible to penicillin, crystalline penicillin G can be given. The dose is 100,000 U/kg/day given in two doses (or four doses in infants older than 1 week). The eye should be irrigated with buffered saline solution until the eye discharge has cleared. In patients who do not respond satisfactorily, co-infection with *Chlamydia* should be considered. The mother and infant should be tested routinely for *Chlamydia* infection.

Pseudomonas eye infection always should be treated with parenteral therapy consisting of ticarcillin or ceftriaxone and gentamicin. Gentamicin ophthalmic drops are used for simple *Pseudomonas* conjunctivitis, and subtenon injections of gentamicin may be indicated for endophthalmitis.[185]

Orally administered erythromycin (50 mg/kg/day in four divided doses for 14 days) is superior to topically applied tetracycline or sodium sulfacetamide in the treatment of chlamydial conjunctivitis. Topical therapy suppresses chlamydial growth only, whereas erythromycin eradicates the organism in most patients. Topical and oral erythromycin regimens have comparable efficacy, but oral therapy has the advantage of eradicating nasopharyngeal carriage of *Chlamydia*.[373] Although infantile hypertropic pyloric stenosis has been associated with erythromycin administered orally to infants younger than 6 months old, erythromycin remains the antibiotic of choice for the treatment of *C. trachomatis* disease in infants.[228] Eight infants with documented chlamydial conjunctivitis were treated with azithromycin (20 mg/kg once daily for 3 days); failure to eradicate the organism occurred in three patients, but compliance was doubtful in these cases.[212] In infants who do not tolerate erythromycin, oral sulfisoxazole (150 mg/kg/day in four divided doses) can be used after the immediate newborn period. Most cases heal without residua, but if not treated, infection may persist and cause corneal and conjunctival scarring.[127,191] Approximately 25 percent of infants with gonococcal ophthalmia have concomitant infection with *Chlamydia* that requires therapy.

Patients with gonococcal ophthalmia should be segregated, and strict handwashing techniques should be used because the exudate is highly contagious.

CUTANEOUS AND GLANDULAR INFECTIONS

PUSTULAR AND VESICULAR LESIONS

Superficial pustular staphylococcal disease (i.e., impetigo neonatorum) is the most common skin infection of neonates. The lesions tend to concentrate in the periumbilical and diaper areas and rarely become invasive, except when extensive areas are involved or when monitoring devices, catheters, or other invasive devices are used in a gravely ill infant. The lesions respond to simple topical measures; systemic antibiotic treatment usually is not indicated unless extensive involvement of the skin occurs.

The organisms should be phage-typed (they usually belong to group I) so that if additional cases are encountered in the same nursery, the infected infants and their cohorts can be evaluated for the possibility of nosocomial staphylococcal disease. If these infections are caused by the same staphylococcal phage type, prompt measures should be instituted to determine the source and extent of infection to prevent further colonization and disease.

A second form of staphylococcal disease has been recognized with increased frequency in recent years. The disease takes one of several clinical forms, including bullous impetigo, the most common manifestation, and Ritter disease, the eponymic equivalent in newborns of toxic epidermal necrolysis of older infants.[321] These illnesses usually are caused by phage group II staphylococci, which produce an exotoxin (i.e., exfoliatin) that causes intraepidermal cleavage through the granular cell layer as a result of disruption of desmosomes.[322] The initial finding in Ritter disease is intense, painful erythema, not unlike a severe sunburn. During the next hours, bullus formation occurs, and when the bullae rupture, a tender, weeping, erythematous area is left. A characteristic desquamation of large epidermal sheets occurs approximately 3 to 5 days after onset of the illness. A finer desquamation commonly is seen periorally.

Bacteremic complications occur more commonly in neonates than in older infants with the scalded skin syndrome. Treatment consists of systemically administered, penicillinase-resistant penicillin because most phage group II staphylococci are resistant to penicillin. The cleavage plane in this syndrome is very superficial in the epidermis, so little risk for the development of superinfection exists. Steroids are contraindicated. Maceration may occur in intertriginous areas, which should be treated by local soaks with Burow solution.

CELLULITIS AND FASCIITIS

Group A streptococci are the usual cause of diffuse, well-demarcated cellulitis (or erysipelas), although we have seen the same diseases also caused by group B organisms. The involved skin usually is intensely red, hot, and moderately indurated. Occasionally, streptococci can be recovered from material aspirated from the lesion, but blood culture rarely is positive. Parenteral therapy is with penicillin G, and, although the borders continue to advance for the first 12 to 24 hours, stabilization of body temperature and improvement in general appearance of the infant give reassurance that the diagnosis and therapy are correct.

Necrotizing fasciitis is a virulent form of cellulitis that is a relatively rare event in newborns but has a case-fatality rate of up to 50 percent in this age group. Initially, it resembles uncomplicated cellulitis, but the baby rapidly becomes "toxic," the lesion advances progressively, and the central portion becomes discolored and anesthetic. The lesion has borders that generally are indistinct when compared with erysipelas, in which the borders are raised and palpated easily. The disease may be associated with surgical procedures, birth trauma, previous omphalitis, fetal monitoring, or cutaneous infection and has been reported after the infant has undergone circumcision. The abdominal wall is the usual site of involvement, but other areas such as the thorax, back, scalp, and extremities also can be involved.[234] Causative agents include several streptococci, *S. aureus*, *P. aeruginosa*, *E. coli*, and anaerobic bacteria.[394,514,521] In this condition, subcutaneous tissues, including muscle layers, are invaded, and the organism spreads along fascial planes. Extensive surgery involving resection of destroyed tissue is imperative in treating necrotizing fasciitis.[521] Blood and tissue cultures should be performed, and initial antibiotic therapy should consist of a penicillinase-resistant penicillin or clindamycin or vancomycin and an aminoglycoside, pending results of these cultures. Hypocalcemia and hypoproteinemia may complicate the illness. If the infant survives the first days, extensive skin grafting generally is necessary. In a retrospective review, the overall mortality rate for 66 neonatal cases was 59 percent.[234] Having a high index of suspicion, performing prompt aggressive surgery, and providing appropriate antibiotics and optimal supportive care are the mainstays of management.[81,149,234] The role of adjuvant hyperbaric oxygen is controversial, and very limited information is available.

FUNISITIS AND OMPHALITIS

The umbilical cord may be colonized with numerous different potential bacterial pathogens, some of which may have significant epidemiologic importance. Hexachlorophene was used in many institutions in an attempt to reduce or eliminate the staphylococci that were responsible for nursery epidemics in the late 1950s and early 1960s. Although this antiseptic is effective in reducing staphylococcal colony counts, it is not effective in controlling nosocomial staphylococcal disease in nursery units. Widespread use of hexachlorophene occasionally has been associated with CNS spongiform degeneration, particularly in premature infants.[454] A single application of triple dye to the cord results in a significant reduction of all bacteria, particularly staphylococci, streptococci, and coliforms, but its use for care of the umbilical stump at home can delay the time until the cord separates.[99,347,384] Mupirocin ointment applied to the cord or the nasal mucosa also is effective in eradicating staphylococcal carriage.[226]

Group A streptococci may colonize the umbilical cord and be important as a focal point for epidemic streptococcal disease in a nursery. Unlike staphylococci, they tend to cause an inflammatory reaction.[134,347] Streptococcal funisitis (i.e., inflammation of the cord) is mild and is characterized by a wet, malodorous umbilical stump with minimal inflammation. Disseminated disease is an uncommon occurrence, but when present, it results from bloodstream invasion or direct extension to the peritoneal cavity by way of the umbilical vessels. Treatment consists of systemic penicillin G and topical therapy with antibiotic ointment or triple dye. Local therapy is provided for epidemiologic reasons to eliminate surface colonization. Identification of a single infant with group A streptococcal disease in a nursery necessitates immediate institution of infection control measures for identification and segregation of all colonized persons. When a nursery outbreak is suspected, specific M and T typing of the organism is useful in defining the source and spread of infection. A single injection of benzathine penicillin G is satisfactory for treatment of mild superficial infection or for elimination of the organism from colonized persons.[178,347]

Omphalitis, or infection of the umbilicus, has many causes and occurs more frequently in low-birth-weight infants and those with complicated deliveries. The incidence is estimated to be approximately 2 percent, and symptoms start at an average age of 3 days. Culture and susceptibility test results are necessary for the selection of an appropriate antibiotic. *S. aureus* is the most frequent pathogen isolated, followed by gram-negative rods.[433] Some of the complications secondary to omphalitis reported in the literature are spontaneous evisceration of the small bowel through the umbilical cicatrix, necrotizing fasciitis, small bowel obstruction, peritonitis, and superficial, retroperitoneal, or hepatic abscesses.[10,156,166]

BREAST ABSCESS

Breast abscesses are encountered most frequently during the second or third week of life and are more common findings in

girls, particularly those older than 2 weeks.[414] The disease does not occur in premature infants, presumably because of underdevelopment of the mammary glands in these infants. Bilateral disease is a rare event, but a case caused by GBS has been reported.[345]

The major clinical finding is swelling of the affected breast with or without accompanying erythema and warmth. Systemic manifestations are uncommon occurrences, and only a fourth of patients have low-grade fever. The disease sometimes can progress rapidly and involve breast tissue and the entire subcutaneous tissue beyond the breast's anatomic area.[453] This condition is associated with considerable toxicity and systemic signs and symptoms. *S. aureus* is the major pathogen, but coliform bacteria and GBS have become more common causes in the past decade.[414,474] Mixed infection rarely occurs. In 36 infants with mastitis seen in Dallas, Texas, during a 16-year period, 32 cases were caused by *S. aureus*, 1 case by *E. coli*, 2 cases by *Salmonella* spp., and 1 case by both *S. aureus* and *E. coli*.

Breast abscess is diagnosed by examination of stained purulent material obtained from gentle manipulation of the nipple or by needle aspiration of the abscess. If gram-positive cocci are identified, nafcillin or another penicillinase-resistant penicillin is given. For gram-negative bacilli, an aminoglycoside or cefotaxime is appropriate. When no organisms are seen, nafcillin and an aminoglycoside or cefotaxime should be used initially until results of culture are available. Bacteremia is a rare finding in this condition.

If the patient has only mild cellulitis and no discernible fluctuance, antibiotic treatment alone may suffice. We have managed several patients with GBS mastitis successfully in this fashion. In most instances, however, surgical incision and drainage by a skilled surgeon are required. The duration of treatment depends on the rate of response. It generally is rapid, and we have found that healing is complete within 5 to 7 days in most instances. Long-term follow-up studies suggest that some girls will have diminished breast tissue on the affected side.[414]

SUPPURATIVE PAROTITIS

Suppurative parotitis of the newborn usually is easy to recognize, although occasionally it is confused with infection of a preauricular or superior anterior cervical lymph node. We have encountered one instance in which delay in initiating therapy was caused by attributing the swelling to trauma from obstetric forceps. Infection occurs more commonly in low-birth-weight infants than in term infants and boys. Dehydration predisposes to stasis of parotid secretions and subsequent infection. Bilateral infection is a rare event.

Although *S. aureus* accounts for most cases, disease may be caused by coliform bacteria, *Pseudomonas*, pneumococci, and group A streptococci.[129,279] The clinical manifestations include fever, anorexia, irritability, and failure to gain weight. Erythema, swelling, and tenderness over the involved gland may occur. The diagnosis can be confirmed by expressing pus through the parotid duct or by needle aspiration of a fluctuant area. Gram staining of this material helps identify the causative agent; however, one should recognize that material expressed from the duct may be contaminated by mouth microflora.

Selection of antimicrobial therapy should be based on interpretation of the Gram-stained smear of expressed pus. If gram-positive cocci are seen, nafcillin or another penicillinase-resistant penicillin should be used. Vancomycin should be added if MRSA is a possibility. Gram-negative organisms are treated best with an aminoglycoside, cefotaxime, or ceftazidime to cover both coliform bacteria and *Pseudomonas*. If no organisms are seen in the purulent material, a combination of nafcillin and gentamicin or cefotaxime should be used until the results of culture are available. In most cases, antibiotic therapy alone suffices, and surgical incision and drainage are unnecessary. The gland should not be extirpated. Response to therapy generally is rapid. Most patients require only 7 to 10 days of therapy until healing is complete.

SCALP ABSCESS

Scalp abscesses usually are a complication of fetal monitoring with scalp electrodes.[82,504] The number of vaginal examinations, use of more than one electrode, and fetal scalp blood sampling are risk factors for the development of scalp abscesses. Pathogens incriminated include staphylococci, gonococci, and gram-negative enteric bacteria. A polymicrobial flora, including anaerobic organisms, frequently is isolated in scalp abscesses caused by electronic fetal monitoring electrodes. Incision and drainage of the infected site usually is sufficient. If an associated cellulitis occurs, antibiotics are administered and continued for 5 to 7 days.

LOWER RESPIRATORY TRACT INFECTIONS

Neonatal lower respiratory tract infections may be acquired congenitally or postnatally. Perinatal infection results from transplacental transfer of the agent (i.e., congenital infection) or from inhalation of infected amniotic fluid (usually associated with prolonged rupture of membranes) or infected vaginal secretions during delivery. Viruses, bacteria, *Chlamydia*, and spirochetes are the most common causative agents that produce perinatal pneumonia. Common viral agents include cytomegalovirus, rubella, and herpes simplex virus. Common bacterial agents are GBS, *L. monocytogenes*, and coliform bacilli. *Chlamydia* organisms have been implicated as the cause of a chronic interstitial pneumonitis of early infancy (i.e., eosinophilic pertussis-like pneumonia).[43] *Treponema pallidum* produces a severe, sometimes fatal pneumonitis, and mycoplasmas have caused a rare form of fatal congenital pneumonia. We also have seen in Panama in the last 4 years a few cases of congenital pneumonia caused by *Candida* spp. (unpublished observation).

Perinatal lower respiratory tract disease generally becomes apparent clinically in infants from birth to 7 days, occasionally up to 2 weeks of age. Of emphasis is that inhalation of amniotic fluid or maternal vaginal secretions usually is not associated with infection, nor is meconium inhalation, in which case the pneumonitis has a chemical cause. Only a small percentage of inhalation pneumonias are bacterial in origin; the pathogens most commonly encountered in such cases are GBS and coliform organisms. The clinical signs of inhalation pneumonia are caused by obstruction, chemical inflammation, or both.

The second category of pneumonia is acquired postnatally and usually beyond the first week of life. These diseases may be caused by viral or bacterial agents and most frequently are bronchopneumonic in type. Viral disease may be sporadic or occur as part of a nosocomial nursery outbreak. Respiratory syncytial virus is the most important pathogen of lower respiratory tract disease in young infants.[51] This agent causes particularly severe disease in infants with congenital heart disease. The parainfluenza viruses and adenoviruses also cause bronchiolitis and pneumonia during early infancy. An obliterating, necrotizing bronchiolitis may be caused by adenoviruses and result in radiographic hyperlucency of a segment or a lobe in later infancy and childhood.[184]

Documented nursery outbreaks of lower respiratory tract disease have been associated with respiratory syncytial virus,

adenoviruses, echoviruses, influenza A and B viruses, and parainfluenza virus infections. During these outbreaks, many infants are colonized with the epidemic strains, but only a few have clinical disease.

Common bacterial pathogens causing postnatally acquired pneumonia are *S. aureus*, coliform bacilli, and *Pseudomonas*. These infections occur sporadically or epidemically and often are of nosocomial origin. They may be rapidly progressive, necrotic pneumonias that result in pyogenic complications (e.g., empyema, pulmonary abscesses) and metastatic disease in the bones or meninges.

CLINICAL MANIFESTATIONS

The early signs of respiratory disease in neonates and young infants frequently are nonspecific and include change in feeding status, listlessness or irritability, and poor color. More specific findings that may not be present at the onset of illness are tachypnea, dyspnea, cyanosis, alteration of temperature (i.e., hypothermia or fever), coughing, and grunting. Accentuation of the normal irregularity of breathing is a common finding in neonates.

The physical findings of pneumonia are variable. Flaring of the alae nasi, rapid respirations, and sternal and subcostal retractions are common findings. Coughing indicates lower respiratory tract involvement; brassy coughing is found frequently in viral disease. Dullness to percussion is difficult to demonstrate, but when present, it indicates consolidation or effusion. Breath sounds also may be diminished over the affected area. Crackles or wheezes usually can be heard on deep inspiration (or when the baby is crying) but may be absent early in disease. The clinician frequently is surprised by the meager clinical signs in the face of clearly demonstrable and sometimes extensive radiographic findings of pneumonitis.

DIAGNOSIS

The WBC count usually does not help differentiate viral from bacterial pneumonia. An exception is seen in premature infants with acute respiratory distress syndrome caused by GBS. In these patients, the WBC count often reveals leukopenia with an increased proportion of band forms.[308]

Cultures of blood and material from the trachea frequently help in defining the etiologic agent of neonatal pneumonia. Results of cultures of the ear canal, throat, and other external sites typically are unreliable in defining the cause of pneumonia; more often, they are misleading. Lung puncture should be considered for severely ill infants with consolidated pneumonia when the cause is unknown or for an infant who fails to respond to conventional antimicrobial therapy. Material obtained by needle aspiration is Gram-stained for direct visualization and cultured.

A chest radiograph should be obtained for all babies with suspected lower respiratory tract disease. Radiographic evidence of pneumonia may not exist in the absence of specific physical findings. Although the cause of neonatal pneumonia usually can be determined from a radiograph, certain radiologic patterns are associated with specific diseases. With acute-onset group B streptococcal disease, the radiograph may mimic one showing hyaline membrane disease. A consolidating bronchopneumonia with pneumatoceles, with or without empyema, suggests staphylococcal disease. When a lobar infiltrate is associated with expansion of the lobe, *K. pneumoniae* infection should be considered. A miliary type of bronchopneumonia in a septic neonate is characteristic of listeriosis.

SPECIFIC CLINICAL SYNDROMES

Staphylococcal Pneumonia

Primary staphylococcal pneumonia occurs quite frequently in young infants. Epidemics of staphylococcal disease caused by phage group I organisms are rare events today. In the epidemic setting, many infants are colonized with a virulent strain, but only a few have disease. Concomitant viral respiratory tract infections possibly play a role in promoting dissemination of staphylococci among infants and in converting colonization to disease, but such has not been established.

Staphylococci cause a confluent bronchopneumonia consisting of extensive areas of hemorrhagic necrosis and irregular areas of cavitation. The pleural surface usually is covered by a thick layer of fibrinopurulent exudate. Multiple, small abscesses are scattered throughout the affected lung. Rupture of a small subpleural abscess may result in pyopneumothorax. If erosion into a large bronchus occurs, a bronchopleural fistula results.

Most patients with staphylococcal pneumonia have radiographic evidence of bronchopneumonia early in the illness. The infiltrate may be patchy and limited in extent or dense and homogeneous and involve an entire lobe or hemithorax. Bilateral disease occurs in half of affected patients. Pleural effusion or empyema is detected in most infants. Pneumatoceles of various size are common findings. Although no radiographic picture can be considered absolutely diagnostic, progression over the course of a few hours from bronchopneumonia to empyema or pyopneumothorax, with or without pneumatoceles, strongly suggests staphylococcal disease.

Klebsiella pneumoniae Pneumonia

Primary *K. pneumoniae* infection is an unusual event in infants and young children. However, nursery epidemics of *Klebsiella* infection have been reported. During these epidemics, colonization rates are high, but most infants remain asymptomatic. Contaminated fomites are the primary source of nosocomial infection with this organism.

K. pneumoniae pneumonia may be difficult to distinguish clinically from pneumonia attributable to other causes. The disease may have a fulminant course characterized by copious, thick purulent secretions and the formation of pulmonary abscesses and cavitation. The case-fatality rate in sporadic cases is approximately 50 percent but is considerably lower during epidemics.

Pertussis

During 1994 to 2004, the reported pertussis rate per 100,000 inhabitants increased from 1.8 to 8.9. This is the highest figure since 1959. In 2004, 10 percent of the cases occurred in infants 6 months or younger; these infants were too young to have received the first three doses of diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine. Adolescents and adults accounted for the majority (67%) of notified cases, which led to a recommendation by the CDC's Advisory Committee on Immunization Practices for the routine use of DTaP vaccine in adolescents aged 11 to 18 years.[96] Although infants formerly acquired disease from siblings, in the past years infection usually has been acquired from one or both parents whose illnesses have not been diagnosed correctly as pertussis. The reason for these epidemiologic changes most likely is better vaccination of schoolchildren. Because immunity starts to wane in adolescence, parents of young infants are susceptible to infection.[346] The infants of these women also are susceptible to the development of infection because of the lack of transplacental immunity.

The onset of disease generally is in the second to sixth weeks of life; the earliest onset reported was at 10 days of age. Most

young infants do not have a characteristic whoop. Pertussis should be suspected when an infant has a paroxysmal cough with excessive mucus. Because apneic spells are common occurrences in these infants, as they also are in those with respiratory syncytial virus, *Chlamydia*, or influenza virus infection, all infants with pertussis are admitted to the hospital for management. Fluorescent antibody testing provides a means of making a rapid diagnosis, but false-negative and false-positive results are common occurrences. Cultures for *Bordetella* should be performed in all infants. PCR-based testing may become the most sensitive means of documenting *Bordetella pertussis* in the future. Mucus for examination is obtained from patients with a flexible nasopharyngeal wire swab or by nasopharyngeal washing or aspiration.

The greatest hazards to an infant with pertussis are asphyxia and secondary bacterial pneumonia. Supportive care is essential. Excessive mucus must be suctioned, and equipment for emergency airway intubation should be at hand. Administration of fluid therapy is necessary, and maintaining adequate nutritional intake may present the greatest challenge. Infants with pertussis should not be placed in mist tents. Mist therapy provides no substantial amelioration of paroxysmal coughing episodes, and it increases the risk for development of secondary infection with *P. aeruginosa* (or with other commensals).

Atelectasis caused by mucus plugs is a common complication of pertussis in small babies. After the infant has passed the stage of severe paroxysms, chest physiotherapy can be initiated. In almost all cases the atelectasis resolves within 2 to 3 weeks.

Chlamydial Pneumonia

Chlamydial pneumonia is manifested between the 4th and 11th weeks of life in most infants.[491] Infants typically are afebrile and tachypneic, and they have a characteristic staccato cough. Only half of the patients have a history of conjunctivitis. Otitis media occurs frequently.[127]

On chest auscultation, rales may be heard, but wheezes are uncommon findings. The chest radiograph reveals hyperexpanded lungs with bilateral interstitial infiltrates. Approximately half of the infants have peripheral eosinophilia (>400 cells/mm^3). A definitive diagnosis made by isolating the organism from the respiratory tract is not possible in many institutions. The role of immunologic techniques for identifying *Chlamydia* in throat swabs is yet to be determined. Serologic testing is available more readily. These infants usually respond to therapy with erythromycin. The clinical course and duration of nasopharyngeal shedding of *Chlamydia* are shortened by treatment with this antibiotic. If left untreated, these infants remain sick for several weeks but do not become acutely ill. Death from this infection seldom occurs.

TREATMENT

Initial antibiotic treatment of suspected bacterial pneumonia should consist of ampicillin or nafcillin and an aminoglycoside or cefotaxime. The most suitable combination of these drugs depends on the clinical features of the illness and the recent experience with bacterial diseases in the local nursery or community. For patients in whom the cause never is defined and staphylococcal disease cannot be ruled out, therapy with nafcillin or vancomycin and an aminoglycoside or cefotaxime is indicated. If the organism is identified, the single most effective drug should be used. Penicillin G or ampicillin is effective against GBS and penicillin-susceptible staphylococci, ampicillin against *Listeria*, and nafcillin or another suitable antistaphylococcal penicillin against penicillinase-producing *S. aureus.* Vancomycin should be used for disease caused by MRSA or coagulase-negative staphylococci. For pneumonia caused by gram-negative bacilli (e.g., *K. pneumoniae* and others), an aminoglycoside or a third-generation cephalosporin should be used. *Pseudomonas* pneumonia is treated best with ticarcillin or ceftazidime in combination with an aminoglycoside. Therapy is continued for 10 to 14 days for disease caused by GBS and *Listeria* and for a minimum of 3 weeks for pneumonia caused by staphylococci or gram-negative bacilli.

Nosocomial pneumonia is a relatively frequent condition of mechanically ventilated premature infants and can be caused by a vast array of microorganisms. Accordingly, treatment with an empiric regimen of broad-spectrum antibiotics is advised until microbial identification is made. Nonetheless, the physician should realize that isolation of bacteria from tracheal aspirates usually represents airway colonization and not necessarily the etiologic agents. For a reliable etiologic approach, a combination of clinical, radiographic, laboratory, and microbiologic findings is recommended. An important matter to recognize is that antimicrobial therapy commonly fails to eradicate microorganisms from the airway of ventilated infants despite clinical and radiographic resolution of pneumonia.[118]

Empyema is managed best by closed drainage and use of chest tubes with the largest possible caliber. Generally, placement of one tube high and anteriorly and a second tube low and posterolaterally is necessary to achieve optimal drainage. Pyopneumothorax is another indication for immediate insertion of a catheter into the pleural space. After the infant has improved clinically and the amount of drainage is minimal, the tubes should be removed. In general, they should not remain in the chest for more than 5 to 7 days. Instillation of antimicrobial agents or enzymes into the pleural space does not help control infection or promote drainage.

Pneumonia may be one manifestation of generalized congenital viral infection. Distinguishing these infections from congenital syphilis and bacterial pneumonia secondary to inhalation is important.

Most infants with inhalation pneumonia do not require antimicrobial therapy. Differentiating infants inhaling sterile fluid from those inhaling infected material frequently is difficult. If doubt exists, therapy with ampicillin and an aminoglycoside should be initiated and continued until the results of cultures are available.

Therapy for pertussis consists of erythromycin administered orally. Antibiotic therapy may lessen the symptoms of pertussis if administered early in the paroxysmal stage and is valuable for rendering the patient noncontagious. Hyperimmune serum probably is not beneficial.

Associations between bronchopulmonary dysplasia and respiratory colonization by *U. urealitycum*, *C. trachomatis*, *M. hominis*, and adenovirus have been shown in different studies.[57,120,216,506]

In a prospective cohort study, isolation of *U. urealyticum* from respiratory tract secretions was associated with radiographic evidence of pneumonia within 7 days of birth, precocious development of bronchopulmonary dysplasia, and a severe pulmonary outcome.[366] A few case reports have suggested that eradication of *Ureaplasma* with erythromycin contributes to faster resolution of symptoms or to a better outcome in neonates with this chronic disease.[8,230,507] Controlled studies are needed to verify these preliminary observations. No experience with the use of newer macrolides in neonates exists.

Recognition of the role of endogenous surfactant inactivation in the pathogenesis of bacterial pneumonia suggests that therapy with exogenous surfactant, in conjunction with antimicrobial drugs, could be beneficial for the management of affected infants. Large, prospective, placebo-controlled randomized trials are needed to explore the effect of surfactant therapy for neonatal bacterial pneumonia.[405]

SECTION XIV

Infections of the Compromised Host

CHAPTER 79

Primary Immunodeficiencies

Javier Chinen ✪ Mark W. Kline ✪ William T. Shearer

Primary immunodeficiencies include a broad range of congenital and hereditary disorders that manifest with a defect in the development or function of the immune system and, as a consequence, with increased susceptibility to infections and autoimmunity. Although the molecular defects are present from birth, clinical manifestations may not be evident until much later in life. Previously considered of rare occurrence, primary immunodeficiency disorders are estimated to occur in 1 in 10,000 live births, with a wide range of severity depending on the degree of compromise of the immune function, including mild presentation variants that are clinically subtle and difficult to diagnose. This rate is minimal and considered underestimated because it is based on hospital records and does not include two frequent conditions that usually manifest with only minor immunologic abnormalities: DiGeorge syndrome (1 in 3000 live births) and selective IgA deficiency (1 in 500 individuals).

In contrast to primary immunodeficiencies, secondary immunodeficiencies are acquired disorders, with immune dysfunction occurring as a result of exogenous factors or along with some other non-immune primary disease process. Causes of secondary immunodeficiency include infection (e.g., human immunodeficiency virus [HIV]), drugs (e.g., corticosteroids), malnutrition, and neoplastic or metabolic diseases (e.g., Hodgkin disease, diabetes mellitus). Secondary immunodeficiency disorders, such as those resulting from malnutrition or HIV infection, are diagnosed far more frequently than primary immunodeficiencies.

Pediatricians refer children for immunologic evaluation when they present with unusually frequent or severe infections or when they present with infections that are caused by uncommon organisms (Table 79–1). Most of these children are immunocompetent and may have risk factors for increased frequency of infections, such as allergic disorders, anatomic abnormalities, or other clinical conditions that secondarily produce increased susceptibility to development of infections, as discussed earlier. Some evaluated children have a known primary immunodeficiency and benefit from early diagnosis and management.

Understanding of primary immunodeficiencies has increased in recent years with the significant scientific progress that has been made, especially with the description of gene defects responsible for most of the observed immunodeficiency syndromes and leading to the restoration of immune function by gene therapy in two forms of severe combined immunodeficiency (SCID) (see later).

This chapter discusses the elements of the medical history and physical examination that can help to establish the diagnosis of a primary immunodeficiency, in addition to screening laboratory tests that are useful to assess clinically significant immune dysfunction. The most common primary antibody, cellular immunity, complement, and phagocyte deficiencies are described. Also, a few rare but distinctive conditions, including ataxia-telangiectasia and Wiskott-Aldrich Syndrome (WAS), are reviewed.

INITIAL EVALUATION FOR SUSPECTED IMMUNODEFICIENCY

MEDICAL HISTORY

A comprehensive medical history is the key element in identifying children who are likely to have an immunodeficiency. Children with immunodeficiencies often have a history of frequent and severe infections (e.g., pneumonia, meningitis, septicemia, osteomyelitis, abscess of soft tissue or an internal organ). Although infections occur commonly throughout childhood, epidemiologic studies have established a range for the average number of infections that a normal child may have per year. Otherwise healthy children younger than 5 years old average three to eight episodes of upper respiratory infection annually.[14,38] By 1 year of age, 62 percent of children have had at least one episode of acute otitis media, and 17 percent have had three or more episodes.[101] By 3 years of age, more than 80 percent of children have had at least one episode of acute otitis media, and 46 percent have had three or more episodes. Although these studies have not been repeated since routine anti–*Haemophilus influenzae* type b (Hib) and anti-pneumococcal vaccinations were introduced, the frequency of respiratory infections has not changed; however, the causal agents have been replaced by viral and other bacterial pathogens.

Approximately 2 percent of children 1 to 5 years old develop symptomatic urinary tract infection.[92] The incidence of gastroenteritis among children in the United States is approximately two to three episodes per child-year, with rates of five episodes per child-year among children attending daycare centers.[12,44] Occurrence of these infections during infancy or early childhood in normal children is the result of several factors, including immunologic immaturity or naiveté (lack of prior exposure to infectious agents); poor hygiene; mouthing behavior; allergic disease; and frequent exposure to ill contacts in the home, school, or daycare setting.

The courses of individual episodes of infection in an immunodeficient child may be unusually prolonged or associated with unexpected complications (e.g., lung abscess in a child with pneumonia or skull bone osteomyelitis as a complication of sinusitis). Generally, infections that develop over time at multiple body sites are more suggestive of immunodeficiency than are infections occurring at only one site (e.g., recurrent otitis media). In the latter circumstance, a mechanical or anatomic explanation for the infections (e.g., foreign body or occult tracheoesophageal fistula in a child with recurrent pneumonia, congenital fistulous tract to the middle ear in a child with recurrent bacterial meningitis) should be considered.

A history of recurrent infections of defined cause is more meaningful than a history of frequent, self-limited infections of presumed viral cause. Children with primary antibody deficien-

TABLE 79–1 When to Suspect an Immunodeficiency Disorder

Increased number of infections
Increased severity of infectious disease
Poor response to antibiotic therapy
Unusual organisms (opportunistic infections)
Failure to thrive
Poor wound healing
"Cold" *Staphylococcus* species infection (absence of pus)
Recurrent periodontitis
Low granulocyte or lymphocyte count

TABLE 79–2 Common Pathogens in Children with Primary Immunodeficiency

Immunodeficiency	Common Pathogens
Antibody deficiencies	*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Mycoplasma* species, *Salmonella* species, *Shigella* species, *Campylobacter* species, rotavirus, enteroviruses, *Giardia* species
Cellular and combined immunodeficiencies	Mycobacteria, *S. pneumoniae*, *P. aeruginosa*, *Candida* species, *Pneumocystis jiroveci*, herpesviruses, adenoviruses
Complement deficiencies	*S. pneumoniae*, *H. influenzae*, *Neisseria* species
Phagocyte deficiencies	*S. aureus*, *Nocardia* species, *P. aeruginosa*, *Serratia* species, enteric gram-negative bacilli, *Candida* species, *Aspergillus* species

cies typically experience infections caused by extracellular bacteria with polysaccharide capsules (e.g., *Streptococcus pneumoniae*, Hib). In contrast, children with primary cellular immunodeficiencies often have infections with unusual or opportunistic viruses, fungi, protozoa, and mycobacteria (Table 79–2). Because of the impairment of T-cell–dependent antibody responses, infections with common bacteria also may be observed. Children with primary deficiencies of complement components typically have recurrent neisserial infections, and children with phagocyte deficiencies may have infections with a variety of catalase-positive bacterial (e.g., *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Serratia marcescens*) and fungal (e.g., *Candida* spp., *Aspergillus* spp.) organisms. Severe infections with atypical mycobacteria often indicate a defect in interleukin-12 (IL-12)–mediated or interferon-γ–mediated responses.

In addition to the microbial cause of infections, several other items of historical information may help to define the risk for and possible nature of a primary immunodeficiency. Because young infants are afforded some protection by the presence of maternal IgG, children with primary antibody deficiencies generally have an initial period of relative well-being, with onset of infections occurring when they are 3 to 18 months of age. Children with severe T-cell, complement, or phagocyte deficiencies may have onset of infections in the first days or weeks of life.

Omphalitis and poor wound healing suggest phagocyte deficiency. Hypocalcemic seizures in the neonatal period and congenital heart disease may be clues to the presence of DiGeorge syndrome. Severe disease associated with administration of live vaccines (e.g., bacille Calmette-Guérin, measles, poliomyelitis, varicella) suggests an immune defect. The absence of potential causes for secondary immunodeficiency should be sought and shown.

Family history can offer important clues to the presence of a primary immunodeficiency. A family history of consanguinity or deaths from infection or from unexplained causes during infancy or early childhood suggests a genetic defect. Many immunodeficiency syndromes have X-linked inheritance patterns (Table 79–3), which explains the male-to-female ratio of 5:1 among children with primary immunodeficiencies seen in the pediatrician's office.

TABLE 79–3 X-Linked Primary Immunodeficiency Disorders

X-linked agammaglobulinemia (Bruton disease)
Immunodeficiency with hyper-IgM (CD40 ligand deficiency)
X-linked ectodermal dysplasia with immunodeficiency (NEMO defect)
Immunodeficiency, polyendocrinopathy, enteropathy, X-linked (IPEX)
X-linked lymphoproliferative syndrome
Severe combined immunodeficiency (common gamma-chain deficiency)
Properdin deficiency
Wiskott-Aldrich syndrome
X-linked chronic granulomatous disease (most cases)

Figure 79–1 Typical facial appearance of a child with DiGeorge anomaly. Notice the microstomia, hypertelorism, upturned nose, and posteriorly rotated and small, low-set ears. (See companion Expert Consult web site for color version.)

PHYSICAL EXAMINATION

Except for patients with DiGeorge syndrome, who have distinctive dysmorphic features, or Omenn syndrome, which is characterized by severe rash during the newborn period, the physical examination in children with primary immunodeficiency may not be revealing, especially when patients are very young and have not been exposed to potential pathogens. Short stature is a feature of some of these congenital disorders (e.g., chronic granulomatous disease [CGD]), with wasting or failure to thrive likely being secondary to recurrent infections or other chronic conditions such as intestinal malabsorption. Oral candidiasis, omphalitis, and multiple skin abscesses may indicate an underlying immune disorder. A paucity of lymphoid tissues (e.g., tonsils, lymph nodes) suggests poor lymphocyte development.

Examples of helpful physical stigmata include the characteristic facial features (Fig. 79–1) and cardiac malformations in chil-

dren with DiGeorge syndrome. Telangiectasia of the bulbar conjunctivae (Fig. 79–2), nasal bridge, ears, and flexor surfaces of the extremities, with or without ataxia, suggests ataxia telangiectasia. Chronic eczema is observed in hyper-IgE and Wiskott-Aldrich syndromes, and severe gingivitis and periodontitis with loss of alveolar bone and dentition can occur in children with LAD (Fig. 79–3).

LABORATORY TESTS

The initial evaluation for immunodeficiency can be done with commonly available, inexpensive laboratory tests to exclude most serious disorders (Table 79–4). This evaluation should be targeted to the type of immunodeficiency (e.g., antibody deficiency versus T-cell defect) suggested by the medical history and physical examination findings. Laboratory test results must be interpreted in the context of the child's age because average normal serum immunoglobulin levels, T-cell counts, and other immune parameters physiologically change with age.[37]

The initial evaluation for immunodeficiency includes a complete blood count and examination of the peripheral blood smear. Because 50 to 70 percent of circulating lymphocytes are T cells, children with severe cellular (e.g., complete DiGeorge syndrome) or combined (e.g., SCID) immunodeficiencies may have lymphopenia. Children with Wiskott-Aldrich syndrome have reduced numbers of platelets, which are small (decreased mean platelet volume), a characteristic that is unique for this syndrome and the related X-linked thrombocytopenia. Large neutrophil cytoplasmic granules are observed in children with Chédiak-Higashi syndrome.

A complete blood count also is useful in excluding congenital neutropenia. Children with LAD often have the opposite, with markedly increased neutrophil and total white blood cell counts. The presence of Howell-Jolly bodies, with or without thrombocytosis, suggests anatomic or functional asplenia. Other tests to rule out HIV infection, malnutrition, or metabolic disorders as causes of secondary immunodeficiency should be considered.

Figure 79–2 Telangiectases of the bulbar conjunctivae in a child with ataxia telangiectasia. (See companion Expert Consult web site for color version.)

TABLE 79–4 Screening Tests for Suspected Primary Immunodeficiency

Immunodeficiency	Screening Tests
All types	Complete blood cell count Peripheral blood smear, for percentage of leukocyte types
Antibody deficiency	Quantitative serum immunoglobulins, IgG, IgA, IgM Post-immunization antibody titers Isohemagglutinins
Cellular immunodeficiency	Delayed hypersensitivity skin tests Chest radiography or chest CT for thymus size Lymphocyte phenotyping for CD3, CD4, CD8, CD19
Complement deficiency	Total hemolytic complement (CH50) assay
Phagocyte deficiency	Nitroblue tetrazolium dye test Dihydrorhodamine (DHR)-1,2,3 Neutrophil CD11a,b,c/CD18 expression

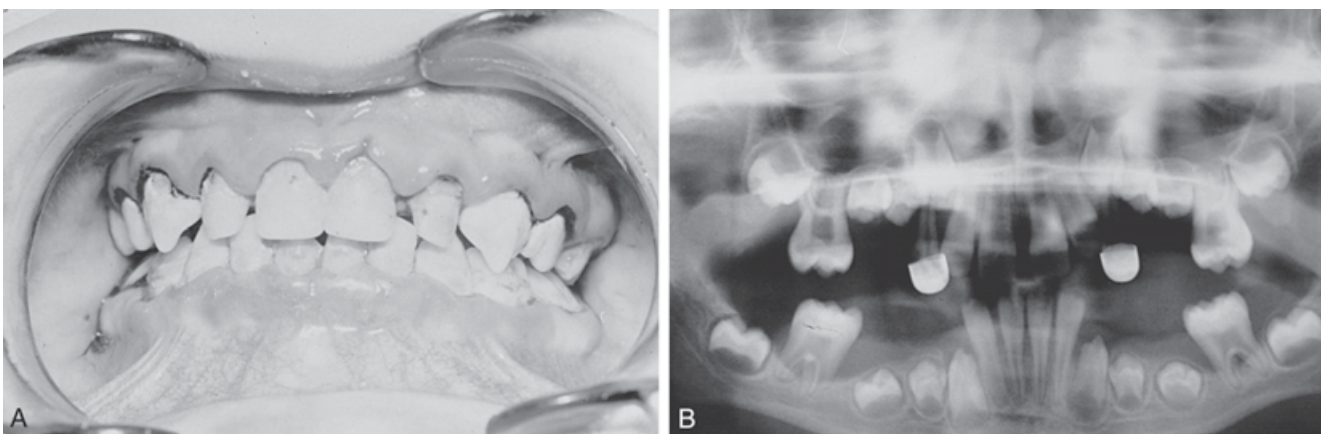

Figure 79–3 **A,** Chronic periodontitis in a boy with leukocyte adhesion deficiency. **B,** Radiograph of the same patient shows extensive alveolar bone loss. *(Courtesy of Dr. Bruce Carter, Texas Children's Hospital, Houston, TX.)*

Evaluation of Humoral Immunity

Screening evaluation of a child with suspected antibody deficiency should include quantitative measurement of serum immunoglobulins and functional assessment of specific antibody responses. Except for the rare deficiency of antibody response to specific antigens, children with primary antibody deficiencies have abnormalities of serum immunoglobulin concentrations. Measurement of serum IgG, IgA, and IgM concentrations identifies children with panhypogammaglobulinemia and children with deficiency of a particular immunoglobulin isotype, such as selective IgA deficiency. Because of marked age-related changes in serum immunoglobulin concentrations, use of age-appropriate normal values for assessment purposes is important.

Functional antibody production usually is evaluated by measuring antibody titers generated in response to immunization with vaccines, such as diphtheria and tetanus toxoids. Antibody responses to polysaccharide antigens do not require cooperation of T cells and are evaluated separately using the pneumococcal polysaccharide vaccine (Pneumovax 23; Merck & Co., West Point, PA) after the child reaches 24 months of age. Younger infants are thought to have a functional immaturity in the ability to respond to this class of antigens. Alternatively, because ABO blood group antigens are polysaccharides and cross-reacting environmental antigen epitopes are ubiquitous, production of anti-polysaccharide antibodies can be assessed by measuring serum isohemagglutinin titers, taking into consideration that children with blood type AB do not form isohemagglutinins. The conjugated pneumococcal (Prevnar; Wyeth-Ayerst, Philadelphia, PA) and Hib (several brand names) vaccines are not suitable for the assessment of anti-polysaccharide antibody responses because they are not pure polysaccharides. Patients vaccinated with the conjugated pneumococcal vaccine still can be evaluated for production of anti-polysaccharide antibodies because the pneumococcal polysaccharide vaccine contains serotype antigens against which the conjugated vaccine does not protect.

Measurement of serum IgG subclasses may be indicated for children with apparent abnormalities in functional antibody production. Further evaluation of children whose screening tests indicate significant quantitative and functional antibody abnormalities should include enumeration of T and B cells in the peripheral blood and in vitro studies of mitogen-induced or antigen-induced B-cell proliferation. The antibody response to neoantigens (e.g., bacterial phages) may be useful for the evaluation of patients receiving immunoglobulin therapy.

Evaluation of Cellular Immunity

The screening evaluation for cellular immunodeficiency starts with delayed hypersensitivity skin tests and, in young infants, posteroanterior and lateral chest radiographs for the assessment of the thymus size (Fig. 79–4). A chest computed tomography or ultrasound scan also may be helpful if available.

Delayed hypersensitivity skin tests are performed using vaccine or microbial antigens to which the child has had prior exposure. Commonly used antigens include tetanus toxoid and *Candida albicans*. Standard initial dilutions are 1:100 for both antigens, but a *C. albicans* dilution of 1:10 may be more appropriate for children aged 5 years or younger because they are less likely to have been exposed to this antigen. The diluted antigen is administered intradermally, and the skin reaction is read at 24 and 48 hours for the presence of wheal formation.

Delayed hypersensitivity skin test responses have low specificity because they depend on previous exposure to the antigen tested and often are absent in children younger than 2 years old. Enumeration of peripheral blood T cells, T-cell subset phenotyping (i.e., $CD4^+$ or $CD8^+$ lymphocyte counts), and mitogen-induced and antigen-induced lymphocyte proliferation studies may be needed to make a reliable assessment of cellular immune function.[37]

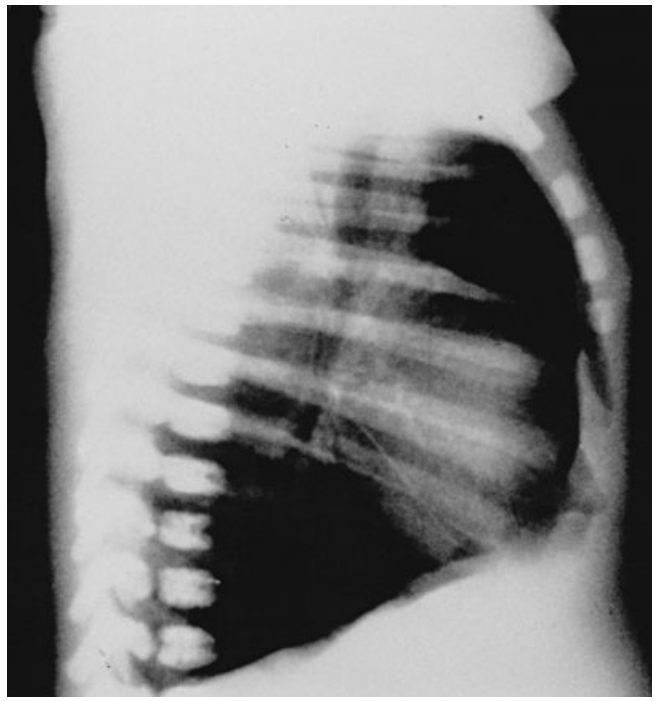

Figure 79–4 Lateral chest radiograph of an infant with severe combined immunodeficiency. Notice absence of the normal thymic shadow.

Evaluation of the Complement System

Deficiencies of components of the classic complement pathway can be detected by performing the total serum hemolytic complement (CH_{50}) assay. This test measures the ability of proteins contained in the fresh patient serum to lyse antibody-coated sheep erythrocytes and reflects the activity of all numbered components of the classic complement pathway from C1 through C9. Complete deficiency of any of these components results in very low levels of CH_{50}. Often, mildly abnormal CH_{50} values are obtained because of inadequate sample handling. Single complement component levels and function should be investigated only when CH_{50} value is zero or near zero, taking into consideration that primary complement deficiencies are rare occurrences. Additionally, measuring the levels of complement components C3 and C4 can be done in most clinical laboratories and may be ordered when complement deficiency is suspected.

Evaluation of Phagocyte Function

A variety of assays are available for assessment of phagocyte function. The nitroblue tetrazolium (NBT) dye test uses the reduction of NBT to formazan by activated phagocytes to measure the oxidative metabolic responses that accompany phagocytosis. Children with CGD show reduced dye reduction (<10% of cells are formazan positive); carriers of X-linked CGD typically have 20 to 90 percent formazan-positive cells. The specificity and sensitivity of this test depend largely on the expertise of the performing laboratory. Flow cytometry is being used increasingly to detect production of hydrogen peroxide in phagocytes, using dihydrorhodamine (DHR)-1,2,3 as the fluorescent indicator, and has proven to be more reliable and sensitive.[50] More sophisticated tests, including assays of chemotaxis, phagocytosis, and bactericidal activity, may be done when the NBT and DHR test results

TABLE 79–5 Gene Defects in Primary Immunodeficiencies

Immunodeficiency	Gene Defect	Chromosome
Antibody Deficiency		
Agammaglobulinemia	Immunoglobulin heavy chain	14q23
	Bruton tyrosine kinase	Xq22
Hyper-IgM syndrome	Activation-induced deaminase	12p13
	CD40 ligand (CD154)	Xq26
Cellular Immunodeficiency		
DiGeorge syndrome	Unknown, TBX1?	22q11.2, 10p13
Severe combined immunodeficiency	RAG1, RAG2	11p13
	JAK3	19p13.1
	Adenosine deaminase	20q13.11
	Common gamma chain	Xq13.1
	IL-7 receptor	5p13
Ataxia telangiectasia	ATM, DNA kinase	11q22.3
Wiskott-Aldrich syndrome	WASP, cytoskeleton protein	Xp11.23
Phagocyte Deficiency		
Chronic granulomatous disease	gp67phox	1q25
	gp47phox	7q11.23
	gp22phox	16q24
	gp91phox	Xp21.1
LAD type I	CD18	21q22

Note: More than 120 gene defects have been shown to cause immunodeficiency syndromes. A more comprehensive list has been compiled by Notarangelo and associates[73] and Geha and colleagues.[41a]

are abnormal, or when high clinical suspicion of a phagocyte disorder exists.[51] Enumeration of CD11a,b,c$^+$/CD18$^+$ white blood cells is indicated when a diagnosis of LAD is suspected.

Genetic Testing

More than 120 gene defects responsible for immunodeficiency disorders have been identified (Table 79–5).[73] Currently, testing for these gene defects is available only in a few specialized laboratories, but testing should be pursued when a primary immunodeficiency with a known genetic defect is suspected. Genetic testing is strongly recommended for an affected patient who is ill, for prenatal diagnosis of an unborn child with an affected sibling, or for an individual who may have inherited or is a carrier of a known immunodeficiency gene defect. For some conditions, knowing the specific gene defect may help when one is assessing the prognosis and therapeutic options. Bone marrow transplantation for X-linked SCID (*IL2RG* gene defect) has been reported to be more successful than for other forms of SCID.[8] Knowledge of the specific gene defect also is useful for genetic counseling, most importantly to answer a common concern of the parents regarding the probability of having another child with a similar condition. Genetic studies for immunodeficiencies usually are used to confirm the diagnosis of DiGeorge syndrome, in which a deletion in chromosome 22 is identified by fluorescence in situ hybridization in approximately 95 percent of patients affected.[98]

MANAGEMENT

Management of an immunodeficient patient requires specialized care that may dictate recommendations according to the specific diagnosis. Hematopoietic cell transplantation is indicated for the most severe immunodeficiencies and necessitates careful individualized assessment of risks and benefits before proceeding with this treatment. One common therapeutic measure is replacement therapy with intravenous or subcutaneous immunoglobulins for patients with proven deficiency of IgG response,

TABLE 79–6 Key Concepts in the Management of Primary Immunodeficiencies

Immune function	T- and B-cell number and function should be assessed periodically
IgG replacement therapy	For patients with low IgG levels and poor antibody function
Immunizations	Live vaccines should not be administered to patients with immunodeficiency except for patients with complement deficiency and selective IgA deficiency
	Patients with complement deficiency may benefit from receiving pneumococcal and meningococcal vaccines because of their increased susceptibility to encapsulated organisms
	Household contacts of children with immunodeficiency should not receive oral poliovirus vaccines because of the risk of transmission to the immunodeficient child
	Other live vaccines (BCG, MMR, and varicella vaccine) may be administered to the household contact
	If the vaccine recipient develops a rash, contact with the immunodeficient child should be avoided[7]
Blood products	When needed, patients with immunodeficiencies should receive only irradiated, cytomegalovirus-negative, leukocyte-depleted blood products
Antibiotic prophylaxis	T-cell–deficient patients should take antibiotic prophylaxis for *Pneumocystis jiroveci*
	Antibiotic prophylaxis is recommended for dental and surgical procedures
	Patients with recurrent infections may benefit from antibiotic prophylaxis
Infectious diseases	Infections should be recognized promptly, and unusual pathogens should be considered
	Antibiotic therapy should be started early and discontinued cautiously
Diet and activity	Patients with immunodeficiency should have a regular diet and lifestyle but should be instructed to avoid eating raw food and playing in environments potentially highly contaminated with pathogens, including daycare centers
	Strict handwashing and reverse isolation may be indicated for patients with poor T-cell function

when presenting alone or in combination with cellular immunity defects. Other recommendations that apply to patients with immunodeficiency include the avoidance of contact with sick individuals and avoidance of live vaccines[6]; the use of irradiated, leukocyte-depleted, cytomegalovirus-negative blood products when needed; use of antibiotic prophylaxis; and prompt establishment of the diagnosis and provision of treatment of infections. Isolation in sterile environments is not recommended, except for patients with severe T-cell deficiency who are awaiting hematopoietic cell transplant, because of the severe impact on psychosocial development and the advances in the treatment and prevention of community-acquired infections (Table 79–6).

SELECTED PRIMARY ANTIBODY DEFICIENCIES

X-LINKED AGAMMAGLOBULINEMIA

Clinical Features

Boys with X-linked agammaglobulinemia (XLA), or Bruton disease, often are healthy during the first months of life because

of the protective presence of transplacentally acquired maternal IgG. As maternal immunoglobulin disappears from the infant, chronic or recurrent infections develop.[25,82,112] Frequent episodes of otitis media, sinusitis, pneumonia, and diarrhea are most common, but infections are not limited to mucosal surfaces; bacteremia, meningitis, and osteomyelitis also may occur. The mean age at establishment of the diagnosis in a retrospective study of 96 patients with XLA was 2.5 years when there was a family history of the disease and 3.5 years when there was not.[112]

S. pneumoniae, Hib, *S. aureus*, and *P. aeruginosa* are the bacterial pathogens observed most frequently in the setting of XLA. *Mycoplasma* spp. infections also occur with increased frequency and have been implicated as a cause of a subacute, destructive arthritis.[107] Gastrointestinal infections may be caused by *Salmonella*, *Shigella*, *Campylobacter*, or rotavirus.[82,112] Chronic giardiasis with intestinal malabsorption has been reported.[75]

Increased incidence of vaccine-associated paralytic poliomyelitis also has been reported.[112] Children with XLA are susceptible to chronic enteroviral meningoencephalitis,[66] which is a severe complication, even with treatment using intrathecal and intravenous immunoglobulin therapy. Most reported cases have a fatal outcome.

Pathogenesis

The defective gene (*BTK*) maps to the midportion of the long arm of the X chromosome. The gene encodes a cytoplasmic protein-tyrosine kinase, the normal function of which is necessary for expansion of B-cell populations during their maturation.[105] Deleterious mutations of the gene have been found in all affected individuals studied. XLA results from developmental arrest of B-cell maturation because lack of the Bruton tyrosine kinase (BTK)–mediated signal. Consequently, blood, lymph nodes, and bone marrow contain markedly diminished numbers of B cells and plasma cells, resulting in hypogammaglobulinemia. Other components of the immune system are not affected.

Diagnosis

Because of the presence of transplacentally acquired maternal IgG, the determination of serum immunoglobulin for establishing the diagnosis of XLA in the child's first 6 months of life is unreliable. Infants with XLA also have low concentrations of other immunoglobulin isotypes (e.g., IgA, IgM), but defining values that clearly differentiate between infants with the disease and normal infants has been difficult. Establishing a definitive diagnosis during early infancy generally relies on immunophenotyping by flow cytometry to show the absence of B cells in peripheral blood. After an infant with XLA reaches 6 months of age, serum IgG concentrations usually are less than 100 mg/dL, and concentrations of other immunoglobulin isotypes are low or undetectable. Isohemagglutinins are absent, and specific antibodies are not produced in response to immunization or natural infection. Recurrent infections in male family members may suggest an X-linked condition. Definitive diagnosis is obtained by finding inactivating mutations in the *BTK* gene sequence.

Treatment and Prognosis

Lifetime immunoglobulin replacement therapy is indicated for all patients with XLA.[61,78] It decreases the frequency of serious infections, reduces the need for hospitalization, and may help to prevent the development of chronic lung disease with progressive decrease of lung function. The dose and frequency of administration of immunoglobulins are adjusted to produce serum IgG trough concentrations of at least 500 mg/dL. For most patients, intravenous immunoglobulins are required at doses of 400 to 600 mg/kg, given every 3 or 4 weeks.

Acute infections in patients with XLA should be treated promptly. Minor middle ear, sinus, and skin infections usually respond to oral antibiotics. Pneumonia and other serious focal or systemic infections should be treated initially with intravenous antibiotics. Empiric antibiotic therapy is directed against common bacterial pathogens, including *S. pneumoniae*, *H. influenzae*, and *S. aureus*. If possible, etiologic diagnosis should be obtained, particularly in cases of severe or chronic infection. Because serum IgG concentrations often decrease during acute infection, the serum IgG concentration should be measured, and additional doses of immunoglobulins may be indicated. Chronic pulmonary disease with bronchiectasis is an important cause of death of patients with XLA. Long-term antibiotic therapy, similar to that used in patients with cystic fibrosis, may be helpful in individual cases. Long-term survivors of XLA are at increased risk for developing lymphoid malignancies.[82]

IMMUNOGLOBULIN DEFICIENCY WITH INCREASED IgM

Clinical Features

Approximately 70 percent of cases of immunoglobulin deficiency with increased IgM (i.e., hyper-IgM syndrome) are associated with X-linked inheritance, due to *CD40L* gene defects, but autosomal recessive and dominant inheritance patterns also have been reported.[57] Patients with this disorder develop recurrent pyogenic infections during infancy as transplacentally acquired IgG wanes. Respiratory tract infections and chronic diarrhea with failure to thrive are common occurrences; septicemia, meningitis, and other serious systemic infections also occur.[60] Opportunistic infections, such as *Pneumocystis jiroveci* pneumonia, also are common occurrences.[113]

Half of patients with hyper-IgM syndrome have neutropenia. It can be intermittent, but it lacks the precise periodicity of cyclic neutropenia. Aphthous ulcers occur commonly. Perirectal ulcers and abscesses also have been reported. Hyperplasia of superficial and deep lymph nodes occur commonly, and intestinal nodular lymphoid hyperplasia may lead to malabsorption and protein-losing enteropathy. Autoimmune conditions, including arthritis and nephritis, have been described. The incidence of lymphoreticular malignancies is increased in these patients.[60,113]

Pathogenesis

Males with hyper-IgM syndrome may have mutations of a gene on the X chromosome that encodes the T-cell ligand (CD154, CD40L) for the B-cell surface molecule CD40.[4,9] Several patients with normal expression of CD40L but defects in the B-cell CD40 signaling pathway also have been described.[26] Interaction of CD40 with CD40L is essential to B-cell proliferation, isotype switching, and terminal differentiation of B cells to antibody-secreting plasma cells. Mutations in the activation-induced cytidine deaminase (*AICD*) and the uracil DNA glycosylase (*UNG*) genes have been found in patients with the autosomal recessive form of hyper-IgM syndrome.[68]

Diagnosis

Patients with hyper-IgM syndrome have a characteristic increase in serum IgM concentrations in association with low to absent concentrations of serum IgA and IgG. Serum IgM concentrations may exceed 1000 mg/dL; however, they can be within normal range. Circulating B cells expressing surface IgM are found in normal numbers, but only a few cells bear surface IgA or IgG. Antibody responses to immunization often are present but consist predominantly or exclusively of IgM because isotype switching does not occur. More than half of patients are diagnosed before

they reach 1 year of age, and 90 percent of patients are diagnosed by the time they are 4 years old. Evaluation of boys with suspected immunoglobulin deficiency with increased IgM should include a determination of CD40L expression in activated T cells, which is done by flow cytometry.[9]

Treatment and Prognosis

Immunoglobulin replacement therapy and antibiotic prophylaxis are indicated.[78] Reports of patients treated successfully with HLA-identical bone marrow transplantation have been published.[102] Patients with hyper-IgM syndrome usually have a clinical course worse than that of patients with XLA. In addition, X-linked forms of hyper-IgM syndrome have increased morbidity and mortality compared with autosomal forms, possibly reflecting that the X-linked condition results from a T-cell defect, rather than a B-cell defect. Causes of mortality include infections other than respiratory, sclerosing cholangitis with liver disease often secondary to *Cryptosporidium parvum* infection, and malignancy.[113]

COMMON VARIABLE IMMUNODEFICIENCY

Clinical Features

Common variable immunodeficiency (CVID) includes a heterogeneous group of disorders with similar clinical manifestations, characterized by hypogammaglobulinemia with low or normal numbers of B cells, abnormal production of antibodies, recurrent infections, and a propensity for autoimmune conditions. Onset can occur at any time from infancy to old age,[27] but symptoms frequently begin during the second or third decades of life.[28]

The clinical manifestations of CVID are similar to those of XLA, with recurrent infections of the respiratory tract, bacteremia, meningitis, osteomyelitis, and septic arthritis. Patients frequently develop bronchiectasis and chronic lung disease. The most common infectious organisms are *S. pneumoniae*, *H. influenzae*, and *S. aureus*.[28] Many individuals with CVID have chronic diarrhea and intestinal malabsorption that have an infectious or autoimmune basis.[28] The inflammation induced by these conditions may result in protein-losing enteropathy and may exacerbate the underlying hypogammaglobulinemia. Organisms implicated in these gastrointestinal infections include *Giardia*, *Campylobacter*, *Salmonella*, and *Cryptosporidium*. Bacterial overgrowth syndrome commonly occurs. Patients with CVID present with increased frequency of ulcerative colitis, Crohn disease, atrophic gastritis with achlorhydria, viral or autoimmune chronic active hepatitis, and cholelithiasis.

Approximately 22 percent of patients with CVID develop autoimmune conditions, which include a chronic arthritis resembling juvenile rheumatoid arthritis; scleroderma, a lupus-like syndrome; hypothyroidism; and autoimmune neutropenia, anemia, and thrombocytopenia.[27,28] Malignancies, including lymphomas and gastric carcinoma, occur commonly among adults with CVID. A pseudolymphoma syndrome with lymphoid hyperplasia of the lung (i.e., lymphoid interstitial pneumonia) and intestine (i.e., nodular lymphoid hyperplasia), massive splenomegaly, and mediastinal adenopathy may be seen in patients with CVID.

Pathogenesis

The pathogenesis of CVID is poorly defined and may correspond to several different genetic defects that result in impaired antibody secretion. Bone marrow B-cell maturation is intact, and normal or low numbers of B cells are present in peripheral blood and lymph nodes, but production of antibody is impaired. Decreased or absent memory B cells is associated with severity of disease and development of autoimmune disorders and malignancies.[2,20] Many patients with CVID seem to have an intrinsic B-cell defect that impairs the ability of these cells to differentiate into immunoglobulin-secreting plasma cells, but a variety of T-cell functional abnormalities, including decreased proliferation of lymphocytes to mitogens and antigens and reduced expression of cytokines, also have been described.[49,96] Most recently, inactivating mutations in the *TACI*, *ICOS*, and *CD19* genes have been reported individually in a small proportion of families with several members affected with CVID and IgA deficiency, providing a link between these two clinical syndromes and supporting the concept of a multiple etiology of CVID.[21]

Diagnosis

Quantitative immunoglobulin determination generally reveals a serum IgG concentration persistently less than 250 mg/dL, with comparable decreases in other immunoglobulin isotypes. Immunophenotyping of peripheral blood lymphocytes shows the presence of mature B cells expressing surface immunoglobulins, with a subset of patients lacking switched memory B cells. Antibody responses to immunizations are subnormal or absent.

Treatment and Prognosis

Treatment of patients with CVID is similar to treatment of patients with XLA. Immunoglobulin replacement therapy is indicated and has been shown to decrease the frequency of respiratory infections.[19] Antibiotic prophylaxis may be indicated as an adjunctive measure in patients who continue to develop infections despite having adequate serum IgG levels. Because of enteric protein loss, patients with CVID and enteropathy may require unusually large doses of immunoglobulin to maintain protective serum IgG concentrations. Chronic lung disease with bronchiectasis resulting from multiple pneumonias is the most frequent cause of morbidity and mortality.[28] Patients with absence of switched memory B cells are at risk of developing lymphoma, splenomegaly, and autoimmune complications.

IgA DEFICIENCY

Clinical Features

IgA deficiency is estimated to occur with a frequency of 1 in 500 individuals and is considered the most common immunodeficiency. Most individuals with IgA deficiency are clinically asymptomatic, however.[33,88] Some patients have frequent, noninvasive viral and bacterial infections of the respiratory tract, although most of these patients also have concomitant IgG2 subclass deficiency. Chronic diarrhea occurs with increased frequency, with *Giardia* being a pathogen commonly implicated. Infections in patients with IgA deficiency usually are less severe than infections observed in patients with XLA or CVID. Individuals with more severe or chronic infections often have another associated immunodeficiency, such as IgG subclass deficiency[80] or, rarely, ataxia telangiectasia.

Patients with IgA deficiency have a higher incidence of atopy than the general population. Autoimmune disorders, including systemic lupus erythematosus, rheumatoid arthritis, and pernicious anemia, and lymphoid and gastrointestinal malignancies are more prevalent in this population.

Pathogenesis

The pathogenesis of IgA deficiency has been compared with that of CVID. The fundamental defect in both disorders is a failure of B cells to differentiate into immunoglobulin-secreting plasma cells. Rare alleles of complement genes within major histocom-

patibility complex III on chromosome 6 have been associated strongly with the development of selective IgA deficiency and CVID, suggesting that these two disorders may be related.[109] Some individuals with selective IgA deficiency subsequently develop CVID. Inactivating mutations in *TACI* and *ICOS* genes have been found in families with members presenting with either of those conditions.[21]

Diagnosis

Selective IgA deficiency is diagnosed by a quantitative serum immunoglobulin determination showing subnormal concentration or absence of circulating IgA, in the presence of normal amounts of the other immunoglobulins. In interpreting test results, an important consideration is that serum IgA concentrations can be undetectable in normal infants younger than 6 to 9 months because of a possible maturational delay. This diagnosis is reliable only after the child reaches 4 years of age.

Treatment and Prognosis

Immunoglobulin replacement generally is not recommended in the management of patients with selective IgA deficiency. Although rarely reported, IgA-deficient patients are at risk for developing IgE-mediated anaphylactic reactions if the patient is sensitized to IgA and receives blood products containing IgA.[17]

Patients deficient in IgA respond adequately to vaccines unless they have concomitant IgG deficiency. Sinopulmonary infections in individuals with IgA deficiency often require unusually long courses of antibiotic therapy. Antibiotic prophylaxis for respiratory infections may be recommended if infections are recurrent. Parenteral antibiotic therapy sometimes is necessary for refractory cases of sinusitis or pneumonia.

IgG SUBCLASS DEFICIENCY

Clinical Features

The most common IgG subclass deficiency reported is IgG2, sometimes occurring in association with deficiency of IgG4 or IgA. The second most common is IgG3 deficiency, which may occur in association with IgG1 deficiency.[46,91] Many individuals with IgG subclass deficiencies are asymptomatic; others have recurrent or chronic bacterial infections, usually of the respiratory tract. Commonly implicated pathogens include *S. pneumoniae*, Hib, and other encapsulated bacteria. Children with selective IgG subclass deficiency usually do not have problems with intestinal malabsorption or autoimmunity.

Pathogenesis

The pathogenesis of IgG subclass deficiency is unknown. Genetic factors have been implicated by studies showing linkage to certain immunoglobulin allotypes.[46] T-cell immunity has been reported to be intact in patients with IgG subclass deficiency.

Diagnosis

A diagnosis of IgG subclass deficiency is supported by finding a marked decrease from age-adjusted normal values in the serum concentrations of one or more IgG subclasses, together with evidence of a functional impairment in antibody responses to immunizations. The total serum IgG concentration may be normal, decreased, or elevated as a result of a compensatory increase in production of unaffected IgG subclasses.

Children with low IgG2 subclass levels may respond poorly to polysaccharide vaccines.[106] Responses to protein antigens (e.g., tetanus toxoid) and protein-conjugated polysaccharide vaccines (e.g., Hib conjugate vaccines) also may be abnormal. In contrast, patients with IgG3 subclass deficiency may respond poorly to protein antigens, but responses to polysaccharides generally are normal. Assessment of the patient's antibody responses to vaccination with polysaccharide and protein antigens can help to establish the functional significance of an IgG subclass deficiency. Because of the age-dependent development of anti-polysaccharide antibody responses, such testing is unreliable in children younger than 2 years.

Treatment and Prognosis

Antibiotic prophylaxis of recurrent sinopulmonary infections and early and prompt treatment of infections form the cornerstone of management for symptomatic IgG subclass deficiency. Immunoglobulin replacement therapy is reserved for patients with abnormal antibody responses and a demonstrated propensity for frequent or chronic infections.[78] Because of the anecdotal evidence of the clinical benefit of this measure, the effectiveness and continued need for immunoglobulins should be reassessed periodically.

TRANSIENT HYPOGAMMAGLOBULINEMIA OF INFANCY

Clinical Features

Many infants come to medical attention because they have recurrent respiratory tract infections (e.g., otitis media, sinusitis) and serum immunoglobulin levels that are lower than laboratory normal ranges. Septicemia, meningitis, and other serious systemic infections are rare findings.[31,65]

Pathogenesis

Transient hypogammaglobulinemia of infancy is a developmental disorder with a delay in the physiologic maturation of immunoglobulin synthesis, resulting in prolongation of the relative hypogammaglobulinemia observed in most normal infants at 4 or 5 months of age, when most maternal immunoglobulins have cleared from the infant's circulation. Patients with transient hypogammaglobulinemia of infancy do not seem to have any inherent defects of B-cell maturation or function, or defects of specific antibody responses.

Diagnosis

Transient hypogammaglobulinemia of infancy is a diagnosis that can be made with certainty only in retrospect. Serum immunoglobulin concentrations may remain low in children until they are several years of age in some cases.[65] Circulating mature B-cell numbers are normal and generate normal antibody responses to diphtheria, tetanus, and pertussis vaccines.

Treatment and Prognosis

Infants with suspected transient hypogammaglobulinemia should be followed clinically, and serial serum immunoglobulin concentration measurements should be performed. Some of these children eventually are diagnosed with CVID, selective IgA deficiency, or another secondary immunodeficiency disorder. Because the condition is self-limited, and production of specific antibodies usually is normal, immunoglobulin replacement therapy is not indicated. Antibiotic prophylaxis for respiratory infections is indicated in cases with recurrent episodes of infection.

SELECTED PRIMARY CELLULAR AND COMBINED IMMUNODEFICIENCIES

DIGEORGE SYNDOME

Clinical Features

DiGeorge syndrome is a common genetic disorder that includes facial, cardiac, parathyroid, and thymic abnormalities.[98] Patients with DiGeorge syndrome may present early in infancy with findings unrelated to immunodeficiency. Congenital heart disease, particularly truncus arteriosus and interrupted aortic arch, usually is detected in the first few weeks of life. Neonatal hypoparathyroidism occurs in almost all infants with DiGeorge syndrome, and hypocalcemic seizures or tetany is a common presenting feature. Characteristic facial features include microstomia and micrognathia; hypertelorism; upturned nose; arched palate; posteriorly rotated and small, low-set ears with notched pinnae; and anti-mongoloid slant of the eyes (see Fig. 79–1). Hypothyroidism, esophageal atresia, tracheoesophageal fistula, and bifid uvula have been described.

Based on the degree of immunodeficiency, clinical manifestations may include predisposition to a wide variety of common and opportunistic infectious diseases. Common findings are recurrent or chronic pneumonias; chronic diarrhea; and candidiasis of the skin, mouth, or esophagus. Recurrent or severe herpesvirus infections (e.g., herpes simplex virus, cytomegalovirus); *P. jiroveci* pneumonia; and other opportunistic viral, fungal, protozoal, and mycobacterial infections occasionally are observed. Fatal graft-versus-host disease may occur if infants receive blood products containing viable lymphocytes during surgical correction of heart defects. Although DiGeorge syndrome is the most common of the cellular immunodeficiencies, with an incidence of 1 in 3000 live births, only a few patients with DiGeorge syndrome have clinically significant immunodeficiency (complete DiGeorge syndrome). Most patients develop adequate T-cell numbers and function by the time they reach 1 year of age and do not have an increased incidence of opportunistic infections (partial DiGeorge syndrome).[23,99] At Texas Children's Hospital, 20 percent of patients with DiGeorge syndrome and mild T-cell deficiency present with an increased incidence of respiratory infections.[23]

Pathogenesis

DiGeorge syndrome is classified as a developmental defect resulting from faulty embryologic development of the third and fourth branchial arches and their derivatives, including parathyroid glands, aortic arch structures, and thymus gland.[98] Partial deletions of chromosomes 22 and 10 are found in more than 90 percent of patients. Three groups of investigators simultaneously reported that they reproduced all the characteristic features of DiGeorge syndrome, working with mice models bearing the deletion of *Tbx-1*, a gene within the chromosome 22 critical region.[116] Whether the absence of this gene in humans is responsible for this syndrome is still not definitive.

Diagnosis

Hypocalcemia, congenital heart disease, and characteristic facies may lead to suspicion of DiGeorge syndrome in the newborn period. A deletion in chromosome 22q is detected by fluorescence in situ hybridization analysis. Lymphopenia varies, and severe T-cell deficiency is rare. Determination of T-cell number and a proliferative response to mitogens allows the clinician to make a better assessment of the degree of immunodeficiency. Quantitative serum immunoglobulin determinations often are normal, but antibody responses after immunization usually are poor. Chest x-ray may show absence of the thymic shadow. A significant group of patients with DiGeorge syndrome are totally or partially thymectomized while heart surgery is performed for repair of characteristic conotruncal cardiac malformations.

Treatment and Prognosis

Initial management should focus on the treatment of hypocalcemia and the surgical correction of congenital heart disease. Immunoglobulin replacement therapy and antibiotic prophylaxis should be considered for patients with recurrent infections. Children with $CD4^+$ lymphopenia or evidence of significant cellular immune dysfunction should receive *P. jiroveci* pneumonia prophylaxis. Infections should be recognized early and treated promptly. Only irradiated, cytomegalovirus-negative blood products and inactivated vaccines should be administered. Several small retrospective studies have suggested that children with partial DiGeorge syndrome and normal or only mildly decreased $CD4^+$ T cell counts may receive vaccines without experiencing serious adverse events.[10,71,81] The safety of live vaccination has not been well established, however, and currently is not recommended. Therapeutic options being investigated for patients with DiGeorge syndrome and severe immunodeficiency include bone marrow transplantation and, experimentally, thymus transplantation.[64]

WISKOTT-ALDRICH SYNDROME

Clinical Features

Wiskott-Aldrich syndrome is an X-linked disorder classically characterized by recurrent infection, bleeding, and eczema. Only a few patients have this classic triad of features, however, and some patients have infectious manifestations alone.[76] Patients commonly present with recurrent otitis media or pneumonia caused by encapsulated bacteria (e.g., *S. pneumoniae*, *H. influenzae*). Septicemia, meningitis, and other serious systemic bacterial infections also may occur. Common opportunistic pathogens include *Candida*, cytomegalovirus, other herpesviruses, and *P. jiroveci*.

Individuals with Wiskott-Aldrich syndrome often have depressed platelet counts. A unique feature is the presence of small platelets (low mean platelet volume) in most cases. Consequently, bruises combined with gastrointestinal bleeding in the first months of life is are common presenting feature of Wiskott-Aldrich syndrome. Life-threatening gastrointestinal or intracranial hemorrhage also may occur. Eczematous lesions are generalized and prone to superinfection.

Patients with Wiskott-Aldrich syndrome have a high incidence of autoimmune disorders.[32] Hemolytic anemia, a juvenile rheumatoid arthritis–like condition, and large or small vessel vasculitis have been reported. Some patients develop autoimmune thrombocytopenia as disease progresses. Lymphoid malignancies, especially non-Hodgkin lymphomas involving the brain, have been reported.

Pathogenesis

The gene (*WASP*) that is mutated in patients with Wiskott-Aldrich syndrome[29] maps to the X chromosome. This gene encodes a protein that is expressed in lymphocytes and platelets and is involved in cytoskeletal organization and formation of pseudopodia. This defect results in failure to form an adequate immunologic synapse, resulting in poor cognate interaction between T cells and B cells.[18] T-cell morphologic and membrane abnormalities and signal transduction defects have been described.[69] X-linked thrombocytopenia without or with only

mild immunodeficiency and eczema has been found to be caused by *WASP* mutations that allow partial protein expression.[108]

Diagnosis

Wiskott-Aldrich syndrome should be suspected in a boy with thrombocytopenia and small platelets. The presence of eczema supports the diagnosis. Serum immunoglobulin concentrations vary, with the most typical pattern showing normal IgG, increased IgA and IgE, and decreased IgM. Antibody responses to protein antigens (e.g., tetanus) usually are normal, but responses to polysaccharides (e.g., *S. pneumoniae*, Hib, isohemagglutinins) are absent.

Patients with Wiskott-Aldrich syndrome are anergic on delayed hypersensitivity skin testing. They have near-normal numbers of circulating T cells, and in vitro proliferative responses to mitogens could be normal. Responses to specific antigens are decreased, however. Monocytes exhibit abnormal chemotaxis and poor antibody-dependent cellular cytotoxicity. The determination of WAS protein expression and the sequencing of the *WASP* gene are available in specialized research laboratories.

Treatment and Prognosis

Bone marrow transplantation results in normalization of cellular immunity, specific antibody responses, and platelet count. It is the definitive treatment of choice; however, mortality is high if the donor is not a matched HLA sibling, or if multiple infections and organ damage have occurred. Splenectomy is indicated for severe thrombocytopenia and may improve the patient's quality of life. Daily antibiotic prophylaxis directed against *S. pneumoniae* and *H. influenzae* should be indicated for patients who have undergone splenectomy. Aspirin is contraindicated because it increases the risk of bleeding. Acute infections should be treated aggressively. Immunoglobulin replacement therapy is indicated for patients with recurrent bacterial infections.

The prognosis of Wiskott-Aldrich syndrome has improved in recent years, with some patients surviving to adulthood.[76] Infection, malignancy, and hemorrhage are the leading causes of death.

ATAXIA TELANGIECTASIA

Clinical Features

Ataxia telangiectasia is characterized by cerebellar ataxia, oculocutaneous telangiectases, variable immunodeficiency with frequent infections, and a high incidence of malignancy.[114] Neurologic signs and symptoms dominate the clinical picture. Ataxia usually becomes evident when the child is approximately 1 year old. Progressive choreoathetosis, myoclonic jerking movements, and oculomotor abnormalities develop subsequently, resulting in severe disability. Telangiectases appear on the bulbar conjunctivae, usually in patients 2 to 5 years old (see Fig. 79–2). They subsequently appear on the nasal bridge, ears, and other areas of sun exposure or trauma. Other cutaneous manifestations include café-au-lait spots, vitiligo, and prematurely gray hair.

Recurrent infections are a major feature of ataxia telangiectasia in most patients. Sinopulmonary infections predominate, but systemic infections are rare despite the immunologic abnormalities.[74] Organisms commonly implicated include S. *pneumoniae* and *H. influenzae*. Fifteen percent of patients with ataxia telangiectasia may develop neoplasias. Non-Hodgkin lymphomas and leiomyomas occur most frequently. Carcinomas (especially of the stomach) occur commonly among adults with ataxia telangiectasia.[114]

Pathogenesis

Ataxia telangiectasia is inherited in an autosomal recessive manner. The defective gene (*ATM*) responsible for the disorder has been identified and maps to chromosome 11.[86] One domain of the ATM protein seems to be important in numerous cellular responses, including cytokine signaling. Another region of the protein is involved in DNA repair. Disease manifestations result from a major defect in one or more DNA repair mechanisms. Breakage and rearrangements of chromosomes, including the T-cell receptor genes and immunoglobulin heavy-chain genes on chromosomes 7 and 14, may explain the observed immunodeficiency.

Diagnosis

A clinical diagnosis of ataxia telangiectasia is possible when the disease is fully manifested. Laboratory studies usually are needed for early diagnosis, however. Increased serum alpha-fetoprotein concentrations are observed in essentially all patients older than 6 months. Most patients have deficiencies in serum IgA and IgE. Specific antibody responses usually decline as the patient ages. Most patients have serum IgM in a monomeric 7S form, rather than the usual pentameric 19S molecule. Common manifestations of immunodeficiency include delayed hypersensitivity skin test anergy and decreased lymphocyte proliferative responses to mitogens and antigens. The sequencing of the *ATM* gene is available in specialized laboratories.

Treatment and Prognosis

No specific treatment is curative for ataxia telangiectasia because of the pathology involving multiple body systems. Infections should be treated promptly with oral or parenteral antibiotics. Continuous prophylactic antibiotic therapy may be beneficial for individual patients. Immunoglobulin replacement therapy is reserved for patients with recurrent infections and abnormal specific antibody responses.

The clinical course and prognosis of ataxia telangiectasia vary. Death from chronic pulmonary disease or malignancy occurs commonly.

SEVERE COMBINED IMMUNODEFICIENCY

Clinical Features

Infants with SCID generally present during the first few months of life with recurrent infections.[16,97] Newborns may present with a rash produced by a graft-versus-host reaction induced by maternal lymphocytes. Recurrent pneumonias, other respiratory tract infections, and persistent oral and cutaneous candidiasis are common, as are chronic diarrhea and failure to thrive. Septicemia and other serious systemic bacterial infections also occur. Causative organisms include routine pathogens (e.g., *S. pneumoniae*, Hib) and more unusual organisms. Life-threatening opportunistic infections, including *P. jiroveci* pneumonia, frequently occur early in infancy. Fatal Epstein-Barr virus–associated lymphocyte proliferative disease has been observed in bone marrow transplant recipients and untreated patients with SCID.[36]

Pathogenesis

SCID represents a heterogeneous group of genetic disorders having in common a profound immunodeficiency with failure of cellular and humoral immune function. Various types of SCID have been defined on the basis of enzymatic, genetic, and immunologic criteria (Table 79–7), including reticular dysgenesis, with

TABLE 79–7 Types of Severe Combined Immunodeficiency (SCID)

Type	Defect
Reticular dysgenesis	Stem cell
RAG1, RAG2 deficiency, Omenn syndrome	Rearrangement of B- and T-cell receptor genes
Artemis deficiency	Rearrangement of B- and T-cell receptor genes
DNA ligase IV	Rearrangement of B- and T-cell receptor genes
X-linked SCID (common gamma-chain deficiency)	Signaling for IL-2, IL-4, IL-7, IL-15, IL-21
JAK3 deficiency	Cytokine signaling
IL-7 receptor deficiency	Signaling for IL-7
CD3 δ or ε deficiency	CD3 signaling
CD45 deficiency	Signaling for CD45, cell activation
Adenosine deaminase deficiency	Metabolite (dATP) toxicity to lymphocytes
MHC class I deficiency	Defect in transporter proteins TAP-1, TAP-2
MHC class II deficiency	Defects in transcription factors RFXAP, RFX5, RFXANK, and transactivator CIITA

impaired lymphoid, myeloid, and erythroid differentiation; absence of T-cell and B-cell differentiation; selective defects of T-cell differentiation; and purine metabolism defects (e.g., adenosine deaminase deficiency [ADA]). Autosomal and X-linked recessive inheritance patterns have been recognized. Individuals with X-linked SCID have a defect in the gamma chain of the IL-2 receptor, and it is the genetic defect identified in approximately half of SCID patients.[16] This protein is a functional component of the receptors for IL-4, IL-7, IL-9, IL-15, and IL-21 receptors.[58,72,85] These functions help to explain why this defect has such a profound effect on lymphoid development and function.

Diagnosis

Infants with SCID typically lack palpable lymph nodes, visible tonsils, and radiographic evidence of a thymus gland. Lymphopenia often is identified.[97] Some patients have panhypogammaglobulinemia, whereas others have depressed concentrations of only one or two immunoglobulin isotypes. Antibody responses almost always are profoundly impaired or absent. Lymphocyte monoclonal phenotyping may reveal the presence of circulating mature B cells. Particularly in boys with X-linked SCID and JAK3-deficient SCID, B cells may account for all circulating lymphocytes. Circulating T cell counts are diminished (<10% of normal range) in most patients with SCID. Delayed hypersensitivity skin test anergy is found, and lymphocyte proliferative responses to mitogens and antigens are severely depressed. Testing for specific genetic defect should be pursued, and a genetic evaluation of immediate relatives for carrier status is recommended for genetic counseling purposes. Biochemical tests for ADA and purine nucleoside phosphorylase levels and enzymatic activities are available in specialized laboratories.

Treatment and Prognosis

Hematopoietic stem cell transplantation (HSCT) is the treatment of choice for most patients with SCID. Prognosis is poor for patients without therapy. HSCT performed with HLA-matched related donors has a survival rate of greater than 95 percent.[8] Most patients do not have such a donor available, however, and receive an HLA-haploidentical transplant. Survival rates with these donors vary from 50 to 75 percent at 5-year follow-up, according to the different transplant centers. This survival rate can increase to greater than 95 percent if the SCID is detected early and HSCT is performed before the infant reaches 3.5 months of age, likely because infections and organ damage are yet to occur at this early age. HLA-matched unrelated donors and HLA-matched cord blood have been used increasingly for different forms of SCID, accompanied with different chemotherapy regimens for myeloablation. Success rates are not uniform; they approximate 75 percent in the best transplant centers.

As an alternative because of the high mortality and morbidity associated with HSCT, French and British investigators have reported success in experimental gene therapy trials for X-linked SCID. Using autologous $CD34^+$ stem cells carrying the correct version of the gene, the investigators were able to restore humoral and cellular immunity in 12 of 14 affected patients.[41,45] Four patients in the French trial developed leukemia that was caused partly by the gene therapy procedure. One of the patients died, and the other three responded to anti-leukemic chemotherapy and are alive and well.

Enzyme replacement[47] and gene therapy[13] have been used for treatment of SCID resulting from ADA deficiency. Polyethylene glycol–adenosine deaminase has shown efficacy to increase lymphocyte counts and provide adequate immunity in most affected patients. Some patients ultimately develop "resistance" to the drug in the form of eliciting neutralizing anti-ADA antibodies or simply showing a decrease of lymphocyte counts. Italian researchers have reported positive results of an experimental gene therapy trial for SCID caused by ADA deficiency with the restoration of cellular and humoral immunity in seven patients, in a treatment protocol that included withdrawal of exogenous ADA and reduced myeloablation.

MISCELLANEOUS CELLULAR IMMUNODEFICIENCIES

Many other disorders of cellular immunity have been described. Particularly noteworthy are disorders characterized for dysregulation of the immune system with autoimmune inflammation. X-linked lymphoproliferative syndrome represents a defect in control of Epstein-Barr virus infection. Mutations in the SLAM-associated protein (SAP), a factor involved in the signal transduction of T cells, have been identified to cause X-linked lymphoproliferative syndrome. The absence of this protein affects the interaction of T cells and B cells, leading to an inability to control B cell proliferation caused by Epstein-Barr virus infection.[42,87] Patients may present with severe and often fatal infectious mononucleosis or with B-cell lymphoma.

Chronic mucocutaneous candidiasis is a condition characterized by chronic, severe *Candida* spp. infection of mucous membranes, skin, and nails, often in association with autoimmune polyendocrinopathy, in which case it is termed *autoimmune polyendocrinopathy ectodermal dystrophy*.[1] T-cell numbers and function usually are normal, but most patients do not manifest delayed hypersensitivity skin test responses to *Candida*, and their lymphocytes fail to proliferate in response to *Candida* antigen in vitro. In cases with autoimmune polyendocrinopathy ectodermal dystrophy, deleterious mutations have been found in the Auto-Immune REgulator (*AIRE*) gene. This gene promotes the expression of many self-antigens in the thymus, facilitating the development of immune tolerance of the newly formed lymphocytes. IPEX (immunodeficiency, polyendocrinopathy, enteropathy, X-linked) is another autoimmune endocrinopathy with immunodeficiency. IPEX results from mutations in the *FoxP3* gene and is characterized by lack of T-regulatory cells and clinically by eczema, chronic diarrhea, diabetes mellitus, and other hormone deficiencies.[56]

Figure 79–5 Conical teeth characteristic of incontinentia pigmentosa with immunodeficiency, resulting from defects in the *IKKb* gene (NEMO defect). (See companion Expert Consult web site for color version.)

Mutations in the interferon-γ receptor genes have been shown in patients with severe infections caused by atypical mycobacteria.[30,53,83] Patients with a mutation in the IL-12 receptor β2-chain gene or in the IL-12 gene also showed increased susceptibility to mycobacterial disease and disseminated nontuberculous mycobacterial infection.[5]

Deficiency in the nuclear factor-κB enhancing modulator (NEMO) is a newly recognized primary immunodeficiency caused by specific missense mutations in the *IKKG* (also known as *NEMO*) gene, located on chromosome Xq28. NEMO participates in signal transduction mediated by nuclear factor-κB. Most mutations in the NEMO gene are lethal for male fetuses, and female carriers of these mutations may present with incontinentia pigmenti. The surviving male patients with specific missense mutations present with anhidrotic ectodermal dysplasia, conical teeth (Fig. 79–5), low IgG, low IgA, normal or increased IgM levels, and poor T-cell proliferative responses to mitogen and antigen stimuli.[77,93,117]

PRIMARY COMPLEMENT DEFICIENCIES

CLINICAL FEATURES

Three types of complement function deficiencies can cause increased susceptibility to infections: deficiency of opsonic activity of complement proteins, deficiency of the complement lytic proteins, and deficiency of the mannose-binding lectin pathway.[110] Patients with deficiencies of early-acting complement components (e.g., C3, C1, C4, C2) are particularly susceptible to infection with encapsulated bacteria, including *S. pneumoniae* and *H. influenzae*; in addition, they have an increased risk of developing autoimmune disorders, such as systemic lupus erythematosus.[52] *Neisseria meningitidis* is the most important bacterial pathogen observed in patients with deficiencies of terminal complement components (C5 through C9). Recurrent episodes of septicemia and meningitis are especially common.[35,55,84] Although patients with deficiencies of late-acting complement components are at increased risk for developing meningococcal septicemia and meningitis, they seem to suffer lower rates of morbidity and mortality than immunologically normal individuals with systemic meningococcal infection. The frequency of primary complement deficiencies in patients with invasive meningococcal disease is approximately 5 to 10 percent[7,67]; however, the likelihood of having complement deficiency increases dramatically (31%) among individuals who have had more than one episode of invasive disease. A deficiency of opsonization in children with recurrent pyogenic infections and failure to thrive led to the recognition of the mannose-binding lectin pathway deficiencies. The clinical characteristic of these patients is the increased frequency of pyogenic infections.[100]

PATHOGENESIS

Various gene defects are responsible for the many distinct primary complement deficiencies. The particular bacteria that cause infection may indicate the missing component in host defense. C3b, the major cleavage product of C3, is an important opsonic ligand that promotes ingestion and killing of bacteria. Consequently, patients with C3 deficiency have increased susceptibility to bacterial infections (e.g., *S. pneumoniae*, *H. influenzae*), for which opsonization is the primary mechanism of host defense.[84,110] Individuals with deficiencies of C1, C4, or C2 also have increased susceptibility to these encapsulated bacteria because these components are necessary for activation of C3 through the classic pathway. Activation of terminal complement components C5, C6, C7, C8, and C9 results in assembly of the membrane attack complex C5b-9, a multicomponent macromolecule capable of bactericidal activity. Only gram-negative bacteria are susceptible to this bactericidal effect. Infections in patients with deficiencies of terminal complement components are limited to gram-negative bacteria, such as *N. meningitidis*.

DIAGNOSIS

When the history of infections is suggestive, the screening test used for complement deficiencies is the CH_{50} assay, which depends on the activity of all numbered components of the classic complement pathway from C1 through C9. When CH_{50} test results suggest a complement component deficiency, specific immunochemical and functional testing can identify the deficient component.[111]

TREATMENT AND PROGNOSIS

No specific therapy exists for primary complement deficiencies. Meningococcal vaccine is recommended for children with terminal complement component deficiencies.[7] Antibiotic prophylaxis and vaccines for other encapsulated organisms may be beneficial.

PRIMARY PHAGOCYTE DEFICIENCIES

The primary phagocyte deficiencies are a heterogeneous group of disorders having in common a susceptibility for frequent infections, resulting from a decreased number of phagocytic cells (e.g., neutropenia) or because of impaired adhesion, chemotaxis, opsonization and phagocytosis, or intracellular killing (Table 79–8). Infections resulting from quantitative or qualitative phagocyte deficiencies tend to be prolonged and recurrent, with a response to antibiotic therapy that is slower than expected. Common pathogens include *S. aureus*, *P. aeruginosa*, enteric gram-negative bacteria, and certain fungi (e.g., *Candida* spp., *Aspergillus* spp.).

TABLE 79–8 Primary Phagocyte Deficiencies

Quantitative Defects
Infantile agranulocytosis
Familial granulocytopenia
Cyclic neutropenia
Qualitative Defects
Adhesion Defects
Leukocyte adhesion deficiency
Type I, β-integrin deficiency
Type II, fucose-transporter deficiency
Intracellular Killing Defects
Chronic granulomatous disease
X-linked
Autosomal recessive
Glucose-6-phosphate dehydrogenase deficiency
Myeloperoxidase deficiency
Chédiak-Higashi syndrome
Griscelli syndrome

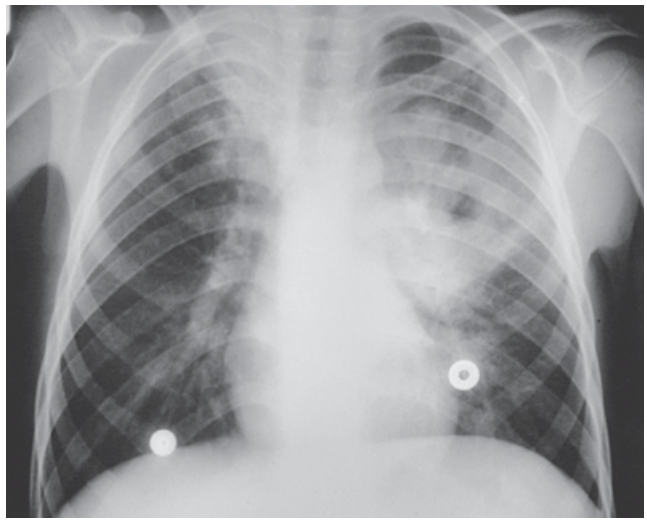

Figure 79–6 Chest radiograph of a 10-year-old boy with chronic granulomatous disease shows a left-sided pulmonary infiltrate and cavitary lung lesion. Biopsy revealed an *Aspergillus fumigatus* infection.

QUANTITATIVE PHAGOCYTE ABNORMALITIES

Primary quantitative phagocyte deficiencies can be observed as solitary defects or in association with other disorders (e.g., Shwachman syndrome). Infantile agranulocytosis (i.e., Kostmann syndrome) is an autosomal recessive disorder characterized by arrest of granulocyte maturation, markedly decreased numbers of circulating granulocytes, and severe infection. The more benign familial granulocytopenia syndrome manifests at various ages from infancy to adulthood, usually with indolent infections of the skin and soft tissues.

Cyclic neutropenia is an autosomal dominant defect of myelopoiesis, resulting from mutation in the leukocyte elastase (*ELA2*) gene, in which periodic disappearance of granulocytes from the circulation occurs.[11] Early granulocyte precursors are present in the bone marrow during periods of granulocytopenia, suggesting transient maturation arrest. Periods of granulocytopenia usually last 5 to 7 days and occur at 14- to 35-day intervals. The length of the cycle generally is constant for any given individual. Fever, malaise, aphthous stomatitis, and skin and soft tissue infections often are observed during periods of granulocytopenia.[94]

Some primary quantitative phagocyte deficiencies, particularly familial granulocytopenia and cyclic neutropenia, respond to therapy with recombinant granulocyte colony-stimulating factor.[39] Alternate-day corticosteroid therapy also has been used with some success in cyclic neutropenia.[115]

CHRONIC GRANULOMATOUS DISEASE

Clinical Features

Patients with CGD present with infections that begin during infancy and recur throughout the patient's life. Occasionally, patients have a mild course of disease and come to medical attention only during adolescence or adulthood.[70] History of suppurative lymphadenitis, soft tissue abscesses, pneumonia, lung abscess, hepatic abscess, and osteomyelitis suggest the presence of CGD. Perirectal abscesses may occur during early infancy. The physical findings of patients with CGD are nonspecific. Lymphadenopathy and hepatomegaly are common, and patients may have aphthous stomatitis. Infections in patients with CGD may progress with few symptoms, and the erythrocyte sedimentation rate and C-reactive protein may be useful to detect active infection.

Patients with CGD generally have infections caused by catalase-positive bacteria and fungi. *S. aureus* accounts for almost one third of all infections of determined cause. *Nocardia*, *S. marcescens*, *Pseudomonas* spp., *Burkholderia cepacia*,[89] and certain enteric gram-negative bacilli also are common findings. *S. marcescens* osteomyelitis particularly is suggestive of the diagnosis of CGD. Fungi, especially *Aspergillus* spp., account for nearly one fifth of all defined infections in patients with CGD (Fig. 79–6).

Patients with CGD often have poor wound healing. Granulomatous obstructive lesions of the urinary[3] and gastrointestinal[62] tracts have been reported. Granulomatous bowel involvement resembles Crohn disease. Corticosteroid therapy may be effective in relieving these sometimes life-threatening lesions.[22] Boys with X-linked CGD may present with the McLeod blood phenotype, which results in difficulty crossmatching for blood transfusion and the potential for hemolytic transfusion reactions.[15]

Pathogenesis

X-linked and autosomal recessive forms of CGD have been described. The various gene defects result in abnormalities of membrane or cytosolic components of the nicotinamide adenine dinucleotide phosphate oxidase complex system.[89] Despite the genetic heterogeneity, all individuals with CGD have in common the failure of the cellular respiratory burst, which ordinarily accompanies phagocytosis and various soluble stimuli. Consequently, oxygen-derived microbicidal factors are not formed, and intracellular killing of phagocytized microorganisms is severely impaired. Catalase-negative microorganisms are killed normally because hydrogen peroxide can accumulate within the phagocytic vacuole.[24,95]

Diagnosis

The diagnosis of CGD historically has been made with the NBT dye test.[51] Neutrophils are stimulated in the presence of NBT, a soluble yellow dye that is reduced by cellular superoxide to formazan, an insoluble blue precipitate. Neutrophils from normal individuals show 100 percent reduction of NBT, asymptomatic carriers show 20 to 90 percent reduction, and patients with CGD show essentially no dye reduction. In patients with mild forms of the disease, the NBT test result may be normal. A more sensitive

method to measure production of hydrogen peroxide is based on chemiluminescence of DHR on activation, detected by flow cytometry; this increasingly is used as a confirmatory test of the disease, replacing the NBT dye test.[50]

Treatment and Prognosis

Specific microbiologic diagnosis of infections should be established whenever possible. Empiric therapy is directed against the organisms known to be common causes of infection: *S. aureus*, *Pseudomonas* spp., and enteric gram-negative bacilli. Surgical drainage or débridement of sites of infection often is required. Anecdotal reports suggest beneficial effects of granulocyte transfusions in patients with CGD and serious bacterial or fungal infections. HSCT has been used successfully with HLA-matched related donors,[59,90] and gene therapy trials for X-linked CGD in humans resulted in gene-corrected, autologous granulocytes detectable for more than 30 months post-treatment, with resolution of chronic infections.[79] The oxidase activity of the gene-corrected cells had decreased progressively, however, by mechanisms of "gene silencing."[79]

Antibiotic prophylaxis with trimethoprim-sulfamethoxazole reduces the frequency of bacterial infections in patients with CGD.[63] Itraconazole and other antifungals given as prophylaxis may be effective for the prevention of *Aspergillus* infections, which usually are severe and difficult to eradicate.[40] The administration of interferon-γ, given by subcutaneous injection three times weekly, reduces the incidence of serious infections in CGD by two thirds without causing major deleterious side effects.[48] Patients should be educated about not performing activities that expose them to environments containing mold spores, such as mulching or raking leaves. The prognosis of CGD has improved remarkably during the past several decades, and now most patients survive to adulthood.

LEUKOCYTE ADHESION DEFICIENCY

Clinical Features

Patients with LAD have severe and recurrent bacterial infections of the skin and soft tissues, mucosal surfaces, and gastrointestinal tract, often beginning during early infancy.[104] Common pathogenic microorganisms include staphylococci and *Pseudomonas* spp. Infants with the severe phenotype may have delayed separation of the umbilical cord secondary to omphalitis. Cutaneous infections may become necrotic, resembling ecthyma gangrenosum or pyoderma gangrenosum. Poor wound healing also is observed. Individuals surviving infancy typically develop severe gingivitis and periodontitis with progressive alveolar bone loss (see Fig. 79–3).

Marked granulocytosis is a hallmark of LAD. Circulating granulocyte counts may range from 15,000/mm^3 to 75,000/mm^3, even in the absence of infection, and counts of 100,000/mm^3 or greater are common during episodes of infection. Despite the presence of granulocytosis, formation of pus is poor because of impaired migration to tissues.

Pathogenesis

LAD type I is an autosomal recessive disorder that maps to chromosome $21_f22.3$. Neutrophils from individuals with LAD are defective in their expression of several surface glycoproteins known as the leukocyte integrin (CD11/CD18) complex. These molecules are crucial for adhesion-dependent functions, and their absence is responsible for defects in leukocyte adherence, chemotaxis, and phagocytosis. The severity of infectious complications of LAD is related directly to the degree of CD18 gene expression. Patients with the severe clinical phenotype have undetectable expression of CD11/CD18 complexes on their phagocytes, whereas individuals with the moderate phenotype generally have 2 to 8 percent expression.

A second form of LAD has been described in two patients with craniofacial dysmorphism, neurologic deficits, recurrent respiratory infections, and marked granulocytosis.[34] Both individuals manifested the Bombay (hh) blood phenotype. In contrast to the neutrophils of patients with LAD type I, neutrophils from patients with LAD type II had normal surface expression of CD18. The molecular basis for the phagocyte dysfunction is a defect in the fucose transporter influencing the glycosylation of sialyl–Lewis X, a carbohydrate ligand for the endothelial adhesion molecules E-selectin and P-selectin. A third form of LAD has been described, characterized by a deficiency of all β integrins, resulting from a deficiency of Rap1 activation, a signal transduction necessary for integrin stabilization.[54]

Diagnosis

The diagnosis of LAD type I is made by flow cytometry using fluorescence-labeled monoclonal anti-CD11/CD18 antibody. In vitro studies reveal abnormalities of phagocyte adherence, chemotaxis, and phagocytosis. Individuals with LAD type II have similar phagocyte function abnormalities, with normal expression of CD18 and down-regulation of selectins. LAD type III is characterized by altered expression of all β integrins.

Treatment and Prognosis

Intercurrent bacterial infections in patients with LAD must be treated aggressively with prolonged courses of parenteral antibiotics. Antibiotic prophylaxis and universal hygiene measures are recommended. Although survival to adulthood is described, almost half of affected individuals die before reaching 2 years of age. Administration of fucose normalizes leukocyte function in LAD type II. Bone marrow transplantation offers the best hope for long-term survival.[103]

OTHER PRIMARY PHAGOCYTE DEFICIENCIES

A variety of other defects of phagocyte chemotaxis, phagocytosis, and intracellular killing have been described. Chédiak-Higashi syndrome is a rare autosomal recessive disorder characterized by partial oculocutaneous albinism, rotatory nystagmus, and peripheral neuropathy. Affected individuals develop recurrent serious or life-threatening infections caused by a wide variety of bacteria. In the accelerated phase of the illness, hepatosplenomegaly, lymphadenopathy, lymphocytic infiltration of multiple body organs, and unexplained febrile illnesses are common. Giant granules are found in numerous different cell types, including leukocytes, in the body. Neutrophils exhibit defective chemotaxis and abnormal bactericidal activity.

Hyperimmunoglobulinemia E (also known as hyper-IgE syndrome, Buckley syndrome, and Job syndrome) is characterized by markedly elevated serum IgE levels, eczema, recurrent staphylococcal abscesses, sinusitis, and otitis media. Coarse facial features are common. In addition to staphylococcal abscesses, recurrent pneumonia with bronchiectasis and pneumatoceles and mucocutaneous candidiasis are common. Other observed features include delay of shedding of primary dentition, recurrent bone fractures, scoliosis, and joint hyperextensibility. Hyper-IgE syndrome manifests with autosomal dominant inheritance and can be diagnosed with certainty only when the patient or family members present with the skeletal manifestations.[43] Missense mutations in STAT 3 gene have been found to cause this disease.[47a]

CONCLUSIONS

Primary immunodeficiencies are rare diseases, with an estimated minimal frequency of 1 in 10,000 live births for most conditions, although the actual incidence is unknown. Mutations in more than 120 genes have been identified to be responsible for primary immunodeficiencies, and several advances have clarified the immunopathogenesis of these conditions.

These diseases should be suspected and investigated in children who present with infections of unusual severity, frequency, or etiologic organisms and unexplained general symptoms, such as fever or failure to thrive. The initial immunologic screening consists of simple laboratory tests, and prompt referral to the clinical immunologist is warranted when a primary immunodeficiency is suspected. Management for these disorders has advanced during recent years to remarkably improved care, reflected in most immunodeficient patients surviving to adulthood. Curative treatment is available for severe immunodeficiencies in the form of allogeneic HSCT; however, it is not without considerable risk of mortality, and cure is not always optimal. Although still experimental, gene therapy has reached the stage of clinical trials for X-linked SCID, ADA-deficient SCID, and CGD, with successful and promising results.

CHAPTER 80

Opportunistic Infections in Hematopoietic Stem Cell Transplantation

Christian C. Patrick

Hematopoietic stem cell transplantation (HSCT) involves the infusion of stem cells from a donor into a recipient who has received a special conditioning regimen for the procedure. In recent years, the term HSCT has replaced the traditional term bone marrow transplantation (BMT) because hematopoietic stem cells can be obtained from bone marrow, umbilical cord blood, and peripheral blood.[86,117] HSCT has become the standard treatment for many patients with hematologic malignancies and solid tumors, as well as nonmalignant conditions such as primary immunodeficiencies, hemoglobinopathies, bone marrow failure syndromes, and a variety of genetic conditions, including inherited metabolic disorders.*

HSCT can be classified as syngeneic, autologous, or allogeneic, depending on the genetic match of the donor to the recipient of the stem cells. Syngeneic HSCT is transplantation of stem cells from an identical twin. In autologous HSCT, the patient's own stem cells harvested before ablative chemotherapy are transplanted. Autologous HSCT is used for patients who require marrow ablative chemotherapy to treat the underlying malignancy but have healthy bone marrow.[4] Allogeneic HSCT involves the transplantation of stem cells from a human leukocyte antigen (HLA)-matched sibling, an HLA-partially matched family member, or an HLA-matched unrelated donor.[4] In general, engraftment is faster for syngeneic and autologous transplantation when a total HLA match between the recipient and the donor exists. Allogeneic HSCT has a higher chance of success when completely HLA-matched sibling donors are used.

The three main sources of stem cells are bone marrow, peripheral blood, and cord blood. The different cell populations harvested from these sites can be correlated with complications. Peripheral blood progenitor cells from an allogeneic donor can increase the incidence of graft-versus-host disease (GHVD) secondary to an increase in T cells from the transplant.[30] Peripheral blood stem cells contain a high amount of $CD34^+$ cells and an increased amount of T cells, which equates to quicker engraftment but an increased rate of GVHD.[30] Cord blood transplants allow less stringent matching of HLA haplotypes because mismatched cord blood stem cells are less likely to cause GVHD, but they have fewer $CD34^+$ cells, which leads to slower engraftment.[159]

*See references 4, 18, 27, 60, 74, 76, 89, 136, 152, 163.

Infectious complications occurring after HSCT are somewhat predictable based on the underlying primary disease and the acquired immunodeficiencies that occur after transplantation.[96,134,142] Patients undergoing HSCT are at increased risk for infectious complications secondary to the acquired immunodeficiencies that occur after the procedure or secondary to medications (e.g., cyclosporine, steroids) used to treat complications of transplantation.[4] Infections are a major cause of morbidity and mortality and represent the most significant barrier to both immediate and long-term survival after HSCT.

Recovery of immune function after undergoing HSCT is a gradual process that takes place over the course of several months to years. Immune reconstitution after HSCT follows the normal pattern of immune ontogeny, with development from immature to mature immune functions. The general early immune mechanisms, such as phagocytic and cytotoxic functions, recover first, usually by post-transplant day 100, but the specialized functions of T and B lymphocytes may remain impaired for a year or even longer.[36,121]

These immune defects and the gradual recovery of host defenses cause infections to occur in three predictable time periods, as shown in Table 80–1. The first or pre-engraftment period begins with onset of the conditioning regimen and continues until engraftment, about 30 days after transplantation. This phase is characterized by profound neutropenia that lasts 3 to 4 weeks. Treatment with colony-stimulating factors can shorten the duration of this phase.[85,143] The middle or early engraftment period starts after resolution of the neutropenia with transplant engraftment and lasts until approximately 100 days after HSCT. The last or late engraftment period starts about 100 days after transplantation and is associated with selected deficits in both cellular and humoral immune responses and reticuloendothelial function.[134]

EPIDEMIOLOGY

Several risk factors place HSCT recipients at increased risk for acquiring infectious complications; however, there are significant differences in the relative risk for infection after HSCT, depending on the type of transplantation. The degree of immunosuppression is less with autologous HSCT because no risk for

TABLE 80–1 Temporal Association of Infections and Predominant Etiologic Agents after Hematopoietic Stem Cell Transplantation

Phase	Predominant Host Defect	Bacterial Infections	Fungal Infections	Viral Infections
Pre-engraftment (0-30 days)	Neutropenia	*Staphylococcus aureus* *Staphylococcus epidermidis* Viridans streptococci *Pseudomonas aeruginosa* Enterobacteriaceae *Escherichia coli* *Klebsiella pneumoniae* *Enterobacter* species	*Candida* species *Aspergillus* species	Herpes simplex virus
Early engraftment (31-100 days)	Cytotoxic and phagocytic functions	*S. aureus* *S. epidermidis* Viridans streptococci *P. aeruginosa* Enterobacteriaceae	*Candida* species *Aspergillus* species *Pneumocystis jiroveci*	Cytomegalovirus Adenovirus Respiratory viruses
Late engraftment (>100 days)	Cellular and humoral immunity	*Haemophilus influenzae* *Streptococcus pneumoniae*	*Candida* species	Varicella-zoster virus

TABLE 80–2 Diagnostic Evaluation of Patients Undergoing Hematopoietic Stem Cell Transplantation

Complete blood count with differential

Liver function tests
Renal function tests
Stool for ova and parasites
Skin testing with Mantoux purified protein derivative
Posteroanterior and lateral chest radiographs

GVHD exists. Preventive therapy against GVHD, which can include cyclosporine, methotrexate, steroids, and purging of T cells from the graft, increases the risk for development of infection. All these agents enhance the infection rate by depressing the cell-mediated immune response and, in the case of methotrexate, by disrupting mucosal barriers. The presence of GVHD increases the infection rate because it is associated with a delay in the return of normal immune function, prolonged immunodeficiency, and ulceration of the gastrointestinal tract.[4,49] The conditioning regimens for most allogeneic HSCT patients include concomitant total-body irradiation, which compromises the immune system and can cause severe mucositis. Diarrhea also is a very frequent complication in the first week after undergoing irradiation.

The serologic status of the donor and recipient is important as well because many infections in transplant recipients are caused by reactivation of previous infections. Serologic evaluation for cytomegalovirus (CMV), Epstein-Barr virus (EBV), hepatitis B virus, hepatitis C virus, human immunodeficiency virus, and toxoplasmosis should be performed on both donor and recipient before transplantation (Table 80–2).[96,147]

All HSCT recipients have a central venous catheter in place for administration of blood products, nutritional supplements, and medications, thus adding a potential site for development of infection.[115,123] The presence of other indwelling medical devices, such as a Foley catheter or a cerebrospinal fluid shunt, is associated with increased risk for the development of infection.

Knowledge of the epidemiology of the hospital and the transplantation unit allows the risk for acquiring environmental organisms to be assessed. Infection rates can be reduced by preventive strategies that inhibit aerosolization of organisms, such as the use of laminar air flow rooms or high-efficiency particulate air (HEPA)-filtered rooms.

CLINICAL MANIFESTATIONS AND APPROACH

The clinical approach to infections in a patient after HSCT is based on understanding the type of transplantation and the natural history of infections that can occur during each of the different at-risk periods based on immune reconstitution after transplantation. Such knowledge provides the framework for matching possible etiologic agents with the clinical syndromes noted during evaluation.[38,134]

INFECTIONS DURING THE PRE-ENGRAFTMENT PHASE

The pre-engraftment phase begins with the conditioning regimen, usually 7 to 10 days before the time of stem cell infusion, and continues to stem cell engraftment, usually 3 to 4 weeks after transplantation. Profound neutropenia is the major immune defect present during this stage of transplantation.[125,129,134] Evaluation of patients in this phase is similar to that of patients with neutropenia after chemotherapy.

Bacterial Infections

During the neutropenic period, bacterial infections are the most frequent infectious complication in HSCT recipients. These patients are at high risk for acquiring bacterial infection, similar to patients with cancer in whom chemotherapy-induced neutropenia develops.[25] Most infections result from invasion and colonization of the oral mucosa, gastrointestinal tract, or skin by the patient's endogenous flora.[109]

Catheter-related infections are common occurrences, and the spectrum of etiologic agents is similar to that in other chemotherapy-induced neutropenic patients. Among gram-positive organisms, *Staphylococcus aureus* and *Staphylococcus epidermidis* are isolated most frequently, with other gram-positive bacteria such as *Stomatococcus mucilaginosus* also being implicated.[70] Infection with *S. epidermidis* and other coagulase-negative staphylococci continues to occur as long as the central venous catheter remains in place.[32,42,115,123] Infection with viridans streptococci is associated with mucositis after chemotherapy and antibiotic prophylaxis with quinolones, and in some series these bacteria have replaced *Staphylococcus* spp. as the most common cause of bacteremia.[10,25,132,145,155]

Gram-negative bacterial infections develop after mucosal damage occurs as a result of translocation of bacteria from the intestinal lumen into the bloodstream. The organisms most frequently involved from this group are *Pseudomonas aeruginosa* and

the Enterobacteriaceae, including *Escherichia coli*, *Klebsiella* spp., and *Enterobacter* spp., although other gram-negative organisms have been identified. *Enterobacter* spp. are especially worrisome because they display a high rate of an inducible β-lactamase, which limits the effect of front-line drugs such as the cephalosporins.

Fungal Infections

Fungal infections, predominantly with *Candida* spp., occur frequently in this phase.[83] *Aspergillus* spp. represent the second most common fungal infection during this time.[77] Less frequently, infections occur with the agents of mucormycosis (*Mucor*, *Rhizopus*, and *Absidia* spp.), *Trichosporon* spp., *Fusarium* spp., and other saprophytic fungi.[100,157] Fungal infections generally occur after a period of antibiotic therapy and correlate with the degree and duration of neutropenia.[59,106,107,158]

Candida spp. colonizing the gastrointestinal tract disseminate after mucosal injury, usually between 2 and 4 weeks after transplantation. Seeding of the portal circulation leads to hepatosplenic candidiasis manifested as fever and hepatosplenomegaly. Ultrasound or computed tomography reveals multiple round defects in the liver and spleen ("bull's eye" lesions). Candidal infections also can involve the lungs, kidneys, and central nervous system, where they lead to meningitis or brain abscess.[83] Although *Candida albicans* is the most frequent *Candida* spp. causing candidemia, *Candida tropicalis* may be more aggressive.[59,158] Other *Candida* spp., including *Candida krusei*, have emerged as pathogens because of their resistance to the antifungal agent fluconazole, which is used as prophylaxis.[75,167]

Aspergillus spp., *Fusarium* spp., and the agents of mucormycosis use the respiratory tract as their portal of entry and generally are associated with sinopulmonary disease and dissemination to other sites, including the central nervous system.[1,15,37,52,106,107,113,176]

Viral Infections

Herpes simplex virus (HSV) infection usually is the result of reactivation in seropositive patients undergoing HSCT and is one of the most common viral infections in patients after HSCT.[97,164] Reactivation generally occurs in the form of oral and genital lesions. Oral lesions can be difficult to diagnose because lip involvement rarely occurs and the mucosal ulcers are similar to the mucositis caused by the conditioning regimen. HSV reactivation can be complicated by esophagitis, pneumonitis, and bacterial superinfection of skin lesions. Mortality is a rare event, and rapid diagnosis allows timely administration of therapy. The use of acyclovir prophylaxis in HSV-seropositive patients has decreased the incidence of this complication.[47]

Diarrhea after transplantation is related mostly to noninfectious causes, especially total-body irradiation, GVHD, and chemotherapy-related toxicity.[29,118] Viral gastroenteritis can occur throughout the transplant period. Etiologic agents to consider are rotavirus, coxsackievirus, and enteric adenovirus.[6,9,22,29,50,56,64,78] Generally, the enteric viruses are seasonal in their appearance. The course of these enteric infections can be very prolonged, especially with the adenoviruses. In approximately 5 percent of HSCT recipients, adenovirus infection develops and can become latent in lymphoid and renal tissue.[173] A recent study in adult transplant patients has shown that human metapneumovirus can occur during the pre-engraftment phase and cause upper and lower respiratory disease with high mortality rates.[44]

Hemorrhagic cystitis can occur throughout the transplantation period. This condition has several infectious and noninfectious causes (Table 80–3).[133] Chemotherapy-induced cystitis (e.g., high-dose cyclophosphamide) occurs soon after the conditioning regimen. Later in the transplantation period, GVHD can be a contributing cause. The most common infectious causes of hemorrhagic cystitis are adenovirus and the polyomaviruses BK or JC.[2,6,24,48,73] Adenoviral infections can be systemic with associated pneumonitis, hepatitis, and renal insufficiency.[64] Allogeneic transplantation and the use of total-body irradiation are risk factors for acquisition of adenovirus infection.[64] BK viremia has been shown to correlate with hemorrhagic cystitis by polymerase chain reaction (PCR) analysis.[48] Of note, shedding of polyomaviruses in urine may occur in as many as 44 percent of HSCT patients without any clinical symptoms. HSV and CMV also have been associated with hemorrhagic cystitis.

INFECTIONS DURING THE EARLY ENGRAFTMENT PHASE

The risk for infection decreases after stem cell engraftment occurs. However, severe abnormalities in host defense still exist. The general early immune functions, such as phagocytic and cytotoxic cells, recover first, followed by the cellular and humoral arms of the immune system.[121,134] Another factor that influences immunologic recovery is the presence of acute GVHD.

Bacterial Infections

Bacterial infections continue to occur in this phase as a complication of indwelling central venous catheters or as a complication of acute GVHD and are accompanied by skin and gastrointestinal tract breakdown. The same organisms that cause illness during the neutropenic phase can produce illness in this phase.[10,42]

Fungal Infections

Fungal infections still occur during this phase, with *Candida* and *Aspergillus* spp. being the prominent pathogens. Systemic candidal infections usually occur earlier than aspergillosis.[37,59,158] Fungal pathogens other than *C. albicans*, *Aspergillus fumigatus*, and *Aspergillus flavus* are increasing in prevalence.[125]

Development of brain abscess after HSCT usually occurs during this phase and, in contrast to immunocompetent hosts, is caused mainly by fungal pathogens. The most common etiologic agents of brain abscess in transplant recipients are *Aspergillus* and *Candida* spp. Despite initiation of aggressive antifungal and surgical therapy, the outcome of this complication after HSCT is very poor.[1,63]

In the past, *Pneumocystis jiroveci* pneumonia occurred in 5 to 10 percent of allogeneic HSCT recipients during this phase. However, the routine use of trimethoprim-sulfamethoxazole

prophylaxis has decreased its incidence significantly. Patients with *P. jiroveci* pneumonia usually have hypoxemia, dyspnea, cough, fever, and bilateral infiltrates.[154] The treatment of choice is trimethoprim-sulfamethoxazole.

Viral Infections

In the past, CMV infections predominated during this phase, but their incidence has decreased since the routine use of prophylactic ganciclovir was initiated. CMV infection generally occurs between 40 and 50 days after the transplantation. Most commonly, it results from reactivation in seropositive patients, but it also can occur in seronegative patients who receive their stem cells from a seropositive donor. The immunomodulatory effects of CMV infection, especially in a CMV-seronegative recipient of a CMV-seropositive donor, place the patient at high risk for developing bacterial and fungal infection.[112] The clinical manifestations of CMV infection vary from asymptomatic infection to the constellation of fever, hepatitis, and leukopenia to life-threatening diseases such as esophagitis, interstitial pneumonitis, and encephalitis.[46,175]

Pneumonia continues to be a common problem after HSCT, and the outcome still is poor.[40] Pulmonary infiltrates in an HSCT recipient must be distinguished from infectious processes or noninfectious pulmonary complications after HSCT (Table 80–4). Diffuse alveolar hemorrhage is manifested as gradually worsening dyspnea and repeated bloody aspirates from bronchoscopic examination.[69] Idiopathic interstitial pneumonitis is a process of widespread alveolar damage characterized clinically by varying degrees of respiratory failure and diffuse interstitial infiltrates in the absence of infection.[91] Idiopathic interstitial pneumonitis occurs in two peaks, one in the first few weeks and the other near the end of the early engraftment period. It is thought to be related to the chemotherapy and total-body irradiation used in the conditioning regimen and has a high mortality rate.

Viral respiratory infections may occur throughout the transplantation period but are more severe during the early engraftment period. Etiologic agents include respiratory syncytial virus, human parainfluenza viruses 1 to 4, influenza viruses A and B, adenovirus, rhinoviruses, and nonpolio enteroviruses.[64,66,165,166] Distinctive features of respiratory viral infections in immunocompromised hosts include a high frequency of nosocomial acquisition, prolonged persistence of infection, a higher rate of progression to pneumonia, and high mortality rate in association with the infection.[95]

Respiratory viral infections occur throughout the year in HSCT recipients, although seasonal variations in the type of respiratory viral infection are similar to those seen in the general pediatric population, with respiratory syncytial virus and influenza viruses predominating during the winter and human parainfluenza viruses during the spring and summer.[95]

The differential diagnosis of jaundice and increase in liver enzymes after HSCT is very broad (Table 80–5) and presents a challenge in distinguishing infectious from noninfectious causes of hepatic disease. Two major noninfectious causes of liver disease after HSCT are GVHD of the liver and hepatic veno-occlusive disease.[49,104] The latter is a complication related to the conditioning regimen and is characterized by weight gain, hepatomegaly, and direct hyperbilirubinemia without elevation of liver enzymes.[104] The differential diagnosis of infectious causes includes viral hepatitis with any of the hepatitis viruses from A through C, as well as other hepatotropic viruses such as CMV, EBV, adenovirus, HSV, and varicella-zoster virus (VZV).[51,64,80,84,147]

EBV can reactivate after HSCT and cause EBV-associated lymphoproliferative disease. This disease is manifested as fever, hepatosplenomegaly, and lymphadenopathy and can progress to lymphoma. These EBV lymphomas are of donor origin and can occur for as long as 6 months after HSCT.[94]

Protozoan Infections

Toxoplasmosis is an infrequent, but almost always fatal, infection after HSCT. It usually occurs 2 to 6 months after transplantation and in most cases is the result of reactivation of a previous infection. The brain is the organ most frequently affected. Cerebral toxoplasmosis is manifested as neurologic focal signs, fever, seizures, headache, and altered mental status. Imaging of the central nervous system typically shows multiple lesions in both hemi-

spheres and basal ganglia with peripheral enhancement after infusion of contrast medium.[102,103,141]

Dermatologic Manifestations

Rash is a common symptom after HSCT and can occur in any phase after transplantation.[99] The differential diagnosis is broad and includes both infectious and noninfectious causes (Table 80–6). Noninfectious causes include acute GVHD, chemotherapy-induced toxicity, and drug eruptions, most commonly caused by the β-lactam antibiotics used for empiric treatment of febrile neutropenia. Because the etiology of these lesions generally is indistinguishable on a clinical basis, skin biopsy is helpful in determining the diagnosis.

Infectious skin disorders after HSCT may be secondary to bacterial, fungal, or viral causes (see Table 80–6). Embolic lesions can be a manifestation of systemic bacterial or fungal infection, especially with *C. tropicalis*, *Aspergillus* spp., and *Fusarium* spp.[15,137] Lesions are tender and usually papular but can be purpuric, nodular, or necrotic and scattered on the trunk and extremities.

Primary infection with human herpesvirus type 6 after HSCT generally is associated with self-limited clinical symptoms, including a diffuse maculopapular rash. Asymptomatic reactivation with human herpesvirus type 6 appears to be a common occurrence after allogeneic HSCT. Human herpesvirus type 6 might have a possible role in pneumonitis, meningoencephalitis, and bone marrow dysfunction after HSCT.[23,26,81] Human parvovirus B19 is another cause of erythroderma after HSCT, as well as a rare cause of anemia.[138]

INFECTIONS DURING THE LATE ENGRAFTMENT PHASE

The late engraftment period is characterized by decreased risk for the development of infection, especially in autologous transplant recipients because they have more rapid recovery of immune function. During this phase, the central venous catheter usually is removed and immunosuppressive therapy to prevent GVHD is discontinued. Most recipients are outpatients at this point, and educating recipients and their families to avoid environmental exposure to opportunistic pathogens is very important.

Serious infections still can occur, particularly in patients with chronic GVHD or inadequate stem cell engraftment. Chronic GVHD predisposes patients to infection by delaying recovery of the immune system and its effects on target organs; in addition, the steroid therapy that patients receive likewise predisposes them to infection. Moreover, the cellular and humoral arms of the immune system are not recovered fully at this stage, thus placing the patient at risk for the development of infection. Most defects in immune function resolve by 1 year after transplantation.[114,131]

Drug-induced (e.g., β-lactam antibiotics)
Radiation for conditioning therapy

Bacterial Infections

Encapsulated bacteria, including *Haemophilus influenzae* type b, *Neisseria* spp., and *Streptococcus pneumoniae*, are the predominant causes of bacterial infection not related to catheters during this phase. These infections are secondary to deficient opsonization activity and decreased function of the reticuloendothelial system.[114]

Viral Infections

The predominant viral infection contracted during this period is caused by VZV, which occurs in 25 to 40 percent of pediatric HSCT recipients. Most infections represent reactivation, and risk factors include both acute and chronic GVHD, as well as allogeneic transplantation. VZV infection usually is characterized by localized vesicles in a dermatomal distribution. Disseminated infection occurs more frequently with VZV than with HSV, especially in patients with GVHD.[65,88,97]

DIAGNOSIS AND LABORATORY FINDINGS

The most important diagnostic evaluation is a complete physical examination because it can identify a site of infection that may be missed by laboratory tests. Sites requiring special attention include the skin, the oral mucosa to look for ulcers and thrush, the nares to look for necrotic lesions suggestive of invasive mold infection, the sinuses to look for tenderness, the chest, the abdomen, and the perianal area. All suspicious lesions should be cultured. Signs of infection may be subtle in patients who are neutropenic because inflammation is minimal.

The diagnostic approach should be guided by knowledge of which organisms are frequent pathogens during the specific phase after the transplantation (see Table 80–1). Except for microbiologic evaluations, laboratory tests are of limited value. Blood cultures for bacteria, fungi, and viruses should be obtained for any febrile episode. Use of the Wampole isolator blood culture system (Wampole Laboratories, Cranbury, NJ) may increase the yield of fungal pathogens and can help in establishing the diagnosis of central line infections by the use of quantitative cultures. Urine cultures are indicated in the presence of hemorrhagic cystitis or if the patient has a Foley catheter in place. Evaluation of cerebrospinal fluid should be reserved for patients with neurologic signs and symptoms.

Diagnosis of mold infections depends on tissue histology and culture of samples obtained by bronchoscopy, bronchoalveolar lavage, paranasal sinus washings, lung biopsy, or skin biopsy because these organisms are not recovered routinely from blood cultures. Recent improvements in antigen-based tests, including galactomannan and 1-3-β-D-glucan, allow establishing the diagnosis and noninvasive monitoring of antifungal therapy, although the false-positive rate appears to be higher in infected children than in adults.[144,149,174] Fungal surveillance cultures are not indicated for asymptomatic HSCT patients.[128] Additionally, Gram stain, acid-fast stains, and other special stains can be useful in identifying microorganisms early in the infectious process.

Nasopharyngeal swabs or washes for viral culture and direct fluorescent antibody testing are helpful for identifying respiratory viruses in patients with upper respiratory tract symptoms. Shell vial assay is a rapid viral diagnostic technique used for a

variety of viruses, including CMV, adenovirus, and respiratory viruses. The base of vesicular skin lesions should be scraped and the cells examined by direct fluorescent antibody stain with specific monoclonal antibodies to confirm the diagnosis of either HSV or VZV infection.

Nucleic acid detection, such as with PCR, has shown usefulness in the rapid diagnosis of certain pathogens, including adenovirus, CMV, EBV, human herpesvirus type 6, and parvovirus B19.[12,23,26,87] Additionally, quantification of viruses has allowed the response to therapy to be evaluated. Blood assays to detect viral antigens such as pp65 also have been used for establishing the diagnosis of CMV infection.[11,13]

Serologic testing is useful for diagnosing toxoplasmosis, *Bartonella henselae*, and fungal infections such as histoplasmosis and blastomycosis. However, serologic assays have limited value because patients are immunosuppressed and immunoglobulin therapy is administered to most patients.

Other laboratory tests are of limited value. Complete blood counts are useful to determine engraftment status. Liver and renal function tests can provide evidence of disease from an infectious agent or can indicate noninfectious causes of hepatic or renal disease such as chemotherapy or GVHD.

Performance of radiology studies should be based on assessment of the patient. A chest roentgenogram should be part of the work-up of a febrile, neutropenic patient and any patient with respiratory symptoms. Computed tomography scans of the paranasal sinuses, chest, and abdomen are helpful in evaluating and monitoring patients with invasive fungal disease.[37] Ultrasound examination can be used to diagnose abdominal problems such as typhlitis. Neuroimaging studies should be reserved for patients with neurologic signs and symptoms.

MANAGEMENT AND THERAPY

The initial management of HSCT recipients with fever and neutropenia is similar to that of cancer patients with chemotherapy-induced fever and neutropenia.[79,124,129] A standardized antibiotic regimen should be developed to ensure adequate coverage of organisms identified by the hospital's environment and to allow the hospital's staff to compare outcomes of patients. Empiric antibiotic therapy directed against the predominant pathogens should be started after obtaining appropriate samples for culture.[79] One approach consists of an empiric antibiotic regimen of ceftazidime with or without vancomycin, a combination that provides adequate therapy for gram-positive cocci and gram-negative bacteria. If *P. aeruginosa* is suspected, an aminoglycoside should be added. Other approaches using cefepime or quinolones have shown equal efficacy.[16,17]

The choice of any specific antimicrobial therapy should take into account the transplantation center's spectrum of organisms, the patient's surveillance isolates, and the antibiotic susceptibility pattern within the community and hospital. If fever persists after 3 or more days, re-evaluation of the patient may lead to modification of the antibiotic regimen.[79]

THERAPY FOR FUNGAL INFECTIONS

Empiric amphotericin B is recommended for the treatment of occult fungal disease in patients who remain persistently febrile after 5 to 7 days of antibiotic therapy, without identification of a bacterial cause.[79] The introduction of expanded-spectrum triazoles and cell wall–active agents such as echinocandins has changed the antifungal armamentarium.

Amphotericin B has been the traditional drug of choice for *Candida* infection, but recent data support the use of liposomal amphotericin B and itraconazole, which have similar clinical efficacy with reduced toxicity.[119,146,160,172] Voriconazole has become the agent of choice for the treatment of invasive aspergillosis in immunocompromised hosts.[33,71] Posaconazole, a triazole, will probably be the best option for the treatment of Zygomycetes. Caspofungin, an echinocandin active against *Candida* and *Aspergillus*, is available only in an intravenous formulation and probably is relegated to a second-line agent.[161] However, interaction with other drugs may impair its use in HSCT recipients. Combination therapy may be potentially antagonistic, but the efficacy of any of these combinations has not been established.[105] Fluconazole has activity against most *Candida* spp. and exhibits good penetration of the central nervous system.[40]

Surgery plays a prominent role in the treatment of mold infections, especially in neutropenic patients. However, the outcome of invasive mold infections in HSCT patients remains dismal.

THERAPY FOR VIRAL INFECTIONS

Treatment of viral infections is started once the diagnosis is established, if therapy is available. Acyclovir is the recommended therapy for both HSV and VZV infections. Famciclovir and valacyclovir also can be used to treat HSV infections, but they are available only for oral administration. CMV pneumonitis is treated with a combination of intravenous gamma-globulin and ganciclovir. In the case of acyclovir-resistant HSV or ganciclovir-resistant CMV infection, foscarnet is the drug of choice.[111] Cidofovir also has been used for CMV infection.[93]

Respiratory syncytial virus infections have been treated with aerosolized ribavirin and more recently with respiratory syncytial virus immunoglobulin.[34,35,45] Aerosolized ribavirin also has been used for the treatment of human parainfluenza virus infection.[41,45]

Intravenous ribavirin has been used for the treatment of adenovirus hemorrhagic cystitis, with anecdotal success.[20,53] More recently, cidofovir treatment of adenoviral infections has been associated with clinical improvement, as well as viral clearance in cultures and PCR analysis.[14,87,110,173]

The recommended therapy for infection with influenza A virus includes oral amantadine or rimantadine. Their efficacy, particularly in the treatment of severe disease, has not been established in immunocompromised hosts. Both drugs also are useful as prophylaxis for influenza A virus infection.[68] Zanamivir and oseltamivir, both neuraminidase inhibitors, appear promising for the treatment of both influenza A and B virus infection, but data are lacking regarding their use in pediatric immunocompromised patients.[68]

Adoptive immunotherapy by transferring virus-specific cytotoxic T lymphocytes to patients who have undergone allogeneic HSCT has proved to be useful in treating CMV and EBV infection and in reconstituting immune dysfunction selectively against these viruses.[72,130,162]

PREVENTION OF INFECTIONS AFTER TRANSPLANTATION

Measures to prevent infectious complications are a high priority for all HSCT recipients. Regular hand hygiene remains the best strategy for prevention of infections in HSCT recipients. Every HSCT recipient should undergo a dental evaluation before conditioning to assess oral health and any needed dental procedures should be performed to decrease the risk for the development of oral complications and infections after transplantation.[31,132] Strong effort should be made to enforce published guidelines for preventing indwelling catheter–related infections.[115,123]

The Centers for Disease Control and Prevention recently published extensive guidelines for the prevention of opportunistic infections in HSCT recipients that go beyond the scope of this chapter.[21] A brief review of preventive strategies, including

targeted antimicrobial prophylaxis, prevention of exposure, enhancement of immune reconstitution with colony-stimulating factors, and active and passive immunization, is presented here.

ANTIMICROBIAL PROPHYLAXIS

Antimicrobial prophylaxis must be weighed against the toxicity and the drug interactions of the prophylactic agent. Prophylaxis against *P. jiroveci* infection with trimethoprim-sulfamethoxazole is started after engraftment and is taken orally three times a week for 6 months after transplantation. For patients with intolerance to sulfa-containing medications, other options for prophylaxis include atovaquone, dapsone, or inhaled pentamidine.[90,98] Quinolone prophylaxis has been the major antibiotic class used to prevent bacterial infections, but breakthrough infections are problematic.[108]

Administration of fluconazole or itraconazole for 75 to 100 days after HSCT is associated with persistent protection against disseminated candidal infections and candidiasis-related death; in a randomized, placebo-controlled trial, these drugs resulted in an overall survival benefit in allogeneic HSCT recipients.[101,169] However, emergence of resistant pathogens such as *C. krusei* and some strains of *C. albicans* has complicated the routine use of fluconazole.[18] Low-dose amphotericin B is similar in efficacy to fluconazole in preventing fungal infections, but the latter is tolerated better.[171] The use of aerosolized amphotericin B to prevent *Aspergillus* infection needs further study.[74,140] In some centers voriconazole is used for prophylaxis.

Antiviral prophylaxis is indicated to prevent infections with herpesviruses during high-risk periods. Acyclovir has been used to prevent reactivation of HSV in seropositive transplant recipients during the neutropenic phase after transplantation. This strategy can reduce the incidence of reactivation of HSV in seropositive recipients from 80 to 5 percent during the first month after transplantation.

Strategies used to prevent CMV infection include prophylactic and preemptive therapy. Prophylactic therapy is administered to all recipients at risk for acquiring CMV infection and is used routinely for allogeneic transplant recipients when the donor is CMV-seropositive.[57,139] Ganciclovir is the agent of choice for prophylaxis of CMV infection.[57,58] Ganciclovir usually is given for 3 to 4 months after engraftment; however, its use has been associated with neutropenia.[57,135] Preemptive therapy is administered only to recipients who have evidence of CMV replication based on plasma PCR or pp65 antigenemia.[11,13] Primary CMV infection also can be prevented in CMV-seronegative HSCT recipients by transfusing blood products that are leukocyte filtered and seronegative for CMV.[148]

ISOLATION MEASURES

The use of laminar air flow protection for HSCT patients is controversial, and, although some studies have proved its effectiveness, it is very expensive.[39] HEPA filtration is associated with similar efficacy as laminar air flow in preventing airborne pathogens such as *Aspergillus* spp. Major indications for strict isolation of patients include colonization with resistant bacteria, viral respiratory infections, and disseminated VZV infection.[13,126]

COLONY-STIMULATING FACTORS

The use of granulocyte and granulocyte-macrophage colony-stimulating factors in stem cell transplant recipients is safe and effective in reducing the period of neutropenia after HSCT.[85,143,153] A meta-analysis of children receiving chemotherapy has shown a significant reduction in febrile neutropenic episodes, documented infections, and length of hospitalizations.[151] However, there has been a report of an increase in myeloid leukemia or myelodysplastic syndrome in patients with acute lymphocytic leukemia receiving granulocyte colony-stimulating factor.[127] These growth factors also appear to be safe and effective in transplant recipients who do not show engraftment 3 to 4 weeks after transplantation.

ACTIVE IMMUNIZATION

Immunizations should be part of the routine follow-up care of HSCT recipients. Most allogeneic and a large proportion of autologous and syngeneic transplant recipients lose their immunity to vaccine-preventable diseases. The degree that immunity is lost depends on multiple factors, including the donor's immunity, the type of transplant, the interval since the transplant, the presence of GVHD, and the use of immunosuppressive medication.[3] Moreover, transplant recipients are at increased risk for acquiring infections with encapsulated bacteria, such as *H. influenzae* type b and *S. pneumoniae*, for which vaccines are available.[7,55] For all these reasons, reimmunization of HSCT recipients between the first and second year after transplantation is very important.[92,142] When immunizing transplant recipients, recent administration of immunoglobulin must be kept in mind because it may interfere with the response to vaccinations.

An optimal schedule for administering vaccinations to pediatric patients after HSCT has not been established. Some experts will reimmunize HSCT recipients without performing serologic titers for specific antigens, such as diphtheria and tetanus, whereas others obtain titers 1 year after transplantation and provide vaccinations accordingly.[170] A schedule for immunization of HSCT recipients based on the recommendations of the Centers for Disease Control and Prevention Advisory Committee on Immunization Practices and the Infectious Diseases Committee of the American Academy of Pediatrics is presented in Table 80–7.[3,21] Specific recommendations probably will change as further data become available.

Immunizations can be started 12 months after HSCT as long as the patient has no persistent complications such as chronic GVHD and is not receiving immunosuppressive therapy. If the patient is younger than 7 years old, diphtheria and tetanus toxoids (DT) or diphtheria and tetanus toxoids with acellular pertussis vaccine (DTaP) can be used for diphtheria and tetanus.[120,156] For patients older than 7 years of age, immunization with DT at 12, 14, and 24 months after transplantation elicits an immune response.

H. influenzae type b vaccine is included in the first round of immunizations 12 months after HSCT. Boosters of these vaccines are given 14 and 24 months after transplantation.[7,62,122,156]

TABLE 80–7 Immunizations in Patients after Hematopoietic Stem Cell Transplantation

Recommended Time after HSCT	Immunizations
12 mo	Td,* IPV, Hib, pneumococcal, meningococcal hepatitis B
14 mo	Td, IPV, Hib, pneumococcal, hepatitis B
24 mo	Measles-mumps-rubella,† varicella, Td, IPV, Hib pneumococcal and hepatitis B

**DTaP or DT if the patient is younger than 7 years; Tdap if >11 years of age and indicated.*

†Do not use live virus vaccines for patients who have active chronic graft-versus-host disease or who are receiving immunosuppressive therapy.

Td and DT, diphtheria and tetanus toxoids; DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccine; Hib, Haemophilus influenzae type b vaccine; IPV, inactivated polio vaccine.

Immunization with the 23-valent pneumococcal vaccine is recommended 12 and 24 months after transplantation.[3,5,21] The second dose is not a booster dose but provides a second opportunity for immunization in patients who failed to respond to the first dose.[3]

The measles-mumps-rubella vaccine (MMR) should be given 24 months after transplantation to both autologous and allogeneic HSCT patients. It should not be given to patients with chronic GVHD or to those receiving steroids or any other form of immunosuppressive therapy.[82] The live attenuated varicella vaccine should be avoided in patients less than 24 months after HSCT.[3] Of note, a report using an inactivated varicella vaccine has shown efficacy in autologous transplant recipients.[67]

Only the inactivated polio vaccine should be given to HSCT patients. This vaccine should be administered 12, 14, and 24 months after transplantation.

The inactivated influenza vaccine (subvirion or purified surface antigen vaccines) should be given 6 months after HSCT and yearly thereafter in early autumn. Children younger than 9 years old who are receiving influenza vaccine for the first time require two doses given 1 month apart. Children younger than 12 years old should receive only split-virus influenza vaccine.[3,21,43,68] Live attenuated influenza vaccine should not be given.

Vaccination for hepatitis A is not recommended routinely but may be considered 12 months or more after HSCT for patients with chronic liver disease or chronic GVHD, for those living in areas endemic for hepatitis A, and for those in areas experiencing outbreaks. Hepatitis A immunization is given in two doses 6 to 12 months apart.[3,21]

Use of hepatitis B vaccine is unclear, but administration 12, 14, and 24 months after HSCT is reasonable with serologic follow-up.

Health care workers and household contacts of HSCT recipients should have immunity to or be immunized against hepatitis A, influenza, polio, measles, mumps, rubella, and varicella.[3,21,142]

PASSIVE IMMUNIZATION

Intravenous immunoglobulin commonly has been administered in the first months after allogeneic HSCT to prevent infections and acute GVHD and is approved by the Food and Drug Administration.[8,19,116] The use of intravenous immunoglobulin in conjunction with ganciclovir after transplantation has been shown to decrease the incidence of CMV pneumonia, as well as bacterial infections and interstitial pneumonia.[150,168] The optimal dose is not known. However, two meta-analyses have drawn divergent conclusions regarding the efficacy of intravenous immunoglobulin.[8,28,61]

The indications for passive immunization with specific immunoglobulin preparations, such as hepatitis B, rabies, and tetanus vaccines, in transplant recipients are similar to those in otherwise healthy individuals.[3,21] Patients with tetanus-prone wounds sustained during the first year after transplantation should be given tetanus immunoglobulin, regardless of their tetanus immunization status.[3] Passive immunization with varicella-zoster immunoglobulin is recommended for susceptible patients with known exposure to varicella.[3]

CHAPTER 81

Infections in Pediatric Heart Transplantation

Sheldon L. Kaplan

Each year in the United States, more than 350 children undergo heart transplantation,[66] and infection is an important cause of morbidity and some mortality in these patients. The Registry of the International Society for Heart and Lung Transplantation found that for children who underwent heart transplantation between 1992 and 2004, non-cytomegalovirus (CMV) infection was the cause of mortality in 14 percent of patients in the first 30 days after receiving transplants, peaked at 16.4 percent for 30 days to 1 year after transplantation, and thereafter accounted for 4.3 to 8.6 percent of deaths until more than 5 years after transplantation.[17] The Pediatric Heart Transplant Study Group prospectively collected data from 22 pediatric centers in the United States from January 1993 to December 1994 on 332 children younger than 18 years (mean age, 5.5 years) who had undergone heart transplantation.[123] One or more infections (276 total) occurred in 41 percent of the patients (mean follow-up time, 11.8 months) for an average of 0.84 infections per patient; 22 percent had one infection, 8 percent had two infections, and 11 percent had three or more infections during the study period (Table 81–1). In a similar multicenter study in adults who had undergone heart transplantation between January 1990 and June 1991, infec-

Data from Schowengerdt, K. O., Naftel, D., Seib, P. M., et al.: Infection after pediatric heart transplantation: Results of a multiinstitutional study. J. Heart Lung Transplant. 16:1207-1216, 1997.

tions developed in 31 percent of 814 patients, with 22 percent having one infection and 9 percent having two or more infections.[91] Bacterial infections were the most common type of infection occurring after transplantation in pediatric and adult patients.

Immunosuppressive therapy for children who have undergone heart transplantation usually consists of some combination of cyclosporine or tacrolimus, mycophenolate mofetil or azathioprine, and corticosteroids. Induction immunosuppression may include interleukin-2 receptor antibodies; OKT3 is now being used less frequently.[29,152] Cyclosporine and tacrolimus predominantly block the effect of interleukin-2 on T cells, an action resulting in a diminished T-cell response to mitogen stimulation.[53] The infections seen in heart transplant patients outside the postoperative period generally are a result of this block in T-cell function. Because the types of infections seen in these patients vary with the time elapsed since transplantation, this chapter is organized in such a manner.

PRETRANSPLANTATION EVALUATION

Several infectious agents may be transmitted to the patient via the transplanted organ or can become "reactivated" after transplantation. Determining the antibody status of the recipient and the donor against selected microorganisms (CMV, Epstein-Barr virus [EBV], *Toxoplasma gondii*) helps physicians anticipate or diagnose infections that develop after transplantation. A reasonable pretransplant evaluation for children is outlined in Table 81–2. The child's immunization status is documented, and vaccinations are completed when possible (i.e., hepatitis B vaccine or *Streptococcus pneumoniae*). The Committee on Infectious Diseases of the American Academy of Pediatrics recommends that for immunized children older than 12 months who are scheduled to undergo solid organ transplantation, serologic tests be performed for rubeola, mumps, rubella, and varicella to determine whether protective titers are present.[4] If possible, appropriate vaccines should be administered at least 1 month before the patient undergoes transplantation. Evidence of selected active infections is a contraindication for transplantation. Chemoprophylaxis should be considered strongly for children with a positive tuberculin skin test (purified protein derivative). Dental status also is assessed.

In addition to having the routine pretransplant evaluation as outlined in Table 81–2, each patient should be screened carefully for selected infections appropriate to the individual circumstances. If surgery is planned during the respiratory disease season and the patient has respiratory symptoms just before having surgery, screening for influenza virus or respiratory syncytial virus (RSV) by rapid techniques may facilitate prescribing antiviral therapy postoperatively. In areas where community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) is an important cause of infection, performing surface cultures to detect MRSA colonization may modify the choice of antibiotics used for surgical prophylaxis.[64] Applying mupirocin intranasally may influence the rate of postoperative MRSA infections.[98] Children from resource-poor countries may harbor *Salmonella* or intestinal parasites asymptomatically, and these organisms can cause serious infection after the child undergoes transplantation. Preoperative stool cultures for enteropathogens and examination of the stool for parasites may alert the clinician that these pathogens are present and could be the etiology of postoperative infections.

If the patient is being mechanically ventilated before undergoing transplantation, review of recent tracheal aspirate cultures may help in the selection of empiric antibiotics for initial treatment of suspected nosocomial sepsis or pneumonia. Pretransplant infections associated with procedures such as implantation of ventricular assist devices may require prolonged antibiotic therapy after transplantation is performed.[85,131] These infections typically are caused by common nosocomial pathogens and are not a contraindication to undergoing heart transplantation.

TABLE 81–2 Evaluation of Children before Heart Transplantation

Serology
Cytomegalovirus
Epstein-Barr virus

SURGICAL PROPHYLACTIC ANTIBIOTICS

Prophylactic antibiotics typically are administered to patients undergoing heart transplantation surgery. For each institution, selection of prophylactic antibiotics should be based partly on the organisms isolated from postoperative wound infections in that center and the antimicrobial susceptibility of these organisms. Cefazolin generally is a reasonable choice for prophylaxis, unless MRSA is a nosocomial pathogen of concern, in which case vancomycin is suggested.[20] In areas where MRSA is a common community pathogen, vancomycin or some other antibiotic active against MRSA might be considered instead of cefazolin, as determined by preoperative surveillance cultures. Routine use of extended-spectrum cephalosporins is discouraged because it may lead to colonization of the patient by antibiotic-resistant, gram-negative organisms that hyperproduce β-lactamase, such as *Enterobacter cloacae*. Recommendations for the duration of prophylactic antibiotic treatment in these patients are not definite, but some centers continue prophylactic antibiotics for 2 to 5 days or more postoperatively, or until all lines and chest tubes have been removed.

IMMEDIATE POSTOPERATIVE INFECTIONS

COMMON INFECTIONS

During the month after the patient undergoes heart transplantation, the types of infections encountered are the same as those complicating major thoracic surgery. Pneumonia and bacteremia are the most common postoperative infections. The frequency of bacteremia and the distribution of organisms are similar in children and adults after undergoing heart transplantation.[91,123] In a multi-institutional pediatric study, the risk of development of any infection was 25 percent 1 month after transplantation. Overall, 60 episodes of bacteremia occurred in the 136 patients who became infected, and the bloodstream was the most common site of bacterial infection.[123] Lung abscesses and mediastinitis are seen less frequently. Familiarity with the organisms and the antimicrobial susceptibility of isolates recovered from other children in the intensive care units (ICUs) in which these patients receive care helps direct the initial selection of empiric antibiotics.

Postoperative bacteremia is related predominantly to the indwelling lines required for monitoring and infusion of medica-

tion. *S. aureus*; coagulase-negative staphylococci; *Enterococcus* spp.; and gram-negative enteric organisms such as *Enterobacter* spp., *Pseudomonas aeruginosa*, *Klebsiella* spp., and *Escherichia coli* are the most common causes of nosocomial bacteremia in the pediatric ICU.[113] Other foci of infection, such as pneumonia or mediastinitis, also may result in bacteremia.[11,49] Vancomycin plus an aminoglycoside is a typical empiric antibiotic combination for suspected bacteremia in patients with central lines in place and without focal evidence of infection. Vancomycin therapy should be discontinued as soon as possible if an organism requiring the administration of vancomycin is not isolated.[110] A bacterial line infection may be eradicated successfully without removing the line, but the line should be removed if blood cultures remain positive or the patient's clinical condition deteriorates.[121] Fungemia, generally with *Candida albicans* or other *Candida* spp., also may be associated with line-related infections. Central lines complicated by fungemia should be removed immediately.[39] Centrally placed lines must be removed as soon as practical so that catheter-associated infections can be prevented.

As in other critically ill children, pneumonia is a particularly common occurrence in heart transplant patients because of the operative site and requirements for intubation and mechanical ventilation. During the first postoperative week, definite bacterial pneumonia developed in 3 of 22 children (14%) in an early study from Pittsburgh.[57] In the pediatric multi-institutional study, 56 bacterial lung infections were identified, 24 of which developed in patients maintained on a ventilator at the time of transplantation.[123] Nosocomial pneumonia caused by gram-negative bacilli such as *Pseudomonas* and *Enterobacter* or *S. aureus* is especially common in this setting.[113] Daily chest radiographs taken until the patient is released from the ICU may identify pneumonitis before it is clinically suspected. Gram stain and culture of a tracheal aspirate can help guide therapy for lobar pneumonia.

A broad-spectrum combination of antibiotics, such as an extended-spectrum penicillin with a β-lactamase inhibitor (i.e., piperacillin-tazobactam or ticarcillin-clavulanate) plus an aminoglycoside, usually is initiated until a pathogen or pathogens are identified. Empiric therapy should be based on the antibiotic susceptibility patterns of the common nosocomial pathogens in the specific ICU in which the patient is receiving care. Vancomycin also should be considered if MRSA is part of the resident flora in the ICU. Computed tomography (CT) of the chest may detect basilar and retrocardiac pneumonia, which may not be visualized readily by conventional chest radiographs. CT or ultrasound generally is helpful in assessing the size or characteristics of pleural effusions that may require drainage.

If interstitial pneumonitis is encountered, a more aggressive approach to determining an etiology is warranted. Bronchoscopy with bronchoalveolar lavage should be considered strongly. In children who have pulmonary infiltrates after undergoing heart transplantation, flexible bronchoscopy is more useful for establishing a fungal or viral etiology as opposed to a bacterial cause of pneumonia because most patients have received broad-spectrum antibiotics before undergoing the procedure.[140] Lavage fluid is pooled and processed for bacteria including mycobacteria, viruses, fungi, and protozoa by using culture techniques and special stains. *Legionella* may be an important consideration in some centers.[19,111] Noninfectious causes of pulmonary infiltrates in these children include pulmonary edema, atelectasis, hemorrhage, and adult respiratory distress syndrome.

Urinary tract infections (UTIs) also are common occurrences in the month after undergoing heart transplantation. Urinary catheterization and the immunosuppressive agents contribute to the risk for developing a UTI. Gram-negative enteric organisms (*E. coli*, *K. pneumoniae*, *P. aeruginosa*, and *Enterobacter* spp.), enterococci, and *Candida* spp. are isolated most commonly. Removal of the catheter as soon as possible minimizes the potential for development of a UTI, which has occurred in approximately 10 percent of adults. In the multicenter pediatric study, the urinary tract was the site of 16 bacterial infections.[123] In addition, UTIs developed in three children (14%) in Pittsburgh during the 2 to 3 weeks after undergoing transplantation.[57]

The broad-spectrum antibiotics used to treat the bacterial complications of transplantation promote *Candida* infection of the urinary tract. Along with removal of the urinary catheter, short-course intravenous amphotericin B for 10 days or less or fluconazole with careful dosing because of drug interactions with cyclosporine and tacrolimus is an option for treating candidal cystitis.[27,43,74,103] In some patients, a urine culture positive for *Candida* is a clue that a disseminated *Candida* infection is present and that further investigation is necessary to exclude the involvement of other organs, especially the kidneys.

Risk factors for early infection in the pediatric multi-institutional study were younger recipient age (particularly <6 months), mechanical ventilation at the time of transplantation, positive donor CMV serology with a CMV-negative recipient, and longer donor ischemic time.[123]

STERNAL WOUNDS AND MEDIASTINITIS

Sternal wound infections and mediastinitis occur in less than 5 percent of adult patients receiving modern immunosuppressive therapy for heart transplantation.[70,91,92] Most of these infections occur during the first postoperative month, usually within the first 2 weeks, and are superficial. Almost all are caused by bacteria. Staphylococci and other gram-positive bacteria generally are responsible for 50 percent of cases, and the remainder are caused by a variety of gram-negative bacilli.[94] Surgical wound infections developed in eight children in the pediatric multi-institution study, although the site of the infection was not noted.[123] Over a 15-year period, 15 (0.2%) children at Texas Children's Hospital, Houston, Texas, developed mediastinitis after undergoing cardiac surgery; 2 children had undergone heart transplantation.[144] At another children's hospital, between 1995 and 2003, 3 percent (5 of 165) of children undergoing heart and lung transplantation developed mediastinitis.[81]

Postoperative bleeding requiring re-exploration is a risk factor for development of mediastinitis. Fever, incisional pain, and an unstable sternum suggest mediastinitis; however, patients may have no specific evidence of infection, including fever. The white blood cell count may be elevated. A pericardial effusion frequently is detected with the development of mediastinitis, and pericardiocentesis may yield purulent material. CT of the chest may show a fluid collection or abscess within the mediastinum and can detect sternal osteomyelitis. Most cases of mediastinitis are caused by *S. aureus*, coagulase-negative staphylococci, or gram-negative bacteria. Median sternotomy wound infections after repair of a congenital heart lesion occur in less than 1 percent of children in large centers. Mediastinitis caused by gram-negative bacilli in association with pneumonia and bacteremia developed in 3 of the 22 children in the Pittsburgh series; each occurred within 2 weeks postoperatively.[57] Two of the three patients died. *Candida* spp. caused both cases of mediastinitis in the two children after heart transplantation. Long and colleagues[81] reported that the mediastinitis that developed in the five patients who had undergone heart and lung transplantation was caused by *E. coli*, *Torulopsis glabrata*, *Aspergillus fumigatus*, *Burkholderia cepacia*, vancomycin-resistant enterococcus.

A superficial median sternotomy wound infection not associated with an unstable sternum can be treated by local drainage of the infected subcutaneous tissue and administration of appropriate antibiotics.[34] Vacuum-assisted closure may be an important aid in addition to antibiotics.[1] A more aggressive approach is required for more serious infections associated with an unstable sternum, mediastinitis, or osteomyelitis of the sternum.[23,34,70]

Adequate drainage and débridement of the area are crucial, and any involved wires should be removed. Mediastinal drains usually are kept in place for several days. Some authorities recommend irrigating the drains with povidone-iodine, but the duration of irrigation is uncertain. A reoperation after the initial drainage procedure may be necessary. Pending culture results, antibiotic therapy is directed against *S. aureus* and gram-negative bacilli. A 4- to 6-week course of antibiotics usually is recommended. Antifungal therapy is initiated if a yeast or fungus is noted on Gram or special stains or isolated from cultures. Careful attention given to surgical technique to minimize postoperative bleeding and early withdrawal of chest and mediastinal tubes placed intraoperatively decrease the incidence of these potentially fatal infections.

OTHER INFECTIONS ENCOUNTERED DURING THE FIRST POSTOPERATIVE MONTH

Herpes Simplex

Herpes simplex infections of the oral mucosa and other superficial surfaces are common after heart transplantation. Oral herpes simplex was observed in 21 percent (11 of 53) of children undergoing transplantation at Stanford.[14] In the pediatric multiinstitutional study, only six episodes of herpes simplex infection were noted. Visceral involvement is unusual, although it may develop.[78] Herpes simplex infections typically occur approximately 13 days (range 0 to 4 months) after transplantation and are reactivation processes, not newly acquired infections.[107] A decrease in lymphocyte transformation in response to viral antigen in vitro may explain the increased rate of infection that occurs in the first 12 weeks post-transplantation. In a large randomized study comparing azathioprine with mycophenolate mofetil in adult heart transplant recipients who also were receiving cyclosporine and steroids, herpes simplex infection occurred more commonly in the group treated with mycophenolate mofetil (23% versus 16%, $p < .05$).[36] Institution of antiviral therapy for herpes simplex infection is warranted in these immunocompromised patients. The most common antiviral agent for herpes simplex is acyclovir, which can be administered orally or intravenously. Valacyclovir dosing in children has not been established, and a suspension is unavailable.

Some authorities recommend providing prophylactic acyclovir for heart transplant recipients who are seropositive for herpes simplex.[52] Acyclovir is given intravenously during the perioperative period and then orally for 30 days. Other physicians suggest that because labial or oral herpes simplex is treated so easily, a prophylactic approach is not warranted. In view of concern related to toxicity, drug interactions, and the possibility of resistance developing, I favor the approach that targets treatment after a mucocutaneous lesion is noted.

Legionella pneumophila

Legionella pneumophila infection should be included in the differential diagnosis for fever, respiratory symptoms, and pulmonary infiltrates that develop after heart transplantation.[25] *Legionella* pneumonia can develop during the first postoperative month, but the frequency with which this infection occurs varies among transplant centers. Although legionnaires' disease is an uncommon occurrence in children, nosocomial infections have been documented in a children's hospital, and immunosuppression is a risk factor.[19,22] Appropriate cultures and direct fluorescent antibody stains for *Legionella* should be performed on sputum, other respiratory secretions (obtained by invasive techniques), pleural fluid, or lung tissue to detect this pathogen in a timely fashion. A *Legionella* urinary antigen test is available for serogroup 1 antigens and is quite sensitive.[141]

Macrolides should be considered for empiric therapy if *Legionella* is a serious consideration in children with nosocomial pneumonia. Erythromycin or azithromycin is provided for 2 weeks to complete therapy. Macrolides interact with many of the immunosuppressive agents administered to these patients, however. Quinolones also are quite active against *Legionella* and avoid many of these interactions; in adult transplant patients, they have become the agents of choice.[141] The use of quinolones should be considered for pediatric organ transplant recipients in whom infection with *L. pneumophila* is suspected.[26] In hospitals caring for patients with transplants, routine surveillance culture of the hospital water supply is recommended.

Respiratory Syncytial Virus

Ten episodes of RSV infection were noted in the pediatric multiinstitutional study.[123] RSV can be acquired in the hospital soon after undergoing transplantation or can be acquired in the community before undergoing surgery or after discharge. Too few patients in whom RSV infection developed after they underwent heart transplantation have been described to comment on the clinical features. Two children in the early Pittsburgh study were noted to be infected with RSV, both infections occurring on postoperative day 10. Rapidly progressive patchy infiltrates on chest radiographs developed in one child after undergoing heart-lung transplantation, and the second child had only mild upper respiratory symptoms.[49] Tachypnea, cough, fever, wheezing, and the use of accessory muscles occurred commonly in the 18 pediatric liver transplant recipients from Pittsburgh with RSV infection.[106] Radiographic changes included interstitial and lobar infiltrates, atelectasis, and pleural effusion in 12 patients. Two patients required mechanical ventilation after the onset of symptoms related to RSV infection occurred; three others were intubated before acquiring RSV infection and subsequently had complicated courses.

Morbidity and mortality rates related to RSV infection are increased in otherwise immunocompetent children with congenital heart disease, especially when associated with pulmonary hypertension.[84] Because RSV can be acquired in the hospital, RSV infection should be considered in a young transplant patient with respiratory symptoms and fever, especially during the colder months.[59] RSV infection is documented by culture or by rapid detection of RSV infection by enzyme-linked immunosorbent assay or fluorescent antibody testing of respiratory secretions.

The decision to administer ribavirin to these patients is based primarily on the severity of the illness. In a small group of children with underlying bronchopulmonary dysplasia or congenital heart disease, aerosolized ribavirin seemed to be associated with more rapid improvement than that in patients given placebo.[60] Administration of aerosolized ribavirin to a heart transplant recipient with proved or suspected moderate to severe RSV infection is reasonable. As is the case with children requiring mechanical ventilation because of severe RSV lower respiratory tract infection, however, the efficacy of ribavirin in this situation is unknown.[137] The 2006 *Red Book* states, "A decision about ribavirin administration should be made on the basis of the particular clinical circumstances and the experience of the physician."[7,109]

The monoclonal antibody palivizumab was found to be safe, well tolerated, and effective in preventing serious RSV infections in young children with hemodynamically significant congenital heart disease in a large multicenter randomized, double-blind, placebo-controlled trial.[41] Although no specific recommendations have been made regarding the use of palivizumab in children who have undergone heart or other organ transplantation, it would be reasonable to administer it to children 24 months or younger after they undergo heart transplantation and especially postoperatively when the patient is stable.[102,108] The combination of ribavirin and RSV immunoglobulin has been administered to

pediatric bone marrow transplant recipients with RSV lower respiratory tract infection.[31] The outcome in these patients was improved over that of historical controls, but no randomized trials have been conducted. RSV immunoglobulin was not efficacious in treating RSV lower respiratory tract infection in children with congenital heart disease who were younger than 2 years.[114] Although palivizumab reduced the concentration of RSV in the tracheal aspirates of children with respiratory failure caused by RSV, its efficacy in treatment is unknown.[86]

INFECTIONS BETWEEN THE FIRST AND SIXTH POSTOPERATIVE MONTHS

CYTOMEGALOVIRUS

CMV is the virus that most frequently infects immunosuppressed cardiac transplant patients. Asymptomatic or symptomatic infections are noted most commonly between the first and sixth months after undergoing transplantation and rarely after the seventh month. In adult series, 12 to 90 percent of patients had evidence of CMV infection postoperatively.[33,55,91] In the multiinstitutional pediatric study, 51 episodes of CMV infection occurred in 332 patients and accounted for 60 percent of the viral infections, with a peak occurrence in the second month after transplantation.[123] CMV infection occurred more frequently in older children than in infants. In another study, infants younger than 120 days had CMV infection and disease less commonly than did infants older than 120 days after undergoing heart transplantation.[46] Maternal antibody to CMV may have been protective in the younger infants. In the Pittsburgh series, seven children (32%) had CMV infections, with onset occurring at a mean of 33 days post-transplant (range 23 to 43 days).

CMV infection in transplant recipients occurs in three or four possible settings. In a seronegative recipient, primary CMV infection is acquired through the transplanted heart, through blood transfusions from seropositive donors, or from the community. Seropositive recipients can have reactivation of latent CMV infection or be re-infected with a second strain of CMV from the heart or from blood products derived from seropositive donors.[24] The exact site within the donor heart where CMV may reside in a latent form is unknown, but it may be either cardiac cells or leukocytes that remain within the donor heart. When primary CMV infection is acquired from the donor organ, CMV disease tends to be more severe than if CMV infection is acquired from blood or blood products.[155]

Several risk factors for development of CMV infection after undergoing organ transplantation are recognized. Donor and recipient serologic status and the immunosuppressive regimen are the most significant risk factors for acquiring CMV infection after undergoing heart transplantation. Gorensek and colleagues[55] found that positive recipient CMV serology before transplantation and a larger than average dose of corticosteroids were significant risk factors for acquiring CMV infection. Among the group of patients with CMV infection, positive recipient serology was associated with asymptomatic infection, and excessive steroid dosing was a risk factor for acquiring symptomatic CMV infection. CMV tissue invasion occurred more commonly in patients receiving mycophenolate mofetil compared with azathioprine.

The clinical manifestations of CMV infection vary. Patients may seroconvert, or a latent infection may be reactivated, as determined by positive cultures, but these patients have no symptoms attributable to the CMV infection. Fever, leukopenia, and thrombocytopenia are common postoperative manifestations of systemic CMV infection. Patients may complain of arthralgias, myalgias, and nonspecific abdominal pain. Atypical lymphocytes are noted more commonly in adult than pediatric patients. CMV infection can cause hepatitis, pneumonitis, retinitis, myocarditis, and gastrointestinal disease, including colitis.[33,40,42,54,55,69,130] The retinitis may be asymptomatic or associated with complaints such as floaters or scotomata. Ophthalmologic screening for CMV retinitis is recommended for all patients 3 to 4 months after cardiac transplantation.[42]

Of the tissues invaded by CMV, involvement of the lung leads to the greatest mortality rate—13 percent in one study.[73] CMV pneumonitis is characterized by fever, hypoxemia, and, usually, diffuse interstitial infiltrates, although lobar consolidation may occur.[129] Pulmonary infections with other viruses or with bacteria or *Pneumocystis carinii* and other pathologic processes (infarction) may coexist with CMV pneumonitis. Gastritis, gastric ulceration, duodenitis, esophagitis, pyloric perforation, and colonic hemorrhage can be documented by endoscopy. In the multiinstitutional pediatric study, the lung or gastrointestinal tract was the site of CMV infection in 13 (lung) and 6 (gastrointestinal tract) episodes.[123] Death related to CMV in the pediatric study occurred in 6 percent. In the 2005 Heart Transplant Registry report, CMV accounted for 2.5 percent of deaths in the 30 to 365 days after transplant, 0.5 percent of deaths 1 to 3 years after transplant, and zero deaths after 3 years.[17]

The diagnosis of CMV infection can be based on changes in antibody titer to CMV in paired sera run in parallel with the use of established tests or on changes in CMV IgM results. Isolation of CMV or detection of CMV DNA from a variety of sources, such as urine, blood, bronchial washings, or tissues, also establishes that CMV infection is present. In a seronegative recipient, the possibility of active CMV infection can be anticipated by periodic monitoring of CMV serology and cultures. Whether the CMV infection is causing a symptomatic or invasive illness is more difficult to establish. Histopathologic evidence of CMV infection, such as typical viral inclusions or detection of antigen in tissue by special stains, is required to confirm organ involvement by CMV, although this criterion often is not considered a requirement for clinical trials of preventive measures for CMV disease. Cultures of the buffy coat are positive more frequently in patients with symptomatic than in patients with asymptomatic CMV infection; in patients with primary CMV infection and lung involvement, CMV cultures tend to be positive earlier in the postoperative period than in patients who do not have lung involvement.[55] CMV antigen-positive leukocytes detected by monoclonal antibodies to the early antigen of CMV were found 10 to 28 days before increases in CMV antibody occurred in five patients with active CMV infection.[148] Polymerase chain reaction (PCR) can detect DNA from CMV in blood and other tissues readily and with great sensitivity.[45] The antigen and PCR techniques have been used for early detection of CMV infection so that preemptive antiviral therapy can be initiated.[35]

In addition to the CMV infection syndromes, CMV infection itself seems to affect the transplant recipient adversely in other ways. Symptomatic or asymptomatic CMV infection is associated with a higher rate of graft rejection or graft loss, a greater risk of development of fungal infection, more frequent and earlier graft atherosclerosis, and a significantly lower survival rate than occur in patients who do not have CMV infection.[45,116] In the multiinstitutional study, CMV-positive donor serology in conjunction with CMV-negative recipient serology was a risk factor for the acquisition of earlier infection with any organism.[123]

CMV infection of the wide variety of cells that it invades leads to the activation of protein synthesis and the production of multiple immunologically active molecules, including cytokines, especially tumor necrosis factor-α, which adds to the immune deficits induced by the immunosuppressive agents.[45,75] Allograft injury or rejection may be associated with CMV infection of the transplanted organ itself.[45]

Successful treatment or suppression of visceral CMV disease by ganciclovir, a nucleoside analogue active in vitro against CMV, requires a timely diagnosis. Ganciclovir has been shown to alter

CMV disease favorably in heart transplant patients, along with allowing a reduction in immunosuppressive therapy, when possible.[71] The standard approach for treating symptomatic CMV infection is administration of 2 to 3 weeks of intravenous ganciclovir, although the optimal duration of this therapy and the need for maintenance oral doses are unclear.[117] The dose is 5 mg/kg every 12 hours with careful monitoring of hematologic parameters and renal function if renal function initially is normal. Modification of the dose is necessary if renal function is impaired. Viremia should be cleared before discontinuing therapy.[45] The most common adverse reactions to ganciclovir are neutropenia, thrombocytopenia, impaired renal function, seizures, and other central nervous system (CNS) abnormalities.

The role of CMV hyperimmunoglobulin in treating CMV infection in these patients requires further study. After bone marrow transplantation, the addition of CMV immunoglobulin to ganciclovir may be superior to ganciclovir alone in treating CMV pneumonia.[38,112]

In one pediatric study, symptomatic CMV disease developed in five children after they had undergone heart transplantation; each had blood cultures and PCR positive for CMV.[48] Four were treated with ganciclovir for 14 days; one received ganciclovir for 30 days. All received CMV-IgG (150 mg/kg) weekly for 3 weeks. Symptomatic CMV disease was treated successfully in each case.

If possible, prevention of CMV infection in heart transplant recipients is optimal. Only seronegative blood should be used for transfusions when the recipient and the donor are seronegative. Careful control of immunosuppressive therapy, especially with corticosteroids, may help avoid the acquisition of some infections. In the situation of a seronegative recipient of a heart from a seropositive donor, prophylactic administration of CMV immunoglobulin may be useful in some patients. In one study involving the prevention of CMV disease, ganciclovir was compared with CMV immunoglobulin (misoprostol [Cytotec]) in 31 CMV-seropositive heart transplant recipients in whom OKT3 monoclonal antibody was used for early immunoprophylaxis.[2] CMV disease and visceral involvement occurred more frequently in the group given CMV immunoglobulin (40%) than in the group given ganciclovir (6%; $p = .03$). CMV-IgG would be expected to be more beneficial in recipients who are CMV-seronegative.

In one large randomized double-blind, placebo-controlled trial of CMV-seropositive transplant recipients, ganciclovir significantly reduced the incidence of CMV illness during the first 120 days after heart transplantation (9% versus 46% in controls, $p < .001$).[89] No differences were noted between the study groups for seronegative recipients. Combining ganciclovir and CMV-IgG for prophylaxis of high-risk seronegative recipients of hearts from seropositive donors has resulted in mixed findings. Avery[11] found that the combination was not particularly effective; symptomatic CMV syndrome developed in 50 percent of patients. Garjarski and associates[48] provided CMV-IgG (150 mg/kg intravenously at weeks 0, 2, 4, 6, and 8 and 100 mg/kg intravenously at weeks 12 and 16) plus ganciclovir (5 mg/kg every 12 hours intravenously for weeks 1 and 2 and 6 mg/kg/day intravenously at weeks 3 and 4) to 19 children who were recipients of heart transplants from CMV-seropositive donors. CMV disease occurred in 3 of the 10 children who were CMV-seronegative and in 1 of the 10 recipients who were seropositive. Adverse effects of these agents were not reported.

In the study from Stanford, high-risk recipients received CMV-IgG immediately after undergoing transplantation (150 mg/kg administered within 72 hours after transplantation, followed by 100 mg/kg at weeks 2, 4, 6, and 8 and 50 mg/kg at weeks 12 and 16).[146,147] In addition, ganciclovir was administered intravenously immediately after transplantation at a dose of 5 mg/kg every 12 hours for 14 days, followed by 6 mg/kg/day for the next 2 weeks. These patients were compared with a historical control group at the same institution that received ganciclovir in the 2 to 3 years before CMV-IgG was used. The 27 recipients treated prophylactically with ganciclovir and CMV-IgG had a higher disease-free incidence of CMV, a lower incidence of rejection, and a higher survival rate than those of the historical cohort treated with ganciclovir alone. The combination looks promising for prevention of CMV disease in high-risk heart transplant recipients but requires a randomized trial before the combination can be recommended routinely.

CMV resistant to ganciclovir may emerge as a result of ganciclovir prophylaxis or treatment.[13] Foscarnet or cidofovir is an alternative agent in this situation.

In a meta-analysis of CMV prevention strategies for post-transplantation CMV disease, Small and associates[136] concluded that universal prophylaxis and preemptive approaches are equally effective in reducing the incidence of CMV disease.

EPSTEIN-BARR VIRUS

EBV may cause a spectrum of diseases, including a mononucleosis-like syndrome, polyclonal lymphoproliferation, or monoclonal lymphoproliferation, usually of B cells, in pediatric heart transplant recipients. The transplanted organ is thought to be the most frequent source of EBV. Post-transplantation lymphoproliferative disorders (PTLDs) refer to B-cell expansion that may be localized, nodal, extranodal, or widely disseminated. The largest series of children who have undergone heart transplantation is from Pittsburgh; in this series, PTLD developed in 7.7 percent (6 of 78) of pediatric heart transplant recipients.[18] A major risk factor for the subsequent development of PTLD was being seronegative for EBV before undergoing transplantation. PTLD developed in one third of seronegative recipients of thoracic organs who acquired primary EBV infection (10 of 30). PTLD developed in none of the children who were seropositive before transplantation. Almost all these cases occurred within 1 year of transplantation.

In another series, 19 children were EBV-seropositive and 31 were EBV-seronegative before undergoing heart transplantation. PTLD developed in 1 of 19 patients who were seropositive before undergoing transplantation and in 12 of 19 who became seropositive after transplantation.[157] It did not develop in any of the 12 recipients who remained EBV-seronegative. In contrast to the Pittsburgh experience, the mean time to confirmation of PTLD was 29 months (range 3 to 72 months).

Webber and associates[153] reviewed the experience with PTLD after heart transplantation among 1184 primary organ recipients in 19 centers from 1993 to 2002. Fifty-six patients (5%) developed PTLD a mean of 23.8 months post-transplantation.

Symptoms of PTLD may include fever, malaise, sore throat, and lymphadenopathy. Some children may have splenomegaly, CNS symptoms such as lethargy or seizures, or gastrointestinal complaints.[15,18] Concurrent opportunistic infections are common. Nodules in the lung may be noted on chest radiographs.

The diagnosis of PTLD requires biopsy of involved tissue showing lymphoid proliferation with an immunoblastic component. Molecular techniques typically detect EBV nucleic acids in tissue. EBV serology also is helpful. Quantitative measurement of EBV DNA and RNA in peripheral blood is used to detect primary infection or reactivation at a very early time point and to monitor viral loads serially over time to detect PTLD in the most timely manner.[115] When reported as EBV copies per 10^5 peripheral blood lymphocytes, patients with PTLD typically have viral loads between 500 and 5000, which are much greater than the loads detected in normal latency.

Management generally involves decreasing the immunosuppressive regimen or discontinuing it temporarily. Anti-CD20

antibody (rituximab) is a commercially available monoclonal antibody that specifically binds to the CD20 antigen of normal and malignant B cells and results in antibody-dependent and complement-dependent cytotoxicity. Rituximab has been administered to children with PTLD after they have undergone solid organ transplantation, with some success.[126] Antiviral therapy with acyclovir or ganciclovir also is administered. Some centers administer ganciclovir, acyclovir, or intravenous gamma-globulin for prevention of PTLD, although no prospective studies have confirmed that such an approach is efficacious.[56]

TOXOPLASMA GONDII

An increased incidence of toxoplasmosis is apparent in recipients of heart transplants compared with other organ transplants, although it remains an uncommon infection after heart transplantation.[138] In the pediatric multi-institutional study, toxoplasmosis was not mentioned. *T. gondii* has a predilection for muscle and can be transmitted to the recipient from the heart of a seropositive donor. Active *T. gondii* infections may occur in donor hearts.[118] Less commonly, reactivation of old infection occurs in the recipient. The greatest risk for acquisition of toxoplasmosis occurs in a seronegative recipient of a heart from a seropositive donor. Clinical symptoms usually develop after the first postoperative month and generally within 3 months of transplantation.[61,83,90] Fever alone may be the only clinical manifestation. Dissemination of the parasite to the CNS may lead to signs and symptoms of meningoencephalitis, such as lethargy, seizures, coma, and hemiparesis. Chorioretinitis may result in diminished visual acuity. A sepsis-like picture, pneumonia, and cutaneous lesions are unusual manifestations.[10]

CT or magnetic resonance imaging of the brain may detect ring-enhancing mass lesions, which typically are multiple and in periventricular locations. Definitive diagnosis of CNS toxoplasmosis requires the demonstration of tachyzoites or cysts in tissue by biopsy or at necropsy. Serologic tests help monitor seronegative patients for seroconversion and allow a more aggressive approach to be taken to the early diagnosis of toxoplasmosis.[135] *T. gondii* has been seen on endomyocardial biopsy specimens routinely obtained to monitor for rejection.[82]

Therapy for toxoplasmosis with pyrimethamine and sulfadiazine may lead to recovery; these drugs also should be administered if the patient seroconverts.[47] Prophylactic administration of pyrimethamine to seronegative recipients of hearts from seropositive donors is recommended.[156] Prophylactic trimethoprim-sulfamethoxazole also seems to be protective in this high-risk situation.[12,94] Spiramycin is not a useful prophylactic agent.[135]

ASPERGILLUS FUMIGATUS

A. fumigatus is the non-*Candida* fungal infection most commonly reported outside the immediate postoperative period in most series and may be noted first at necropsy.[104] In an early Stanford series, *Aspergillus* infections (four pulmonary, four disseminated) occurred in 8 of 72 (11%) cyclosporine-treated patients 12 to 45 days postoperatively.[65] In a follow-up report, 54 *Aspergillus* infections developed in 620 consecutive heart transplant recipients between 1980 and 1996.[94] Most commonly, *Aspergillus* infections were in the lung (n = 31) or were disseminated (n = 17). The median time to onset was 52 days. Disseminated aspergillosis was the most common infectious episode responsible for the highest mortality rates in this series. One child in Pittsburgh had disseminated aspergillosis.[57] In the multi-institutional study, seven non-*Candida* fungal infections occurred: *Aspergillus* spp., two; *Cryptococcus*, *Rhizopus*, and *Rhizomucor*; one each; and unspecified, two.[123] All patients with disseminated infection died.

CNS invasion occurs in many patients with pulmonary aspergillosis, and aspergillosis is the most common cause of brain abscess in organ transplant recipients.[61,93,133] Alterations in mental status occur most frequently, and seizures may occur in 40 percent of cases. On CT scans of the head, multifocal lesions are seen commonly and show a predilection for the junction of the gray and white matter. Mediastinitis and endocarditis are other manifestations of invasive aspergillosis.[79,127] Although isolation of *Aspergillus* from respiratory secretions in a patient with pneumonitis does not establish a diagnosis, aspergillosis is so difficult to establish firmly and is so frequently fatal that treatment should be considered seriously based on this culture alone.

Voriconazole is the agent of choice for invasive aspergillosis.[63] The prospective administration of the combination of voriconazole and caspofungin has been found to be superior to liposomal amphotericin B in historic control solid organ transplant patients with invasive aspergillosis.[134] Itraconazole should not be used for aspergillosis in heart transplant recipients now that superior agents are available.[96] Caspofungin alone also may be beneficial in some patients.[9] Performing surgical drainage and débridement is important for managing most infections.[24] Some type of drainage procedure is indicated if CNS aspergillosis is documented or suspected, although the response to therapy with amphotericin B generally is dismal. In some centers, inhalation of aerosolized amphotericin B (20 mg in sterile water three times per day) has been used prophylactically throughout the hospital stay to prevent the acquisition of invasive aspergillosis.[81] Liposomal amphotericin B may provide an alternative therapy for patients failing treatment with or intolerant of conventional amphotericin B for other mycoses.[37,150]

INFECTIONS AFTER THE SIXTH POSTOPERATIVE MONTH

NOCARDIA ASTEROIDES

A dry cough, fever, and the presence of a solitary pulmonary nodule or abscess on a chest radiograph are characteristic of infection with *N. asteroides*.[77,132] Although pulmonary nodules are characteristic of *Nocardia*, *Aspergillus* and CMV can be associated with nodules as well.[95] Some patients are asymptomatic despite having an abnormal chest radiograph. Infection with *Nocardia* was noted in only 3 percent of cyclosporine-treated patients in the early Stanford series.[65] The median time to the onset of infection was 225 days. A similar incidence of lung nodules or masses secondary to *Nocardia* was noted in a series from New York.[62] In the follow-up Stanford series, 23 episodes of *Nocardia* infection (3.7%) occurred, 19 in the lung.[94] The median onset of infection in the second series was 147 days. *Nocardia* infections are rare in pediatric heart transplant recipients.

Nocardia is isolated best from direct lung tissue specimens, but it may be cultured from bone, skin, or other sites of involvement as well. If a cutaneous skin lesion of *Nocardia* is recognized, other sites should be evaluated promptly for involvement.[51] The formation of single or multiple abscesses in the CNS may result from hematogenous dissemination.[61] Seizures may develop after invasion of brain parenchyma.

The drug of choice for treating *N. asteroides* infection is a sulfonamide. Prolonged administration (average 10 months) generally leads to clearing of the pulmonary lesions. Minocycline is an alternative therapy.[105] The incidence of *Nocardia* infection has declined with the introduction of routine prophylaxis with trimethoprim-sulfamethoxazole.

PNEUMOCYSTIS CARINII

P. carinii pneumonia has been reported in approximately 3 to 4 percent of heart transplantation recipients during the post-cyclosporine era.[44,58,65] In the multi-institutional study, *P. carinii* was noted in seven children (2.1%).[123] Fever, a nonproductive cough, and tachypnea are typical symptoms; hypoxemia is characteristic. The chest radiograph classically shows a diffuse interstitial infiltrate that can progress rapidly. The most expeditious method of documenting *P. carinii* pneumonia in children is methenamine silver or specific antibody staining of fluid or tissue obtained by bronchoalveolar lavage or lung biopsy. Co-infection with CMV or other pathogens occurs commonly.

Treatment of *Pneumocystis* pneumonia in a pediatric heart transplant recipient is identical to that for other immunocompromised children. Use of trimethoprim-sulfamethoxazole prophylaxis for at least 4 months after transplantation has decreased markedly the incidence of this infection in recipients of heart transplants.[100]

STREPTOCOCCUS PNEUMONIAE

S. pneumoniae is an important community-acquired pathogen in heart transplant recipients, who are at increased risk for acquiring this organism.[3] In the multi-institutional pediatric study, two episodes of pneumococcal infection were recorded.[123] During a 10-year period, 9 (11%) of 80 cardiac transplant patients in Little Rock, Arkansas, had 12 episodes of pneumococcal bacteremia.[142] Over an 11-year period, 4 of 105 children undergoing heart transplantation in Toronto had systemic pneumococcal infections.[145] In the follow-up series from Stanford, seven pulmonary infections with *S. pneumoniae* were reported.[94] In an eight-center pediatric surveillance study spanning 5 years, pneumococcal infection developed in 10 patients after a median time from transplantation of 17 months (range, 5-76 months).[125] Three of the 10 patients had two episodes, and one patient had three episodes of pneumococcal infection. The median age of the 10 patients at the time of the first pneumococcal infection was 26 months (range, 15-89 months). The pneumococcal serotypes of the isolates from these patients were the same as noted in healthy children and generally would be covered by the 23-valent pneumococcal vaccine or the 7-valent pneumococcal conjugate vaccine.

OTHER VIRUSES

Influenza and parainfluenza viruses can cause serious infections at any time after transplantation, but especially in the immediate postoperative period.[8,87] Additional risk factors for development of severe disease leading to death are young age and augmentation of immunosuppression. Fever, cough, rhinorrhea, and pharyngitis are typical symptoms of upper respiratory infections. More serious manifestations include adult respiratory distress syndrome; a requirement for intubation and mechanical ventilation; a sepsis-like picture; or CNS symptoms such as headache, photophobia, and lethargy. Viral infection may enhance the likelihood of allograft rejection occurring.

For influenza A infection, oseltamivir, amantadine, or rimantadine should be considered in younger children older than 12 months of age with a heart transplant because of their enhanced predisposition for severe or complicated influenza infection.[5] In older children, zanamivir or oseltamivir is indicated. Experience with these agents in patients with solid organ transplants is limited, however.[119] Early antiviral treatment of influenza in bone marrow transplant recipients was associated with decreased progression to pneumonia and shortened viral shedding in one study.[97]

Parvovirus B19 infection is recognized to cause severe anemia associated with low or no reticulocytes in recipients of heart transplants, similar to the red blood cell suppression in other immunosuppressed patients.[99] In one child, severe pneumonia developed in association with fever and a blanching maculopapular rash involving the face, trunk, and extremities.[68] The parvovirus B19 genome also has been detected in myocardial biopsy specimens of children experiencing cardiac allograft rejection. Of six children described in one report, one had a diffuse rash and two had persistent rejection despite receiving aggressive therapy.[124] In a series of children from Loma Linda who underwent myocardial biopsy for possible rejection, parvovirus genome was detected in 5 of 553 biopsy samples taken from 149 children.[128] Intravenous immunoglobulin is beneficial for the treatment of anemia related to parvovirus B19, but its efficacy in treating pneumonia or possible allograft rejection is unknown.

Varicella virus infection remains a common childhood illness that can cause life-threatening disease in immunocompromised children. In a group of 28 children younger than 10 years old at the time of undergoing heart transplantation who had been monitored for at least 1 year between 1986 and 1999, 14 cases of primary infection with varicella-zoster virus were identified.[32] The mean time post-transplant was 3 years (range, 9 months to 7.5 years). All children were seronegative at the time of transplantation. These children were treated successfully with either parenteral followed by oral acyclovir or oral valacyclovir (mean dose 77 mg/kg/day) for 7 days. Only one child had recurrent varicella, and none had zoster. Routine administration of varicella vaccine to young children helps to decrease most concerns about varicella developing after organ transplantation because of herd protection. Some patients do lose serologically measured immunity to varicella after undergoing transplantation, although the significance of this loss is unclear.[151]

Adenovirus has been associated with serious infections after solid organ transplantation. Among 28 children with solid organ transplants (9 heart) and adenoviral infections, the most common symptoms were fever, diarrhea, vomiting, and abdominal pain.[28] Infection occurred a median of 1.6 months after transplantation. Only two of these patients received antiviral therapy, and all survived the infection. Cidofovir may be beneficial in some patients with disseminated infection, especially of the lungs, or increasing viral loads determined by PCR.[66]

IMMUNOSUPPRESSIVE AGENTS AND ANTIBIOTICS

Cyclosporine and tacrolimus have improved the success of organ transplantation considerably. Generally, the incidence of infection seems to be less since the introduction of cyclosporine than with the earlier immunosuppressive regimens, although morbidity and morality rates remain high in heart transplant recipients.[62] Cyclosporine serum levels are monitored carefully to ensure that concentrations associated with optimal immunosuppression and minimal adverse effects are maintained. Some antibiotics interfere with the pharmacokinetics of cyclosporine or tacrolimus, which may lead to an increase or decrease in their levels.[21,76,101,120,122,139,143] Table 81–3 outlines these interactions. Because cyclosporine and tacrolimus are nephrotoxic, the antimicrobial agents (amphotericin B, aminoglycosides, acyclovir, ceftazidime) administered to heart transplant recipients may be additive; renal function must be monitored carefully.

TABLE 81–3 Effect of Various Antibiotics on Cyclosporine/Tacrolimus Levels

Increase Cyclosporine/Tacrolimus Level	Decrease Cyclosporine/Tacrolimus Level
Clarithromycin	Sulfadiazine
Azithromycin	Rifampin
Erythromycin	Trimethoprim-sulfamethoxazole
Ketoconazole	? Nafcillin
Fluconazole	? Isoniazid
Voriconazole	? Ciprofloxacin (counteracts immunosuppression)
Itraconazole	
Caspofungin	

IMMUNIZATIONS

No specific guidelines exist for the immunization of children after they have received a heart transplant, although studies examining the immunogenicity of selected vaccines in this population are being conducted. A prudent approach is to follow the recommendations that the Committee on Infectious Diseases of the American Academy of Pediatrics has developed for immunizing immunosuppressed children.[4] Ideally, the patient will have received the recommended routine vaccines before undergoing transplantation.

Children who have received transplants before reaching 2 to 3 years of age do not respond to the pneumococcal polysaccharide vaccine as well as do children who are older when they receive a transplanted heart, even though the vaccine is administered several years after they receive the transplant.[50] An impairment in immunoglobulin isotype switching from IgM to IgG and especially IgG2 seems to result from the immunosuppressive therapy that these children are receiving.[49] In one study, the antibody response of children aged 2 to 18 months old following solid organ transplantation was compared with age-matched children to the 7-valent pneumococcal conjugate vaccine (PCV7) followed by the 23-valent polysaccharide vaccine (PV23) 2 months later.[80] The antibody levels achieved were significantly higher in the controls, and a second dose of PCV7 given 2 months after the administration of the first PCV7 dose did not lead to higher antibody levels.

For previously unimmunized transplant recipients aged 2 to 18 years old, conjugate pneumococcal vaccine is recommended, followed by the 23-valent pneumococcal vaccine at least 2 to 12 months later. Ideally, children will have completed their PCV7 series before undergoing transplantation.[6] Ongoing immunosuppression seems to prevent maturation of the response to polysaccharide antigens in younger children, which it is hoped that the conjugate vaccine can overcome. The 23-valent pneumococcal vaccine is less immunogenic in adults after they have undergone heart transplantation than it is in healthy controls.

Antibodies to the influenza vaccine develop in most children, but previous exposure predicts a better response.[88] Annual administration of influenza vaccine seems to be safe and immunogenic in children after they have undergone solid organ transplantation. In one study, low-level histologic rejection occurred after the administration of influenza vaccine.[16] In a later study, the administration of inactivated influenza vaccine was not associated with an increased risk of rejection.[154] Depending on the time of year and the approximate date of transplantation, influenza vaccination is appropriate for the patient and all household contacts and health care workers to whom the patient might be exposed. The live-attenuated influenza vaccine is not recommended for individuals receiving immunosuppressive therapy or their close contacts.

After transplantation has been performed and after immunosuppressive therapy has been initiated, administration of live viral vaccines is contraindicated. The enhanced inactivated polio vaccine should be given to the child and to normal siblings. Measles, mumps, rubella, and varicella vaccines can be given to the siblings. Diphtheria, tetanus, and acellular pertussis inactivated vaccines should be given at the routine booster schedule, although antibody responses may not be equivalent to those observed in normal children. Varicella vaccine should be administered before transplantation is performed if varicella antibody is not detected at the pretransplant evaluation in a child aged 12 months or older. Whether the antibody response data generated in children with leukemia during maintenance chemotherapy can be applied to heart transplant recipients who must continue daily immunosuppressive therapy is unclear.

CHAPTER 82

Infections in Pediatric Lung Transplantation

Jill A. Hoffman

The first pediatric lung transplant was reported to the International Society for Heart and Lung Transplantation (ISHLT) in 1986, and by the end of 2005, a total of 963 transplants had been reported to the registry.[446] In addition, living lobar transplantation (LLT) is being performed at some centers as a way to address the shortage of available organs,[395,408,461] but it still accounts for less than 10 percent of all pediatric lung transplants.[446] At Children's Hospital Los Angeles (CHLA), the first pediatric LLT was performed in 1993 on a 13-year-old boy with cystic fibrosis (CF). He received lobes from each of his parents and survived for 5 years, unfortunately succumbing to renal failure while waiting for a kidney transplant.[461] Fifty-three LLT procedures (34% of total lung transplants) have been performed on pediatric patients at CHLA.[40]

The primary indication for lung transplantation in the pediatric population is CF. Most pediatric transplants, 56 percent regardless of age and almost 70 percent of transplants in 12- to 17-year-old patients, were performed for this diagnosis. By age, most pediatric transplant recipients are adolescents (>60%).[446] The most common diagnoses were complex congenital heart disease in infants younger than 1 year of age undergoing lung transplantation and primary pulmonary hypertension in children aged 1 to 5 years. Since 2000, approximately 66 pediatric lung transplants have been performed annually at 27 centers.[446]

Infectious morbidity and mortality rates remain high for lung transplant recipients (LTRs) and are probably greater than for most other solid organ transplant recipients (SOTRs).[8] This high incidence results from constant communication of the lungs and fresh bronchial anastomosis (BA) with the environment and from the high preoperative microbial burden of patients who constitute the majority of recipients of pediatric lung transplants. Denervation of the transplanted lung, interruption of the bronchial and lymphatic circulation, abnormal cough reflexes, and impaired mucociliary clearance also probably play roles.[8] In addition, these patients receive relatively high-dose, long-term immunosuppression; at 5 years, most patients still are maintained on tacrolimus (60% of patients) and corticosteroids (98% of patients).[446] In the first year after lung transplantation at CHLA, the overall incidence of infection was 0.24 episode per patient per month, or 2.88 infections per patient per year.[237] Fifty-five percent of all infections occurred in the first month after transplantation, with infections becoming much less frequent thereafter (Tables 82–1 and 82–2).[237] A summary of the causes of infection in this cohort during the first year after transplantation is presented in Tables 82–3 and 82–4.[237]

The additional indirect impact of infections on the outcome of LTRs also is recognized. Cytomegalovirus (CMV) and probably other viruses, as well as bacterial infections, have been implicated in immunologically mediated processes leading to bronchiolitis obliterans syndrome (BOS) or chronic graft dysfunction, acute rejection, graft loss, and death.[8]

The overall survival of pediatric LTRs as reported to the ISHLT is 74, 59, 49.5, and 30 percent at 1, 3, 5, and 10 years, respectively, similar to that of adult recipients.[446] There is no difference in survival according to donor lung source, living versus deceased.[33,408,446] Infection is the single most common cause of death from 1 month to 1 year after transplantation (44%), and it remains a significant cause of death in all periods through 5 years after transplantation.[446] BOS causes approximately 40 percent of deaths after the first year. Graft failure accounts for a third of deaths in the first month and 8 to 20 percent thereafter.[446] In the series of 75 pediatric transplants at CHLA (12 heart-lung, 18 cadaveric, 45 LLTs), the mortality rate

TABLE 82–1 Timetable of Infections for Pediatric Lung Transplant Recipients

Time of Initial Evaluation	Infection/Pathogen	Comments
0-1 Month	Wound, respiratory tract, line/bloodstream, and urinary tract infections	Related to the surgical procedure: *Candida*, *Staphylococcus* species, *Pseudomonas* species
	HSV stomatitis	Reactivation
	CMV infection	
	HHV-6?	
	Bronchial anastomosis (*Aspergillus*)	
	Other: rabies, West Nile virus, lymphocytic choriomeningitis virus, endemic mycoses	Unusual pathogens preexisting in the recipient or in the donor graft
1-6 Months	CMV disease	Onset of opportunistic infections from immunosuppression
	EBV	
	Aspergillus	
	Mycobacterium tuberculosis	
	Pneumocystis jiroveci	
	Endemic mycoses	
	HHV-6	
	Respiratory tract, line/bloodstream, and urinary tract infections	Continued bacterial (*Pseudomonas*) and candidal infections common through 3-4 months
	Respiratory viruses	Community-acquired infections
>6 Months	Respiratory viruses	Community-acquired infections
	Persistent *Pseudomonas*, *Burkholderia cepacia*, and *Aspergillus* infections	Persistence of organisms from cystic fibrosis in the proximal airways and sinuses
	Opportunistic infections:	Patients receiving continuous high-level immunosuppression or therapy for steroid-resistant rejection, CMV infection
	Pneumocystis jiroveci	
	Cryptococcosis	
	Nontuberculous mycobacteria	
	EBV/PTLD	
	Herpes zoster	

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV, human herpesvirus; HSV, herpes simplex virus; PTLD, post-transplant lymphoproliferative disease.

TABLE 82–2 Timing of Infections in 75 Pediatric Lung Transplant Recipients at Childrens Hospital Los Angeles

Months after Transplantation	% of Episodes
0-1	55
1-3	18
3-6	13
6-9	8
9-12	7

TABLE 82–3 Etiology of Infections in 75 Pediatric Lung Transplant Recipients in the First Postoperative Month at Childrens Hospital Los Angeles

Etiology	Number of Episodes
Pseudomonas, respiratory tract	22
Candida, respiratory tract	13
Herpes stomatitis	12
Cytomegalovirus infection	10
Aspergillus infection of the respiratory tract, bronchial anastomosis	4

TABLE 82–4 Etiology of Infections in 75 Pediatric Lung Transplant Recipients in the First Year at Childrens Hospital Los Angeles

Etiology	% of Total Infections
Bacterial infections	55
Pseudomonas spp.	18 (35% of bacterial infections)
Viral	27
Cytomegalovirus	12 (42% of viral infections)
Fungal	16
Candida	10
Aspergillus	4

was 18.6 percent at 1 year, 50 percent of which was attributed to infection.[237]

IMMUNOSUPPRESSION AND TIMING OF INFECTION

An understanding of the mechanisms and effects of immunosuppressive therapy is fundamental to predicting the timing and types of infections that occur after transplantation, and several excellent reviews are available.[349,352] This predictability of certain infections has facilitated establishing more timely diagnosis and determining strategies for preventive antimicrobial therapy.[127] Historically, the mainstay of therapy has included corticosteroids and combinations of the following medications: azathioprine, the calcineurin inhibitors (CNIs) cyclosporine and tacrolimus, sirolimus, mycophenolate mofetil (MMF), and polyclonal and monoclonal antibodies. In recent years, substitution of MMF and tacrolimus for azathioprine and cyclosporine, respectively, has become standard, and "steroid-sparing therapy" also is gaining favor. These regimens may provide a superior cost-benefit ratio in terms of prevention of rejection and risk of infection. A general time line of the occurrence of specific infectious agents in pediatric LTRs is presented in Table 82–1.

OVERVIEW OF INFECTIONS AND ANTIBIOTIC USE IN SOLID ORGAN TRANSPLANTATION

The "therapeutic prescription," as described by Rubin and colleagues,[352] for successful organ transplantation requires a careful balance between immunosuppression and the use of antimicrobials therapeutically, prophylactically, or preemptively to manage the risk of rejection versus infection. A transplant recipient's risk for developing infection is determined by multiple factors, including (1) the technical skill of the surgeon; (2) the quality of perioperative care; (3) the net state of immunosuppression; (4) the patient's infectious exposure, including that from the community, hospital, and donor grafts; (5) the underlying condition of the patient (e.g., colonization in CF); and (6) the virulence of the organisms. Preventive/prophylactic strategies can alter these patterns, most notably for CMV and fungal infections, and delay their appearance past the expected time periods.[350] In sum, these considerations indicate that although a standard set of antimicrobials can be prescribed, they must be tailored closely to the risks, exposure, and immunosuppression of each individual.[353]

General principles of infection and therapy have been proposed by Rubin and Marty [353] and include the recognition that a transplant recipient is likely to have a greater microbial load and more advanced infection at the time of diagnosis, thereby requiring longer therapy with greater potential for drug toxicity. Early establishment of the diagnosis and provision of therapy are paramount to a successful outcome. Furthermore, a broader range of organisms must be considered. Although a common practice in medicine is to assume a single diagnosis for a given manifestation, a recognized caveat is that transplant recipients may have "simultaneous and sequential" infections.[353] In fact, many infectious processes are influenced directly by proceeding or concurrent events. The prototype of this interaction is the immunomodulating effect of CMV infection such that alterations in the cytokine/chemokine milieu, T-lymphocyte subsets and function, neutrophil activity, and activation of endothelial cells emerge. The result of these derangements is further immunosuppression, enhanced production of virus, and subsequent increased susceptibility to additional infections. Other putative immunomodulating viruses include human herpesvirus-6 (HHV-6), Epstein-Barr virus (EBV), and the hepatitis viruses.[353,373]

Length of therapy depends on consideration of the degree of current immunosuppression and location of the infection. In general, experts suggest treating until all signs and symptoms of infection are gone, followed by a "buffer period" of weeks to months, depending on the infection.[353] Finally, drug interactions and toxicities, which may be synergistic, must be taken into consideration when prescribing medications in these complex patients.[265,352]

SITES OF INFECTION

THORACIC CAVITY: RESPIRATORY TRACT INFECTIONS, INCLUDING PNEUMONIA AND ANASTOMOTIC SITE INFECTIONS

The vast majority (80%) of infections in LTRs occur in the thorax—lung, mediastinum, pleural space[132]—with 35 to 66 percent of all infections being manifested as pneumonia.[8] In the CHLA cohort of patients during the first 12 months after transplantation, 62 percent of all infections were pneumonia.[237] The onset of pneumonia in LTRs appears in a bimodal pattern, with most cases occurring in the first postoperative month. A second, albeit smaller group has late (<6 to 12 months) recurrent episodes of gram-negative pneumonia associated with a poor outcome. The immunologic consequences of these infections in some patients may include bronchiolitis obliterans with organizing pneumonia (BOOP), which is characterized by inflammation and fibrotic granulation tissue of the small airways extending into the alveoli. The mortality rate of patients with BOOP is high (50%), and those who survive appear to be at an increased risk for developing BOS (41%).[8,69,132]

Unique to lung transplantation are BA infections, most of which are fungal and caused by *Aspergillus* and sometimes *Candida* species.[162,176,217,298,318] The BA is susceptible to such infections for a variety of reasons. Anatomically, the post-transplant bronchus is relatively devascularized, with the blood supply flowing retrograde from the pulmonary arterial circulation; neovascularization from collaterals takes as long as 1 month to occur. In the interim, the bronchus may experience ischemia and subsequent necrosis and sloughing of bronchial epithelium. Evolving surgical techniques have diminished this risk of ischemia in recent years. This environment is optimal for developing infection caused by saprophytic flora, such as *Aspergillus*, present in ambient air to which the airways are in direct contact. In addition, local reaction to suture material, postoperative corticosteroid use, and immunosuppressive therapy have a negative impact on healing and increase the patient's susceptibility to infection. As a result of this early tenuous anatomy, infections at this site are most likely to occur within the first 2 to 3 months after surgery.[76,162,176,298,300] BA infections rarely can lead to early catastrophic complications, such as dehiscence and hemorrhage. They are linked to substantial late bronchial complications, including dehiscence, bronchial stenosis, malacia, and retransplantation.[294,298]

Some studies have demonstrated that pretransplant isolation of *Aspergillus* spp. has not been found to be a risk factor for the development of *Aspergillus* infection after transplantation.[199,300,323] Others suggest that patients with CF and perioperative *Aspergillus* colonization may be at heightened risk for the development of early BA infection. Although the numbers are small, the authors speculate that the presence of *Aspergillus* at the site of the fresh, devascularized anastomosis renders it more vulnerable.[300] Postoperative isolation of *Aspergillus* from airways appears to identify patients at risk for the later development of BA abnormalities.[76,176,294,298] The overall incidence of airway infections, complications, or both ranges from 5 to 25 percent.[76,162,176,216,298] The mortality rate associated with BA infection and its complications is reported to be 2 to 7 percent.[176,298] Finally, one small study evaluating the effect of early sirolimus-based immunosuppression on the rate of rejection described poor wound healing and anastomotic complications in an unexpectedly high number of patients treated with sirolimus, which resulted in changes in immunosuppression strategies at that institution.[158]

BLOODSTREAM INFECTIONS

The second most common site of infection is the bloodstream. Two recent studies have looked specifically at the epidemiology of bloodstream infections (BSIs) in pediatric and adult LTRs.[91,315] Both studies found that BSI occurred in approximately 25 percent of transplant recipients, with staphylococci, *Pseudomonas aeruginosa*, and *Candida* spp. being the most common organisms identified. Late infections in both groups consisted of a wide range of gram-negative organisms. Both studies demonstrated that post-transplant BSI, especially early (<30 days) BSI in children and candidal BSI in both populations, was associated significantly with mortality. In the pediatric population, most BSI was related to central venous catheters and was not secondary to other sites of infection (5% with pneumonia, sternal wound, ruptured subglottic cysts). These infections were most likely to occur in the first 7 days after transplantation. In adult transplant recipients, BSI largely was associated with pulmonary infections. Specifically, *P. aeruginosa* bacteremia was more likely to develop in adult

patients with CF (20% of the transplant cohort) than in patients with other indications. *Burkholderia cepacia* and *Staphylococcus aureus* BSI was seen in similar frequency in non-CF patients. In addition, BSI in patients with CF was associated with a decreased risk for death when compared with other LTRs with similar infections, possibly because antimicrobials active against resistant gram-negative organisms were being administered at the time that the infection developed. In children, *Pseudomonas* BSI was not associated with the diagnosis of CF (45% of the transplant cohort), nor with any outcome measures in this study.

Empiric therapy in patients with suspected BSI should include agents active against staphylococcal and pseudomonal spp., with a low threshold for adding antifungal therapy. Furthermore, the need for indwelling central catheters should be assessed routinely, and catheters should be removed as soon as clinically feasible.

SELECTED PATHOGENS

BACTERIA

Pseudomonas aeruginosa and *Burkholderia cepacia* Complex

P. aeruginosa and *B. cepacia* play prominent roles in postoperative infections in patients with CF, the majority of pediatric LTRs. Despite the removal of colonized lung tissue with the procedure, the proximal airways and sinuses remain colonized and a source of infection postoperatively in the immunosuppressed transplant recipients. In patients with multidrug-resistant (MDR) organisms, this concern is heightened. MDR, gram-negative organisms have been defined as those resistant to all agents in two or more classes of effective drugs[357] (e.g., resistance to all aminoglycosides, β-lactams, fluoroquinolones). *B. cepacia* complex organisms are resistant to aminoglycosides intrinsically, having high rates of resistance to β-lactams, inducible resistance to fluoroquinolones, and resistance to colistin and polymyxin.[53]

As lung transplantation was emerging as a treatment option, patients with MDR organisms generally were excluded.[299] Such exclusion was based on data suggesting that pretransplant infection with MDR *P. aeruginosa* and *B. cepacia* complex diminished the chance of survival and, therefore, was considered a (relative) contraindication to transplantation.[213,262,388]

More recent data have documented that the presence of preoperative MDR and even pan-resistant *P. aeruginosa*, but not *Burkholderia cenocepacia*, may not have an impact on survival; these patients may be more likely to acquire postoperative infections, but they generally respond to treatment without increases in mortality rates.[22,107,128,199,299] The most recent ISHLT guidelines for selection of LTRs list "colonization with highly resistant or highly virulent bacteria, fungi, or mycobacteria" as a relative contraindication.[309] Additionally, it acknowledges that although "certain resistant pathogens may increase risk of poor outcome . . . it is not possible currently to identify absolute contraindications based on either the type of organisms or the pattern of antibiotic resistance." Despite the status of the immunocompromised host, the relatively low virulence of some of these organisms, the new healthy lung epithelium and improved airway function of the transplanted lungs, the aggressive use of antimicrobials during and after the procedure, and discordance between in vitro susceptibilities and in vivo efficacy may account for the diminished influence that MDR organisms have on the outcomes of transplant recipients.[29]

Recent analysis has shown that *B. cepacia* complex represents a group of nine related species that possess variable pathogenic potential in abnormal hosts.[240,241] Misidentification of *B. cepacia* complex organisms at the genus (*Alcaligenes*, *Stenotrophomonas*, and *Pseudomonas* most commonly) and species levels is a common occurrence.[240,271] This information is critical to evaluating patients considering transplantation and, in postoperative care, to assessing their risk for developing invasive disease.[240] There are species-specific differences in antimicrobial resistance and virulence. Several putative virulence/transmissibility factors that have been identified for *B. cenocepacia* (formerly genomavar III, ET-12 strain)[240] include quorum sensing,[389] cable pili (*cbl*A) for enhanced binding to respiratory epithelium,[359] increased neutrophil recruitment with suboptimal activation of polymorphonuclear neutrophils and macrophages,[358] and production of exopolysaccharides that inhibit neutrophil chemotaxis and scavenge reactive oxygen species.[56]

In the United States, *B. cepacia* complex is present in 3.2 percent of the CF population, with *B. cenocepacia* accounting for 50 percent of cases. In Canada, 15 percent harbor *B. cepacia* complex,[70] and as many as 80 percent of cases involve *B. cenocepacia*.[99] Some controversy continues regarding performing transplantation on patients who have *B. cenocepacia*. Data demonstrate increased morbidity and mortality rates associated with this organism in nontransplanted patients with CF[195,228,229,255] and in LTRs,[23,70,100,240] although successful transplantation has been accomplished in several centers.[70,101,237]

One of the largest and best characterized reports of *B. cepacia* complex in LTRs comes from the Toronto Lung Transplant Program, which documented that from 1988 to 1995, 15 of 28 (54%) patients with preoperative sputum positive for *B. cepacia* (genomavar III, ET-12) died after undergoing transplantation of causes related to this infection, whereas 4 of 25 (16%) *B. cepacia*–negative patients died. The 1-year survival rate for colonized patients was 67 percent versus 92 percent for those without colonization. Of note, 60 percent of *B. cepacia*–related deaths took place in the first 3 months after transplantation, with the additional deaths occurring between 14 and 48 months post-transplantation as a result of infection associated with BOS. Of the 13 surviving patients, 4 had complications related to *B. cepacia*, including abscess and empyema, and were successfully treated medically and surgically. In all surviving patients (34 total), the rate of BOS in the *B. cepacia* group (46%) was comparable to that in the *B. cepacia*–negative group (48%).[70]

More recently, the Toronto center has had improved mortality statistics with the use of 2 to 3 weeks of aggressive antimicrobial therapy, including tobramycin (intravenous, inhaled), ceftazidime, chloramphenicol, and trimethoprim-sulfamethoxazole (TMP-SMX), and a reduction in immunosuppressive therapy. Only one of five transplant patients with MDR *B. cepacia* has died of *B. cepacia*/BOS since this regimen was implemented. One other patient survived a postoperative *B. cepacia* abscess, and three additional patients remained *B. cepacia*–negative and clinically stable.[70]

In vitro synergy or multiple combination bactericidal testing (MCBT) for MDR or pan-resistant gram-negative organisms has been suggested to facilitate the use of effective multidrug regimens.[1,2,53,224,357] In vitro testing can identify combinations of antimicrobials that inhibit bacterial growth. How these data translate to patient care, however, has yet to be fully demonstrated. Recent published data did not reveal better outcomes, specifically the time to the next exacerbation, when using combination therapy to treat CF patients infected with MDR bacteria.[2] In this report, study patients received two-drug combinations based on MCBT, but these patients did not necessarily have MDR/pan-resistant organisms, nor had they failed conventional therapy. Extrapolating these results to LTRs with MDR organisms is difficult. The CHLA has been using MCBT from the University of Ottawa since 2001; our experience suggests that this approach, with as many three or four drugs used in combination, is helpful for managing preoperative and postoperative patients with MDR/pan-resistant organisms, including *B. cepacia* complex.[237] Clearly,

additional data are needed to assess this approach for LTRs with MDR organisms.

Optimal therapy for infections caused by these gram-negative organisms is not known. Therapy should be tailored to susceptibility studies. The duration of therapy requires individualization but generally is no less than 2 weeks, and treatment should be continued for a significant period after the signs and symptoms of infection have resolved. Combination therapy (two or three drugs) usually is recommended. For *P. aeruginosa*, an extended-spectrum, antipseudomonal β-lactam and an aminoglycoside, if renal status allows, with or without aerosolized tobramycin, can be used. Aerosolized tobramycin can deliver drug levels above the minimal inhibitory concentrations (MICs) of resistant organisms directly to the lungs and thereby reduce the bacterial burden with minimal systemic toxicity.[141] Aerosolized tobramycin should not be used as single therapy in transplant recipients at risk for dissemination. Colistin in either an aerosol or intravenous formulation may be helpful for pan-resistant organisms, but renal toxicity may preclude its systemic use. For *B. cepacia*, combinations that include ceftazidime, meropenem, TMP-SMX, tetracyclines, quinolones, and chloramphenicol may be used.[185] A protocol using aerosolized aztreonam has shown some benefit at CHLA.[124,145,462] Therapy is initiated in patients identified with *B. cepacia* complex, preoperatively if possible, and continued through the first year after transplantation. Preliminary data suggest that outcomes are similar to those of patients who are colonized with susceptible *Pseudomonas* organisms. Further investigation is needed in this promising area of therapy.

Other Gram-Negative Organisms

Infections with other gram-negative organisms, including extended-spectrum, β-lactamase–producing organisms (*Escherichia coli* and *Klebsiella pneumoniae*), have been described in other transplant populations, such as pediatric liver or intestinal transplantation, and notably in outbreak situations.[152,337] No data exist on rates in pediatric LTRs. Some increased risk related to antimicrobial exposure, infection control practices, stays in intensive care units, and hospitalization is likely.[289] Carbapenems (meropenem, imipenem) generally are considered the drugs of choice for extended-spectrum, β-lactamase–producing organisms, especially for empiric therapy.

Mycobacterium tuberculosis

M. tuberculosis (MTB) remains an important pathogen in SOTRs. As noted by many authors, it behaves as an opportunistic infection in these patients in that its frequency is greatly increased in comparison to the normal population (up to 74-fold in some U.S. studies), it has diverse manifestations with high rates of extrapulmonary disease, and mortality rates are high (20-40%).[290,351,383] Most cases of MTB arise from reactivation of latent infection, although acquired cases are seen, especially in pediatrics.[269,287,425] Multiple cases of donor-derived MTB infection, including pulmonary MTB in LTRs[340] and extrapulmonary MTB in renal and liver transplants, have been documented.[150] In addition, nosocomial transmission to transplant recipients has occurred.[193]

Important differences appear to exist in the epidemiology of MTB infection in different transplant populations and for adults versus pediatric patients. Most data are available for the former, who are more likely to have reactivation of latent disease and higher rates of liver toxicity with therapy. In the United States and Europe, MTB infections occur most frequently in LTRs (2-6.5%), followed by liver (0.9-2.3%) and heart (1-1.4%) recipients.[383] Studies of MTB infection in SOTRs, including small numbers of children, suggest that most cases occur within the first post-transplant year, with a median time of 9 months for all SOTRs and 3.5 months for LTRs. Risk factors for early MTB infection include allograft rejection; receipt of OKT3 or anti–T-cell antibodies, which also predict dissemination; and previous exposure to MTB, with radiographic evidence of old infection or a history of a positive tuberculin skin test (TST). Co-infection with CMV, mycoses, *Pneumocystis jiroveci*, and *Nocardia* has been associated with the development of disease.[287,290] As would be expected, most manifestations include pulmonary disease (71%), with interstitial infiltrates, nodules, effusion, and cavities seen on imaging studies. Extrapulmonary disease (16%) includes a wide variety of gastrointestinal (GI) disease and skin, musculoskeletal, genitourinary, lymph node, and central nervous system (CNS) involvement. In one study, a third of patients had disseminated disease, 91 percent of whom were febrile as compared with 64 percent of those with localized disease.[383] Significant predictors of mortality, which was 17 percent for LTRs, were disseminated disease, previous rejection, and receipt of OKT3 or anti–T-cell antibodies.[383]

Several studies have investigated mycobacterial infections in LTRs.[46,202,257,287] Two of the studies were conducted in countries with a low endemicity of MTB, Australia and North America (rates of MTB, 5 to 15/100,000), and two in Spain (rates of MTB, 25 to 49/100,000). Rates of MTB in LTRs in the two former studies were less than 1 percent,[202,257] but they were 2.6 percent and 6.4 percent (500-fold higher than the national average) in the Spanish studies.[46,287] Indeed, nontuberculous mycobacterial (NTM) infections were more common than were MTB infections in the first two reports, whereas NTM infection was encountered only once in the Spanish study. No deaths from mycobacterial disease were reported in three studies,[46,202,257] but the mortality rate was 43 percent in the final report.[287]

Few data exist on MTB in pediatric SOTRs and none in LTRs in particular. Two small series of MTB in pediatric liver transplants have been published.[269,425] Initial symptoms included fever in most patients. Pulmonary findings were most common. Pediatric patients may be seen later than adults after transplantation (median of 8 months versus 4 months) as a result of differences in acquisition of disease.[425] TST results were negative or minimal in all patients. A 5-mm induration (two patients) should be considered positive in an immunocomprised patient with compatible symptoms.[18] Furthermore, screening of family members was very useful in both series of patients, thus suggesting that as for immunocompetent children, the index case of exposure is in the home. Invasive diagnostic procedures were needed to confirm the diagnosis in most patients. No deaths were directly attributable to MTB. An additional case report of MTB complex disease in a pediatric renal transplant recipient highlights another potential difference between pediatric and adult cases.[73] *Mycobacterium bovis* disease, which can be indistinguishable from MTB but often is manifested as abdominal disease, developed in this child. It usually is acquired from the ingestion of unpasteurized milk products from infected cows. It appears to be distinctly more common in children and, in the United States, is seen most often in children who have immigrated from or visited countries where *M. bovis* is endemic in cattle, such as Mexico.[88] The importance of recognizing this infection is its inherent resistance to pyrazinamide and the implications that this resistance has for therapy.

Diagnosis of MTB in the transplant setting can be challenging because symptoms may be nonspecific, such as fever of unknown origin, or unusual, such as abdominal manifestations; co-infections also may modify the signs and symptoms. Delayed-type hypersensitivity often is suppressed in transplant candidates and recipients, thus rendering TST unreliable. Moreover, just a minority of patients undergo skin testing before transplantation. Consequently, a high index of suspicion is required, and frequently, aggressive diagnostic techniques, such as bronchoscopy, laparoscopy, and tissue biopsy, are needed.[269,299,425]

Several new methods are available for culture-based diagnosis. Broth-based culture systems coupled with DNA probes allows rapid (2 or 3 weeks for positive and negative smears, respectively) establishment of a diagnosis.[314,363] In addition, culture-based diagnostics are the only widely available methods by which to assess susceptibility. Technologies for the rapid detection of MDR organisms are still experimental.[24,363,412] Two commercially available kits are available in the United States for diagnosis based on nucleic acid amplification (NAA) assays.[314] They are approved for smear-positive (MTD, GenProbe; Amplicor, Roche) and smear-negative samples (MTD), but there is still some debate on the optimal use of these tests. The American Thoracic Society and the Centers for Disease Control and Prevention have published recommendations,[19,65,363] although they have not been studied in transplant recipients or pediatric populations specifically. Newer modalities such as the microscopic-observation drug susceptibility (MODS) assay may allow rapid, inexpensive diagnosis and susceptibility testing in countries with limited resources.[190,286,314] Finally, new tests exist for the detection of latent MTB: the "QuantiFERON-TB Gold," a whole-blood enzyme-linked immunosorbent assay (ELISA), and "T-SPOT. TB," an ex-vivo enzyme-linked immunospot (ELISpot) assay.[267,339,363] Both assays rely on interferon production from peripheral blood mononuclear cells in response to MTB antigens. The advantage of these tests is they may allow MTB to be distinguished from NTM infection and bacille Calmette-Guérin (BCG) vaccine response. In adults, these tests have higher specificity than TST does, especially with regard to BCG, and may be most useful in low-endemic, high-income settings.[267,313,394] However, their use in young children and immunocompromised patients has not been fully evaluated.[313,394]

Specific guidelines exist for the treatment of MTB in children infected with human immunodeficiency virus (HIV).[15] None is available for pediatric SOTRs, and the optimal therapy has not been defined.[41] Clearly complicating factors include liver toxicity from single- and multiple-drug regimens and drug interactions, most notably between rifampin and CNIs. Isoniazid (INH) alone and in combination with other first-line drugs, such as rifampin and pyrazinamide, can lead to toxicity requiring discontinuation of all or some of these drugs and the need to institute new regimens.[290,383] Drug toxicity is most notable in adult liver transplant recipients. Liver biopsy may be necessary to distinguish drug toxicity from rejection or hepatic granuloma from MTB infection.[290,351,383] Pediatric patients generally tolerate first-line therapy, with occasional need for reduced dosage and rarely discontinuation.[73,269,425]

The use of rifampin in SOTRs remains controversial. Significant morbidity of MTB from graft dysfunction and loss can be due to the simultaneous use of rifampin with CNIs. Rifampin lowers serum levels of cyclosporine and tacrolimus considerably, as well as decreases steroid levels somewhat, via induction of cytochrome P-450. Some authors argue that rifampin can be used successfully with increased CNI dosing and careful monitoring of CNI serum levels.[257,425] Others suggest that a longer duration of therapy (up to 50%) with rifampin-free/INH-containing regimens has a comparable outcome without the risk of rejection and potential graft loss, and they do not recommend the use of rifampin.[46,290] Most authors agree that regimens should contain INH if at all possible.[46,287,290,383] If rifampin-free regimens are used, therapy should be prolonged to a minimum of 12 to 18 months.[46,383] Ethambutol and second-line therapies (aminoglycosides and quinolones) may be considered if a first-line drug cannot be used.[290,351] If both INH and rifampin are not used, therapy should be continued for 2 to 3 years.[350]

Recommendations for chemoprophylaxis of MTB infection are similarly without consensus. Some authors suggest that all SOTRs with a positive TST of 5-mm or greater induration be treated with INH. They reason that the morbidity and mortality from MTB and the potential risk for nosocomial transmission from unidentified patients are high enough to warrant the risk of hepatotoxicity.[383] Others use a staged approach in which INH therapy is initiated in LTRs and other non–liver transplant recipients as soon as possible but deferred in liver recipients until liver function is stable.[290] A third strategy is active surveillance, with initiation of INH only if additional risk factors are present, such as recent conversion, exposure to active MTB, recipient or donor with a history of MTB without adequate therapy, or the existence of significant abnormalities on chest radiographs.[351]

Nontuberculous Mycobacterial Infections

NTM infections are more common occurrences in LTRs in areas where MTB is not endemic, including the United States.[110] NTM organisms are divided into slowly growing species, *Mycobacterium avium* complex (MAC), *Mycobacterium kansasii*, *Mycobacterium marinum*, and *Mycobacterium ulcerans*, and rapid growers, *Mycobacterium fortuitum* group, *Mycobacterium abscessus*, and *Mycobacterium chelonae*.[16] Patients with chronic lung disease and CF in particular have a high incidence of NTM colonization. As many as 24 percent of patients with CF are colonized with NTM organisms, most commonly *M. abscessus* or MAC.[121,305,308,330] The contribution of these organisms to progression of lung disease in pretransplant patients still is being defined.[87,121,156,166,305-307] In one center, 20 percent of patients with end-stage CF referred for transplantation were colonized with NTM organisms, which were isolated from 14 percent of CF LTRs. The prevalence of post-transplant invasive disease was approximately 3 percent.[66] Most authors do not consider that the presence of NTM infection before transplantation should serve as an exclusion to transplantation, but these organisms clearly are responsible for serious and fatal post-transplant infections.[66,74,110,202,257,360,410]

Clinical manifestations of NTM infection in lung transplantation vary by organism and include pulmonary, cutaneous, and disseminated disease.[110] In a survey of transplant centers regarding *M. abscessus* infection in LTRs, the majority had pulmonary infections, followed by skin involvement; several patients had both. Disease occurred at a median of 18.5 months after transplantation (1-110 months). Pulmonary disease may be manifested as chronic cough, sputum production, and fatigue. Skin infections may involve surgical sites (sternal wounds) and the extremities.[66,257] Painful, erythematous cutaneous or subcutaneous nodules may develop into abscesses and ulcerate.[74]

Diagnosis requires a high level of suspicion. Cutaneous lesions should be subjected to biopsy for histology, special stains, and culture. The differential diagnosis includes fungal and nocardial infections. These organisms are ubiquitous, and differentiating respiratory colonization from infection may be difficult. The diagnosis of NTM infection should be entertained, with a low threshold for performing bronchoalveolar lavage (BAL) or biopsy for any unexplained or unresolving pleuropulmonary disease.[110,157] The American Thoracic Society has published diagnostic criteria that include signs and symptoms present after the treatment of other possible diseases, such as radiologic evidence of progressive pulmonary disease, including infiltrates, cavities, nodules or bronchiectasis, and bacteriologic evidence of NTM infection, generally on multiple respiratory specimens or on biopsy.[157]

Providing therapy for NTM infection may be difficult and depends on the species isolated. Most authors recommend combination therapy that includes a macrolide. For MAC, therapy with a macrolide, ethambutol, and rifampin, with or without an aminoglycoside, depending on the severity of disease, is recommended.[157] Therapy for *M. abscessus* is undefined because this organism is notoriously resistant to many antimicrobials. Even regimens based on in vitro susceptibilities may not produce a cure. Combinations that include a macrolide, amikacin, and cefoxitin or a carbapenem, based on susceptibility testing, are

general recommendations. Acquired resistance mutations to clarithromycin and amikacin can occur.[157] The duration of therapy is prolonged and depends on the patient's clinical, radiologic, and microbiologic response, but the suggested minimum duration is 12 to 18 months. Reduction of immunosuppression, surgical excision or débridement, and treatment of co-infections may improve the outcome.[74] Relapses are not uncommon. Consideration of lifelong suppression is recommended by some experts for patients with a high burden of disease and persistently high levels of immunosuppression.[110] Most patients who can complete long-term therapy improve (32% cleared their infection, 36% improved); minimal response to therapy was seen in 23 percent of LTRs.[116] Fatal infections occur rarely.[74,360,410] Drug interactions between macrolides and rifampin and CNIs and sirolimus occur. Both can lower serum levels of immunosuppressive drugs and trigger rejection.

The optimal management of patients infected or colonized with NTM organisms before transplantation is debated. A report of 146 patients with CF who underwent lung transplantation found a highly significant association between pretransplant isolation of *M. abscessus* and post-transplant disease, thus suggesting that these patients remain colonized in respiratory tree sites above the anastomosis. The hilar lymph nodes in two patients were positive for *M. abscessus*, thus suggesting other potential reservoirs.[66] Given the concern for emergence of resistance and toxicity related to long-term therapy, prolonged antimycobacterial therapy cannot be recommended for all patients. Some centers opt for pretransplant or peritransplant prophylaxis, whereas others observe for evidence of disease.[110]

FUNGAL INFECTIONS

Aspergillus

Aspergillus infections remain a major challenge to the success of lung transplantation. Manifestations range from semi-invasive tracheobronchitis and BA infections (up to 60% of infections) to invasive pulmonary disease (30%) and, rarely, dissemination to extrapulmonary sites, including the CNS (10%).[139,376] The published incidence of invasive *Aspergillus* (IA) infections varies considerably and probably reflects differences in dates of publication, patient populations that included adults and children, underlying disease such as CF, net state of immunosuppression, use of prophylactic measures, local issues of exposure (e.g., construction), and rates of rejection and viral infection, among others. In addition, distinguishing between isolation of *Aspergillus* from airway cultures versus true invasive disease may be difficult. Despite these caveats, rates of IA infection in LTRs are the highest among SOTRs. Studies suggest that invasive disease occurs in 3 to 33 percent of LTRs, although rates of colonization/isolation of *Aspergillus* may be considerably higher. In most cases, colonization appears to be transient and does not lead to invasive disease.[57,139,148,173,273,283,285,300,376]

Infections usually develop 1 to 6 months after transplantation and are a major cause of death during this time period.[217,273,283,376] Early infections, those that develop less than 3 months after transplantation, are more likely to be tracheobronchitis or BA site infections, whereas invasive pulmonary or disseminated aspergillosis occurs more often in late-onset infections.[376,390] Patients who require retransplantation or have BA infection may present in the first month.[76,162,176,283]

Recent studies have identified different risk factors for the bimodal pattern of the development of IA.[139,375] Risk factors for early disease in LTRs include *Aspergillus* colonization in the 6 months before transplantation or early post-transplant colonization, a complicated postoperative period, and CMV disease.[57,139,173,189,285,300] Corroboration of the importance of CMV is the observation that a significant decrease in IA was associated with the use of prophylactic ganciclovir in heart transplant recipients. This decrease no doubt reflects the immunomodulating effects of the virus on host immune status.[347,437] Patients in whom IA infection developed later than 3 months after transplantation were older (<50 years); "overimmunosuppressed" with the use of sirolimus, tacrolimus, or both for chronic or refractory graft rejection or dysfunction; or both older and overimmunosuppressed.[139,378] In both the early and late groups, IA was associated with renal failure and repeated bacterial infections.

Aspergillus fumigatus causes the majority of disease, although non-*fumigatus* species are becoming more common.[57,273] Such species include *Aspergillus flavus*, *Aspergillus niger*, *Aspergillus nodularis*, *Aspergillus ustus*, and *Aspergillus terreus*. This change may be important because of the recognized potential for differences in antifungal susceptibility of some non-*fumigatus* species. For example, *A. terreus* is innately resistant to amphotericin B, and *A. ustus* has diminished susceptibility to the azoles.[32]

Clinical findings in patients with pulmonary disease are largely nonspecific and may include cough, shortness of breath, and hypoxia, although chest pain and occasionally hemoptysis may raise clinical suspicion of IA.[84,272] Symptoms are seen more commonly in patients with diffuse disease than in those with focal or nodular disease.[95] Although fever is a common early manifestation of IA in neutropenic hematology patients,[95] it occurred in only 15 percent of LTRs with *Aspergillus* infection and usually more often in patients with disseminated (50%) or invasive pulmonary disease (20%) than in those with tracheobronchial or BA infections (0%).[376] Lack of fever also has been documented in other studies of non-neutropenic patients with IA.[84,272] Patients with disseminated disease may have involvement of the sinuses, orbits, musculoskeletal system (osteomyelitis), ophthalmologic structures, cutaneous sites, and CNS. Symptoms of CNS disease may include headache, sinus pain, cranial nerve abnormalities, seizures, changes in mental status, or other focal neurologic findings.[32,95,148]

The radiologic manifestation of IA in LTRs is highly variable.[95,104,369,414] Chest radiographs are highly insensitive and nonspecific for IA. Computed tomography (CT) of the chest has become an integral part of early diagnostic strategies and has been incorporated into recent definitions of invasive fungal infections in immunocompromised hosts.[25] On chest CT scans of neutropenic adults, large nodules and cavitary lesions are common findings.[25,95,155] In addition, much has been made of the early "halo sign," a macronodule surrounded by a perimeter of ground-glass opacity (edema and hemorrhage), and the later "air crescent sign," a crescent-shaped air interface between viable lung and infarcted tissue at the periphery of a nodule, seen with recovery and return of neutrophils. These findings are considered highly suggestive, though not pathognomonic, of IA.[25,59,155] Unfortunately, these findings are seen less commonly in LTRs and in children in general. Multiple ill-defined pulmonary nodules were the most common findings in adult LTRs, with approximately half demonstrating halo signs. Cavitation was rarely seen, and no air crescent signs were observed.[84,104] In a review of immunocompromised children with IA, radiographic findings were highly variable and included consolidations and small nodular masses and effusions, with little evidence of cavitation and no halo or crescent signs.[414]

The gold standard for diagnosis of IA is the demonstration of small hyaline, septate, dichotomously branched hyphae in tissue with evidence of associated tissue damage or positive cultures from a normally sterile body site in the face of signs and symptoms of invasive disease in an immunocompromised host.[25,32,95,179] Blood cultures rarely are positive and, therefore, are not helpful. Unfortunately, obtaining adequate tissue specimens in a timely manner frequently is not possible. An immunocompromised patient with neutropenia or taking steroids may not exhibit

obvious signs or symptoms of invasive disease until late in the course of infection.[6] Additionally, these patients often are deemed too ill to undergo the invasive procedures necessary to obtain tissue for culture.[384] Therefore, the diagnosis is established late in the course of the disease or at autopsy. Indeed, frequently it is not established but is based on radiology and host factors.

Early diagnosis is thought to be critical to improving the outcome of patients with IA, especially now with the availability of more active therapeutic agents and the possibility of combination therapy. In addition to early and frequent CT scanning in high-risk patients, especially those who do not respond to broad-spectrum antibiotics, several recent advances have been achieved in molecular/non–culture-based approaches to establishing a diagnosis. The most widely used and well characterized of these modalities is the Platelia *Aspergillus* serum galactomannan antigen, detected by double-sandwich ELISA.[276,277,403,452,454] This test detects very small amounts of a polysaccharide cell wall component of *Aspergillus* and other fungal species that is released into blood with invasive growth in tissues. A positive test (<0.5 ng/mL) requires confirmation by a second sample for diagnosis. False-positive tests have been documented, notably in patients receiving piperacillin-tazobactam,[3,26,246,250,382,406,435,444] which may be related to cross reactions to *Penicillium* spp.–derived semisynthetic penicillins,[404] although this theory has not been proved conclusively. In general, false-positive tests result in transient and low-positive findings.[276,452] Pediatric patients appear to have higher rates of false positivity,[175,342,405] but the mechanism for this observation remains unclear. Previous antifungal therapy has been shown to decrease the sensitivity of the assay.[258,261,342]

In controlled trials, twice-a-week galactomannan screening of very-high-risk adults with hematologic malignancies and hematopoietic stem cell transplant (HSCT) recipients had high sensitivity and specificity and allowed the diagnosis of IA to be established, often many days before the development of fever and CT findings, with the potential for initiating early therapy.[252-254,258] The addition of galactomannan testing to early CT scans also was found to be helpful in establishing the diagnosis of IA.[55,251,342] The galactomannan assay has been incorporated into recent diagnostic criteria for the diagnosis of IA in immunocompromised patients with cancer and in HSCT recipients.[25] To date, no studies have documented a survival advantage in patients with early diagnosis by galactomannan testing.

In SOTRs and non-neutropenic patients, this test appears to be less sensitive.[129,183,223,327,426] For example, twice-a-week screening of 70 consecutive LTRs, with IA documented in 17.1 percent, revealed a sensitivity of 30 percent and a specificity of 95 percent.[183] False-negative results occurred most commonly in patients with tracheobronchitis, followed by pulmonary disease, versus patients with disseminated disease. Two of five patients with pulmonary *Aspergillus* and negative tests had received antifungals previously. False-positive results occurred in 36 tests on 14 patients, with a median value of 0.868; consecutive positive tests were seen in 5 patients. The majority of these results occurred in the first 2 weeks after transplantation. None of these patients was receiving piperacillin-tazobactam.

Finally, use of the galactomannan assay for specimens other than serum is being evaluated for cerebrospinal fluid (CSF) and BAL fluid.[35,208,247,292,361,436] Assays on these fluids appear to be more sensitive and to offer some advantage in certain patient populations, such as non-neutropenic SOTRs, although controlled clinical trials have not been published. False-positive galactomannan results have been linked to the use of Plasmalyte (Baxter) for lavage fluid instead of normal saline.[163] The product contains gluconate, which is produced by fermentation in *A. niger* and results from contamination of small amounts of galactomannan by this process.

Several other molecular-based methods for detection that are being investigated include the Fungitell beta-glucan assay, which measures a cell wall component found in many fungi, including *Aspergillus* and *Candida* spp., and, like the galactomannan assay, does not detect zygomycetes.[201,284,301,310,325] It is approved by the Food and Drug Administration (FDA) and is available in kit form. Cross-reacting glucan-containing material occurs commonly in the environment, and false-positive tests have been demonstrated in patients maintained on dialysis or exposed to gauze and with gram-positive bacteremia. In addition, false-positive results are associated with the use of some antimicrobials and with sample manipulation, thus suggesting that laboratory contamination is possible.[106,179,264,325,328,454]

The *Aspergillus* polymerase chain reaction (PCR) remains nonstandardized, but most assays rely on detection of fungal sequences of 18S or 28S rRNA or mitochondrial genes in whole blood, plasma, serum, or BAL fluid.* More recent protocols have used real-time PCR, which allows rapid, automated, quantitative, and reliable results, with less chance of contamination.† Clinical information is limited on both these methods. No studies have been published on the use of these tests in SOTRs, but some show promise in febrile neutropenic cancer patients and HSCT recipients. The optimal clinical specimen and PCR protocol have yet to be established.

Several studies have compared the use of these three methods.[48,52,201,292,325,361] No reproducible results suggest that one test is convincingly or consistently better than the others. Several authors suggest that combining two methodologies may improve diagnostic reliability.[48,85,109,281,292,325,361]

Despite historically poor outcomes of IA in immunocompromised patients, new mold-active therapies appear to be improving mortality figures.[40] The Infectious Diseases Society of America (IDSA) practice guidelines for *Aspergillus* infections, published in 2008, recommends therapy with voriconazole as primary therapy for most patients,[445a] as it has demonstrated superiority.[27,97,174] Additionally, voriconazole has shown promise for treatment of CNS disease, which historically has been uniformly fatal.[174,364,442] Lipid formulations of amphotericin B can be recommended as alternative therapy for patients unable to receive voriconazole. For patients refractory to or intolerant of primary therapy, lipid formulations of amphotericin B, itraconazole, and caspofungin are FDA approved for treatment of IA. Other antimicrobials that have activity against *Aspergillus* include posaconazole and other echinocandins, although these are not approved for this indication.

Most data on the use of voriconazole for IA involved adult HSCT recipients and patients with leukemia, although some studies contained small numbers of pediatric patients and SOTRs. The paucity of data in these groups is important for several reasons. The optimal dosing for pediatric patients remains unclear, and much higher doses than currently recommended probably may be tolerated and beneficial.[396,441] This dosing information is currently under investigation.[396] In addition, several important drug interactions occur with medications routinely used in SOTRs. The most important of these interactions involve tacrolimus and sirolimus, in which concomitant use with voriconazole can lead to decreased metabolism, via cytochrome P-450 3A4/5 (CYP3A4/5), and result in greatly increased serum levels of the immunosuppressant.[354] The use of tacrolimus can be controlled safely by reducing the dose by 50 percent generally and monitoring daily levels.[354,424] The effect of voriconazole on sirolimus levels is even more pronounced, and it is labeled as an absolute contraindication by the manufacturer.[354,356] Several case reports/small series describe the use of these two drugs together, with significant dose reduction of sirolimus (up to 90%) and close follow-up of serum sirolimus levels.[263,266,356] The second azole to be approved for use by the FDA recently is posaconazole, which

*See references 51, 118, 165, 168, 196, 226, 244, 386, 420, 460.
†See references 47, 67, 86, 197, 198, 201, 207, 292, 361, 392, 457, 458.

is available only in an oral formulation. Currently, based on several randomized multicenter studies, it is licensed for prophylaxis of invasive fungal disease in patients with fever and neutropenia and those with chronic graft-versus-host disease.[82,418] Posaconazole also has been used for the treatment of *Aspergillus* in patients refractory or intolerant of other therapy, most of these patients having received an amphotericin product or itraconazole.[215,365,443] The use of posaconazole as primary therapy for IA currently is being investigated. Azoles are generally well tolerated. Unique events associated with voriconazole include transient visual disturbances (photopsia) and cutaneous photosensitivity. Both drugs have been associated with hepatic toxicity, which can be fatal.[108,174]

The polyenes AmBD and its lipid formulation (LFAB) are active against *Aspergillus* spp., except for *A. terreus*, and exert their activity on the cell membrane. AmBD was the "gold standard for serious fungal infections for almost 40 years" but now has been supplanted by newer, more effective and less toxic agents, including the azoles, echinocandins, and LFAB. The recent consensus suggests that LFAB may be more effective than AmBD is in certain settings and is clearly less toxic. LFAB and posaconazole are the most broad-spectrum antifungals and are the only agents active against zygomycetes.[108] One of these drugs should be used singly or in combination if the diagnosis of a zygomycelial infection, which can be clinically indistinguishable from IA and equally fatal, is being considered.

Echinocandins have a unique mode of activity; they inhibit the biosynthesis of 1,3-β-glucan in the fungal cell wall, which is absent in mammalian cells, thus offering a high therapeutic index.[108] Moreover, fewer notable drug interactions have occurred. Initial reports suggested that concomitant use of caspofungin, the first licensed echinocandin, with cyclosporine caused increased hepatotoxicity, although subsequent studies did not substantiate this interaction.[108,260] Caspofungin has been demonstrated to be useful in and has been licensed for the treatment of IA in patients refractory to or intolerant of other therapies[249] and for empiric antifungal therapy in patients with fever and neutropenia.[445] Several studies have addressed the safety, efficacy, and dosing of caspofungin in pediatric patients.[130,159,278,302,440] All studies have found caspofungin to be safe and well tolerated in children, even neonates. As was seen with voriconazole, extrapolation of pediatric dosing from adult dosing led to underdosing of caspofungin, which has been revised on the basis of pediatric pharmacokinetic data.[440] No prospective data on the efficacy of caspofungin for IA in immunocompromised pediatric patients have been published, although two small retrospective studies (64 and 25 patients), consisting mostly of children with leukemia, showed promising results with caspofungin, either alone for less aggressive disease or in combination with voriconazole for first-line therapy.[159,278] A second echinocandin, micafungin, also has been licensed recently for prophylaxis of *Candida* infections in HSCT recipients and for treatment of esophageal candidiasis.[103,421] Randomized, controlled data on the use of micafungin for primary treatment of IA are lacking. Several reports of high-risk patients (HSCT recipients, hematologic malignancy) suggest that it is useful, either alone or in combination, in the setting of refractory IA.[68,96,209] Some studies included small numbers of children, who appeared to have similar success rates. In an assessment of its safety, tolerability, and pharmacokinetics in febrile, neutropenic children, dose-limiting toxicity did not occur with doses of 4 mg/kg/day or lower, and young children cleared the drug up to 1.5 times faster than older children and adults did.[367] Optimal dosing regimens are still under investigation. A final echinocandin, anidulafungin, has been approved for the treatment of candidal infection.[423] It also has potent in vitro activity against *Aspergillus*. A unique property of anidulafungin is that its pharmacokinetics is similar across a variety of patient populations, including children, which suggests that dose adjustments are not necessary. The drug appears to have an excellent safety profile, with minimal drug-drug interactions. Its use in the treatment of IA has yet to be defined, but most likely it will be similar to other echinocandins.

Combination therapy remains controversial. Advantages of combination therapy include possible synergistic interaction of two drugs with different targets, lower doses leading to less toxicity, greater spectrum of activity, and decreased potential for the development of resistance.[234] Potential disadvantages include antagonistic antifungal activity, increased overall drug interactions, enhanced toxicity when adding new agents, and great increases in cost.[194,288,434]

Preclinical data from in vitro and animal studies investigating the use of combinations of antifungal agents against *Aspergillus* are generally promising.[194,288,397,399,434] Complexities and differences in methodologies used to determine in vitro efficacy, experimental design, and animal models confound interpretation of the data and render extrapolating to patients difficult.[288,397,399,453]

The comparator to combination therapy in most clinical data to date is primary therapy with LFAB, not voriconazole, which is now considered the drug of choice for IA. Combination treatment also has been studied for salvage therapy in patients who have already failed therapy; however, most studies are retrospective.[96,211,212,248,259,297,320,377,399] Preferred combinations include azoles (voriconazole or posaconazole) with echinocandins (caspofungin or micafungin).

A single prospective multicenter observational study has evaluated combination therapy in SOTRs.[377] Forty transplant recipients (13 lung transplants, or 33%) received voriconazole and caspofungin as primary therapy for IA (2003 to 2005); 47 patients (9 lung transplants, or 19%) received LFAB (1999 to 2002). A trend toward decreased mortality rates at 90 days in the combination group was noted, and subset analysis demonstrated that in transplant recipients with renal failure or *A. fumigatus* infection, combination therapy was associated with improved 90-day survival ($p = 0.04$ and $p = 0.03$, respectively). No patient required discontinuation because of side effects or intolerance. These authors note that currently, "combination therapy constitutes our standard for the therapy of invasive aspergillosis."[291] Data from prospective, randomized trials in which voriconazole is compared with combinations that include voriconazole still are needed to evaluate first-line therapy. Many authors recommend caution in using combination therapy before the results of controlled, prospective investigations are available, even though they acknowledge that widespread use of combination therapy already is evident.[30,194,288,397,399,434]

No definitive data are available on how long to treat IA, although the natural history of disease, assessment of risk factors, and the state and length of immunosuppression, along with investigations on response to therapy and animal studies, can inform us on regimens most likely to be effective. Clearly, one must balance the risk of incomplete therapy and recurrent disease with the dangers of increased toxicity and expense from prolonged therapy. One thoughtful approach, based on these many variables, suggests use of the "most effective therapy first for 10 to 12 weeks, or for at least 4 to 6 weeks beyond resolution of all clinical and radiographic abnormalities, whichever is longer."[372] Length of therapy should be individualized, and factors such as recovery from neutropenia or other immunocompromised state, extent of disease, presence of graft-versus-host disease, and coinfections (e.g., CMV) predict poorer outcome and slower response and probably will prolong duration of therapy for patients with these comorbid findings.

In terms of adjunctive therapy, surgery may be recommended for cutaneous and soft tissue infections,[171] for lesions on the great vessels or major airways to prevent massive hemoptysis[37,58,60,312] in patients with endophthalmitis[447] and osteomyelitis,[205] and for removal of remove of residual lesions before hematopoietic stem

cell transplantation is performed. Immunomodulatory strategies that improve host immune response, in theory, are attractive adjuvant therapies. Alveolar macrophages, polymorphonuclear neutrophils, and pulmonary dendritic cells are critical first-line defenses against IA.[344] Therefore, modalities that improve the number or function of these cells may improve outcome. Decreasing the use of immunosuppression and steroids as much as possible should be the goal in transplant recipients with IA. Additional strategies, including enhancement of T_H1 immune responses, exogenous administration of colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF]) or cytokines (interferon-γ) to activate or recruit phagocytes (or both), G-CSF donor-primed white blood cell transfusions, and augmentation of innate pathogen recognition pathways (toll-like receptors, pentraxins), all still are investigational.[137,140,343,366,398,400] Finally, vaccine strategies and adoptive immunotherapy have shown promise in animal models of IA and await further refinement and clinical trials.[43-46,64,366]

When *Aspergillus* causes invasive disease, mortality rates are high (30% to 100%) and notably so for invasive and disseminated forms of the infection.[57,139,273,390] In a review of English language articles on *Aspergillus* infections in LTRs, the overall mortality rate was 53 percent (59/112), 24 percent (9/38) for tracheobronchial or BA infections, 82 percent (18/22) in patients with invasive pulmonary disease, and 67 percent (2/3) for disseminated invasive infection.[376] These published data are on adult patients (19-64 years old) and reflect the limited therapeutic options previously available (before the advent of extended-spectrum azoles and echinocandins). Somewhat surprisingly, several studies in which the mortality of IA in neutropenic patients was compared with that of non-neutropenic patients found a comparable or higher incidence of mortality in the latter group.[84,272] Authors speculate that a lower index of suspicion may delay establishing the diagnosis and that suboptimal monitoring or lack of the use of *Aspergillus* active fungal prophylaxis may lead to high mortality rates.

Despite the lack of controlled trials, two surveys document that most lung transplant centers in the United States and worldwide use prophylactic or preemptive systemic antifungals (itraconazole or amphotericin formulations), aerosolized amphotericin formulations, or both in patients with preoperative or postoperative isolation of airway *Aspergillus*.[113,188] Because *Aspergillus* infections are acquired through the lungs and most infections are pulmonary, attaining high pulmonary drug levels via aerosolization and limiting systemic toxicity are attractive options for prevention.[384] Several nonrandomized, non–placebo-controlled trials have suggested a reduction in IA infections with the use of aerosolized amphotericin formulations.[61,111,112,176,283,285,316,338] A single retrospective study incorporating the use of voriconazole prophylaxis in LTRs has been published.[184] This study compared targeted itraconazole prophylaxis, with or without inhaled amphotericin, in patients colonized by *Aspergillus* preoperatively or postoperatively with universal voriconazole for a minimum of 4 months. The rate of IA at 1 year was 1.5 percent in patients receiving voriconazole versus 23.5 percent in the other group. In addition, there was a significant delay in *Aspergillus* colonization in patients receiving voriconazole, thereby permitting healing of the BA, and a considerable decrement in immunosuppressive therapy in most patients by that time. Abnormalities in liver enzymes were common findings; twice as many patients had to discontinue antifungal therapy in the voriconazole group because of side effects. All liver enzymes returned to normal within 2 months of terminating therapy. Finally, interactions with CNIs need to be managed by decreasing doses and monitoring serum levels of tacrolimus. Based on two phase III studies, posaconazole appears to be the drug of choice for prophylaxis of invasive fungal infections in certain high-risk patient populations.[82,418] The generalizability of these findings to SOTRs has not been examined. Further randomized, multicenter studies are needed to clarify which agents and prophylactic strategies are most effective.

Prevention of IA through environmental controls also is important.[319,324,336] Cases of IA in transplant recipients can be nosocomial or community acquired. Most germane to prevention is air control inasmuch as both epidemic IA and sporadic IA correlate with concentrations of *Aspergillus* in the air.[5] A protective hospital environment should consist of high-efficiency particulate air (HEPA) filtration, positive air pressure, high air exchange rate, properly sealed rooms, and removal of carpets, plants, and water-damaged ceiling and floor tiles.[83,116,164,324,413] In addition, the environment and air should be monitored frequently for changes in particulates and fungal spores. Patients should be wearing "fit-tested" masks (N95) when leaving protected environments, effort should be made to have construction barriers in place, and patient transport routes should be adjusted accordingly if construction is occurring in the hospital and clinics.[319] When patients are discharged home, they should be counseled to avoid certain high-risk exposure to agents such as dust and mold if possible.[324]

Candida

Candida infections in LTRs often occur early, within the first month, in the form of BSI; urinary tract infections, especially if indwelling catheters remain in place; respiratory tract infections (tracheitis); pneumonia; and, rarely, BA site infections. Although colonization of the respiratory tract is a common occurrence, primary invasive candidal pneumonia is not. Invasion usually occurs when comorbid conditions are present.[217] Rarely, disseminated disease of abdominal organs and the CNS occurs.[321] The source of infection usually is endogenous, although contributions from donor organs also are possible. Risk factors for candidal infections in transplant recipients include surgical complications, use of broad-spectrum antibiotics, CMV infection, and indwelling foreign bodies.[217,321]

The diagnosis of candidal infection can be challenging and requires differentiating colonization from infection because *Candida* spp. are ubiquitous, especially in the upper GI and respiratory tracts. Although the diagnosis of most candidal infections is made by culture, these techniques are insensitive and, except for blood culture, nonspecific. If recovery of *Candida* spp. from BAL fluid is associated with respiratory symptoms or deterioration of lung function (e.g., increased sputum production), treatment should be considered, although other causes such as rejection and co-infections should be taken into account. *Candida* in the blood should be treated, and indwelling catheters should be removed as soon as feasible. Organisms should be identified to the species level because of species-specific susceptibility profiles. Early germ tube determination can confirm the presence of *Candida albicans*, and a negative test can alert the physician to the presence of non-*albicans* species, which may have an impact on the choice of antifungal agent.[321] Newer molecular probes, such as PNA FISH, can identify *C. albicans* rapidly from positive blood cultures.[7]

The Fungitell beta-glucan assay measures a cell wall component of many fungi, including *Candida* spp., and, therefore, is not specific for *Candida*. It has been FDA-approved as an adjunct for the diagnosis of invasive *Candida*, although its role in the early diagnosis of these infections is under investigation.[321] Use of the serum galactomannan antigen assay and PCR techniques shows some promise, but these techniques are still experimental, and the ubiquity of *Candida* increases concern about contamination with PCR.[133,321] The usefulness of these tests in LTRs with candidal infections is currently unknown.

The choice of agent for the treatment of *Candida* infections has become more complicated; non-*albicans Candida* spp. are becoming more prevalent, as are azole-resistant *C. albicans* isolates.[321,326] *Candida krusei* is innately resistant to fluconazole and itraconazole, whereas *Candida glabrata* has variable susceptibility

to these drugs. Voriconazole and posaconazole are likely to be effective. Treatment failures have been noted with the use of echinocandin therapy for *Candida parapsilosis* infections, and some *Candida lusitaniae* strains may be resistant to polyene antifungals.[108] Putative risk factors for infections with these organisms include widespread use of fluconazole, prolonged pretransplant hospitalization, and long-term use of broad-spectrum antibiotics. The choice of initial antifungal therapy should be based on azole exposure, susceptibility profiles, dominant species at the institution caring for the patient, comorbid conditions, sites of involvement, and the use of other medications that might have significant drug-drug interactions.[321] Fluconazole is appropriate for *C. albicans* infections in moderately ill patients. For severely ill or hemodynamically unstable patients or for those with suspected or proven *C. glabrata* or *C. krusei* infection, the use of LFAB or an echinocandin is preferred. Alternative agents include the newer azoles voriconazole and posaconazole. Duration of therapy, as with other infections, should be individualized, but treatment should be continued for at least several weeks after the last positive culture has been obtained and the signs and symptoms have resolved.[322] As noted earlier for *Aspergillus* infections, issues of dosing in pediatrics with the newer antifungals and drug-drug interactions should be considered. Several excellent resources are available for detailed treatment algorithms.[321,322,391] Updated IDSA guidelines for the treatment of candidal infections are expected in 2007. Antifungal susceptibility testing should be considered on non-*albicans Candida* spp. and for *C. albicans* infections that are refractory to conventional therapy. Interpretive breakpoints are available for most common antifungals, although those for the echinocandins still are being determined.[6,13,321]

Cryptococcus

Though relatively rare, cryptococcosis is the third most common fungal infection seen in solid organ transplantation, after *Aspergillus* and *Candida*.[430] Disease can be newly acquired, reactivated from latent disease, or derived from the donor organ.[147,187,464] Although meningitis generally is thought to be the most common manifestation of cryptococcal disease,[187,464] two recent studies suggest that in SOTRs, CNS disease and pulmonary disease are equally common occurrences.[374,430,433] Disseminated disease also is a common finding (61% of cases) and is most likely to be seen in liver transplant recipients and least likely in LTRs.[374] Infection occurs less frequently in pediatric patients than in adults[385] and more commonly in the northeastern United States than in other locations.[430] It is most common in heart and liver transplant recipients and least common in LTRs.[430,433,464] Additional unique properties of cryptococcal infections appear to be seen in the SOTR population, notably an intriguing relationship between the immunosuppressive regimen and clinical findings. A review of published reports of cryptococcal infections in transplant recipients and a prospective multicenter study suggest that patients receiving CNI-based immunosuppressive therapy were less likely to acquire CNS disease and had lower mortality rates.[187,374] A proposed mechanism for protection of this site is the temperature-dependent antifungal activity of CNIs, which suppresses fungal growth at 37° C but not at 24° C, coupled with the high level of CNS penetration by tacrolimus.[187] Additionally, these authors suggest that cutaneous infections may appear more like bacterial cellulitis than the typical molluscum contagiosum–like lesions seen in HIV-infected patients.[187,385] Finally, an immune reconstitution syndrome that correlates with the evolving host response to infection also has been described in SOTRs with cryptococcosis,[381] and it may be associated with allograft loss, as described in renal transplant recipients.[380]

The diagnosis can be made by culture, visualization of encapsulated yeast with India ink or other special stains, and cryptococcal capsular polysaccharide antigen in serum or CSF.[72] Serum cryptococcal antigen is most reliable for CNS and disseminated disease but not for pulmonary infection.[430,433]

The mainstay of therapy for severe, disseminated disease with CNS involvement remains combination induction therapy with an amphotericin-containing regimen plus flucytosine.[355,379] Therapy should continue for an extended period because relapses are well documented, especially in HIV-infected patients. The risk of relapse in SOTRs and the optimal length of therapy are not known. Suppressive therapy with fluconazole for 6 to 12 months has been suggested after induction therapy.[355] Duration of treatment less than 6 months has been associated with an increased rate of relapse.[379] Management of elevated intracranial pressure also should be considered.[72] For less severe disease localized to the lungs, fluconazole alone may be adequate.[355,379] Mortality rates vary by site of infection and type of transplant and possibly by immunosuppressive regimen. The overall mortality rate for cryptococcal disease in SOTRs is 14 to 30 percent. The highest rates are seen in liver and kidney transplant recipients with disseminated disease or fungemia, or both (20-70%). The lowest mortality rates (3-13%) are seen in localized pulmonary disease.[374,433,464]

Pneumocystis jiroveci (Formerly *Pneumocystis carinii*)

Pneumocystis pneumoniae (PCP) infections are caused by the renamed fungal pathogen *Pneumocystis jiroveci*.[402] PCP has been associated notably with defects in T-cell immunity, as in HIV infection, in patients with leukemia, and with the immunosuppression used in SOTRs. It also is described in patients with other immune defects, including those associated with steroid use and radiation therapy, neutropenia, and congenital immunodeficiency.[341] Serologic data suggest universal, albeit asymptomatic, infection occurs by the time the patient is 4 years of age. In most cases, symptomatic PCP in an immunocompromised host is thought to be reactivation of latent infection, although person-to-person transmission also may occur.[93]

Heart-lung recipients and LTRs are at increased risk for developing infection, with reported attack rates of 6.5 to 43 percent without prophylaxis, up to a 10-fold increase from heart transplants alone.[341] Higher rates of infection in LTRs have been associated with CMV co-infection, use of cyclosporine and steroids, and receipt of therapy for rejection. In addition, cases can occur many years after transplantation. Therefore, many experts suggest the benefit of long-term and perhaps lifelong prophylaxis, especially if additional risk factors are ongoing.[332,341] The drug of choice for prophylaxis remains TMP-SMX, and its use is associated with dramatic decreases in the incidence of PCP infection. Additional benefits of this drug include prevention of many community-acquired respiratory, GI, and urinary tract pathogens and protection against most *Toxoplasma gondii* and *Nocardia* infections. Multiple regimens exist, and 3-day/wk dosing appears to be as effective as is daily dosing in all populations studied. Toxicity remains an issue for some patients and includes bone marrow suppression, decreased renal function, hepatitis, and rash/Stevens-Johnson syndrome, which may be severe. Alternative regimens exist for patients intolerant of TMP-SMX, but they should be considered second line because of breakthrough PCP infection or diminished coverage of non-PCP pathogens mentioned earlier. Such alternatives include pentamidine, dapsone, atovaquone, and clindamycin/pyrimethamine. Details of these regimens have been reviewed recently.[341]

PCP infection is manifested as progressive dyspnea, cough, tachypnea, chest pain, and cyanosis over the course of days to weeks. In addition, fevers, sweats, and flulike symptoms may be prominent. Hypoxia and shortness of breath, in the context of normal or minimal findings on chest radiographs, are common findings. Steroids and CNIs may alter the signs and symptoms and render early diagnosis more difficult to establish. The diag-

nosis is confirmed by identification of *P. jiroveci* in respiratory samples or lung tissue. Immunofluorescent staining of organisms with monoclonal antibodies is the technique of choice; Gomori methenamine silver nitrate, which stains cyst forms only (5-10% of the total organisms), is the most reliable staining method.[332] BAL fluid and tissue obtained by open lung biopsy are preferred specimens because they have the highest diagnostic yield.[341] Newer molecular techniques, including PCR, are promising but are nonstandardized and not commercially available.[114,238]

The mainstay of therapy for severe PCP infection remains high-dose TMP-SMX for 14 to 21 days.[126] Therapy can be continued through mild adverse events, such as rash and minimal perturbations in transaminases and complete blood counts. Dose reduction, desensitization, or both may be helpful, and renal dosing should be implemented if renal dysfunction is present. Steroids may be added for severe disease.[332] For patients intolerant of TMP-SMX or those less seriously ill, alternative therapies can be used. Second-line drugs are dapsone with trimethoprim, atovaquone, and intravenous pentamidine. Third-line therapies include trimetrexate, clindamycin/primaquine, and pyrimethamine/sulfadiazine, as well as several others under study.[126] Relapse in patients without acquired immunodeficiency syndrome (AIDS) is an uncommon occurrence with TMP-SMX therapy if a reduction in immunosuppression can be accomplished and co-infections such as CMV do not occur.[126]

Endemic Mycoses

Cases of endemic mycoses—histoplasmosis, blastomycosis, and coccidioidomycosis—causing disease in SOTRs have been reported. Infection may be caused by latent reactivated disease or by donor-derived and newly acquired infections. Because of the nonspecific findings, latency of these organisms, increased worldwide travel, and organ procurement from different parts of the country, infections in transplant recipients may be difficult to recognize, especially if they occur in nonendemic areas.

Coccidioidomycosis, caused by *Coccidioides immitis* and *Coccidioides posadasii*, is the endemic mycosis most commonly seen after transplantation. It occurs in as many as 9 percent of SOTRs in endemic areas of the southwestern United States (especially California and Arizona), northern Mexico, and Central America.[40] Unlike histoplasmosis and blastomycosis, pretransplant infection poses an increased risk for development of post-transplant disease. In addition, if secondary prophylaxis is not given, the mortality rate is very high (70%).[40] Pulmonary infections may be accompanied by an acute onset of respiratory symptoms and fever and progress rapidly to respiratory failure. Nonspecific symptoms of anorexia, weight loss, and fatigue may herald extrapulmonary disease. Dissemination to bones, skin, and the CNS occurs commonly. The time of highest risk appears to be in the first 3 months after transplantation, with the majority of infections occurring by 1 year. Donor-derived coccidioidomycosis has been established in LTRs and liver and renal organ recipients.[280,415,463] None of the patients had evidence of pretransplant coccidioidomycosis, and none lived or traveled to endemic areas. Several of the donors had documented epidemiologic risk factors. These patients all had fulminant pulmonary or disseminated infection within the first 2 weeks after undergoing transplantation. Three of the four infections were fatal.

The diagnosis of coccidioidomycosis can be made definitively by culture, usually from respiratory samples or urine and rarely from blood or CSF.[20] Histopathologic evaluation may reveal large spherules with the presence of endospores. Serologic tests also are available and include tube-precipitin antigen (IgM), which can be detected early in disease, and complementation fixation (IgG), which arises later in the course of infection and is helpful in monitoring response to therapy.[20,40] Immunocompromised patients may have negative serologic findings. Skin testing for delayed hypersensitivity no longer is available in the United States. The optimal therapy for SOTRs with coccidioidomycosis is unknown. Most experts suggest that patients with rapidly progressive, nonmeningeal disease should receive amphotericin B–based therapy until stabilized, followed by a prolonged course of azole therapy (fluconazole, itraconazole, possibly voriconazole or posaconazole). For meningitis, high-dose azoles are indicated, probably lifelong. Patients with evidence of previous infection should receive secondary prophylaxis with azole therapy for a minimum of 6 to 12 months after undergoing transplantation.[20,40,135]

Histoplasmosis capsulatum infection is a rare occurrence after transplantation, even in patients with presumed pretransplant infection. Cases have been observed in conjunction with outbreaks in areas hyperendemic for histoplasmosis, the Mississippi and Ohio River valleys and Central America.[419] Two cases of histoplasmosis in renal transplant recipients were linked by molecular typing to donor-derived disease.[236] Manifestations include pulmonary, mediastinal, inflammatory, and disseminated syndromes with or without CNS involvement.[455] The diagnosis can be made by culture, histopathology, serology, or antigen detection.[455] In immunosuppressed patients with disseminated disease, urine antigen detection and culture appear to be the most useful (sensitivity of 80%).[451] Long-term therapy (3 to 4 months) with LFAB generally is recommended for immunocompromised patients with disseminated or CNS involvement, followed by 6 to 12 months of itraconazole or posaconazole.[450,455] Monitoring antigen levels is beneficial to assess response to therapy and relapse.[451]

Blastomycosis dermatitidis, the causative agent of blastomycosis, appears to be even more uncommon in the post-transplant setting. Indeed, it is a rare event in series of fungal infections in immunocompromised patients, including patients with AIDS, even in endemic areas of the south central and north central United States. Several case reports of post-transplant disease have been described. Manifestations can involve pulmonary, cutaneous, and disseminated disease with or without CNS involvement.[200,368] Most immunocompromised patients should receive an amphotericin-containing regimen until stabilized, followed by a prolonged course (6-12 months) of an azole. Most data are available for itraconazole, although voriconazole and posaconazole also may be effective.[71,200]

Emerging non-*Aspergillus* Mycelial Fungi

The impact of non-*Aspergillus* mycelial fungi is currently unknown for LTRs. Published reports suggest that these mold infections are becoming increasingly common. These organisms include non-*Aspergillus* hyalohyphomycetes, or hyaline hyphae without pigment (*Scedosporium apiospermum*, *Fusarium* spp.); phaeohyphomycetes, or dematiaceous pigmented molds (*Cladophialophora bantaina*, *Scedosporium prolificans*, *Exophiala jeanselmei*, *Pyrenochaeta romeroi*, *Cladosporium* spp.); and zygomycetes, or nonseptated hyphae (*Rhizopus* spp., *Mucor* spp.). All have been described in SOTRs.[182] Many of these organisms have unique susceptibility profiles and thus are less amenable to conventional antifungal agents. The newer azoles, voriconazole and posaconazole, show some promise for therapy.[108] Indeed, these infections may be more likely to be disseminated and fatal than those caused by *Aspergillus* spp.[182]

VIRAL INFECTIONS

Cytomegalovirus

The epidemiology of CMV in SOTRs has changed in recent years. Advances in diagnosis and in preemptive and prophylactic

strategies and therapy have decreased the impact of early CMV in transplant populations. However, it remains one of the most important pathogens in SOTRs, with wide-ranging effects on morbidity and mortality. The source of infection can be endogenous reactivation, or it can be carried by the donor graft or leukocyte-containing blood products and cause primary infection or re-infection. Rarely, primary infection may be acquired from the community.[346]

The publication of definitions has helped standardize studies on rates of CMV and the impact of therapy.[242] The effects of the virus have both profound direct and indirect consequences.[242,346,466] Direct effects of the virus range from CMV infection, which can be detected by viremia (culture positive), antigenemia (pp65 in leukocytes), and DNAemia or RNAemia (generally by PCR), to true end-organ disease. The diagnosis of end-organ disease, such as pneumonitis, GI disease, hepatitis, and CNS disease, requires signs or symptoms of disease at that site with detection of CMV by culture, histopathology, immunohistochemical staining, or in situ hybridization. Except for CNS disease, detection by PCR is not sufficient for establishing the diagnosis because it is probably too sensitive and may signify transient viremia. In addition, the identification of co-pathogens is important and may confound the diagnosis. CMV syndrome with fever, neutropenia, or thrombocytopenia (or any combination) and detection of CMV in blood also have been defined in SOTRs.[242]

The indirect, immunomodulatory effects of CMV appear to have broad-reaching consequences, as mentioned previously. Epidemiologically, CMV has been associated with dysfunction and rejection of the graft, accelerated atherosclerosis (heart transplant), secondary infections, and BOS.[242,467]

The incidence of CMV infection in LTRs is higher than that in other SOTRs. The reasons are multifactorial but include intense immunosuppression, high levels of CMV latency, viral load, and recurrence associated with the lung and its transplantation.[31,468] The incidences of infection and disease are reported to be 54 to 92 percent without prophylaxis[468] and 30 to 86 percent with various different strategies, thus pointing to the difficulty in identifying the optimal regimen.[467] The greatest risk factor for developing CMV infection is donor/recipient (D/R) mismatch, with D^+/R^- having the highest rate of infection, although infection does occur in D^+/R^+ and rarely in D^-/R^- matches.[89] Other risks include the use of antilymphocyte antibody and blood-product transfusion.[468] A study of pediatric LTRs reported that CMV viremia developed in 23 percent of 194 patients.[89] CMV prophylaxis was given to all D^+ or R^+ patients and consisted of 42 days of intravenous ganciclovir. The median time at onset was 80 days. A first episode of viremia was associated with retransplantation or death between days 90 and 365. Early viremia, before 42 days, was not associated with mortality. This study did not find an association between viremia and BOS, but patients with viremia were statistically more likely to experience two or more episodes of acute rejection.

A combination of tools can be used to reduce the incidence of CMV infection. The use of CMV-negative or leukocyte-free blood products for CMV-negative recipients is standard practice in most transplant centers and has been shown to reduce infection rates. Matching of D/R serologic status probably would reduce infection rates but also would limit the donor pool for R^- recipients significantly and is not considered to be indicated. The final strategies use different regimens of antivirals to suppress replication and immunoglobulin products for enhanced passive immunity.[467] These regimens can be prophylactic, in which all patients at risk are treated for a certain period, or preemptive, in which highly sensitive screening techniques, antigenemia (pp65) or DNAemia, are used to identify patients needing therapy. To complicate matters, regimens can include multiple antivirals such as intravenous ganciclovir or acyclovir, and/or oral ganciclovir, acyclovir, or valganciclovir for various periods. A recent international survey of pediatric lung transplant centers reported variable approaches to reducing the incidence of CMV infection.[90] All centers used prophylactic ganciclovir or valganciclovir, generally based on serostatus stratification; the duration of therapy ranged from 3.5 weeks to indefinitely, but most used 12 weeks. In addition, 50 percent of responding centers used CMV intravenous immunoglobulin (IVIG) with variable schedules. One center used a combination of prophylaxis followed by preemption using antigenemia. Although most centers used active surveillance of antigenemia for detection of CMV, PCR also was used, and one center used viral culture. The monitoring regimen also varied considerably.

A consensus of evidence-based recommendations by an expert advisory group has been published recently.[468] The recommendations are as follows: 1. All D^+ or R^+ LTRs should be considered for prophylaxis. 2a. Prophylaxis with valganciclovir for at least 100 days significantly reduces CMV infection. Some limited data suggest that longer duration (up to 180 days) may reduce infection rates further.[142,469] 2b. Combination prophylaxis with CMV IVIG should be considered, if available, because evidence suggests that its use may reduce infection rates further.[466,469] 3. Monitoring should be performed every 2 weeks for the first 6 months after transplantation to assess for breakthrough viremia and disease. Whole-blood quantitative PCR is the method of choice and should be validated at each center. If a preemptive approach is being used, monitoring should be performed more frequently. 4. Breakthrough disease should be treated with ganciclovir, 5 mg/kg every 12 hours for up to 21 days, until the viral load is below detection. Immunosuppression should be reduced if possible. 5. Infection that occurs after the initial prophylaxis has been stopped should be treated with ganciclovir or valganciclovir until the viral load is below detection. 6. Resistance should be considered in patients with breakthrough viremia, recurrent infections, or poor response to therapy. Genotypic analysis should be performed on isolates recovered from these patients. Foscarnet is the drug of choice, with or without ganciclovir, for possible resistant strains. Of note is that valganciclovir is not FDA-approved for prophylaxis in LTRs, although it is for other SOTRs. Available data suggest that it is safe and effective in LTRs as well.[181,469] Data in pediatric patients are lacking. These authors believe that the data are stronger for the safety and efficacy of prophylaxis than for preemptive strategies, although they acknowledge that some centers have used the latter approach effectively.

Epstein-Barr Virus/Post-transplant Lymphoproliferative Disorder

The disease manifestations of primary EBV infection in SOTRs range from uncomplicated mononucleosis to conditions indistinguishable from malignant lymphoma. Early lesions of EBV-driven lymphoproliferation, such as the plasmacytic hyperplasia, are seen in mononucleosis-like syndromes, within the context of normal tissue architecture. The term post-transplantation lymphoproliferative disease (PTLD) generally is reserved for proliferation of EBV-positive immunoblasts and atypical lymphocytes associated with effacement or destruction of normal tissue architecture. These disorders can be classified further into polymorphic or monomorphic PTLD and finally malignant lymphomas that may contain clonal chromosomal abnormalities. These tumors are characterized by rapid and progressive growth despite a reduction in immunosuppression. Fatal non-PTLD viral syndromes can occur in SOTRs as well.[154] The reader is referred to several excellent, in-depth reviews on these topics.[154,335,409]

The manifestation of EBV/PTLD is varied and depends on the site of involvement, which may be intrathoracic, extrathoracic

(abdominal, head and neck, CNS), or disseminated and intranodal or extranodal.[235] Often, PTLD is seen in the allograft, as with lung, liver, and intestinal transplantation.[154] Signs and symptoms of PTLD can be nonspecific, such as fever of unknown origin, malaise, weight loss, and sore throat.[42] Abdominal pain, GI bleeding, intestinal obstruction and perforation, allograft dysfunction such as changes in respiratory status in LTRs, diffuse lymphadenopathy on physical examination or CT, or hepatosplenomegaly should raise the index of suspicion for PTLD. Focal neurologic findings also can be seen with CNS disease. An additional challenge is to differentiate allograft rejection from PTLD; both entities in LTRs may be characterized by allograft dysfunction with diffuse consolidation on imaging, without obvious lymphadenopathy or a mass. Because the therapies for these two conditions are diametrically opposed, increasing or decreasing immunosuppression, this distinction obviously is critical.[154,335]

Risk factors for the development of PTLD have been identified.[42,79] Pretransplant EBV seronegativity (as a surrogate marker for the risk of development of post-transplant primary EBV infection) is probably the most important predisposing factor for the development of PTLD. Because primary EBV infection occurs almost universally in children, older individuals are already immune and young children undergoing transplantation are, therefore, at greatest risk. In addition, concomitant CMV infection or CMV mismatch before transplantation increases the risk for developing PTLD. Patients at highest risk by type of transplant include recipients of lung and intestinal organs. This risk is probably multifactorial and includes more intense immunosuppressive regimens and transplantation of large amounts of lymphoid tissue with the graft, thereby increasing recipients' potential exposure to donor-derived EBV. The published incidence of PTLD in pediatric LTRs ranges from 7.7 to 26.3 percent.[42,79,329] Certain immunosuppressive regimens, such as the use of OKT3 and polyclonal antilymphocyte antibodies and possibly tacrolimus in pediatric patients, are linked to the development of PTLD. Many experts acknowledge that the overall intensity of immunosuppression, not a specific agent, is most important in defining the risk for development of PTLD.

PTLD most often occurs within 12 months after transplantation.[42] Late PTLD has been documented and appears to have specific properties, including an increased incidence in older recipients, long duration of immunosuppression, EBV-negative disease, and poorer prognosis.[79,120,227]

The diagnosis of PTLD requires a high index of suspicion. The gold standard is histopathologic examination of tissue from either excisional or fine-needle biopsy. Specimens should be processed by pathologists familiar with the morphologic classifications, and ancillary tests that may be helpful include staining for EBV-encoded RNA 2 by in situ hybridization (EBERS) and the presence of CD20, which has implications for therapy.[335] Imaging also can be used for presumptive diagnosis, to guide biopsy, and for follow-up.[329,370] In LTRs, CT of the chest may reveal discrete nodules, airspace consolidation, or mediastinal lymphadenopathy. Extrathoracic involvement is less common but may include abdominal lymphadenopathy, liver/spleen lesions, and a thickened bowel wall. On head and neck imaging, the cervical lymph nodes, pharynx, orbit, sinus, and rarely the brain are found to be involved occasionally.

Patients at the highest risk for mortality are those in whom primary EBV infection develops early after transplantation is performed; therefore, every effort should be made to identify these patients. Pretransplant serologic assessment of donors and recipients for both EBV and CMV can alert physicians to most of these high-risk patients, as donor/recipient mismatch of either virus appears to play an important role.[42,79] Once identified, these patients should be monitored carefully by PCR for evidence of primary infection, and careful examination and use of CT scanning for early diagnosis of disease should be included. Several strategies have been used for the prevention of EBV/PTLD in high-risk patients.[154,335] The use of EBV-negative donors, though probably effective, would reduce the donor pool substantially and generally is not advocated. The use of prophylactic antiviral therapy has not been proved to prevent the development of PTLD. Although these agents are active against the lytic viral infection that proceeds PTLD, they are not active in the latent viral phase that characterizes PTLD. Acyclovir and ganciclovir often are used for prevention of CMV, and historical comparisons of the incidence of PTLD in certain high-risk patients receiving them suggest some benefit[92]; however, PTLD has developed in some patients while receiving these antiviral agents. The use of IVIG is similarly a potential, but unproven strategy and is currently undergoing evaluation.[154]

Preemptive strategies aimed at identifying primary infection by blood PCR monitoring have received significant attention.[29,36,151,154,335,345,401,417] In these protocols, high-risk patients undergo EBV quantitative viral load monitoring at frequent intervals, usually weekly, to identify increases associated with infection, a prerequisite for the development of EBV/PTLD. Many issues remain regarding the use of EBV viral load.[151,153,335] For example, these assays are not standardized and therefore are difficult to compare among institutions. Many questions are raised: Which compartment is most revealing and should be sampled—peripheral blood lymphocytes, whole blood, or serum? Is there a threshold level at which therapy should be instituted? How does serostatus affect the sensitivity and specificity of viral loads? Additionally, not all patients with EBV/PTLD have elevated viral loads, and viral loads may be elevated without evidence of disease; therefore, these assays lack specificity. Although these assays are now widely used at transplant centers, further controlled studies are necessary to optimize their use in immunocompromised patients.

When patients with high viral loads are identified, several therapeutic options are available; however, few controlled trials of these interventions have been performed, and the optimal timing and use of each are unknown at this time.[151,336] All experts agree on immediate reduction or cessation, if possible, of immunosuppressive regimens. Most patients with nonmalignant lesions will respond to this maneuver alone. The use of antiviral agents has become routine, though without proven benefit. Patients with a persistently high viral load should be evaluated aggressively for the presence of PTLD on examination and imaging, and suspicious lesions should undergo biopsy for the diagnosis of EBV/PTLD. When the diagnosis of PTLD is made, ideally, immunosuppression should be discontinued, the optimal duration of which is uncertain. Re-initiation of immunosuppressive agents usually is prompted by rejection or clear evidence of clinical and virologic response. Surgical resection and local radiation therapy may be beneficial for localized disease and in the event of GI involvement.

Monoclonal B-cell antibody therapy is now an attractive option for $CD20^+$ lesions not responsive to a reduction in immunosuppression.[335] The currently available product is an anti-CD20 antibody (rituximab). Initial retrospective data reported complete remission rates of 62.5 percent,[282] and these data have been corroborated in several prospective trials.[39,119,303] This therapy generally is well tolerated, although long-term hypogammaglobulinemia is a common occurrence in recipients. In addition, severe CMV and hepatitis B and C infections, as well as parvovirus B19–induced aplasia and enteroviral meningoencephalitis, have been associated with its use.[334] Detailed recommendations for the initial approach to pediatric transplant recipients with EBV/PTLD have been published.[151] For refractory disease, cytotoxic chemotherapy may be indicated. Other investigational therapies include anticytokine therapy (anti–interleukin-6), adoptive immu-

notherapy (EBV-specific cytotoxic T lymphocytes, lymphokine-activated killer cells), and boosting of the host immune response (interferon-α). Vaccine technology is in progress.[151,334]

Other Herpesviruses: Herpes Simplex Viruses 1 and 2, Varicella-Zoster Virus, Human Herpesviruses 6, 7, and 8

Infections with herpes simplex virus (HSV) 1 and 2 are common occurrences in SOTRs, and in older children and adults, HSV usually is a reactivation disease manifested as orolabial or genital disease.[311] Primary disease occurs in young children who contract the infection from viral shedding of close contacts. In LTRs, serious or disseminated disease such as esophagitis, hepatitis, and pneumonitis can occur.[387] Infections tend to occur early, within the first month after transplantation, unless prophylaxis is used. As with other herpesviruses, concomitant infection with CMV is not an uncommon event. The diagnosis can be made clinically when typical lesions are present. Culture and PCR technology can be helpful for unusual manifestations. Prophylactic strategies with ganciclovir or acyclovir for CMV can prevent HSV. Intravenous acyclovir and oral valacyclovir or famciclovir are effective therapies for localized mucocutaneous disease. More severe disease should be treated with intravenous formulations only. Resistance of HSV in SOTRs is rare, but when it occurs, it should be treated with foscarnet.[311]

Primary varicella-zoster virus (VZV) infection can occur in pediatric LTRs, as can reactivation of previous disease leading to herpes zoster. No data on VZV infections in SOTRs have been published since the widespread use of varicella vaccine (Varivax), but, presumably, rates of infection after transplantation are low. Patients should be screened for evidence of immunity, and seronegative transplant candidates should receive varicella vaccine, optimally at least 6 weeks before transplantation.[311] If the vaccine does not prevent disease, it may mitigate development of severe disease. In addition, susceptible family members also should receive vaccine. Exposure in postoperative patients should be treated with a high-titer varicella immunoglobulin preparation if available or IVIG within 96 hours of exposure. Additionally, some experts recommend the use of prophylactic acyclovir if exposure such as household or intimate contact is likely to lead to development of disease or is revealed past the window for immunoglobulin prophylaxis to be effective. Varicella vaccine, which is an attenuated live viral product, generally is not recommended in post-transplant recipients at this time. Limited data suggest that it is safe and may ameliorate disease in some immunocompromised patient populations, such as those with leukemia, HIV infection, or renal transplants.[54] Detailed recommendations for prophylaxis are given in the American Academy of Pediatrics *Red Book*.[17]

Patients taking steroids, especially during the incubation period, are at increased risk for the development of severe disease. Hemorrhagic and disseminated disease, including encephalitis, hepatitis, and pneumonitis, can occur in immunocompromised patients.

Herpes zoster is a common event in adult transplant recipients; rates in children have not been published for SOTRs. A recent study of SOTRs aged 16 to 74 years found a 15 percent incidence of herpes zoster in LTRs, with a mean time to onset of 14 months and a median of 9 months (9 days-5.8 years).[149] The diagnosis is made clinically and with the use of viral culture or PCR techniques if necessary. Infections should be treated with intravenous acyclovir and pain control. Steroids should be diminished if possible.

HHV-6 is an emerging opportunistic viral pathogen. Seropositivity reaches nearly 100 percent in early childhood, and HHV-6 is responsible for febrile illnesses with or without GI or upper respiratory symptoms, febrile seizures, roseola (exanthema subitum, sixth disease), and asymptomatic infection in normal infants and young children.[9] Therefore, disease in all but the very youngest transplant recipients probably represents reactivation. Several studies have documented HHV-6 by PCR or culture (or both) in a majority (66-90%) of apparently asymptomatic adult LTRs.[192,231] Reactivation of HHV-6 can occur in the setting of CMV antiviral prophylaxis. These infections occur early after transplantation (median of 6 and 18 days), and most are without obvious clinical manifestations that could be ascribed to HHV-6 alone. In immunocompromised patients, HHV-6 appears to exert direct and indirect effects on the host. It probably is responsible for rare cases of encephalitis, hepatitis, pneumonitis, febrile illnesses, and bone marrow suppression.[231] The presence of HHV-6 alone or as a cofactor to CMV may augment the immunomodulatory effects and increase the risk associated with fungal and other infections, as well as allograft rejection, BOS, and mortality.[192,275,296]

Many questions regarding HHV-6 in this population remain unanswered. PCR of peripheral blood lymphocytes is the most sensitive method for detection of virus, but it cannot differentiate between latent and active virus. Routine monitoring of asymptomatic patients is not recommended. Data are insufficient to recommend prophylactic or preemptive therapies, although the virus is susceptible to achievable levels of ganciclovir, foscarnet, and cidofovir. Finally, which patients should be treated remains unclear. Treatment with ganciclovir, foscarnet, or cidofovir may be considered in patients with compatible syndromes if other causes are eliminated. Whether asymptomatic patients with documented HHV-6 infection would benefit from therapy with regard to the indirect effects of the virus remains unknown.[5]

The role of HHV-7 and HHV-8 in SOTRs is undefined. HHV-7 is similar to HHV-6 in normal hosts, although it appears to be less prevalent and occurs later in life. Symptomatic disease is less well characterized, but it may be responsible for similar syndromes seen with HHV-6 in normal children and transplant recipients.[311] Evidence of HHV-8 infection in normal children is rare. It is associated with Kaposi sarcoma in immunocompromised patients, as well as body cavity lymphomas, PTLD, and Castleman disease.[10] It also may be associated with fever and bone marrow suppressive syndromes of donor origin in transplant recipients.[245]

Community-Acquired Respiratory Viruses: Respiratory Syncytial Virus, Parainfluenza Virus, Human Metapneumovirus, Influenza, and Adenovirus

The paramyxoviruses respiratory syncytial virus (RSV), parainfluenza virus (PIV), and human metapneumovirus (hMPV) are common causes of upper and lower respiratory tract disease in normal children; symptoms range from congestion and rhinorrhea to laryngeal tracheobronchitis (croup), bronchiolitis, and pneumonia.[12-14] Disease can be severe and persistent in immunocompromised patients, although the exact impact of these viruses on LTRs is not well studied. Co-infection and sequential infection with other respiratory viruses, including CMV, probably occurs.[143] Importantly, transmission occurs from person to person, from exposure to nasopharyngeal secretions, from infected individuals, and from fomites. Consideration should be given to screen recipients for incubating respiratory viruses before they undergo transplantation, especially if high levels of circulating virus are present in the community or illness is present in family members, or both. Strict adherence to hospital infection control practices is most important in reducing nosocomially acquired disease from visitors and health care workers. Patients and their families should be counseled on avoidance of exposure and on good handwashing practices when discharged from the hospital.[81]

RSV can cause severe lower respiratory tract disease in LTRs. Although most infections resolve, with or without therapy, fatal

cases have been reported, as have long-term declines in pulmonary function.[38,143,268,448] The diagnosis can be made by rapid antigen-detection kits, standard viral culture, or more rapid shell vial culture methods, and some centers offer PCR detection; the preferred specimen is nasal washings, although in adults with lower tract disease, BAL fluid is recommended,[14,81] Risk factors for poor outcome in immunocompromised patients include neutropenia, lymphopenia, age younger than 1 year, underlying lung disease, and augmented immunosuppression.[81] High mortality rates in HSCT recipients have led to prevention and treatment strategies that can serve as models for care in SOTRs,[102,144,456] though they are not without controversy because no controlled data exist.[38,146] Supportive care remains the mainstay of therapy. For children with upper tract disease and risk factors or lower tract disease, aerosolized ribavirin should be considered. In addition, because outcomes, even in treated HSCT recipients, are poor with ribavirin alone, some experts suggest combination therapy with RSV IVIG or monoclonal antibody (palivizumab) for immunocompromised patients with significant infections.[38,81,407] Effective prophylaxis with palivizumab and RSV IVIG has been achieved in young infants with lung disease.[160,274] Care must be taken when extrapolating to other patient populations, given the unexpected results of some studies in infants with complex congenital heart disease who are administered RSV IVIG[371] but not pavilizumab.[123] Some experts would consider the use of immunoprophylaxis in young infants undergoing organ transplantation during the RSV season.[81]

hMPV was described in healthy young children in 2001. It appears to have signs and symptoms similar to those of RSV, and almost universal infection probably occurs by 5 years of age.[422,459] The impact of hMPV on immunocompromised patients is as yet uncharacterized, in part because it has been identified relatively recently and diagnostic tests are not widely available. The virus can be cultured, but reverse transcriptase PCR appears to be the test of choice. Antigen assays are not yet available.[12] When found in adult LTRs with upper and lower respiratory tract symptoms, it usually is a single pathogen or co-pathogen.[143,225] In addition, it has been associated with episodes of allograft rejection and mortality.[225] Therapy is supportive, with treatment of co-pathogens if identified.

PIV (types 1 to 4) is isolated frequently as a cause of upper respiratory infections and croup in normal children.[13] PIV can cause severe lower tract infection in immunocompromised patients, including respiratory failure in LTRs, most notably caused by serotype 3.[21,431,449] Though rarely fatal in adults, persistent declines in pulmonary function and acute allograft rejection are important consequences of PIV infection.[268,431,449] A retrospective study on PIV in pediatric SOTRs (liver, small bowel, lung, heart, kidney) found significant age-related morbidity and mortality.[21] Although 44 percent of all patients with PIV had upper respiratory infections, only 11 percent of children younger than 1 year old had limited disease. A 16 percent mortality rate was associated with PIV, and predictors of mortality included age younger than 6 months, infection occurring less than 3 months after transplantation, and augmented immunosuppression. Infection in these children occurred in the context of community outbreaks. The diagnosis can be made most rapidly by antigen detection; culture isolation can take weeks. Respiratory secretions obtained from nasal washings or BAL fluid can be used.[38] No proven therapy for PIV in LTRs is available. Intravenous and aerosolized ribavirin has been used in immunocompromised hosts, but without randomized controlled data or clear evidence of efficacy.[38,268]

Despite available immunoprophylaxis and chemoprophylaxis, influenza viruses A and B remain an important cause of morbidity in the normal population and lead to a considerable rate of mortality in the very young and the elderly.[11] Transplant recipients are at risk for acquiring community-acquired infection during the yearly epidemics, as well as nosocomial infection from visitors, hospital workers, and other transplant recipients as a result of outbreaks occurring in the inpatient setting.[256,348,429] Influenza infection is relatively rare in SOTRs—4.2 percent of adult LTRs over the course of a 10-year-period and 2.6 percent of pediatric SOTRs over a similar period[21,38]—but LTRs appear to be at a uniquely high risk of acquiring infection. In the adult study, the incidence was 41.8 cases per 1000 person-years for adult LTRs versus 2.8 and 4.3 per 1000 in liver and kidney transplant recipients, respectively.[432] The authors speculate that optimal protection from influenza infection afforded by serum and secretory antibodies in the respiratory tract are altered in LTRs, thereby leading to higher attack rates.

In addition to the usual symptoms of acute onset of malaise, fever, myalgias, and respiratory symptoms, GI symptoms also may be prominent.[136] Most pediatric SOTRs with influenza had minimal disease consisting of upper respiratory symptoms, although 3 of 13 patients (23%) died.[21] In these children, steroid bolus and OKT3 therapy given within a week of diagnosis of infection were associated with mortality. Transplant recipients may be at increased risk for acquiring secondary bacterial infections and nonpulmonary complications such as hepatitis, myocarditis, and aseptic meningitis.[38,432]

Influenza is unique among the respiratory viruses in that both vaccine and chemoprophylatic strategies are available, as are several effective therapies. Unfortunately, immunosuppressed patients may not respond well to influenza vaccine, and, if disease is not recognized promptly, the effectiveness of therapy for established disease may not be optimal. Studies on the immunogenicity of influenza vaccine in pediatric SOTRs are more encouraging than in adult reports, which have documented poor response, especially when associated with MMF or sirolimus, and occasional association with acute rejection.[54,167] In pediatric renal transplant recipients, response was similar to that of normal controls, without evidence of rejection,[117,134] although in pediatric heart transplant recipients protective antibody responses were not achieved until three doses of vaccine were administered.[4] The current recommendation is that influenza vaccine be administered yearly to all SOTRs and those awaiting transplantation, as well as to household contacts and caretakers.[11,54,81] Chemoprophylaxis can be administered to patients who have not been vaccinated or who have not had sufficient time to respond to vaccination, especially if influenza is circulating in the community. Agents that are approved for prophylaxis of influenza A in children older than 1 year include amantadine and rimantadine, although resistance commonly is reported to these antivirals, and oseltamivir, which is additionally active against influenza B.[11,429]

The diagnosis of influenza can be made by rapid antigen testing, which is highly sensitive in ill children, though less so in adults with a lower burden of disease. PCR techniques, including multiplex assays for detection of multiple respiratory viruses in one sample, are currently under development but are not yet widely available.[80,131,222,411]

Most experts would recommend therapy with antiviral agents in an LTR with suspected (community epidemic with compatible symptoms) or proven influenza, although their utility in such patient populations has yet to be defined.[38] The choice of agent depends on the type of virus (A or B) and information about resistance. The neuraminidase inhibitors oseltamivir and zanamivir are currently favored because of their broad spectrum of activity and less reported resistance.[81,429] Some would consider the addition of aerosolized ribavirin for severe lower tract disease.[81] The implications of pandemic influenza, including higher disease burdens and mortality and longer duration of viral shedding with considerable potential for spread of disease, for those who already have undergone transplantation and those awaiting transplants probably would be significant. These authors speculate that transplantation under these circumstance probably would be curtailed.[220]

Despite recent interest, published data on adenovirus (AdV) infections in pediatric SOTRs are limited, and most describe infection in liver transplant recipients. The majority of information on AdV in pediatric immunocompromised hosts comes from those undergoing hematopoietic stem cell transplantation. AdV infections in SOTRs appear to be more common occurrences in young pediatric than adult transplant recipients[94,279,304] because young transplant recipients may remain naïve to many of the 51 recognized serotypes. AdV infections have multiple putative sources, including the donor organ, reactivation from latency in host tissues, and infection acquired from the community or nosocomially.[62,210,270,279,331]

Cases of acute, disseminated, and fatal disease have been described in cardiothoracic transplant recipients. In LTRs, infections occur in the early post-transplant period and often cause disease in the graft in the form of necrotizing pneumonia.[49,304] AdV has been associated with graft dysfunction, BOS, retransplantation, and death.[50]

Several methods that are used for the identification of AdV include culture, direct identification of antigens, and serology, as well as histologic examination of tissues for the presence of AdV inclusions and immunohistochemical staining.[75,81] Viral isolation by culture can be expedited by centrifugation in shell vial assays and immunofluorescent staining with adenoviral monoclonal antibodies, although viral serotyping cannot be done with this method. Direct identification of AdV antigens, usually performed on respiratory specimens, can be achieved by radioimmunoassay, immunofluorescence, or ELISA techniques, which are rapid and specific but less sensitive than culture.

Detection of virus with culture techniques and direct antigen detection are insensitive in identifying patients at risk for the development of disseminated disease. In addition, cultures may take a week or longer, and neither method may detect low levels of circulating virus. PCR is emerging as a powerful tool for detection of AdV in body fluids and tissues and for serotyping.[115,161,170,232,239,362] The virus's ability to establish latency can render interpreting the presence of virus or viral DNA in clinical specimens a challenge.[138,233] A single determination of the presence of AdV by PCR in immunocompromised patients may be nonspecific and perhaps misleading. As with other important viruses that establish latency, quantitative viral load patterns appear to be more informative with regard to the pathogenic role of AdV in these patient populations. Studies in pediatric HSCT recipients support the use of blood PCR surveillance as a method to identify patients at risk for disseminated disease.[78,115,161,170,232,239,362,439] These methods have not been validated in LTRs.

The optimal therapy for AdV has not been determined. Supportive care and reduction of immunosuppression are the mainstays of therapy currently recommended.[81] Recent data suggest that administration of cidofovir may be helpful in severely ill patients with disseminated disease and rising viral loads.[63,178,230,243,438,465] Use of this agent may be associated with significant renal toxicity,[169,230,333] and use of modified dosing regimens has been investigated with some success.[63,178,293,438] Strategies involving adoptive immunotherapy also may be feasible and efficacious in the future. Data on these therapeutic modalities have been reviewed recently.[177]

Although a detailed discussion is beyond the scope of this chapter, the link between respiratory viruses and BOS or chronic allograft dysfunction should be addressed briefly. BOS is a progressive condition, without good treatment options, and the greatest impediment to long-term survival for LTRs. It affects 50 percent of patients alive 5 years after transplantation and is the leading cause of death in adult and pediatric LTRs 1 year after transplantation.[416,446] Although the exact mechanisms are still being determined, the final common pathway is epithelial injury and intraluminal proliferation of fibroblasts leading to air flow obstruction.[186,203,427] Stimulation of T cells and release of cytokines and chemokines by viruses are leading candidates for the initiation of these pathways. Many studies have linked viral infections, such as CMV, AdV, RSV, PIV, and others, often working in concert, to the development of BOS.[122,136,219,317,428,431] The role of these agents has yet to be proved, although it is biologically plausible.[186] Reduction of BOS remains an incentive for the continued development of preventive strategies against these viral infections.

ZOONOSES: RABIES, WEST NILE VIRUS, LYMPHOCYTIC CHORIOMENINGITIS VIRUS, AND *BORDETELLA*
