CHAPTER 231

Malaria

Elizabeth D. Barnett

Malaria is a disease of global importance, affecting approximately 270 million people and causing 1 to 2.5 million deaths yearly. Most malaria deaths worldwide occur in children.[128] Malaria is transmitted regularly in parts of Africa, Asia, the Middle East, Central and South America, Hispaniola, and Oceania. It has been imported by travel to nearly every part of the world. Because of the ubiquity of malaria, the ability to recognize its signs and symptoms and knowledge about methods of prevention and treatment are important for health care professionals wherever they practice.[32,39]

Malaria usually is transmitted by bites of infected female anopheline mosquitoes. Disease typically results from infection with one or more of the four species of *Plasmodium* (*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, or *Plasmodium malariae*) that infect humans. A fifth species, *Plasmodium knowlesi*, has also been identified to cause human malaria.[18a] These protozoa have complex life cycles involving arthropod and vertebrate hosts. Untreated, *P. falciparum* malaria can progress to coma, renal failure, pulmonary edema, and death. Asymptomatic carriage may last decades in the case of *P. malariae*. Relapses are common with *P. vivax* and *P. ovale*. Resistance of the parasites to antimalarial agents and incomplete success in developing and maintaining programs to eradicate the mosquito vectors have contributed to making malaria a persistent worldwide challenge.

HISTORY

Malaria has been known since antiquity and probably affected prehistoric humans. Fossilized mosquitoes have been found in geologic strata 30 million years old. Descriptions of the signs and symptoms of malaria have been found in early Hindu and Chinese writing, and Hippocrates described seasonal and geographic aspects of the disease.[120] Numerous references to malaria occur in literature, ranging from Shakespeare's *The Tempest* to Laura Ingalls Wilders' *Little House on the Prairie*. The name is derived from the Italian *mal aria* ("bad air") based on recognition of the connection between malaria and swamps. The first methods of malaria control, draining of swamps, were based on this association.

The first malaria treatment known to Europeans, bark of the cinchona tree, was identified in the early 17th century almost 200 years before the active ingredient (quinine) was isolated. Not until the late 1800s was the vector-borne nature of malaria understood and described; for their roles in this discovery, Laveran, a French military surgeon working in Algeria, and Ross, a British military physician working in India, were awarded Nobel prizes. Further work by many investigators rounded out the current understanding of the life cycle of the malaria parasites and the complex interrelationship with vector mosquitoes.

During the 20th century, parallel efforts directed toward vector control and discovery and development of drugs to treat malaria were undertaken. The development of larvicides and insecticides permitted control of the mosquito vector. The spectacular success of house spraying with dichlorodiphenyltrichloroethane (DDT) was instrumental in eradicating malaria from most of North America and Europe and in significantly decreasing its prevalence in the Mediterranean area, the Middle East, the Far East, and parts of southern Africa.[100] The development of antimalarial drugs, stimulated largely by the need to protect soldiers during World Wars I and II during shortages of the standard antimalarial agent quinine, allowed for successful treatment of malaria cases.

The World Health Organization (WHO) launched a global campaign for eradication of malaria in 1957. Early successes, attributable to the efficacy of DDT and development of new antimalarial agents, subsequently were hindered by resistance of mosquito vectors to DDT and resistance of the parasites to antimalarial drugs. In 1969, the WHO philosophy on malaria was altered to emphasize the development of health services and research. The goals of malaria control since then have been refined and broadened to include implementation of selective and sustainable preventive measures, early diagnosis and prompt treatment, early detection or prevention of epidemics, and strengthening of local infrastructures to allow better understanding of the determinants of local transmission and malaria control.[100,120]

During the past several decades, transmission of malaria has increased in many areas despite adoption of these measures. Factors contributing to increases in the number of cases of malaria in many areas and re-emergence in areas thought to be free of disease include lapses in local control measures; resistance to antimalarial drugs; changes in climate; and population movement as a result of urbanization, mass displacement of populations, and international travel.[8,58,65,69]

ORGANISM

The life cycle of malaria parasites is complex and requires a suitable population of anopheline mosquitoes and infected humans for completion (Fig. 231–1). To begin the cycle, the female anopheline mosquito injects sporozoites along with saliva in preparation for taking a blood meal from a vertebrate host. Sporozoites, the infective stage of *Plasmodium*, remain in the circulation for less than 1 hour and then migrate to the liver, where they invade hepatocytes and multiply asexually. Proliferation within hepatocytes takes approximately 1 week for *P. falciparum* and *P. vivax* and approximately 2 weeks for *P. malariae*. At the end of this period, mature tissue schizonts rupture and release thousands of merozoites, which then invade red blood cells (RBCs). *P. vivax* and *P. ovale* have a second type of exoerythrocytic form, the hypnozoite, which can remain dormant for weeks to years. Dormant hypnozoites may develop weeks, months, or years later into merozoites, which then can enter RBCs and cause relapse of malaria. The factors that influence which exoerythrocytic form develops are not understood.

Merozoites released from tissue schizonts invade RBCs, where the erythrocytic phase of the life cycle occurs. Two pathways exist in the erythrocytic, or blood, phase: asexual and sexual. In the asexual phase, development of the parasite begins with the youngest stage, the trophozoite, or ring form. The parasite undergoes nuclear division to form schizonts and then merozoites in the asexual multiplication process, called *erythrocytic schizogony/merogony*. Lysis of RBCs releases the merozoites, which invade other RBCs, perpetuating the asexual erythrocytic cycle. The cycle continues until interrupted by treatment or by the host's immune response.

In the sexual phase, subpopulations of merozoites in the erythrocytic phase differentiate into gametocytes, or sexual forms, which then are available for ingestion by mosquitoes to complete the life cycle within the mosquito. Female macrogametocytes and male microgametocytes appear in the circulation within 3 to 15 days of the onset of symptoms. Gametocytes of *P. vivax* may appear in 4 days, whereas gametocytes of *P. falciparum* may require 10 days for development.

In the stomach (midgut) of the mosquito, male gametocyte nuclei divide into four to eight nuclei and form motile gametocytes that fertilize the female gametocytes. The zygotes become motile ookinetes that migrate through the wall of the midgut, attach to its outer surface, and form oocysts. The oocysts rupture 9 to 14 days later and release sporozoites that invade the mosquito salivary glands, where they are ready for inoculation into the next vertebrate host.

EPIDEMIOLOGY

Transmission of malaria occurs in large parts of Africa, the Indian subcontinent, Southeast Asia, the Middle East, Oceania, and Central and South America (Fig. 231–2). Although indigenous transmission of malaria has been eradicated almost completely from the United States, Canada, northern Europe, most of the Caribbean, parts of South America, Israel, Lebanon, Reunion, Singapore, Hong Kong, Japan, Korea, Taiwan, Brunei, and Australia, many cases of imported malaria occur in these countries each year.[120]

P. falciparum is the major malaria species in sub-Saharan Africa and the island of Hispaniola, with *P. malariae* assuming a more minor role. *P. vivax* occurs alongside *P. falciparum* in the Indian subcontinent, Central and South America, Mexico, Southeast Asia, and Oceania. *P. ovale* occurs mainly in Africa. *P. vivax* occurs rarely in sub-Saharan Africa because most Africans lack the Duffy blood group antigen necessary for parasite invasion.

TRANSMISSION

EPIDEMIOLOGIC TERMINOLOGY

Patterns of transmission of malaria include stable endemic malaria (natural transmission occurring over many years, with a

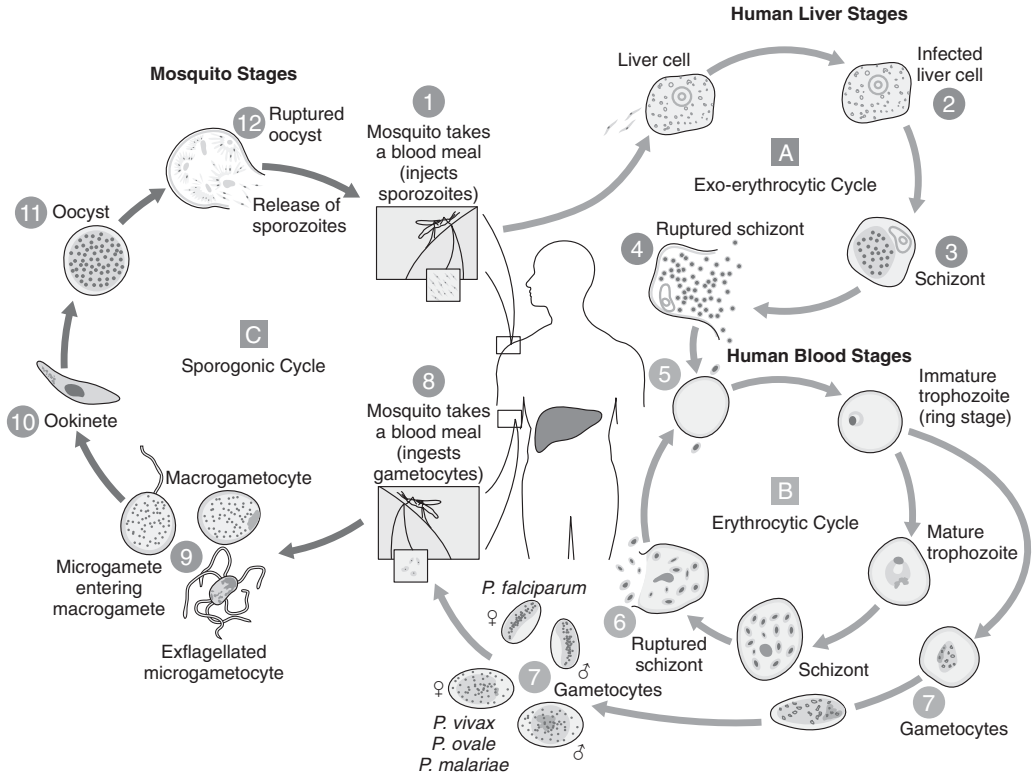

Figure 231–1 Life cycle of the human malaria parasites. The malaria parasite life cycle involves two hosts. During a blood meal, a malaria-infected female *Anopheles* mosquito inoculates sporozoites into the human host ❶. Sporozoites infect liver cells ❷ and mature into schizonts ❸, which rupture and release merozoites ❹. (Of note, in *P. vivax* and *P. ovale* a dormant stage [hypnozoites] can persist in the liver and cause relapses by invading the bloodstream weeks, or even years later.) After this initial replication in the liver (exo-erythrocytic schizogony **A**), the parasites undergo asexual multiplication in the erythrocytes (erythrocytic schizogony **B**). Merozoites infect red blood cells ❺. The ring stage trophozoites mature into schizonts, which rupture releasing merozoites ❻. Some parasites differentiate into sexual erythrocytic stages (gametocytes) ❼. Blood stage parasites are responsible for the clinical manifestations of the disease. The gametocytes, male (microgametocytes) and female (macrogametocytes), are ingested by an *Anopheles* mosquito during a blood meal ❽. The parasites' multiplication in the mosquito is known as the sporogonic cycle **C**. While in the mosquito's stomach, the microgametes penetrate the macrogametes generating zygotes ❾. The zygotes in turn become motile and elongated (ookinetes) ❿, which invade the midgut wall of the mosquito where they develop into oocysts ⓫. The oocysts grow, rupture, and release sporozoites ⓬, which make their way to the mosquito's salivary glands. Inoculation of the sporozoites ❶ into a new human host perpetuates the malaria life cycle. (See companion Expert Consult web site for color version.) (*From http://www.cdc.gov/malaria/biology/life_cycle.htm.*)

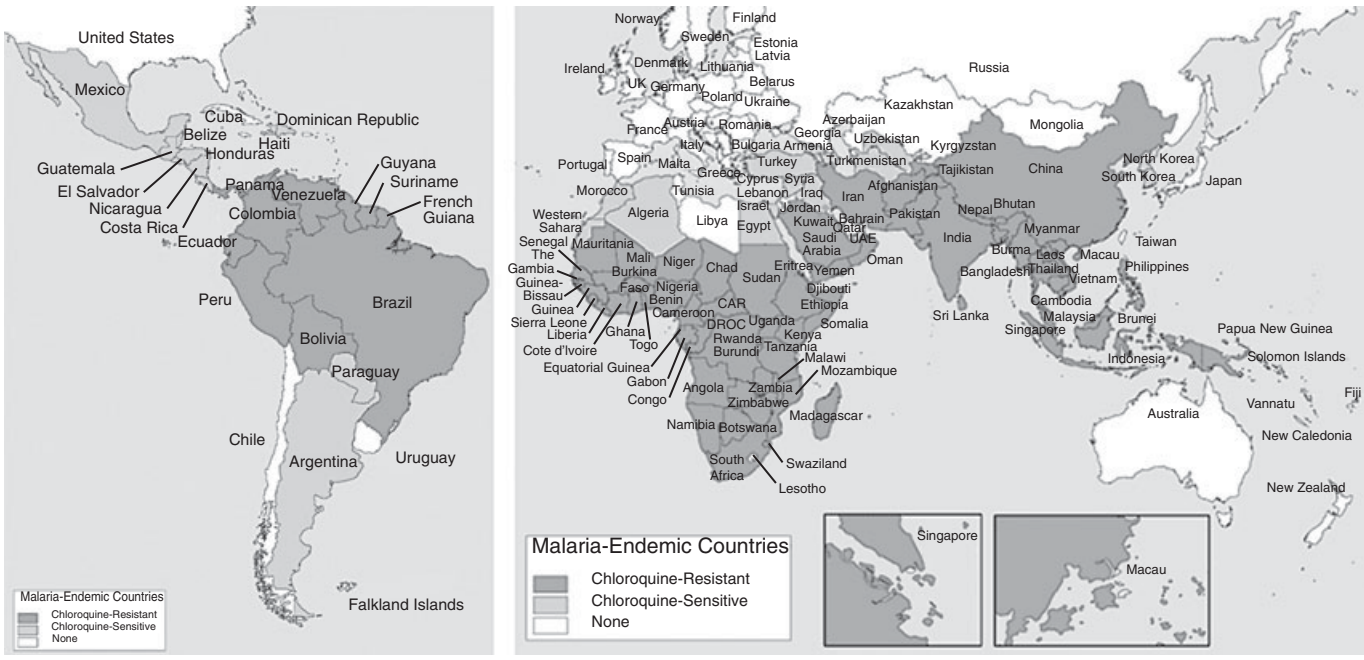

A B

Figure 231–2 **A** and **B,** Malaria endemic countries in the Western (**A**) and Eastern (**B**) Hemispheres, 2007. (See companion Expert Consult web site for color version.) *(From Centers for Disease Control and Prevention. Available at http://wwwn.cdc.gov/travel/yellowBookCh4-Malaria.aspx. Accessed March 8, 2007.)*

predictable incidence of illness and prevalence of infection) and unstable malaria (transmission rates vary from year to year, and immunity is low, with a greater likelihood of epidemics occurring). The degree of endemic malaria is based on the parasite rate in children 2 to 9 years old. Types of endemic malaria include hypoendemic (parasite rate of 0 to 10%), mesoendemic (parasite rate of 11 to 50%), hyperendemic (parasite rate consistently >50%, with a high proportion of adults having enlarged spleens), and holoendemic (parasite rate consistently >75%, with a low proportion of adults having enlarged spleens).[120]

Autochthonous malaria is acquired locally and may be indigenous or introduced. Introduced malaria may occur when migrant populations with asymptomatic infection provide blood meals for feeding anopheline mosquitoes under conditions that allow for the life cycle to be completed in the mosquito and enable the mosquito to infect others. Imported malaria cases may occur in non-endemic areas, but result from infection in an endemic area. Induced malaria is acquired by exposure to infected blood, such as from blood transfusion, needle-stick injury, laboratory accident, or, historically, medical treatments. Cryptic malaria cases are cases for which no explanation can be found, and no epidemiologic link to other cases can be identified.

MOSQUITO-BORNE TRANSMISSION

The most typical means of transmission of malaria is through the bite of an infected anopheline mosquito. Although more than 350 species of anopheline mosquito exist, only approximately 45 have been shown to be effective vectors of malaria. A population of infected humans is necessary to sustain transmission because of the short life span of mosquitoes (5 to 20 days) and the long incubation period required in the mosquito (8 to ≥10 days).

BLOOD-BORNE TRANSMISSION

Transmission of malaria via blood transfusion is well documented.[79] Transmission also may occur through organ donation or needle-stick injury.[35,132] Relapses of malaria cannot occur with blood-borne transmission, even if the infecting species is *P. vivax* or *P. ovale*, because the infection is produced by the transmission of infected RBCs, rather than forms that invade the liver.

CONGENITAL MALARIA

Infants can acquire malaria from their mothers during pregnancy. Transplacental transmission of parasites has been proposed as the most likely route of transmission, although breakdown of placental barriers allowing transmission of maternal blood cells to the infant during labor or delivery also has been suggested as a mechanism of transmission.[42,75] *P. vivax* most often is associated with this phenomenon, but it may occur with all species. Congenital malaria is less likely to occur in infants of semi-immune mothers because of passage of maternal antibody at the time of birth. As with transfusion-associated malaria, relapses do not occur.

CRYPTIC MALARIA

The category of cryptic malaria includes cases for which no source of infection can be identified. Typical cases include confirmed malaria in U.S. residents who have never traveled to or resided in malarial areas, who have not received blood transfusions, and who are not linked epidemiologically with other cases.[56,95,132] Airport malaria, one kind of cryptic malaria, occurs in proximity to international airports and is thought to occur when mosquitoes arriving with airplanes from endemic areas infect individuals working in or living near airports.[51]

HOST-PARASITE INTERACTION

The intensity of transmission of malaria depends on factors that affect the density of vectors and the extent of vector-human contact. Transmission of malaria may be continuous or seasonal, or it may depend on local site-specific factors, such as the presence of irrigation projects or intermittent flooding. Mosquito vectors differ in their efficiency to transmit malaria; the principal vector in sub-Saharan Africa, *Anopheles gambiense*, is known for being a highly effective vector. Variations in climate may affect the viability of mosquitoes.

The incidence and severity of malaria are affected by the intensity of exposure, the presence of immunity, and genetic factors. Distinction must be made between malaria infection (presence of parasitemia) and malaria illness. A major puzzle in malaria is why individuals with similar degrees of parasitemia may exhibit radically different clinical manifestations.

Individuals who reside in endemic areas and are exposed continually to infected mosquitoes acquire immunity to malaria illness. Adults in these areas continue to become infected, but they have lower levels of parasitemia. Infants born to mothers with acquired immunity may be protected transiently by placental passage of maternal antibody. The highest incidence of infection with malaria occurs in infants and young children who are no longer protected by maternal antibody, but who are too young for significant acquired immunity to have developed. Children also are more susceptible to certain manifestations of severe illness, such as cerebral malaria. Lack of acquired immunity in infants and young children accounts partly for their increased risk of acquiring disease and having severe manifestations. Acquired immunity diminishes during pregnancy, and pregnant women are at high risk for development of severe complications of malaria. Individuals in the population who remain asymptomatic but harbor gametocytes in their blood are reservoirs of infection when bitten by mosquitoes.

Clinical manifestations of malaria may be severe in non-immune patients. Malaria is the most common life-threatening infection acquired by travelers to malaria-endemic regions. Individuals with acquired immunity who then leave endemic areas for long periods may lose their immunity and be at risk for severe disease if re-exposed.

Genetic factors determine the risk of acquiring malaria and having severe infection. Individuals who have a Duffy-negative blood type lack specific receptors for invasion of the merozoites of *P. vivax* and are resistant to infection with *P. vivax*.[76] This resistance is the basis for the low incidence of vivax malaria in Africa. Specific human leukocyte antigens present in individuals from West Africa may protect against the development of severe complications of malaria, including cerebral malaria and severe anemia. The best-known example of the relationship between malaria and genetics is the association between sickle hemoglobinopathies and protection against severe falciparum malaria. This balanced polymorphism is thought to have helped ensure survival of the gene for hemoglobin S in the population because of the selective advantage provided on a population basis to those who are heterozygous for sickle-cell disease. Individuals with sickle hemoglobinopathies still may be infected and manifest signs and symptoms of malaria, although the risk of acquiring severe malaria or dying of malaria may be 60-fold to 70-fold less in children with hemoglobin AS than in children with hemoglobin AA.[53]

PATHOPHYSIOLOGY

The pathogenesis of malaria is multifactorial because of the effects of blood-stage parasites, and it involves multiple organ systems. Pathophysiologic changes are caused by the destruction of RBCs, production of cytokines, stimulation of intravascular synthesis of nitric oxide, and sequestration of infected erythrocytes.

Lysis of RBCs leads to anemia, which may be severe, and its attendant hemodynamic consequences. Anemia may develop as a result of hemolysis, impaired erythropoiesis, or bone marrow depression secondary to folic acid deficiency.[91] Intravascular hemolysis may be so severe that it results in pronounced hemoglobinuria ("blackwater fever"), which may be a precipitating event in the development of renal failure. This complication has been noted in association with treatment using quinine. Hematopoiesis is suppressed during acute infection, and such suppression may not be reversed as readily in iron-deficient individuals, contributing to chronic anemia.

Cytokines such as tumor necrosis factor (TNF) and interleukin-1 have important roles in the pathogenesis of malaria.[10,54] Severe disease has been associated with higher concentrations of TNF, and TNF polymorphisms may play a role in the development of specific complications.[71,72] Parasite factors responsible for release of cytokines have not been identified. One possible role of TNF in malaria is to stimulate nitric oxide, a short-lived neurotransmitter. Nitric oxide may have a role in cerebral malaria, and its transient nature may provide a partial explanation for the complete recovery noted in some patients with severe cerebral malaria. TNF and nitric oxide have harmful and beneficial roles in the pathogenesis of malaria; both have been shown to be correlated with clearance of parasites and eventual recovery and the severity of illness.

Sequestration of infected RBCs has long been thought to contribute to the clinical manifestations of malaria, particularly that caused by *P. falciparum*. Late-stage parasites induce host cells to develop knobs on the surface of erythrocytes that facilitate adherence of these cells to vascular endothelium. The effects of these sequestered RBCs on the perfusion, nutrition, and oxygenation of surrounding tissues may be responsible for the complications of *P. falciparum* infection, including cerebral malaria, renal failure, and watery diarrhea.[81,94] Consumption of glucose by metabolically active late-stage parasites contributes to hypoglycemia and lactic acidosis. Despite these changes, the histopathologic appearance of tissue is remarkably benign, consistent with the reversible nature of the changes. This phenomenon also lends support to the role of cytokines and secondary messengers in the pathogenesis of complications of cerebral malaria.[53,120]

CLINICAL FEATURES

The clinical manifestations of malaria depend on the species of malaria parasite causing the infection, the immune status of the individual, the mode of transmission of infection, whether the individual was taking prophylaxis, and host immune factors (Table 231–1). Acute malaria generally is understood to refer to the signs and symptoms associated with disease caused by infection with malaria parasites.

Recurrent infections are of three types: relapse, recrudescence, and re-infection. Relapses occur as a result of delayed maturation of the dormant liver stages (hypnozoites) of *P. vivax* or *P. ovale*. Recrudescence occurs when parasitemia caused by the same parasite responsible for the initial infection recurs after clearance or a significant reduction in the initial parasitemia. It occurs most commonly with *P. falciparum* because of drug resistance. Re-infection with different parasites and infection with more than one type of *Plasmodium* occur especially in areas with a high intensity of transmission. Persistent infection is noted with *P. malariae*. Hypnozoites have not been identified with *P. malariae*, so the organism is thought to persist as a low-level parasitemia that can exist for years without causing symptoms.

ACUTE MALARIA

A classic description of malaria includes features of the malaria paroxysm resulting from the lysis of parasitized RBCs and release of merozoites into the circulation at the completion of asexual reproduction. The paroxysm is characterized by fever and chills accompanied by constitutional symptoms of headache, body ache, fatigue, dizziness, and malaise. Gastrointestinal symptoms include nausea and vomiting, abdominal pain, and diarrhea. Cough and dyspnea may accompany an attack. Although periodicity of the paroxysms in primary attacks is thought to be pathognomonic for malaria species, this periodicity may take several days to become established, may not occur at all in asynchronous infections, or may be modified by previous immunity or treatment.

In children, fever and headache may be the sole symptoms, or gastrointestinal symptoms may predominate. Physical signs of malaria include anemia, jaundice, and hepatosplenomegaly. Rash and lymphadenopathy typically are not associated with malaria, although malaria may precipitate recrudescence of latent herpes infections.

TABLE 231–1 Characteristics of the Four *Plasmodium* Species Responsible for Human Malaria

	P. falciparum	*P. vivax*	*P. ovale*	*P. malariae*
Incubation period in days (range)	12 (8-25)	14 (8-27)	17 (15-≥18)	28 (15-≥40)
Periodicity of febrile attacks (hr)	None	48	48	72
Earliest appearance of gametocytes (days)	10	3	?	?
Relapse	No	Yes	Yes	No
Duration of untreated infection (yr)	1-2	1.5-4	1.5-4	3-50
RBC preference	Younger cells (but can invade cells of all ages)	Reticulocytes	Reticulocytes	Older cells
Characteristic morphology	Ring forms Multiply infected cells Banana-shaped gametocytes	Schüffner dots Enlarged RBCs	Schüffner dots Enlarged RBCs	Normal-sized cells Band or rectangular forms of trophozoites

RBCs, red blood cells.

LABORATORY FINDINGS

Anemia is the most common abnormality in malaria. Thrombocytopenia is common and may be the first manifestation in patients with uncomplicated malaria.[53] Leukopenia also may occur, but high white blood cell counts are less usual and should provoke investigation for other conditions. Liver function test abnormalities may be present and can be mistaken for evidence of hepatitis, especially in patients with jaundice and tender hepatosplenomegaly. Hypoglycemia occurs frequently with falciparum malaria and may develop before or as a consequence of treatment with quinine. When present in children before treatment, hypoglycemia is associated with a poor prognosis.[119] Hyponatremia may occur as part of the syndrome of inappropriate secretion of antidiuretic hormone in some patients. Serum creatinine and blood urea nitrogen may be elevated transiently or may increase significantly with acute renal failure.

Malaria stimulates a polyclonal increase in immunoglobulins associated with rapid production of malaria-specific antibodies and reduced complement levels. False-positive tests for syphilis, rheumatoid factor, heterophil agglutinins, and cold agglutinins may occur.[120]

MALARIA IN SPECIAL POPULATIONS

MALARIA IN CHILDREN

The signs and symptoms of malaria in children range from asymptomatic infection to life-threatening illness. Severe anemia is most likely to develop in children younger than 2 years old, whereas cerebral malaria is most likely to occur in older children (mean age 3.5 years). The greatest burden of disease is borne by infants and young children, although the impact of disease on adolescents has not been studied extensively. Malaria in pregnant adolescents may be of particular concern.[55]

In endemic areas, lack of diagnostic facilities, limited resources, and encroaching drug resistance complicate the ability to make a rapid, accurate diagnosis and provide expedient treatment to children with malaria. Malaria often is difficult to distinguish from other common illnesses such as pneumonia. Clinical algorithms that can distinguish children with malaria from children with pneumonia or other illnesses have been developed and studied, but do not eliminate completely the overlap in conditions with similar clinical manifestations.[97,98,102] Risk factors for a fatal outcome in children with malaria were studied in Kenya; the presence of coma or respiratory distress, or both, at initial evaluation identified children at high risk of dying.[68]

Imported malaria occurs in children in many non-endemic countries. The diagnosis often is delayed because of lack of consideration of malaria as a cause of illness and unfamiliarity with the disease. In children with acquired immunity, the signs and symptoms of disease may be subtle and nonspecific, but fever or a history of fever is universal.[23,62] Other symptoms include anorexia, vomiting, diarrhea, headache, lethargy, and abdominal pain. Laboratory findings include anemia, thrombocytopenia, and leukopenia. The diagnosis of malaria should be considered in every child with fever or a history of recent fever who has visited an area where malaria occurs.

CONGENITAL MALARIA

All four types of human malaria can be transmitted congenitally, but the disease most often is associated with *P. vivax*. That congenital malaria is not seen more frequently is due partly to the effective barrier function of the placenta. Congenital malaria develops in infants of approximately 0.1 percent of immune mothers and 10 percent of non-immune mothers in endemic areas, although placental infection occurs in one third of pregnant women.[47] In endemic areas, distinguishing malaria acquired congenitally from malaria acquired by transmission from mosquitoes is difficult. In non–malaria endemic countries, congenital malaria is very rare; five cases have been reported in the United States since 2000.[11]

The onset of symptoms is insidious and usually occurs at 2 to 8 weeks of age. The typical malaria paroxysm is absent, with the infant instead having poor feeding, fever, vomiting, diarrhea, irritability, and hepatosplenomegaly on physical examination.[42] The most common laboratory finding is anemia, but thrombocytopenia and hyperbilirubinemia also are common findings. Therapy for the infected species of malaria is curative, and the infant does not need treatment of the exoerythrocytic stages of the parasite (although the mother does).

MALARIA IN PREGNANCY

The effects of malaria on the mother depend on the degree of immunity that she has attained and her parity.[75] Relapses and recrudescence of malaria are common during pregnancy, probably because of the immunosuppression associated with the pregnant state. Malaria can exacerbate the anemia occurring during pregnancy, and hypoglycemia and renal insufficiency may complicate falciparum malaria during pregnancy.[31]

Placental infection during pregnancy may be associated with low birth weight, particularly in primigravidas. Vivax malaria has been linked to maternal anemia and low birth weight in multigravidas and primigravidas.[83] Severe falciparum malaria is harmful to the fetus because of fetal tachycardia and distress secondary to maternal fever; disruption of maternal-fetal blood flow and exchange of metabolic substrates by malaria parasites trapped in the placenta; and the potential for reduction in fetal glucose supply, which may be exacerbated by treatment with quinine, a drug that is able to stimulate the release of insulin.[60] Heavy infection of the placenta interferes with transfer of tetanus antibodies from the mother to the fetus, but the effect on other antibodies is unknown.[9] Prompt treatment of pregnant women with severe malaria is critical to survival of the mother and the fetus.

SEVERE AND COMPLICATED MALARIA

Non-immune individuals are most susceptible to the severe complications of falciparum malaria, which include cerebral malaria, pulmonary failure or acute respiratory distress syndrome, renal failure, and severe anemia.[63] Hypoglycemia and metabolic acidosis may occur. Falciparum malaria in non-immune patients should be considered a medical emergency, and treatment of *P. falciparum* should be initiated in all ill patients with malaria until the species can be confirmed.

CEREBRAL MALARIA

Cerebral malaria is the most common complication of falciparum malaria in children and occurs most often in children 3 to 6 years old.[44,92] Alteration of consciousness in a patient with falciparum malaria and no other explanation for the condition constitutes the general definition. Clinical manifestations are broad. Patients may be comatose without response to stimuli and may assume an opisthotonic posture. Generalized convulsions may occur, but focal findings are uncommon. Intracranial pressure often is increased in children with cerebral malaria, but a relationship between the presence of increased intracranial pressure and morbidity and mortality has not been established. Factors associated

with neurologic sequelae include prolonged coma, severe anemia, and multiple seizures. Mortality rates range from 15 to 30 percent of affected children; most survivors recover completely, but approximately 10 percent may have neurologic sequelae. The most common neurologic sequelae in children noted in a study in the Gambia were hemiplegia, cortical blindness, aphasia, and ataxia.[10]

Many factors, including hypoglycemia, anemia, microvascular obstruction, acidosis, and elaboration of inflammatory mediators, contribute to the syndrome of cerebral malaria. Histopathologic features are minor, with occasional hemorrhages and perivascular infiltrates.

SEVERE ANEMIA

Children younger than 1 year old, especially in sub-Saharan Africa, are those most likely to experience severe malarial anemia. This complication is thought to occur most often in areas with year-round transmission. Clinical consequences of anemia are determined by rate of development of anemia and by severity of anemia, with high risk of complications as hemoglobin decreases to less than 5 g/dL.[128]

HYPOGLYCEMIA

Hypoglycemia (blood glucose <40 mg/dL) may be present on initial evaluation in 20 percent of children with severe malaria and is associated with a poor prognosis. The etiology of pretreatment hypoglycemia is thought to be a combination of parasite consumption of glucose and inadequate gluconeogenesis in the liver. Hypoglycemia also can occur as a result of treatment, most typically with quinine. Rapid intravenous infusion of quinine may cause hypoglycemia by stimulating insulin secretion; pregnant women seem to be especially susceptible to this complication. In addition, hypoglycemia may occur several days into a course of oral quinine, presumably caused by resolution of the reduced tissue sensitivity to insulin that is a feature of acute malaria.

ACID-BASE CHANGES

Metabolic acidosis is a marker of severity and clinically may be manifested as hyperpnea. Acidosis often is associated with hypoglycemia. Fluid resuscitation and treatment with antimalarial drugs often result in rapid resolution of acidosis, although persistence of acidosis may occur in patients who eventually die of malaria.

RENAL COMPLICATIONS

Acute renal failure is a potentially life-threatening consequence of acute malaria that occurs more commonly in adults than in children. It typically is oliguric in nature and often is reversible if the patient can be supported by dialysis through the oliguric phase. Acute renal failure is a rare development in residents of endemic areas and long has been thought to occur more frequently in patients treated with quinine or quinidine (blackwater fever). The histologic changes resemble those of acute tubular necrosis.

Nephrotic syndrome and chronic renal failure occur more frequently in areas where malaria is endemic and usually are associated with *P. malariae*. Symptoms occur in individuals younger than 15 years old in approximately half the cases, with gradual progression to renal failure over 3 to 5 years. Most patients have asymptomatic proteinuria and the gradual development of hypertension and deterioration in renal function. Adults more commonly have hematuria and azotemia; adults and children may have hematuria. The disease does not respond to antimalarial agents. Treatments with steroids, cyclophosphamide, and azathioprine have had variable results, with remission occurring only in patients with mild changes on renal biopsy.[120]

PULMONARY EDEMA

Pulmonary edema typically develops late in the course of severe malaria when other complications are already present, and it occurs more commonly in adults than in children. The pathogenesis is consistent with capillary leak syndrome. Supplemental oxygen or mechanical ventilation with positive end-expiratory pressure may be necessary to manage respiratory complications.

HYPERREACTIVE MALARIAL SYNDROME (TROPICAL SPLENOMEGALY SYNDROME, HYPERREACTIVE MALARIAL SPLENOMEGALY)

Hyperreactive malarial syndrome is characterized by massive splenomegaly, high concentrations of total serum IgM and malarial antibodies of multiple immunoglobulin classes, and clinical and immunologic response to antimalarial agents.[135] Hyperreactive malarial syndrome is correlated with malaria endemicity, with an incidence ranging from 0.5 to 80 percent of the adult population. The pathogenesis is unknown, but seems to involve chronic exposure to malaria, resulting in chronic stimulation of the immune system, and genetic factors. Findings on physical examination include a huge spleen and an enlarged liver. Laboratory findings include anemia and an increased reticulocyte count; some patients may have thrombocytopenia or neutropenia. Patients may have an increased risk of acquiring bacterial infections, and some researchers have suggested that hyperreactive malarial syndrome is a premalignant condition.[5] Lifelong treatment with antimalarial agents is the treatment of choice for patients who reside in endemic areas.[120] Treatment of patients who have left endemic areas has not been standardized; some experts recommend a single treatment course of antimalarials with close monitoring of the size of the spleen.

DIAGNOSIS

The most important first step in establishing the diagnosis of malaria is to consider the diagnosis in all individuals with febrile illness, especially febrile individuals with a history of travel to endemic areas. Having a high index of suspicion for the diagnosis of malaria cannot be overemphasized; failure to diagnose and treat malaria promptly contributed to fatal outcomes in U.S. civilians who died of malaria between 1963 and 2001.[82] Manifestations of the disease are most classic in non-immune individuals or in individuals in areas where malaria transmission is seasonal. The signs and symptoms of disease may be nonspecific in semi-immune individuals, individuals who have received malaria prophylaxis, or individuals who have been partially treated.

In non-endemic areas, a history of travel to an endemic area should suggest the diagnosis in all individuals with a febrile illness, regardless of the accompanying signs and symptoms. Common diagnoses mistakenly assigned to patients ultimately determined to have malaria include gastroenteritis and viral syndrome. The course of disease may be modified by exposure to antimalarial drugs, such as agents that may have been used for prophylaxis, and the incubation period may be prolonged after the administration of antimalarial chemoprophylaxis. Because malaria may be transmitted by blood transfusion or an organ

transplant, may be congenitally acquired, and, rarely, occurs cryptically, the diagnosis also should be considered in patients with compatible signs and symptoms of malaria, anemia, or thrombocytopenia, and no other explanation for their illness.

Microscopy is the technique used most commonly for establishing the diagnosis of malaria. Alternatives to microscopic diagnostic techniques for malaria include tests using reagents based on parasite antigens or enzymes, fluorescent microscopy, DNA probes, polymerase chain reaction (PCR), antibody detection, and flow cytometry. Only a few of these methods meet the requirements of low cost, high reliability and reproducibility, and rapid turnaround time. Some of them are suitable for use in field conditions, however, and have been used in endemic areas under field conditions and for self-diagnosis.

MICROSCOPY

Microscopy is the gold standard for establishing the diagnosis of malaria. Identification of typical parasite forms by an experienced microscopist is the mainstay of diagnosis worldwide (Figs. 231–3 to 231–6). There are many advantages of using light microscopy: it can be performed at low cost, it can be done rapidly, it allows identification of the infecting species and estimation of parasite load, and it can be performed with a small amount of blood. The major disadvantage of microscopy is the need for an experienced microscopist. In settings where malaria is not endemic, the need for specialists to review microscope slides may lead to a delay in establishing the diagnosis.

Thin smears are the most useful in diagnosing malaria. They are easy to prepare, with only a single drop of blood required. The drop of blood is placed at one end of the slide, and the edge of a second slide is placed at the edge of the blood smear and drawn across the slide.[113] RBC morphology is preserved, so invasion of large RBCs by the parasites can be identified, and speciation of the organism is possible (see Table 231–1). Oil-immersion magnification (×1000) should be used for viewing the slide because many young asexual intraerythrocytic parasites are only 2 to 3 μm in diameter and may be missed when using high-dry (×440) magnification. Examining a thin smear is easiest, so the microscopist begins by looking at the thin edge of the blood film, farthest from where the drop of blood was placed. Giemsa stain is preferred to Wright stain when available because it preserves details such as Schüffner dots in *P. vivax* and *P. ovale* infections. When individual RBCs can be seen at low magnification (×100), switching to oil immersion allows examination for parasites within the cells. The major disadvantage of thin films is low sensitivity. With low parasite loads (<100 to 300/μL), the amount of blood on the smear may be too small to detect the parasites.

Thick smears have greater sensitivity than thin smears do as a result of the larger quantity of blood used. Because the RBCs are lysed during preparation of the slide, the types of cells containing parasites cannot be identified. To make a thick smear, a drop of blood is placed on the slide and spread in a circle. The slide is stained without using methanol fixation, a procedure that lyses RBCs.

Estimating parasite density often is useful for assessing the likelihood of development of complications associated with high parasite density and for evaluating response to therapy. The density of parasites can be determined on thick or thin smears.[53] When thin smears are used, the proportion of RBCs infected is counted while the smear is viewed under an oil-immersion lens.

FLUORESCENT MICROSCOPY

The quantitative buffy coat test relies on identification of parasitized RBCs stained with acridine orange in the RBC layer of centrifuged blood.[116] Experienced personnel can perform the test rapidly, but the reagents are costly when compared with those needed for microscopy, and the species of parasite cannot be identified. If a fluorescent microscope is available, identification of parasitized RBCs can be accomplished by staining a thick smear with acridine orange and examining it under fluorescent light.

DETECTION OF PARASITE ANTIGEN

Antigen capture dipstick assays based on detection of histidine-rich protein 2 (HRP-2) (ParaSight F; Becton Dickinson), HRP-2 and aldolase (ICT Malaria Pf/Pv; ICT Diagnostics), or parasite lactate dehydrogenase (LDH) (OptiMAL-IT; Flow, Inc) have been developed.[22,64,78] These assays use a finger-prick sample of blood and give a result in 10 to 15 minutes. Assays detecting HRP-2 are specific for *P. falciparum*, whereas assays based on parasite LDH or HRP-2 and aldolase can identify all four species of *Plasmodium*.[16,78] The Binax Now malaria test, based on detection of a pan-malaria antigen and a circulating antigen specific to *P. falciparum*, was licensed recently in the United States.[24a] The ParaSight F dipstick test, when studied in field trials in Kenya, showed a sensitivity of 96.5 to 100 percent in patients whose parasitemia was greater than 60 parasites/μL, with lower sensitivity noted at lower levels of parasitemia. Antigen persisted to day 6 in 11.9 percent of children whose blood smears were clear at that time.[6] When studied in travelers, the sensitivity of the ParaSight F test ranged from 40 percent in subjects with less than 50 parasites/μL to 93 percent or more in subjects with more than 100 parasites/μL, and positive dipstick tests occurred in 68 percent of blood smear–negative patients on day 7 and in 20 percent on day 28.[43]

Compared with PCR, the HRP-2 assays performed well, with sensitivity of 88 to 95 percent and specificity of 95 to 97 percent; compared with microscopy, sensitivity ranged from 80 to 95 percent, and specificity ranged from 85 to 100 percent.[87] The test also performed well when used in non-immune travelers; a meta-analysis of 21 studies identified sensitivity of 88 to 98 percent and specificity of 95 to 100 percent for detection of *P. falciparum*.[70] The HRP-2/aldolase-based assay that can detect all four species of malaria has a lower sensitivity for diagnosis of *vivax* malaria, although this assay has a higher sensitivity for detection of malaria than the HRP-2 assay.[17,45,78] A limitation of HRP-2-based assays is that they remain positive after therapy because HRP persists in the blood after acute infection.

LDH-based assays are able to distinguish between *P. falciparum* and other malaria species, although the test is unreliable in detecting *P. vivax* in the presence of *P. falciparum*.[96] The sensitivity of OptiMAL-IT was 85 to 95 percent, with specificity of nearly 100 percent for *P. falciparum* and lower specificity (75 to 85%) for *P. vivax*. Sensitivity decreased with decreasing parasite density. An advantage of LDH-based assays is the ability to distinguish between viable and nonviable parasites, rendering the test useful for monitoring response to therapy.[18,45,78,89] Dipstick tests may have a role in cost-effective diagnosis of malaria in situations in which laboratory services are inadequate, in mobile clinics, in locations where levels of malaria transmission are low and drug resistance is high, when the cost of treatment exceeds the cost of the dipstick test, and when blood films are negative and determining the diagnosis is critical. In developed countries, dipstick assays would benefit laboratories with less experienced microscopists by helping them establish a rapid diagnosis, confirm a diagnosis made by microscopy, or determine the species an infection. Current limitations of the tests are decreased sensitivity compared with expert microscopy, especially at low levels of parasite density; cost; and lack of approval by the Food and Drug Administration for use in the United States of some of the tests.

Dipstick malaria tests have been proposed for use by travelers in the self-diagnosis of malaria and have been tested for this

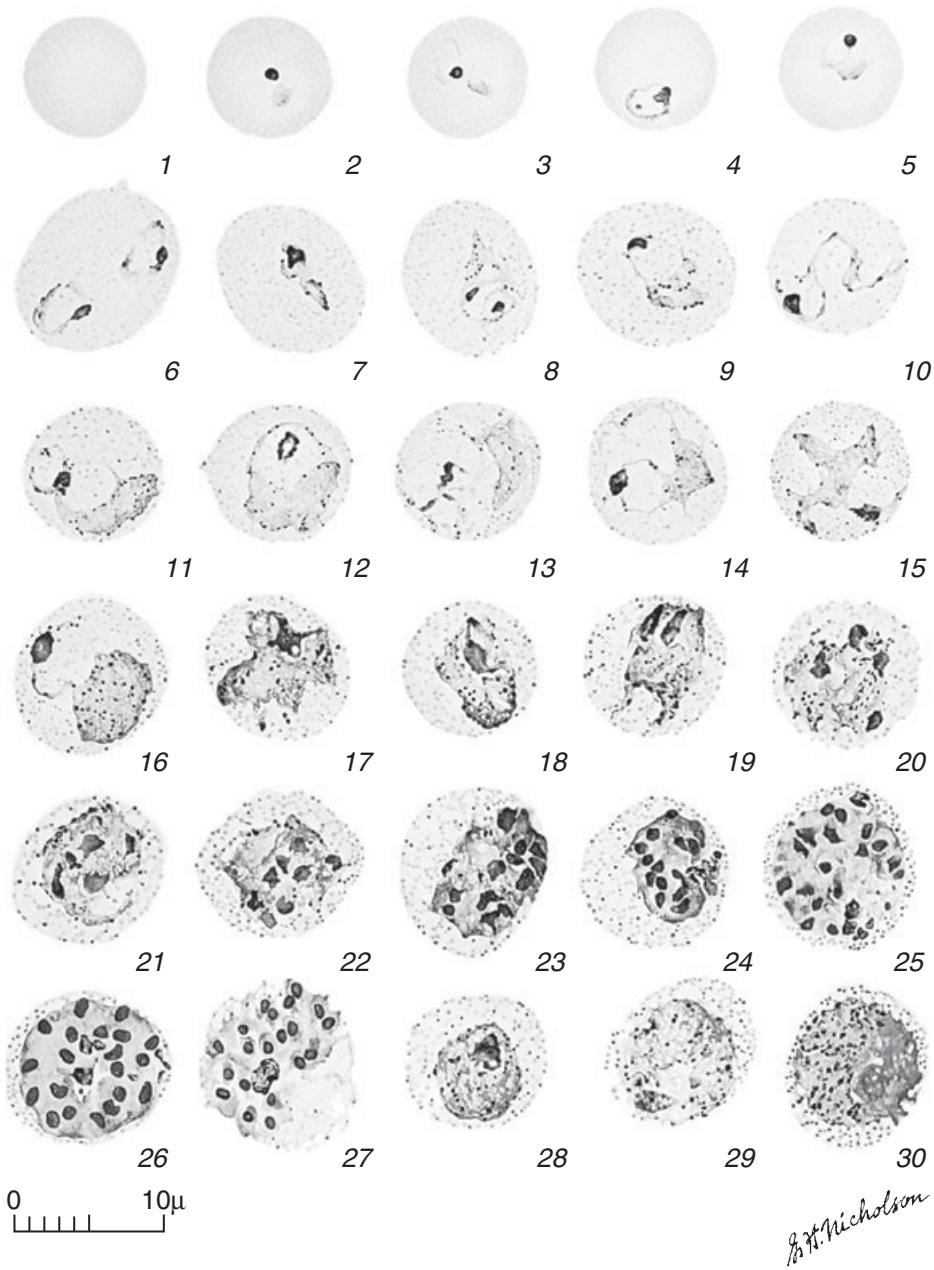

Figure 231–3 *Plasmodium vivax. 1*, Normal erythrocyte; *2-5*, young trophozoites; *6-16*, growing trophozoites; *17*, *18*, mature trophozoites; *19-21*, early schizonts; *22*, *23*, developing schizonts; *24-27*, nearly mature and mature schizonts; *28*, *29*, nearly mature and mature macrogametocytes; *30*, mature microgametocyte. purpose. The use of these tests for self-diagnosis is controversial, with some experts supporting this use and others contending that technical improvements in the tests are necessary before they can be used accurately to guide decisions about self-treatment of malaria.[46,106]

DNA PROBE

Specific DNA probes for identification of *P. falciparum* have been developed and tested in field conditions in Thailand.[4] The technique compared favorably with microscopy and could be used to test large numbers of samples at a time, but it had the disadvantage of needing a radiolabeled probe. Non-isotope probes have been used in other field trials in Madagascar, where an enzyme-linked probe was compared with microscopy for the diagnosis of *falciparum* malaria. The results were comparable to examination of thick smears by microscopy for *P. falciparum* infection, but the assay could not identify infection with *P. vivax*, *P. ovale*, or *P. malariae* alone.[73]

POLYMERASE CHAIN REACTION

PCR-based techniques used for establishing the diagnosis of malaria are highly sensitive and now are able to detect mixed infections. Compared with thick and thin smears, sensitivity and specificity are nearly 100 percent. PCR techniques can be useful for determining the species of an infection when microscopy is equivocal. Early detection of resistance to antimalarial drugs is another benefit of PCR-based techniques, which have been used

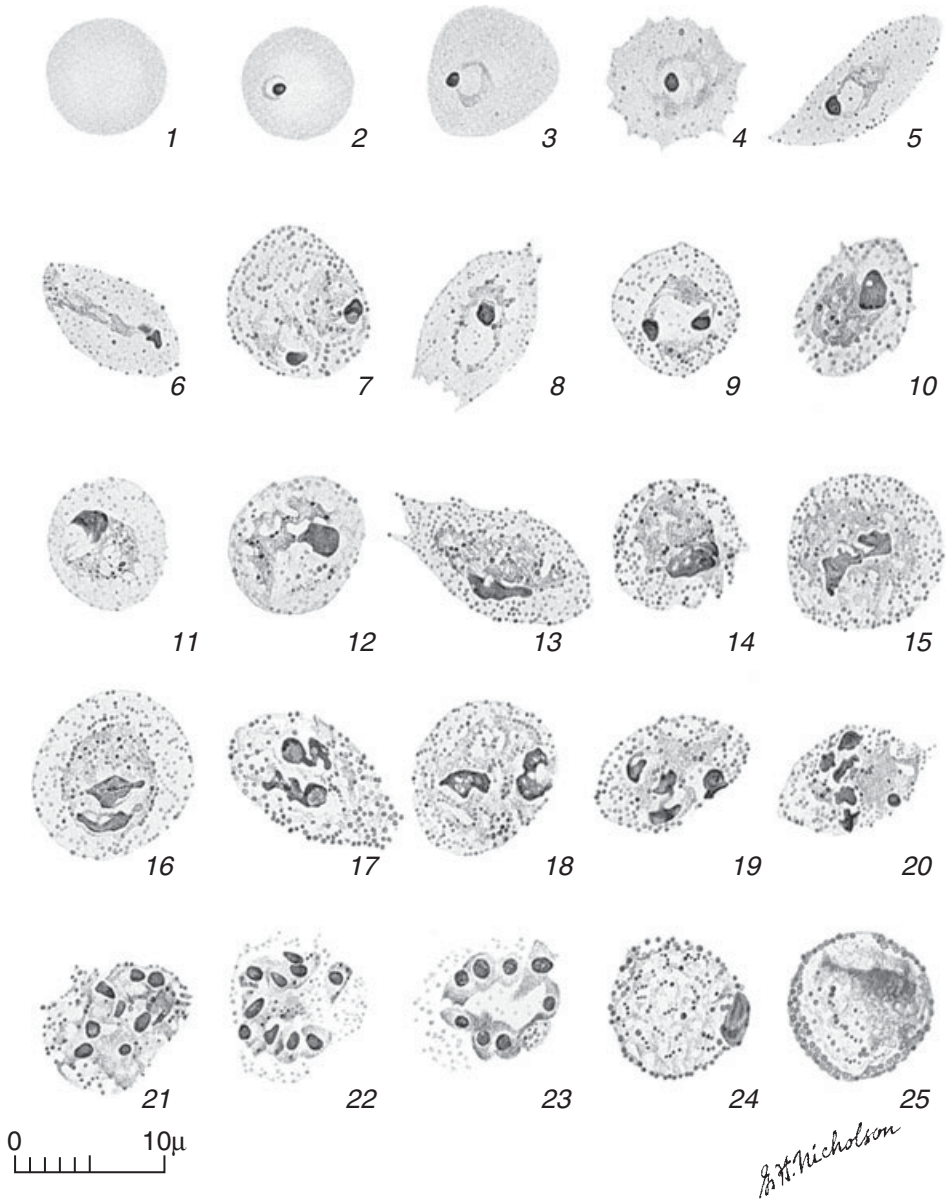

Figure 231–4 *Plasmodium ovale*. *1*, Normal erythrocyte; *2-5*, young trophozoites; *6-12*, growing trophozoites; *13-15*, mature trophozoites; *16-22*, developing schizonts; *23*, mature schizont; *24*, adult macrogametocyte; *25*, adult microgametocyte. to detect a mutation of *P. falciparum* associated with resistance to chloroquine.[24,48]

Major disadvantages of PCR include the need for expensive equipment and reagents, significant technical expertise, and the length of time required to perform the testing. At this time, PCR may be better suited for use in large-scale epidemiologic surveys, rather than for establishing the diagnosis of acute malaria in the clinical setting.

FLOW CYTOMETRY

Automated blood cell analyzers based on flow cytometry have been shown to display cells containing malaria pigment as a population of cells distinct from other blood components. To date, this discovery has been serendipitous in patients not suspected to have malaria, and the diagnosis must be confirmed by conventional methods.[34,49] A future application of this technology could be to modify automated blood cell analyzers to flag specimens that need to be examined further by thin or thick smears (or both).[49]

ANTIBODY DETECTION

Malaria antibodies develop rapidly after infection and remain present for years; they are of limited value in diagnosing malaria in individual patients. Occasionally, antibody tests might prove useful in the diagnosis of non-immune individuals with cryptic febrile illnesses or on a population basis to assess the degree of community-wide immunity. Measurement of antibody may have a role in the diagnosis of hyperreactive malarial syndrome.[135]

TREATMENT

Treatment of malaria depends on identification of the species of *Plasmodium* causing infection, knowledge of the presence of resis-

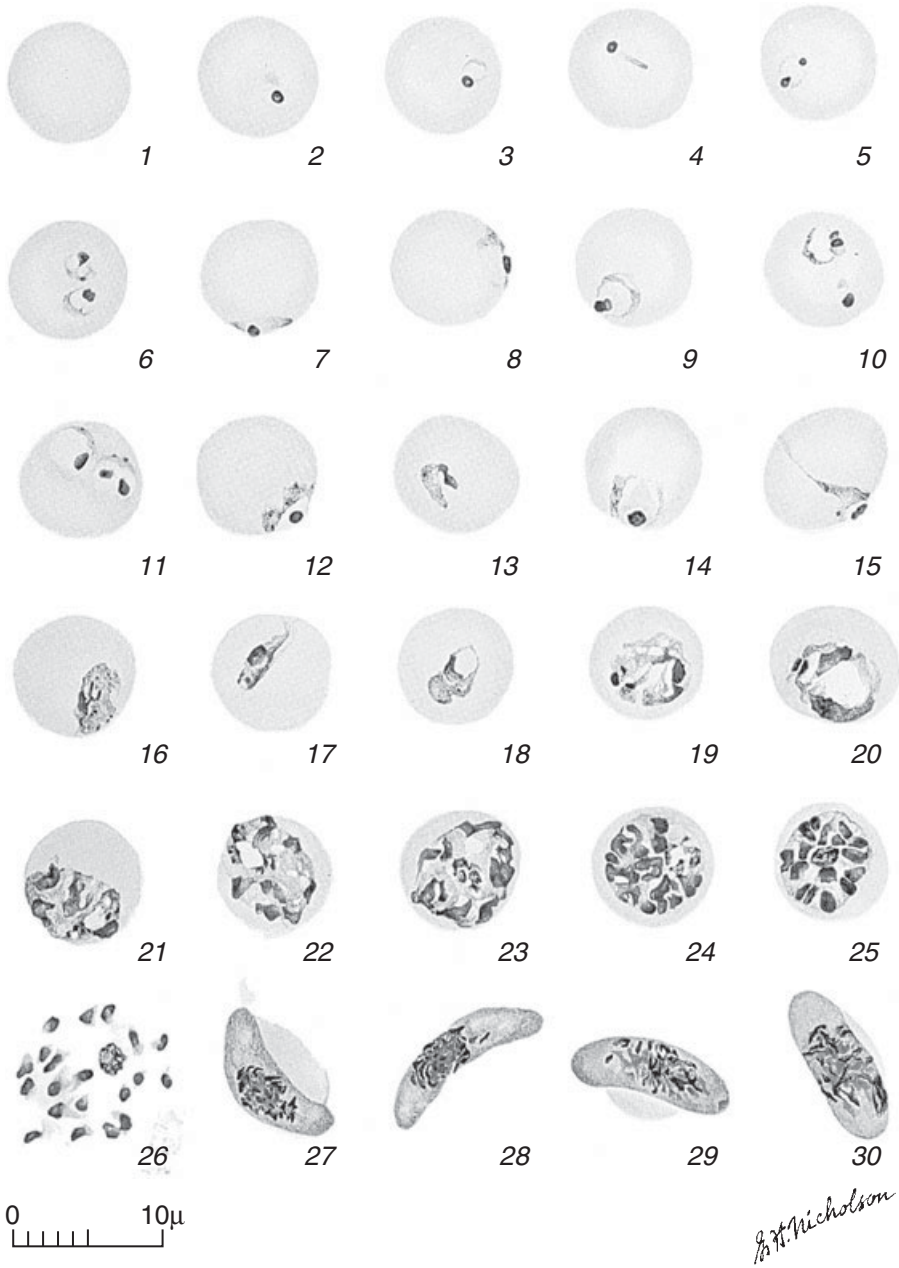

Figure 231–5 *Plasmodium falciparum*. *1*, Normal erythrocyte; *2-11*, young trophozoites; *12-15*, growing trophozoites; *16-18*, mature trophozoites; *19-22*, developing schizonts; *23-26*, nearly mature and mature schizonts; *27*, *28*, mature macrogametocytes; *29*, *30*, mature microgametocytes. tance to chloroquine in the area in which malaria was contracted, and therapeutic goals (treatment of acute illness, eradication of the exoerythrocytic phase of malaria, or prevention of infection). Drugs and classes of drugs currently in use for treating malaria include 4-aminoquinolines and related compounds (chloroquine, mefloquine [Lariam], amodiaquine); primaquine; sulfadoxine-pyrimethamine (Fansidar); halofantrine; atovaquone-proguanil (Malarone); artemisinin (qinghaosu) and other artemisinins (artemether, artesunate); cinchona alkaloids (quinine, quinidine); and the antimicrobial agents doxycycline, tetracycline, and clindamycin. Other combination drugs are available outside the United States, and multiple investigational compounds are in various stages of development. Drugs that may be used for the treatment of malaria are listed in Table 231–2. Drugs used for the prevention of malaria are discussed in a subsequent section.

The choice of agent to treat symptomatic malaria depends on the presence of resistance to chloroquine and other antimalarial drugs, the availability of drugs in the local area, and the age of the patient. Local and national guidelines for the treatment of malaria differ, and practitioners treating patients with malaria should consult local resources and experts. Information about countries and regions with chloroquine-resistant malaria is available in the United States from the Centers for Disease Control and Prevention (CDC) (http://www.cdc.gov/malaria/diagnosis_treatment/tx_clinicians.htm) and outside the United States from local and national health organizations and WHO (http://www.who.int/malaria/diagnosisandtreatment.html). In malaria endemic areas, strategies such as intermittent treatment of infants and pregnant women are being employed in combination with use of insecticides and treated bed nets to prevent and treat

malaria.[105] A full discussion of these programs is beyond the scope of this chapter.

ANTIMALARIAL AGENTS AVAILABLE FOR USE IN THE UNITED STATES

Chloroquine

Chloroquine is the drug of choice for chloroquine-susceptible malaria caused by *P. falciparum* and *P. vivax* and for all infections with *P. ovale* and *P. malariae*. Chloroquine is a 4-aminoquinoline with rapid schizonticidal activity. It is not effective against exoerythrocytic forms of the parasite, and patients treated with chloroquine after acquiring *P. vivax* or *P. ovale* infection need to have additional treatment to eliminate these forms. Chloroquine is most active against late ring stages and mature trophozoites. Response to treatment is rapid, with disappearance of parasitemia within 48 to 72 hours after initiation of treatment when the parasite is susceptible.

Chloroquine is available as an oral preparation and, in many areas, as intramuscular and intravascular formulations. Oral absorption is excellent, and the drug is safe and effective when given by nasogastric or orogastric tube in comatose children.[130] Intramuscular and intravenous administration may be associated with an increased risk for cardiac arrhythmias.

Adverse reactions to chloroquine rarely occur at the doses used for suppression or treatment of malaria. Side effects include gastrointestinal symptoms such as nausea, vomiting, and diarrhea; dizziness; headache; and fatigue. Pruritus may be a troubling adverse event, especially in black patients. Chloroquine has no known teratogenic effects, and it may be used in pregnant and lactating women. The drug is not contraindicated in glucose-6-phosphate dehydrogenase (G6PD)–deficient individuals. Serious adverse events, including hypotension, cardiac arrest, and circulatory failure, may occur after intravenous or intramuscular use of the drug, especially in children. Psychotic symptoms may occur rarely with chloroquine.[28] Chloroquine always should be given

TABLE 231–2 Guidelines for Treatment of Malaria in the United States*

Clinical Diagnosis/ *Plasmodium* species	Region Infection Acquired	Recommended Drug and Adult Dose[1,8]	Recommended Drug and Pediatric Dose[1,8] *Pediatric dose should NEVER exceed adult dose*
Uncomplicated malaria/*P. falciparum* or Species not identified If "species not identified" is subsequently diagnosed as *P. vivax* or *P. ovale:* see *P. vivax* and *P. ovale* on p. 2912. retreatment with primaquine	**Chloroquine-sensitive** (Central America west of Panama Canal; Haiti; the Dominican Republic; and most of the Middle East)	**Chloroquine phosphate (Aralen and generics)** 600 mg base (=1000 mg salt) PO immediately, followed by 300 mg base (=500 mg salt) PO at 6, 24, and 48 hr Total dose: 1500 mg base (=2500 mg salt) ***2nd line alternative for treatment:*** **Hydroxychloroquine (Plaquenil and generics)** 620 mg base (=800 mg salt) PO immediately, followed by 310 mg base (=400 mg salt) PO at 6, 24, and 48 hr Total dose: 1550 mg base (=2000 mg salt)	**Chloroquine phosphate (Aralen and generics)** 10 mg base/kg PO immediately, followed by 5 mg base/kg PO at 6, 24, and 48 hr Total dose: 25 mg base/kg ***2nd line alternative for treatment:*** **Hydroxychloroquine (Plaquenil and generics)** 10 mg base/kg PO immediately, followed by 5 mg base/kg PO at 6, 24, and 48 hr Total dose: 25 mg base/kg
	Chloroquine-resistant or unknown resistance[1] (All malarious regions except those specified as chloroquine-sensitive listed above. Middle Eastern countries with chloroquine-resistant *P. falciparum* include Iran, Oman, Saudi Arabia, and Yemen. Of note, infections acquired in the newly independent states of the former Soviet Union and Korea to date have been uniformly caused by *P. vivax* and should therefore be treated as chloroquine-sensitive infections.)	**A. Uncomplicated malaria/*P. malariae*	**All regions**	**Chloroquine phosphate:** Treatment as for mefloquine ***2nd line alternative for treatment:*** **Hydroxychloroquine:** Treatment as for mefloquine	**Chloroquine phosphate:** Treatment as for mefloquine ***2nd line alternative for treatment:*** **Hydroxychloroquine:** Treatment as for mefloquine

**Based on drugs currently available for use in the United States. If outside the United States, contact national authorities about current recommendations.*

[1]*Note: There are three options (A, B, or C) available for treatment of uncomplicated malaria caused by chloroquine-resistant P. falciparum. Options A and B are equally recommended. Because of a higher rate of severe neuropsychiatric reactions seen at treatment doses, we do not recommend option C (mefloquine) unless options A and B cannot be used. For option A, because there is more data on the efficacy of quinine in combination with doxycycline or tetracycline, these treatment combinations are generally preferred to quinine in combination with clindamycin.*

[2]*For infections acquired in Southeast Asia, quinine treatment should continue for 7 days. For infections acquired in Africa and South America, quinine treatment should continue for 3 days.*

[3]*U.S.-manufactured quinine sulfate capsule is in a 324 mg dosage; therefore, 2 capsules should be sufficient for adult dosing. Pediatric dosing may be difficult due to unavailability of non–capsule forms of quinine. If unable to provide pediatric doses of quinine, consider malarone (recommendation B) or mefloquine (recommendation C).*

[4]*Doxycycline and tetracycline are not indicated for use in children younger than 8 years of age. For children younger than 8 years of age with chloroquine-resistant P. falciparum, quinine (given alone for 7 days or given in combination with clindamycin) and atovaquone-proguanil are recommended treatment options; mefloquine can be considered if no other options are available. For children younger than 8 years of age with chloroquine-resistant P. vivax, quinine (given alone for 7 days) or mefloquine is the recommended treatment option. If none of these treatment options is available or is not being tolerated and if the treatment benefits outweigh the risks, doxycycline or tetracycline may be given to children younger than 8 years of age.*

[5]*Give atovaquone-proguanil with food. If patient vomits within 30 minutes of taking a dose, then the dose should be repeated.*

[6]*Treatement with mefloquine is not recommended in persons who have acquired infections from the Southeast Asian region of Myanmar, Thailand, and Cambodia due to resistant strains.*

TABLE 231–2 Guidelines for Treatment of Malaria in the United States—cont'd

Clinical Diagnosis/ *Plasmodium* species	Region Infection Acquired	Recommended Drug and Adult Dose[1,8]	Recommended Drug and Pediatric Dose[1,8] *Pediatric dose should NEVER exceed adult dose*
Uncomplicated malaria/*P. vivax* or *P. ovale*	**All regions**[8] *Note:* for suspected chloroquine-resistant *P. vivax*, see row below	**Chloroquine phosphate plus primaquine phosphate**[7] **Chloroquine phosphate:** Treatment as for mefloquine **Primaquine phosphate:** 30 mg base PO qd × 14 days ***2nd line alternative for treatment:*** **Hydroxychloroquine plus primaquine phosphate**[7] **Hydroxychloroquine:** Treatment as for mefloquine **Primaquine phosphate:** 30 mg base PO qd × 14 days	**Chloroquine phosphate plus primaquine phosphate**[7] **Chloroquine phosphate:** Treatment as for mefloquine **Primaquine phosphate:** 0.5 mg base/kg PO qd × 14 days ***2nd line alternative for treatment:*** **Hydroxychloroquine plus primaquine phosphate**[7] **Hydroxychloroquine:** Treatment as for primaquine phosphate **Primaquine phosphate:** 30 mg base PO qd × 14 days
Uncomplicated malaria/*P. vivax*	**Chloroquine-resistant**[8] (Papua New Guinea and Indonesia)	**A. Quinine sulfate**[2] **plus either doxycycline or tetracycline plus primaquine phosphate**[7] **Quinine sulfate:** Treatment as for primaquine phosphate **Doxycycline or Tetracycline:** Treatment as above **Primaquine phosphate:** Treatment as for primaquine phosphate	**A. Quinine sulfate**[2,3] **plus either doxycycline**[4] **or tetracycline**[4] **plus primaquine phosphate**[7] **Quinine sulfate:** Treatment as for primaquine phosphate **Doxycline or tetracycline:** Treatment as for primaquine phosphate **Primaquine phosphate:** Treatment as for primaquine phosphate
		B. Mefloquine plus primaquine phosphate[7] Mefloquine: Treatment as for primaquine phosphate Primaquine phosphate: Treatment as above	**B. Mefloquine plus primaquine phosphate**[7] Mefloquine: Treatment as for primaquine phosphate Primaquine phosphate: Treatment as for primaquine phosphate
Uncomplicated malaria: Alternative for pregnant women[9-12]	**Chloroquine-sensitive**[12] (see uncomplicated malaria sections above for chloroquine-sensitive *Plasmodium* species by region)	**Chloroquine phosphate:** Treatment as for primaquine phosphate ***2nd line alternative for treatment:*** **Hydroxychloroquine:** Treatment as for primaquine phosphate	Not applicable
	Chloroquine-resistant *P. falciparum*[9-11] (see uncomplicated malaria sections above for regions with known chloroquine resistant *P. falciparum*)	**Quinine sulfate**[2] **plus clindamycin** **Quinine sulfate:** Treatment as for primaquine phosphate **Clindamycin:** Treatment as for primaquine phosphate	Not applicable
	Chloroquine-resistant *P. vivax*[9-12] (see uncomplicated malaria sections above for regions with chloroquine-resistant *P. vivax*)	**Quinine sulfate** **Quinine sulfate:** 650 mg salt PO tid × 7 days	Not applicable
Severe malaria[13,14,15,16]	**All regions**	**Quinidine gluconate**[14] **plus one of the following:** **Doxycline, tetracycline, or clinidamycin** **Quinidine gluconate:** 6.25 mg base/kg (=10 mg salt/kg) loading dose IV over 1-2 hr, then 0.0125 mg base/kg/min (=0.02 mg salt/kg/min) continuous infusion for at least 24 hr. An alternative regimen is 15 mg base/kg (=24 mg salt/kg) loading dose IV infused over 4 hr, followed by 7.5 mg base/kg (=12 mg salt/kg) infused over 4 hr every 8 hr, starting 8 hr after the loading dose (see package insert). Once parasite density <1% and patient can take oral medication, complete treatment with oral quinine, dose as above. Quinidine/quinine course = 7 days in Southest Asia; = 3 days in Africa or South America.	**Quinidine gluconate**[14] **plus one of the following:** **Doxycline,**[4] **tetracycline,**[4] **or clinidamycin** **Quinidine gluconate:** Same mg/kg dosing and recommendations as for adults. **Doxycycline:** Treatment as for primaquine phosphate. If patient not able to take oral medication, may give IV. For children <45 kg, give 2.2 mg/kg IV every 12 hr and then switch to oral doxycycline (dose as above) as soon as patient can take oral medication. For children ≥45 kg, use same dosing as for adults. For IV use, avoid rapid administration. Treatment course = 7 days. **Tetracycline:** Treatment as for primaquine phosphate **Clindamycin:** Treatment as for primaquine phosphate. If patient not able to take oral medication, give 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 hr. Switch to oral clindamycin (oral dose as for primaquine phosphate) as soon as patient can take oral medication. For IV use, avoid rapid administration. Treatment course = 7 days.

	Doxycycline: Treatment as for quinidine gluconate. If patient not able to take oral medication, give 100 mg IV every 12 hr and then switch to oral doxycycline (as above) as soon as patient can take oral medication. For IV use, avoid rapid administration. Treatment course = 7 days. **Tetracycline:** Treatment as for quinidine gluconate **Clindamycin:** Treatment as for quinidine gluconate. If patient not able to take oral medication, give 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 hr. Switch to oral clindamycin (oral dose as above) as soon as patient can take oral medication. For IV use, avoid rapid administration. Treatment course = 7 days. ***Investigational new drug (contact CDC for information):*** **Artesunate followed by one of the following: Atovaquone-proguanil (Malarone),[5] Doxycycline (clindamycin in pregnant women), or mefloquine**	***Investigational new drug (contact CDC for information):*** **Artesunate followed by one of the follow: Atovaquone-proguanil (Malarone),[5] clindamycin, or mefloquine**

[7] *Primaquine is used to eradicate any hypnozoite forms that may remain dormant in the liver, and thus prevent relapses, in P. vivax and P. ovale infections. Because primaquine can cause hemolytic anemia in persons with G6PD deficiency, patients must be screened for G6PD deficiency prior to starting treatment with primaquine. For persons with borderline G6PD deficiency, or as an alternate to the above regimen, primaquine may be given 45 mg orally one time per week for 8 weeks; consultation with an expert in infectious disease and/or tropical medicine is advised if this alternative regimen is considered in G6PD-deficient persons. Primaquine must not be used during pregnancy.*

[8] *Note: There are two options (A or B) available for treatment of uncomplicated malaria caused by chloroquine-resistant P. vivax. High treatment failure rates due to chloroquine-resistant P. vivax have been well documented in Papua New Guinea and Indonesia. Rare case reports of chloroquine-resistant P. vivax have also been documented in Burma (Myanmar), India, and Central and South America. Persons acquiring P. vivax infections outside of Papua New Guinea or Indonesia should be started on chloroquine. If the patient does not respond, the treatment should be changed to a chloroquine-resistant P. vivax regimen and the CDC should be notified (Malaria Hotline number: 770-488-7788 or 770-488-7100). For treatment of chloroquine-resistant P. vivax infections, options A and B are equally recommended.*

[9] *For pregnant women diagnosed with uncomplicated malaria caused by chloroquine-resistant P. falciparum or chloroquine-resistant P. vivax infection, treatment with doxycycline or tetracycline is generally not indicated. However, doxycycline or tetracycline may be used in combination with quinine (as recommended for nonpregnant adults) if other treatment options are not available or are not being tolerated, and the benefit is judged to outweigh the risks.*

[10] *Because there are no adequate, well-controlled studies of atovaquone and/or proguanil hydrochloride in pregnant women, atovaquone-proguanil is generally not recommended for use in pregnant women. For pregnant women diagnosed with uncomplicated malaria caused by chloroquine-resistant P. falciparum infection, atovaquone-proguanil may be used if other treatment options are not available or are not being tolerated, and if the potential benefit is judged to outweigh the potential risks. There are no data on the efficacy of atovaquone-proguanil in the treatment of chloroquine-resistant P. vivax infections.*

[11] *Because of a possible association with mefloquine treatment during pregnancy and an increase in stillbirths, mefloquine is generally not recommended for treatment in pregnant women. However, mefloquine may be used if it is the only treatment option available and if the potential benefit is judged to outweigh the potential risks.*

[12] *For P. vivax and P. ovale infections, primaquine phosphate for radical treatment of hypnozoites should not be given during pregnancy. Pregnant patients with P. vivax and P. ovale infections should be maintained on chloroquine prophylaxis for the duration of their pregnancy. The chemoprophylactic dose of chloroquine phosphate is 300 mg base (=500 mg salt) orally once per week. After delivery, pregnant patients who do not have G6PD deficiency should be treated with primaquine.*

[13] *Persons with a positive blood smear OR history of recent possible exposure and no other recognized pathology who have one or more of the following clinical criteria (impaired consciousness/coma, severe normocytic anemia, renal failure, pulmonary edema, acute respiratory distress syndrome, circulatory shock, disseminated intravascular coagulation, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, repeated generalized convulsions, and/or parasitemia of >5%) are considered to have manifestations of more severe disease. Severe malaria is practically always due to P. falciparum.*

[14] *Patients diagnosed with severe malaria should be treated aggressively with parenteral antimalarial therapy. Treatment with IV quinidine should be initiated as soon as possible after the diagnosis has been made. Patients with severe malaria should be given an intravenous loading dose of quinidine unless they have received more than 40 mg/kg of quinine in the preceding 48 hours or if they have received mefloquine within the preceding 12 hours. Consultation with a cardiologist and a physician with experience in treating malaria is advised when treating malaria patients with quinidine. During administration of quinidine, blood pressure monitoring (for hypotension) and cardiac monitoring (for widening of the QRS complex and/or lengthening of the QTc interval) should be monitored continuously and blood glucose (for hypoglycemia) should be monitored periodically. Cardiac complications, if severe, may warrant temporary discontinuation of the drug or slowing of the intravenous infusion.*

[15] *Consider exchange transfusion if the parasite density (i.e., parasitemia) is >10% OR if the patient has altered mental status, nonvolume overload pulmonary edema, or renal complications. The parasite density can be estimated by examining a monolayer of red blood cells (RBCs) on the thin smear under oil immersion magnification. The slide should be examined where the RBCs are more or less touching (approximately 400 RBCs per field). The parasite density can then be estimated from the percentage of infected RBCs and should be monitored every 12 hours. Exchange transfusion should be continued until the parasite density is <1% (usually requires 8-10 units). IV quinidine administration should not be delayed for an exchange transfusion and can be given concurrently throughout the exchange transfusion.*

[16] *Pregnant women diagnosed with severe malaria should be treated aggressively with parenteral antimalarial therapy.*

From http://www.cdc.gov/malaria/pdf/treatmenttable.pdf

slowly when administered intravenously and in small doses when given by intramuscular injection; some experts discourage the use of parenteral chloroquine. Oral doses are absorbed rapidly. The risk of aspiration occurring while giving a dose by tube to a comatose patient must be weighed against the risk of delaying therapy if parenteral treatment is unavailable or of complications developing when giving chloroquine by the intravenous or intramuscular route. The lethal dose of chloroquine is 1 g in children and 4 g in adults. Cumulative doses exceeding 100 g are associated with an increased risk for development of retinopathy. Dose reduction may be required for patients with renal and hepatic disease.

Atovaquone-Proguanil

A fixed-dose combination (available in adult and pediatric formulations) of atovaquone and proguanil hydrochloride is available for treatment of malaria caused by *P. falciparum* for individuals who were not taking this agent for prophylaxis. The combination is significantly more effective than either drug alone, and is effective for the treatment of malaria strains resistant to other antimalarial drugs. It has fewer reported adverse events than quinine-based regimens. The combination also is likely to be active against the blood stages of *P. vivax*, *P. ovale*, and *P. malariae*, but the regimen does not have activity against the hypnozoites of *P. vivax*. Atovaquone-proguanil is significantly more effective than mefloquine, chloroquine, amodiaquine, or pyrimethamine-sulfadoxine in locations where parasites are resistant to these drugs.[59]

Mefloquine

The development of mefloquine was a major advance in the treatment of chloroquine-resistant malaria, although resistance has developed rapidly in some parts of the world where it is used widely. Mefloquine is a 4-quinolone-carbinolamine whose exact mechanism is unknown. Its main target is early trophozoites. Similar to chloroquine, it is not active against exoerythrocytic phases. Mefloquine has been associated with neurologic and psychiatric side effects when used for treatment or prophylaxis.[120] Vomiting occurs commonly when mefloquine is given to children younger than 5 years old and may decrease its efficacy.[114] Mefloquine should not be administered concurrently with quinine, quinidine, or halofantrine because of concern about arrhythmias. The drug has been used in the second and third trimesters of pregnancy without adverse outcome.

Quinine and Quinidine

Quinine has been used for the treatment of malaria for centuries.[120] It is active against the mature asexual erythrocytic forms of all four species of human malaria and against the gametes of all species except *P. falciparum*, where it has activity against only immature gametes. It is not effective against exoerythrocytic forms. Quinine is the drug of choice for severe or complicated malaria. It may be given orally, but intravenous and intramuscular forms are available. Quinine crosses the placenta easily and may be used in the treatment of pregnant women, although close monitoring for hypoglycemia is warranted.[60]

Adverse reactions to quinine include tinnitus, headache, nausea, visual and hearing disturbances, and tremors, a constellation of symptoms called *cinchonism*. Symptoms may appear during the first 1 to 3 days of therapy and stop when treatment is terminated. Hypoglycemia may occur, particularly when the drug is used to treat pregnant women. Severe adverse events are rare, but may occur idiosyncratically. Blackwater fever (hemoglobinuria) seems to occur after treatment with quinine, but the causal mechanism is unknown.

Recrudescence rates may be high when quinine is used alone because of the presence of quinine-resistant strains of *P. falciparum*. A second drug usually is added to treat the remaining forms. Drugs that may be used with quinine include doxycycline, tetracycline, and clindamycin.

Quinidine is a related drug that may be given intravenously; in some developed countries where intravenous quinine is unavailable, it is the drug of choice for severe malaria. The mechanisms of action and adverse events are similar, although cardiac arrhythmias occur more commonly with quinidine, and cardiac monitoring is advised.[129]

Tetracycline and Doxycycline

Tetracycline, doxycycline, and the related drug minocycline have very slow activity against malarial schizonts.[120] Doxycycline and minocycline may be given once daily. They are active against chloroquine-resistant and pyrimethamine-sulfadoxine–resistant *P. falciparum*. Resistance to tetracycline has not been shown. Because of their slow activity, these agents should be given in combination with a rapidly acting drug such as quinine. These drugs should not be used in children younger than 8 years old or by pregnant or nursing women.

Primaquine

Primaquine, an 8-aminoquinoline derivative that is effective against exoerythrocytic hypnozoites, is used primarily to prevent relapses of *P. vivax* and *P. ovale*, although it may not be completely effective against some strains of *P. vivax*. It is not an effective blood schizonticide, but is an active gametocidal and sporontocidal drug for all four species of *Plasmodium* that cause human malaria. Primaquine can cause intravascular hemolysis in individuals with G6PD deficiency. Other adverse events include gastrointestinal symptoms such as nausea, epigastric pain, anorexia, and abdominal cramps. Other rare side effects include methemoglobinemia, hemoglobinuria, and bone marrow suppression. Safety in pregnancy has not been established, and the drug should not be used by pregnant women. Patients should be tested for G6PD deficiency before being treated with primaquine.

ANTIMALARIAL AGENTS NOT CURRENTLY AVAILABLE OR RECOMMENDED FOR TREATMENT OF MALARIA IN THE UNITED STATES

Artemesinin Derivatives

Artemesinin (qinghaosu) is a sesquiterpene lactone that, along with its derivatives (artemether, artesunate, arteether, and others), has antimalarial activity thought to be due to the ability to cause free radical damage in parasite membrane systems.[38] These compounds are unique in their ability to cure malaria more rapidly than other agents, with no apparent adverse events. Except for parenteral artemesinin, available on an emergency basis only from the CDC, they are unavailable in the United States, but are used widely in other parts of the world. When used alone, recrudescence rates are high, and the drug class seems to have limited potential for prophylaxis. Oral preparations, suppositories, and oil-based preparations for intramuscular injection are available, although standardization of preparations is lacking.[99] The major utility of these drugs at this time is for severe malaria in areas where quinine resistance is appearing or, in combination with other antimalarials, in areas of multidrug-resistant *P. falciparum*.[1,37] In clinical trials in the Gambia, artemether was as effective as quinine and chloroquine for treatment of cerebral malaria in children.[125,131] When used in sequence with mefloquine, the combination was effective and tolerated well by patients with acute, uncomplicated *falciparum* malaria in Thailand, an area with multidrug resistance.[61] Later studies showed that the use of this combination may have helped halt the progressions of mefloquine resistance in the region.[86]

Artemether-Lumefantrine

The fixed dose combination of artemether (20 mg) and lumefantrine (120 mg) will be available in the United States, and is considered a first-line agent for treatment of uncomplicated *falciparum* malaria in countries where it is available. It is well tolerated and effective against multidrug-resistant *falciparum* malaria.[128] A six-dose regimen compared favorably with other agents in African children and adults with uncomplicated *falciparum* malaria.[80,93]

Pyrimethamine-Sulfadoxine

The combination pyrimethamine-sulfadoxine, a sulfonamide plus a dihydrofolate reductase inhibitor, exhibits synergy in its action against malaria parasites; the combination is active even against strains resistant to the individual drug components. Although pyrimethamine-sulfadoxine has been used for presumptive treatment of malaria in travelers who are taking other drugs for prophylaxis in areas where chloroquine resistance occurs, widespread resistance to the drug combination and its slow action should limit its use in non-immune individuals with *falciparum* malaria. The CDC no longer recommends pyrimethamine-sulfadoxine for treatment of malaria. Although safety has not been established in pregnancy, the drug has been used effectively for intermittent presumptive treatment of pregnant women in endemic areas to decrease the risk for severe anemia.[111]

Amodiaquine

Amodiaquine, similar to chloroquine, is a 4-aminoquinolone. It has similar efficacy, but may have increased activity compared with chloroquine for the treatment of strains of *P. falciparum* resistant to chloroquine.[88] It is available in an oral preparation and is more palatable. Significant adverse events, including agranulocytosis, hepatotoxicity, and death, when used as a prophylactic agent have limited its use as a first-line agent. It is not licensed or marketed in the United States.

Halofantrine

Halofantrine is a 9-phenanthrene-methanol that has been used to treat malaria caused by chloroquine-resistant *P. falciparum*. Its major side effect is dose-related prolongation of the QT interval, and it has been associated with cardiac arrhythmias and sudden death, especially in individuals taking mefloquine prophylaxis.[84,118] Its major use was in uncomplicated malaria in areas of multidrug resistance, but cardiac toxicity at the doses required to be effective may limit its widespread use.[121] It is contraindicated in pregnant and lactating women because of embryotoxic effects. Resistance to halofantrine has limited its use in some areas. Travelers who are taking mefloquine for prophylaxis should be cautioned against accepting treatment with halofantrine if they are diagnosed with malaria during their travels. Halofantrine is unavailable in the United States.

INVESTIGATIONAL DRUGS

Targets for new antimalarial drugs include malaria proteases, which play a crucial role in malaria pathogenesis.[101] Adjuvant therapy that would modify or prevent the effects of inflammatory mediators also may have a role in the treatment of complications of malaria.

SUPPORTIVE AND ADJUNCTIVE THERAPY

Malaria, especially that caused by *P. falciparum*, is a potentially fatal illness even in patients who may have developed partial immunity. Patients, especially children, with falciparum malaria should have immediate treatment and generally should be admitted to the hospital, especially in non-endemic countries such as the United States. Patients with severe malaria should be managed in intensive care units, and experts in treatment of malaria and its complications should be consulted. Blood smears should be examined at least every 12 hours (every 4 to 6 hours for severe malaria) until parasitemia is less than 1 percent. Most patients can be treated with oral medication, although patients should be switched promptly to parenteral medication if oral medication is not tolerated. WHO guidelines for treatment of malaria, including management of severe malaria, are available (http://www.who.int/malaria/diagnosisandtreatment.html).

The goals of supportive therapy are to maintain oxygenation and treat acidosis and hypoglycemia. Treatment with glucose infusion, oxygen, and blood transfusion may be necessary. Mechanical ventilation with positive-pressure ventilation may be needed to manage acidosis and acute respiratory distress syndrome. In some cases, hemodialysis may be needed. A high index of suspicion should be maintained for other concomitant or nosocomial infections, such as meningitis or septicemia.

Adjunctive therapies that have been shown to be beneficial include antipyretics and anticonvulsants. Exchange transfusion remains a controversial option.[53,129] Some therapies, such as high-dose corticosteroids for cerebral malaria or heparin, have been shown to be harmful.[129,134] The search for effective adjunctive therapy for severe and complicated malaria continues.

PREVENTION

Prevention of malaria can be accomplished by reducing the mosquito population, using personal protection methods to prevent mosquito bites, and initiating chemoprophylaxis. Reduction of mosquito vectors is most successful when locally controlled programs are developed and maintained.[52] Strategies that take into account local circumstances, such as applying insecticide to cattle in communities where families share their homes with domestic animals, are most likely to be successful.[103] Most programs in endemic areas require a combination of preventive strategies and effective treatment modalities. Many non-endemic countries have developed recommendations for prevention of malaria in travelers.

PERSONAL PROTECTIVE MEASURES

A significant reduction in the incidence of malaria in children in communities where bed nets, especially when impregnated with insecticide, are used consistently has been reported from many countries.[21,29,115] In northern Ghana, community-wide use of bed nets was associated with a reduction in all-cause child mortality in young children.[7] The use of bed nets, especially bed nets impregnated with insecticide, is recommended for travelers to malarial areas. Other personal protective measures include using mosquito repellents and insecticide-impregnated clothing or gear; wearing clothing that covers areas likely to be bitten; and remaining, if possible, in air-conditioned or well-screened areas during times when mosquitoes are biting. DEET-containing repellents are recommended most commonly for prevention of mosquito bites and are highly effective.[25] Other agents, such as picaridin and oil of lemon eucalyptus, are available. Picaridin is available only in a 7 percent formulation, which may not have the same duration of protection as higher concentrations of DEET. Other agents have not been studied extensively against *Anopheles* mosquitoes.[74]

CHEMOPROPHYLAXIS

Country-specific information regarding recommendations for the use of antimalarial drugs may differ, and readers are urged to seek recommendations from national or local authorities. In the United

TABLE 231–3 Drug Regimens Used for Prevention of Malaria

Drug	Adult Dosage	Pediatric Dosage	Comments
Chloroquine-Sensitive Areas			
Chloroquine phosphate (drug of choice)	500 mg salt (300 mg base) orally once/wk beginning the week before exposure and continuing for 4 wk after exposure	5 mg/kg base (8.3 mg/kg salt) once/wk, up to adult dose of 300 mg base beginning the week before exposure and continuing for 4 wk after exposure	May be used in pregnant women
Chloroquine-Resistant Areas			
Mefloquine	250 mg salt (228 mg base) salt once/wk orally beginning the week before exposure and continuing for 4 wk after exposure	<15 kg: 5 mg/kg salt 15-19 kg: 1/4 tablet 20-30 kg: 1/2 tablet 31-45 kg: 3/4 tablet >45 kg: 1 tablet All doses: orally, once/wk beginning the week before exposure and continuing for 4 wk after exposure	See text for contraindications
or			
Doxycycline	100 mg daily beginning 1-2 days before exposure and continuing for 4 wk after exposure	2 mg/kg/day up to 100 mg/day	Not to be used in children <8 yr old or pregnant women
or			
Atovaquone-proguanil	250 mg/100 mg (1 tablet) daily beginning 1-2 days before exposure and continuing for 7 days after exposure	11-20 kg: 62.5 mg/25 mg (1 pediatric tablet) 21-30 kg: 125 mg/50 mg (2 pediatric tablets) 31-40 kg: 187.5 mg/75 mg (3 pediatric tablets) >40 kg: 1 adult tablet daily	
alternatives			
Primaquine	30 mg base daily up to 30 mg daily and glucose-6-phosphate	0.6 mg/kg base daily in pregnancy, lactation, dehydrogenase deficiency	Contraindicated; use in consultation with malaria experts
or			
Chloroquine phosphate *plus*	Same as chloroquine-sensitive	Same as chloroquine-sensitive	
Proguanil	200 mg daily	<2 yr: 50 mg daily 2-6 yr: 100 mg 7-10 yr: 150 mg >10 yr: 200 mg	Breakthroughs may occur frequently in areas of intense transmission with this combination

States, these recommendations are available widely in publications from the CDC[12] (http://wwwn.cdc.gov/travel/yellowBookCh4-Malaria.aspx) or national health information sources. Many excellent sources of health information for travelers include discussions of malaria prevention.[13-15,26,67,104,107,110,117] The Infectious Diseases Society of America has published detailed pre-travel guidelines that include recommendations for malaria prevention.[39] Table 231–3 lists drugs available for malaria prevention. Prevention of malaria for travelers is best discussed in the context of providing complete pre-travel services, advice, and information.

ANTIMALARIAL AGENTS AVAILABLE IN THE UNITED STATES FOR PREVENTION OF MALARIA

Chloroquine

A major determinant of appropriate chemoprophylaxis is whether a child is to travel to an area of chloroquine resistance. In areas of the world that have no resistance to chloroquine, the drug of choice for prevention of malaria is chloroquine. This drug is tolerated well and may be given to children of all ages, including infants. Dosing of chloroquine in children is based on the child's weight and can be found in Table 231–3. In the United States, chloroquine is available only in tablets that have a very bitter taste, although some compounding pharmacies may be willing to make liquid preparations. Pharmacies can prepare appropriate doses in capsules, and the contents of the capsule can be mixed with a small amount of liquid or semisolid food for administration. Although liquid preparations are widely available overseas and are stable for long periods,[77] many U.S. pharmacies are reluctant to prepare them. If patients are considering purchasing liquid preparations overseas, the family should be given information with the child's medication dose calculated as the base and the salt because concentrations of liquid preparations may vary. Families also should be cautioned about the greater incidence of ineffective or counterfeit medications available in some areas.

Adverse events caused by chloroquine are uncommon when the medication is used at doses needed for malaria prophylaxis. Minor side effects include gastrointestinal upset, headache, diz-

ziness, blurred vision, and pruritus. Adverse events rarely require discontinuation of medication. Chloroquine may be taken during pregnancy and is not contraindicated in children with G6PD deficiency.

The choice of antimalarial agents in locations where drug-resistant parasites have been identified is more challenging. Chloroquine-containing regimens are not recommended for travel to areas with known chloroquine-resistant *P. falciparum*, and deaths from malaria have occurred when these regimens have been used.[66] The choice of regimen depends on the type of drug resistance, length of stay, age of the traveler, and individual medical history. Drugs currently available in the United States include mefloquine, doxycycline, atovaquone-proguanil, and primaquine. Tafenoquine may be available in the future.[41,50,109]

Atovaquone-Proguanil

Atovaquone-proguanil is becoming one of the most popular choices for malaria chemoprophylaxis because of the favorable profile of side effects and the need to take the medication for only 1 to 2 days before and 7 days after leaving the area of malaria risk. The drug is effective against most *P. falciparum*, including resistant strains. It is available in adult and pediatric dosing forms. It must be taken daily, preferably at the same time each day. Adverse events most commonly reported with atovaquone-proguanil are abdominal pain, nausea, vomiting, and headache. It is not recommended at this time for prophylaxis of infants weighing less than 5 kg, for mothers nursing such infants, or for pregnant women.

Mefloquine

Mefloquine generally is well tolerated in children and can be given to infants. Dosing is based on weight, and no liquid preparation is available. Doses for older children can be supplied by breaking tablets; when small fractions of tablets are needed, pharmacists can provide individual doses in capsules. The medication has a pasty consistency, but does not taste bitter. Infants tend to swallow doses better when given liquids or semisolid foods after the medication. Adverse events with mefloquine are self-limited in most cases and include gastrointestinal disturbance, insomnia, and dizziness.[57] Withdrawal rates in adults, presumably caused by the incidence of these adverse events, may impair the efficacy of mefloquine.[19] Rarely, serious adverse events, such as psychosis or seizures, have occurred after prophylactic doses of mefloquine. Consequently, mefloquine should not be used in individuals who have seizures or neuropsychiatric disorders or in individuals who have had previous adverse events with mefloquine. Mefloquine also is contraindicated in patients with cardiac conduction abnormalities, although it may be used in individuals concurrently taking beta blockers for indications other than arrhythmias.

Mefloquine must be taken weekly, beginning 1 to 2 weeks before travel and continuing weekly during travel and for 4 weeks after leaving the malarial area. Families may be counseled to choose a day of the week to take the medicine and to take their first dose or doses on that day of the week 1 to 2 weeks before departure. Mefloquine may be used by pregnant women, preferably after the first trimester.[85,124]

Doxycycline

Doxycycline is an effective antimalarial drug in parts of the world where chloroquine resistance is present. It also has been shown to be effective in areas where mefloquine-resistant *P. falciparum* exists, such as portions of Cambodia, Burma (Myanmar), and Thailand. Limitations in the use of this drug include contraindications in children younger than 8 years, the need for daily dosing, and photosensitivity. In women, daily use of doxycycline may be associated with an increased risk of *Candida* vulvovaginitis. Gastrointestinal side effects, including nausea and vomiting, can be limited by taking the medication with meals and by avoiding bedtime dosing. Doxycycline must not be used by pregnant or lactating women. Prophylaxis with doxycycline needs to begin 1 to 2 days before travel and should be continued daily for 4 weeks after leaving the malarial area.

Primaquine

Primaquine, used most often to eradicate the exoerythrocytic stages of *P. vivax* and *P. ovale*, has been licensed as a prophylactic agent for individuals who are unable to tolerate any other drug. Individuals must be tested and shown not to be deficient in G6PD before they take this drug. Primaquine can be used to prevent *vivax* and *falciparum* malaria in non–G6PD-deficient individuals, and its efficacy compared favorably with that of mefloquine, doxycycline, and chloroquine plus proguanil in children in the holoendemic area of western Kenya.[27,108,127] It cannot be used in pregnant women.

ANTIMALARIAL AGENTS NOT AVAILABLE OR RECOMMENDED IN THE UNITED STATES FOR PREVENTION OF MALARIA

Tafenoquine

Tafenoquine is an investigational long-acting primaquine analogue that kills parasites in the liver and in blood. It is thought to be more effective and less toxic than primaquine, but it cannot be used by individuals with G6PD deficiency or by pregnant women. No dosing regimen has been established, and it is not licensed for use.[33,109,126]

Proguanil

Proguanil has been used in combination with chloroquine to prevent chloroquine-resistant *P. falciparum*, but is less effective than mefloquine, and is not recommended or available in the United States.

Pyrimethamine-Sulfadoxine

Pyrimethamine-sulfadoxine has been used for prevention of malaria in areas of chloroquine-resistant *P. falciparum*. An unacceptably high incidence of Stevens-Johnson reactions (fatalities in 1 in 11,000 to 25,000 users) resulted in withdrawal of the indication for using this drug for malaria prophylaxis.

VACCINE

Vaccination against malaria has been a subject of active research for several decades, but a licensed vaccine still is not on the immediate horizon. Development of a vaccine is challenging because of the complexity of the parasite life cycle, heterogeneity of the host immune response, lack of animal models, and absence of surrogate markers of protection. Testing of vaccines is difficult because vaccine efficacy depends on conditions of transmission and the degree of immunity present in the population being studied.[122] Targets for development of a vaccine include the sporozoite (prevention of infection), the merozoite (prevention of disease manifestations by preventing invasion of RBCs), or the gametocyte (prevention of transmission by interfering with development of the parasite within the mosquito). Hundreds of candidate vaccine antigens have been identified by the *P. falciparum* genome project; choosing the most promising ones is challenging.[30]

The first malaria vaccines were directed against circumsporozoite antigen, an antigen present over most of the surface of the sporozoite. Development of these vaccines was based on the concept that sporozoites should be susceptible to antibody-mediated destruction in the extracellular space. Results of early studies with these vaccines were disappointing, with inadequate protection provided against sporozoite challenge, inconsistent relationships between antibody response and clinical efficacy, and numerous local side effects.[36,40] More recently, the candidate vaccines RTS,S/AS02A and RTS,S/ASOIE have shown promise in trials in Mozambique[2] and Kenya. Merozoite surface proteins are another group of antigens that have been studied in connection with the development of a blood-stage, or asexual, malaria vaccine.[90] The SPf66 vaccine, derived from three merozoite proteins linked to a 4-amino acid from a *P. falciparum* circumsporozoite protein, has been tested in clinical trials in Colombia, Tanzania, and the Gambia.[3,20,123] Although initial studies in countries in South America with low malaria endemicity showed promise, investigations in African countries with high endemicity have been disappointing, with protective efficacy ranging from 31 percent (95% confidence interval 0 to 52%) in Tanzania to 8 percent (95% confidence interval –18 to 29%) for first or only clinical episodes and 3 percent (95% confidence interval –24 to 24%) in overall incidence of clinical episodes in the Gambia.

Vaccines that block transmission from humans to mosquitoes would reduce the reservoir of infected mosquitoes and reduce transmission on a population level. The poor immunogenicity and diversity of gametocyte antigens have proved challenging to this approach to the development of a vaccine, and no vaccines of this type have been used yet in clinical trials. Future vaccines are likely to use a combination approach that incorporates target antigens from all three stages of the parasite. To have a significant impact on decreasing worldwide burden of malaria, vaccines ultimately may need to be combined with other prevention strategies, including protection against mosquito bites with insecticides and treated bed nets, and intermittent preventive treatment with antimalarial drugs.[30]

Acknowledgments

With gratitude to Dr. Brant Viner for critical reading of the manuscript and helpful comments.

CHAPTER 232

Leishmaniasis

Lynne S. Garcia ❂ Karin Nielsen-Saines

Leishmaniasis consists of a group of diseases that may affect the skin, mucous membranes, and viscera with a wide range of clinical presentations caused by obligate intracellular hemoflagellates of the genus *Leishmania*. Infection is transmitted by several genera and species of bloodsucking sandflies. Three major clinical syndromes usually are recognized: cutaneous (CL), mucocutaneous (MCL), and visceral (VL) leishmaniasis. Macrophages of the skin; mucous membranes; and spleen, liver, and bone marrow (reticuloendothelial system) are parasitized.

Studies on the components of sandfly saliva suggest that substances may influence partially the tropism of the parasite and the resulting disease. The amount of a vasodilatory peptide, maxadilan, in sandfly saliva seems to correlate with the type of human infection.[40] Sandflies in Brazil that transmit *Leishmania chagasi* VL have large amounts of maxadilan in their saliva, which causes marked vasodilation and may encourage visceralization of the parasites. The same complex of sandflies in Costa Rica, which have small amounts of the vasodilatory peptide in their saliva, transmit organisms that produce a non-ulcerating and nonvisceralizing *L. chagasi* infection that is limited to the dermis.

The clinical manifestations of leishmaniasis seem to depend on a complex set of factors, including tropism and virulence of the parasite strain, and the susceptibility of the host, which may be determined genetically.[27] Cell-mediated immune mechanisms seem to be the major factors in modulating these diseases (Table 232–1). Disease syndromes range from self-healing cutaneous lesions to debilitating mucocutaneous infections, subclinical viscerotropic dissemination, and fatal visceral involvement.

In cutaneous disease, *Leishmania tropica* (with some notable exceptions), *Leishmania major*, *Leishmania aethiopica*, and *Leishmania mexicana* tend to be restricted to reticuloendothelial cells of the skin, and infections generally are self-limited, with spontaneous healing. Similarly, *Leishmania braziliensis* can invade the reticuloendothelial cells of the skin and the mucous membranes of the nose, mouth, and pharynx, resulting in serious disfigurement or even death. Some strains of *L. tropica* may cause viscerotropic disease. In cases of VL (kala-azar), *Leishmania donovani*, *L. chagasi*, and *Leishmania infantum* invade cells of the reticuloendothelium of viscera, usually causing splenomegaly and occasionally hepatomegaly and pancytopenia; untreated, the disease is progressive and generally fatal.

Individuals with acquired immunodeficiency syndrome (AIDS) may have atypical manifestations. Dermatotropic strains of *L. infantum* are known to cause visceral infection in immunocompromised patients with AIDS.[39] VL is quite prevalent in patients with AIDS in certain geographic areas (e.g., southern Spain), with a high proportion of cases being subclinical. Similar to other opportunistic infections, subclinical VL can be found at any stage of human immunodeficiency virus (HIV)-1 infection, but symptomatic cases occur mainly when severe immunosuppression is present.[5] HIV-*Leishmania* co-infection is being seen with increasing frequency in the Mediterranean basin, especially in Spain, France, and Italy.

ORGANISM

In vertebrate hosts, *Leishmania* spp. are obligate intracellular parasites that exist only in the amastigote stage. The species that infect humans usually are morphologically indistinguishable from

TABLE 232–1 Clinical Syndromes Caused by *Leishmania* Species and Their Geographic Distribution

Clinical Syndromes	*Leishmania* Species	Location
Visceral Leishmaniasis		
Kala-azar: generalized involvement of the reticuloendothelial system (spleen, bone marrow, liver)	*L. (L.) donovani*	Indian subcontinent, northern and eastern China, Pakistan, Nepal
	L. (L.) infantum	Middle East, Mediterranean littoral, Baikans, central and southwestern Asia, northern and northwestern China, northern and sub-Saharan Africa
	L. (L.) donovani (archibaldi)	Sudan, Kenya, Ethiopia
	L. (L.) spp.	Kenya, Ethiopia, Somalia
	L. (L.) chagasi	Latin America
	L. (L.) amazonensis	Brazil (Bahia State)
	L. (L.) tropica	Israel, India, and viscerotropic disease in Saudi Arabia (U.S. troops)
Post–kala-azar dermal leishmaniasis	*L. (L.) donovani*	Indian subcontinent, East Africa
Old World Cutaneous Leishmanias		
Single or limited number of skin lesions	*L. (L.) major*	Middle East, northwestern China, northwestern India, Pakistan, Africa
	L. (L.) tropica	Mediterranean littoral, Middle East, western Asiatic area, Indian subcontinent
	L. (L.) aethiopica	Ethiopian highlands, Kenya, Yemen
	L. (L.) infantum	Mediterranean basin
	L. (L.) donovani (archibaldi)	Sudan and East Africa
	L. (L.) spp.	Kenya, Ethiopia, Somalia
Diffuse cutaneous leishmaniasis	*L. (L.) aethiopica*	Ethiopian highlands, Kenya, Yemen
New World Cutaneous Leishmaniasis		
Single or limited number of skin lesions	*L. (L.) mexicana (chiclero ulcer)*	Central America, Mexico, Texas
	L. (L.) amazonensis	Amazon basin and neighboring areas, Bahia and other states in Brazil
	L. (V.) braziliensis	Multiple areas of Central and South America
	L. (V.) guyanensis (forest yaws)	Guyana, Suriname, northern Amazon basin
	L. (V.) peruviana (uta)	Peru (western Andes) and Argentinean highlands
	L. (V.) panamensis	Panama, Costa Rica, Colombia
	L. (V.) pifanoi	Venezuela
	L. (V.) garnhami	Venezuela
	L. (V.) venezuelensis	Venezuela
	L. (V.) colombiensis	Colombia and Panama
	L. (V.) chagasi	Central and South America
Diffuse cutaneous leishmaniasis	*L. (L.) amazonensis*	Amazon basin and neighboring areas, Bahia and other states in Brazil
	L. (V.) pifanoi	Venezuela
	L. (L.) mexicana	Mexico and Central America
	L. (L.) spp.	Dominican Republic
Mucosal leishmaniasis	*L. (V.) braziliensis* (espundia)	Multiple areas in Latin America

(L.), subgenus Leishmania*; (V.), subgenus* Viannia.

Data from Laison, R., and Shaw, J. J.: Evolution, classification and geographic distribution. In *Peters, W., Killick-Kendrick, R. (eds.): The Leishmaniases in Biology and Medicine. London, Academic Press, 1987, pp. 1-120; modified from Pearson, R. D., and Sousa, A. Q.: Clinical spectrum of leishmaniasis. Clin. Infect. Dis. 22:1-13, 1996; from Pearson, R. D., Jeronimo, S. M. B., and de Queiroz, A.: Leishmaniasis. In Guerrant, R. L., Walker, D. H., and Weller, P. F. (eds.): Tropical Infectious Diseases: Principles and Practice. Philadelphia, Churchill Livingstone, 1999.*

one another at the light microscopic and ultrastructural levels. The organisms are round-to-oval bodies approximately 2 to 4 μm in diameter with a single nucleus, a specialized mitochondrial structure that has extranuclear DNA termed a *kinetoplast*, and no free flagellum. Amastigotes are engulfed by macrophages and reside within the parasitophorous vacuole of the macrophage host. They multiply by binary fission and eventually destroy the host cell. Subsequently, they are phagocytized, and the process occurs repeatedly.

When the vector, a female sandfly, feeds on an infected person, it may ingest an infected cell from blood or tissue. Amastigotes are liberated in the fly's midgut, and within a few hours, transformation to the promastigote stage occurs.[21] Promastigotes are elongated flagellates 15 to 25 μm long by 1.5 to 3.5 μm wide, each having an anterior, free flagellum that measures approximately 15 to 28 μm in length and may vary morphologically from short and stumpy to an elongated form. Binary fission begins, and large numbers of promastigotes are produced and gradually move forward to the pharynx, buccal cavity, and mouth parts. Depending on temperature and the species of sandfly, at 8 to 20 days, the mouth parts of the fly may be blocked partially or completely by huge numbers of promastigotes. These organisms may be dislodged into the bite wound when the female sandfly (*Phlebotomus*, *Lutzomyia*) next takes a blood meal. Promastigotes have surface molecules that bind to several macrophage receptors. The phagocytized promastigote forms transform into amastigotes within the parasitophorous vacuole, and multiplication occurs.

Amastigotes can be seen in Giemsa-stained or Wright-stained tissues or smears by light microscopy with the nucleus and kinetoplast staining bright red and the cytoplasm staining pale blue. In Novy-McNeal-Nicolle (NNN) culture medium at 24° C, the organisms grow readily and assume the promastigote or insect form.

In the past, specific and subspecific taxonomy designations were determined by the clinical syndrome caused by an isolate in a particular geographic area. More recently, various molecular

techniques have been used to characterize the strains and species of clinical isolates, including endonuclease restriction studies of kinetoplast DNA, buoyant density of kinetoplast DNA and mitochondrial DNA on cesium chloride, leishmanial isozyme patterns, monoclonal antibody specificity, and exoantigen secretory factor 4 serotyping.[3]

EPIDEMIOLOGY

Leishmaniasis is mainly a zoonosis, although primarily human-vector-human transmission occurs in certain areas of the world. The World Health Organization estimates that 1.5 million cases of CL and 500,000 cases of VL occur every year in 88 countries.[16] Estimates indicate that approximately 350 million people are at risk for acquiring leishmaniasis, with 12 million currently infected.[4] With more recent outbreaks in many areas of the world, including Brazil, India, Italy, Spain, Sudan, and Kenya, leishmaniasis has become more widely recognized as an important emerging infectious disease in many developed and underdeveloped countries.[10,22] Although the parasite usually is transmitted via the bite of the sandfly vector, it also may be transmitted as a result of a laboratory accident, direct person-to-person transmission, and blood transfusion.[30] In addition, evidence indicates that it may be transmitted either in utero or during the peripartum period.

The bloodsucking sandfly, the vector for leishmaniasis, was identified first by Bonanni in 1691.[15] The name of the genus *Phlebotomus* was coined in 1840 by Rondani and Berte. In 1907, the first description of an American bloodsucking sandfly was made by Coquillet. In 1909, Vianna in Brazil identified the parasites responsible for CL, later identified as *L. braziliensis* in 1911.[14] Concurrently, Lutz and Neiva identified the first three species of sandflies in Brazil. *Lutzomyia* sandflies were later named after Lutz. To date, 229 species have been identified. It was not until 1921, however, that the Sergent brothers implicated the bloodsucking sandflies in the transmission of CL in Algeria. The evidence was substantiated by the work of Aragao in 1922 and Pessoa and Pestana in Brazil in 1940. In 1950, researchers discovered that the different forms of leishmaniasis infesting the American continent were caused by distinct species of the parasite. The research on leishmaniasis and sandflies has shed light on the transmission of other zoonotic illnesses, including Trypanosomatids (*Crithidia*, *Endotrypanum*, *Trypanosoma*), and several viruses, including Rhabdoviridae, Bunyaviridae, and Reoviridae, all isolated from bloodsucking sandflies. In the Amazon region, 69 serotypes of different arboviruses isolated from sandflies have been identified.[15]

OLD WORLD CUTANEOUS LEISHMANIASIS

DEFINITION AND EPIDEMIOLOGY

Old World CL is caused by *L. major* (rural), *L. tropica* (urban), and *L. aethiopica*. It is found throughout the Middle East; along the Mediterranean basin and islands; and in East and West Africa, India, and southwestern Asia.[43] In humans, infection by *L. tropica* usually produces skin ulcers in which intracellular (amastigote) parasites can be found within macrophages in and around the lesions. These organisms are rarely found in spleen, liver, or bone marrow; however, several more recent reports have described *L. tropica* isolates from patients with VL. In many areas, dogs or rodents are found to be naturally infected and are thought to be the natural reservoirs of infection. Various *Phlebotomus* spp. transmit the infection, although person-to-person transmission is possible and is the basis of the long-time practice in middle and central Asia of immunizing inoculation—that is, "vaccination" to prevent possible disfigurement by a natural infection (Fig. 232–1).

Figure 232–1 *Leishmania tropica.* Immunization by an induced lesion. *(From a nonprofit cooperative endeavor by numerous colleagues under the editorship of Dr. Herman Zaiman, New York.)*

Old World leishmaniasis, or Oriental sore (Delhi boil, Aleppo button) can be classified into "wet" and "dry" types. The wet or rural form is caused by *L. major*; and is found chiefly in various rodents on the edge of deserts. The dry or urban type is caused by *L. tropica*, and is transmitted by bloodsucking species that frequently feed on humans and dogs. The dry or urban form of Oriental sore has a long incubation period, long duration of active infection, and numerous parasites in the dermis. The moist or rural type has a short incubation period, with rapid healing and few parasites in the skin. *L. aethiopica* is restricted to the mountain valleys of the Rift Valley of Ethiopia and Kenya, where rock and tree hyraxes are infected regularly. Humans become infected when they intrude in these areas. This form of CL is usually self-limited,[53] although in a few individuals (1 per 100,000), nonhealing diffuse cutaneous leishmaniasis (DCL) disease has been reported.

PATHOLOGY

At the bite site, promastigotes are engulfed by histiocytes, in which they multiply. The histiocytes are destroyed, and amastigotes are released into tissues, where the process is repeated. Lymphocytic and plasma cell infiltration along with histiocytic hyperplasia occurs, and in some lesions, epithelioid and giant cells may be seen. Hypertrophy of the stratum corneum and hyperplasia of dermal papillae occur early, usually followed by necrosis of the area caused by capillary obstruction and endothelial proliferation eventually. The epithelium overlying the center of the lesion becomes necrotic and is sloughed, with the formation of a characteristic ulcer. Secondary neutrophil infiltration also occurs. At this point, a depressed ulcer with a raised purpuric indurated border and a base of friable granulation tissue is present. Amastigotes are located within the cells, although during the period of necrosis, organisms may be seen outside cells, but division does not occur.

With *L. tropica*, development of the lesion may take weeks to months, with large numbers of parasites present in nests of mac-

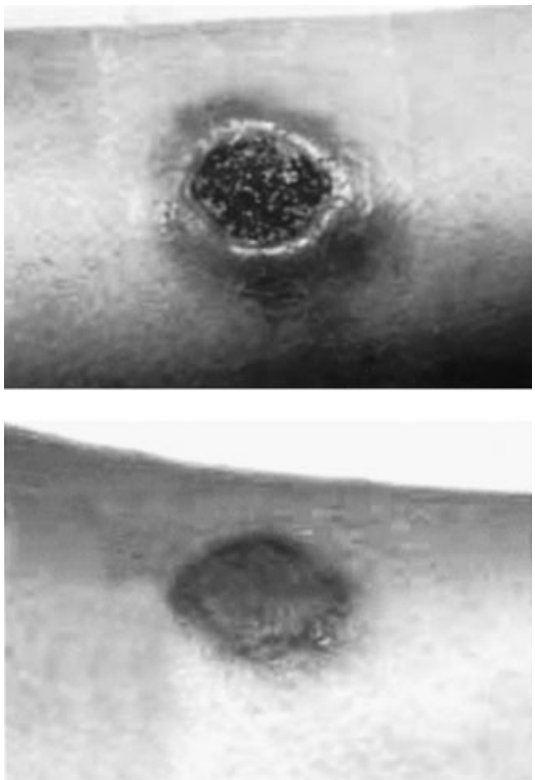

Figure 232–2 *Upper*, Typical cutaneous leishmaniasis ulcer. *Lower*, Healed cutaneous leishmaniasis ulcer.

Figure 232–3 Healing cutaneous leishmaniasis in a patient from Venezuela.

rophages. In *L. major* infection, the onset is rapid, with an outpouring of lymphocytes and plasma cells; parasites sometimes are difficult to find. In some cases, satellite lesions form close to the primary lesion so that local spread is seen. The pathologic reaction may be florid, with marked pseudoepitheliomatous hyperplasia that can be mistaken for carcinoma. Secondary bacterial infection may complicate the lesion and delay healing. After the ulcer heals, however, usually by fibrosis, the patient has long-lasting immunity (Fig. 232–2).

Several manifestations of CL have been described and seem to be associated with the ability of the patient to respond to the infection by cell-mediated immune mechanisms. Whether these mechanisms are directly responsible for protection in humans still is uncertain. In a few patients, the inability to mount a suitable cell-mediated immune reaction is associated with specific anergy to leishmanin, however, and an indolent nonhealing lesion.[12] This condition is known as DCL. Characteristically, lesions in DCL are filled with large, parasite-containing histiocytes, and lymphocytes are absent. More recent studies of DCL from the Dominican Republic suggest that immunosuppression plays an important role in this form of the disease.

At the other extreme are a few patients whose cell-mediated immune response to infection with leishmanial organisms is exaggerated, and the lesions heal by scarring. At the edge of the scar, new lesions appear, however, so the disease seems to extend from the margins. Eventually, tissue damage may be extensive. On histologic examination, many lymphocytes, plasma cells, epithelioid cells, and large multinucleated giant cells are seen. Organisms are difficult to locate, but sometimes can be cultured from these lesions. This form of CL is called *leishmaniasis recidivans*. Patients exhibit marked delayed hypersensitivity to leishmanin. The work of Turk and Bryceson[50] has provided the concept that CL may be a spectrum of diseases analogous to leprosy. They consider DCL to be at one end of the spectrum and representative of anergy, and leishmaniasis recidivans to be at the other end and representative of marked delayed hypersensitivity, with an ordinary Oriental sore as the center in which balance exists.

CLINICAL MANIFESTATIONS

The disease usually begins with a pruritic, red, vesicular papule that appears weeks to months after the bite of a sandfly. The papule gradually enlarges, often measuring 1 to 2 cm in diameter. When the surface of the papule dries, it encrusts and drops off to reveal a shallow ulcer. The ulcer may or may not enlarge progressively, and characteristically has raised, sharp, indurated, deep purpuric margins. Healing usually occurs in 3 to 18 months, with an obvious hypopigmented or hyperpigmented depressed scar frequently remaining (Fig. 232–3). Single or multiple papules often heal directly without extensive ulceration, however. If the lesions do not become infected secondarily, usually no complications occur.

DIAGNOSIS

Definitive diagnosis depends on showing the amastigotes in tissue specimens or the promastigotes in culture. Microscopic examination of Giemsa-stained or Wright-stained smears of tissue obtained from non-necrotic areas of the ulcer or from the base should be performed. Aspiration and culture of tissue fluid taken from the ulcer margin can be positive; however, biopsy material taken from the edge of the ulcer is preferred and should be examined histologically, as should small fragments macerated in saline and inoculated into NNN medium or Schneider's insect medium supplemented with antibiotics. The specimen of choice would be a collection of several punch biopsy specimens taken from the most active lesion areas. Clinically, the lesions often are

characteristic, so the diagnosis should be suspected in a patient who has visited an endemic area.

Although the leishmanin test usually is positive in patients with ulcerated lesions, the material is not readily available in the United States. A positive leishmanin skin test may help distinguish various skin lesions, however, such as syphilis, tropical phagedenic ulcer, yaws, tuberculosis, and various fungal diseases. The indirect fluorescent antibody test or direct agglutination test may be positive in this infection, although often at low titer and of little value.

TREATMENT

Uncomplicated *L. tropica* lesions generally respond well to chemotherapy or to conservative management. Because Old World CL usually remains a local lesion, if the ulcer is not disfiguring and appears to be healing, allowing the lesion to heal spontaneously is appropriate.[53] In most cases, systemic therapy with stibogluconate sodium is effective.[23] Several reports have indicated limited success in treating skin lesions with heat. Generally, increasing intralesional temperature to 40° C to 42° C for 12 hours a day was necessary to obtain a satisfactory result. Recombinant interferon-γ has been reported to accelerate healing. Various parenteral, topical, and oral agents have been used, but the data are anecdotal or conflicting, or both. Allopurinol and various imidazoles (e.g., ketoconazole, itraconazole) have been used and seem to have limited antileishmanial activity. An ointment containing paromomycin (aminosidine) and methylbenzethonium chloride (Leshcutan) has been reported to show some promise in treating cutaneous lesions, especially in Israel.[46]

A 31-year-old man who since age 3 had had DCL, a disease with profound physical and psychosocial repercussions and no effective treatment at present, was treated with miltefosine.[55] The patient was treated for 120 days, 100 mg/day for 1 week, and then 150 mg/day subsequently. Lesions were free of parasites at 43 days, and no signs of infiltration were present at day 76. No adverse side effects were observed. The dramatic clinical effect of miltefosine in this patient seems to justify fully further evaluation of this experimental therapy in DCL.

PREVENTION

Residual spraying for sandflies, eradication of reservoir hosts, and vaccination procedures have reduced and limited Old World CL in many areas of the Middle East and central Asia. Because of the indolent nature of the healing with vaccination and the possibility of visceralization, this practice has been discontinued in Israel. The customary method for controlling leishmaniasis and sandfly bites in Israel involves the spraying of large quantities of residual insecticides on walls of houses and neighboring surfaces. The high summer temperatures, strong radiation, and dust limit the efficacy of the method, however.[36]

AMERICAN CUTANEOUS LEISHMANIASIS

The epidemiology and etiology of American CL are quite complex. In South and Central America, many varieties of leishmaniasis exist, including MCL, or espundia. In contrast to Old World CL, American CL is tied closely to the forests of South and Central America, and each variety has its own distinct epidemiologic, pathologic, and clinical picture.[20] Whether designating each of the clinical types of American CL by a separate species of *Leishmania* is justified is unclear. With regard to the American cutaneous forms, two main groups of organisms are distinguished: the *L. mexicana* and *L. braziliensis* complexes (Figs. 232–4 and 232–5). The former often are characterized by rapid growth in culture medium and in hamsters, and the latter are organisms that grow slowly in culture and hamsters.

Figure 232–4 Chicle ulcer *Leishmania (mexicana) mexicana*. A typical chronic lesion of the external ear is evident. Such lesions never metastasize.

Figure 232–5 Mucocutaneous leishmaniasis: *Leishmania (braziliensis) braziliensis*. The entire nasal septum has been eroded. Few organisms could be found by smear or biopsy; however, promastigote forms were cultured from the lesion.

LEISHMANIA MEXICANA COMPLEX

L. (mexicana) mexicana is transmitted by species of sandflies of the genus *Lutzomyia* (Fig. 232–6). Many rodent reservoir hosts exist. This species is found in Mexico, Guatemala, and Belize. It causes mild infection, often a single cutaneous lesion that is self-limited, persistent chronic ear lesions, or chiclero ulcer.[2] One case of disseminated disease has been reported. This species probably is responsible for the occasional cases of CL found in the southern portion of the United States. The range of endemic infection has been expanded within the United States to include areas within Arizona that are farther north than the southern Texas site previously identified.[44] Apparently, wood rats serve as the primary wild reservoir hosts in these two states.

L. (mexicana) amazonensis is found along the Amazon basin and in Trinidad. It rarely infects humans, but is transmitted by various species of *Lutzomyia* in rodents. In humans, it causes a mild and

Figure 232–6 Sandfly.

self-limited skin lesion. Occasionally, disseminated disease reportedly develops.

LEISHMANIA BRAZILIENSIS COMPLEX

L. (braziliensis) braziliensis or *L. (viannia) braziliensis* is transmitted by various species of *Lutzomyia* in Brazil and the forest areas east of the Andes. It was described originally by Vianna in Brazil as the cause of Bauru ulcer.[14] This organism is the "prototype" of American CL or MCL, or espundia. It may cause destructive ulcerative lesions of the naso-oropharynx as a result of early or late metastases from a more superficial site.

Leishmania (braziliensis) guyanensis is transmitted by species of *Lutzomyia* in Guyana, Suriname, Brazil, and Venezuela. It causes single or multiple spreading cutaneous ulcers over many parts of the body, and is thought to metastasize along the lymphatics, but does not visceralize. The organism sometimes spreads to the naso-oropharynx and causes mucosal disease. It sometimes is referred to as *pian bois*, or *forest yaws*.

L. (braziliensis) panamensis is transmitted by species of *Lutzomyia* in Panama and possibly farther north and south. It may cause single to several superficial ulcers and may metastasize along the lymphatics to the naso-oropharynx.

Leishmania (braziliensis) peruviana is seen in Peru on the western slopes of the Andes to an altitude of 3000 m. It causes a single or a few self-healing ulcers. No oronasopharyngeal spread occurs. Often, it is referred to as *uta*. Dogs are regarded as the reservoir hosts.

In MCL as represented by espundia, researchers estimate that nasal involvement may occur in 80 percent of infections, 30 percent of which eventually mutilate the mucous membranes of the mouth, nose, palate, larynx, and trachea. These cases often are fatal because of the intervening sepsis. Lesions of the mucous membranes often occur years to decades after a cutaneous ulcer has healed. When mucous membrane involvement occurs, the infection may be difficult to cure using chemotherapy.

DIAGNOSIS

The discussion of Old World CL includes the methods for diagnosis. In MCL, the fluorescent antibody test using amastigote antigen is most useful in that it is positive in 75 to 85 percent of cases, with declining titers after therapeutic cure.[52] A direct agglutination test using promastigotes also is used frequently, as is enzyme-linked immunosorbent assay (ELISA).[52] More recently, a DNA-DNA hybridization or dot-blot test, which is highly sensitive and species-specific in tissue or biopsy specimens, has been used.[32] Isozyme analysis of isolated organisms currently is being used to help identify the species causing the infection.

TREATMENT

As in Old World CL, treatment of most lesions is effective using pentavalent antimonials. Because prompt and adequate therapy for primary cutaneous lesions may reduce the risk of subsequent development of metastatic disease in potentially mucocutaneous infections, pentavalent antimony should be used. If lesions should prove unresponsive to antimony therapy, amphotericin B should be tried. Although the experience is limited, liposomal amphotericin treatment has been useful in selected studies.[41] Relapses with this form of leishmaniasis are common and must be retreated. Pentavalent antimonials are moderately effective in treating mild mucosal disease, but often are unsatisfactory with severe mucosal involvement. Diffuse CL, a disseminated form of the disease, should be treated with stibogluconate sodium[23]; when relapses occur, amphotericin B should be used next because this disease usually is refractory to further antimony therapy.[41] Pentamidine also has been used with limited success when lesions have proved resistant to antimony compounds. Pentavalent antimony-resistant CL, such as leishmaniasis recidivans, has been treated with limited success with ketoconazole, 400 to 600 mg daily for 4 weeks. Miltefosine, an oral antileishmanial agent effective against VL, has shown promise for the treatment of American CL (*Leishmania panamensis/Leishmania amazonensis*).[48]

PREVENTION

American CL is extremely difficult to prevent because it is a forest disease. It can be avoided only by sleeping in tents under fine-mesh netting, wearing long-sleeved clothing, and using insect repellents. The presence of *Leishmania* parasites in the unaffected skin and peripheral blood monocytes of a high proportion of patients even after treatment and the acquisition of infection by sandflies support the plausibility of anthroponotic transmission of American CL.[51] As travel to Latin America has become more common, CL increasingly is seen among returning travelers; the number of observed cases has doubled in the Netherlands and tripled in the United Kingdom in the past decade.[45] A high proportion of cases are acquired in rural or jungle areas of the Amazon basin. In children acquiring cutaneous *L. (viannia) braziliensis* infections, the major risk factor for acquisition of disease was the presence of an adult in the household with CL within the past year.[1] Humans may serve as reservoir and source of infection for young children. Development of a vaccine against American CL is under way.[25,38,42]

VISCERAL LEISHMANIASIS

VL is caused by various organisms in the *L. donovani* spp. complex, although more recently, strains of *L. tropica* from the Middle East and *Leishmania amazonensis* from Latin America have been found to cause this syndrome. VL, or kala-azar, is found in a broad belt that extends from the Strait of Gibraltar across the Mediterranean through Asia to the east coast of China, at latitudes between 30 and 48 degrees north. It is transmitted by various species of sandfly, although congenital and blood-borne infections also can

occur.[54] VL has been reported from 47 countries, but the Sudan and India account for more than half of the cases. In the Western Hemisphere, it is found in Brazil, northern Argentina, Paraguay, Venezuela, Colombia, Guatemala, and Mexico. Kala-azar seems to exist in at least three epidemiologic forms:

1. The Mediterranean type of VL, with a canine reservoir, infects young children (1 to 4 years old). Dogs, foxes, or feral animals are the reservoirs (*L. infantum*). This type extends from the Mediterranean littoral through central Asia into China; it also is present in parts of South America (*L. chagasi*), where foxes and dogs are reservoir hosts. In Brazil, boys are infected most often.
2. An Indian type (*L. donovani*) of VL with a human reservoir predominates in Indian children 5 to 15 years old; humans are the only known reservoir. Although sought, evidence of natural infection in dogs has not been found. No evidence of rodent reservoirs exists.
3. The African type of VL has rodents for the reservoir hosts. The Nile rat in the Sudan and probably the gerbil in Kenya are the reservoirs. In Kenya, researchers have noted that kala-azar often is related to old or eroded termite mounds where boys often congregate.

PATHOLOGY

The main pathologic lesions are the result of reticuloendothelial cell hyperplasia, especially in the spleen and liver (Fig. 232–7). Later, the bone marrow and lymph nodes are filled with infected macrophages, and a concomitant leukopenia and anemia develop (i.e., pancytopenia). Also, the kidneys may be filled with infected macrophages, and invasion of the submucosa and mucosa of the duodenum and jejunum results in hypertrophic congested and edematous villi. Small ulcerations and hemorrhages may occur. The spleen gradually enlarges, sometimes assuming enormous proportions, and eventually extends into the pelvis. Splenic infarcts frequently develop. The capsule is thickened, and, more deeply, the sinuses are dilated. Erythrophagocytosis by histiocytes is seen commonly, and the anemia so typical of kala-azar may be partly the result of such sequestration of red blood cells. Kupffer cells of the liver, filled with amastigotes, are swollen and hyperplastic, and centrilobular necrosis or fatty infiltration of the hepatic parenchyma often is observed. In late-stage or chronic disease, increased hepatic fibrosis may give a nodular cirrhotic appearance. Lymphadenopathy, especially of the mesenteric glands, is an early finding, and numerous parasite-filled macrophages are present. The bone marrow often is filled with parasitized histiocytes that replace the normal marrow elements; such replacement results in myelophthisic anemia.

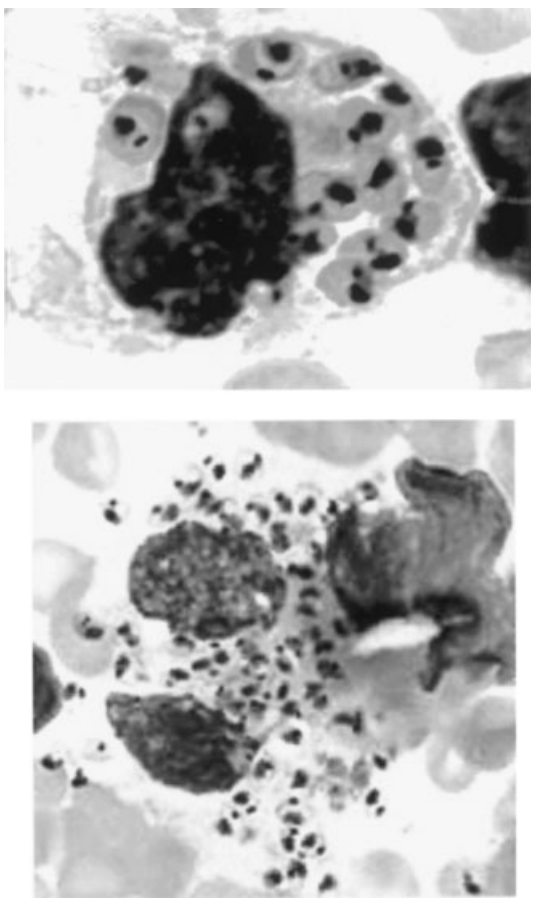

Figure 232–7 *Upper*, *Leishmania tropica* in a macrophage. *Lower*, *Leishmania donovani* in a liver touch preparation.

The immunologic response to kala-azar infection is imperfectly understood. At the bite site, a small, pea-sized dermal lesion may form (i.e., a leishmanioma); the parasites, initially localized in dermal macrophages, disseminate within the macrophages to the spleen, liver, bone marrow, and lymph nodes.

The infection outcome depends on the host's ability to raise a suitable cell-mediated immune response and the virulence of the invading organism. Experimentally, resistance in mice seems to be determined by a single autosomal gene. Researchers have shown in experimental infections that the disease is controlled by the T_H1 subset of $CD4^+$ and $CD8^+$ T cells; these cells are related to the production of cytokines such as interferon-γ, interleukin-2, and tumor necrosis factor-α.[31] Infection with *L. donovani* amastigotes induces a T_H1 cytokine milieu in dendritic cells and T cells.[19] Cytokines activate macrophages to kill intracellular amastigotes by oxidative and non-oxidative mechanisms.

Studies in mice indicate that nitric oxide is an important factor in killing amastigotes. If the infection is not eliminated or controlled by the host's cellular immune response, it becomes clinically evident. Lymphocytogenesis and histiocytogenesis occur in affected organs, with resultant hepatosplenomegaly and lymphadenopathy. Polyclonal B-cell activation ensues and causes hyperglobulinemia. This outpouring of humoral antibodies, chiefly IgG and largely nonspecific, is not protective and may represent more than half the total serum proteins of the patient. The specific antibodies produced during active disease have diagnostic significance. Fluorescent antibody, ELISA, indirect hemagglutination, and complement-fixation tests are reasonably reliable diagnostic procedures.

Resistance to kala-azar is essentially absent when the infection has become evident clinically. After chemotherapeutic cure, acquired immunity emerges; delayed hypersensitivity, as shown by the Montenegro (leishmanin) skin test (see later), also becomes apparent. The hypergammaglobulinemia abates concomitant with chemical cure and the appearance of delayed hypersensitivity. Usually, immunity to VL is complete and long-lasting after chemotherapeutic cure. Relapse, as seen in post–kala-azar dermal leishmaniasis, is characterized by delayed hypersensitivity, dermal localization of parasites, and moderate hypergammaglobulinemia. Although macrophage activation results in enhanced phagocytosis of parasites, macrophages remain unable to eliminate parasites. The occurrence of dermal delayed hypersensitivity at the time that acquired immunity occurs suggests that cell-mediated immunity plays an important role in protection. Further work on this aspect of VL is needed. The genetics of resistance in humans remains unclear.

CLINICAL MANIFESTATIONS

The incubation period varies from 6 weeks to 6 months, but has been reported to be as short as 10 to 14 days and as long as 10 years. A primary skin nodule rarely is seen, although in African leishmaniasis, it is a more regular feature. Infantile VL may begin either suddenly with high fever and vomiting or insidiously with irregular daily fever, anorexia, weight loss, lassitude, and pallor. When fever is present, double daily spikes are a characteristic sign, with temperatures reaching 40° C to 40.6° C. The spleen gradually enlarges so that by the end of the first month, it can be palpated. If the symptoms continue unabated, the spleen may extend to the umbilicus or into the pelvis. Diarrhea or frank dysentery is not an unusual development, and blood sometimes is observed. A general bleeding diathesis often becomes evident shortly before death. After several months, if the disease is untreated, patients usually die. Acute fulminant disease is seen more often in infants and young children.

In other cases, the clinical course is more protracted and generally ends fatally after 1 or 2 years. In older age groups, the disease tends to assume a more chronic course, with marked emaciation, brittle hair, massive splenomegaly, lymphadenopathy, and a dusky slate-gray complexion. Hyperglobulinemia, leukopenia, and anemia typically are found. As a result of general debility, death results from concurrent infections, such as pneumonia, amebic or bacillary dysentery, malaria, or cancrum oris, in more than 90 percent of cases. Infantile VL has been associated with alterations in lipoprotein metabolism.[6] A handful of cases of presumed congenital VL have been reported.[18,54] These infants were born of infected mothers, and in some, evidence of parasitism of the placenta was found.[18] However, whether these cases represent congenital infection or peripartum infection is unclear because sophisticated serologic techniques were unavailable.

Cutaneous manifestations of kala-azar are encountered frequently. In India, the dark gray appearance of the skin is known as kala-azar (black sickness). In some cases of inadequately treated VL, a skin condition termed *post–kala-azar dermal leishmaniasis* may ensue. In Indian VL, this complication is encountered in 15 to 20 percent of cases and appears several years after therapy. Individuals with VL or kala-azar and individuals with post–kala-azar dermal leishmaniasis are considered to be reservoirs of transmission of *L. donovani* in India.[47] In African disease, post–kala-azar dermal leishmaniasis occurs much less commonly, often during therapy in approximately 2 to 3 percent of cases, and it heals spontaneously in a few months. The lesions are characterized by the appearance of hypopigmented, erythematous, or nodular lesions on the skin of the face, chest, neck, and buttocks. At times, the nodular lesions of the face may resemble lepromatous leprosy.[50] The lesions are thought to represent a modified form of *L. donovani* infection, in which the parasites no longer invade the viscera and are localized to the skin. These lesions seem to be related to the host's immune response. This change to dermal tropism is said to coincide with recovery from VL and to disappear with relapse. Infection with *L. chagasi* causes VL in young children. More recently, atypical CL has been reported in older children with this infection.[7]

Pancytopenia is not unusual. Characteristically, anemia is always evident, with hemoglobin levels less than 8 g/dL. Survival of red blood cells is shortened as a result of several possible factors, including Coombs-positive hemolytic anemia and hypersplenism. Leukopenia of 2000 to 3000 cells/mm^3 typically is found with neutropenia, relative lymphocytosis, an almost total absence of eosinophils, and thrombocytopenia. Serum albumin usually is less than 3 g/dL, and globulin levels (mostly IgG) often are greater than 5 g/dL (5 to 10 g/dL).

Kala-azar has been reported as an important opportunistic infection in patients infected with human immunodeficiency virus type 1 (HIV-1) and not known to have contracted *Leishmania* infection previously. These patients seem to have a more severe and fulminant form of kala-azar. In this regard, inapparent *Leishmania* infection may become evident after immunosuppression, such as chemotherapy for malignant disease. The diagnosis may be particularly difficult to make inasmuch as the findings often are atypical and consist of low-grade fever, fatigue, cough, and gastrointestinal complaints. In patients with AIDS, VL is a recurrent disease that is highly prevalent, and the clinical course is modified by HIV. VL is very prevalent among HIV-1-infected patients in southern Spain, with a high proportion of cases being subclinical.[33] Symptomatic cases occur mainly when severe immunosuppression is present. An association also exists among VL, male gender, and intravenous drug use. Similarly, atypical visceral disease caused by *L. tropica* was seen in individuals who participated in Operation Desert Storm in the Persian Gulf.[28]

DIAGNOSIS

VL is diagnosed by finding the organism in stained smears of spleen aspirate,[11] peripheral blood, or bone marrow (see Fig. 232–7). In Indian kala-azar, the parasites may be found regularly in peripheral blood monocytes (i.e., buffy coat), but in the African and Mediterranean forms, they may be difficult to find by this technique. Blood and marrow cultures grown on NNN medium or in Schneider insect medium with 15 to 20 percent fetal calf serum are most useful (Fig. 232–8). Some investigators regard splenic rather than bone marrow aspiration as the most sensitive procedure, although it can be especially hazardous in individuals with a bleeding diathesis. Contraindications include a soft or diffluent, acutely enlarging spleen. Patients with low platelet counts or a prolonged prothrombin time (or both) should not undergo the needle biopsy procedure. In children younger than 5 years old, splenic aspiration should be performed only by a physician fully experienced in the procedure. Spleen and bone marrow aspirates should be placed in culture medium and smeared on slides, and saline-diluted aspirates should be inoculated into the peritoneal cavity of hamsters.

In a study in pediatric patients in the Mediterranean region, antibody detection techniques, antigen detection in urine (KAtex kit), and *Leishmania*-nested polymerase chain reaction (LnPCR) analysis of the blood were useful for diagnosis of the first clinical episode.[13] After treatment, clinical improvement was associated with negative NNN cultures and microscopy of bone marrow aspirate, KAtex test, and LnPCR blood analysis results. New

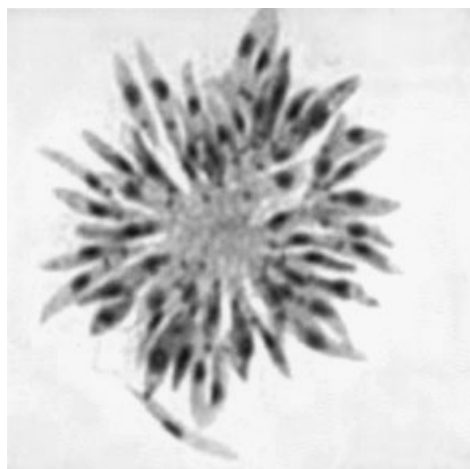

Figure 232–8 *Leishmania* sp. promastigotes from culture system.

noninvasive techniques tested showed high diagnostic sensitivity. LnPCR analysis of the bone marrow was the most sensitive, however, and was able to detect the persistence of parasites and predict potential relapses.[13]

Nonspecific tests reflecting the markedly elevated serum globulins, such as the formol gel test, are helpful in acute disease and are performed readily in the field. Antileishmanial antibodies usually are present and can be used to aid in the diagnosis. The fluorescent antibody test is highly specific, as are the indirect hemagglutination and gel diffusion tests. The complement-fixation test is positive in only 65 to 70 percent of cases, however. Sera from patients with VL are known to give false-positive results when antibodies to *Trypanosoma cruzi* are present; consequently, in the Western Hemisphere, absorbing out these antibodies may be necessary. Fluorescent antibody titers usually decline after complete cure, so a negative titer often is regarded as a sign of successful therapy. DNA-DNA hybridization tests are being evaluated and promise exquisite specificity and sensitivity for the diagnosis of leishmaniasis.[32] Serologic tests may be positive as a result of past or subclinical inapparent infection. An ELISA that detects antibodies to a cloned recombinant antigen, K39, of *L. chagasi* has been shown to be specific in active VL and could detect antibodies in patients with AIDS. A study has shown that this test could be applied to field situations.

In HIV-1-infected patients with active VL, the sensitivity of a peripheral blood smear is approximately 50 percent, owing to a high parasitemia in these patients. In patients with HIV-1 and subclinical VL, the sensitivity of a routine blood smear is less than 10 percent.[5] In these patients, serology and *Leishmania* skin tests have low sensitivities and are not very helpful. Cultures have proven to be effective in patients with VL who are co-infected with HIV-1. The usual diagnostic tests also may be negative in patients with *L. tropica* infection or in otherwise profoundly immunocompromised patients. More recently, two genomic fragments encoding portions of a single 210-kd *L. tropica* protein have proved useful for the diagnosis of viscerotropic *L. tropica* infection in Desert Storm patients.[17]

The leishmanin or Montenegro skin test, similar to the lepromin and tuberculin skin tests, is a measure of delayed hypersensitivity to leishmanial antigen. It consists of 10^6 phenol-killed, culture-grown promastigotes in 1 mL of 0.5 percent phenol in saline. The test is performed similar to the tuberculin test—0.1 mL is injected intradermally. A positive result is a palpable area of induration at least 5 mm in diameter in 48 to 72 hours. Because the leishmanin test can be positive in CL or VL, the results must be evaluated carefully. In VL, the test remains negative throughout the period of active disease. When chemotherapeutic control starts to take effect, and immunocompetent lymphocytes are able to respond, the test begins to turn positive.[9] Recovery from kala-azar is characterized by the development of cell-mediated immunity. The change from a negative to a positive leishmanin test in VL is regarded as an important prognostic sign that protective immunity is developing or has developed. Because numerous reports noting positive leishmanin tests in individuals who have had no history of VL have appeared more recently, researchers have postulated that many individuals in an endemic area may become immune by previous inapparent infection.

PROGNOSIS

Untreated VL is fatal in 75 to 85 percent of infantile cases and 90 percent of adult cases. Properly treated at an early stage, VL can be cured in 85 to 95 percent of cases. The prognosis usually is poor for patients in whom pancytopenia or bleeding diatheses develop or in whom a delayed hypersensitivity skin reaction fails to develop.

TREATMENT

VL generally responds to treatment with pentavalent antimonials, such as stibogluconate sodium (Pentostam, Triostam), which is the usual drug of choice in the United States and is available through the Drug Service of the Centers for Disease Control and Prevention.[23] Meglumine antimoniate (Glucantime) is available in French-speaking countries and Latin America.[8] The pediatric and adult dose is 20 mg/kg daily administered intramuscularly or intravenously for 28 days. Treatment can be repeated. In areas where leishmanial parasites may have acquired relative resistance to pentavalent antimonials, such as India, Nepal, and East Africa, extending therapy for more than 4 weeks may be necessary.[26] Side effects occur commonly and include nausea, vomiting, headache, anorexia, and abdominal pain. Elevated levels of serum amylase and lipase, indicative of pancreatitis, are encountered occasionally and can be severe. Electrocardiographic changes, including decreased T-wave amplitude and T-wave inversion, prolongation of the QTc interval, and nonspecific ST-T wave changes, are seen. They resolve shortly after therapy is concluded. (Treatment should be discontinued if the QTc interval is >0.5 second.) Deaths, presumably caused by arrhythmias, have been reported in patients who were receiving more than 20 mg/kg/day.

Primary antimony resistance and relapses after receiving pentavalent antimony therapy occur with all types of VL, but most often is encountered with the Indian form. The mechanism of antimonial resistance is unclear.[26] Among HIV-infected patients, almost 25 percent fail to respond to antimony therapy, and almost 40 percent of responders subsequently relapse.[35,37]

Liposomal amphotericin B (AmBisome) has been approved by the U.S. Food and Drug Administration for the treatment of VL.[34] This compound is taken up by cells of the reticuloendothelial system, where amastigotes reside, and is less nephrotoxic, allowing for higher daily doses with shorter courses of therapy. The approved, recommended regimen for immunocompetent VL patients is 3 mg/kg/day on days 1 through 5 and days 14 and 21. In immunosuppressed and HIV-infected patients, treatment of VL with AmBisome has resulted in an almost 100 percent response rate. Most of these patients relapse, however.[35,37] The recommended treatment is 4 mg/kg/day on days 1 through 5, 10, 17, 24, 31, and 38. Without maintenance therapy, almost all patients relapse. Because resistance to pentavalent antimonials has developed in Bihar, India, amphotericin B is used and is highly efficacious. Several more recent studies have used liposomal amphotericin B successfully for the treatment of VL presumably caused by *L. infantum* in immunocompetent children.[29]

Parenteral pentamidine isethionate (Pentam 300) is administered intramuscularly. The dosage is 4 mg/kg given three times weekly for up to 15 doses, depending on side effects, such as hypotension, vomiting, and blood dyscrasias. Pentamidine occasionally may exacerbate diabetes mellitus or precipitate latent diabetes. Shock and liver and renal damage have been reported.

In several more recent clinical trials, miltefosine, an oral alkyl phospholipid agent initially developed as an oral antineoplastic drug, has been used as an effective agent for the treatment of antimony-resistant Indian VL.[24,49] The treatment dose was 2.5 mg/kg/day for 4 weeks.

Patients may require hospitalization for therapy; supportive and corrective measures should be instituted in the event that other infections are present. Occasionally, a patient may be encountered who may require splenectomy to relieve the profound hypersplenism and the resulting anemia. Response to therapy often can be assessed by return of the patient's temperature to normal, a brisk reticulocytosis, a gradual reduction in spleen size, and the reappearance of eosinophils on the peripheral blood smear.

Allopurinol has been used with pentavalent antimonials to treat cases of VL that did not respond to pentavalent antimonials

alone. Several reports suggest that recombinant interferon-γ is helpful, along with pentavalent antimonial drugs, in successfully treating this disease. Because assessing whether a cure has been achieved is difficult, patients must be monitored at 6-month intervals for 2 years. Fluorescent antibody titers should be absent by the end of 1 year, and complement-fixation titers should be absent by 6 to 8 months. If post–kala-azar dermal leishmaniasis occurs, treatment should be re-instituted.

PREVENTION

Control of VL has many aspects. Sandflies (*Phlebotomus* and *Lutzomyia*) can be eliminated readily by residual spraying. Because sandflies ordinarily do not fly very high, sleeping quarters should be above ground level. Permethrin-impregnated bed nets can be highly effective in preventing sandfly bites. Animal reservoirs, such as infected dogs and rodents, should be destroyed. Early therapy prevents family and neighborhood transmission. A vaccine against different forms of leishmaniasis should be feasible, considering the wealth of information on genetics and biology of the parasite, clinical and experimental immunology of leishmaniasis, and the availability of vaccines that can protect experimental animals against challenge with different *Leishmania* spp. At present, however, there is no vaccine against any form of leishmaniasis for human use. One major obstacle is the lack of a confirmed market for human leishmaniasis vaccines. Ninety percent of visceral leishmaniasis occurs in five countries (Bangladesh, Brazil, India, Nepal, and Sudan). Nonetheless, local studies for vaccine development are ongoing in India and Brazil.

CHAPTER 233

TRYPANOSOMIASIS

Lynne S. Garcia ✪ Lawrence A. Ross ✪ Murray Wittner ✪ Herbert B. Tanowitz

AMERICAN TRYPANOSOMIASIS

American trypanosomiasis, or Chagas disease, is caused by the protozoan hemoflagellate *Trypanosoma cruzi*, which was discovered first by Chagas in 1909 in the blood of a seriously ill, wasted Brazilian child with fever, lymphadenopathy, and anemia.[56] The disease, transmitted by reduviid bugs, is limited to the Western Hemisphere and is a major health problem in Latin American countries. Chagas disease presently is identified in 18 countries within the Western Hemisphere. In endemic areas, it occurs most commonly in the rural poor who live in an environment with many feral reservoir hosts. Several autochthonous and laboratory-acquired cases have been reported from the United States in recent years.[36] Chagas disease in some endemic areas is the most important cause of heart disease and may result in serious chronic digestive tract pathology.

Collaborative efforts, in particular the Southern Cone and Andean initiatives, have resulted in substantial strides in vector control. These efforts, combined with screening of potential blood donors, has diminished the estimated number of individuals at risk of acquiring Chagas disease from 100 million to 40 million.[64,60] An estimated 16 to 18 million people are actually infected, with approximately 200,000 new cases and 20,000 deaths occurring each year. In certain areas of endemic infection, approximately 10 percent of all adult deaths are caused by Chagas disease. The southern United States, particularly Texas, is identified as having many cases. The geographic distribution of *T. cruzi* infection overlaps that of *Trypanosoma rangeli* infection; the trypomastigotes may be misidentified.

ORGANISM

Two evolutionary lineages have been identified in *T. cruzi—T. cruzi* I and II. Before 2005, epidemiologic and immunologic data suggested that chronic infections occurring in Brazil and Argentina were caused primarily by *T. cruzi* II strains. Using polymerase chain reaction (PCR) techniques, this hypothesis has been confirmed, and future studies can establish which strains are responsible for Chagas disease in other geographic locations.[30]

T. cruzi is a pleomorphic, spindle-shaped organism with a quite variable size, depending on the strain. The length of the blood forms (trypomastigote) in humans may vary widely, from 11 to 30 μm, including a free anterior flagellum. Most trypomastigotes assume a C or S shape, with the nucleus located just anterior to the middle of the cell. Trypomastigotes occur in the blood in two forms, a long slender form and a short stubby one. The nucleus is situated in the center of the body, with a large oval kinetoplast located at the posterior extremity. The kinetoplast consists of a small blepharoplast and a large oval parabasal body; the kinetoplast often appears to protrude from the cell surface (Fig. 233–1). The kinetoplast contains thousands of minicircle and maxicircle DNA that serve in the synthesis of mitochondrial proteins. A flagellum arises from the blepharoplast and extends along the outer edge of an undulating membrane until it reaches the anterior end of the body, where it projects as a free flagellum. When the trypomastigotes are stained with Giemsa stain, the cytoplasm stains blue, and the nucleus, kinetoplast, and flagellum stain red or violet.

Trypomastigotes are ingested by the reduviid bug as it obtains a blood meal. Within a few hours after taking an infective blood meal, short, spindle-shaped forms lacking a free flagellum can be found in the insect's foregut. These forms develop into small epimastigotes that continue to divide and give rise to large (35 to 40 μm) epimastigotes; by the third or fourth day after the blood meal, these organisms can be found attached to the rectal epithelium. By about the fifth day, the epimastigotes have begun to round up and gradually develop into short, stout trypomastigotes, which then proceed to elongate, and by the seventh and eighth days, they become the long, slender (17 to 22 μm), infective, metacyclic trypomastigotes. After 8 to 10 days, metacyclic trypomastigotes develop from the epimastigotes and are passed in the feces to infect humans when rubbed into the insect's puncture wound or rubbed onto exposed mucous membranes. These forms do not divide again, but are passed out with the feces some time after the blood meal. There may be 3000 to 4000 organisms per microliter of excreta. Transmission may occur by means of infected insect excreta, and metacyclic forms readily negotiate mucosa, conjunctiva, and abraded or otherwise broken skin (puncture site). Extensive experimental evidence has shown that infection is by contamination rather than insect inoculation.

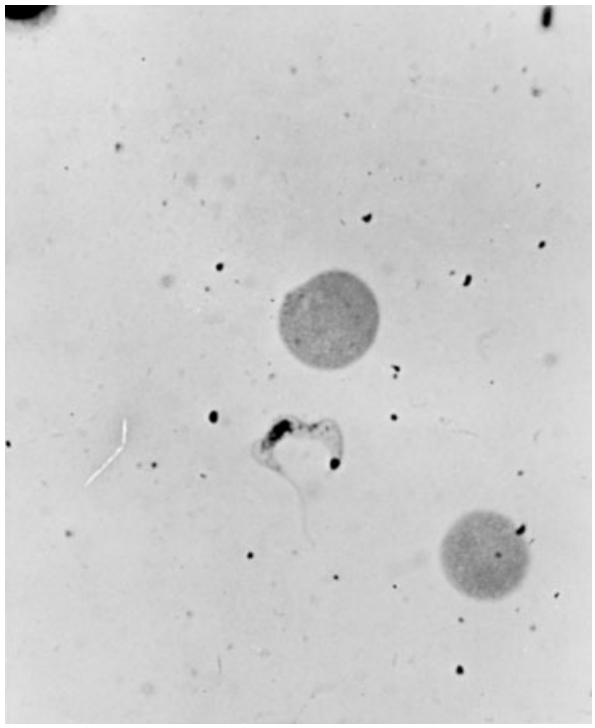

Figure 233–1 *Trypanosoma cruzi* trypomastigote forms in a blood smear. Note the large posterior kinetoplast (original magnification ×288).

On invasion of a cell, the trypomastigote loses its flagellum and undulating membrane and divides by binary fission to form an amastigote. The amastigote continues to divide and eventually fills and destroys the infected cell. Amastigote and trypomastigote forms are released from the cell. The amastigote is indistinguishable from those found in leishmanial infections. It is 2 to 6 μm in diameter and contains a large nucleus and rod-shaped kinetoplast that stains red or violet with Giemsa stain. The cytoplasm stains blue. Only the trypomastigotes are found free in the peripheral blood.

When the infective metacyclic trypomastigotes traverse the skin, they invade and multiply locally in many cell types after having transformed into intracellular amastigote forms. Host-cell entry by the parasite is a complex process involving many host and parasite factors. Trypomastigotes released from infected host cells may infect adjacent uninfected cells or enter the bloodstream and lymphatics to infect distant tissues. No tissue is spared from infection, but *T. cruzi* strains may vary in tissue tropism. The cells of the reticuloendothelial system and nervous and muscular (striated and cardiac) systems seem to be particularly vulnerable. In the ensuing weeks, during which time repeated cycles of multiplication, cell destruction, and cell re-invasion have occurred, flagellates enter the bloodstream as trypomastigotes, and the infection becomes disseminated.

EPIDEMIOLOGY

Chagas disease is a zoonosis occurring throughout American continents and involves reduviid bugs living in close association with human reservoirs (dogs, cats, armadillos, opossums, raccoons, and rodents). The most ubiquitous sylvatic reservoir host is the opossum, *Didelphis*, which is found throughout much of the range of *T. cruzi* in the Americas. Multiple nesting or resting sites of the opossum encompass many types of triatomine habitat. High *T. cruzi* prevalence rates are due partly to the fact that opossums eat triatomid bugs and may transmit infection via anal gland secretions. Sylvatic cycles of *T. cruzi* transmission extend from southern Argentina and Chile to northern California.

The vectors are distributed in rural wooded areas closely associated with feral animal species; humans intervene only occasionally. This infection usually is a zoonosis. Many species have become adapted to houses, however, where they may live in cracks; on roofs, walls, and floors; and beneath seldom-moved objects. Other triatomine species have developed regular visiting habits to human dwellings, but have not taken up residence as yet. Although Chagas disease always has been associated with rural areas and low socioeconomic groups, some vectors have adapted to areas undergoing urbanization. Various suitable hosts that often live close to humans, such as the opossum, may provide the transition between wild and domestic infection. Investigators frequently have observed that domestic animals such as pigs, cattle, goats, and sheep are kept in close contact with the domicile, and that triatomid bugs closely associated with these animals can be carried into the home.

Although 12 species of reduviids occur within the United States, they have not adapted themselves to household habitation. Humans should avoid sleeping in thatch, mud, or adobe houses; bed nets should be used by individuals sleeping in these types of houses. Travelers planning to stay in hotels, resorts, or other well-constructed housing facilities are not at high risk for contracting Chagas disease. Insecticides can be used to kill the vectors and reduce the risk of transmission.

Aside from natural transmission via the vector, other modes of transmission include congenital, blood transfusion, maternal milk, organ transplantation, and laboratory accident. The overall incidence of congenital Chagas disease has been reported as ranging from 2 to 6.7 percent.[5,10,52]

Blood transfusion is an important mode of transmission. In many large urban areas of South America, 3 to 15 percent of blood donors were reported to have a positive serology. The problem is compounded when one considers that in stored refrigerated blood, blood forms can live for weeks without losing their infectivity. In areas where seroprevalence is high, rather than discarding all positive blood units, laboratorians add gentian violet to the units, which are stored at 4° C for 24 hours before use, to kill the organism. In recent years, an influx of immigrants has occurred from these areas into North America and Europe. Some of these individuals are seropositive for Chagas disease.[44] With this immigration, an increase in the diagnosis of clinical Chagas disease has occurred in the United States, as has the recognition of blood transfusion–associated Chagas disease in nonendemic areas.[32]

Ingestion of infected mice by cats or cannibalism among rodents has been shown to transmit the infection successfully. Several reports have indicated the acquisition of infection by humans from infected meat. How important these routes of infection might be in maintaining the disease in nature or in humans is unclear, however. In endemic areas, large numbers of feral and domestic reservoirs of *T. cruzi* exist. Dogs and cats, especially in Brazil and Chile, have been shown to have a high index of infection and are thought to represent important domestic reservoirs. In some areas, armadillos have been implicated. In the United States, naturally occurring Chagas disease has been reported from Louisiana, Oklahoma, and Texas. In addition, the wood rat, raccoon, armadillo, and opossum are important feral hosts.

PATHOGENESIS AND PATHOLOGY

When metacyclic trypomastigotes penetrate the skin or mucous membrane, they may be phagocytized by tissue macrophages or

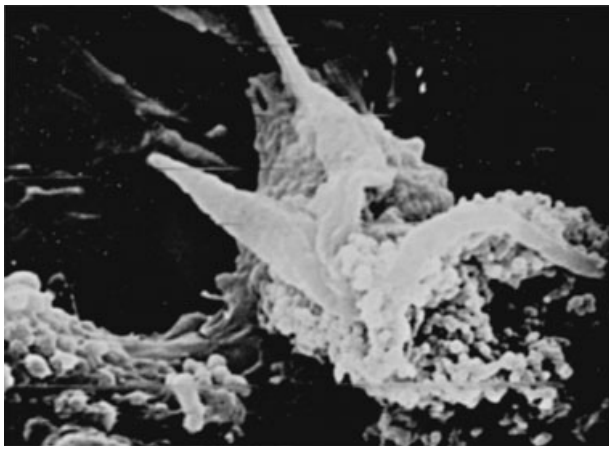

Figure 233–2 *Trypanosoma cruzi* phagocytized by a mouse peritoneal macrophage (scanning electron micrograph ×6000).

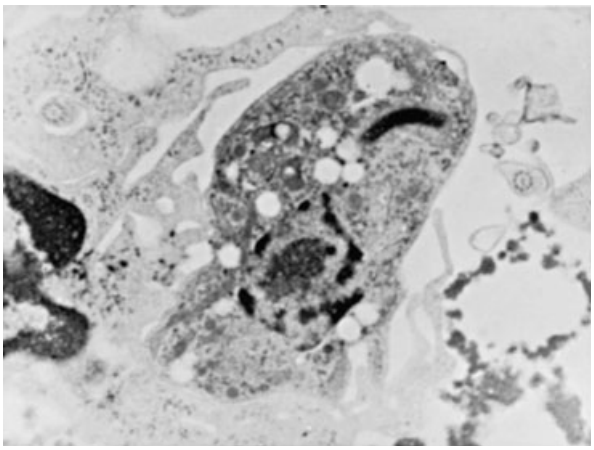

Figure 233–3 *Trypanosoma cruzi* phagocytized by a mouse peritoneal macrophage (transmission electron micrograph ×7000).

actively penetrate other cells (Figs. 233–2 and 233–3).[33] Within the cell, trypomastigotes rapidly transform into rounded amastigotes, and division begins (Fig. 233–4). In vitro studies have shown that parasites within macrophage vacuoles may be killed by the cytocidal mechanisms of the host cell, which include nitric oxide. The parasite may escape the parasitophorous vacuole by elaborating a hemolysin and reach the cytoplasm, where it reproduces. Within these cells, large numbers of amastigotes are formed, and within a few days, the greatly distended cell ruptures and frees trypomastigotes and amastigotes into tissues. They actively invade previously uninfected cells, and the process is repeated.

A nodular swelling, or chagoma, develops at the site of entry (Fig. 233–5). This area soon is infiltrated with macrophages surrounded by lymphocytes, eosinophils, and neutrophils. The process spreads to the regional lymph nodes, where focal lymphadenitis may be seen. Shortly thereafter, blood forms appear and disseminate throughout the body. Acute pathology is caused by the invasion and subsequent destruction of cells by the replicating intracellular parasites. There also is a marked host inflammatory reaction characterized by local accumulation of neutrophils, lymphocytes, and plasma cells. Although any tissue can be involved, cardiac and skeletal muscle and the cells of the reticuloendothelial and nervous systems are infected more frequently.[45]

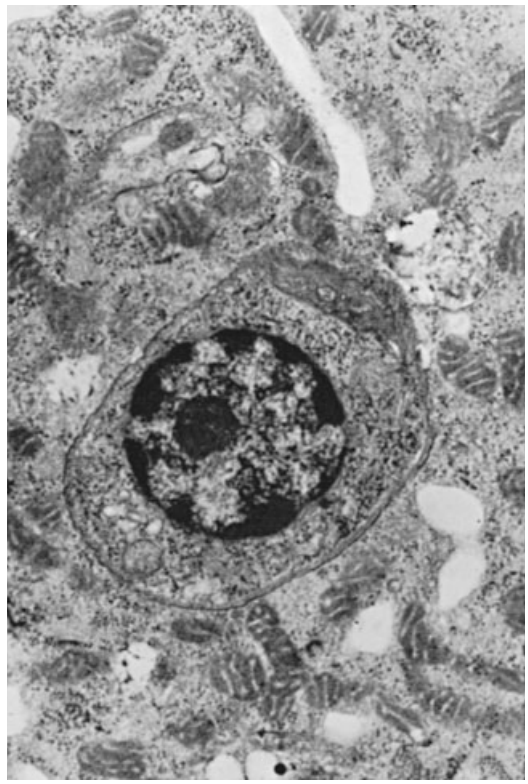

Figure 233–4 *Trypanosoma cruzi* amastigote forms in the cytoplasm of a macrophage (transmission electron micrograph ×7000).

Figure 233–5 Chagas disease. A chagoma on the mucocutaneous junction of the lip and moderate unilateral periorbital edema are present. *(From a nonprofit cooperative endeavor by numerous colleagues under the editorship of Dr. Herman Zaiman, New York.)*

The myocardium reveals focal myonecrosis, contraction band necrosis, interstitial fibrosis, and lymphocytic infiltration. Interspersed among the degenerating fibers is a marked mixed inflammatory cell exudate, which with time becomes predominantly mononuclear. The course of the acute infection can be quite

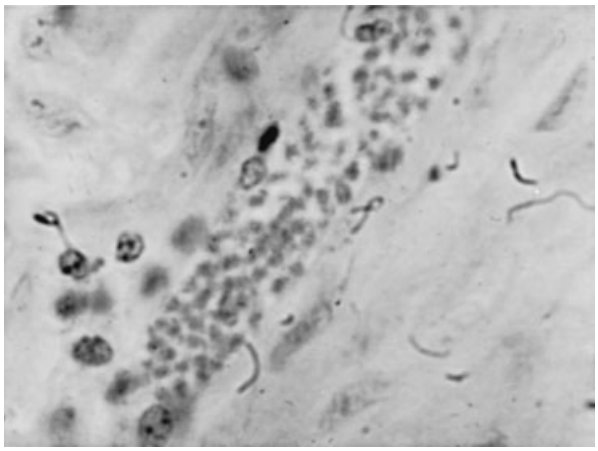

Figure 233–6 *Trypanosoma cruzi* amastigote forms in cardiac muscle (original magnification ×288).

variable, with severe tissue destruction, or the infection can be silent, with little or no obvious pathology. Nonetheless, the parasites have entered various cells of the body successfully and have formed pseudocysts, each containing hundreds to thousands of amastigotes (Fig. 233–6). Individuals who recover from the acute episode, including those who have remained asymptomatic, probably harbor these intracellular parasites for the rest of their lives.

The immunology of Chagas disease in experimental animals and humans is very complex. It is clear, however, that cell-mediated immunity and antibody play important roles in the immune response.[49] Cytokines such as interferon-γ and nitric oxide contribute to the intracellular killing of this parasite and to myocardial and gastrointestinal tract dysfunction.

Chagasic heart disease represents the interplay of inflammation and ischemia. During acute infection, foci of myonecrosis, myocytolysis, and vasculitis are observed, along with an inflammatory exudate consisting primarily of leukocytes. Pseudocysts containing amastigotes can be found interspersed among the degenerating fibers. *T. cruzi* gains access to cardiac myocytes by first invading endothelial cells, the interstitial areas of the vascular wall, and the myocardium. Parasites can be seen in and around the endothelium of infected mice. The trypomastigotes pass two basal laminae and two layers of extracellular matrix. Parasite enzymes such as proteases, gelatinases, and collagenases degrade native type I collagen, heat-denatured type I collagen, and native type IV collagen. Proteolytic activities against laminin and fibronectin also have been detected. These enzymes may play an important role in the degradation of extracellular matrix and subsequent parasite invasion.

Degradation of the collagen matrix, evident in acute murine Chagas disease, has been proposed to result in chronic pathology such as apical thinning of the ventricle. When damage such as that caused by ischemia and necrosis occurs, extracellular matrix degradation ensues and leads to slippage of the ventricular layers, with mural thinning and formation of an aneurysm. Damage to this area of the heart and remodeling of the wall frequently are encountered in chagasic heart disease. Remodeling refers to the structural changes associated with inflammation, necrosis, hypertrophy, and ventricular dilation. In the course of chronic chagasic heart disease, myonecrosis, myocytolysis, and contraction band necrosis are evident. The necrosis results from transient hypoperfusion followed by reperfusion, such as occurs after local spasm of the coronary microvasculature. Focal and diffuse areas of myocellular hypertrophy may be observed with or without inflammatory infiltrates. In other areas, focal fibrosis replacing previously damaged myocardial tissue is evident.

An important feature of chagasic heart disease is a dense accumulation of extracellular collagen that encloses fibers or groups of fibers. All areas of the heart, including the conduction pathways, may be involved. Microvascular involvement, manifested by basement membrane thickening, has been shown. These irreversible changes lead to functional disturbances. The remodeling process results in replacement of cardiac myocytes and cells of the vasculature by fibrous tissue, which leads to thinning of the myocardium and hypertrophy of the remaining cardiac myocytes. Chronic chagasic cardiomyopathy is characterized by focal lymphocytic infiltrates (predominately $CD8^+$), myocyte necrosis, and marked reactive and reparative fibrosis. The role of apoptosis in the pathogenesis of chronic chagasic cardiomyopathy is unclear.

In the chronic stage of Chagas disease, the heart usually is enlarged. The chambers may be dilated and associated with an apical left or right ventricular aneurysm, which rarely ruptures. Mural thrombi, especially of the right atrium and apex of the left ventricle, commonly are seen. They may cause widespread embolization, especially to the brain, lungs, spleen, and kidneys. The myocardium often reveals diffuse fibrosis with small numbers of mononuclear cells scattered throughout, and in many patients, finding parasites in the myocardium may be quite difficult.

The apparent absence of parasites in the myocardium during routine histologic examination in chronic Chagas cardiomyopathy, even in the presence of marked morphologic and functional changes, has engendered much speculation regarding possible pathogenic etiologies. Parasite persistence, autoimmunity, disturbances in the autonomic nervous system, and vascular compromise have emerged as possible important factors. Experimental studies indicate that endothelin-1 and thromboxane A_2, potent vasoconstrictors, and nitric oxide may contribute to the pathogenesis of Chagas cardiomyopathy.[46] In addition, genetic epidemiologic studies suggest that susceptibility to infection and progression to chronic disease may be partly genetically determined. Researchers have estimated that destruction of more than 95 percent of the ganglion cells of the myenteric plexus in the esophagus and colon is required for evidence of megaesophagus and megacolon. In experimental studies, destruction of ganglion cells mediated by inflammatory mediators is the result of parasitic destruction during the acute phase of the disease.

CLINICAL MANIFESTATIONS

Clinically, Chagas disease can be viewed as having three phases: acute, indeterminate, and chronic. Seroepidemiologic studies indicate that overt or clinically recognizable disease fails to develop in most individuals infected with *T. cruzi*, and researchers estimate that 99 percent of individuals infected have inapparent or subclinical infection. Most individuals in whom clinical disease develops as a result of natural infection are infants unable to ward off the bite of triatomes, or "kissing bugs," and other young children up to 10 years old. After an incubation period of approximately 7 to 14 days, acute clinical symptoms may begin with anorexia, lassitude, headache, and intermittent or remitting fever with temperatures of 38° C to 40.5° C. In young infants, swelling and edema of the Bichet fat pad may make feeding painful.

Early Disease

Locally, or near the site of initial infection, a characteristic unilateral, painless palpebral edema, often with conjunctivitis, may be recognized. This so-called Romaña's sign, when present in an endemic area (25 to 30% of patients), is highly suggestive of early acute Chagas disease. The edema may be generalized and mistaken for nephrotic syndrome, however, or swelling of the preauricular region may be so severe that it suggests mumps. The

edema does not pit on pressure, and the skin is dry. Generalized lymphadenopathy, hepatosplenomegaly, vomiting, diarrhea, and signs of meningeal irritation commonly are encountered. Skin lesions can vary from a generalized maculopapular or morbilliform eruption to urticaria. Neurologic symptoms, found more often in younger infants than in older patients, include focal to generalized seizures.

Acute-Stage Disease

Acute-stage symptoms occur in only approximately 1 percent of patients, usually are seen in younger children, and are less obvious in older individuals because of the nonspecific nature of the symptoms and the lack of availability of health care. Symptoms generally last 4 to 8 weeks and then may subside, even without therapy. Acute systemic signs occur around week 2 to 3 of infection and are characterized by high fevers, which may be intermittent, remitting, or continuous; hepatosplenomegaly; myalgia; erythematous rash; acute myocarditis; lymphadenopathy; keratitis; and subcutaneous edema of the face, legs, and feet. There may be signs of central nervous system (CNS) involvement, including meningoencephalitis, which has a very poor prognosis. Myocarditis is manifested by electrocardiographic changes, tachycardia, chest pain, and weakness. Amastigotes proliferate within the cardiac muscle cells and destroy the cells, leading to conduction defects and a loss of heart contractility. Death may occur secondary to myocardial insufficiency or cardiac arrest. In infants and very young children with acute Chagas disease, swelling of the brain can develop, causing death.[42] Also, in some areas of endemic infection, a high frequency of early electrocardiographic abnormalities in children who are seropositive for *T. cruzi* suggests a rapid evolution from infection to disease. Under such conditions, a public health chemotherapy program targeted to this population would be recommended.

During acute infection, echocardiography may reveal abnormal segmental left ventricular wall motion, most commonly in the anterior or apical regions (or both). The overall size of the left ventricle and ejection fraction are typically normal. Fatal acute myocarditis may occur in a few patients. Examination of blood during the acute infection often reveals trypomastigote forms, leukocytosis with a relative lymphocytosis, and an elevated erythrocyte sedimentation rate. Trypomastigotes may be present in cerebrospinal fluid (CSF), even in the absence of neurologic abnormalities. Although most patients recover, apparently without sequelae, 2 to 10 percent may die of severe myocarditis, meningoencephalitis, or an underlying bacterial or viral infection. As the acute stage subsides in 8 to 12 weeks, fewer and fewer parasites can be found in the peripheral blood as antibody levels increase. The disease enters the indeterminate period, and evidence of infection may be detected by special techniques described later. During acute infection, most of the antibody is IgM. Later, in the indeterminate and chronic stages, antibodies predominantly are IgG. From a global perspective, *T. cruzi* infection is recognized as the most common cause of myocarditis.

Indeterminate Phase

The indeterminate phase of Chagas disease represents the period between acute infection and the onset of chronic signs and symptoms. The duration of this period can span 10 to 40 years, and in most cases, overt clinical disease never develops despite the fact that in asymptomatic individuals, organisms often can be identified by culture or molecular methods and by xenodiagnosis. During the indeterminate phase, electrocardiographic or radiologic abnormalities may not be detectable. Echocardiography often reveals significant changes, however. Many of these individuals (10 to 30%) eventually experience the serious and potentially fatal chronic phase of the disease. A report from a hospital in Brazil identified Chagas heart disease in 11 percent of patients who died of a cardiovascular cause.[26]

The patient may have a subpatent parasitemia and develop antibodies to various *T. cruzi* antigens. Chronic Chagas disease is diagnosed more commonly than the acute disease. The chronic stage may be initially asymptomatic (indeterminate stage), and although trypomastigotes seldom are seen in peripheral blood, transmission by blood transfusion is a serious problem in areas where the disease is endemic. There are regional variations in disease severity, which may account for the geographic differences in morbidity. Approximately 8 to 10 weeks after infection, the indeterminate stage begins, during which the patients do not have any symptoms.

Chronic Stage

Chronic Chagas disease shows close interaction between the parasite and the host, causing many different clinical syndromes. Approximately 30 percent of patients may develop chronic Chagas disease, including cardiomyopathy, megacolon, and megaesophagus. Symptoms of the chronic stage are related to the damage sustained during the acute stage of the disease, the state of the host's immune system, and the inflammatory response. Other contributing factors include the host genetic background, environmental and social factors, the genetic composition of the parasite, and mixed infections and re-infections. The inflammatory response undergoes periods of exacerbation, and is probably responsible for neuronal damage, microcirculatory changes, heart matrix deformations, and possible cardiac failure. Selenium deficiency also has been linked with some cardiomyopathies and apparently is a biologic marker for Chagas disease and related to progressive pathology.

Chronic chagasic heart disease occurs insidiously or abruptly with an arrhythmia, dilated congestive cardiomyopathy, thromboembolic phenomena, and sudden death. An apical aneurysm, with or without thrombus formation, is a hallmark of this disease and is commonly found, although not exclusively, in the left ventricle. Although significant major coronary artery lesions are usually absent, several instances of myocardial infarction in individuals with Chagas disease have been reported. Destruction of conduction tissue results in conduction abnormalities.[41]

In endemic areas, electrocardiographic abnormalities may suggest chagasic cardiomyopathy. A right bundle branch block alone and a right bundle branch block together with an anterior fascicular block are highly suggestive of chagasic heart disease. These abnormalities have been reported in teenagers and young adults. Premature ventricular contractions and right bundle branch block occur in 50 percent of cases, atrioventricular block of varying degrees develops in about 30 percent of cases, complete atrioventricular block is seen much less commonly, and left bundle branch block is not characteristic. Chest radiographs may reveal cardiomegaly. Heart sounds may be distant, and murmurs of functional mitral and tricuspid insufficiency sometimes are heard. More recently, echocardiography and cardiac magnetic resonance imaging have been used to diagnose and suggest prognosis of chronic chagasic cardiomyopathy.[61] When congestive heart failure ensues, it is usually intractable and difficult to treat. Models have been formulated to identify risk scores predictive of survival probabilities from Chagas heart disease. Such models may facilitate development of clinical trials for therapeutic intervention.[48]

Megaesophagus and megacolon are the result of destruction of the ganglion cells of the autonomic plexus. Although these complications are not usually fatal except in congenital disease, the marked dilation of the colon and esophagus can be debilitating.[21] Any hollow viscus, including the gallbladder and ureters, can be involved, but esophageal and colonic disease are encountered most frequently. Dysphagia, gastroesophageal reflux, and

paroxysmal night coughs, presumably caused by aspiration while sleeping, are associated with megaesophagus; chronic constipation, long-term fecal retention, impaction, and volvulus are observed with megacolon. In some regions, patients with digestive disease have symptomatic chagasic heart disease as well. Wide geographic variation in the prevalence of cardiac and gastrointestinal disease has been noted. In Panama, Venezuela, and Colombia, megaesophagus and megacolon are rarely encountered, whereas in parts of Brazil, both forms of Chagas disease may be seen in the same individual.

Congenital Disease

Congenital Chagas disease is caused by vertical transmission of the infection.[8,29] Pregnant women in endemic areas may experience abortion or placentitis and may give birth to infants with congenital infection associated with prematurity. In its acute stage, congenital Chagas disease often resembles the acquired disease. The onset may be at birth or a few months later, with the infant manifesting hepatosplenomegaly, anemia, jaundice, edema, thrombocytopenia, petechiae, tremors, and seizure disorders. The clinical and laboratory findings may resemble those of congenital toxoplasmosis, cytomegalovirus and herpes simplex virus, or erythroblastosis fetalis. Although meningoencephalitis has been observed, it is more likely to be silent. The prognosis of meningoencephalitis in congenital disease is better than in the acquired form of disease. Examination of CSF often reveals trypomastigotes. Necrotic and hemorrhagic lesions of the oral mucosa and skin are thought to represent hematogenously disseminated chagomas. Megacolon and megaesophagus can be present and cause constipation and aspiration pneumonitis.[9,19]

Immunocompromised Patients

Chagas disease has been reported in patients with human immunodeficiency virus (HIV), and neurologic sequelae caused by *T. cruzi* have been major findings in these patients.[17,39] Individuals who were previously infected with *T. cruzi* and later became positive for HIV are at risk of reactivation of Chagas disease.[50] These patients develop a severe multifocal or diffuse meningoencephalitis with numerous tissue parasites.[51] Meningoencephalitis is rare in patients without acquired immunodeficiency syndrome and is seen most frequently in immunocompetent children younger than 4 years. Because of the immunodeficiency associated with HIV infections, concomitant infection with *T. cruzi* may be difficult to recognize, particularly in individuals who have moved to areas where the disease is not endemic. *T. cruzi* infection also may have a protracted asymptomatic course in immunosuppressed HIV patients. Although a positive blood smear has been considered the key indicator of Chagas disease reactivation in immunocompromised patients with chronic disease, this finding may occur late, rather than early, in the reactivation process. Apparently, there is no association between given *T. cruzi* genotypes and specific clinical forms of Chagas disease–HIV associations.

Recrudescence of *T. cruzi* infections in immunosuppressed patients, particularly transplantation patients, is concerning. Transplant recipients also can become infected through receipt of infected organs.[14] Treatment guidelines for HIV-infected adults and adolescents with Chagas disease have been formulated.[6] In patients with end-stage Chagas cardiomyopathy, heart transplantation is an option that has had variable success. Reactivation of the disease with the development of cutaneous lesions has been seen. Bone marrow transplant recipients also are at risk of Chagas disease owing to reactivation or transfusion. Prophylactic treatment of these patients has led to favorable outcomes.

There seems to be a link between *T. cruzi* seropositivity and human T-cell lymphotrophic virus 2 (HTLV-2) infection in studies of the Indians in western Paraguay. In this particular group, an individual infected with HTLV-2 is 2.28 times more likely to be *T. cruzi*–positive than an HTLV-2-negative individual. The public health significance of these findings is emphasized by the fact that approximately 18 million people are infected with *T. cruzi* in the Americas, and the frequency of HTLV-2 continues to increase.[27]

DIAGNOSIS

Routine Methods

The diagnosis of Chagas disease should be considered if there is a history of consistent exposure to reduviid bug bites, residence in or travel to areas where the disease is endemic, laboratory accident, or recent blood transfusion in an area where the disease is endemic, or if cardiac or digestive tract lesions are compatible with Chagas disease. A definitive diagnosis depends, however, on demonstration of the trypomastigotes in the blood, amastigote stages in tissues, or positive serologic reactions. Methods used for examination of blood are similar to the methods used for the diagnosis of African trypanosomiasis. Trypomastigote stages may be detected easily in the blood in young children; however, in chronic disease, this stage is rare or absent except during febrile exacerbations. Trypomastigotes may be detected in blood by using thin and thick blood films or by buffy coat concentration techniques. The most sensitive methods to detect trypomastigotes are concentration techniques, such as the Strout method of buffy coat preparations.[31] With the Strout method, blood is collected without anticoagulant and allowed to clot. The serum is centrifuged at low speed to remove the remaining blood cells and then at a higher speed ($600 \times g$) to concentrate the parasites in the sediment. The stain of choice is Giemsa for trypomastigote and amastigote stages; other blood stains also are acceptable.

Examination of peripheral blood is valuable only during the initial acute disease (6 to 12 weeks) or during chronic exacerbation. Although inoculation of animals with the patient's blood often aids in the diagnosis, this is not a practical approach in most diagnostic laboratories. In chronic stages, the investigator frequently must take 30 to 50 mL of the patient's blood and inoculate numerous cultures to obtain a positive diagnosis. Aspirates, blood, and tissues also can be cultured, which is valuable in detecting low-grade parasitemias. The medium of choice is Novy, McNeal, and Nicolle medium. Cultures should be incubated at 25° C and observed for epimastigote stages for 30 days before they are considered negative.

Aspirates from chagomas and enlarged lymph nodes can be examined for amastigotes and trypomastigotes. Histologic examination of biopsy specimens also may be performed. Liver biopsy, bone marrow aspiration, or splenic puncture also can be tried to confirm the diagnosis. Sometimes, xenodiagnosis may be the only means by which organisms can be found. In this technique, laboratory-reared reduviid bugs are permitted to feed on the patient or the patient's fresh blood; subsequently, the bugs are allowed to feed on uninfected guinea pigs. The guinea pigs are examined for trypomastigotes after approximately 45 days. Although 100 percent specific, this test is less than 50 to 80 percent sensitive. If organisms are present in the blood meal, the parasites multiply and are detected in the bug's intestinal contents, which should be examined monthly for flagellated forms over 3 months.

Serologic Tests

Serologic tests can be useful during various stages of the disease. The precipitin test may be positive during the acute episode, whereas complement fixation (Machado-Guerreiro test) is useful for the diagnosis of chronic disease. The indirect fluorescent antibody and indirect hemagglutination tests are valuable tools

for the diagnosis of Chagas disease. Patients with leishmaniasis, malaria, collagen vascular disease, and syphilis may give false-positive reactions, however. In congenital disease, an indirect fluorescent antibody test using anti-IgM or an enzyme-linked immunosorbent assay for IgA antibodies may provide evidence of congenital disease.[23,40] Tests also have been developed to detect antigen in serum and urine.

Polymerase Chain Reaction

Tests using recombinant methods that have the potential for high specificity and high sensitivity have been developed. During chronic infection, the number of circulating parasites is very low, but PCR-based assays can detect low numbers of organisms because the parasite has highly repetitive nuclear and kinetoplast DNA sequences that can be amplified by PCR.[43] During the chronic stage, serologic methods may be the only means to arrive at a diagnosis. The differential diagnosis of chronic chagasic cardiomyopathy includes rheumatic and arteriosclerotic heart disease and cardiomyopathies of other etiologies.

Immunoassays

Immunoassays have been used to detect antigens in urine and sera in patients with congenital infections and patients with chronic Chagas disease.[7] Determination of antigenuria can be valuable for early diagnosis of Chagas disease and for diagnosis of chronic cases in patients with conflicting serologic test results. A highly sensitive and specific chemiluminescent enzyme-linked immunosorbent assay has been developed for blood bank screening and to monitor patients who are undergoing chemotherapy.[15]

TREATMENT

Although numerous drugs have been tried, including agents used to treat African trypanosomiasis and leishmaniasis, few have proven to be effective for therapy of Chagas disease.[37,58] In acute and congenital Chagas disease and infections caused by laboratory accidents, treatment should be administered as soon as possible, even though in some cases symptoms are self-limited. At present, therapy for Chagas disease is recommended for patients with acute disease, children with congenital infection, and patients in the early phase of chronic disease (in particular, children <15 years old).[3,55] In addition, therapy should be prescribed for patients co-infected with HIV who experience Chagas reactivation. Whether therapy can modify the progression of chronic Chagas disease has not been conclusively shown. Data published more recently suggest a beneficial effect of therapy in diminishing the risk of progression to severe chronic cardiomyopathy.[62] A randomized trial in progress is expected to define more clearly the role of therapy on cardiac outcomes in chronic Chagas disease.[22]

Nifurtimox (Lampit), a nitrofurfurylidine derivative, is tolerated better in younger than older patients and should not be used during pregnancy. It reduces the duration and severity of illness and decreases mortality resulting from acute and congenital Chagas disease. Reversible gastrointestinal, cutaneous, and neurologic adverse effects are common. Treatment success varies from one country to another, possibly indicating differences in the susceptibility of strains of *T. cruzi*. There is no indication that treatment of patients with chronic Chagas disease is beneficial. Nifurtimox must be taken orally for prolonged periods, and there can be severe side effects, including abdominal pain, nausea, vomiting, anorexia, and neurologic symptoms. Nifurtimox is available in the United States from the Parasitic Drug Service of the Centers for Disease Control and Prevention. It is supplied in 30-mg and 120-mg tablets. The usual dose for adults is 8 to 10 mg/kg body weight per day. For adolescents (11 to 16 years old), it is 12.5 to 15 mg/kg/day, and for children (1 to 10 years old), the dose is 15 to 20 mg/kg/day. It is given in four divided doses daily for 90 to 120 days. This drug has many untoward reactions, including abdominal pain, nausea, vomiting, anorexia, restlessness, disorientation, insomnia, twitching, paresthesia, polyneuritis, and seizures. Skin reactions also may be observed.

Benznidazole (Rochagan) is similar to nifurtimox and seems to have similar efficacy. Some researchers consider it to be tolerated well, with fewer adverse reactions. It is used extensively in Brazil at 5 mg/kg/day for 30 to 120 days in two divided doses (adult dose). For children up to 12 years old, the dose is 10 mg/kg/day in two doses for 30 to 90 days. Bone marrow depression and peripheral neuritis have limited its use, however. Additional chemotherapeutic agents are urgently needed and are under investigation.[59]

Interferon-γ has been used in conjunction with drug therapy because experimental data suggest that it is a useful adjunct in treatment by activating macrophage killing. Allopurinol and antifungal drugs have been suggested as alternatives in some patients. Patients with chronic chagasic cardiomyopathy may be helped for a varying period by implantation of a cardiac pacemaker, but the congestive heart failure is often refractory to cardiac glycosides and vasoactive drugs. More recently, inhibitors of angiotensin-converting enzymes have been advocated to reduce cardiac remodeling in these individuals. Heart transplantation also has been performed for the management of chronic cardiomyopathy. The use of high-fiber diets, occasional laxatives, and enemas may assist in the management of megacolon. When these measures fail, surgical resection may be required. Megaesophagus is usually amenable to therapy consisting of a combination of diet and dilation of the esophagogastric region. In more severe disease, various surgical procedures have been used with variable success to relieve the symptoms of achalasia.

PREVENTION

Regular insecticide spraying programs with benzene hexachloride could reduce transmission of the infection, at least around domiciles. Proper screening and improved housing for individuals in endemic areas also help reduce transmission. In endemic areas, thorough screening of blood donors would help prevent transmission by transfusion. The development of a chemoprophylactic agent or vaccine holds the best hope for prevention and subsequent eradication of Chagas disease.

Transfusion-acquired disease is a major public health problem in endemic areas. Treatment of blood with gentian violet inactivates the parasite. Transfusion-acquired infection has been reported in North America. Because no effective rapid means of detecting the parasite exists, researchers have suggested that individuals from endemic areas be rejected as blood donors.

AFRICAN TRYPANOSOMIASIS

African sleeping sickness is caused by two morphologically identical subspecies of hemoflagellate protozoans: *Trypanosoma brucei gambiense*, the cause of West African or Gambian sleeping sickness, and *Trypanosoma brucei rhodesiense*, the cause of East African or Rhodesian disease. Although these parasites produce similar disease, the Gambian form is usually chronic and evolves slowly, often over many years, and ends fatally if untreated, whereas the Rhodesian form is characterized by being acute, usually killing the host in a matter of weeks or months. These diseases exist

wherever the various species of *Glossina*, the tsetse fly, are found. The completion of the *Trypanosoma brucei* genome should facilitate greatly the discovery of new drug targets and genetic markers.[12]

ORGANISM

T. b. gambiense and *T. b. rhodesiense* are pleomorphic flagellates 15 to 30 μm in length by 1.5 to 3.5 μm in breadth. In Giemsa-stained blood smears, they may appear long and slender with an undulating membrane and free anterior flagellum or appear short and broad without a free anterior flagellum. No intracellular forms exist. At various stages of disease, trypomastigote forms may be found in the peripheral blood, lymphatics, lymph nodes, CSF, and neural tissue. Although the two species are morphologically indistinguishable and share major biochemical features, isozyme and molecular analysis has shown substantial variation among species, particularly regarding clinical disease. In addition, the two species maintain separate biologic characteristics, especially with regard to virulence in cross-inoculation experiments. Humans are the only important reservoir host for *T. b. gambiense*, whereas *T. b. rhodesiense* naturally infects wild game animals.

The haploid genome size of *T. brucei* spp. is approximately 40 Mb, with 14 percent variation within the same subspecies and 29 percent variation among different subspecies. Homologous chromosomes, when probed by Southern blot, can differ in size by 20 percent. In addition to the large chromosome pairs, *T. brucei* has approximately 100 linear minichromosomes ranging in size from 50 to 150 kb. These minichromosomes contain transcriptionally silent copies of variant surface glycoprotein (VSG) genes. *T. brucei* has approximately 1000 genes capable of coding for *VSG* genes; these genes are switched at a rate of 10^{-2} to 10^{-6} switches per generation, which serves as the main mechanism of immune evasion for *T. brucei*.[24] Only one VSG expression site is active at any given time. Studies comparing homologous nuclear genes between *T. cruzi* and *T. brucei* have shown large evolutionary divergence in codon usage. Comparison of the nuclear small-subunit and large-subunit rRNA gene sequences yields genetic distances comparable to that between plants and animals.

Within the insect vector, the tsetse fly, that has ingested a blood meal, settles in the posterior portion of the midgut and multiplies by binary fission for approximately 7 to 10 days. The slender trypomastigotes migrate anteriorly to the foregut, where they remain for the next 2 to 3 weeks. They next move further forward and finally enter the salivary glands, in which they transform into epimastigote forms—forms in which the kinetoplast has migrated just anterior to the nucleus—and continue to replicate. After multiplication cycles, they transform into infective metacyclic trypomastigote forms, which are the small, broad or "stumpy" forms that lack a free anterior flagellum. When next feeding, the infective tsetse fly may inoculate into the bite wound thousands of these infective trypomastigotes. The entire life cycle of the tsetse fly spans 15 to 35 days. Within the human host, trypomastigotes multiply by binary fission in blood, lymph, and extracellular spaces. The CNS eventually is invaded, at which time multiplication continues unabated. Transmission by blood transfusion, hypodermic needle, other insects, and congenital transmission has been reported.

EPIDEMIOLOGY

African sleeping sickness (*T. b. gambiense* and *T. b. rhodesiense*) and veterinary trypanosomiasis caused by *T. brucei* subgroup parasites are responsible for much human suffering and economic loss. Factors contributing to disease resurgence include socioeconomic unrest resulting in population shifts of animal reservoirs, insufficient financial allocations, emergence of drug-resistant parasitic strains, climatologic alterations, and altered susceptibility of populations at risk.[35] Because the larval stages of the tsetse fly are vulnerable to desiccation, *Trypanosoma* spp. are restricted to an area spanning 10 million km^2 south of the Sahara, encompassing 200 separate foci from 36 countries, where the annual rainfall exceeds 500 mm (20 inches). The most recent estimates are that 25,000 new cases occur each year, and a human population of 60 million is at risk (only 4 to 5 million of whom are under surveillance), along with cattle and other species of agricultural importance. In the past, 10,500 cases have been reported annually in Zaire. These figures are probably low in light of more recent military activity in the Sudan, Democratic Republic of Congo (formerly Zaire), Angola, and Rwanda. Movement of populations in war areas has increased the risk of epidemics in these and neighboring regions.

The Gambian form occurs mainly in the western portion of tropical Africa, with focal incursions eastward north of Lake Victoria into the Sudan. *Glossina palpalis* is the main tsetse fly vector, although other related species, such as *Glossina tachinoides* and *Glossina fuscipes*, are implicated as well. The Rhodesian form is found in the southeastern portion of Africa. Of great concern is the recent identification of a focus of *T.b. rhodesiense* in Uganda, which has substantially diminished the geographic separation of the two species of African trypanosomiasis. Because control of human African trypanosomiasis requires different strategies for the two parasites, emergence of geographic overlap would add greatly to costs.[28,47]

Although *T. b. gambiense* can infect various mammals, humans seem to be more susceptible and maintain a high enough parasitemia to sustain the fly-human-fly cycle. The prolonged chronicity of Gambian disease with infectious individuals continually exposed to tsetse flies undoubtedly helps sustain the disease. Asymptomatic carriers of the infection also may be an important factor in maintaining the disease in a community. Among the important factors that may limit Gambian infection to humans is the transient and low parasitemia that results from an infective tsetse fly bite in mammals, usually ungulates. Researchers have observed that Gambian disease usually is sustained only when a close and repeated relationship exists between humans and tsetse flies. The practical result of all this is that West African sleeping sickness is maintained by members of the *G. palpalis* group of tsetse flies that use or prefer human blood almost exclusively.

In contrast to Gambian disease, *T. b. rhodesiense* infection generally is maintained in wild mammals. The fly-human-fly cycle tends to be unimportant inasmuch as the severe nature of the disease usually quickly removes acutely ill humans as an infective source. The intervention of wild game animals, in which the disease tends to be less acute and whose blood seems to be more attractive, seems to have relegated humans to an occasional or facultative host for *T. b. rhodesiense*. The *Glossina morsitans* group of tsetse flies that inhabit the dry East African savannah readily feed on wild ungulates, especially the bushbuck *Tragelaphus scriptus* and the hartebeest *Alcelaphus buselaphus*. Occasionally, Rhodesian disease may reach epidemic proportions, and during these epidemics, direct human-fly-human cycles may occur.

All age groups are susceptible to infection. The factors that influence human prevalence rest more on occupational exposure to suitable tsetse flies and the flies' breeding and feeding habits. Young men are found to be infected most frequently. During epidemics, all groups are infected, however, and mechanical transmission probably occurs. Tourists on safari are possibly at risk. In that regard, reports of African trypanosomiasis in Europe, the United States, and Australia have been increasing, although fewer than 50 cases/year of human African trypanosomiasis are diagnosed outside of Africa.

PATHOGENESIS AND PATHOLOGY

The metacyclic infective trypomastigote forms are inoculated by the tsetse fly into the skin, where they multiply at the inoculation site. A characteristic, hard, sometimes painful chancre develops. By approximately the 10th day, long slender forms are found in the bloodstream and lymphatics, and for the next several days, their numbers increase logarithmically. Soon thereafter, the organisms nearly disappear from the bloodstream as a result of immune lysis, only to reappear again.

The interval between waves of parasitemia may vary from 1 to 8 days, with clinical symptoms accompanying each bout of parasitemia. These parasitemic waves can be accounted for by the highly developed antigenic variation strategy of the parasite. The trypomastigote is covered with VSG, and with each peak of parasitemia, a predominant variable antigen type is displayed by the organism. The specific antibody response to this coat protein (VSG) leads to the destruction of parasites that display the predominant variable antigen type or homotype. Numerous heterotypes are found within each population of parasites, one of which, not recognized by the host's immune system, becomes the next homotype. The parasite in each successive wave of parasitemia bears a different variable antigen type. A single trypomastigote may contain 1000 genes, each encoding for a specific VSG. Each successive parasitemic wave represents a new antigenic variant that has emerged to elude the host's antibody response to the previous antigen.

As a result of successive waves of immune lysis and parasitemia, a marked early humoral antibody response, predominantly involving IgM, is seen regularly. *In an immunocompetent host, the absence of elevated IgM levels in serum rules out trypanosomiasis.* These macroglobulins contain not only antitrypanosomal antibodies, which are directed against the surface antigens, but also a variety of other antibodies such as heterophile and rheumatoid factor. Researchers have shown experimentally that because of polyclonal B-cell activation, many antibodies are produced to a wide variety of antigens, including brain-specific autoantibodies directed against myelin basic protein, gangliosides, and cerebrosides. Circulating immune complexes have been reported regularly and may be responsible for the glomerulonephritis, hypocomplementemia, and hemolytic anemia that often accompany acute and chronic disease. Cell-mediated immunity also is important in African trypanosomiasis, and increased production of nitric oxide may be important in depression of T-cell responsiveness and generalized immunodepression.

The main pathologic lesions involve the posterior cervical, submaxillary, supraclavicular, and mesenteric lymph nodes and the CNS. The lymphatic tissue usually reveals generalized hyperplasia with diffuse proliferation of lymphocytes. Later, the nodes may become small and fibrotic; however, they initially are markedly hemorrhagic and contain large numbers of trypomastigotes. The CNS remains normal until invaded by organisms, but then a progressive chronic leptomeningitis develops. The brain becomes edematous, and prominent perivascular cuffing by glial cells, lymphocytes, and plasma cells is present. When the latter become vacuolated with pyknotic nuclei, they often are referred to as the morula cells of Mott and Marshalko. Organisms often can be found in brain tissue in proximity to vessels and may be detected in CSF. Glomerulonephritis, myocarditis, pericardial effusion, pulmonary edema, and hypoplastic bone marrow with associated anemia may be seen.

The pathogenesis of the neuropsychiatric manifestations is not understood. More recent experimental studies suggest that changes in levels of brain neurotransmitters; deposition of immune complexes; and alteration in production of prostaglandin, cytokine, and nitric oxide may account partly for these behavioral changes.[2,53]

CLINICAL MANIFESTATIONS

The clinical manifestations of *T. b. gambiense* and *T. b. rhodesiense* disease are similar except that Rhodesian infection is a more fulminant, acute disease that may run its course in several weeks to 6 to 9 months, whereas Gambian infection may last for years. Typically, the incubation period in Rhodesian infection is brief (3 to 21 days), whereas the onset of symptoms with Gambian infection may be delayed for several weeks or years. Approximately 1 week after infection and at the site of the tsetse fly bite, a hard and painful chancre sometimes appears and lasts several weeks. During the early stages, when recurrent bouts of fever may be the only symptom, the blood and lymphatics primarily are involved, and infection often is mistaken for malaria, especially if a chancre is not obvious, or a history of exposure to tsetse flies is not obtained. The period of intermittent fever may last months to years with Gambian infection. During this time, persistent headache and tachycardia often are encountered, and a circinate erythematous rash or erythema multiforme sometimes is noted. The fever abates gradually.

In many patients, characteristic posterior cervical lymphadenopathy becomes evident (Winterbottom sign). The nodes are nontender and attain a diameter of approximately 1 cm. They tend to become small and fibrotic in approximately 6 months.

Signs of CNS invasion often develop in untreated patients with Gambian disease. The initial signs and symptoms of neurologic involvement can be difficult to assess. They may consist of alterations in behavior or personality (or both) that eventually may be manifested as a severe psychosis. Severe headache, loss of nocturnal sleep, and a feeling of impending doom typically are described. Next, progressive mental deterioration may occur, and with unrelenting deterioration, patients become incapable of caring for themselves. Tremors, especially of the tongue, hands, or feet, and generalized or focal convulsive episodes may occur. Almost any neurologic or psychiatric manifestation can be seen, and with progressive mental deterioration, patients finally lapse into a coma and die.

During the final period of the disease, patients often die of concurrent infections such as bacterial pneumonia, amebiasis, and malaria. Wasting and malnutrition are a large component of the progressive deterioration in these patients. Sleeping sickness can be a difficult disease to diagnose early in young children. It usually is found only after a child is evaluated for obtundation, seizures, or psychomotor retardation.[13,42]

T. b. rhodesiense produces a more rapid, fulminating disease than *T. b. gambiense*. Fever, severe headaches, irritability, extreme fatigue, swollen lymph nodes, and aching muscles and joints are common symptoms. Progressive confusion, personality changes, slurred speech, seizures, and difficulty walking and talking occur as the organisms invade the CNS. The early stages of the pathologic process parallel those of *T. b. gambiense* infections; however, the disease progresses more rapidly, such that death may occur before there is extensive CNS involvement, even though CNS invasion occurs early. The incubation period is short, often within 1 to 4 weeks, with trypomastigotes being more numerous and appearing earlier in the blood. Lymph node involvement is less pronounced, and Winterbottom sign may be absent. Febrile paroxysms are more frequent, and the patients are more anemic and more likely to develop myocarditis or jaundice. Some patients may develop persistent tachycardia, and death may result from arrhythmia and congestive heart failure owing to pancarditis.

Second-Stage Human Disease

The clinical symptoms and signs of patients with second-stage human African trypanosomiasis are described for a large cohort ($N = 2541$) of patients treated in a prospective multicenter, multinational study.[11] Special emphasis was given to the influence of

disease stage (duration, number of white blood cells in CSF) and patient age on the clinical picture. Although the frequencies of symptoms and signs varied greatly among centers, the clinical picture of the disease was similar for all countries. Headache (78.7%), sleeping disorder (74.4%), and lymphadenopathy (56.1%) were the most frequent symptoms and signs, and they were similar for all stages of the disease. Lymphadenopathy tended to be highest in the advanced second stage (59%). Neurologic and psychiatric symptoms increased significantly with the number of white blood cells in the CSF indicating the stage of progression of the disease. Pruritus was observed in all stages and increased with the number of white blood cells in CSF from 30 to 55 percent. In children younger than 7 years, lymphadenopathy was reported less frequently (11.8 to 37.3%) than in older children or adults (56.4 to 61.2%). Fever was reported most frequently in children 2 to 14 years old (26.1 to 28.7%), and malnutrition was observed significantly more frequently in children of all ages (43 to 56%) than in adults (23.5%).

DIAGNOSIS

Diagnostic options for human African trypanosomiasis are limited in field settings.[16] Even in field settings, however, positive results from screening assays, such as the card agglutination test, must be confirmed by demonstration of the parasite. Absence of confirmatory testing may lead to unnecessary administration of toxic drugs.[34]

Routine Methods

As indicated earlier, a definitive diagnosis can be made only by finding trypanosomes in blood and bone marrow smears, in lymph node aspirates in early or acute disease, and in CSF in late or chronic disease.[63] For examination of thick and thin smears and the buffy coat, 10 to 20 mL of citrated whole blood or the sediment from 5 mL of centrifuged CSF is essential. Numerous microscopic techniques, including capillary tube centrifugation, quantitative buffy coat examination, miniature anion-exchange centrifugation, density gradient centrifugation, and acridine orange staining, have been used to enhance parasite detection. Culture or animal inoculation, or both, is sometimes the only successful means of making a diagnosis. In advanced CNS disease, lymphocytosis and elevated IgM are detected in the CSF.

Serologic Tests

A serologic diagnosis of African trypanosomiasis usually depends on detection of high levels of nonspecific serum IgM. Detection of specific antibody by indirect fluorescent antibody is helpful, especially when the serum is tested with trypanosomes of the homologous human species. Direct agglutination and a microscale version of enzyme-linked immunosorbent assay are highly reliable methods for making a specific diagnosis of trypanosomiasis.[4]

Polymerase Chain Reaction

Antigen-detection and PCR tests have been developed to detect circulating parasites.[18] The development of a peptide nucleic acid fluorescence in situ hybridization probe seems to offer an excellent diagnostic tool. By combining this test with a cytospin step, the limit of detection from blood can be improved to 5 parasites/mL, a level of sensitivity that equals an optimal PCR detection limit on blood specimens. A newer PCR technique targets the gene encoding the small ribosomal subunit to identify and differentiate all clinically important African trypanosome species and some subspecies. This method seems to be more economical, simple, and sensitive than some other screening methods and yields more detailed information.[18]

Immunoglobulin Levels

In advanced, untreated sleeping sickness, the IgM level in CSF often is elevated, but it has no relationship to the presence of trypanosomes in CSF. After successful treatment, the IgM level declines gradually and disappears after approximately 1 year. If 1 year after therapy a constant high level is present, or an abrupt increase in IgM occurs, however, relapse should be suspected. Nonetheless, the IgM level should not be used as the sole method to arrive at a diagnosis or prognosis.

The differential diagnosis of African trypanosomiasis includes many diseases, but chronic relapsing fever associated with enlarged cervical lymph nodes in an individual who has been to Africa is suggestive. As indicated earlier, considering diseases such as malaria, syphilis, lymphoma, visceral leishmaniasis, and leprosy is not unusual. Later, encephalitis of other etiologies must be excluded. An important diagnostic feature is the frequent finding of a strikingly elevated erythrocyte sedimentation rate, which is a reflection of the markedly increased serum macroglobulins.

Molecular Dipstick

The development and the first-phase evaluation of a simple and rapid test (human African trypanosomiasis–PCR–oligochromatography) for detection of amplified *T. brucei* DNA has been reported more recently.[20] Through hybridization with a gold-conjugated probe (oligochromatography), PCR products are visualized on a dipstick. Visualization is simple and takes only 5 minutes. Controls for the PCR and for DNA migration are incorporated into the assay. The lower detection limit of the test is 5 fg of pure *T. brucei* DNA. One parasite in 180 μL of blood is still detectable. Sensitivity and specificity for *T. brucei* were calculated at 100 percent when tested on blood samples from 26 confirmed sleeping sickness patients, 18 negative controls (nonendemic region), and 50 negative control blood samples from an endemic region. Human African trypanosomiasis–PCR–oligochromatography is a promising new tool for diagnosis of sleeping sickness in laboratory settings.

Animal Inoculation and Culture

T. b. gambiense isolation in small laboratory animals is usually unsuccessful; in contrast, *T. b. rhodesiense* readily infects animals. Cultivation is not practical for most diagnostic laboratories, but is more successful than animal inoculation.[31]

PROGNOSIS

If therapy is initiated before significant CSF involvement, the outcome is usually favorable. Untreated infection often ends fatally.

TREATMENT

All drugs currently used in the treatment of African trypanosomiasis are toxic and require prolonged administration. Treatment should be started as soon as possible and is based on the patient's symptoms and laboratory findings. The choice of antiparasitic drug depends on whether the CNS is infected.[38] Pentamidine isethionate or suramin can be used when the CNS is not infected. The main chemotherapeutic agents for human trypanosomiasis are pentamidine and suramin for early-stage disease.

Pentamidine Isethionate

Pentamidine is a water-soluble aromatic diamidine that has been in use for nearly 60 years. It is administered as either the isethionate form (Pentam 300) or methanesulfonate (Lomidine). The dose is 4 mg/kg/day for 10 days for adults and children. Pentamidine is effective against early-stage *T. b. gambiense* infection, but less effective against *T. b. rhodesiense* infection and ineffective against late-stage disease. African trypanosomes have a nucleoside (adenine/adenosine: P_2) transporter that takes up pentamidine, which results in concentrations of the agent many times that in plasma. Although laboratory-induced resistant strains seem to have reduced transport properties, naturally derived clinical isolates seem to have retained transport, indicating that most resistance may be caused by alteration of a metabolic target, rather than drug uptake. Pentamidine isethionate does not cross the blood-brain barrier and is administered intramuscularly; side effects include an immediate hypotensive reaction, nausea, vomiting, and Herxheimer-type (inflammatory) reactions.

Suramin

Suramin is a sulfonated naphthylamine that has been used successfully against early-stage sleeping sickness caused chiefly by *T. b. rhodesiense*. It was first used in 1922 and was developed from the closely related azo dyes trypan red and trypan blue. Suramin is administered intravenously. The adult dose is 100 to 200 mg (test dose), then 1 g on days 1, 3, 7, 14, and 21. The pediatric dose is 20 mg/kg on days 1, 3, 7, 14, and 21. Suramin has an extremely long half-life in humans (44 to 54 days), which is the result of avid binding to serum proteins. Suramin binds to many plasma proteins, including low-density lipoprotein, which trypanosomes avidly bind and endocytose as a result of specific membrane receptors. Low-density lipoprotein is a prime source of sterols for bloodstream trypanosomes. Suramin is taken up as a protein complex and has been shown to inhibit all the glycolytic enzymes in *T. b. brucei* in low concentrations, which in most cases are severalfold lower than for the corresponding mammalian enzyme. Suramin also has been found to affect thymidine kinase and dihydrofolate reductase.

Suramin (Bayer 205), a diamidine, also is effective in treating the hemolymphatic stage and CNS disease of *T. b. gambiense*. When using suramin, a test dose should be given to the patient to ensure the drug can be tolerated. It should not be given to patients with renal disease, and if protein, red blood cells, or casts are detected in the urine, treatment should be stopped. Suramin is given intravenously; its side effects include nausea, vomiting, loss of consciousness, seizures, pruritus, edema, and hepatitis. Although rare, fatalities have been reported during suramin therapy. Suramin can be obtained under an investigational new drug protocol from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, Georgia, 30333; 404-639-3670 (evenings, weekends, or holidays: 404-639-2888).

Melarsoprol

Melarsoprol (mel B; Arsobal) is an arsenical created by the efforts of Freidheim in the late 1940s. His initial compound, melarsen oxide, *p*-(4,6-diamino-*s*-triazinyl-2-yl) aminophenylarsenoxide, was complexed with dimercaptopropanol (British antilewisite) to form a less toxic complex, melarsoprol. Until 1990, it was the only agent available for curing late-stage (CNS) disease of East African and West African origin. Usually, each series is followed by a week interval before the next series. Melarsoprol is insoluble in water and must be dissolved in propylene glycol. It must be given intravenously; otherwise, it induces a severe localized inflammatory reaction. This drug is administered intravenously. The adult dosing schedule is 2 to 3.6 mg/kg/day for 3 days. This is followed in 1 week with 3.6 mg/kg/day for 3 days. This schedule is repeated after 10 to 21 days. The pediatric dose is 18 to 25 mg/kg total over 1 month; the initial dose is 0.36 mg/kg at intervals of 1 to 5 days for a total of 9 to 10 doses.

Side effects include nausea, vomiting, encephalopathy, and exfoliative dermatitis. Melarsoprol has been used for CNS involvement for years; however, relapse occurs in 6 percent of patients. Arsenic-related encephalopathy occurs in 10 percent of patients, and prednisolone treatment may help reduce the incidence. The mortality resulting from this side effect depends on whether supportive treatment is given, but it is often greater than 50 percent. Resistance to melarsoprol by *T. b. gambiense* and *T. b. rhodesiense* has been noted.

Reactive arsenical-induced encephalopathy is an important toxicity of melarsoprol and is followed by pulmonary edema and death within 48 hours in more than half the cases. The incidence of reactive arsenical-induced encephalopathy has been estimated at 2 to 10 percent. In one clinical study, the co-administration of steroids significantly reduced the incidence of reactive arsenical-induced encephalopathy–related deaths during therapy with melarsoprol. Although the mechanism of action of melarsoprol has been studied extensively, it still remains unclear.[1]

Eflornithine

Eflornithine (DL-a-difluoromethylornithine; DFMO) is an enzyme-activated inhibitor of ornithine decarboxylase, the lead enzyme of polyamine biosynthesis. DFMO was developed as an antitumor agent. After initial testing in model infections, DFMO was studied extensively in human trials in Africa, with some trials in Europe and the United States. The standard treatment regimens resulting from trials indicate that DFMO is more than 95 percent active when given intravenously at 400 mg/kg/day in four doses every 6 hours for 14 days. In these studies, DFMO cured children and adults, patients with melarsoprol-refractory strains, and patients with late-stage disease.[25] The short plasma half-life of DFMO necessitates constant dosing when given as an intravenous drip. The most frequent toxic reaction was reversible bone marrow suppression, which was reversed by reducing the dosage.

The major drawbacks of DFMO are its cost and the duration of treatment and availability. DFMO is not trypanocidal and depends on a functional immune system to rid the host of nondividing forms. It is curative for laboratory infections of *T. b. brucei* and *T. b. gambiense*, but not all strains of *T. b. rhodesiense*. The reason for this selectivity is not evident, although it is not caused by uptake of DFMO because the drug enters by passive diffusion, not transport. DFMO treatment leads to intracellular concentrations of approximately 5 mmol/L, an increase of approximately 50-fold over untreated parasites. The basis for DFMO selectivity lies in the rapid turnover of the mammalian enzyme as opposed to trypanosome ornithine decarboxylase. Because mammalian ornithine decarboxylase is synthesized constantly at a high rate, DFMO must be continuously available, and this availability is made more difficult by rapid excretion.

DFMO has been used for more than 10 years for melarsoprol-resistant *T. b. gambiense* infection with or without CNS involvement; treatment is started intravenously and is followed by oral therapy. In one study, 47 patients with a relapse after a first treatment were treated with a 7-day course of intravenous eflornithine (100 mg/kg every 6 hours) and monitored for 2 years; the failure rate was 6.5 percent. This approach seems to provide adequate treatment in cases of Gambian trypanosomiasis relapsing after treatment with another drug. Disadvantages of eflornithine therapy include the prolonged course of treatment and frequent side effects of diarrhea and anemia. With adequate treatment, non-CNS disease has a cure rate greater than 80 percent.

Newer Therapeutic Agents

As previously noted, available treatment regimens are limited in number, are associated with serious adverse effects, and are potentially compromised by the emergence of drug-resistant parasites. These considerations underscore the urgent need to develop inexpensive, safe, and efficacious new drugs.[37] It is hoped that efforts led by the Tropical Disease Research/World Health Organization Committee on Genomics and Discovery Research and the Drugs for Neglected Diseases Initiative will encourage further pharmaceutical efforts.[12]

PROPHYLAXIS AND PREVENTION

Chemoprophylaxis with suramin, 0.3 to 0.7 g intravenously every 2 to 3 months, is reported to be highly effective. With few exceptions, the vector has proved to be difficult to control. Preventing tsetse fly bites and chemoprophylaxis may be the best means of eliminating the disease from an area. Development of a vaccine has been hindered by antigenic variation.

At present, there are no endemic areas where *T. b. gambiense* and *T. b. rhodesiense* coexist. Although foci of both exist in Uganda, they apparently are geographically separate. Based on evidence of the spread of cattle carrying *T. b. rhodesiense* further north, a merger of the two foci could create tremendous problems because the diagnosis and treatment of the two diseases differ significantly.

Vector control measures have met with limited success. Methods have included clearing streams of underbrush, eliminating breeding grounds, using insecticides, using fly traps, and releasing sterile male flies. Because tsetse flies have a slow reproductive rate and have not developed insecticide resistance, *Glossina* spp. are tempting control targets. The most effective control measures include an integrated approach to reduce the human reservoir of infection and to use insecticides and fly traps.

In regions where the disease is endemic, natives seem to be more resistant to infection than new arrivals to the area, although there is no evidence of acquired immunity. West African sleeping sickness affects primarily rural populations, and tourists are rarely infected. Chemoprophylaxis is not recommended because of drug toxicity, and vaccines are unavailable. Despite antigenic variation, it may be possible to develop a vaccine because immunity to reinfection occurs with *T. b. gambiense*.

Tourists are usually not at great risk unless they are spending long periods in rural areas of western and central Africa.[54] Individuals visiting areas where the disease is endemic should avoid tsetse fly bites by wearing protective clothing (long-sleeved shirts and long pants); khaki or olive-colored clothing is optimal because the tsetse fly is attracted to bright colors and very dark colors. Because heavy clothing is not always practical owing to heat and humidity, other measures, including the use of insect repellents, bed netting, and screens, are recommended. It also has been recommended not to ride in the back of jeeps, pickup trucks, or other open vehicles; the tsetse fly is attracted to the dust created by moving vehicles and wild animals. Bushes should be avoided because the tsetse fly is less active during the hot period of the day and rests in bushes, but bites if disturbed.

CHAPTER 234

NAEGLERIA, ACANTHAMOEBA, AND *BALAMUTHIA*

Patrick J. Gavin ✪ Tina Q. Tan

Interest in free-living amebae has increased since demonstration of their pathogenicity and, more recently, their role as reservoirs and vectors for potentially pathogenic bacteria, such as *Legionella pneumophila* and *Mycobacterium avium*. Small free-living amebae of the genera *Naegleria*, *Acanthamoeba*, and *Balamuthia* cause severe central nervous system (CNS) infections in humans and animals that are characterized by few distinguishing symptoms and an almost uniformly poor prognosis. Although these severe infections are uncommon, for optimal treatment, it is important to recognize and diagnose them early.

Although small free-living amebae share structural and pathogenic similarities, the infections they cause have distinctive epidemiology, clinical presentation and course, neuroimaging, immunology, and pathology. Primary amebic meningoencephalitis caused by *Naegleria fowleri* is an acute fulminant illness that affects healthy children and young adults, and usually results in death within 1 week of presentation. Almost invariably, the patient has a recent history of swimming in bodies of warm fresh water. In contrast, granulomatous amebic encephalitis caused by *Acanthamoeba* spp. or *Balamuthia mandrillaris* (formerly leptomyxid amebae) is an insidious, subacute, and protracted illness that affects primarily, but not exclusively, immunocompromised or debilitated patients and leads to death in weeks to months. Typically, the patient has no history of recent exposure to fresh water.

Despite these differences, the prognosis of CNS infection caused by *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* is similarly dismal, with few reports of survival. In the handful of cases that survived, recognition, early diagnosis, and timely administration of appropriate antimicrobial treatment were crucial to achieving a successful outcome. *Acanthamoeba* spp. also are associated with disseminated cutaneous, pulmonary, or sinus infection in immunocompromised hosts, and with chronic painful and potentially sight-threatening keratitis in association with use of contact lenses or corneal trauma in otherwise healthy patients.

The pathogenic potential of small free-living amebae was recognized first during polio vaccine trials in the 1950s, when they were found to cause cytotoxicity in contaminated cell cultures.[22,53] Subsequently, the fulminant fatal encephalitis that followed intracerebral injection or intranasal instillation of tissue culture fluid in experimental mice and monkeys showed pathogenicity and a potential route for human infection.[19,22,23] The first cases of human infection caused by small free-living amebae were recog-

nized in four children from southern Australia by Fowler and Carter[36] in 1965, and soon afterward by Butt[12] in Florida.

More recently, Visvesvara and colleagues[126,129] isolated and named *B. mandrillaris*, a new agent of amebic meningoencephalitis, from the brain of a mandrill baboon. The first reported human case of *B. mandrillaris* encephalitis was in a patient with acquired immunodeficiency syndrome (AIDS).[3] Reports of infection in immunocompetent hosts have followed.[6,25,38,59,94] Subsequently, infections caused by free-living amebae have been reported worldwide.[4,60,69,72,79,96] Finally, the first case report of nonfatal CNS disease, in an otherwise healthy adult, caused by *Sappinia diploidea*, a free-living ameba normally found in soil contaminated with elk and buffalo dung, adds to the list of pathogenic small free-living amebae, and suggests that others may be identified in the future.[41]

EPIDEMIOLOGY

Free-living amebae are found worldwide and are cosmopolitan in their distribution, living primarily in soil, but also in water, inside vertebrates, on plants, and in the air.[93] They are spread readily by wind and water currents. In humans, infection with free-living amebae causes primary amebic meningoencephalitis, granulomatous amebic meningoencephalitis, disseminated granulomatous disease (cutaneous, pulmonary, or sinus), and keratitis.[69,72,106]

Although they are rare, cases of infection caused by *N. fowleri* have been reported throughout the world.[35] As of 2004, more than 200 cases of primary amebic encephalitis were documented worldwide, with approximately half occurring in the United States.[20,106] In the United States between 1989 and 2000, 24 fatal cases of primary amebic meningoencephalitis were reported to the Centers for Disease Control and Prevention (CDC).[82] Most of them occurred in the summer and in young children. Increased water temperatures, whether from thermal pollution or sunlight, provide the ideal environment for proliferation of *N. fowleri*.[122,130] Cases typically are associated with a history of swimming, diving, or playing in bodies of warm fresh water, brackish habitats with a soil and water interface, artificial lakes, hot springs, and thermally polluted rivers and streams.[20,26,35,70,82,122] Researchers have postulated that thermal pollution, particularly from overflow of power plants, or inadequate chlorination of water, kills off normal thermosensitive and chlorine-sensitive fauna, shifting the balance in favor of thermotolerant, less chlorine-sensitive, pathogenic *N. fowleri*.[106]

In North America, cases of primary amebic meningoencephalitis tend to be clustered in the warmer southern states and Mexico.[106] In one study, almost 50 percent of fresh-water lakes in Florida contained *N. fowleri* when the temperature was 30° C or higher.[130] *N. fowleri* may be found in colder areas, however. In temperate regions, distribution of *N. fowleri* is limited by seasons, being greatest during summer and early fall.[122] *N. fowleri, Acanthamoeba* spp., and *B. mandrillaris* were present year-round in lakes in the Tulsa region of Oklahoma.[55] Although it is most prevalent in areas where water temperatures are higher, *N. fowleri* has the ability to overwinter, in cyst form, in lake bottom sediment.[130]

Small outbreaks of primary amebic meningoencephalitis have been described. Over a 3-year period, from 1962 to 1965, 16 swimmers died after being exposed to warm contaminated and inadequately chlorinated water in an indoor pool in Czechoslovakia.[16,106] Similarly, 8 cases of fulminant meningoencephalitis associated with an artificial lake in Richmond, Virginia, were recognized retrospectively as being caused by *N. fowleri*.[14] Finally, 5 cases of primary amebic meningoencephalitis caused by *N. fowleri* occurred in 1990 in patients swimming in a drainage canal in Mexicali, Mexico.[65]

Disease also has been documented in patients with no history of exposure to fresh water. Atypical exposures have included bathing in domestic bath water, playing in a warm muddy puddle, and being baptized by full body immersion.[4,8,74] *N. fowleri* also has been shown in domestic tap water.[29,74] Although cases of infection have not followed ingestion of drinking water contaminated by amebae, fatal infection was associated with washing in tap water heated to high temperatures in pipes by the summer sun in South Australia, and with exposure to contaminated domestic water in Arizona.[2,29,74]

Infections occur far more frequently in previously healthy children and young adults than in other age groups, presumably because youngsters are most likely to remain in water for prolonged periods and to disturb sediment containing amebae by diving and swimming underwater.[20,82] In one series of primary amebic meningoencephalitis cases, boys outnumbered girls 12 to 1, presumably because boys are more likely than girls to engage in aquatic horseplay.[128] The incubation period in natural human infection is 2 to 15 days after exposure.[8,20,82] Death usually ensues within 1 week of presentation (generally within 72 hours).

Acanthamoeba spp. are among the most prevalent protozoa found in the environment, being found in soils from tropical to arctic regions. They are important components of the food chain and promote plant growth by predation on soil bacteria. *Acanthamoeba* spp. are prevalent in natural and artificial habitats that include fresh, brackish, potable, or stagnant water; in sewage; in improperly treated swimming pools; and in taps, sinks, hot tubs, air-conditioning units, aquaria, flowerpots, showers, ventilators, and ventilation in homes and hospitals.[17,33,72,104,106] Although warm waters might enhance their numbers, pathogenic amebae may be isolated year-round from water samples in the United States.[130] Their distribution and viability are governed primarily by availability of a bacterial food source; soil texture; water temperature, pH, and salinity; and ultraviolet light and desiccation.[93,106] Growth of *Acanthamoeba* spp. is inhibited by temperatures of 35° C to 39° C. Although *Acanthamoeba* spp. seemingly are ubiquitous in water, *Acanthamoeba* infections generally are not associated with a history of recent swimming or water activities.[106] Acquisition occurs by inhalation or direct contact with contaminated soil or water.

In contrast to *N. fowleri*, *Acanthamoeba* spp. are opportunistic pathogens. Granulomatous amebic encephalitis and disseminated disease caused by *Acanthamoeba* spp. generally are seen in immunocompromised hosts or in patients with underlying disease or debilitation, such as that due to malignancy, cancer chemotherapy, steroid treatment, organ transplantation, human immunodeficiency virus, diabetes, or malnutrition.[69,72] *Acanthamoeba* spp. cause keratitis in otherwise healthy individuals by directly attacking the corneal surface, usually in association with poor contact lens care or corneal trauma. Although cases of CNS or disseminated *Acanthamoeba* infection are extremely rare, in 2004, estimates of cases of amebic keratitis worldwide exceeded 3000.[106]

Comparatively less is known about *B. mandrillaris*. It is closely related to *Acanthamoeba* and causes a similar spectrum of infections that includes granulomatous amebic encephalitis and cutaneous and sinus disease.[106] Although initial cases of *B. mandrillaris* infection were confined to immunocompromised and debilitated hosts, its ability to cause disease in apparently healthy children is well documented.[6,25,39,59,94] By 2004, more than 100 cases of human infection had been reported.[106] *Balamuthia* is assumed to inhabit soil and water; it has been isolated more recently in soil from a flowerpot associated with a case of amebic encephalitis in a child from northern California.[100]

As with *Acanthamoeba* spp., granulomatous encephalitis caused by *B. mandrillaris* seems to occur after inhalation of airborne cysts or soil contamination of breaks in the skin. The patient generally has no history of recent exposure to fresh water. To date, 50 percent of cases of *Balamuthia* infection reported in the United

States have occurred in patients of Hispanic ethnicity.[6,102] Although this statistic most likely is a result of environmental exposure, a genetic predisposition may exist. Among California cases of balamuthiasis, most cluster in the southern part of the state. Researchers have postulated that the area's dry warm soil is conducive for the amebae, and that large-scale agriculture in these areas increases the likelihood of workers being exposed to soil or wind-blown particles. Cases of *B. mandrillaris* infection linked directly to incidental exposure to soil or to blowing soil while traveling in an open car or by motorcycle are reported.[25,59,100,104] Although *Balamuthia* encephalitis is a zoonosis, animals do not represent a source of infection for humans.

Despite their seeming ubiquity in the environment and ample opportunity for contact with humans compared with other parasitic protozoa, such as *Entamoebae*, malaria and trypanosome infections caused by free-living amebae are extremely rare. Given the enormous number of exposures to water containing *Naegleria*, why so few individuals become infected remains unknown. Only seven cases of primary amebic meningoencephalitis were reported in Florida during a 14-year period, despite estimates of billions of potential exposures in contaminated fresh-water lakes during that time period.[130] Epidemiologic investigations of cases typically find that many other individuals swam in the same water at the same time, but did not become ill. Factors other than the presence of amebae, such as host susceptibility, anatomy, inoculum size, and activity at the time of exposure, have been implicated.[130] Nonetheless, in recent years, an increase in the number of diagnoses of primary amebic meningoencephalitis cases has been noted.[67,135] The increase probably reflects a combination of greater recognition of the pathogenic potential of free-living amebae, improved diagnostic techniques, and a growth in the numbers of immunocompromised hosts.

Acanthamoeba organisms can infect the cornea directly, after trauma, or, most commonly, in association with the combination of extended-wear soft contact lens use and subsequent exposure to contaminated water.[108,117] Major risk factors for development of amebic keratitis include poor compliance with care of daily wear soft contact lenses, particularly use of homemade saline solutions using nonsterile tap water that may be contaminated with amebae; use of chlorine release lens disinfection systems; and inadequate cleansing of lens cases, which encourages growth of a bacterial biofilm that acts as a nidus and a food source for amebae.[90,116] Wearing contact lenses while swimming or in hot tubs, which potentially may be contaminated with amebae, is similarly risky.[95]

Since the first cases of amebic keratitis were described in the early 1970s, the incidence has increased dramatically. Between 1973 and 1984, slightly more than 200 cases of amebic keratitis were reported to the CDC. By 2002, in the United States, greater than 3000 cases had been reported, and 1 in 250,000 people were estimated to be affected.[57,64,84,106] The increased incidence most likely is due to increased use of contact lenses, particularly of the soft, extended-wear variety. Although many of these lenses were marketed as products requiring "low care," many patients interpreted this designation as meaning "no care."[90]

ORGANISMS

In contrast to the related true parasite protozoa *Entamoeba* spp., *Naegleria*, *Acanthamoeba*, and *Balamuthia* spp. are amphizoic protozoa, capable of existing as free-living amebae and as parasitic pathogens.[106] *Naegleria* spp. are ameboflagellates found primarily in moist soil and warm fresh water.[70] Although more than 27 separate *Naegleria* spp. have been identified, to date only *N. fowleri* is associated with human infections.[26,106] *Naegleria* spp. can exist in three forms: an active feeding trophozoite, a rarely seen dormant cyst (Fig. 234–1), and a flagellate form (Fig. 234–2).[70]

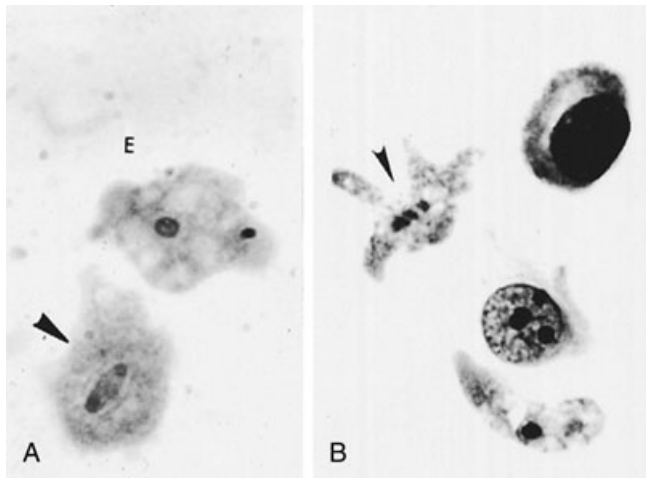

Figure 234–1 **A** and **B,** Trophozoites of *Naegleria*.

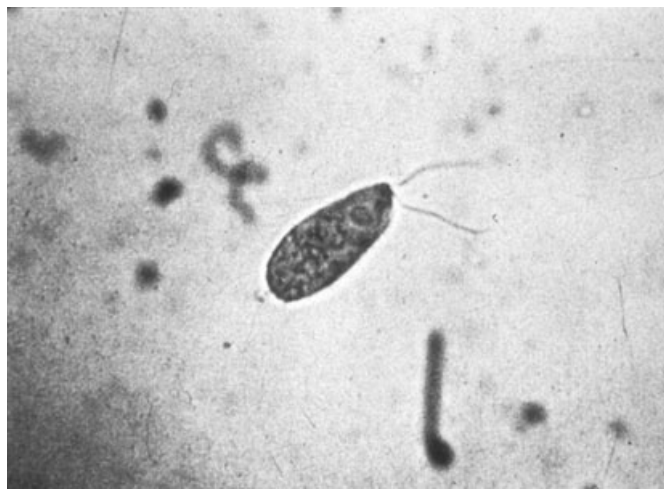

Figure 234–2 Flagellate form of *Naegleria fowleri*.

Of these forms, only the trophozoite is found in tissue or cerebrospinal fluid (CSF). The trophozoite of *N. fowleri* is smaller than that of *Acanthamoeba* spp., measuring 8 to 15 μm in diameter, with a conspicuous nucleus containing a large, dense central karyosome without peripheral chromatin lining the membrane.[78] *Naegleria* trophozoites move slowly by extension of broad, rounded anterior pseudopodia (lobopodia). This feature may be noted on a warm saline preparation or in CSF specimens. *Naegleria* cysts are spherical, measure 7 to 12 μm in diameter, and have a single-layered outer membrane.

Approximately 20 *Acanthamoeba* spp. are identified by morphologic criteria.[106] Because morphologic distinctions do not always correlate with results of molecular typing, however, classification is complex and is currently under review.[72] Molecular classification is ongoing. The life cycle of *Acanthamoeba* spp. consists of two stages: an actively feeding and dividing trophozoite and a dormant cyst stage (Fig. 234–3).[86] The trophozoite is 15 to 40 μm. The nucleus is vesicular; has a large, dense central "targetoid" nucleolus; and is surrounded by vacuolated cytoplasm. Locomotion typically is sluggish, by extrusion of multiple fine spiny pseudopodia (acanthopodia).[78] *Acanthamoeba* trophozoites feed on bacteria, yeasts, and algae. *Acanthamoeba* cysts are smaller, 15 to 20 μm, with a distinct, wrinkled, thick double wall. Encystation occurs in response to adverse environmental condi-

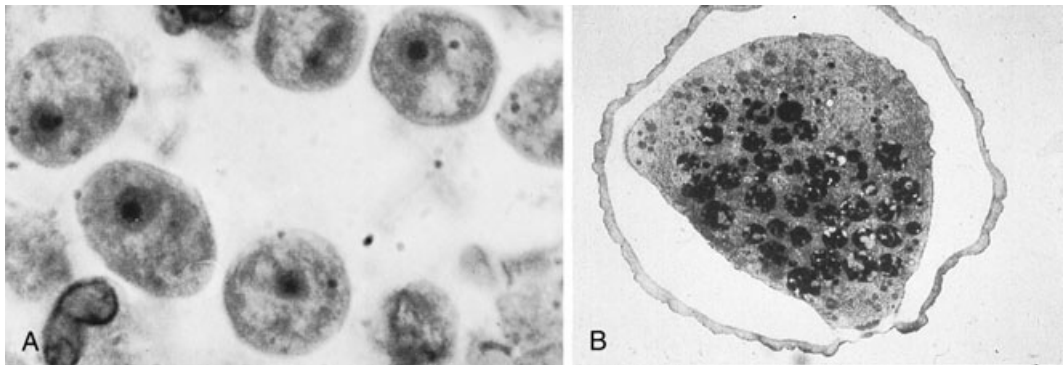

Figure 234–3 **A,** Trophozoite of *Acanthamoeba*. **B,** Cyst of *Acanthamoeba* (scanning electron micrograph). *(A from Jager, B. V., and Stamm, W. P.: Brain abscesses caused by free-living amoeba probably of the genus Hartmannella living in a patient with Hodgkin disease. Lancet 2:1343-1345, 1972. Copyright © by the Lancet Ltd.)*

tions, such as desiccation, scarcity of food, and changes in pH or temperature. *Acanthamoeba* cysts are particularly hardy; they are intrinsically resistant to chlorination and sterilization of potable water, to biocides used for disinfecting bronchoscopes and contact lenses, and to antibiotics; they may remain viable for decades after freezing.[27,62,80] *Acanthamoeba* is the only pathogenic free-living species isolated from marine water. *Naegleria* spp. do not tolerate seawater.

Few *Acanthamoeba* spp. have been associated with human infections. Among the potentially pathogenic species, *Acanthamoeba culbertsoni*, *Acanthamoeba castellanii*, *Acanthamoeba astronyxis*, and *Acanthamoeba polyphaga* are prominent.[79] On the basis of 18S rRNA gene sequences *Acanthamoeba* spp. are divided into 15 genotypes (T1 through T15). At present, no clear consensus has been reached regarding which genotypes are pathogenic. Genotypes T1, T4, T7, T10, and T12 are found among cases of granulomatous encephalitis, whereas isolates associated with keratitis fall into genotypes T3, T4, and T11.[10,34,72,119] Genotype T4 makes up 94 percent and 80 percent of keratitis and nonkeratitis *Acanthamoeba* isolates,[10] presumably reflecting the preponderance of this genotype in the environment. Rare genotypes, such as T1, T10, and T12, are found only in CNS disease and are not found in the environment.

B. mandrillaris is the only pathogenic *Balamuthia* spp. identified to date.[106] It exists as either a vegetative trophozoite or a dormant cyst (Fig. 234–4). Trophozoites are similar in appearance to *Acanthamoeba* spp., but larger (50 to 60 μm in diameter), and the spherical cyst stage (10 to 30 μm in diameter) has a triple-layered wall on electron microscopy. *Balamuthia* trophozoites typically have a single vesicular nucleus, often with multiple large, dense nucleoli. Movement occurs by extension of broad pseudopodia. *Balamuthia* has been isolated more recently from environmental soil samples.[31] Because of its slow growth, it may have been obscured in environmental cultures by overgrowth of more rapidly growing bacteria, fungi, or other amebae. In contrast to *Naegleria* and *Acanthamoeba* spp., *Balamuthia* feeds on smaller amebae and protozoa and does not prey on bacteria.

S. diploidea is a species of free-living amebae that is found worldwide. The life cycle of this organism involves animal feces. The trophozoites are 40 to 70 μm in diameter and can be distinguished by the presence of a large cytoplasmic vacuole, mitochondria with characteristic tubular crystal patterns, a juxtanuclear Golgi-like network, and a double nucleus.[41]

CLINICAL MANIFESTATIONS

NAEGLERIA FOWLERI

Primary amebic meningoencephalitis caused by *N. fowleri* is an acute, rapidly progressive illness that almost uniformly is fatal. Patients present with abrupt onset of severe headache, fever, nausea and vomiting, malaise, rhinitis, meningitis, and changes in mental status 2 to 15 days after exposure, most frequently after swimming or bathing in warm contaminated fresh water.[35,69,82,110] A history of disturbances of taste and smell has been noted in many cases. Progression from fever to signs of meningitis and encephalitis is unrelenting and rapid. Seizures are common. Coma is present at or develops soon after hospital admission. In

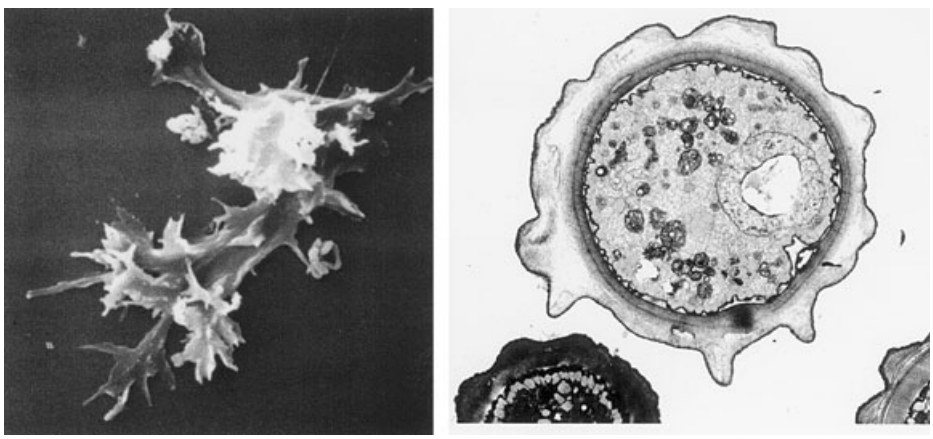

Figure 234–4 Trophozoite and cyst of *Balamuthia mandrillaris*. *(Courtesy of Dr. G. S. Visvesvara, Centers for Disease Control and Prevention.)*

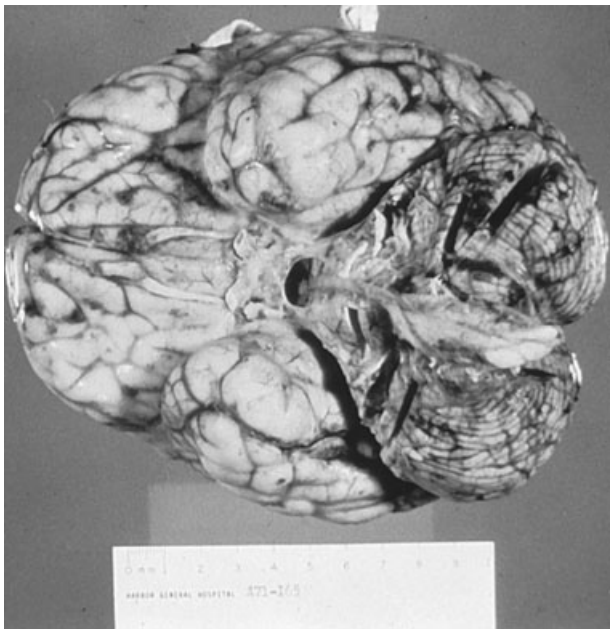

Figure 234–5 Brain from a fatal case of *Naegleria* meningoencephalitis. Note the areas of necrosis on the basilar surface of the brain.

the absence of early diagnosis and appropriate treatment, the illness characteristically progresses rapidly to death within 1 week of onset of symptoms (median 72 hours).[8]

Other than the clue of a recent history of exposure to warm water, there is little to distinguish primary amebic meningoencephalitis from fulminant bacterial meningitis. A high peripheral polymorphonuclear leukocytosis may be present. CSF findings are similarly nonspecific, with increased pressure, elevated protein, a normal to low glucose, and modest polymorphonuclear pleocytosis, but no bacteria, mycobacteria, or fungi are identified. Patients with a suggestive history and CSF indices suggestive of purulent meningitis, but without bacteria on Gram stain should have a wet mount examined for the presence of motile trophozoites (Fig. 234–5).

ACANTHAMOEBA SPECIES

Acanthamoeba spp. and *B. mandrillaris* cause granulomatous amebic encephalitis. The course typically is prolonged, with progression from focal neurologic signs to diffuse meningoencephalitis over weeks to months after exposure.[72,106] Patients most susceptible to contracting this disease include very young, old, debilitated, immunosuppressed, and chronically ill patients. The clinical picture resembles that of a bacterial brain abscess or brain tumor, with insidious headache, intermittent low-grade fever, nausea, vomiting, and symptoms of increased intracranial pressure. Altered mental status is particularly prominent. As the infection progresses, depending on the area of the brain affected, focal neurologic signs, hemiparesis, drowsiness, aphasia, behavioral and personality changes, and seizures develop. The incubation period after exposure to onset of CNS disease is unknown, but is of the order of several weeks to months.

Acanthamoeba skin lesions often have been present for months before the onset of CNS disease. Routine CSF findings frequently are abnormal but nonspecific, with elevated protein, low glucose, and, typically, a mononuclear pleocytosis. *Acanthamoeba* spp. also may cause cutaneous, pulmonary, bone, and nasopharyngeal or sinus disease.[42,68,76] Cutaneous *Acanthamoeba* infection is characterized by pustules and hard erythematous nodules, which develop into nonhealing indurated draining ulcers or subcutaneous abscesses.[37,72] Disseminated disease without CNS involvement has a slightly better prognosis. In patients with AIDS, mortality rates of 70 percent and 100 percent are reported for *Acanthamoeba* skin disease alone and in association with CNS disease.[58]

Acanthamoeba Keratitis

In contrast to its role as an opportunistic pathogen in CNS and skin disease, most cases of *Acanthamoeba* keratitis occur in otherwise healthy individuals who wear contact lenses or who have a history of corneal trauma. Contact lenses of any type, including daily wear and disposable soft and extended-wear lenses, have been implicated in infection. All soft contact lenses contain 50 to 75 percent water. These lenses can absorb pathogens from contaminated cleaning solutions, carrying cases, and hands. When the lens comes into contact with the contaminated fluid, the amebae quickly adhere to the lens surface. If corneal trauma is present, the organisms invade the corneal tissue and produce infection.[56] The nidus for infection most likely is trauma to the cornea, but also may be related to preexisting herpesvirus or bacterial conjunctivitis (Fig. 234–6).

Amebic keratitis characteristically is painful, progressive, and sight-threatening, and fails to respond to conventional antibacterial or antiviral treatment.[5,72] Typically, only one eye is involved. Early symptoms include severe eye pain, lacrimation, foreign body sensation, and photophobia. *Acanthamoeba* keratitis frequently is misdiagnosed, initially, as herpetic, bacterial, or fungal infection. The course usually is more indolent, however. Periods of temporary remission delay establishing the diagnosis further. Recurrent corneal epithelial breakdown with dendritic infiltrates progresses to nonsuppurative keratitis, which waxes and wanes over several months and ends in a characteristic ring-shaped stromal abscess with secondary uveitis leading to loss of the cornea.[5,124] Infection that follows severe trauma deteriorates more rapidly than that which follows contact lens wear. In addition, complications of infection include iritis, cataracts, hypopyon, glaucoma, scleritis, and penetrating keratitis.[5]

BALAMUTHIA MANDRILLARIS

B. mandrillaris causes granulomatous encephalitis and cutaneous, sinus, and nasopharyngeal disease.[106] The incubation period of CNS disease is unknown, but is thought to be weeks to months (not <10 days).[79] In animal models, extensive CNS necrosis develops 1 to 3 weeks after inoculation.[77] Onset of symptoms of granulomatous encephalitis is insidious, with low-grade fever, severe frontal headache, nausea and vomiting, meningismus, personality change, and prominent focal neurologic signs that have included cranial nerve palsies, hemiparesis, dysarthria/aphasia, focal seizures, and ataxia.[6,47] A history of recent otitis was noted by many authors.[6,47] A slow relentless deterioration to coma and death ensues over several weeks to months (as long as 2 years afterward). Death usually results from cardiorespiratory failure secondary to severe cerebral edema. In many reports, manifestation of cutaneous lesions (facial, nasal, and limb) has preceded development of CNS disease.[25,52,88,91,131] Although normal CSF parameters have been described in *B. mandrillaris* CNS infection, moderately increased protein (may be >1 g/dL), normal or mildly decreased glucose, and a pleocytosis (about 500 cells/mm^3), which commonly but not invariably has a mononuclear predominance, are the typical findings.[6,39,47,77,106]

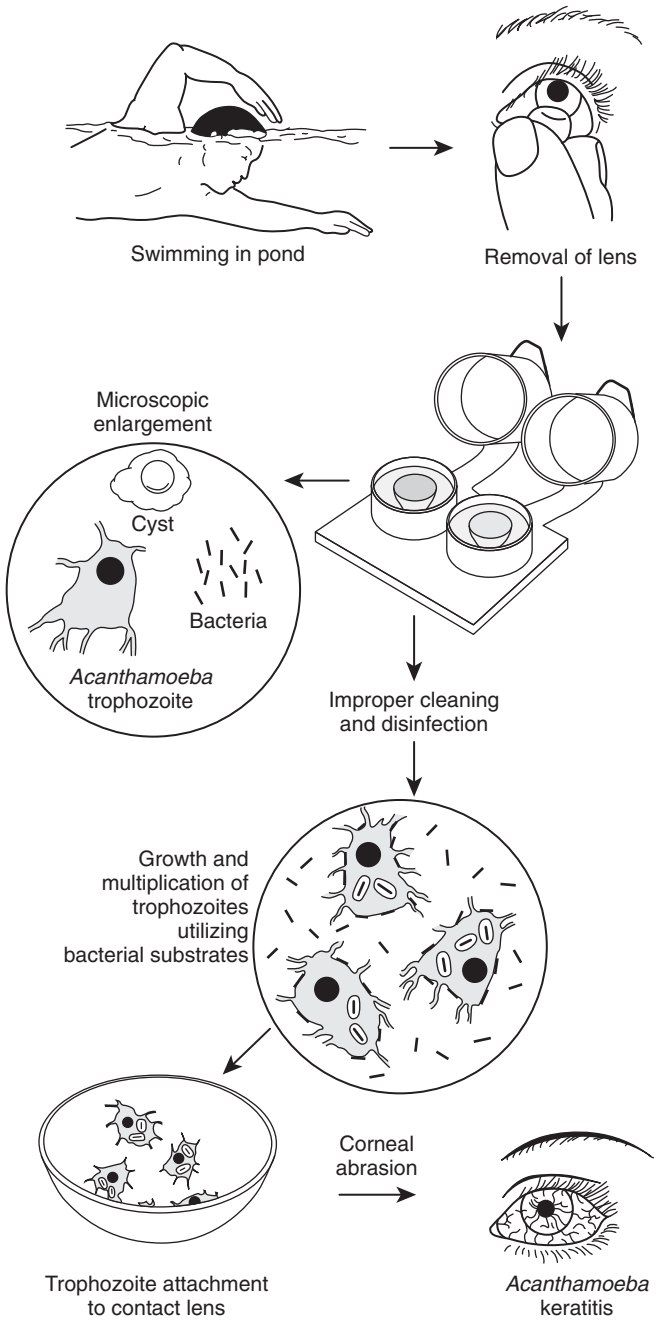

Figure 234–6 Proposed mechanism for *Acanthamoeba* keratitis. Bacterial contaminants in the water on the lens support the growth of amoebae, which leads to an increased number of invading organisms. The organisms adhere to the contact lens and enter tissue through the damaged cornea, with the subsequent development of keratitis.

NEUROIMAGING

Neuroimaging findings in infections caused by free-living amebae are nonspecific, and alone do not provide clues to an earlier diagnosis. In addition, in the early stages of infection, computed tomography (CT) and magnetic resonance imaging (MRI) may be normal. In primary amebic meningoencephalitis, cranial CT and MRI show obliteration of basal cisterns and signs of diffuse brain edema, focal and basilar meningeal enhancement, and infarction.[63,97,111] In granulomatous encephalitis, neuroimaging reveals variable but nondiagnostic abnormalities that include, alone or in combination, discrete corticomedullary lesions; large, solitary, masslike lesions (which may be confused with brain abscess or tumor); large arterial occlusions; and spinal cord infarctions.[63,97,111] Similarly, in *Balamuthia* infection, neuroimaging is helpful, but nondiagnostic; CT scans show a focal enhancing mass or ring-enhancing cystic lesions or both, vascular occlusion, and diffuse edema that frequently progresses to communicating hydrocephalus.[6,25,47]

PATHOGENESIS

Naegleria trophozoites or cysts enter the nasal cavity by aspiration of water or inhalation of soil. After active phagocytosis by sustentacular neuroepithelial cells of the olfactory nerve occurs, trophozoites migrate along the nerve, pass through the cribriform plate, and gain entry to the CNS.[54,79] From the olfactory bulb, which is bathed in CSF and lies in the highly vascularized subarachnoid space, *N. fowleri* disseminate throughout the CSF and CNS. Only *Naegleria* trophozoites are found in the CNS lesions. In contrast, most *Acanthamoeba* spp. infections seem to follow hematogenous dissemination from a primary lower respiratory or cutaneous focus.[79] Researchers have postulated that *Acanthamoeba* spp. are inhaled or inoculated through skin in the cyst phase. Less commonly, *Acanthamoeba* is capable of causing CNS infection directly via the olfactory neuroepithelium.

Virulence factors described for free-living amebae include the ability to adhere to brain microvascular epithelium, production of extracellular protease and elastases, and phagocytosis by foodcups or amebostomes.[1,33,48,61,70,72] Among *Naegleria* spp., pathogenicity is closely related to thermotolerance.[26] *N. fowleri*, the only species pathogenic for humans, is unusually thermophilic and can tolerate temperatures of 45° C.[106] In addition, *N. fowleri* has less demanding growth requirements than nonpathogenic *Naegleria* spp. Trophozoites of pathogenic *Acanthamoeba* spp. also are thermophilic, being able to tolerate temperatures of 37° C, relative to their nonpathogenic counterparts.[98,106] Thermotolerance seems to be less important for *Acanthamoeba* strains that cause keratitis, presumably because corneal temperatures are lower (32° C to 35° C).[106]

PATHOLOGY

Pathologic changes of infection with small free-living amebae are most marked in the CNS. The pathology of primary and granulomatous amebic encephalitis differs fundamentally.[79] Macroscopically, *N. fowleri* produces diffuse meningoencephalitis, most severely affecting the cortical gray matter. It is characterized by marked cerebral edema and purulent leptomeninges, particularly adjacent to the olfactory bulbs, at the base of the frontal and temporal lobes and at the hypothalamus.[78] Frequently, the olfactory bulbs are necrotic and hemorrhagic. Microscopically, an acute mononuclear and polymorphonuclear inflammatory infiltrate is seen throughout the cerebrum, brainstem and cerebellum, and upper spinal cord. Trophozoites tend to concentrate in the perivascular spaces and adventitia of arteries, and they may contain ingested erythrocytes and brain tissue. Characteristically, only trophozoites are seen in the CSF or brain tissue.[79] Presumably, *N. fowleri* cysts are not found in clinical specimens because progression of *Naegleria* infection is so rapid and fatal that the patient dies before transformation from trophozoite into the cyst can occur.[69]

CNS infections caused by *Acanthamoeba* spp. and *B. mandrillaris* are characterized macroscopically by diffuse cerebral edema and hemorrhage, with areas of softening and abscess formation. The meninges are spared except for areas overlying involved cerebrum. Additional areas of hemorrhagic necrosis are concen-

trated in the posterior fossa, brainstem and cerebellum, midbrain, cerebral cortex, and basal ganglia.[6,25,28,69] Narrowing of the sulci and flattening of the gyri are noted in areas of active infection. Microscopic changes consist of multinucleated giant cells, with trophozoites and cysts seen within the lesions.[78] The olfactory bulbs and spinal cord are relatively spared.

Microscopically, necrotizing hemorrhagic encephalitis and subacute or chronic necrotizing granulomatous infiltrates and multinucleate giant cells are scattered throughout the CNS, particularly in the cerebral hemispheres, basal ganglia, midbrain, and brainstem. Typically, trophozoites and cysts of *Acanthamoeba* spp. or *B. mandrillaris* are present within necrotic cerebral tissue, particularly in perivascular spaces. Invasion of blood vessels causes severe necrotizing arteritis and hemorrhagic necrosis. The angiotropic distribution of *Acanthamoeba* or *Balamuthia* infection supports a hematogenous mechanism of spread. In severely immunocompromised patients, the inflammatory reaction may be negligible and lacks a granulomatous component.[9,77] In the absence of a vigorous granulomatous response, hemorrhagic necrosis that resembles primary amebic meningoencephalitis may occur.[132]

Skin lesions of acanthamebiasis and balamuthiasis are characterized by nodules, ulcers, and abscesses, and the presence of amebic trophozoites, cysts, and granulomas in tissue.[76,79,131] Amebic keratitis is characterized by moderate chronic inflammation of corneal stroma, a mixed polymorphonuclear and lymphocytic infiltrate, and presence of amebic trophozoites and cysts within the corneal ulcerations.[128]

DIAGNOSIS

Previously, most cases of amebic meningoencephalitis were diagnosed with certainty only at autopsy or by brain biopsy.[9] Routine laboratory tests did not distinguish amebic meningoencephalitis from other causes of meningoencephalitis. The first and most important diagnostic step is to recognize the possibility that small free-living amebae may cause infection in the appropriate clinical setting. Among the few reported therapeutic successes, all are notable for early diagnosis and timely institution of appropriate antimicrobial therapy.[25,87]

Primary amebic meningoencephalitis should be included in the differential diagnosis of any child or young adult with meningoencephalitis. A history of recent exposure to fresh water should be sought, and a wet mount should be performed on centrifuged CSF. *Naegleria* is isolated most readily from CSF, but may be isolated from brain tissue, particularly olfactory lobes. In contrast, *Acanthamoeba* trophozoites characteristically are absent from CSF, and *B. mandrillaris* has yet to be seen in CSF. *Acanthamoeba* spp. are more likely to be isolated from brain tissue or skin biopsy, or from corneal scrapings in cases of keratitis.[98] Diagnostic techniques include direct microscopy of wet-mount and stained CSF specimens, histologic stains of tissue, fluorescent and immunofluorescent antibody stains of CSF and tissue, direct immunohistochemical stains of tissue, serology, molecular diagnostics, and culture.[127]

DIRECT MICROSCOPIC IDENTIFICATION

If amebic infection of the CNS is suspected, a wet-mount preparation of fresh CSF should be examined for the presence of motile amebae.[69,78,79,127] This method remains the most rapid means of diagnosis. Ideally, the CSF specimen should be kept at room temperature and examined soon after it has been collected. *Naegleria* is particularly fragile. Although the specimen may be kept at 4° C for short periods, it never should be frozen.[127] If present, amebae tend to attach to the test tube wall or surface of the container, so gentle shaking and low centrifugation at 150 *g* for 5 minutes are recommended to dislodge and concentrate the amebae.[78,127] The supernatant should be placed gently on a slide. The wet mount is examined best by light microscope under low power (10× and 40× objectives), phase-contrast microscopy, or darkfield illumination, and may be warmed to promote amebic motility. *Naegleria* trophozoites move in a characteristic "slug-like" fashion by extrusion of a few broad pseudopodia (lobopodia) anteriorly.[106] Leftover specimens can be frozen at –20° C for later antigen or antibody testing. Although *N. fowleri* may be shown by histologic stains of fixed CSF smears, Gram stain is not useful because it does not stain amebae, and the heat fixation causes lysis.

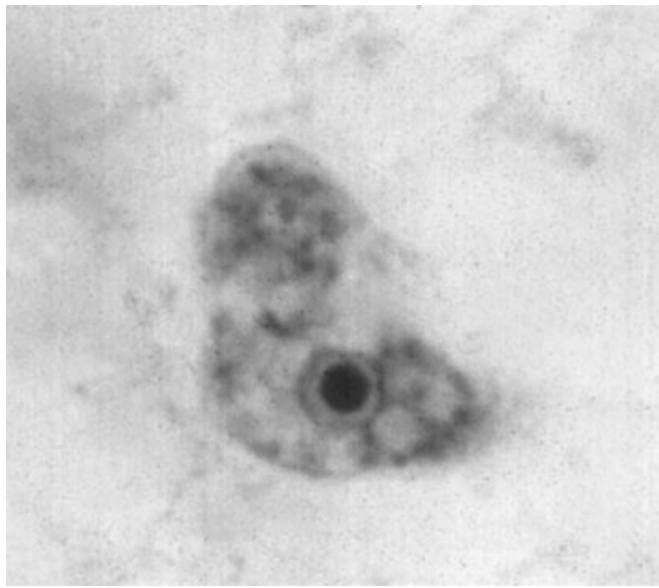

Figure 234–7 Trichrome stain of a trophozoite of *Naegleria fowleri*.

Naegleria, *Acanthamoeba* spp., and *Balamuthia* may be shown in fixed sections of brain tissue biopsy or autopsy specimens by hematoxylin and eosin, Masson trichrome, periodic acid–Schiff, Wright-Giemsa stain, and Gomori–methenamine silver stains (Fig. 234–7).[69,72,78,79] Reliably differentiating *Acanthamoeba* and *Balamuthia* by histology alone is difficult. In addition, *Acanthamoeba* trophozoites have been variously mistaken for macrophages or "atypical mononuclear" or epithelial cells on routine histology.[78,132]

Immunofluorescent stains using monoclonal and polyclonal anti-*Acanthamoeba* and anti–*B. mandrillaris* antibodies (available at the CDC), immunoperoxidase staining, and electron microscopy of tissue sections have been used to confirm the diagnosis (Fig. 234–8).[25,59,72,127,129] Amebic keratitis may be diagnosed by direct detection of trophozoites or cysts in smears of deep corneal scraping or biopsy using Wright-Giemsa, trichrome, periodic acid–Schiff, calcofluor white, or indirect fluorescent antibody stains.[69,78,133]

CULTURE

Culture has a limited role in diagnosis, but is useful for confirmation, speciation, and antimicrobial susceptibility testing. *N. fowleri* and *Acanthamoeba* spp. can be cultivated using bacteria as a food source (xenic cultures) or without bacteria, in an enriched cell-free nutrient (axenic) medium that contains antimicrobials to inhibit growth of contaminating bacteria.[21,98,109,127] *N. fowleri* and *Acanthamoeba* spp. are readily cultured from CSF, brain, and lung

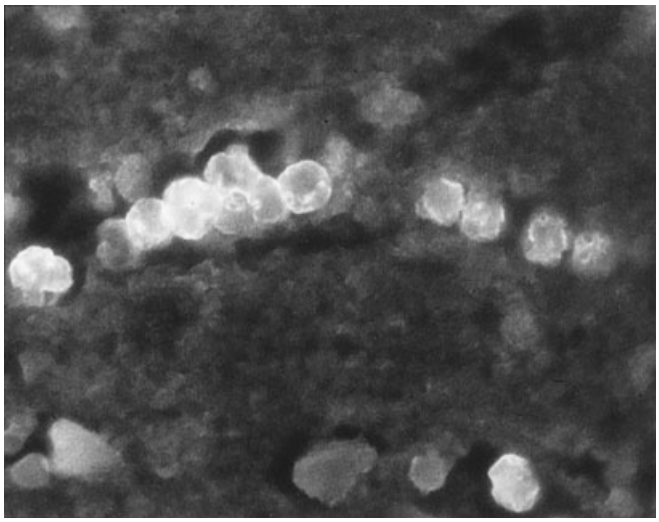

Figure 234–8 Indirect fluorescent antibody examination of *Naegleria fowleri*. *(Courtesy of Dr. G. S. Visvesvara, Centers for Disease Control and Prevention.)*

tissue on various non-nutrient agars or with low concentrations of nutrients, in the presence of a lawn of living or killed bacteria (e.g., most commonly nonmucoid strains of *Escherichia coli* or *Enterobacter* spp.).[78,98,127] Amebae feed on the lawn of bacteria and grow to cover the plate after 1 to 2 days' incubation at 37° C. Culture plates are incubated at 37° C and examined under low power daily for 10 days.[78,127]

Amebae can be visualized directly through the back of the inverted agar plate with a conventional microscope under low power.[98] The characteristic slow, sluglike movement of *Naegleria* trophozoites that is readily seen in a wet mount of CSF is difficult to distinguish on an agar plate.[98] The ability of *Naegleria* to transform into the flagellated stage after suspension in distilled water is useful diagnostically.[98,127] Trophozoites of *Acanthamoeba* spp. move slowly by extrusion of multiple, finger-like pseudopodia (acanthopodia).

Culture and isolation of *Balamuthia* is more challenging. Generally, *B. mandrillaris* is more fastidious, does not use bacteria as a food source, grows slowly, and requires a heavily enriched basic medium. *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* all grow vigorously, however, and produce detectable cytopathic effects in mammalian cell cultures (monkey kidney, HeLa, and lung fibroblast tissue), which can be examined for cytopathic effect.[78,129] Typically, *Balamuthia* grows slowly and may require several weeks to proliferate.[129] Use of a positive control culture is advised to ensure correct methodology and to aid recognition.[98]

Although no outbreaks of infection caused by free-living amebae in laboratory workers have been reported, care must be taken when handling specimens to avoid getting culture materials on skin and in cuts or abrasions. Specimens should be handled in a biologic safety cabinet by technologists wearing masks and gloves.[78,127]

SEROLOGY

Although specific *N. fowleri* antibody has been shown in survivors of primary encephalitis, serologic tests are of no use diagnostically.[110] Onset of primary amebic meningoencephalitis is rapid, and almost all patients die before significant antibody production can occur. In contrast, because the clinical courses of *Acanthamoeba* spp. and *B. mandrillaris* infections usually are chronic, there is time for robust antibody responses to develop. Detection of serum or CSF antibody against *Acanthamoeba* spp. or *Balamuthia* by indirect immunofluorescence staining has helped establish the diagnosis in many cases.[25,59,106] By this method, amebae fixed on a slide bind antibody present in the patient's serum or CSF, which then is detected by fluorescein-conjugated, antihuman antibody.

Serologic testing has been most useful as an epidemiologic tool. Although the incidence of infection with free-living amebae seems low, results of seroepidemiology studies suggest that human exposure to amebae occurs frequently. Sera from healthy adults and children contain antibody against *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris.*[24,50,73,101,104] Detection of antibodies to *N. fowleri* and *Acanthamoeba* spp. in asymptomatic adult and pediatric populations from North Carolina, Virginia, and Pennsylvania in the United States and from Czechoslovakia and New Zealand presumably reflects unavoidable environmental contact with these ubiquitous organisms.[15,73] All specimens from a group of 93 asymptomatic patients from New Zealand contained anti-*Naegleria* and anti-*Acanthamoeba* IgG and IgM antibodies.[24] Antibodies were neutralizing against *Acanthamoeba* spp., but not against *N. fowleri*. In virtually all cases of infection caused by *Acanthamoeba* spp., disease occurs in the setting of immunocompromise or in an immunologically privileged site, such as the cornea. Whether neutralizing antibodies play a role in the very low incidence of infections in healthy individuals, despite seemingly frequent environmental exposure, is unknown.

Immunofluorescent antibody staining of serum for antibodies against *Acanthamoeba* spp. and *B. mandrillaris* has proved to be a rapid noninvasive diagnostic test in many clinical cases.[29,59,134] Potentially, this test may be useful clinically for establishing an earlier definitive diagnosis and initiation of therapy. Because the presence of *Balamuthia* antibodies may represent asymptomatic environmental exposure, confirmation of results of immunofluorescent antibody testing by histology, indirect immunofluorescent staining of tissue, or polymerase chain reaction (PCR) of CSF is advised. More recently, immunofluorescent antibody staining of serum from patients with encephalitis, predominantly from California, revealed seven previously unrecognized or misdiagnosed cases of *Balamuthia* and one case of *Acanthamoeba* encephalitis.[104] Most serum specimens showed some evidence of antibody (<1:64), which was attributed to cross-reactivity or subclinical exposure to contaminated soil. A cutoff value of greater than 1:64 for *Balamuthia* serology was considered positive pending results of confirmatory tests (e.g., histology, immunohistochemistry, or PCR).[104] Low levels of antibody may reflect preceding subacute disease or contact with environmental amebae.[104]

MOLECULAR DIAGNOSTICS

Although microscopic assessment of a wet-mount preparation or histology may be useful in experienced hands, definitive identification in most centers awaits results of specimens sent out for immunofluorescence tests. Advances in molecular diagnostics offer the real possibility, however, of sensitive, specific, and rapid diagnosis being made by any laboratory with the capability to perform PCR. PCR of DNA extracted from frozen brain tissue has been used to confirm *N. fowleri* infection diagnosed by histopathology and immunofluorescent staining.[20] Similarly, nested and real-time PCR provide rapid, sensitive, and specific screening of environmental and recreational water sources for the presence of *N. fowleri.*[74,92] PCR, using mitochondrial 16S rRNA gene DNA as the target, has been used to detect *B. mandrillaris* in clinical samples of CSF and formalin-fixed brain and lung tissue of patients with encephalitis.[118,134] These assays have the ability to detect a single ameba per reaction mixture.[134]

Finally, the development of a multiplex real-time PCR assay for simultaneous detection of *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* in clinical specimens of CSF and brain tissue offers the possibility of highly sensitive and specific rapid confirmatory diagnosis of CNS infection by free-living ameba and the chance of initiating earlier, more effective treatment.[89] The assay is sensitive down to detection of a single ameba in a specimen and is species-specific for *N. fowleri* and *B. mandrillaris*, and genus-specific for *Acanthamoeba*.[89]

TREATMENT

Mortality among patients with primary and granulomatous amebic encephalitis is greater than 95 percent.[8,107] The high fatality rate undoubtedly is due partly to late diagnosis or misdiagnosis and late initiation of potentially effective treatment. Inclusion of amebic infection in the differential diagnosis, in the appropriate clinical setting, and timely administration of effective antiamebic treatment are emphasized in successful cases.[11,87] In the future, availability of real-time PCR may facilitate accurately establishing an early diagnosis. Although no randomized trials of optimal treatment for infection caused by free-living amebae have been performed, potentially effective treatment is available if the condition is recognized early.

If infection is suspected, treatment should not be withheld pending the results of confirmatory testing. Treatment regimens are based on results of in vitro susceptibility, in vivo animal experiments, and empiric treatment of individual cases. If amebic infection is suspected, accurate determination of the species is important to ensure optimal treatment. No one drug is effective against all free-living amebae (e.g., amphotericin is the drug of choice for *N. fowleri* infection, but is neither static nor cidal for *Acanthamoeba* spp., and varies in its efficacy against *Balamuthia*).[30,105] Previously, authors have suggested initiating treatment with a combination of agents such as amphotericin B and flucytosine, which have activity against *Naegleria* and *Acanthamoeba* or *Balamuthia*, until amebae can be identified definitively.[132] Among newer antibiotics, miltefosine and voriconazole are potentially attractive as treatments for infection caused by free-living amebae. Both drugs penetrate into brain tissue and have a low toxicity profile. Although differences in susceptibility exist among strains, voriconazole has activity in vitro against *Acanthamoeba* spp. and *N. fowleri*, whereas miltefosine has in vitro activity against *Acanthamoeba* spp. and *Balamuthia*.[103]

NAEGLERIA MENINGOENCEPHALITIS

N. fowleri is exquisitely susceptible in vitro to amphotericin B, which remains the treatment of choice for primary amebic meningoencephalitis.[107] All successfully treated cases have included amphotericin B in the treatment regimen. *Naegleria* also is susceptible in vitro to azithromycin and miconazole, with synergism in vitro and in the animal model with the combination of amphotericin and miconazole or tetracycline.[30,43,110,114,125] Treatment regimens in cases with successful outcomes have included intravenous amphotericin, high-dose intravenous and intrathecal amphotericin and miconazole, oral rifampin, intravenous sulfisoxazole, and intravenous and intrathecal amphotericin in combination with oral rifampin.[4,11,110] Rifampin has yielded conflicting results in in vitro testing.[44] Liposomal amphotericin B seems less effective in vitro and in the animal model than conventional amphotericin (10-fold higher minimum inhibitory concentration), and is not recommended.[44] In contrast to *Acanthamoeba* spp. and *B. mandrillaris*, *N. fowleri* remains a trophozoite and does not encyst in tissues, so after it is destroyed by antimicrobial therapy, infection with *N. fowleri* should not recur.

Optimal treatment for CNS disease caused by *Acanthamoeba* spp. has not been established, and the prognosis remains grim, with few reports of survivors.[107] Most cases are diagnosed at autopsy or a few days before death, leaving little time to evaluate treatment. Treatment successes have been attributed to initiation of treatment before spread of infection into the CNS. Combination treatment is favored because no single drug is active against trophozoites and cysts, and many drugs are amebostatic rather than amebocidal.[72] Among the few reports of successful treatment, oral trimethoprim-sulfamethoxazole, ketoconazole, and rifampin were associated with a favorable outcome in two apparently immunocompetent children with CNS disease.[112] Fluconazole, rifampin, metronidazole, and sulfadiazine were used successfully in a 64-year-old immunocompetent host with early disease.[87]

Similarly, Slater and colleagues[113] reported successful treatment of disseminated cutaneous acanthamebiasis in a renal transplant recipient using 4 weeks of intravenous pentamidine, topical chlorhexidine, and 2 percent ketoconazole followed by maintenance oral itraconazole. A combination of pentamidine, 5-fluorocytosine, itraconazole, and topical chlorhexidine gluconate/ketoconazole cream was used to treat disseminated acanthamebiasis successfully in a lung transplant recipient.[85] Pentamidine is considered the most suitable treatment before CNS invasion has occurred because of its low penetration into the CNS. Because of its low penetration across the blood-brain barrier and nephrotoxicity, 5-fluorocytosine was preferred to pentamidine for CNS infection and in renal transplant recipients.[30,72]

Optimal treatment for *B. mandrillaris* infection also remains to be determined. Reports of successful treatment for granulomatous encephalitis caused by *Balamuthia* based on empiric regimens are few. If it is recognized early in its course, however, a more favorable outcome apparently is possible. In two successful cases, treatment regimens included flucytosine, pentamidine, fluconazole, sulfadiazine, a macrolide, and a phenothiazine.[25] Pentamidine treatment frequently was discontinued or interrupted because of side effects. Both patients recovered and showed no evidence of relapse 5 and 7 years later.[25] Treatment failures have been reported in patients treated with similar regimens, however, possibly because of late initiation of treatment.[39] Pentamidine and azithromycin were more effective in vitro than fluconazole, flucytosine, or sulfasalazine.[107] Some researchers have postulated, however, that some of these drugs may be synergistic in vivo.[107] Because of concern about reactivation from dormant cysts in the brain, both patients remained on long-term fluconazole and on sulfadiazine or clarithromycin prophylaxis.

Use of corticosteroids to treat cerebral edema and inflammation seems to exacerbate *Acanthamoeba* infection. A precipitous decline in the clinical condition of one patient has been reported after administration of corticosteroid therapy.[39] At present, the risk of corticosteroid treatment probably outweighs any potential benefit and is best avoided.[39,72,94]

AMEBIC KERATITIS

Untreated, amebic keratitis invariably progresses to visual loss and enucleation. Although amebic keratitis is more amenable to antimicrobial treatment than systemic infection, treating it is still difficult. The presence of *Acanthamoeba* cysts in deeper corneal layers renders exposure to adequate drug levels problematic. In addition, *Acanthamoeba* cysts are resistant to most antibacterial agents at concentrations that are achievable but nontoxic to the cornea. As with systemic infection, establishing

the diagnosis early is required for treatment to be most effective.

In the early stages of infection, prolonged frequent application of drug is recommended. Combination treatment is preferred during prolonged treatment because of concerns for development of resistance. Nonetheless, cures have been reported with a variety of topical agents; the cationic antiseptic, chlorhexidine gluconate, and 0.02 percent polyhexamethylene biguanide, a swimming pool disinfectant, alone or in combination with propamidine are among the drugs of choice for amebic keratitis.[32,66,107,108] Both drugs are effective against trophozoites and dormant cysts and are well tolerated in the eye.[66] Neomycin and oral azoles (e.g., miconazole or itraconazole) also have proved useful. Newer agents, such as myristamidopropyl dimethylamine and miltefosine, are effective *Acanthamoeba* cysticidal agents, possess excellent antifungal and antibacterial activity, and show promise in treating recalcitrant keratitis.[51,99,107]

Many cases of keratitis, particularly when chronic or where medical treatment alone fails, require keratoplasty and corneal grafting. In these cases, prolonged medical treatment aims to cure or control disease to allow for successful transplantation. Timing of surgery is controversial. Antiamebic drugs usually are continued for months after surgery to prevent late excystation of residual dormant cysts.[5] Use of topical or systemic corticosteroid to treat severe pain or inflammation is controversial. Severe complications have been described in clinical cases, and dexamethasone induces encystment and increases cytopathogenicity of emerging trophozoites in animal models.[81,119]

ROLE OF *ACANTHAMOEBA* SPECIES AS RESERVOIRS OF INTRACELLULAR PATHOGENS

Although most bacteria are prey for free-living amebae, some bacteria have evolved to survive uptake by amebae. Many *Acanthamoeba* spp. act as environmental reservoirs of recognized intracellular pathogens for humans, including *Coxiella burnetii*, *Legionella pneumophila*, *Mycobacterium* spp., *Pseudomonas aeruginosa*, and *Cryptococcus neoformans*, and for potential emerging pathogens, such as *Rickettsia*-like organisms and *Parachlamydia* spp.[45,46,49,75,121] Some ameba-resistant microorganisms coexist with amebae as endobacterial symbionts, whereas others exploit the amebae as hosts for survival, for multiplication, or as vectors of disease.[7] Free-living amebae act as a "Trojan horse" in the transmission of bacterial passengers, such as for *L. pneumophila* or *M. avium*, or as an "evolutionary crib" for the selection of virulence traits and for adaptation of microorganisms to life within human macrophages, such as for *C. neoformans*.[7,46]

For *L. pneumophila*, prior multiplication within free-living amebae, principally *Acanthamoeba* spp., seems to be a prerequisite for acquisition of infection in humans.[120] In addition, many bacteria, such as *M. avium*, survive protected from chlorination, biocides, antibiotics, and desiccation within ameba cysts.[71,118] Similarly, growth of *M. avium* in amebae results in enhanced survival in macrophages. Researchers also have postulated that free-living amebae may have adapted some microorganisms for successful intracellular survival within macrophages.[40,115] Free-living amebae also apparently promote virulence traits and antimicrobial resistance in *L. pneumophila*, *M. avium*, and *C. neoformans*.[18,19,83] Researchers have postulated that capsule formation evolved in *C. neoformans* in response to selective pressure to resist environmental amebae. Production and maintenance of a capsule allows *Cryptococcus* to survive in human macrophages.[115] Some microorganisms resistant to amebae seem to behave as endosymbionts and to influence development and maintenance of virulence traits that enhance pathogenicity of free-living amebae.[38,46] Clinical and environmental *Naegleria* spp. do not support bacterial endosymbionts.

PREVENTION

Infections caused by free-living amebae are reported to be characterized by an absence of distinguishing symptoms, delayed diagnosis or misdiagnosis, and an almost uniformly poor prognosis without early appropriate treatment. Prevention of infection is of paramount importance. Strategies to prevent *Naegleria* infection exist; *N. fowleri* is susceptible to 1 μg/mL or less of chlorine, and adequate chlorination of water in swimming pools or hot tubs is a simple and sensible preventive measure. If water temperatures are higher, use of increased concentrations of chlorine (>2 to 3 mg/L) is recommended.[79] In certain parts of the world, environmental levels of *N. fowleri* are monitored to ensure it is safe to swim, and that the probability of acquiring an infection is low.[13] A prudent measure is to educate the public on the potential dangers associated with exposure to warm bodies of fresh or thermally polluted water, especially when temperatures are high and water levels are low, and to avoid immersion, diving, jumping, or horseplay that might force water up the nasal passages or disturb sediment.[135]

Prevention of infection caused by *Acanthamoeba* spp. or *B. mandrillaris* is problematic and involves regular inspections of hot-water tanks, plumbing, and eye-wash stations. *Acanthamoeba* keratitis associated with use of contact lenses is preventable, however. Contact lens wearers should be aware of the importance of proper care of the lenses. Lenses should be cleansed in sterile benzalkonium-preserved saline or disinfected by heat. Use of homemade cleansing solutions and wearing lenses while swimming are contraindicated.

Although the incidence of infections caused by free-living amebae is small at present, the number of these infections is likely to grow with increasing numbers of transplant patients and patients with AIDS. Similarly, some researchers have predicted that climate change associated with global warming may increase further numbers of free-living amebae in the environment.[20]

CHAPTER 235

TOXOPLASMOSIS

James B. McAuley ✪ Kenneth M. Boyer ✪ Jack S. Remington ✪ Rima L. McLeod

Toxoplasma gondii is an obligate intracellular protozoan parasite (phylum Apicomplexa, class Sporozoasida, order Eucoccidiida).[181] Infection may be clinically inapparent or result in disease, called *toxoplasmosis*. This parasite was observed first in 1908 by Nicolle and Manceaux[136,137] in mononuclear cells in the spleen and liver of a North African rodent, the gundi (*Ctenodactylus gundi*). The organism soon was identified as a cause of disease in other animals,[177] and in 1923, Janku[85] first recognized a case in a human. He described a parasite found in the retina of an infant; it was recognized later by Levaditi[102] as *Toxoplasma*.

In 1937, Wolf and Cowen[189] reported a case of congenital granulomatous encephalitis that they considered to be caused by an "encephalitozoon." Sabin,[155] who previously had encountered *T. gondii* in guinea pigs, made the correct diagnosis. The discovery of *Toxoplasma* as a cause of disease acquired later in life has been credited to Pinkerton and Weinman,[141] who in 1940 described a generalized fatal illness caused by this organism in a young man. In retrospect, a case of acquired toxoplasmosis had been reported in 1908 by Darling.[41] In 1948, Sabin and Feldman[156] described a serologic test, the dye test, which allowed numerous investigators to study the epidemiologic and clinical aspects of toxoplasmosis and define the spectrum of disease in humans. In 1969, some 60 years after the parasite was discovered, Frenkel and colleagues[54,60,61] established that *Toxoplasma* was a coccidian protozoan, and that its definitive host was the cat.

ORGANISM AND TRANSMISSION

T. gondii exists in three forms, or stages—the proliferative stage, or tachyzoite; a tissue cyst that contains bradyzoites; and an oocyst, within which sporozoites develop. The oocyst is formed during the intestinal epithelial stage of infection, exclusively in members of the cat family, the definitive host. The tachyzoite and tissue cyst are found in the extraintestinal tissues of cats and in other mammalian and avian hosts. Each stage of the organism has antigens in common with the other stages and unique antigens. Many of these antigens have been cloned, sequenced, and localized to microanatomic structures.[123]

The tachyzoite form (Fig. 235–1A to C) is crescent-shaped or oval, is approximately 3 to 7 μm, and is seen during the acute stage of infection. It stains well with Wright or Giemsa stain. Ultrastructural features include the apical complex of microtubules and rings, secretory organelles called *rhoptries*, and a chloroplast-like structure with its own unique DNA.[27,181] Tachyzoites can invade all mammalian cells except perhaps non-nucleated red blood cells. They cannot withstand freezing and thawing, desiccation, or brief exposure to gastric or duodenal digestive juices. After penetration occurs, the tachyzoite multiplies by endodyogeny, ultimately causing disruption of the cell and cell death.

The bradyzoite (see Fig. 235–1D to F) is able to persist in encysted form in all tissues and cause a chronic (latent) infection for the entire life span of the infected host. Cysts are demonstrable in tissues the first week of infection and range in size from approximately 10 to 100 μm. They have an argyrophilic wall, but stand out most clearly from surrounding tissue when stained with periodic acid–Schiff stain. Usually, no inflammatory reaction occurs around cysts. Because this form may persist for many years in the tissues of clinically normal children and adults, its demonstration in histologic sections does not signify recent infection. Peptic or tryptic digestive fluids immediately disrupt the cyst wall, but the liberated bradyzoites (which resemble the tachyzoite form under light microscopy) can survive in these fluids for several hours, which allows time for invasion of local cells. The cyst is destroyed by heating to 66° C, by freezing (<–20° C) and thawing, and by desiccation. It can survive for some months at refrigeration temperatures (4° C) if it is in tissue. Infection in humans may be acquired by eating inadequately cooked meat that contains cysts (Fig. 235–2). In carnivorous animals, infection may be acquired by eating raw meat or prey species that contain encysted organisms or by ingesting sporulated oocysts as discussed subsequently.

The oocyst form (see Fig. 235–1G to I) is found only in feces of members of the cat family, the definitive host for *Toxoplasma*, and is the result of gametogony and schizogony, which occur in the intestinal epithelium.[83] The oocyst is ovoid and approximately 10 to 12 μm. Infected cats may shed 10 million oocysts each day, which may be excreted for 3 weeks after primary (acute) infection develops, but rarely thereafter. Excreted oocysts become infectious only after they undergo sporulation (eight sporozoites form in each oocyst); sporulation occurs 1 to 21 days (most commonly 2 to 8 days) after excretion occurs, depending on temperature and the availability of oxygen. The oocyst is far more resilient than the other life cycle forms and can survive for months in water and for 1 year or more in moist soil. Ingestion of sporulated oocysts transmits the infection. This fact suggests that the oocyst plays a major role in transmission by the fecal-oral route in animal reservoirs and by inadvertent ingestion in humans.

The genome of *T. gondii* consists of 8×10^7 base pairs distributed among 12 chromosomes. Much of the genome has been sequenced, a genetic linkage map has been constructed, and three clonal genotypes (I, II, and III) have been identified.[95,163,181] Some of the factors that regulate stage conversion from tachyzoite to bradyzoite have been defined.[123,181] The shikimate pathway, an enzyme system that is absent in animals, is important for the production of many essential aromatic compounds in plants, bacteria, and fungi. This biochemical pathway has been identified in *Toxoplasma* and in other apicomplexan parasites, such as *Plasmodium falciparum* and *Cryptosporidium parvum*.[148] Biochemical inhibition of this pathway suppresses the growth of these parasites.[145] Understanding of the regulation of life cycle stages and the unique pathways of intermediary metabolism in *T. gondii* may provide new approaches to therapy.

EPIDEMIOLOGY

ACQUIRED INFECTION

The cat is central in the parasite's life cycle, and humans and other mammals are intermediate hosts. If infected tissue (e.g., a mouse) is consumed by a susceptible cat, the sexual cycle is induced in the cat intestine; oocysts are excreted and are infectious for mammals and birds, in which the life cycle (tachyzoites and cysts) is perpetuated. Cats shed oocysts for only brief durations (days to weeks), but in extremely large numbers (1×10^7/day). A cat is more likely to become infected if it is an outdoor cat or a predator or is fed fresh, uncooked table scraps. Humans

come in contact with cat excrement either directly (e.g., emptying the litter pan) or by more insidious means (e.g., cleaning a horse stall, weeding the garden, playing in a sandbox). Meat for human consumption may serve as a source of infection if it is eaten raw or undercooked. Accidental ingestion may occur under circumstances that are unsuspected. Examples include an Amish farm wife preparing sausage, a couple consuming steak tartare in an expensive restaurant, and a rancher butchering a deer.[16]

Infection with *Toxoplasma* occurs commonly in humans. In the United States, the prevalence of seropositivity has been determined from studies of military recruits, surveys in major cities, and most comprehensively from the National Health and Nutrition Examination and Surveys (NHANES). The NHANES surveys are periodic cluster sample surveys representing the entire population of the United States. In the early 1960s, the overall prevalence in military recruits was 14 percent, with the lowest rates in the Mountain (3%) and Pacific (8%) states, and the highest rates in the Northeastern (20%) and East South Central (19%) states.[164] A more recent study from the late 1980s showed a similar geographic distribution, but prevalence rates were approximately a third lower throughout the country.[164] This decline has continued as documented in the NHANES surveys.

The NHANES III survey (1988-1994) showed an overall seroprevalence in individuals of child-bearing age (12 to 49 years old) of 14.1 percent compared with a rate of 9 percent for the same age cohort in the NHANES 1999-2004 survey.[87] The consistent gradual increase in seropositivity with increasing age in the NHANES surveys suggests dietary exposure as a major mode of acquisition in the United States.[88] Previous estimates were that approximately 8 percent of commercial beef, 20 percent of commercial pork, and 25 percent of commercial lamb contain encysted *Toxoplasma* bradyzoites.[144] More recent data suggest much lower levels of viable tissue cysts in commercial meat.[53] The NHANES III survey failed to show an association, however, with specific dietary habits such as meat consumption. *Toxoplasma* infection was associated with foreign birth, low educational level, living in crowded conditions, and having a soil-related occupation.[88]

During these decades of declining prevalence of *Toxoplasma* infection, the rate of cat ownership has increased in the United States.[87,88] The decline may be explained partly by improved meat safety, with decreasing prevalence of viable *Toxoplasma* in commercial meat.[53] A common practice is to freeze commercial meat before releasing it for sale, which, combined with the use of home freezers, also may be having a beneficial effect.[163] Additional modes of transmission, such as water-borne,[10,14,52] have been described. Their exact contribution to the overall prevalence of toxoplasmosis in the United States is unclear, however. During the decades of the NHANES studies, an increasing proportion

of U.S. water supplies have added filtration to decrease *Giardia* and *Cryptosporidium* transmission. This filtration also likely would eliminate *Toxoplasma* oocysts.[88]

Urban studies in U.S. women of child-bearing age have yielded variable prevalence rates: Denver, 3 percent; Palo Alto, 10 percent; Chicago, 12 percent; Boston, 14 percent; and Birmingham, 30 percent.[144] Internationally, rates also vary: Thailand, 3 percent; Japan, 6 percent; Australia, 23 percent; United Kingdom, 35 percent; Poland, 36 percent; Belgium, 53 percent; Tahiti, 77 percent; and France, 87 percent.[144] The prevalence of infection is determined partly by climate; colder regions and regions that are hot and dry or at high altitude have lower rates of human infection than warmer and moister regions. Prevalences are declining in Europe, as in the United States, owing to educational efforts and improved meat safety.

Common-source outbreaks of acute acquired *Toxoplasma* infection have been authenticated. Unique and clear-cut sources that have been documented to be highly likely[14] include exposure to aerosolized cat excrement in a riding stable[173] and consumption of unpasteurized goat milk.[157] In other circumstances, extensive investigations have failed to yield convincing answers.[110,161] Because of the possibility of common-source exposure, however, families of patients with acute acquired infection should be evaluated for subclinical infection.[107]

Accidental self-inoculation with a needle contaminated with *Toxoplasma* has resulted in many acquired infections in laboratory workers. Infections also have been ascribed to blood transfusions and organ transplantation.[59]

CONGENITAL INFECTION

Congenital infection is thought to occur, with rare exception, only after primary maternal infection with *Toxoplasma*.[46,144] The only two well-documented exceptions to this rule occurred in immunodeficient pregnant women.[127,144] In a large series that carefully studied more than 800 women who had given birth to congenitally infected children, not a single congenital infection occurred in subsequent pregnancies.[144] A general consensus is that only acute infection beginning *during* pregnancy can lead to congenital infection. Despite the existence of a few well-documented cases of biopsy-proven lymphadenopathic toxoplasmosis occurring 2 months *before* conception that resulted in congenitally infected infants,[177] this pattern of occurrence also seems to be extremely rare.[65]

The prevalence of congenital toxoplasmosis in a population is determined by the risk of a woman's experiencing primary infection while she is pregnant. This prevalence depends on three factors: (1) the age-specific incidence of primary infection during the child-bearing years, (2) the age distribution of pregnant women in the population, and (3) the fetal transmission rate in primary infection. A theoretical analysis by Frenkel[60] based on these three factors, assuming a child-bearing age group of 20 to 29 years and an overall fetal transmission rate of 40 percent, showed that maximal risk occurs when the age-specific incidence rate in a population is 3 to 5 percent per year, which corresponds to a seropositivity rate of 50 to 80 percent in women of child-bearing age. In such a population, the predicted prevalence of congenital toxoplasmosis would be 4.4 to 4.6 per 1000 pregnancies. At higher age-specific incidences, rates of congenital toxoplasmosis would be lower because nearly all pregnant women already would be infected chronically. At lower incidences, rates also would be lower, but because of less frequent infection.

Studies in the early 1970s revealed a prevalence of congenital toxoplasmosis in the United States of approximately 2 per 1000 births.[1,11,96,144] The only prospective data currently available in the United States are derived from the screening of approximately 600,000 newborns in Massachusetts and New Hampshire with an IgM enzyme-linked immunosorbent assay (ELISA) as applied to filter paper blood samples.[76] The prevalence of infection identifiable at birth in this more recent study was approximately 1 in 12,000. The limitations of the testing method (small serum volumes, a test that yields positive results in only 75% of cases) undoubtedly render this estimate a conservative one, but it supports the notion that the prevalence has declined in recent years.

PATHOLOGY

After intracellular multiplication at the site of entry occurs, tachyzoites are disseminated in blood and may invade all organs and tissues. The severity of infection probably is a function of strain virulence, host susceptibility, tissue tropism, and the immune privilege of the eyes and central nervous system (CNS).[73,109,144] Proliferation of tachyzoites results in death of the invaded cells and, eventually, small necrotic foci surrounded by intense cellular reaction. With recovery, cysts without an inflammatory response around them may persist in the brain, bone marrow, lymph nodes, liver, spleen, and lungs, and in skeletal, heart, and smooth muscle.[59-61]

In active infection of the CNS, *Toxoplasma*-filled cells are scattered throughout the gray matter, where they produce diffuse meningoencephalitis with miliary microglial nodules and foci of perivascular inflammation.[30] Large lesions may mimic cerebral tumors. Areas of basal ganglial and periventricular inflammation may calcify in the fetus.[50,139] Obstruction of the aqueduct of Sylvius or the foramen of Monro may result in hydrocephalus in congenital infection.

The enlarged lymph nodes in acute acquired toxoplasmosis show characteristic pathologic changes that may warrant making a presumptive diagnosis.[51,177] Such changes include reactive follicular hyperplasia, epithelioid histiocytes encroaching on and blurring the margins of germinal centers, and distention of subcapsular and trabecular sinuses by monocytoid cells. Tachyzoites and cysts rarely are seen.[51]

In the eye, active chorioretinitis begins in the retina with severe inflammation and necrosis and exudation into the vitreous. Single or multiple foci occur, and secondary involvement of the choroid is always present. Tachyzoites and cysts have been found in these lesions.[17,144,146,147]

In immunocompromised hosts, widespread necrotizing lesions may be seen in the heart, muscle, brain, and other organs. These lesions, particularly those involving the CNS, have been found frequently with reactivation of toxoplasmosis in patients with acquired immunodeficiency syndrome (AIDS).[105]

IMMUNOLOGY

Cell-mediated immune responses are the major immunologic mechanisms that prevent reactivation of *T. gondii* in a chronically infected normal host.[28,39] Numerous effector mechanisms contribute to protection in murine models and human infection: $CD8^+$ cytotoxic T lymphocytes, $CD4^+$ T lymphocytes, monocyte oxidative mechanisms, production of interferon-γ by natural killer cells, and activation of macrophages by interferon-γ and tumor necrosis factor-α.[67,77,89,91,162,169] Killing of the parasite within activated macrophages is associated with the intracellular production of nitric oxide. Interleukin-2 and interleukin-12 enhance host resistance to *T. gondii*; interleukin-10 impairs the ability of macrophages to kill the parasite.[66]

In murine models, evidence exists for genetic determination of host resistance to infection.[18,19,109,119] Presence of the DQ3 allele seems to be associated with toxoplasmic encephalitis in patients with AIDS and hydrocephalus in infants with congenital

toxoplasmosis.[19] Successful immunization of mice[20] and sheep[21] with *T. gondii* components and live tachyzoites of an "incomplete" strain[22] raises the possibility of developing a human vaccine.[86,120,181]

CLINICAL SYNDROMES

The disease in children may be considered in three categories: postnatally acquired, congenital, and ocular (which may be congenital or acquired). Clinically apparent infection in older children may have been acquired recently or caused by reactivation of latent congenital or postnatally acquired infection. Congenital and acquired infections usually are subclinical, but congenital infection ultimately leads to serious sequelae in most cases.

ACUTE ACQUIRED TOXOPLASMOSIS

Acquired *Toxoplasma* infection is asymptomatic in most cases and frequently goes unrecognized because only 10 to 15 percent of infected individuals have clinical symptoms and signs. In certain outbreaks related to infection by oocysts, however, more than half of infected patients have been symptomatic.[173] The most common findings are lymphadenopathy and fatigue without fever.[112] The nodes are discrete and may or may not be tender. They do not suppurate. The groups of nodes most commonly involved are the cervical, suboccipital, supraclavicular, axillary, and inguinal. The adenopathy may be localized or involve multiple areas, including the retroperitoneal and mesenteric nodes. Uncommonly, the lymphadenopathy is accompanied by fever, malaise, fatigue, sore throat, and myalgia, a picture that closely simulates that of infectious mononucleosis, but without serologic evidence of acute Epstein-Barr virus infection. The differential diagnosis of the lymphadenopathy often includes lymphoma. Chorioretinitis may develop during acute acquired infection, but it does not occur commonly.[110,132] The liver may be involved, and liver function tests may reflect hepatocellular damage. In individuals with normal immunologic function and no severe underlying disease, the infection usually is self-limited and rarely requires treatment.

In contrast, more severe and frequently fulminant infections are seen in patients receiving immunosuppressive therapy, in patients who have disease of the bone marrow or reticuloendothelial system, in patients with agammaglobulinemia, in recipients of bone marrow or stem cell transplants, and in patients with AIDS.[43,84,103,105,111,154,176] Encephalitis and rarely pneumonitis and myocarditis are the most important localized forms that may be encountered in immunocompromised patients. In toxoplasmic encephalitis, the predominant neurologic symptoms are headache, disorientation, and drowsiness. These symptoms may simulate aseptic meningitis or a mass lesion. In view of the various clinical manifestations of CNS involvement, it is important to consider toxoplasmosis whenever evidence of acute CNS disease is present.

CONGENITAL TOXOPLASMOSIS

Congenital infection usually is the result of an asymptomatic acute infection in the mother.[16,57] In a small proportion of cases, spontaneous abortion, prematurity, or stillbirth may result. Congenital toxoplasmosis has a wide spectrum of clinical manifestations, but usually is subclinical in newborns. When clinically apparent, it may mimic other diseases of the newborn. Fever, hydrocephalus or microcephaly, hepatosplenomegaly, jaundice, convulsions, chorioretinitis (usually bilateral), cerebral calcifications, and abnormal cerebrospinal fluid (CSF) (markedly increased protein and mononuclear pleocytosis) are considered the classic features of congenital toxoplasmosis.[50,125,144] These manifestations occurred commonly in an early series of patients reported by Eichenwald[56] (Table 235–1). The case-fatality rate was 12 percent. In survivors in this series, sequelae included mental retardation in 86 percent; convulsions, spasticity, and palsies in almost 75 percent; and severely impaired vision in 60 percent.[56] Other occasional findings included rash (maculopapular, petechial, or both), myocarditis, pneumonitis and respiratory distress, hearing defects, an erythroblastosis-like picture, thrombocytopenia, lymphocytosis, monocytosis, and nephrotic syndrome. These signs now are known to be most typical of the severe form of the infection in the absence of treatment.

The often subclinical nature of congenital toxoplasmosis in the newborn was shown in a French prospective study of 154 mothers who had acquired *Toxoplasma* infection during pregnancy and did not receive treatment.[46] Nine pregnancies (6%) ended in stillbirth, and 85 (55%) resulted in the birth of infected live-born infants. Of the live-born infants who were infected, 64 (75%) had subclinical infection, 14 (16%) had mild disease, and only 7 (8%) had clinically obvious severe disease at birth.[46,144]

TABLE 235–1 Signs and Symptoms Occurring before Diagnosis or during the Course of Untreated Acute Congenital Toxoplasmosis*

Signs and Symptoms	Frequency of Occurrence† in Patients with	
	Neurologic Disease‡	*Generalized Disease*§
Infants	*N* = 108	*N* = 44
Chorioretinitis	102 (94)	29 (66)
Abnormal spinal fluid	59 (55)	37 (84)
Anemia	55 (51)	34 (77)
Jaundice	31 (29)	35 (80)
Splenomegaly	23 (21)	40 (90)
Convulsions	54 (50)	8 (18)
Fever	27 (25)	34 (77)
Intracranial calcification	54 (50)	2 (4)
Hepatomegaly	18 (17)	34 (77)
Lymphadenopathy	18 (17)	30 (68)
Vomiting	17 (16)	21 (48)
Hydrocephalus	30 (28)	0 (0)
Diarrhea	7 (6)	11 (25)
Pneumonitis	0 (0)	18 (41)
Microcephalus	14 (13)	0 (0)
Eosinophilia	6 (4)	8 (18)
Rash	1 (1)	11 (25)
Abnormal bleeding	3 (3)	8 (18)
Hypothermia	2 (2)	9 (20)
Cataracts	5 (5)	0 (0)
Glaucoma	2 (2)	0 (0)
Optic atrophy	2 (2)	0 (0)
Microphthalmos	2 (2)	0 (0)
Children ≥4 years old	*N* = 70	*N* = 31
Mental retardation	62 (89)	25 (81)
Convulsions	58 (83)	24 (77)
Spasticity and palsies	53 (76)	18 (58)
Severely impaired vision	48 (69)	13 (42)
Hydrocephalus or microcephalus	31 (44)	2 (6)
Deafness	12 (17)	3 (10)
Normal	6 (9)	5 (16)

**In 152 infants and 101 of these same patients after ≥4 years of follow-up.*

‡Patients with central nervous system diseases in the first year of life.
§Patients with non-neurologic diseases during the first 2 months of life.
Modified from Eichenwald, H. G.: A study of congenital toxoplasmosis, with particular emphasis on clinical manifestations, sequelae, and therapy. In *Siim, J. C. (ed.): Human Toxoplasmosis. Copenhagen, Munksgaard, 1960, p. 44.*

The risk of transmission to the fetus varies significantly with the trimester of gestation in which the mother becomes infected. For untreated women, the rate is approximately 25 percent in the first trimester, 54 percent in the second trimester, and 65 percent in the third trimester; these figures are minimal estimates derived from placental isolation studies.[46] In contrast, the severity of clinical disease in congenitally infected infants is related inversely to the gestational age at the time of primary maternal infection. In two studies from France,[34,46] severe disease or fetal/neonatal death occurred in approximately 40 to 79 percent of infants born to mothers with first-trimester infection, in 15 to 18 percent with second-trimester infection, and in 0 to 3 percent with third-trimester infection.

Another French prospective study of 210 congenitally infected infants born to mothers who were identified to have primary infection acquired during pregnancy revealed significant morbidity in 94 newborns.[34] Overall, 2 (0.9%) cases were fatal, 21 (10%) were severe, and 71 (33.8%) were mild; 116 cases were asymptomatic. Approximately 40 to 45 percent of the mothers in this study had been treated with spiramycin during pregnancy. These observations confirm that most congenital infections are subclinical at birth. Obvious manifestations occur infrequently. In the same study by Couvreur and associates,[34] 116 infants initially were thought not to be infected on the basis of a routine newborn physical examination. On more intensive examination, however, 39 (34%) of them were found to have one or more abnormalities. Twenty-two (19%) had abnormal CSF on lumbar puncture, 17 (15%) had chorioretinitis on indirect ophthalmoscopic examination, and 10 (9%) had intracranial calcifications on head radiographs or computed tomography (CT) scans. Guerina and colleagues[76] made remarkably similar observations in the congenitally infected newborns that they identified in New England by heel-stick blood sampling.

Some infected children without overt disease as neonates may escape serious sequelae of the infection; however, a significant number (24 to 85%) develop chorioretinitis, strabismus, blindness, hydrocephalus or microcephaly, cerebral calcifications, developmental delay, epilepsy, or deafness months or years later. Three studies provide data that define the incidence of these late sequelae.[96,97,99]

In a study from Paris,[99] 26,402 apparently healthy infants were tested routinely for serologic evidence of *Toxoplasma* infection at 10 months of age. Of these infants, 51 had positive serologic results for *Toxoplasma*, indicative of congenital infection. None had been treated for *Toxoplasma* infection in infancy. Of the 51, 5 were found to have chorioretinal scars by ophthalmologic examination, and chorioretinal lesions had developed in another 4 children by the time they reached 4 years of age, the longest period of follow-up. Some eventually lost functional vision in one eye. Three had intracranial calcifications.

Similarly, in a study from Holland in which a cohort of 1821 pregnant women were screened serologically, 12 congenitally infected infants were detected, and 11 of them were monitored for 20 years.[96,97] Of the 11, 5 were treated as neonates for 1 month only, and 6 were not. Of the 5 treated infants, 4 had eye disease as neonates, and 1 had parasites in CSF, which prompted therapy. Nine of these 11 (82%) had chorioretinal scars by the time that they reached 20 years of age, and 4 of them, including 2 who were initially normal, had severe visual impairment or blindness in one eye. The onset of disease leading to blindness occurred as late as 18 years of age. No neurologic or cognitive sequelae were observed.

The results of this prospective study are similar to those previously reported by Wilson and associates[187] from Alabama in a retrospective analysis of patients from the United States. Over a mean follow-up period of 8.3 years, sequelae developed in 11 of 13 congenitally infected children (85%) who had no signs of disease on detailed examination in the newborn period. Sequelae included chorioretinal lesions in 11 children (85%), severe neurologic disability in 1 child (8%), and mental retardation in 2 children (15%). Sequelae first were noted at ages ranging from 1 month to 9 years. These 13 children were detected either as a result of routine screening of cord serum for IgM antibodies to *Toxoplasma*,[9] performed because acute *Toxoplasma* infection was diagnosed in the mother,[2,188] or as a result of nonspecific findings in the neonatal period (2 were small for gestational age, and 1 had transient borderline thrombocytopenia).

That treatment may decrease the frequency or severity of sequelae is suggested by the Alabama and Paris studies, in which chorioretinitis developed only in untreated infants between 10 months and 4 years old. Taken together, these data indicate that most congenitally infected children who receive no or brief treatment, including children with inapparent infection as neonates, experience untoward sequelae during childhood. Current treatment regimens—prolonged for at least 1 year and often initiated before birth—seem to be associated with substantially less frequent and severe sequelae (see section on treatment).

Congenital toxoplasmosis may mimic or coexist with infection by other organisms. It must be differentiated from other perinatal infections caused by cytomegalovirus, herpes simplex virus, rubella virus, *Treponema pallidum* (syphilis), human immunodeficiency virus type 1 (HIV-1), lymphocytic choriomeningitis (LCM) and certain bacteria (e.g., *Listeria*). Herpesvirus and cytomegalovirus infection, syphilis, and rubella may cause chorioretinitis; cytomegalovirus and HIV-1 may cause encephalopathies associated with cerebral calcifications. Degenerative encephalopathies and storage diseases in older children also may resemble congenital toxoplasmosis.

Many infants or preschool children with coexisting HIV infection and toxoplasmosis have been reported.[126,127] In at least six of these patients, HIV and *Toxoplasma* infection seem to have been acquired in utero. Of these six patients, all but one had clinical evidence of CNS disease, and in most of these children, the CNS disease was associated with other findings common in congenital infection. These findings included hepatosplenomegaly, fever, and chorioretinitis, and were evident at birth (one infant) or developed by the time the infant reached 4 months of age. Two of the other infants remained asymptomatic; one was treated for *Toxoplasma* infection, and the other was not treated. One additional infant who acquired HIV infection at 18 months of age from a blood transfusion died at 5 years of age of toxoplasmic encephalitis. The findings in this patient resembled those in adults with AIDS and toxoplasmic encephalitis.[105] The advent of highly active antiretroviral therapy (HAART) along with the widespread use of trimethoprim-sulfamethoxazole for *Pneumocystis jiroveci* pneumonia prophylaxis has decreased greatly the frequency of clinical toxoplasmic encephalitis in children and adults with HIV.

OCULAR TOXOPLASMOSIS

In active congenital toxoplasmosis, the retinal lesions usually are bilateral.[125] In older children, chorioretinitis may involve only one eye and may be the sole manifestation of congenital toxoplasmosis. Toxoplasmic chorioretinitis, even in older children and adults, usually is considered to be the result of congenital infection.[132] A report of 38 children diagnosed with symptomatic chorioretinitis between 2002 and 2004 in the United Kingdom confirmed that 58 percent of cases were the result of congenital infection.[69] In some studies, *Toxoplasma* infection has accounted for 5 percent of severe visual impairments in children.[90] Active lesions on the fundus appear as white or yellowish foci with elevated, edematous margins surrounded by a zone of hyperemia (Fig. 235–3). Cells and fibrinous exudate in the vitreous may obscure the fundus. Older lesions appear as glial scars, and in

areas in which the retina has been destroyed, the choroid and sclera are visible. Around the depigmented areas, deposition of pigment from the destroyed retina is present. The position of the lesion may be macular, juxtapapillary, or peripheral.

Patients may experience loss of central vision (caused by a perimacular lesion), hazy vision (caused by accumulated exudate), or "floaters" (caused by reactivation of peripheral foci). Neonates or infants with toxoplasmic eye disease may have microphthalmos, small corneas, posterior cortical cataract, anisometropia, strabismus, and nystagmus.[125] Strabismus and nystagmus in a child of any age should raise the possibility of congenital toxoplasmosis. The appearance of lesions in the fundus is not specific for toxoplasmosis. Similar lesions may occur with other, less common granulomatous diseases in the eye, such as toxocariasis, LCM virus, cat-scratch disease, and tuberculosis. Chorioretinitis may be recurrent, most commonly with reactivation at the margins of preexisting lesions.

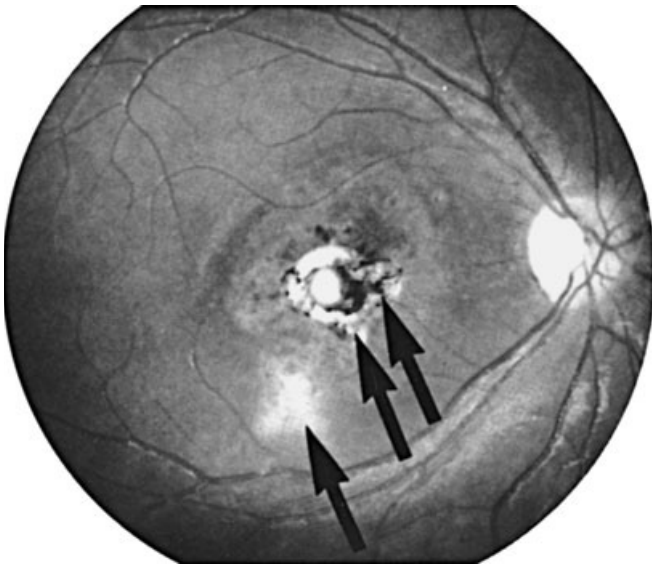

Figure 235–3 Example of active and quiescent chorioretinitis caused by congenital toxoplasmosis in a 12-year-old patient. The active lesion *(single arrow)* is a satellite of an old chorioretinal scar *(two arrows). (From Mets, M., Holfels, E., Boyer, K. M., et al.: Eye manifestations of congenital toxoplasmosis. Am. J. Ophthalmol.* 122*:309-324, 1996. Published with permission from the* American Journal of Ophthalmology. *Copyright © by The Ophthalmic Publishing Company.)*

LABORATORY DIAGNOSIS

Acute infection can be diagnosed by isolation of *T. gondii* from blood or body fluids; demonstration of tachyzoites in histologic sections of tissue or cytologic preparations of body fluids; characteristic lymph node histology; demonstration of *Toxoplasma* cysts in the placenta, fetus, or neonate; detection of the *Toxoplasma* genome by polymerase chain reaction (PCR) in body fluids; and characteristic serologic test results.[15,129,188] Each of these methods is discussed, but serologic tests are emphasized because they are the most common method of establishing the diagnosis (Table 235–2).[188]

SEROLOGIC METHODS

Measurements of IgG Antibody

The most useful tests for detection of IgG antibodies to *Toxoplasma* include the Sabin-Feldman dye test,[156] indirect immunofluorescent antibody (IFA) test, agglutination tests, and ELISA. Titers in ELISA are expressed in different terms for different commercial kits, precluding a discussion of IgG ELISA titers per se in relation to the diagnosis of acute infection.[49,180,188] In these

TABLE 235–2 Guidelines for Interpretation of Serologic Tests for Toxoplasmosis

IgG	IgM	IgG Avidity	Interpretation
Positive	Negative	—	Remote infection, immune. IgG avidity testing is best used when both IgG and IgM are positive, and timing of infection is crucial, as in pregnancy (see below) For evaluation of infection in the newborn, false-negative IgM occurs in approximately 25% of cases. If infection is suspected in this setting, further testing (dye test, IgM EIA, IgA EIA, IgE EIA/ISAGA, PCRs, ideally with paired maternal serologies—see text) is necessary in a reference laboratory (*Toxoplasma* Serology Laboratory, Palo Alto Medical Foundation, 860 Bryant Street, Palo Alto, CA 94301, 415-326-8120)
Positive	Positive or equivocal	High	Infection within the past 18 mo, but likely >12 wk ago. If pregnant and beyond first trimester, consider sending specimen to reference laboratory for dye test, repeat IgG avidity and IgM EIA, IgA EIA, IgE EIA/ISAGA, and AC/HS testing (see above)
Positive	Positive or equivocal	Low	Infection within the past 12 wk. Consider sending specimen to a reference laboratory (see above) to time infection more accurately (dye test, repeat IgG avidity and IgM EIA, IgA EIA, IgE EIA/ISAGA, and AC/HS) in the setting of pregnancy
Equivocal	Negative	—	Indeterminate. Test a new specimen or consider a different assay (IFA or ELISA)
Equivocal	Equivocal	—	Indeterminate. Test a new specimen or consider a different assay (IFA or ELISA)
Equivocal	Positive	—	Acute infection or false-positive IgM. Test a second specimen; if IgG becomes positive or remains equivocal, consider sending specimen to a reference laboratory to time infection more accurately (dye test, IgG avidity, IgM EIA, IgA EIA, IgE EIA/ISAGA, AC/HS—see text) in the setting of pregnancy
Negative	Negative	—	No evidence of *Toxoplasma* infection. Not immune
Negative	Equivocal	—	Either false-positive IgM result or possible recent infection. Obtain a new specimen and retest. If infection is recent, IgM and IgG should become positive, with low IgG avidity. If repeat testing is still IgG negative and IgM equivocal, patient is likely uninfected. Consider IgM ISAGA
Negative	Positive	—	Acute infection or false-positive IgM. Repeat testing on new specimen. If results the same, likely a false-positive IgM. Consider IgM ISAGA

AC/HS, differential agglutination test; EIA, enzyme immunoassay; ELISA, enzyme-linked immunosorbent assay; IFA, immunofluorescence assay; ISAGA, immunosorbent agglutination assay; PCR, polymerase chain reaction.

tests, IgG antibodies appear within the first week of primary infection and reach peak titers (usually ≥1:500) within 1 to 2 months; detectable titers usually persist for life. Although the dye test is the most reliable method, it is available in only a few reference laboratories. IFA test and ELISA are the most widely available and, when properly performed, yield results similar to those obtained with the dye test; however, many laboratories use commercially available kits that are not consistently reliable. Some sera that contain antinuclear antibodies yield false-positive IFA results. The direct agglutination tests that currently are available use formalin-fixed tachyzoites or antigen-coated latex particles, are simple to perform, and are accurate.[164,188]

Initially after primary infection occurs, the avidity of IgG antibody for *T. gondii* antigen is low. Urea dissociates low-avidity antibodies, and a test has been developed that determines the percentage of antibodies that resist elution by 6 mol/L urea. This test is useful in the first 12 weeks of gestation in that the presence of high-avidity antibodies excludes the acquisition of infection in the previous 3 months.[23,188]

Other tests vary in their reliability. Indirect hemagglutination is widely available, but the results frequently are negative in newborns with congenital infection.[188] This test should *not* be used for screening pregnant women because detectable increases in titer are delayed compared with the increases detected by ELISA and by the dye, IFA, and agglutination tests. Meaningful interpretation of changes in titer on sequential sera requires that assays on each sample be performed in the same run by a reliable laboratory.[188]

Measurements of IgM Antibody

IgM antibodies are detected most commonly by IgM IFA, IgM immunosorbent agglutination assay (ISAGA), or IgM ELISA. IgM antibodies appear in the first week of primary infection and peak within 1 month. Depending on the sensitivity of the method used, IgM antibodies may be demonstrable for 2 to 3 months or 1 year or longer. IgM ELISA and IgM ISAGA are much more sensitive than IgM IFA. Absence of IgM ELISA or IgM ISAGA antibodies in an immunologically normal older child (>1 year old) or adult essentially rules out a recently acquired infection.[187] A negative IgM IFA result is not as sensitive in ruling out recently acquired infection. Of sera that were negative with IgM IFA and obtained from adults who had acquired toxoplasmosis recently, 93 percent were strongly positive in IgM ELISA.[134] IgM IFA detects specific IgM antibody in only 25 percent of infants with proven congenital infection, whereas IgM ELISA detects antibody in approximately 75 percent of such cases.[134] The presence of rheumatoid factor or antinuclear antibodies may cause false-positive results in IgM IFA.[2]

The "double-sandwich" IgM ELISA avoids the false-positive results caused by the presence of rheumatoid factor, which the infant can produce in utero, and the false-negative results caused by competition from the high levels of maternal IgG antibody that occur in IgM IFA.[133,188] In addition, the false-positive results in IgM IFA caused by antinuclear antibodies are not found in IgM ELISA.[2,133]

ISAGAs are used widely in Europe. Similar to IgM ELISA, they capture IgM on a solid surface, detect specific IgM, and involve the addition of whole formalin-fixed organisms or *Toxoplasma* antigen–coated latex particles.[48,142] These assays are available commercially and give results comparable to those of IgM ELISA, are simpler to perform, and do not require expensive equipment.

Measurements of IgA and IgE Antibodies

Demonstration of IgA and IgE antibodies in the fetus or newborn by ELISA and ISAGA seems to be at least comparable in sensitivity for the diagnosis of congenital *Toxoplasma* infection compared with demonstration of IgM antibody.[42,167,190] The IgA test also seems to be more sensitive than the IgM test for detection of acquired infection. Specificity remains an issue, however, so neither IgA/IgE ELISA nor IgA/IgE ISAGA has superseded the IgM test for diagnosis of acquired infection. IgA and IgE antibodies persist longer than of IgM and may be useful in cases of subacute illness or when IgM titers are low.

Differential Agglutination

Acetone-fixed and formalin-fixed *T. gondii* tachyzoites may yield differing agglutination titers depending on the acuity of the infection. The test based on this phenomenon is called the AC/HS differential agglutination test.[38] Generally, a disproportionately high agglutination titer with acetone-fixed organisms suggests acute infection; a disproportionately high titer with formalin-fixed organisms suggests chronic infection. Interpretative norms for this test have been established.[38] This test, when combined with the dye test, IgM ELISA, IgA ELISA, IgE ELISA/ISAGA, and avidity studies, yields a "toxoplasmic serologic profile" that permits the most accurate evaluation of infection acuity in pregnant women,[131,188,191] and often can resolve any inconclusive or discrepant results obtained in a hospital or commercial laboratory.

NONSEROLOGIC METHODS

Nonserologic methods are used less commonly for establishing the diagnosis of *Toxoplasma* infection because they are not widely available and require tissue specimens.[188]

Isolation of the Organism

Isolation of *Toxoplasma* from blood or body fluids (e.g., CSF) establishes that the infection is acute. In the case of a neonate, isolation from the placenta or the infant's tissues is sufficient to diagnose congenital *Toxoplasma* infection. In 90 percent of placentas from which *T. gondii* is isolated, congenital infection occurs.[144] Isolation of *Toxoplasma* from the tissues of older children or adults may reflect, however, only the presence of latent infection (cyst form). The organism may be isolated by inoculation of body fluids, leukocytes, or tissue specimens into the peritoneal cavities of mice or into tissue cultures. Specimens should be processed and inoculated immediately; however, tissue and blood may be stored at 4° C overnight. Freezing and thawing or formalin treatment kills the organism. Establishing definitive diagnosis by isolating *Toxoplasma* from tissues usually takes 4 to 6 weeks by mouse inoculation; tissue culture is less sensitive for recovering *Toxoplasma*, but the results are available sooner.

Histology

Demonstration of tachyzoites, but not cysts, in tissue sections or smears of body fluids (e.g., CSF) establishes a diagnosis of acute infection. The organism may be difficult to see with routine stains. The peroxidase-antiperoxidase technique is exquisitely sensitive and has been used with a high degree of sensitivity and specificity to show the organism in the CNS of patients with AIDS.[30] In older children and adults, the histopathologic changes in toxoplasmic lymphadenitis are sufficiently distinctive to enable pathologists to make a presumptive diagnosis of acute acquired toxoplasmosis (see section on pathology).[51,177] Histologic demonstration of cysts establishes that a patient has *Toxoplasma* infection, but they are diagnostic of toxoplasmosis only in the placenta, fetus, or newborn.

Antigen-Specific Lymphocyte Transformation

Lymphocyte transformation in response to *Toxoplasma* antigens is a specific and sensitive indicator of previous *Toxoplasma* infection in adults, and has been used successfully to diagnose congenital *Toxoplasma* infection in infants 2 months or older.[116,168,185] Lymphocyte transformation often is absent in the newborn period, however, particularly in more severely affected infants, because of specific immune tolerance.[116,122]

Polymerase Chain Reaction

Amplification of the B1 genome of *T. gondii* DNA by PCR permits detection of the parasite in body fluids or tissues such as CSF, amniotic fluid, and lymph nodes.[29,75,78,153,177] Experience with the test in France, where PCR of amniotic fluid was compared with the results of percutaneous umbilical blood sampling in 339 pregnant women, has shown that agreement of the two methods is almost 100 percent for the diagnosis of intrauterine infection.[78] In view of the considerably lower risk accompanying amniocentesis than percutaneous umbilical blood sampling, and the fact that amniocentesis potentially can be performed earlier in gestation, this diagnostic procedure seems to be a major advance in prenatal diagnosis. A prospective study in France has shown, however, that only 48 (64%) of 75 amniotic fluid specimens from congenitally infected infants were positive by PCR on a single sample obtained soon after maternal seroconversion. The test had a 100 percent positive predictive value, but a single negative assay did not rule out fetal infection.[153]

DIAGNOSIS IN SPECIFIC CLINICAL SITUATIONS

Acute Acquired Toxoplasmosis

If IgM and IgG antibody are not detectable, the diagnosis of acute *Toxoplasma* infection in an immunocompetent child virtually is excluded.[188] The diagnosis of recently acquired infection is confirmed if seroconversion from a negative to a positive titer is noted, or if a serial fourfold increase in titer to high levels is observed when sera drawn at 3-week intervals are run in parallel. A single high titer in any test is not diagnostic. A dye test or IFA titer of 1:500 or greater in the presence of a high IgM antibody titer probably is diagnostic of recent acute infection. Because IgM can remain positive for 18 months after acute infection, a serum IgG avidity test can be performed to time the infection more accurately. Low IgG avidity suggests infection has occurred within the past 12 weeks, whereas high avidity suggests more remote infection. The absence of IgM antibodies in IgM ELISA or IgM ISAGA essentially excludes the diagnosis of acute infection. In contrast, the absence of IgM antibodies in IgM IFA does not mean that the infection is not acute; in one series, 25 percent of results in adults with acute infection were negative by IgM IFA.[134]

Toxoplasma Infection in Immunodeficient Children

Serologic tests should be done to identify individuals at risk of acquiring toxoplasmosis, such as recipients of organ, stem cell, and bone marrow transplants. The available serologic tests may be inadequate to detect acute active infection in some immunodeficient patients because their antibody response may be abnormal, which is especially the case in stem cell and bone marrow transplant recipients.[44,111] Experience in the Palo Alto, California, reference laboratory has revealed that acute infection may be present in patients with AIDS and in bone marrow transplant recipients without any demonstrable IgM antibody, and in some immunocompromised patients who have little or no IgG antibody.[106] In patients with AIDS and active *Toxoplasma* infection, antibody titers in the modified direct agglutination test[49] may be elevated in the presence of low or undetectable titers in the dye or IFA test.[113] These and other immunodeficient patients can have progressive, lethal toxoplasmosis. In almost all cases, encephalitis, brain abscesses, or both are the predominant findings; hepatic involvement, pneumonitis, and myocarditis may be present. A high index of suspicion is necessary in these patients, and immunoperoxidase staining of appropriate biopsy specimens often is required to establish the diagnosis. Real-time PCR may be a valuable aid in these situations, although tissue immunoperoxidase staining remains the most reliable test.[29]

Toxoplasma Infection in Pregnant Women

Toxoplasma infection acquired during pregnancy is associated with clinical signs (e.g., lymphadenopathy) in only 10 to 15 percent of patients. The fetus is at risk, however, for contracting the infection regardless of whether the mother is symptomatic. To detect acute infection in a pregnant woman in the absence of a routine screening program in which serologic tests are performed periodically throughout pregnancy, a suitable test for IgM antibody (IgM ELISA or IgM ISAGA) should be performed if other serologic tests are positive at any titer. If a suitable IgM antibody test is unavailable, and the original serum contains IgG antibodies, the IgG antibody test should be repeated in 3 weeks, in parallel with the original serum, to determine whether the titer is stable or increasing.[188] More recent experience with IgG avidity testing on a single maternal specimen suggests this additional tool may be helpful in attempting to define maternal infection as acute (within the previous 12 weeks) or remote.[23]

If the IgM ELISA or IgM ISAGA result is negative, and the IgG antibody titer is stable and less than 1:500, no further evaluation is necessary. Because IgG titers usually stabilize at high levels (e.g., the dye test or IFA titer ≥1:500) at 6 to 8 weeks or longer after acquisition of the infection, if the dye test or IFA titer is 1:500 or less and stable (regardless of IgM antibody titer), infection was acquired at least 4 weeks, and probably more than 8 weeks, before the serum was obtained. In the United States, an asymptomatic woman commonly is evaluated for the first time more than 8 weeks after conception, however. If her dye test or IFA titer is 1:500 or greater, her IgM ELISA or IgM ISAGA result is negative, and no significant increase in titer in any test can be shown, her infection almost certainly was acquired before conception. In women with elevated IgM titers or increasing IgG test titers, infection possibly was acquired during pregnancy. A complete toxoplasmic serologic profile[131] in a reference serologic laboratory is recommended to settle the question.

Fetal Diagnosis

As noted earlier, severe disease almost always is associated with primary maternal infection in the first or second trimester of pregnancy, but only 25 percent and 54 percent of such maternal infections result in fetal infection. These rates in exposed fetuses may be reduced by half by maternal treatment with spiramycin. Identification of cases in which the fetus already is infected permits a parental decision to terminate the pregnancy or treat the fetal infection more aggressively with pyrimethamine-sulfadiazine.

Studies by workers in Paris have established an approach that allows establishment of definitive diagnosis and treatment of fetal infection in utero.[36,47,78] These researchers initially sought to establish the diagnosis of fetal infection at 20 to 29 weeks of gestation by isolation of *Toxoplasma* from amniotic fluid or from fetal blood obtained by percutaneous umbilical blood sampling and use of the sensitive mouse inoculation method. Prenatal diagnosis was attempted in 746 pregnancies in which seroconver-

sion occurred near the time of conception or before the 26th week of gestation. In 39 of these pregnancies, fetal infection was diagnosed in utero. *Toxoplasma* was isolated from fetal blood alone in 12 cases, from amniotic fluid alone in 7 cases, and from both in 15 cases, for a total of 34. *Toxoplasma*-specific IgM antibodies were detected in fetal blood in only 9 cases with the highly sensitive ISAGA, and none was positive before 24 weeks of gestation. By follow-up examination until 3 months postpartum or by examination of aborted fetal tissue, a total of 42 cases were proved to have been infected. These researchers were able to detect 39 (93%) of 42 cases of fetal infection occurring before the 26th week of gestation; no false-positive diagnoses occurred.

These investigators subsequently extended their series and reported that a definitive diagnosis of infection was established in utero in 80 (90%) of 89 cases in which the fetus was infected.[79] These results may not be reproduced easily by other investigators for various reasons: the ability to detect maternal infection soon after it occurs depends on monthly monitoring for new maternal infection, sampling of fetal blood and amniotic fluid on more than one occasion, the use of optimal laboratory methods and conditions, and experience in these procedures.

With the use of PCR to amplify the B1 gene of *Toxoplasma* in amniotic fluid obtained after 18 weeks of gestation, these same investigators were able to achieve a sensitivity and specificity for the diagnosis of fetal infection that approached 100 percent.[78] In the more recent multicenter collaborative French study, in which only single specimens were studied, the specificity and positive predictive value remained 100 percent, but the sensitivity was only 64 percent.[153] The sensitivity and specificity for this test as specimens currently are processed and handled in the United States remains to be determined.

Most of the mothers in these French studies had received treatment with spiramycin soon after primary maternal infection was diagnosed, with the intention of continuing therapy until delivery. In contrast to its beneficial effect on maternal-to-fetal transmission, spiramycin does not seem to decrease the severity of fetal infection after it has been established. The impetus for proving fetal infection in early to middle gestation is to allow for intervention either to terminate the pregnancy or to treat the fetus more aggressively. In an extended series of 89 infected fetuses reported by Hohlfeld and colleagues,[79] 34 pregnancies were terminated at the request of the parents. In each of these cases, which were selected either for detectable CNS disease on ultrasound examination or for onset of maternal infection before 12 weeks of gestation, brain necrosis was found on examination of tissue.

These data indicate the value of specifically identifying fetuses that truly are infected and are at high risk for acquiring severe disease because selective termination of these pregnancies allowed successful completion of most pregnancies in which fetal infection did not occur. In addition to the 34 terminated pregnancies with proven fetal infection, 52 pregnancies with 55 offspring were carried to term. In these 52 pregnancies, 43 had fetal infection proven prenatally, and 9 additional offspring were found to be infected by postnatal examination. In the 43 pregnancies in which prenatal diagnosis of fetal infection was established, more aggressive therapy with pyrimethamine and a sulfonamide compound alternating with spiramycin was given in the latter part of pregnancy. This treatment seemed to decrease the number of parasites, as indicated by an approximate 50 percent reduction in the fraction of placentas from which *Toxoplasma* was isolated at delivery compared with cases in which no treatment or spiramycin alone was given.

Regarding clinical outcome, the authors interpreted their data to indicate that such treatment decreased the incidence of severe disease.[79] This conclusion was based, however, on a retrospective comparison with a group of historical controls in which data regarding fetal deaths and termination of pregnancy were unavailable. Because pregnancies with proven or probable severe fetal infection were terminated selectively at the parents' request, one cannot conclude with certainty that the outcome of the infants born to mothers with first-trimester infection was improved by the administration of more aggressive therapy; the outcome of infants born to mothers with second-trimester infection seems to have been improved.[184] A meta-analysis of selected published cohorts on prenatal treatment of congenital toxoplasmosis showed only a weak association between early treatment and a reduced risk of acquiring congenital toxoplasmosis.[174]

It would be desirable to have data from studies in which the effects of such therapy are compared directly in a randomized, concurrent study[174,175]; such studies are unlikely to be performed, however. Nonetheless, these published studies have established the utility of an aggressive approach to prenatal diagnosis in allowing physicians to make an accurate, early diagnosis of fetal infection. If the fetus is infected and affected, as determined by ultrasound, a decision for selective termination of pregnancy can be made rationally. Aggressive therapy with pyrimethamine-sulfadiazine may be offered in cases in which termination is not considered desirable, and it may improve the outcome.

Diagnosis of Congenital Toxoplasmosis after Birth

Performing a thorough clinical and laboratory evaluation is necessary to evaluate fully the existence and extent of congenital toxoplasmosis in a newborn (Table 235–3). Demonstration of

TABLE 235–3 Evaluation of a Neonate When Serology of the Mother or Illness of the Neonate Indicates That a Diagnosis of Congenital Toxoplasmosis Is Suspected or Probable

In addition to a careful general examination, the infant is examined by the following:
Clinical Evaluation and Nonspecific Tests
Pediatric ophthalmologist
Pediatric neurologist
Brain CT (data suggest excellent agreement between CT and ultrasound,[99] which can be obtained more quickly and without the need for sedation)
Blood tests
Complete blood cell count with differential and platelet counts
Serum total IgM, IgG, IgA, and albumin
Serum alanine aminotransferase, total and direct bilirubin
CSF cell count, glucose, protein, and total IgG
***Toxoplasma gondii*–Specific Tests**
Newborn serum analyzed for antibody detected by Sabin-Feldman dye test, IgM ISAGA, IgA EIA, IgE EIA/ISAGA (0.5 mL serum to *Toxoplasma* Serology Laboratory, Palo Alto Medical Foundation, 860 Bryant Street, Palo Alto, CA 94301, 415-326-8120)
Newborn blood for inoculation into mice (1-2 mL clotted whole blood in red-topped tube to *Toxoplasma* Serology Laboratory)
Lumbar puncture: CSF dye test and IgM EIA (0.5 mL CSF to *Toxoplasma* Serology Laboratory); consider PCR (1 mL frozen CSF to *Toxoplasma* Serology Laboratory)
Sterile placental tissue (100 g in saline, from fetal side near insertion of cord, no formalin, to *Toxoplasma* Serology Laboratory for subinoculation)
Maternal serum analyzed for antibody detected by dye test, IgM EIA, IgA EIA, IgE EIA/ISAGA, and AC/HS

AC/HS, differential agglutination test; CSF, cerebrospinal fluid; CT, computed tomography; EIA, enzyme immunoassay; ISAGA, immunosorbent agglutination assay; PCR, polymerase chain reaction.

Modified from McLeod, R., Wisner, J., and Boyer, K.: Toxoplasmosis. In *Krugman, S., Katz, S. L., and Gershon, A. A. (eds.): Infectious Diseases of Children. St. Louis, Mosby-Year Book, 1992, p. 539.*

IgM, IgA, or IgE antibody in an infant's blood or CSF at any time is diagnostic of congenital infection if contamination by maternal blood can be reasonably excluded.[188] Specimens obtained after the infant reaches 10 days of age are more reliable in this regard. If the much less sensitive IgM IFA is used, the presence of antinuclear antibody and rheumatoid factor also must be excluded. As mentioned earlier, the detection rate of congenitally infected infants is 25 percent for IgM IFA and 75 percent for IgM ELISA and IgM ISAGA. Data are insufficient for predicting how often IgA and IgE antibodies are detected. IgM antibodies may be demonstrable in the first few days of life or may appear at variable times after birth.

If *Toxoplasma* is not isolated, and IgM, IgA, or IgE antibodies are not detected, follow-up serologic testing is the only means of establishing the diagnosis. Maternally transmitted IgG antibodies may persist for 6 to 12 months or longer, depending on the original titer. The higher the original titer, the longer maternal antibody is detectable in the infant. The presence of IgG antibody at 8 to 12 months of age does not prove that the infant is infected. Synthesis of IgG *Toxoplasma* antibody usually can be shown by the third month of life if the infant is not treated; it may be delayed until the sixth or ninth month if the infant is treated. At the time that the infant begins to synthesize IgG antibody, infection may be documented by computing the specific "antibody load"—the ratio of specific serum antibody titer to the level of serum IgG in the infant.[144] In the absence of infection, the antibody load decreases in the second or third month as the infant begins to produce IgG that does not contain specific *Toxoplasma* antibodies. In the presence of *Toxoplasma* infection, the infant produces specific antibodies, and the antibody load remains the same or increases. Most infected infants who are treated during the first year of life have a substantial increase in antibody after termination of therapy ("serologic rebound").[178] This phenomenon permits the diagnosis to be confirmed in some uncertain cases.

Ocular Toxoplasmosis

Toxoplasma has been estimated to cause 35 percent of cases of chorioretinitis in the United States and central and western Europe.[81,158,172] Acquired toxoplasmosis usually is not accompanied by chorioretinitis. Most cases are thought to result from congenital infection that does not become clinically apparent until after reactivation. This event occurs most commonly in adolescence. Although the presence of chorioretinitis should prompt a search for *Toxoplasma* infection, proof that *Toxoplasma* caused the eye disease often is lacking. The titer of antibody in serum does not correlate with the presence of active lesions in the fundus. Low titers of IgG antibody are the usual finding in patients with reactivation *Toxoplasma* chorioretinitis. IgM antibodies generally are absent.

Toxoplasma probably is excluded as a cause of chorioretinitis if the results of serologic tests are negative in undiluted serum. If the retinal lesions are characteristic, and serologic test results are positive, the diagnosis is probable. If the retinal lesions are atypical, and the serologic test results are positive, the diagnosis of *Toxoplasma* chorioretinitis is less certain because of the increasing prevalence of *Toxoplasma* antibodies with age in the normal population. Finding *Toxoplasma* antibodies in the child's mother supports the possibility of congenital infection, as does detection of intracranial calcification on CT scan of the patient. Demonstration of local antibody production in aqueous humor obtained by paracentesis of the anterior chamber can be used to establish the diagnosis of *Toxoplasma* chorioretinitis in equivocal cases.[144,188] The risk of this procedure in a situation of threatened vision, when weighed against the low risk of a short course of treatment, is such that it seldom is performed.

TREATMENT

The need for therapy and the duration of therapy are determined by the nature and severity of the clinical illness and by the immune status of the infected patient. Antibody titers are not useful indicators of therapeutic response, and an increasing antibody titer soon after discontinuation of therapy ("serologic rebound") is not an indication of therapeutic failure. Specific therapy acts primarily against the tachyzoite form; the drugs currently available do not eradicate the encysted form containing bradyzoites. Close, longitudinal follow-up and supportive interventions are crucial contributors to therapeutic success.

THERAPEUTIC AGENTS

The therapeutic agents used, their dosages, and indications for their use in the management of toxoplasmosis are included in Table 235–4 and discussed next.

Spiramycin

Spiramycin is a macrolide that has been used extensively in Europe to reduce transmission of infection from an acutely infected mother to the fetus in utero.[31] It is concentrated in the placenta and is reported to reduce transmission by 50 to 60 percent. It reduces the ability to isolate the organism from the placentas of definitively infected newborns from 95 to 80 percent.[33] Spiramycin is less effective than pyrimethamine-sulfadiazine in the treatment of congenital infection and toxoplasmic encephalitis.[33,45,159,160] Toxoplasmic encephalitis has developed in patients receiving spiramycin and has been treated effectively with pyrimethamine-sulfadiazine. Toxicities include allergic manifestations, gastrointestinal intolerance, and paresthesias.

Spiramycin apparently does not treat manifestations of *T. gondii* infection in the fetus in utero.[33,45,79,159] It formerly was used in alternate-month regimens with pyrimethamine and sulfadiazine for treatment of congenital toxoplasmosis in France.[144] Spiramycin is not approved by the U.S. Food and Drug Administration, but may be obtained with compassionate clearance by calling 301-827-2127. The manufacturer (Aventis-Pasteur) provides the drug after the diagnosis has been documented and Food and Drug Administration forms have been completed.

Pyrimethamine

Pyrimethamine has been shown to be effective against *T. gondii* in vitro,[121,124] in animal models,[63] and in human infections.[35,37,63,108,124,191] When used in conjunction with sulfadiazine, synergy can be shown. The pharmacokinetics of pyrimethamine have been studied in infants and adults.[124] Pyrimethamine is metabolized in the liver. Its pharmacokinetics are not altered by renal insufficiency, but are affected by concomitantly administered drugs (e.g., phenobarbital). Pyrimethamine toxicities include reversible marrow suppression (most commonly) and allergy. Aplastic anemia, hepatotoxicity, and various allergic manifestations (including Stevens-Johnson syndrome) also have been listed as toxicities of this medication. Pyrimethamine always should be administered in conjunction with leukovorin (i.e., folinic acid) because human cells can use folinic acid for synthesis of nucleic acids, but *T. gondii* cannot.[124]

Leucovorin

Leucovorin (folinic acid) always is administered during treatment with pyrimethamine. Folinic acid has a protective effect for human cells that folic acid does not. Increased doses of leucovorin are used in the event of marrow suppression. Because of the long

TABLE 235–4 Treatment of Toxoplasmosis

Disease	Medication	Dosage	Length of Therapy
Acute acquired—generally not treated unless severe/ persistent symptoms or vital organ damage or host is immunosuppressed	Pyrimethamine *plus*	2 mg/kg/day for 2 days, then 1 mg/kg/ day	4-6 wk or 2 wk after symptoms resolve for normal host; 4-6 wk beyond resolution for immunosuppressed hosts. In AIDS, treat until $CD4^+$ count >200
	Sulfadiazine *plus*	75-100 mg/kg/day divided twice daily (maximum 4 g/day). Consider the lower dose in children >20 kg (see text)	
	Folinic acid	5-20 mg 3 times weekly. Use higher doses if marrow suppression	
Ocular, older child	Pyrimethamine *plus*	2 mg/kg/day for 2 days, then 1 mg/kg/ day (maximum 50 mg/day)	4-6 wk or 2 wk after symptoms resolve
	Sulfadiazine *plus*	75-100 mg/kg/day divided twice daily (maximum 4 g/day). Consider the lower dose in children >20 kg (see text)	Prednisone should be continued until resolution of sight-threatening active chorioretinitis
	Folinic acid *plus*	5-20 mg 3 times weekly	
	Prednisone	1 mg/kg/day divided twice daily	
Congenital	Pyrimethamine *plus*	2 mg/kg/day for 2 days, then 1 mg/kg/ day for 6 mo, then 3 times weekly (M-W-F) for 6 mo	1 yr
	Sulfadiazine *plus*	100 mg/kg/day divided twice daily	
	Folinic acid *plus*	5-10 mg 3 times weekly	
	Prednisone	1 mg/kg/day divided twice daily	Until resolution of elevated CSF protein or sight-threatening active chorioretinitis
Pregnant women—acute infection first 21 wk of gestation	Spiramycin	3 g/day divided twice daily without food	Until fetal infection documented or excluded at 21 wk of gestation. If fetus infected, change to pyrimethamine plus sulfadiazine plus folinic acid until delivery
Pregnant women—fetal infection confirmed (amniotic fluid PCR positive)	Pyrimethamine *plus*	100 mg/day divided twice daily for 2 days, then 50 mg/day	Until delivery
	Sulfadiazine *plus*	3 g/day divided twice daily	
	Folinic acid	5-20 mg/day	

AIDS, acquired immunodeficiency syndrome; CSF, cerebrospinal fluid; PCR, polymerase chain reaction.

half-life of pyrimethamine, continuation of leucovorin therapy for 1 week after discontinuing pyrimethamine is recommended.

Sulfadiazine, Sulfamerazine, and Sulfamethazine

The three sulfonamides sulfadiazine, sulfamerazine, and sulfamethazine (known as *triple sulfa* when used in combination) are the most active of the sulfonamides against *T. gondii*, and are synergistic with pyrimethamine in their activity against *T. gondii*. Of the three, only sulfadiazine is available in the United States. All other sulfonamides are less active in vitro.[121] The sulfonamides are excreted by the kidney, and the dosage must be adjusted for patients with renal insufficiency. Nephrolithiasis can occur in older children and adults, in whom urinary acidification is more effective, and fluid requirements are lower on a weight basis than in infancy. The risk of development of stones in these groups can be reduced by aggressive fluid supplementation (1 to 2 L above maintenance) and urine alkalinization.[26] In older children who weigh more than 20 kg, a dose of 75 mg/kg/day (rather than the conventional 100 mg/kg/day) should be considered because this dose more closely approximates the calculated adult dose based on body surface area. Other sulfonamide toxicities include allergy (including Stevens-Johnson and DRESS syndromes), marrow suppression, and hepatotoxicity.[120a] Sulfonamide pharmacokinetics have been studied in infants.[144]

Clindamycin

Although the effect of clindamycin is delayed, it does have an effect in vitro against *T. gondii* with prolonged time in culture.[140] It also has been shown to be effective in murine models. Clindamycin has been found to be comparable in efficacy to sulfadiazine for the treatment of toxoplasmic encephalitis in adult patients with AIDS when used in a combined high-dose regimen with pyrimethamine.[37,108] High-dose pyrimethamine also is effective alone. It was not compared directly with the other two regimens in the latter study.

Other Antimicrobial Agents

Numerous other antimicrobial agents have been shown to be effective in vitro or in animal models against either tachyzoites or encysted bradyzoites,[3-6,80,82] but their role, if any, in the treatment of human disease remains to be defined. Atovaquone (5-hydroxynaphthoquinone) was effective against bradyzoites within cysts in vitro.[82] Forty percent of patients with AIDS had a relapse of toxoplasmic encephalitis, however, while being treated with this antimicrobial agent. Other antimicrobial agents with an effect on *T. gondii* in vitro or in vivo include cycloguanil[80]; artemisinin[80]; pyrimethamine-sulfadoxine (Fansidar)[121]; rifabutin[7]; trovafloxacin (no longer available owing to liver toxicity)[92]; and the newer macrolides clarithromycin, azithromycin, and roxithromycin.[3,5,6]

Because the activity of sulfamethoxazole is less than that of sulfadiazine, trimethoprim-sulfamethoxazole has been considered less effective as treatment for toxoplasmosis. Many investigators have used this combination successfully, however, to treat toxoplasmic encephalitis in adults with AIDS. Doses of trimethoprim-sulfamethoxazole, as used to prevent *P. jiroveci* pneumonia in the context of HIV infection, also seem to prevent episodes of reactivated toxoplasmosis.[24] A randomized controlled trial has shown that trimethoprim-sulfamethoxazole is as

effective as pyrimethamine-sulfadiazine in the treatment of isolated ocular toxoplasmosis in young adults.[165] Pyrimethamine combined with sulfadoxine, despite having lower in vitro activity than that of pyrimethamine-sulfadiazine, also has been used in Europe to treat reactivated and congenital infection.[12]

THERAPY IN SPECIFIC CLINICAL SETTINGS

Acquired Toxoplasmosis

Most immunologically normal patients with the lymphadenopathic form of toxoplasmosis do not require specific treatment. Indications for treatment in these cases are the presence of severe and persistent symptoms or damage to vital organs. Because of the high incidence of severe morbidity and mortality in immunocompromised patients, toxoplasmosis should be treated in this population. Most immunocompromised patients in whom the diagnosis is established ante mortem improve when specific therapy is administered. The major problem lies in establishing the diagnosis early enough to institute treatment.

The optimal duration of specific therapy for toxoplasmosis is unknown. Patients who seem to be immunologically normal, but who have severe and persistent symptoms or damage to vital organs should receive specific therapy for 2 to 6 weeks, provided that symptoms resolve. In immunocompromised patients, therapy should continue at least 4 to 6 weeks beyond complete resolution of all signs and symptoms of active disease. Careful follow-up of these patients is imperative because relapses may occur and require prompt re-institution of therapy. In patients with AIDS in whom toxoplasmosis develops, suppressive therapy with pyrimethamine-sulfadiazine, pyrimethamine-clindamycin, or trimethoprim sulfamethoxazole should be continued for life, or until immune reconstitution has been sustained for at least 6 months.

Pregnant Women

Treatment of an acutely infected woman during pregnancy may prevent transmission of the infection to her fetus. The rationale for such treatment is derived from the observation that the lag period between the onset of maternal infection and acquisition of infection in the fetus may be significant. Data from France,[45,46] where women were treated with spiramycin, and from Austria[8,9] and Germany,[98] where women were treated with pyrimethamine and sulfonamides, indicate that the incidence of congenital infection in the offspring of mothers treated during gestation is at least 50 percent less than that in the offspring of untreated mothers. None of these studies was controlled rigidly. A meta-analysis including 20 cohorts with 1721 infected mothers and 506 infected children suggested a reduction in the incidence of transmission (odds ratio 0.48, 95% confidence interval 0.28 to 0.80) was achieved if therapy was started within 3 weeks of maternal seroconversion.[174] These results combined with the numerous women studied by the group from France (154 untreated and 388 treated patients) strongly suggest that intrauterine treatment does reduce the incidence of transmission of maternal infection to the fetus.[51,167] The meta-analysis failed to show that intrauterine treatment ameliorated the manifestations of congenital infection in children who were born infected, but the large single-site studies from France suggest a benefit.

Spiramycin treatment of pregnant women with recently acquired primary infection should be instituted empirically in the hope of preventing spread of infection to the fetus. When fetal infection has occurred, however, maternal treatment with spiramycin does not seem to alter the evolution and severity of disease in the fetus, which is why evaluation of a potentially exposed fetus by PCR amplification of amniotic fluid permits informed decisions to be made about termination of pregnancy or treatment of the fetus in utero with pyrimethamine-sulfadiazine.

Congenital Infection

POSTNATAL TREATMENT

Data regarding the efficacy of postnatal treatment of infants with congenital *Toxoplasma* infection are becoming available. Uncontrolled studies in humans and controlled studies in experimental animals[144] have been interpreted as indicating beneficial effects of postnatal treatment on the development of sequelae in symptomatic and asymptomatic infants with congenital *Toxoplasma* infection. The controlled National Collaborative Treatment Trial is now in progress in Chicago. This study seeks to define optimal therapeutic regimens. Physicians treating patients with congenital *Toxoplasma* infection who are younger than 2.5 months may wish to contact this multidisciplinary group regarding potential enrollment of their patients in that study (773-834-4152).

Outcomes to date from the National Collaborative Treatment Trial are substantially better for most, but not all, infants treated from the neonatal period for 12 months with pyrimethamine-sulfadiazine and leucovorin than for historical controls receiving no or short-course therapy.[117] Signs of active infection resolve within weeks of initiation of treatment. In many children, the appearance of brain CT scans has improved remarkably. Cerebral calcifications have diminished in size or resolved in most such treated children.[139] In conjunction with this improvement in brain CT scans, cognitive function has been in the normal range for 69 percent of treated children.[151,170] Overall, 18 of 66 (27%) children in the National Collaborative Treatment Trial have IQ results less than 70 compared with 86 of 101 (85%) in the reported literature (see Table 235–1).[48,117]

No significant diminution in cognitive function occurs over time, and most treated children function well in regular school classrooms. Although the number of children compared is limited, for a small subset of these children, measures of cognitive function seem to be less than those for their siblings. No sensorineural hearing loss has been ascribable to congenital toxoplasmosis in treated children.[117] Despite the much improved neurologic outlook for most of these children, a subset of children with significant irreversible neurologic damage already present in the perinatal period have manifested profound developmental delay, motor impairment, and seizures. For the most part, these were children with hydrocephalus, high CSF protein, minimal improvement in brain CT scans after shunting, and often substantial delays in shunt placement or needed revision for shunt failure or other intercurrent medical problems.[170] This experience emphasizes the importance of recognizing hydrocephalus and managing it aggressively.

Although treatment during the first year of life arrests all signs of active disease, results in normal cognitive and motor outcomes for most children, and may result in resolution of seizures without recurrence for some treated children, the drugs currently available do not eradicate all cysts containing bradyzoites. In most children, serologic titers of *T. gondii*–specific antibodies rebound in the 3 to 4 months after treatment is discontinued.[117,178]

To date, new retinal lesions have occurred in 17 of 58 children in the National Collaborative Treatment Trial during 3 to 10 years' follow-up after the 1-year course of treatment.[117] These active lesions have responded to brief courses of treatment with pyrimethamine, sulfadiazine, and leucovorin without subsequent loss of visual acuity. Although follow-up durations are shorter, this result contrasts with the almost uniform eventual development of retinal lesions in studies of untreated or briefly treated children.[31,56,96,97,187] We recommend that infected children undergo retinal examination each month for 3 months after

discontinuing treatment around their first birthday, then every 3 months until they are old enough to describe visual symptoms accurately, and then every 6 months. In addition, an ophthalmologic evaluation should be performed promptly for any acute visual signs or symptoms that may be related to recrudescence of congenital ocular toxoplasmosis.[125]

SEQUENTIAL FETAL AND POSTNATAL TREATMENT

Hohlfeld and colleagues[36,79] described outcomes in patients treated in utero with continuing treatment during the first year of life. As noted earlier, however, pregnancies in which fetuses had obvious manifestations on ultrasound examination and most pregnancies with definite first-trimester infection were terminated.

When the French method of initiating aggressive treatment of fetuses in utero was applied, retinal disease was reported in only 3 of 50 such infants monitored to 2 years of age. This finding contrasts with the presence of retinal or neurologic involvement in 50 percent of asymptomatic newborns detected by serologic screening in Massachusetts[76] and in 75 percent of children whose pediatricians referred them to our National Collaborative Treatment Trial for treatment in the perinatal period.[125] A prospective, carefully controlled study (as part of the National Collaborative Study) is under way to compare directly outcomes in infants identified and treated in utero, as detected by systematic neonatal screening and by pediatricians in the neonatal period and then referred. The outcome of pregnancies with infection acquired in the first trimester after in utero treatment also has been reported to be favorable in another study,[13] in which only pregnancies in which the fetus had hydrocephalus were terminated.

Toxoplasmosis and coexistent HIV infection in children is increasingly rare since the advent of HAART. Most children reported with toxoplasmosis and HIV have had congenital toxoplasmosis and have been symptomatic. For such children, therapy with pyrimethamine and sulfadiazine plus folinic acid is recommended in the doses described in Table 235–4. Adult and adolescent patients receiving secondary prophylaxis (i.e., long-term maintenance therapy) for acquired toxoplasmic encephalitis are at low risk for recurrence when they have successfully completed initial therapy, remain asymptomatic with regard to signs and symptoms of toxoplasmic encephalitis, and have a sustained increase in $CD4^+$ T lymphocyte counts of more than 200 cells/μL after receiving HAART (e.g., >6 months).

Although the numbers of patients who have been evaluated remain limited, and occasional recurrences have been reported, on the basis of these observations and inference from more extensive cumulative data indicating the safety of discontinuing secondary prophylaxis for other opportunistic infections during advanced HIV disease, discontinuing long-term maintenance therapy among such patients is a reasonable consideration. The highest risk for relapse seems to occur within the first 6 months of discontinuing secondary prophylaxis. Certain specialists would obtain a magnetic resonance image of the brain as part of their evaluation to determine whether discontinuing therapy is appropriate. Zidovudine antagonizes the toxoplasmacidal effect of pyrimethamine and its in vitro synergy with sulfonamide. Whether this effect occurs in vivo is unknown.[101]

Prompt initiation of specific treatment in active ocular toxoplasmosis is mandatory to preserve vision. Inflammatory reactions in the vitreous frequently are a major pathogenetic phenomenon in patients with active disease, and in such cases, administration of corticosteroids in addition to specific anti-*Toxoplasma* therapy is recommended strongly.[160] Their use also is recommended for cases of retinochoroiditis involving the macula, maculopapillary bundle, or optic nerve. The initial daily dosage of prednisone is 1 mg/kg orally to a maximum of 75 mg in 24 hours. The equivalent dosage of another corticosteroid may be given. The dosage of corticosteroid may be reduced gradually when the lesion appears to be well demarcated and pigmentation has begun. Some physicians have used systemic or intraocular clindamycin to treat patients in whom the use of corticosteroids and pyrimethamine plus sulfadiazine has failed[171]; its efficacy has not been proved in humans.

PREVENTION

Congenital infection may be avoided by preventing primary *Toxoplasma* infection during pregnancy.[58,114,191] The responsibility of all physicians caring for pregnant women at risk is to inform them of specific hygienic measures (Table 235–5) for avoiding *Toxoplasma* infection. Similar measures are useful for prevention of acquired infection in other settings as well. The effectiveness of a 10-minute education program, offered as part of prenatal care, to reduce the risk of acquiring *Toxoplasma* infection by modifying the behavior of pregnant women with regard to cats, food, and personal hygiene has been shown.[25] Pamphlets that describe methods to prevent toxoplasmosis in pregnant women are available from the March of Dimes (312-435-4007), from Abbott Diagnostics (800-323-9100), and on the Internet (http://www.iit.edu/~toxo/pamphlet).

When primary maternal infection has occurred, several problems are inherent in the secondary prevention of congenital toxoplasmosis by therapeutic abortion or by treatment of the pregnant woman. Because 80 to 90 percent of women with primary *Toxoplasma* infection are asymptomatic, most primary infections are overlooked, unless sequential serologic testing is performed routinely in pregnant women. The cost-effectiveness of routine screening in the prevention of congenital toxoplasmosis is clear in some European countries where screening is mandated by law.[45] In countries with a lower incidence, cost-efficiency has not been proved.[148] In the absence of such data, physicians may choose to screen patients on an individual basis.[185] If screening is undertaken, a reliable serologic test for IgG antibodies (see section on laboratory diagnosis) should be performed before conception occurs or as soon as possible thereafter, and then repeated every 2 to 3 months until the time of delivery. Serologic test results that suggest the acquisition of primary infection during

TABLE 235–5 Prevention of *Toxoplasma* Infection

Prevention of Acquired Infection (Primary Prevention)
Cook meat to medium (66° C [150° F]), smoke it, or cure it in brine
Wash fruits and vegetables before consumption
Avoid touching mucous membranes of the mouth and eyes while handling uncooked meat or unwashed fruits or vegetables
Wash hands and kitchen surfaces thoroughly after contact with raw meat or unwashed fruits or vegetables
Prevent access of flies, cockroaches, and other coprophagous insects to fruits and vegetables
Avoid contact with materials that potentially are contaminated with cat feces, such as cat litter boxes, or wear gloves when handling such materials and when gardening
Disinfect cat litter boxes for 5 min with nearly boiling water
Prevention of Congenital Infection (Secondary Prevention)
Identify women at risk by serologic testing
Treatment during pregnancy results in an approximately 50% reduction in the incidence of infection in infants
Therapeutic abortion prevents birth of an infected infant—consider only for women who acquire infection in the first or second trimester

CHAPTER 236

PNEUMOCYSTIS PNEUMONIA

Walter T. Hughes

Pneumocystis pneumonia (PCP) is an opportunistic infection characterized by a life-threatening bilateral diffuse alveolar disease occurring almost exclusively in the immunocompromised host. Even in fatal cases, the organism and the disease are limited to the lungs. Since 1980, the pneumonia has gained prominence as a major opportunistic infection in infants, children, and adults with acquired immunodeficiency syndrome (AIDS), while continuing as a complication of cancer, congenital immunodeficiency disorders, and organ transplantation. The causative organism is a fungus-like microbe best known as *Pneumocystis carinii*, although some investigators prefer the controversial term *Pneumocystis jiroveci* Frenkel to designate the organism found in human lungs. Effective chemoprophylaxis and treatment are available.

ORGANISM

In 1909, Chagas[22] identified what he interpreted as spherical and sickle-shaped forms of the parasite *Trypanosoma cruzi* in the lungs of experimentally infected guinea pigs. The same organism was found later by Carini[18] in animals with trypanosome infections. In 1912, Delanoe and Delanoe[34] identified this parasite in the lungs of rats and guinea pigs not infected with trypanosomes and proposed an independent genus of *P. carinii*.[74] These and other investigators, including Chagas, subsequently showed that this agent was not related to the trypanosome.[52] *P. carinii* was first found in human lungs as a cause of pneumonitis in 1942,[183] and immunologic studies in 1972[100] showed a difference in *P. carinii* from humans and rats. During the past 2 decades, the application of molecular technology has resulted in extensive data to delineate the genetic diversity of the organism. Researchers have established that *P. carinii* found in each mammalian host is specific for that host.

Although previously considered a protozoan, *P. carinii* generally is accepted as belonging to the Fungi kingdom. In support of the fungal nature of the organism are the observations that ribosomal RNA sequences are homologous to fungi[43]; the dihydrofolate reductase, in contrast to that of protozoa, is not a bifunctional polypeptide with thymidylate synthetase[42]; the cyst wall contains chitin and beta-1,3-glucan[121]; poorly developed mitochondria contain lamellar cristae; and the organism is susceptible to echinocandins.[165] The antifungal drugs amphotericin B, ketoconazole, nystatin, 5-flucytosine, fluconazole, and miconazole have no effect against PCP, whereas the drugs with demonstrated anti–*P. carinii* activity also are antiprotozoan drugs: pentamidine (*Leishmania donovani* and *Trypanosoma gambiense*), trimethoprim-sulfamethoxazole (*Isospora belli*, *Toxoplasma gondii*), and pyrimethamine-sulfadiazine and atovaquone (*T. gondii* and *Plasmodium falciparum*).

Three developmental forms of this organism have been identified by light microscopy: cysts, sporozoites, and trophozoites. Cysts occur in lung tissue or respiratory secretions as spherical or crescent-shaped structures approximately 5 μm in diameter (Figs. 236–1 and 236–2). They may contain eight oval bodies or sporozoites 1 to 2 μm in diameter. A third extracystic pleomorphic structure, called a *trophozoite*, which varies in size from 2 to 5 μm in diameter, is identified in association with cysts. The ultrastructural morphologic features identified by electron microscopy and scanning electron microscopy are well described in the literature.[17,148,151] The major protein component of trophozoites and cysts[57,58] is referred to as the major surface glycoprotein or glycoprotein A, with molecular weight ranging from 95 to 140 kd. Genes encoding the major surface glycoprotein are repeated, highly polymorphic, and distributed among all of the

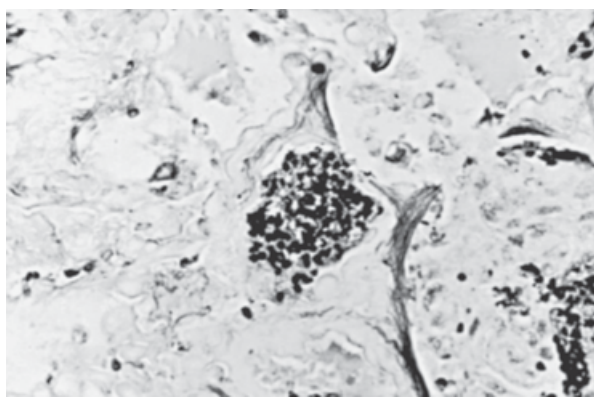

Figure 236–1 Typical cyst forms shown by Gomori silver methenamine stain of lung tissue obtained by open lung biopsy from a 20-month-old child with severe combined immunodeficiency disease (×100).

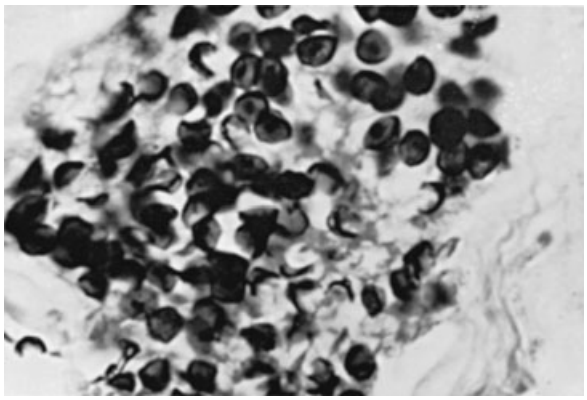

Figure 236–2 Typical cyst forms shown by Gomori silver methenamine stain of lung tissue obtained by open lung biopsy from a 20-month-old child with severe combined immunodeficiency disease (×1000).

14 to 15 chromosomes.[106,189] The major surface glycoprotein is antigenically specific for *P. carinii* of various animal hosts.[55,58,106] This mannose-containing carbohydrate is important in attachment of organisms to mammalian host cells.[180] To date, none of the culture systems reported[7,30,107,123,148] has been established and standardized to provide prolonged propagation and growth of the organism.

Efforts have been made to adopt new nomenclature for *P. carinii*, primarily to distinguish between strains derived from humans and strains from lower mammals. In 1976, Frenkel[49] suggested *P. jiroveci* n. sp. for isolates from humans. During the ensuing 3 decades, this term was not used. In 1988, Hughes and Gigliotti[81] proposed a nomenclature merely designating the host from which the organism was obtained (e.g., *P. carinii*, *humanus*; *P. carinii*, *rattus*). In 1994, Stringer and the Pneumocystis Workshop[177] used DNA sequence data to employ a "special forms" designation (e.g., *P. carinii* f. sp. *hominis*). A subsequent system put forth in 2002 by Stringer and colleagues[177] is currently used by some investigators and designates the human form as *P. jiroveci* Frenkel. Because of issues discussed elsewhere[56,73] and the expected future proposals for change, I continue to use *P. carinii* here to designate the organism in human disease.

TRANSMISSION AND EPIDEMIOLOGY

TRANSMISSION

P. carinii has been recognized in many wild and laboratory animal species over a wide geographic distribution. An association between animal reservoirs and human infection has not been established. Animal-to-animal transmission by the airborne route has been shown in laboratory rats.[69,76] DNA sequences identical to those of *P. carinii* have been detected in ambient air.[190] Genotypic studies of human *P. carinii* isolates in Britain suggest the clustering of specific genotypes in residential areas and are consistent with person-to-person transmission of the organism by the airborne route.[129] Evidence for transmission of *P. carinii* DNA from an infected infant to close hospital contacts has been reported.[185] Before and during World War II, epidemics of interstitial plasma cell pneumonitis secondary to *P. carinii* were recognized in debilitated and premature infants throughout European institutions and nursing homes.[12,164] In 1942, Van der Meer and Brug[183] identified *P. carinii* in the lungs of humans with interstitial plasma cell pneumonitis. Subsequent studies confirmed this organism as the cause of the pneumonitis. Interruption of outbreaks by the introduction of strict isolation of affected patients within these institutions suggests the probable importance of person-to-person spread of disease within that setting.[168] Most investigators believe the organism is acquired very soon after birth in rats and humans, and these neonates serve as reservoirs of infection.[29,134,180]

In contrast to the early European patterns, American cases largely have been sporadic and have occurred almost exclusively in children with impaired host defenses.[32,144] A few outbreaks of PCP within families[197] or among closely associated groups of hospitalized cancer patients have been reported, further suggesting the importance of contagion in the spread of this disease.[13,162,173]

Autopsy studies have shown the occasional presence of *Pneumocystis* organisms in the lungs of patients without evidence of underlying host defense disorders or pulmonary disease,[111] and have shown that unapparent (asymptomatic) infection occurs frequently in patients with cancer and in other immunocompromised patients.[146,201] The epidemiologic importance of asymptomatic carriers in the transmission of *Pneumocystis* disease is unknown. Organisms are detected frequently in sputum, pharyngeal secretions, and tracheal aspirates of symptomatic patients.[66] Cysts have been shown to remain intact for several months in dried lung specimens maintained at room temperature.[88] These observations, in addition to the almost universal localization of disease within the lungs of affected patients, suggest that infection probably results from inhalation of the organism. In view of this possibility, respiratory isolation of symptomatic patients should be maintained to prevent exposure of other highly susceptible patients. No data support the isolation of such patients from otherwise healthy individuals.

Although intrauterine transmission of *P. carinii* has been documented in one stillborn infant and has been implicated in three siblings with no demonstrable immunologic abnormalities who were infected in the neonatal period,[8] the paucity of such cases does not support the epidemiologic importance of this mode of transmission. Of the infants of eight women with AIDS and PCP during pregnancy, one infant had evidence of *P. carinii* infection.[70,133] Studies in severe combined immunodeficiency mice have failed to show transplacental passage of this organism.[92]

EPIDEMIOLOGY IN THE NORMAL HOST

Asymptomatic *P. carinii* infection is highly prevalent in humans. Serologic studies have shown that more than 90 percent of normal adults have antibody to *P. carinii*, and that approximately 75 percent have acquired *P. carinii* antibody before reaching 4 years of age.[104,126,145,149] Molecular techniques show that during periods of immunosuppression, PCP can occur either by reactivation or by the acquisition of new organisms.[72]

Some evidence suggests that *P. carinii* pneumonitis may occur in immunocompetent infants.[175] In a prospective study of 67 infants 2 to 12 weeks old with pneumonitis in Birmingham, Alabama, 10 were found to have serologic evidence of this infection. In 1 of the 10 infants, the diagnosis was proved by lung biopsy. In serial observations conducted every 2 months on a cohort of 107 normal healthy infants in Chile, *P. carinii* DNA was detected in nasopharyngeal aspirates obtained during episodes of mild respiratory infection in 24 (32%) of 74 infants from whom specimens were available. Three (12.5%) of the 24 infants versus 0 of 50 infants who tested negative for *P. carinii* had apnea episodes. Of the infants, 85 percent seroconverted by 20 months of age.[184] Further delineation of the clinical features of *P. carinii* infection in normal hosts is needed.

Studies in Santiago, Chile, and Oxford, United Kingdom, found *P. carinii* in 15 to 35 percent of infants with sudden infant

death syndrome (SIDS) versus 2.9 percent of infants in the same age groups who died of other causes.[186] In another report of 112 infants younger than 1 year who died in Santiago from 1998 to 2000, *P. carinii* DNA was detected in 51.7 percent of 89 infants (75 had SIDS) from the community and 20 percent of 25 infants who died in the hospital ($p = .006$). Viral infections were found more commonly in hospitalized patients than in patients in the community.[187] Because of the scarcity of organisms, the terminal event in SIDS cannot be explained by PCP; the association remains unexplained.

EPIDEMIOLOGY IN HOSTS NOT COMPROMISED BY ACQUIRED IMMUNODEFICIENCY SYNDROME

The European outbreaks of PCP in debilitated infants, the studies of *P. carinii* in malnourished children in Africa, and the well-known association of malnutrition and impaired resistance to various infectious disorders suggest the importance of malnutrition as an additional host determinant for the development of *P. carinii* infection.[89,96,167] Before the AIDS epidemic, PCP occurred almost exclusively in patients with primary immunologic disorders or in patients receiving immunosuppressive therapy for oncologic disease or organ transplantation.[54,146,188,195] Studies before the advent of chemoprophylaxis for PCP reflect the natural pattern of PCP in the compromised host.

Of 194 cases of PCP reported to the Centers for Disease Control and Prevention (CDC) between 1967 and 1970, 29 occurred in infants younger than 1 year; 83 percent of these infants had primary immunodeficiency disorders. In contrast, acute lymphocytic leukemia was the most common underlying disease in children older than 1 year.[195] Of 1251 children with malignancies at the St. Jude Research Hospital (1962 to 1971), PCP occurred in 51 (4.1%), whereas in 379 patients with other types of neoplasias and in 1669 children without malignant disease, *P. carinii* infection was not encountered.[88] *P. carinii* infection occurs more commonly in patients with cancer involving generalized lymphoproliferative malignancies than in patients with solid tumors.[15,172] The extent of malignant disease and the intensity of the chemotherapy or radiotherapy provided were associated with an increased risk for the development of *Pneumocystis* infection.[78,146,172]

Chemoprophylaxis for PCP has been in widespread use for 3 decades in the management of severely immunosuppressed hosts. Changes have occurred in the treatment of the primary underlying diseases, raising the question as to whether PCP is still the threat to the compromised host that was revealed in earlier studies. Reports from several cancer centers show that the incidence or prevalence, or both, of PCP has increased during the past decade.[73,142,203] Investigators at University Hospitals in Leiden[5] and Basel[136] show the emergence of PCP in patients with organ transplants and others with vasculitis/autoimmune diseases. During 1990 to 2003 at the University of Texas M.D. Anderson Cancer Center, Houston, 80 episodes of PCP occurred in 79 patients; 29 percent of the patients had undergone hematopoietic stem cell transplantation.[181]

Among 519 patients undergoing allogeneic hematopoietic stem cell transplantation in Paris, 13 cases of PCP occurred (10 were not on prophylaxis). The median $CD4^+$ T cell count was 131/μL at diagnosis.[33] In a review of 4581 solid organ transplant recipients who were not receiving prophylaxis, 4.9 percent had PCP, with considerable variation seen among organ groups (33% of 106 lung, 4.2% of 895 heart, 11% of 278 liver, and 3.8% of 3301 kidney transplants).[60] During the decade 1991 to 2001, 118 episodes (108 patients) of PCP occurred at one hospital in Goteborg, Sweden. The most common underlying entities were human immunodeficiency virus (HIV) infection in 29 cases and organ transplantation in 26 cases. Of the episodes, 75 percent were in non-AIDS patients. The number of PCP cases did not increase during the study period.[128]

More recent evidence suggests that patients with connective tissue diseases, such as lupus and rheumatoid arthritis, who are receiving immunosuppressive therapy and have $CD4^+$ T lymphocyte counts less than 250/μL are at risk for development of PCP.[115] In 88 consecutive patients with cystic fibrosis, *P. carinii* mitochondrial RNA was detected in 21.5 percent of cases. None of the patients developed PCP or clinical evidence of infection.[155]

EPIDEMIOLOGY IN ACQUIRED IMMUNODEFICIENCY SYNDROME PATIENTS

On June 5, 1981, the CDC reported five cases of *P. carinii* pneumonia in previously healthy men. These were the first cases of AIDS in the United States, discovered because the opportunistic *P. carinii* infection served as a badge of immunodeficiency and led to a search for a host defect. Since that time, HIV/AIDS and the associated opportunistic infections have caused the deaths of more than 22 million people worldwide and 500,000 people in the United States.[21]

Individuals infected with HIV type 1 (HIV-1) have a remarkably high risk for the development of *P. carinii* pneumonitis. The pneumonitis was diagnosed in 1080 (39%) of the 2786 pediatric patients with AIDS reported to the CDC through 1990.[171] Pneumonitis develops in approximately 75 percent of untreated adults with AIDS. Among children with AIDS, *P. carinii* pneumonitis may occur at any age, but most frequently it is found in infants 3 to 6 months old.[103,169,171] The introduction of *P. carinii* prophylaxis alone without antivirals in the treatment of AIDS provided a per-person survival benefit of 3.1 months.[193] The use of highly active antiretroviral therapy (HAART) plus chemoprophylaxis for PCP has reduced drastically the incidence of PCP infections in children with AIDS. Gona and associates[59] found the incidence rate of PCP per 100 person-years to be 1.3 in 3331 HIV-infected children from 1981 to 1988, before the introduction of HAART, and less than 0.5 in 2767 HIV-infected infants from 2001 to 2004 with use of HAART.

PATHOGENESIS

P. carinii is an organism of low virulence found almost exclusively in the alveoli of the lung with the potential for provoking life-threatening diffuse alveolar disease. This paradox is based on the fact that the extent of the disease is due primarily to the magnitude of the host's defensive response.

In recent years, the application of molecular technology has provided a vast amount of information to aid in the understanding of the pathogenesis of this infection and disease. Thomas and Limper[180] provided a comprehensive composite of these data.

When *P. carinii* reaches the lungs by the airborne route, the organism may elicit no host response, and the subject remains asymptomatic; alternatively, if the host is severely immunocompromised, a life-threatening pneumonitis may evolve. Cyst and trophozoite forms may bind avidly to the epithelial cells of the alveolus, activating specific signaling pathways in the organisms.[180] Alveolar macrophages ingest and degrade the organisms. The macrophages elaborate proinflammatory cytokines, which, in addition to aiding in removal of organisms, evoke pulmonary injury. Tumor necrosis factor–α promotes neutrophil, lymphocyte, and monocyte infiltration, which may cause alveolar damage and diminished gas exchange, and result in respiratory failure.[26,64] The $CD4^+$ T lymphocyte is of major importance in the recruitment and activation of other immune effector cells, including monocytes and macrophages.[9,61] The $CD4^+$ cell mediates inter-

leukin-1 and macrophage-derived tumor necrosis factor–α, which are necessary for pulmonary responses to the organism. The lymphocytes also proliferate in response to *P. carinii* antigens to produce lymphotactin and interferon-γ.[9] With pneumonitis, an increase in $CD8^+$ lymphocytes occurs in the lungs.[10]

Surfactant phospholipids and apoproteins are affected by *P. carinii*.[11,139,202] Reduction in lung surfactant has been shown in animal studies.[196,202]

CLINICAL STUDIES TO ELUCIDATE PATHOGENESIS

The ability of corticosteroids to induce *P. carinii* infection in laboratory animals, the occurrence of PCP in patients with AIDS and pure T-cell deficiency disease, and the development of PCP in malnourished hosts with significantly impaired cellular immune responses[89,96,110,167] provide indirect evidence of the potential importance of cellular immunity in protecting the host against this opportunist. Because corticosteroids, cytotoxic agents, and malnutrition variably depress humoral and cellular immune mechanisms and nonspecific immune responses (inflammation), no absolute statement can be made regarding the importance of each defense mechanism, other than that strong evidence has implicated the importance of T-lymphocyte competence in the pathogenesis of PCP. Experimental studies in rats show provocation of the pneumonitis after the administration of cyclosporine, a compound that specifically affects T cell–mediated immune responses related to impairment of interleukin-2 production and receptor site inhibition and with no direct effect on other components of the immune system.[91] Especially convincing is the remarkable susceptibility of patients with AIDS to acquisition of PCP. In this syndrome, host compromise is limited primarily to impaired T-cell function, and PCP develops in at least 50 percent of affected untreated adults.

In infants, children, and adults with AIDS, the quantity of peripheral blood $CD4^+$ helper T lymphocytes serves as a useful risk predictor of development of *P. carinii* pneumonitis. As the $CD4^+$ lymphocyte count decreases, the risk for acquiring *P. carinii* pneumonitis increases. In adults, a $CD4^+$ cell count less than 200/μL is highly predictive of impending *P. carinii* pneumonitis. Because infants and children have relatively higher total lymphocyte counts, absolute $CD4^+$ cell counts are higher than in adults. The threshold for the risk of acquiring *P. carinii* infection is age-related.[103,170]

No characteristic pattern of serum immunoglobulin abnormality has been shown. Low levels of IgG were the most consistent finding in two reported series of children with immunodeficiency disease.[15,195] In contrast, normal or elevated levels of IgG were documented in 70 percent of leukemic children with PCP. Administration of serum immunoglobulin to infected children with these disorders usually provided no therapeutic benefit.[195] The role of IgA antibody in host defense against *P. carinii* probably is not of major importance because secretory IgA levels are normal in most affected patients, and patients with immunodeficiency states characterized by IgA deficits are not unduly susceptible.[15,195]

The development of specific antibodies to *P. carinii* in infected patients has been inconsistent, in part because of the lack of a standardized method for testing. During "epidemic" disease in malnourished infants, IgM values frequently increase markedly, with variable changes occurring in IgG and IgA values. IgG antibody concentrations increase in serum 4 to 6 weeks after infection and are thought to provide permanent immunity in these infants.[102] In selected instances, specific antibody responses (IgG, IgA, and IgM) have been shown in normal individuals who have been associated closely with infected patients.[15,125]

Using immunofluorescent staining techniques, Brzosko and colleagues[14] showed IgG and IgM antibody with smaller amounts of IgA antibody and β_{1c}-globulin deposits on the surface of *Pneumocystis* organisms within the alveoli of infants with "epidemic" PCP. Late in their disease, less immunoglobulin was present within alveoli, whereas increased numbers of plasma cells and alveolar macrophages containing fluorescent material were identified. Possibly, specific antibody fixes complement (β_{1c}-globulin) on the surface of *Pneumocystis* organisms, allowing subsequent phagocytosis by alveolar macrophages.[14]

PATHOLOGY

P. carinii infections are unique in that the pathologic findings, with rare exceptions, are limited to the lungs, even in fatal cases. In the infantile "epidemic" form of disease, essentially all alveoli contain large numbers of organisms. Extensive interstitial plasma cell infiltrates distend the alveolar walls 5 to 20 times over their normal thickness, and almost no intra-alveolar fibrinous exudate is noted.[40,66]

In the childhood and adult forms of PCP, the histogenesis has been described in three stages.[66,88,151] An initial stage is characterized by the presence of cysts and trophozoites attached by fibronectin to the alveolar walls.[150] No septal inflammatory or cellular response is evident, and no clinical disease is associated with this stage. A second stage, which may or may not be associated with clinical signs and symptoms, is characterized by desquamation of alveolar cells and an increase in the number of cysts within alveolar macrophages. Tumor necrosis factor may be a major mediator involved in the killing of *P. carinii* by activated alveolar macrophages and may be induced by oxidative stress in the alveoli.[147] The final stage is typified by extensive reactive and desquamative alveolitis manifested by marked cytoplasmic vacuolization of macrophages, mononuclear and plasma cell infiltrates within alveolar septa, and clusters of organisms located predominantly within macrophages in the lumen of alveoli. The histopathology of this final stage definitely is associated with clinical manifestations of pneumonitis (see Figs. 236–1 and 236–2).[151]

Rarely, *P. carinii* organisms have been detected in the lymph nodes, spleen, liver, retina, bone marrow, gastrointestinal tract, pancreas, heart, adrenals, and peripheral blood.[62,152,179] A fatal case of disseminated *P. carinii* infection in a 13-month-old infant with thymic alymphoplasia has been reported.[152]

CLINICAL MANIFESTATIONS

The natural course of *P. carinii* infection in children varies greatly and depends primarily on the status of host defenses in individual patients. The onset may be insidious, with a clinical course of 3 or more weeks, or be fulminant and rapidly progressive over a few days.

The clinical course of infantile epidemic pneumocystosis is typified in premature, debilitated, or marasmic infants 2 to 6 months of age. These patients often have chronic diarrhea and weight loss before developing respiratory symptoms. Characteristically, the onset is insidious, with progression of cough, tachypnea, and respiratory distress occurring over a 1- to 4-week interval. Fever is either absent or of low grade in most cases.[39]

Symptoms in immunosuppressed children or adults without AIDS may be more abrupt in onset and more rapidly progressive than in patients in infantile epidemic cases. Even with these patients, the course also varies greatly.[15,54,66,88,153,195] The mortality rate is approximately 100 percent in untreated cases because of the overall severity of the disease in immunocompromised patients.[66] In cases in children and adults, in contrast to infantile cases, fever generally is present and of high grade. It often precedes the onset of nonproductive cough, tachypnea, and severe dyspnea. Fever, tachypnea, and the radiographic appearance of

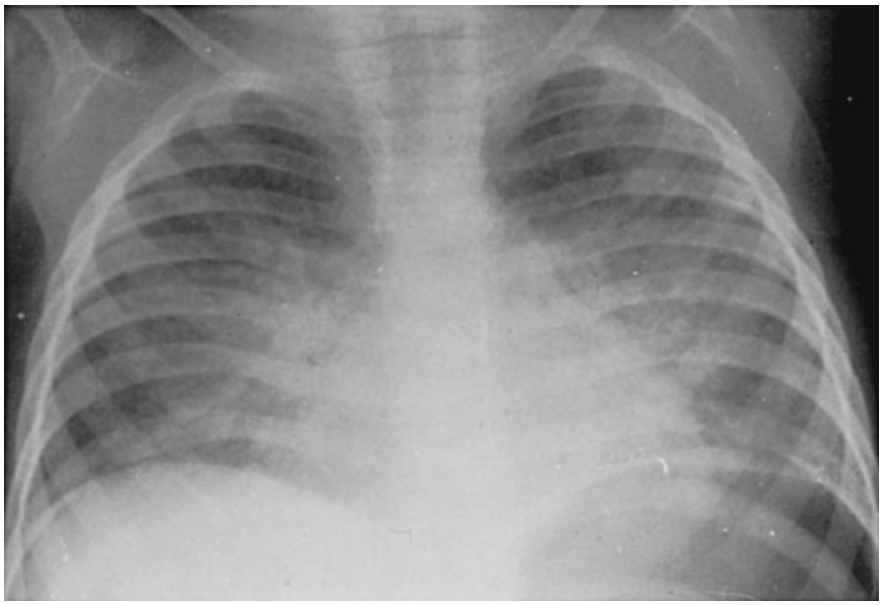

Figure 236–3 Typical diffuse interstitial infiltrates seen in a 20-month-old child with severe combined immunodeficiency disease at the time of evaluation for clinical *Pneumocystis carinii* pneumonitis.

pulmonary infiltrates, in that sequence, 1 to 21 days before diagnosis was established, occurred in a group of children with malignancies.[88] In half of these patients, signs and symptoms occurred within 5 days before initiation of treatment. In a select group of 10 untreated patients, the extent of fever, respiratory distress, and radiographic abnormalities varied from mild to severe. Pulmonary infiltrates were apparent 1 to 13 days before death, and the total course of infection ranged from 4 to 21 days.

The time of onset of clinical disease in non-AIDS, high-risk patients is unpredictable, but disease often occurs after discontinuance or a reduction in the dose of corticosteroid therapy. Rifkind and coworkers[156] noted the clinical onset of infection in transplant recipients when the prednisone dosage was reduced to less than 1 mg/kg body weight per 24 hours. In another series, PCP developed in 9 of 46 patients while steroid therapy was being reduced.[15] The relationship may be to the duration of corticosteroid therapy, however, rather than the withdrawal or reduction in dosage. Patients with severe combined immunodeficiency disease who receive a bone marrow transplant subsequently may contract fulminant PCP when apparent immunologic reconstitution has occurred.[15] These observations imply that the development of clinical disease depends partly on normal inflammatory responses, which may be impaired as a result of the patient's underlying disease, the therapeutic regimen, or both.

Infants and children with AIDS usually are acutely ill with fever (79%), cough (86%), dyspnea (88%), tachypnea (88%), and an alveolar-arterial oxygen gradient greater than 30 mm Hg (95%) at the time of onset of *P. carinii* pneumonitis. The median length of survival after the diagnosis of *P. carinii* pneumonitis was established was only 2 months in a study by Connor and associates.[27]

In children and adults with and without AIDS, physical examination at the time of initial evaluation may reveal tachypnea; nasal flaring; and intercostal, subcostal, or supracostal retractions. An ashen color or cyanosis may be present or may develop rapidly. Auscultation of the chest frequently is characterized by a conspicuous absence of adventitious sounds despite the presence of rapid (80 to 100/min), shallow respirations. Scattered rales, rhonchi, or wheezes most often are detected later in the clinical course as resolution occurs. Aside from variable elevation in temperature, few other physical abnormalities are noted except those referable to pulmonary disease or secondary to the patient's underlying disease or treatment.[15,66,88,195]

Various radiographic abnormalities have been observed in documented cases of isolated PCP.[36,47] These variations result partly from observations at different stages in the course of disease. Bilateral diffuse parenchymal infiltrates (Fig. 236–3) occur most commonly, but no pattern is sufficiently specific either to exclude or to confirm a consideration of *P. carinii* disease. Although initially a reticulogranular interstitial process, *Pneumocystis* pneumonitis progresses to a predominantly alveolar process with coalescence and air bronchogram formation. Late in the course of the disease, lung fields may opacify completely.[36,47] Hilar adenopathy and pleural effusion are not characteristic, unless they are a result of an underlying disorder. During treatment, radiographs show gradual clearing after a variable latent period, during which they may appear worse. Residual interstitial fibrosis occurs in a small percentage of patients. Unusual radiographic findings, including an asymmetric distribution, consolidated lobar infiltrates, pneumothorax and pneumomediastinum, localized parenchymal nodular densities, and pleural effusion, have been documented. One investigator noted the occurrence of at least one "atypical" radiographic finding in 56 percent of 30 cases of PCP.[36] In 23 episodes of PCP in stem cell transplant recipients, 23 percent had nodular infiltrates on the chest radiograph.[181]

DIAGNOSIS

Characteristic clinical features are not sufficiently specific to differentiate PCP from other opportunistic pulmonary infections in highly susceptible pediatric patients. Mixed infections with viral, bacterial, fungal, or parasitic agents have been documented along with *P. carinii*.[15] Implicit in these observations is the importance and urgency of establishing a definitive diagnosis before the institution of specific therapy. An etiologic diagnosis can be ascertained only by the demonstration of *P. carinii* organisms in lung tissue or respiratory secretions.

Numerous techniques have been used to obtain suitable material for diagnostic purposes. Although specimens obtained by noninvasive methods from sputum[48,116] or pharyngeal,[45] tracheal,[109] or gastric[24,178] secretions occasionally reveal *P. carinii* in infected patients, these sources are not sufficiently reliable to exclude the diagnosis if organisms are not identified.[66] Bronchopulmonary lavage,[37,66,137] endobronchial brush biopsy,[46,154] and

transbronchial lung biopsy[63,97] have been used successfully to establish a diagnosis of PCP in adult patients.

Invasive techniques, including open lung biopsy, closed needle biopsy, and percutaneous needle aspiration, are the most reliable methods for confirming a diagnosis.[66,127,158,194] Open lung biopsy provides the most dependable specimen from which identification of the organism and the extent of the infection can be ascertained.[1,204] The chief disadvantage is the need for general anesthesia. A closed needle biopsy procedure is less reliable in providing adequate tissue and is associated with significantly greater morbidity than open thoracotomy.[98] Percutaneous needle aspiration has proved to be a consistent and safe procedure in selected centers.[66,99]

Bronchoalveolar lavage has been safe and successful, especially in patients with AIDS, in whom organisms are in great abundance.[143,65] Bye and colleagues[16] used bronchoalveolar lavage in infants 2 months old. Regardless of the procedure selected, it is crucial to avoid undue delay in establishing a diagnosis before the patient's condition deteriorates sufficiently to preclude any definitive diagnostic procedure.

For diagnostic purposes, the methenamine silver nitrate method of Gomori and the less widely used, but more rapid, toluidine blue O[23] and calcofluor white[180] stains are most useful for showing cyst forms in tissue sections, aspirates, or imprints. For more detailed morphologic study of intracystic sporozoites and trophozoites, polychrome stains, including Giemsa, Wright, Gram, and methylene blue stains, are more suitable.[99] In tissue sections, the Gomori stain in combination with hematoxylin and eosin staining allows study of the organism and host tissue.[79] A direct immunofluorescent monoclonal antibody technique has become commercially available (Merifluor; Meridian Bioscience, Inc., Cincinnati, OH). This technique has no definite advantage over the more conventional methods, although one report describes slightly higher detection rates of *P. carinii* in sputum samples by the immunofluorescence method.[104,105]

Serologic methods, including complement fixation, immunofluorescence,[135] enzyme-linked immunosorbent assay, and latex agglutination, have been developed, but are not useful for diagnostic purposes. A lack of specificity or sensitivity inherent in the procedures themselves, in addition to the likelihood of impaired immune responses in affected patients, precludes interpretation of results in most cases.

A method for the detection of *P. carinii* antigenemia by counterimmunoelectrophoresis was described in 1978.[149] Although this study indicated promise for use of counterimmunoelectrophoresis as a diagnostic test, subsequent studies have yielded conflicting results.

Several investigators[4,38,118,138,163,190,192] have amplified *P. carinii* DNA by polymerase chain reaction (PCR) as a molecular diagnostic method. In a study of bronchoalveolar lavage or lung biopsy specimens (or both) from 47 HIV-infected patients, all of the 18 with documented PCP and 4 of 29 with other pulmonary conditions were positive by PCR analysis (sensitivity 100%, specificity 86%).[182] In a study using nested and quantitative real-time PCR for the amplification of *Pneumocystis* dihydropteroate synthase gene, in 71 confirmed cases of PCP and 70 cases without PCP, the sensitivities and specificities were 94 percent and 81 percent for nested PCR and 94 percent and 96 percent for real-time PCR, favoring real-time PCR ($p = .015$) with few false-positive results.[3] At this time, PCR remains a research tool and is not applicable to general clinical practice.

Hematologic studies are of no diagnostic value, primarily because of baseline abnormalities reflecting the underlying disease of affected patients. Eosinophilia has been reported in isolated cases, but usually is not present. Depressed serum total protein and albumin values frequently are noted because of the poor nutritional status of representative patients.[89] Lactate dehydrogenase activity is increased, but it is not a specific reaction for PCP and is of little diagnostic benefit.

PROGNOSIS, TREATMENT, AND PREVENTION

PROGNOSIS

Before the availability of specific therapeutic agents, the overall prognosis of patients with PCP was poor. Despite supportive care, almost 100 percent of infected patients with underlying neoplastic or immunodeficiency disorders died, whereas approximately 50 percent of infants in the European epidemics died as a result of this pulmonary infection.[72,112,130] To control the European epidemics, Ivady and Paldy[93] first suggested the use of pentamidine isethionate, a diamidine with previously shown antifungal and antiprotozoal activity. Use of this therapeutic agent in infants during the next several years resulted in a dramatic reduction in the mortality rate from 50 to 3.5 percent.[94]

Pentamidine became available to investigators in the United States through the CDC in 1967. During the next 3 years, of 163 children and adults with documented PCP who were treated with pentamidine, 43 percent recovered.[194,199] Of 404 patients to whom the drug was administered for suspected or documented *P. carinii* infection, 189 (47%) experienced significant toxic manifestations. Toxicity ranged from localized reaction at injection sites (18%) to systemic effects, including impaired renal function (24%), liver toxicity (10%), hypoglycemia (6%), hematologic abnormalities (4%), hypotension (10%), and hypocalcemia (1%).[199] Although pentamidine was effective, the high incidence of toxicity emphasized the need for an alternative therapeutic agent.

An immunosuppressed rat model has been useful in the discovery and development of therapeutic and prophylactic drugs for PCP.[50,87] Initial studies of trimethoprim and sulfamethoxazole (co-trimoxazole) in infected rats showed therapeutic efficacy equal to that of pentamidine and successful prevention of *Pneumocystis* infection.[87] The efficacy of co-trimoxazole was shown in the treatment of PCP complicating childhood leukemia.[79,80] A controlled, randomized study involving 50 leukemic children with PCP was reported. Overall recovery rates of 75 percent for pentamidine and 77 percent for co-trimoxazole suggest that these drugs are equally effective in the treatment of PCP in this patient population. No significant toxicity secondary to co-trimoxazole therapy was observed in this investigation.[79] Subsequent studies have confirmed the efficacy of this drug combination in the treatment of pneumonitis.[67,68,108]

TREATMENT

Co-trimoxazole presently is the drug of choice for the treatment and prevention of PCP. A minimum of 2 weeks of therapy is recommended for non-AIDS patients; 3 weeks may be optimal for patients with AIDS. The CDC, the National Institutes of Health, and the Infectious Diseases Society of America have provided consensus guidelines for the treatment of PCP in patients with AIDS (Table 236–1).[20] This scheme also can be applied to non-AIDS patients with PCP. Patients with AIDS have a remarkably high rate of adverse reactions to co-trimoxazole[16] and pentamidine, and should be treated with the alternative drugs recommended in Table 236–1.

Atovaquone, a hydroxynaphthoquinone approved by the U.S. Food and Drug Administration, is effective and has few side effects (rash, nausea, and diarrhea). It can be administered only by the oral route.[83,86] The sulfone dapsone[71] has been evaluated in children[53,122] and may be used alone, but is synergistic with trimethoprim[114] against *P. carinii*. Dapsone

TABLE 236–1 Recommendations for the Treatment of *Pneumocystis carinii* Pneumonia in HIV-Exposed and HIV-Infected Infants and Children

Preferred Therapies and Duration

Trimethoprim-sulfamethoxazole (TMP/SMX) 15-20 mg/kg body weight TMP plus 75-100 mg/kg body weight SMX administered IV or PO 3-4 times daily. After acute pneumonitis has resolved in mild to moderate disease, IV TMP/SMX may be changed to PO

Treatment Duration

21 days for AIDS and about 14 days for non-AIDS, followed by long-term suppressive prophylaxis doses

Alternative Therapies (if TMP/SMX Intolerant or Clinical Treatment Fails after 5-7 Days of TMP/SMX)

Pentamidine 4 mg/kg body weight IV once daily is first-choice alternative regimen. Pentamidine may be changed to atovaquone after 7-10 days IV therapy; *or*

Atovaquone 30-40 mg/kg body weight (maximum 1500-mg dose) PO in two divided doses daily with food; infants 3-24 mo may require a higher dose of 45 mg/kg/day

Other Options and Issues

Dapsone 2 mg/kg once daily (maximum 100 mg/day) plus trimethoprim 15 mg/kg PO in three divided doses daily has been used in adults, but data on children are limited

Primaquine base 0.3 mg/kg PO once daily (maximum 30 mg/day) plus clindamycin 10 mg/kg IV or PO (maximum 600 mg administered IV and 300-450 mg administered PO) q6h has been used in adults, but data in children are unavailable

Indications for Corticosteroids

Pao_2 <70 mm Hg at room air or alveolar-arterial oxygen gradient >35 mm Hg

Prednisone 1 mg/kg PO twice daily for 5 days, then 1 mg/kg PO daily for 5 days, then 0.5 mg/kg PO daily for days 11-21

Secondary Prophylaxis

Recommended for lifetime after initial therapy course, or until immunodeficiency has resolved

From Centers for Disease Control and Prevention: Guidelines for the prevention and treatment of opportunistic infections among HIV-exposed and infected children: Recommendations from CDC, the National Institutes of Health and the Infectious Diseases Society of America. M. M. W. R. (in press). Available at http://aidsinfo.nih.gov/contentfiles/Pediatric_01.pdf (accessed 22 Dec. 2008).

may cause rashes, neutropenia, thrombocytopenia, anemia, and methemoglobinemia.

Several other promising drugs are in various stages of clinical evaluation, although none has been investigated systematically in children. Agents with evidence of efficacy include pyrimethamine plus sulfadoxine,[101,160] trimetrexate,[2] and clindamycin plus primaquine.[161] Animal studies show that the combination of erythromycin-sulfisoxazole has strong anti–*P. carinii* activity through a synergistic mechanism.[84]

Some studies in adults with AIDS and *P. carinii* pneumonitis suggest that the administration of corticosteroids early in the course of moderately severe pneumonitis reduces the occurrence of respiratory failure and improves oxygenation.[28] Other studies show no benefit from corticosteroids.[35] More limited studies of this supportive therapy have been reported to increase survival in children.[6,174] If used, a reasonable approach (see Table 236–1) seems to be to withdraw corticosteroids as soon as pulmonary function has become stabilized.

PREVENTION

P. carinii pneumonitis can be prevented in more than 95 percent of patients at high risk for acquiring the disease.[85,90] Patients in high-risk groups, such as patients with cancer, acquired and congenital immunodeficiency disorders, and organ transplants, should be placed on a chemoprophylaxis regimen throughout the risk period. Underlying non-AIDS conditions at high risk for associated acquisition of PCP are lymphoproliferative malignancies, solid tumors with intensive immunosuppressive therapy, corticosteroid therapy, bone marrow transplantation, certain solid organ transplants, prior episode of PCP, severe malnutrition, brain tumor on intensive immunosuppressive therapy, severe combined immunodeficiency syndrome, certain other congenital immunodeficiency disorders, and $CD4^+$ T-lymphocyte counts less than 200/μL.[75,158] Revised guidelines from the CDC, National Institutes of Health, and Infectious Diseases Society of America for *P. carinii* prophylaxis in infants and children with AIDS[20] are given in Table 236–2, and generally can be applied to non-AIDS patients, although the significance of the $CD4^+$ lymphocyte has not been well established in this group.

Because of the high risk for acquiring PCP during the first year of life, often before HIV infection is recognized,[169,170] PCP prophylaxis should be initiated at 4 to 6 weeks of age in all infants

TABLE 236–2 Recommendations for *Pneumocystis carinii* Pneumonia Prophylaxis for HIV-Exposed Infants and HIV-Infected Children

	Preventive Regimens	
Indications	***First Choice***	***Alternatives***
HIV-infected or HIV-indeterminate* infants 1-12 mo	Trimethoprim-sulfamethoxazole 150/750 mg/m^2/day in 2 divided doses PO 3 times/wk on consecutive days	Dapsone (≥1 mo), 2 mg/kg (maximum 100 mg) PO qd, or 4 mg/kg (maximum 200 mg) PO per wk
HIV-infected children 1-5 yr with $CD4^+$ count <500/μL or $CD4^+$ percentage <15%	Acceptable alternative schedules	Aerosolized pentamidine (≥5 yr), 300 mg every month via Respirgard II nebulizer
HIV-infected children 6-12 yr with $CD4^+$ count <200/μL or $CD4^+$ percentage <15%	Single dose PO 3 times/wk on consecutive days	
Previous PCP	2 divided doses PO qd	Atovaquone 30 mg/kg PO qd (1-3 mo and >24 mo), 45 mg/kg PO qd (4-24 mo)
	2 divided doses PO 3 times/wk on alternate days	

**No prophylaxis for infants <1 month because of the rarity of* Pneumocystis carinii *pneumonia (PCP) at this age. Human immunodeficiency virus (HIV) infection can be reasonably excluded in infants who have had two or more negative HIV diagnostic tests (i.e., HIV culture or polymerase chain reaction, both of which are performed at ≥1 month old and one of which is performed at ≥4 months old, or two or more negative HIV IgG antibody tests performed at >6 months old in children who have no clinical evidence of HIV disease. Prophylaxis is not recommended for infants who meet criteria for HIV-uninfected and presumptively uninfected with HIV status.*

From Centers for Disease Control and Prevention: Guidelines for the prevention and treatment of opportunistic infections among HIV-infected persons—2002. Recommendations of the U. S. Public Health Service and Infectious Diseases Society of America. M. M. W. R. (in press). Available at http://aidsinfo.nih.gov/contentfiles/Pediatric_01.pdf (accessed 22 Dec. 2008).

born of HIV-infected women, regardless of $CD4^+$ lymphocyte cell counts. The use of chemoprophylaxis in this age group has been highly effective in HIV-infected infants.[157] When infants are shown not to be infected with HIV, prophylaxis may be discontinued. HIV-infected infants and infants with undetermined status should be continued on prophylaxis during the first year of life. In addition, at 1 year of age and subsequently, the use of chemoprophylaxis is based on the $CD4^+$ lymphocyte count and other AIDS-defining features (see Table 236–2).

Co-trimoxazole given 3 days per week is the preferred drug for chemoprophylaxis. For patients unable to take co-trimoxazole, dapsone (2 mg/kg/day or 4 mg/kg/wk) is suggested.[53,131] Studies in adults show that daily doses of dapsone[124] or one dose of dapsone per week[82] is effective prophylaxis.[122] An alternative to dapsone is aerosolized pentamidine (300 mg via Respirgard II inhaler monthly).[132] The dosage for aerosolized pentamidine is the same as the dosage for adults.[113,131] Atovaquone is effective and safe in children[31] and adults.[44] A controlled study compared prophylaxis with atovaquone and azithromycin with co-trimoxazole in 366 high-risk, HIV-infected children.[77] The regimens were similar in effectiveness in prevention of bacterial infections, and PCP occurred with equal frequency. Table 236–2 summarizes the approach to selection of patients at risk.

Several studies in adults[41,51,166,200] show that PCP prophylaxis can be discontinued safely in patients responding to HAART with a sustained increase in $CD4^+$ T lymphocytes from less than 200 cells/μL to greater than 200 cells/μL. Similar consideration may be given to children in accordance with age-related $CD4^+$ T-lymphocyte counts (see Table 236–2).

Although currently available anti–*P. carinii* drugs may prevent activation of latent infection, they do not eradicate the organism. Patients are protected from pneumonitis only while receiving chemoprophylaxis and become susceptible again when use of the drugs is discontinued. No vaccine is available, although mice immunized with a recombinant mouse *P. carinii* antigen exhibited evidence of reduced infection.[198]

SUBSECTION 2

Nematodes

CHAPTER 237

Parasitic Nematode Infections

Peter J. Hotez

INTESTINAL NEMATODES

The three major intestinal nematodes of children, *Ascaris lumbricoides*, *Trichuris trichiura*, and the hookworms, together have a substantial impact on the health and well-being of children living in less developed nations of the world.[1] This "unholy trinity" of soil-transmitted helminths (STHs), or "geohelminths," deprives hundreds of millions of young children of their full intellectual and growth potential. Current estimates suggest that 2 billion people are infected with STHs, 300 million of whom have severe morbidity. An estimated 400 million schoolchildren are infected with STHs. Building on studies from the early part of the 20th century,[9,10] extensive new data from many different geographic regions confirm that chronic intestinal nematode infections acquired during childhood suppress cognitive and intellectual development,[3,7,10] and impair physical growth and fitness.[4,11-13] Because many of these detrimental effects are reversible with the use of anthelmintic drugs to eliminate nematodes from the intes-

tinal tract,[12,13] several investigators and international relief agencies have advocated the administration of benzimidazole anthelmintics (sometimes known as "deworming") as a cornerstone of public health programs directed at school-age children.[1,2,8]

A 2001 World Health Assembly resolution urges its member states to deworm at least 75 percent and up to 100 percent of school-aged children at risk for acquiring STH infections (www.who.int/wormcontrol). Because in highly endemic areas reinfection with *A. lumbricoides*, *T. trichiura*, and hookworms sometimes occurs within 6 months of receiving anthelmintic treatment,[14] however, this strategy is not always a practical means of control, unless the drugs are used frequently. Concern about the potential for emerging anthelmintic drug resistance also exists. Some researchers have pointed to the use of genetically engineered antihelminth vaccines as one possible solution to the problem of worm re-infection and disease during childhood.[5] Still another public health concern about the chronic effects of STH infections is new evidence suggesting that they may promote the susceptibility to, or worsen the severity of, malaria and human immunodeficiency virus/acquired immunodeficiency syndrome.[6] Interest has developed in examining the impact of large-scale deworming on these killer diseases.

In addition to the chronic effects seen when children harbor numerous intestinal nematodes are the increasingly recognized unique neonatal and infantile syndromes that new information indicates may result from vertical transmission of the infective stages of some intestinal nematodes, probably in colostrum and breast milk.[1,4] The best documented example of vertical transmission in infants results in the "swollen belly syndrome" caused by *Strongyloides fuelleborni*, although other perinatal nematode infections probably also occur (discussed later). Finally, children experience significant morbidity during zoonotic transmission of the infective stages of intestinal nematodes of companion animals such as dogs and cats. The resultant aberrant migration of these foreign nematode larvae (visceral larva migrans) has become a major pediatric public health problem in large urban areas of the United States and Europe.

ASCARIS LUMBRICOIDES

Ascariasis is one of the most prevalent infections in the world,[21] with an estimated 800 million cases in the developing world.[1] Accurate determinations based on 1,477,742 fecal examinations conducted during the 1990s indicated that more than 500 million cases of ascariasis occur in China alone[34]; however, revised estimates now suggest that those numbers have declined significantly, especially in economically developed regions of Eastern China.[1] Currently, the greatest number of cases of ascariasis occur in Southeast Asia and the Indian subcontinent and sub-Saharan Africa.[1] Surveys conducted in the rural southern communities of the United States during the 1970s indicated that the prevalence of ascariasis was 20 to 67 percent.[16] Those rates most likely have declined significantly over the past few decades, however.

Ascaris infection, when relatively light, is usually inapparent until the patient passes a worm through the rectum. In heavy infections, constitutional symptoms may occur during the early phase, and intestinal malabsorption and obstruction may occur in the later phase. The infection is acquired by ingestion of the infective eggs, which hatch in the upper part of the small intestine and free the larvae. The larvae penetrate the intestinal wall, reach venules or lymphatics, and pass through the portal circulation to the liver, the right side of the heart, and the lungs.

In the lungs, the larvae break out of the capillaries and begin ascending through the respiratory radicles until they reach the glottis; passing over the epiglottis, they enter the esophagus and are carried down to the small intestine, where they mature and become adult worms. The adult female *Ascaris* produces huge numbers of eggs—possibly 200,000 a day. To ensure adequate quantities of egg-requiring cholesterol, the parasite sequesters oxygen through a specially modified hemoglobin.[22] The entire cycle, beginning with the infective eggs and resulting in ovipositing females, lasts approximately 2 months. Infection is maintained in the community by the deposition of human stool in soil, which permits embryonated eggs to develop into the infective stage. This process takes approximately 2 weeks. The high prevalence of infection results not only from deficient sanitary facilities for disposal of human excreta, but also from the deliberate use of human feces as fertilizer.

EPIDEMIOLOGY

In many regions of the developing world, *Ascaris* eggs are almost ubiquitous in the environment. All ages are affected by the parasite; young children, who are exposed more often to the contaminated soil, are affected most frequently. These children usually harbor greater numbers of adult worms in their intestine than do adults living under similar conditions.[11-13,20] High worm burdens in children also occur with *Trichuris* infections (see later). Because the phenomenon of heavy *Ascaris* and *Trichuris* worm burdens in childhood is found throughout most of the developing world, pediatric predisposition to "worminess" is widely thought to have a possible genetic or immunologic basis.[4]

Ascaris eggs are extremely hardy and resistant to extremes of temperature and desiccation, which may explain the common finding of high rates of ascariasis in impoverished urban environments (e.g., Guatemala City, Mexico City) and in rural environments. The eggs also are resistant to chemical disinfectants and are not destroyed readily by sewage treatment. In some areas, pigs may serve as a reservoir for zoonotic *Ascaris* infection.[15]

PATHOPHYSIOLOGY

During the migratory phase of the infection, the larvae evoke an inflammatory response associated with eosinophilic infiltration. *Ascaris* antigens—so-called ABA-1 allergen—released during the molting of larvae evoke an immune response, and IgE antibodies directed against ABA-1 may be associated with resistance.[30] *Ascaris* larvae also release immunomodulatory glycosphingolipids that inhibit T_H1 responses.[1,20] A controversial role of IgE anti-*Ascaris* antibodies is in protecting children against atopic states, including asthma.[29] During the intestinal stage of infection, symptoms derive primarily from the physical presence of the worms in the gut, from aberrant migration into other lumina, or from perforation into the peritoneum. As a protective mechanism for its own survival, *Ascaris* secretes peptides that block the action of pancreatic digestive enzymes (trypsin, chymotrypsin, elastase),[23,26] which may play a role in parasite-associated nutrient malabsorption, including the malabsorption of vitamin A.[19] Ascariasis also results in lactose intolerance.[19] Whether these phenomena provide the basis of observed *Ascaris*-associated physical growth retardation during childhood[3,11-13,20,31] is unknown.

CLINICAL MANIFESTATIONS

The degree of disease induced by the migratory phase of *Ascaris* is related directly to the number of larvae migrating simultaneously. In light infections, this phase is typically unrecognized. Heavy infection, such as that induced in himself by Koino,[28] who swallowed 2000 infected eggs, may cause severe pneumonitis. In

some regions of the world, pediatric *Ascaris* pneumonitis is seasonal.[1]

In the lumen of the intestine, *Ascaris* adult worms may become matted together and form a bolus large enough to cause intestinal obstruction, sometimes leading to bowel infarction and intestinal perforation. This is a particular problem in very young children because of the small luminal diameter of their intestines.[27] The incidence of this complication has been estimated at 2 per 1000 infected children per year.[16] Children with *Ascaris* obstruction exhibit a toxic appearance, often with signs and symptoms of peritonitis.[1] When recognized early, the obstruction can be treated with medical management, but in many cases surgical intervention is mandatory.

Hepatobiliary and pancreatic ascariasis (HPA) results from blockage of the bile duct and pancreatic duct. Patients with HPA are subject to cholecystitis, acute cholangitis, "biliary colic," acute pancreatitis, or hepatic abscess.[27] In contrast to intestinal obstruction, HPA tends to be more common in adults, especially women.[27] Certain irritants, such as halogenated hydrocarbons (e.g., carbon tetrachloride and tetrachloroethylene, used in the past to treat certain hookworm infections), elevation of body temperature, and general anesthesia, have been known to precipitate aberrant migration. *Ascaris* screening by fecal examination should be considered before performing elective surgery on a child who might have immigrated recently from an impoverished area of the tropics.

Whatever the mechanism of interference by *Ascaris* with growth or nutrition, treatment with anthelmintics leads to substantial catch-up growth in previously parasitized children.[3,11-13,29,31] Ascariasis in pregnant women results in intrauterine growth retardation.[33] Most individuals with light infections rarely are symptomatic (they become aware of the parasites by passage of adult worms in stool or through regurgitating and vomiting the adult worms), although researchers have conjectured that even these individuals may exhibit subtle deficits in cognitive and intellectual development.[3]

Several cases of neonatal ascariasis have been described in the literature.[17,18] The mode of acquisition of these infections is unknown, but canine and feline ascarid infections commonly are acquired by a transplacental route, suggesting the possibility that this route also may occur in humans.

DIFFERENTIAL AND SPECIFIC DIAGNOSES

The differential diagnosis of pneumonia caused by *Ascaris* suggests a parasitic etiology because of the peripheral eosinophilia. Any nematode with a migratory phase through the lungs can mimic this infection, however. *Ascaris* must be considered as a cause of intestinal obstruction in any geographic locale where its prevalence is high.

The diagnosis of intestinal ascariasis is established by identifying the characteristic ascarid eggs through microscopic examination of stool. Efforts have been made more recently to detect *Ascaris* metabolites in the urine by gas-liquid chromatography.[24,25] HPA is suspected in heavily infected children who have signs of biliary obstruction. Ultrasonography and endoscopic retrograde cholangiopancreatography are useful adjunctive diagnostic procedures for these conditions.[27]

TREATMENT

For an ordinary *Ascaris* infection, either albendazole administered at a fixed dose of 400 mg once or mebendazole administered at a fixed dose of 100 mg twice daily for 3 days is effective. A single fixed dose of 500 mg of mebendazole also may be effective, but it may be unsuitable for the treatment of other STH co-infections. As an alternative, pyrantel pamoate administered in a single dose of 11 mg/kg, not to exceed 1 g, is effective. The benzimidazoles and pyrantel pamoate are not approved for children younger than 2 years old, and all the printed statements caution against the use of these drugs in the younger age group. An examination of the use of benzimidazoles in children 12 to 24 months old concluded, however, that these agents are probably safe and should be used if the circumstances warrant it.[31] In such cases, the dose of albendazole in these young children should be reduced to 200 mg.[1] The risk of treatment in this younger age group currently is undergoing more rigorous investigation because of mounting evidence that the growth and cognitive delay caused by STHs may be corrected with albendazole or mebendazole.[11-13,31,32] These drugs have a potential for embryotoxicity, however, so judicious use in young children is warranted. The World Health Organization is evaluating the use of benzimidazoles during pregnancy, particularly for use during the second and third trimesters.

In cases of intestinal obstruction, piperazine citrate may be effective because this drug paralyzes the myoneural junction of *Ascaris* and may result in relaxation of the matted bolus of worms. It is antagonistic to pyrantel pamoate, and these two drugs should not be administered together.

Management of intestinal obstruction or HPA often is surgical. For some patients, biliary decompression may be performed with endoscopic retrograde cholangiopancreatography.[27]

PROGNOSIS

The prognosis is excellent in most cases of ascariasis. In patients with obstruction or perforation, the prognosis depends entirely on the speed of recognition and therapy.

PREVENTION

Ascaris infection could be eliminated entirely through proper disposal of human excreta. As an isolated means of health improvement in the world, this approach seldom is successful. Elimination of *Ascaris* from a community or a substantial reduction in the incidence of this infection usually occurs after general poverty reduction efforts and improvements in the standard of living have been achieved. Periodic administration of community-wide therapy with anthelmintics has been effective in reducing worm burden as a short-term strategy. In the absence of aggressive sanitation and other control measures, however, re-infection can occur within 6 months after treatment in areas of high transmission,[14] although in areas of periodic therapy the intensity of infection is decreased, even if the prevalence is little affected.

TRICHURIS TRICHIURA

Trichuriasis has a prevalence approximating that of the other major intestinal nematode infections, or approximately 600 million cases worldwide,[1] but the infection usually is asymptomatic because in most cases it is light. Children with so-called asymptomatic light infection may have deficits in cognition, however.[3,7,44]

The infection is acquired by the ingestion of embryonated eggs acquired from the soil on hands or through contaminated food. The eggs hatch in the upper part of the small intestine, and the liberated larvae penetrate the villi. In contrast to the larvae of *Ascaris*, *Trichuris* larvae do not undergo extraintestinal migration, but remain in situ for approximately 1 week, at which time they begin a progressive descent into the cecum and the colon.

They mature there, and the attenuated anterior end of the adult worm embeds itself in the colonic mucosa. Creation of syncytial tunnels (derived from the columnar epithelium of the colon) is facilitated by the release of a parasite-derived, pore-forming protein.[38] The parasites derive their nourishment from these colonic mucosal tunnels. The entire cycle from the ingestion of embryonated ova to the development of sexually mature adults takes approximately 2 months. Persistence of the infection in a community depends on continual contamination of the soil with human feces.

EPIDEMIOLOGY

These parasites are found most commonly throughout the developing countries of the tropics and subtropics. The distribution of this worm often parallels that of *Ascaris*. In addition, as in the case of *Ascaris*, children with trichuriasis usually harbor greater numbers of worms than adults living under similar conditions.[35,36] Consequently, children have greater morbidity from trichuriasis than adults do. The mechanistic basis of added worminess in children is unknown, although researchers have observed that for all of the soil-transmitted helminthiases, including trichuriasis, infections are aggregated, with a few children having particularly heavy infections. These heavily infected children seem to have a genetic or immunologic predisposition to *Trichuris* infection.[35,36] Children also are the major source of *Trichuris* eggs in the environment, which when deposited in the soil become infective in approximately 1 month and remain viable for several months. They are killed by exposure to temperatures greater than 40° C within 1 hour. Freezing temperatures less than –8° C also destroy these eggs. Similar to ascarid eggs, they are resistant to chemical disinfectants.

PATHOPHYSIOLOGY

At the site of attachment, the adult worm elicits characteristic changes in the colonic mucosa as noted earlier. Inflammatory cells also are found at these sites, but they do not seem to account entirely for the clinical resemblance of trichuriasis to some forms of inflammatory bowel disease.[35,42] Similar to many other intestinal worms, *Trichuris* is expelled through the action of the host's immune system. This expulsion results from a combined effect of antibody and lymphoid cells.[45] Regulation of *Trichuris* populations in the gut has been ascribed to a carefully orchestrated balance of host-derived cytokines.[39] Although anemia has been attributed to trichuriasis,[40] the amount of blood loss caused by this parasite is much less than hookworm-associated blood loss and is insufficient to account for anemia.[41] One possibility is that *Trichuris*-induced anemia results from chronic inflammation, similar to the anemia of inflammatory bowel disease.[35,36]

CLINICAL MANIFESTATIONS

Two major disease syndromes are caused by heavy *Trichuris* infection during childhood.[35,36] *Trichuris* dysentery syndrome (TDS) is associated with severe diarrhea with blood and mucus. Children with TDS are anemic and frequently manifest growth retardation and failure to thrive.[37] Infants and toddlers with TDS are at risk for protracted tenesmus, which leads to rectal prolapse. *Trichuris* colitis is a more chronic manifestation of moderate to heavy infection that is characterized by a form of inflammatory bowel disease similar to what occurs in Crohn disease or ulcerative colitis. Children with this form of colitis also can have chronic malnutrition and short stature. Moderately and heavily infected (and possibly even lightly infected) children are at risk for having deficits in cognition and intellectual development.[44]

DIFFERENTIAL AND SPECIFIC DIAGNOSES

The diagnosis is established by identification of the characteristic barrel-shaped eggs through microscopic examination of stool. Clinically, heavily infected children with TDS may resemble children with amebic or bacillary dysentery. Children with *Trichuris* colitis may have signs and symptoms that resemble other forms of inflammatory bowel disease. The erythrocyte sedimentation rate is not elevated in children with *Trichuris* colitis, however.

TREATMENT

In the past, when noxious or toxic drugs had to be used, only patients with heavy infection were treated. Currently, any patient with this infection can be treated by the administration of either albendazole, administered as a single fixed dose of 400 mg (except for very heavy infections, in which consecutive doses for 3 days may be required), or mebendazole, 100 mg twice daily for 3 days.[43] A single dose of 500 mg of mebendazole also is used for mass drug administration in some developing countries. The dose does not need to be adjusted to the weight of the patient because the drug is not well absorbed from the gastrointestinal tract. As noted earlier, the safety of the benzimidazoles in very young children has not been established, but this may not preclude its use in the practice of pediatrics.[26] As an alternative, the drug oxantel is effective for the treatment of trichuriasis. In some countries, oxantel is formulated with pyrantel pamoate.[35]

PREVENTION

As in the case of other nematodes, sanitary disposal of excreta—but more important, improvement in the standard of living—tends to reduce the incidence of infection. Frequent mass treatments with mebendazole reduce the worm burden in a community.

HOOKWORMS

Hookworm infection is one of the most important infections of adults and children in the developing world, with an estimated prevalence of approximately 600 million cases.[1,5] Hookworms exert their pathogenic effect by causing intestinal blood loss, which leads to iron-deficiency anemia.[51] By considering the average daily blood loss induced by each worm, a moderate hookworm infection comprising 40 adult hookworms produces sufficient blood loss to rob a child of his or her daily iron requirement. Because loss of blood represents loss of erythrocytes *and* plasma, heavy infections also contribute to protein malnutrition.[51]

Two major species of hookworms infect the human intestine: *Ancylostoma duodenale* and *Necator americanus*, although *N. americanus* is found more commonly worldwide, especially in sub-Saharan Africa, Southeast Asia, and the Americas.[51] Two other members of the genus *Ancylostoma*, *Ancylostoma ceylanicum* and the dog hookworm *Ancylostoma caninum*,[52] are much less frequent causes of intestinal pathology in humans.[51]

The infection is acquired either by exposure of skin to moist soil infested with the larvae of these worms (*A. duodenale* and *N. americanus*) or by ingestion of the infective larvae (*A. duodenale* only). The most propitious circumstances for infection are shady areas and sandy or loamy soil. Infection is particularly likely to

occur early in the morning, when the ground is moist with dew, or after a rainfall. After the larvae enter the host, they initiate a developmental program that continues until they enter the intestine.[4,51] This process is coupled to the release of parasite-derived proteases and other virulence factors.[46,57] Larvae that enter through the skin are carried by the venous circulation to the right side of the heart and there follow the route described for *Ascaris*, whereas larvae that are ingested may develop entirely within the gastrointestinal tract.

On reaching the small intestine, the larvae mature to adult worms, which become attached with their mouth parts to the intestinal mucosa. The worms sustain themselves by releasing hydrolytic enzymes that degrade the intestinal mucosa and then feed on cellular and connective tissue debris.[51] During this process, capillaries and arterioles are eroded and lacerated, with subsequent extravasation of blood. The adult worms also ingest hemoglobin in blood through the action of parasite gut brush border proteases.[56] Anticoagulants that block the activity of host factor Xa and VIIa/tissue factor facilitate blood flow and are responsible for continued bleeding from the original site after the worm has moved to a new one.[47]

The entire cycle from penetration of the skin or ingestion of larvae to the development of mature worms usually takes approximately 6 to 8 weeks. At that time, hookworm eggs appear in the feces. *A. duodenale* larvae also may undergo a period of developmental arrest within the human host that lasts weeks or months. Intestinal ancylostomiasis can occur up to 1 year (and possibly longer) after initial exposure to infective larvae has occurred.[55] Investigators have conjectured that the reservoir of arrested *A. duodenale* larvae enters the mammary glands and breast milk.[50] This sequence of events may account for cases of infantile ancylostomiasis noted in Africa, India, and China.[50] Humans are the major reservoir of these organisms, and this infection is maintained by continual contamination of soil by human feces.

EPIDEMIOLOGY

Although in ancient times these parasites had a worldwide distribution, they currently are most prevalent in areas of rural poverty in the tropics and subtropics. *A. duodenale* predominates in many parts of the Indian subcontinent and focal areas of China north of the Yangtze River.[4] *N. americanus* is the predominant hookworm in the world, especially in the Western Hemisphere, most of Africa, China south of the Yangtze River, Southeast Asia and Indonesia, and certain islands of the Pacific. *A. duodenale* also is a major parasite in Egypt and other parts of the Mediterranean region, Africa, and a few focal areas in South America, including Paraguay and northern Argentina. A small Central American focus also exists in southern Honduras and El Salvador, and one exists among Aboriginal populations in Australia. This differential distribution is not always absolute, and small numbers of either parasite can be present where the other predominates. Mixed infections with both species are common. *A. ceylanicum* occurs in focally endemic areas of southern Asia,[51] whereas the dog hookworm *A. caninum* has been described as a cause of human eosinophilic enteritis in Australia and possibly elsewhere.[52]

Larvae survive in soil for 6 weeks. They are destroyed by drying, freezing temperatures, and heat greater than 45° C. Hookworm infection occurs in areas with high agricultural intensity and is not found frequently in urban areas, where *Ascaris* and *Trichuris* might predominate. Because shade and moisture are essential for survival at the infective larval stage, a not surprising finding is high rates of hookworm infection in families that harvest tea in India and Bangladesh, mulberry leaves (for the silkworm industry) in eastern China, sweet potatoes and corn in western China, coffee and bananas in Central and South America, and rubber in Africa.

Similar to other STHs, hookworm infections usually are aggregated such that most individuals harbor light worm burdens, whereas a substantial minority harbor moderate or heavy infections.[51,55] Even after receiving specific anthelmintic chemotherapy, moderately and heavily infected individuals seem to be predisposed to the reacquisition of heavy infection.[55] A predisposition to hookworm infection may have a genetic or immunologic basis.

In contrast to the other STHs, high rates of hookworm infection occur in adults and children. In some regions, the age-associated prevalence and intensity increase linearly, with the heaviest infections occurring in elderly populations.[48]

PATHOPHYSIOLOGY

During the migratory phase of the infection, the larvae evoke an inflammatory response associated with eosinophilic infiltration. Immune responses to the infection have been difficult to study in humans, but in an animal model, a dog infected with *A. caninum* can be rendered immune to challenge infection by receiving repeated dosing with the infective larvae. This observation has provided a means of producing a live attenuated larval vaccine in the laboratory, but one that is unsuitable for humans. Reproduction of this larval vaccine effect by using specifically genetically engineered polypeptides is in progress.[5,46,49]

The major source of injury to the host is loss of blood, with *A. duodenale* producing greater blood loss than *N. americanus*. Rarely, massive bleeding has been reported.[53] Iron-deficiency anemia results when iron loss exceeds the host's iron reserves. Because children and women of reproductive age generally have lower iron reserves than do other populations, they are at the highest risk for developing hookworm disease and anemia.[51] Long-standing moderate and heavy infections result in the characteristic features of severe iron deficiency. Loss of protein contributes further to malnutrition. Together the iron and protein malnutrition result in impaired growth and physical fitness.[9,11-13,51] In some cases, hypoproteinemia can be corrected by a high-protein diet without deworming the patient,[53] although the World Food Program and other international agencies now frequently incorporate deworming into their nutritional supplementation programs. In addition to the physical deficits noted earlier, hookworms may affect cognitive development because iron is important for the development of dopaminergic neurons and for the biosynthesis of some neurotransmitters.[51]

CLINICAL MANIFESTATIONS

Penetration by larvae causes "ground itch" or "dew itch," a pruritus that occurs after walking in the morning dew. These cutaneous manifestations can occur on almost any part of the body. This phase of early infection is followed within days to weeks by a pneumonitis, which typically is less pronounced than *Ascaris* pneumonitis.

The acute intestinal phase in heavy infections is characterized by abdominal pain, diarrhea, nausea, and anorexia.[50] Eosinophilia occurs approximately at the onset of the intestinal phase. Subsequently, well-nourished individuals with light infections have mild gastrointestinal symptoms, but no evidence of anemia or malnutrition. At the other extreme, heavily infected children can have hemoglobin values of 2 g/dL and edema or anasarca caused by hypoproteinemia. Infants with severe ancylostomiasis can exhibit failure to thrive, profound pallor, and melena.[50]

Deficits in physical and intellectual growth as a result of chronic hookworm infection in childhood have been reported

since the early part of the 20th century.[3,4,9,10,51] Some recovery has been described after "deworming," although some deficits occurring in infancy may be irreversible.

DIFFERENTIAL AND SPECIFIC DIAGNOSES

Hookworm pneumonitis resulting from the early migratory stages typically is nonspecific in its presentation and difficult to diagnose. Hookworm anemia is caused by blood loss; it must be distinguished from all other causes of intestinal loss of blood. In the developing countries, where severe hookworm anemia is common, the probability of the occurrence of rarer causes of intestinal blood loss, such as Meckel diverticulum and polyps, is low. The opposite holds true for regions where hookworm infections are light or infrequent. In sub-Saharan Africa, the distribution of hookworm overlaps with other significant causes of so-called agricultural anemias, including malaria, schistosomiasis, malnutrition, and hemoglobin polymorphisms.[6]

The diagnosis is established by identifying the characteristic eggs by microscopic examination of stool. The eggs of *A. duodenale* and *N. americanus* cannot be distinguished from each other by morphologic criteria, but the worms can be differentiated by direct examination of the infective larvae or adults. One must assume that it is one or the other species on the basis of the geographic origin of the patient. Although this decision is not of paramount importance, it does have some therapeutic implications, including the possibility that arrested larvae of *A. duodenale* would become reactivated and either repopulate the intestine at some point after treatment or enter breast milk during or after parturition.

TREATMENT

For *N. americanus* infection, the drug of choice is either albendazole, administered at a fixed dose of 400 mg, or mebendazole, given as 100 mg twice daily for 3 days. Pyrantel pamoate given as a dose of 11 mg/kg, not to exceed 1 g, for 3 days is a suitable alternative drug. In areas endemic for ancylostomiasis, the health care provider should be aware of the potential of arrested tissue larvae to repopulate the intestine or enter breast milk and infect infants during the perinatal period. Iron supplementation and transfusion are occasional important adjunctive therapies for severe hookworm disease.

PREVENTION

As in all cases of all STH infections, the sanitary control of the disposal of excreta represents an important public health control measure. Accomplishing effective sanitation in resource-poor settings has not been feasible in most of the developing world. The popular recommendation to wear shoes is naive because *N. americanus* larvae also enter through the upper extremities, torso, and legs, and because *A. duodenale* also is orally infective. Studies to develop and test a first-generation recombinant hookworm vaccine are in progress.[5,46,49]

ENTEROBIUS VERMICULARIS

Pinworm infection (enterobiasis), or oxyuriasis (the older term), is one of the most frequent of all human helminth infections and one that is common in North America and Europe.[63] Some investigators think that the overall prevalence of enterobiasis is declining in the United States, however. Most infected individuals are children, and the infection is found in all socioeconomic classes. It is acquired by the ingestion of infective eggs picked up on the perianal skin, in the air, or on bedclothes and underwear. Swallowed eggs, transmitted to the mouth by fingers or through inhalation, hatch in the duodenum, and the liberated larvae undergo additional maturational steps in the small intestine before reaching the cecum. There, the sexually mature worms copulate and proceed to the rectum and eventually to the perianal skin, where the gravid females lay eggs. The eggs become infective within 2 to 4 hours after deposition.

The entire cycle from ingestion of the egg to the egg-laying phase of the gravid female is 4 to 6 weeks. Rarely, a retrograde infection occurs in which eggs hatch on the anal mucosa, and the larvae migrate up the bowel and mature to adult worms. Although enterobiasis is a human infection, anthropoid apes can be infected experimentally.

EPIDEMIOLOGY

The infection is worldwide in distribution, and children are infected most frequently. Communal living, especially assembling in school gymnasia and living in crowded households, promotes transmission of the infection. Adults tend to be infected through their contact with children; parents and teachers are the most vulnerable. Orphanages and daycare centers frequently are affected.[63]

PATHOPHYSIOLOGY

No intestinal reactions occur during the migratory phase, and because no tissue migration takes place, no eosinophilia occurs to the degree seen with some other nematodes. Occasionally, hypersensitive individuals may have a slight increase in eosinophils. The deposited ova induce pruritus on the perianal skin. No evidence indicates that some individuals are more susceptible than others to this infection.

Enterobius occasionally has been found in vermiform appendixes removed at surgery. A causal relationship to appendicitis has not been established, but some evidence points to the possibility that this worm induces granuloma formation and may cause obstruction of this vestigial structure.[58]

When the adult gravid female migrates along the perineal skin into the vagina, it may cause vulvitis as a reaction to the eggs deposited in that region. Some investigators speculate that migrating pinworms may introduce bacteria into the lower urinary tract and result in urinary tract infection.[62] Other aberrant infections, such as those causing hepatic granuloma, occur more infrequently.[61]

CLINICAL MANIFESTATIONS

Pruritus is the most common symptom; its intensity varies from mild itching to acute, intractable pain. Secondary cellulitis also may occur in severely pruritic cases.[60] Vaginal discharge and vulval itching are symptoms in the rare cases in which a worm has migrated into the vagina. Insomnia, restlessness, irritability, loss of appetite, loss of weight, and grinding of teeth all have been reported anecdotally in individuals with pinworm infection, but no evidence has shown that any of these symptoms is related causally to *Enterobius* infection. Enuresis also has been blamed on the pinworm, but one epidemiologic study failed to determine the causality.[64] An unusual form of eosinophilic ileocolitis resulting from massive infestation with many *E. vermicularis* larvae has been described in a homosexual man.[59]

SPECIFIC DIAGNOSIS

E. vermicularis eggs are identified readily by low-power microscopic examination of transparent adhesive tape previously applied to the perianal skin and then affixed to a microscope slide.

TREATMENT

Single-dose therapy with mebendazole (100 mg), albendazole (400 mg), or pyrantel pamoate (11 mg/kg, not to exceed 1 g) is effective. With the current availability of these three highly effective drugs, the intensive laundering of underwear and bed clothing, recommended in the older literature, no longer is necessary. Treating all members of the household is advisable, however, because they all must be presumed to be infected. Re-treatment in 2 or 3 weeks to destroy any adult worms that have hatched from the eggs swallowed at the time of initial therapy may be necessary. None of these drugs destroys the eggs.

One of the most important aspects of management of this infection is reassurance that its ubiquity virtually precludes effective eradication. Re-infection can be anticipated in any family infected with pinworms because of the high prevalence of this worm in the community. It also is important to reassure families that the presence of pinworms does not suggest poor hygienic standards in the family.

STRONGYLOIDES STERCORALIS AND *STRONGYLOIDES FUELLEBORNI*

Strongyloides stercoralis and *S. fuelleborni* are among the most virulent helminthic pathogens of humans, although they are much less prevalent than *Ascaris* or hookworm. *S. stercoralis* has the unusual ability to cause autoinfection, which can lead to hyperinfection and disseminated infection in immunocompromised hosts.[68,70,72-77,79,83,84] *S. fuelleborni* causes an aggressive infantile protein-losing enteropathy that leads to ascites and high mortality rates.[65,66]

S. stercoralis infection is acquired by the exposure of skin to infective larvae in the soil, much as in the case of hookworm infection. Similar circumstances that promote the survival of hookworm larvae in soil (i.e., moisture, sandy or loamy soil, and shade) promote the survival of *Strongyloides*. Larvae penetrate skin, facilitated by a potent histolytic protease that they secrete.[67,81] From the moment of penetration of the skin to the arrival of the worms in the intestine, the cycle commonly is thought to be similar to that of hookworms, although experimental evidence suggests that *S. stercoralis* also may explore routes of migration that bypass the lungs.[86] Within the intestine, the small adult worms do not attach to the mucosa as hookworms do, but instead lie embedded in its folds. The cycle from penetration of skin to development of mature worms in the intestine is approximately 28 days.

No parasitic adult male worms exist to fertilize the eggs. Instead, the mature eggs develop by parthenogenesis. In addition, in contrast to the eggs of other parasitic nematodes, these eggs usually are not found in feces but instead embryonate within the intestine and develop into larvae, which are deposited in soil with human stool. These so-called rhabditiform larvae must molt before they become infective.

This cycle has two variations. One permits the development of nonparasitic male and female adults in soil, which can maintain infestation of the soil for a certain period; this free-living phase sometimes is called the *heterogonic life cycle*. The second variation has much greater clinical relevance. Under certain conditions that are not well defined, the rhabditiform larvae molt to new infective larvae while still in the intestine. These new infective larvae can penetrate the intestine and set up a new cycle, commonly called *autoinfection* or the *autoinfective cycle*.[75] In this fashion, this nematode, in contrast to most other intestinal nematodes of humans, actually can increase in number without re-infection from the outside world. This phenomenon also is responsible for persistence of this infection for decades in an untreated host.[77] Some investigators think that low levels of autoinfection occur in most patients with strongyloidiasis.

When host defenses are impaired, especially through use of high-dose steroids (discussed later), *S. stercoralis* can undergo multiple rounds of autoinfection, leading to the production of thousands to hundreds of thousands of adult parasites in the intestine. This phenomenon is known as *hyperinfection*.[68,72,76,83] One possible consequence of hyperinfection is disseminated infection, in which larval and adult worms are identified at extraintestinal sites.

S. fuelleborni larvae are passed to infants by ingestion in breast milk.[65,69] Transmammary infection by nematode larvae is an extremely common route of transmission in nonhuman nematode infections[8]; although not well studied, it probably also occurs commonly in humans.

EPIDEMIOLOGY

S. stercoralis infection has worldwide distribution, but it is most prevalent in tropical and subtropical regions. In North America, strongyloidiasis is focally endemic in some parts of Appalachia[70] and is common in Southeast Asian immigrants.[78] In one study, 76.6 percent of Kampuchean immigrants and 55.6 percent of Laotian immigrants were seropositive for *S. stercoralis* infection.[78] Strongyloidiasis also is endemic in Jamaica and presumably elsewhere in the Caribbean.[84] Because of the possibility of autoinfection and, by extension, infection through contamination of skin by infested feces, strongyloidiasis is highly prevalent in mental hospitals, prisons, and homes for retarded children. Dogs and anthropoid apes may serve as animal reservoir hosts for *S. stercoralis*. *S. fuelleborni* infection is endemic in Papua New Guinea and parts of sub-Saharan Africa.[65,66]

PATHOPHYSIOLOGY

During the migratory phase of the infection, the larvae of *S. stercoralis* evoke an inflammatory response associated with eosinophilic infiltration. The adult phase in the intestine, even in moderate infection, may be associated with an inflammatory reaction sufficient to be symptomatic. Some evidence suggests that *Strongyloides* induces a malabsorption syndrome, which has been treated effectively by deworming.[70,82] It also has been noted, however, that the diarrhea associated with strongyloidiasis in young children occurs more frequently in those with underlying malnutrition.[72] Young children with *S. stercoralis*–induced malabsorption experience growth stunting and failure to thrive.[70]

The deficits in host defense that promote hyperinfection and disseminated strongyloidiasis are not well understood. Although cell-mediated immune deficits, such as those occurring in immunosuppression, organ transplantation, severe malnutrition, and cytotoxic chemotherapy for neoplasms and collagen vascular disease, are associated with this phenomenon, certain established deficits in cell-mediated immunity, such as those in human immunodeficiency virus infection, do not trigger hyperinfection.[75] Researchers have suggested that patients receiving large

doses of corticosteroids are particularly susceptible to hyperinfection because the corticosteroids themselves function as direct signals or ligands for the parasite to undergo autoinfection.[75] Patients in Japan and Jamaica with human T-cell lymphotropic virus type I seem to be at high risk for acquiring opportunistic strongyloidiasis,[73,79] possibly because of a specific deficit in their effector IgE immune response.[84] The pathogenesis of the marked protein-losing enteropathy that leads to ascites in the swollen belly syndrome of *S. fuelleborni* infection has not been established.

CLINICAL MANIFESTATIONS

During the migratory phase of larval strongyloidiasis, patients may be susceptible to the development of pneumonitis associated with eosinophilia. Larval migration through the skin can result in larva currens. Although most patients harboring *S. stercoralis* in their intestine are asymptomatic, patients with moderate or heavy infection classically have intense diarrhea productive of watery, mucous stool. Periods of alternating diarrhea and constipation may occur. Anorexia and cachexia, which lead to failure to thrive and other deficits in physical growth, are common features of pediatric strongyloidiasis.[70]

In disseminated strongyloidiasis caused by the hyperinfective cycle, larvae may invade all tissues, including the central nervous system (CNS). Because larvae penetrate the intestine, they may carry with them enteric flora and cause sepsis or meningoencephalitis.[68] Although diarrhea is the most commonly recognized consequence of *Strongyloides* infection, the hyperinfective cycle has the greatest portent for immunosuppressed patients. Infants with *S. fuelleborni* infection may manifest the swollen belly syndrome with marked abdominal ascites and pleural effusions that can be fatal.

DIFFERENTIAL AND SPECIFIC DIAGNOSES

Strongyloides pneumonitis can resemble the clinical manifestations associated with the lung migration of other nematode parasites, such as *Ascaris* and hookworm. The differential diagnosis of diarrhea must include causes of chronic diarrheal disease. In some patients, eosinophilia is a presenting sign of strongyloidiasis, either in patients with diarrhea or even in asymptomatic immigrants from developing countries.

The diagnosis is established by identification of the characteristic larvae during microscopic examination of stool, which is not easy because rhabditiform larvae usually are not produced in abundance. Specific stool concentration techniques are available to increase the sensitivity of fecal examination, although they are not as effective as amplifying the heterogonic life cycle by the Baermann technique or by looking for characteristic larval tracks on nutrient agar plates.[87] The stool of all immunosuppressed individuals, including those given corticosteroids for any reason, who have ever been in a region where *Strongyloides* is found must be examined to rule out this infection. If routine stool examination results are negative, the stool should be processed as outlined earlier. In addition, examination of duodenal contents can be attempted by the string test (Enterotest). This examination only divulges the contents of the duodenum, however, and can miss the larvae in the lower part of the small intestine. An enzyme-linked immunosorbent assay (ELISA) for detection of *Strongyloides*-specific antibodies is available on a research basis.[78,84]

Children with the swollen belly syndrome from *S. fuelleborni* infection shed eggs rather than larvae in their feces. Large numbers of eggs are common findings in clinical cases.

TREATMENT

Previously, the drug of choice for *S. stercoralis* and *S. fuelleborni* infection was thiabendazole,[71] administered at a dose of 50 mg/kg/24 hours divided into two equal doses on each of 2 successive days. The drug has high toxicity, however, which frequently includes nausea, vomiting, and vertigo, and sometimes requires interruption of therapy. Rarely, it induces leukopenia, rash, and Stevens-Johnson syndrome. Because the drug is detoxified in the liver, its dose may have to be reduced for patients with liver failure. Another benzimidazole used with increasing frequency is albendazole, 400 mg twice daily for 7 days. In the United States, albendazole is still considered investigational for this purpose.

Ivermectin is considered the treatment of choice for strongyloidiasis. It is administered at a dose of 200 μg/kg/day for 2 days. Treatment with ivermectin gives a cure rate of 80 percent.[79,80] Because the mortality rate of patients with disseminated strongyloidiasis remains high despite specific anthelmintic therapy, a common practice is to treat with a prolonged course or with a repeat course. In addition, several case reports have now described the use of veterinary parenteral formulations in patients too ill to take oral medications,[80] or use of ivermectin combined with albendazole.[82] Secondary bacterial complications, such as sepsis and meningitis, are common with disseminated strongyloidiasis, so judicious use of broad-spectrum antimicrobial agents frequently is indicated for this condition. As an additional supportive measure, patients who have hyperinfective strongyloidiasis and are receiving high-dose corticosteroid therapy probably benefit from steroid taper. Patients with transplants and cyclosporine immunosuppression may benefit from some of the direct helminthotoxic properties of this compound.[85]

PROGNOSIS

The prognosis is excellent in patients who do not have disseminated infection and are treated promptly. Unrecognized disseminated infection can be lethal.

PREVENTION

Proper disposal of human excreta substantially reduces the prevalence of strongyloidiasis in any community. In closed institutions, where control of direct spread is not likely to be achieved, identification plus treatment of infected individuals is the only feasible control.[74]

ABERRANT INFECTIONS WITH INTESTINAL NEMATODES

TOXOCARA CANIS

As indicated in the previous sections, the life cycles of the intestinal nematodes are adjusted precisely through evolutionary selection. In many instances, only one host in which the cycle can be completed is parasitized by the nematode. Infection of an unnatural host, in most cases, leads to complete failure of development and causes no disease. In a few instances, an infection may be established, but the cycle is not completed. Under such circumstances, the process of aberrant migration of larvae may be more pathogenic than steps in the natural cycle.

One of the most dramatic examples of an aberrant infection is visceral larva migrans, caused by infection with *Toxocara canis*. This roundworm causes intestinal infection in the dog, in which

its cycle resembles that of *A. lumbricoides* in humans. Humans become infected by *Toxocara* through the ingestion of an embryonated egg, much as in human infection with *Ascaris*. Larvae hatch in the small intestine, penetrate the villi, and begin a migration that takes them through every organ and tissue of the body. Because they cannot mature, the larvae tend to migrate for months until they are overcome by the inflammatory reaction of the host and die. Although larvae of other toxocarids such as *Toxocara cati* and *Toxascaris leonina* have been suggested as possible causes of visceral larva migrans, they are probably much less important as zoonotic pathogens in humans.

Because population-based serologic testing is limited to only a handful of research studies,[88,97,104,105] the prevalence of toxocariasis in North America and elsewhere may be underestimated. *T. canis* infection may have replaced *E. vermicularis* as the most common helminth parasite in the United States.

EPIDEMIOLOGY

The prevalence of toxocariasis is difficult to assess because of the failure of establishing the diagnosis in many cases. The disease has been reported from many parts of the world, including temperate climates, and one can assume that it is found wherever humans and dogs coexist. Young children often come into contact with *T. canis* eggs while playing in sandboxes and on playgrounds that were contaminated by a family pet.[99,100] The level of contamination of public areas also is difficult to ascertain. In several studies, ova were present in 5 to 25 percent of soil samples obtained, and surveys of dogs in urban communities have shown the occurrence of frequent infections, particularly in puppies, which are infected almost universally with *T. canis* (canine infection occurs transplacentally).[94,95]

Subsequent dissemination of *T. canis* eggs in the environment probably is aided by migrating earthworms and other soil invertebrates.[92] The seroprevalence of toxocariasis in the United States is high, and the parasite should be considered an emerging pathogen in some poor urban areas. In some groups of socioeconomically disadvantaged black children, the seroprevalence is 30 percent,[98,103] with even higher rates occurring among U.S. inner-city Hispanic children.[105] Toxocariasis is endemic to Puerto Rico. Major risk factors for acquiring toxocariasis include having a litter of puppies in the home and the habit of geophagia.[101] The latter risk factor probably accounts for the observed association between toxocariasis and elevated lead levels.[101] In Ireland, the prevalence of ophthalmologist-diagnosed ocular toxocariasis is 9.7 per 100,000.[98]

The presence of a positive skin test for toxocariasis is associated with poliomyelitis statistically.[108] No direct causal relationship exists; possibly, the circumstances leading to ingestion of *Toxocara* ova also are conducive to ingestion of poliomyelitis virus. Likewise, seizures are correlated with seropositivity for *Toxocara* antibodies, but a causal relationship has not been established.[88] Some investigators have postulated that toxocariasis may be an important cause of so-called idiopathic seizures in young children.[96,99]

PATHOPHYSIOLOGY

The entire infection is restricted to the migratory phase and represents an "exaggeration" of the symptoms found during the early phases of *A. lumbricoides* infection. Symptoms are protean and depend on which organ or tissue is infected. For unknown reasons, visceral migration through the liver, lungs, and brain occurs more commonly in toddlers and children younger than 5 years old, whereas older children tend to have ocular involvement almost exclusively.[99,100] Epidemiologic evidence suggests that this infection produces two distinct syndromes, visceral and ocular, because involvement of one tends to occur in the absence of the other.[97] Visceral migration elicits eosinophilic granuloma formation in the target organs and leads to hepatitis, pneumonitis, or cerebritis. Larval migration in the retina results in ocular larva migrans, which includes granuloma formation in the retina.[89,93,106] The lesion can resemble retinoblastoma so that it often is confused with it. Endophthalmitis[93] or papillitis[92] also may develop. Invasion of other organs and tissues induces granuloma formation there.

CLINICAL MANIFESTATIONS

Most patients infected with *T. canis* are thought to be asymptomatic. Some of these individuals have isolated findings, including eosinophilia, or wheezing and asthma. The term *covert toxocariasis* is used by some investigators to describe these patients, who often are identified by their circulating anti–*T. canis* antibody titers. An association between asthma and covert toxocariasis has been well described in Europe, but as yet this association is unproven in North America.[105]

Visceral larva migrans, the extreme form of toxocariasis, typically occurs in a toddler with the symptoms and signs of a multisystem disease. It is associated with fever, hepatosplenomegaly, lung infiltrates accompanied by wheezing, a high degree of eosinophilia (approaching 80%), and elevated immunoglobulin levels, particularly of the IgM class.[96,99-101] Seizures and neuropsychiatric disturbances also are common. In one case report, the child's major neurologic manifestation was a static encephalopathy.[96]

In contrast, ocular larva migrans is characterized by a unilateral vision deficit and, sometimes, strabismus. Ophthalmologic examination frequently reveals one or more posterior poles or peripheral pole granulomas.[93,100,106] More global eye inflammation also can occur (discussed earlier). Children with ocular involvement usually have few, if any, systemic manifestations. Often, no laboratory abnormalities are detected.

DIFFERENTIAL AND SPECIFIC DIAGNOSES

Visceral larva migrans must be distinguished from the migratory phase of the other nematode infections. Because of hepatosplenomegaly and hypereosinophilia, eosinophilic leukemia occasionally has been suspected, but it can be ruled out readily by examining bone marrow.

T. canis larvae can be identified in tissues in liver biopsy specimens, but the diagnostic yield is low. One must resort to indirect means and be aware that a multisystem disease with elevated IgM and hypereosinophilia fits the diagnostic criteria. An ELISA test available at the Centers for Disease Control and Prevention is highly specific and diagnostic.[100,103,104]

Ocular larva migrans usually is diagnosed by an experienced ophthalmologist who recognizes the characteristic granulomas and larval tracks on retinal examination. Presumably because of minimal antigen presentation by a few migrating larvae in the eye, often no measurable immune response occurs in this condition. For this reason, ELISA frequently is unreliable for establishing the diagnosis of ocular larva migrans.[98,100,101,103,104]

TREATMENT

Traditionally, treatment of visceral larva migrans was primarily symptomatic, especially because much of the morbidity is associated with immunopathologic responses against dying parasites. In the 1960s, thiabendazole and diethylcarbamazine were determined to be effective against migrating larvae.[102] Since then, new

agents of the benzimidazole class have been claimed to be equally effective, but associated with fewer drug toxicities.[99] In a comparative study with thiabendazole, the drug albendazole (10 mg/kg/day in two divided doses for 5 days) was shown to be well tolerated and less toxic.[107] Another benzimidazole, mebendazole, also may be effective when given in doses high enough to achieve significant extraintestinal levels.[90] Albendazole (400 mg twice daily for 5 days) is the treatment of choice. Although anecdotal experience with albendazole and mebendazole overseas suggests that these drugs are safe in children,[91] the large doses required for the treatment of larva migrans may be associated with hepatic and other toxicities (including embryotoxicities), and they have not been approved for this purpose.

Treatment of ocular larva migrans often requires surgical management, particularly in cases associated with tractional retinal detachment.[93,106] Specific anthelmintic adjunctive chemotherapy seems to be beneficial in some cases.[94,99,106]

PROGNOSIS

Except for patients in whom blindness develops as a consequence of retinal damage and a rare fatal case resulting from the intensity of the acute clinical reaction, most patients recover. The recovery phase may be slow, however, and may take 2 years.

PREVENTION

Theoretically, the disease can be prevented by elimination of dog feces from the human environment, but in practice, it is no less difficult to achieve than control of human excrement disposal.

OTHER ABERRANT INFECTIONS WITH INTESTINAL NEMATODES

Baylisascaris procyonis, a parasite of raccoons, also can cause visceral larva migrans. *Baylisascaris* infection occurs when humans accidentally ingest parasite eggs that are shed in barn lofts and attics accessible to raccoons.[101,113,114,116,118] In at least one reported human case, the infection was fatal in an infant.[116] Similar to *Toxocara* infection, *Baylisascaris* larvae within aberrant hosts cannot complete their cycle and continue their aimless migration through the tissues of these hosts. Baylisascariasis is probably more severe owing to the propensity of the larval stages of the parasite to invade the CNS, however, along with the continued growth of the larvae during migration resulting in greater mechanical damage.[113,114] The lesions caused by the larvae are eosinophilic granulomas, which tend to be concentrated in the CNS and result in eosinophilic meningitis. Neither the frequency nor the range of severity of this infection in humans is known. Most human cases have been diagnosed at autopsy. Because baylisascariasis is so uncommon, no studies are available to evaluate different anthelmintic chemotherapy regimens systematically. Some clinicians have recommended prolonged treatments with high doses of albendazole.[113,114]

Other, less severe aberrant infections of importance to humans are those caused by the dog hookworm, primarily *Ancylostoma braziliense*, but also *A. caninum* and *Uncinaria stenocephala*.[50,113,115,126] Infection with the larvae of *A. braziliense* and *U. stenocephala* cannot be completed, and larvae remain viable and migrate in the skin (usually between the epidermis and dermis); hence the terms *cutaneous larva migrans* and *creeping eruption* are used. In North America, cutaneous larva migrans is common along the Gulf Coast and along the Atlantic seaboard.[51] It also is common in the Caribbean. Failure of these zoonotic hookworms to complete entry through the human skin may reflect differences in the hydrolytic enzymes released.[115] Infection is acquired in the same fashion as that of the human hookworms. Children who expose their whole bodies to contaminated soil may be infected at any site. Adults are most likely to have infection in the lower extremities, but plumbers in the tropics, who often must crawl beneath houses, acquire infection on the elbows and knees.

The interval from exposure to appearance of the first symptoms is approximately 2 weeks; papules 2 mm in diameter then begin to appear on the skin. Behind them usually are serpiginous, erythematous, intracutaneous tunnels. The entire area itches intensely. Left untreated, cutaneous larva migrans tends to last 2 months. Albendazole (400 mg daily for 3 days) or ivermectin (200 μg/kg daily for 1 to 2 days) is effective treatment when administered orally. Topical therapy with a 15 percent aqueous suspension of thiabendazole was successful in one reported series. Forty-seven of 50 patients achieved permanent cure in 2 weeks, and 2 more patients were cured after a third week of treatment.[129] Placebo-treated patients were used as controls in this study. In contrast with skin penetration of zoonotic hookworms, oral ingestion of the dog hookworm *A. caninum* results in an eosinophilic enteritis syndrome (discussed in the section on hookworm infection).

Rarer aberrant infections include those caused by various species of *Trichostrongylus*, *Oesophagostomum*, *Angiostrongylus*, *Capillaria*, and *Anisakis*. *Trichostrongylus* is a common parasite of many mammals, and it has been found in the small intestine of humans, mainly in Asia, Africa, and Australia. Ingestion of larvae leads to the development of adult worms in the small intestine. Whether this development results in any disease remains a moot point because infections tend to be mild and usually are associated with other helminth infections.[114] *Oesophagostomum bifurcum* is a common nematode of subhuman primates in Africa and has been reported to be a common intestinal nematode that causes nodular disease of the intestines in humans living in West Africa.[120,123] Human oesophagostomiasis has been treated successfully with pyrantel pamoate.[120]

Land snails and slugs serve as intermediate hosts for *Angiostrongylus* spp. *Angiostrongylus cantonensis* is a cause of eosinophilic meningitis throughout East Asia and Hawaii[111,119,124,125]; *Angiostrongylus costaricensis* is a cause of mesenteric arteritis and abdominal pain in Central and South America and in Latin American immigrants to the United States.[117] The rat serves as the natural host of these parasites, which live either in the lung (*A. cantonensis*) or in mesenteric arteries (*A. costaricensis*). The rat eats the infected mollusks and ingests the larvae, which migrate to their final destination. An incomplete infection develops in individuals who ingest either the mollusks or food contaminated by the mollusks. *A. cantonensis* infection usually is limited to the CNS and is manifested as eosinophilic meningitis.[111,119,124,125]

Signs and symptoms include meningismus, severe headache, paresthesias, and, less commonly, cranial nerve palsies. No specific treatment is available (although the anthelmintics thiabendazole and ivermectin are effective in some experimental animal models[111]), but the disease is self-limited and lasts no longer than 2 weeks. Symptomatic relief has been reported with the use of prednisone. In contrast, *A. costaricensis* infection typically is manifested as abdominal or right iliac fossa pain, fever, and eosinophilia. In children with this condition, appendicitis or Meckel diverticulum may be diagnosed.[117] High doses of mebendazole have been tried as therapy for this condition, as well as albendazole.

Capillaria philippinensis is a common parasite of water fowl in the Philippines.[110] The mode of transmission of this parasite to humans is unknown, but human cases have been reported in which 40,000 adult worms were found embedded in the crypts of the small intestine. *C. philippinensis*, similar to *S. stercoralis*, can undergo autoinfection and hyperinfection in humans.[110] No associated inflammatory reaction occurs, but flattening of villi, loss

of epithelial surface area, and severe malabsorption have been reported.[110,112,128] In one series of 1000 cases of *C. philippinensis* infection, a mortality rate of 10 percent was reported.[112] Thiabendazole may be effective in shortening the course of the infection,[128] although albendazole has become the treatment of choice more recently.[110] Another member of the genus, *Capillaria hepatica*, a rare zoonosis of humans, has been known to disseminate to the lungs, liver, and other viscera.[122]

Anisakis spp. are nematode parasites of marine mammals, with fish being intermediate hosts. When the infective larvae of the parasite are ingested as a result of eating raw or poorly cooked fish, they may become embedded in the gastric mucosa and cause eosinophilic granuloma.[51,109,121,127,130,132] In adults, it may resemble carcinoma of the stomach clinically and radiographically. Human anisakiasis occurs frequently in Japan, where raw marine fish are eaten commonly, and in Holland, where lightly pickled herring is considered a delicacy.

FILARIAL PARASITES

Except for rare instances of zoonotic *Brugia* infection, the filarial worms parasitizing humans affect people within the geographic area almost entirely limited to the developing world, especially sub-Saharan Africa and India. Although accurate data are lacking, approximately 100 million people are infected with lymphatic filariasis (LF), and 18 million are infected with onchocerciasis. The various human parasites in this category have certain characteristics in common. They all are spread by vectors, and the adults invade and occupy the lymphatics, skin, connective tissue, or blood. They produce live embryos called *microfilariae* that enter the bloodstream or skin, where they can survive for months or years without further development. The range of disease caused by these worms is wide; some produce no symptoms, whereas others can be responsible for severe clinical disorders.

The life cycles of the filarial worms are similar in that infections are acquired through an insect bite, during which transmission is effected by introduction of infective larvae onto the skin of the host from the mouth parts of the insect. The larvae enter the wound in the skin and make their way to the respective tissue, where they mature into adult worms. The adults mate and produce live microfilariae, which, in LF, migrate to the blood through the walls of the lymphatics or through the thoracic duct. To complete the life cycle, the microfilariae are ingested by blood-sucking insects, in which they undergo metamorphosis through two larval stages until they reach the third, infective stage. The interval from the infective bite to the appearance of microfilariae in the blood of the host can be 6 to 12 months.

Mass drug administration with ivermectin alone (for onchocerciasis), or ivermectin together with albendazole (for LF), or diethylcarbamazine with albendazole (also for LF) can reduce the microfilarial load of human populations living in endemic regions.[131] For onchocerciasis, reductions in microfilarial loads lead to reductions in chronic morbidity, with marked improvement in the serious skin manifestations of the infection and the prevention of blindness. For LF, widespread implementation of mass drug administration one day may reduce transmission to the point of elimination. Such programs are currently under way in 10 countries of sub-Saharan Africa. In Egypt, five rounds of mass drug distribution already may have effectively eliminated transmission.[132] Mass drug administrations provide the core activities of several international public and private partnerships, including the Global Alliance to Eliminate Lymphatic Filariasis, the African Programme for Onchocerciasis Control, and the Onchocerciasis Elimination Program for the Americas.[133,134]

LYMPHATIC FILARIASIS: *WUCHERERIA BANCROFTI* AND *BRUGIA* SPECIES

EPIDEMIOLOGY

Wuchereria bancrofti is prevalent primarily between the two Tropics, but also is encountered north of the Tropic of Cancer in Africa. An estimated 100 million infections exist in 80 countries worldwide, with approximately half of the infected individuals living in sub-Saharan Africa.[132] In each of its geographic locales, it has a specific anopheline, culicine, or aedine mosquito vector. In the Caribbean area, South America, Asia, East and West Africa, and Papua New Guinea, the microfilariae of this worm exhibit nocturnal periodicity; in the South Pacific, their periodicity is diurnal. *W. bancrofti* has no animal hosts.

Brugia malayi occurs in India, Malaysia, and other parts of Southeast Asia. Some strains of *B. malayi* are associated with animal reservoirs, as are certain other members of the genus *Brugia*, such as *Brugia timori*. In the United States, zoonotic *Brugia* infections caused by *Brugia beaveri* and *Brugia lepori* may infect humans, but cannot develop patent infections.[134,137,138]

PATHOPHYSIOLOGY

The pathology of LF is caused principally by the adult-stage parasite, the host response, and bacterial superinfection of tissues with compromised lymphatic function. Adult worms induce lymphatic dilation that results in lymphatic dysfunction, lymphedema, and a greater susceptibility to bacterial infection. The consequent inflammation, plus that caused by host responses to dying parasites, damages the delicate lymphatic vessels further and compromises lymphatic function further. When such processes occur in the lymphatic vessels of the scrotum, hydrocele develops. Microfilaremia often is "asymptomatic," but frequently is associated with immune complex nephritis; more rarely, the microfilariae can be the target of immunologic hyperresponsiveness and result in a severe "tropical pulmonary eosinophilia" syndrome.[135]

CLINICAL MANIFESTATIONS

Asymptomatic microfilaremia often develops in children living in endemic areas. Using highly sensitive diagnostic tests, including antigen detection and ultrasound, one third of children living in endemic areas can be seen to be infected before age 5 years. Damage to the lymphatics of these young children frequently is subclinical, however.[139] With repeated exposure, these children begin to have episodes of acute adenolymphangitis, sometimes associated with fever and lymphangitis. These "filarial fevers" may reflect either an inflammatory response to dying parasites (with "retrograde" lymphangitis) or bacterial superinfection.[133] Progression to lymphedema of the upper and lower extremities, the most common sequela of chronic LF, is an uncommon occurrence in children until after the age of puberty. Benign lymphedema has been described in a few patients in the United States with zoonotic *Brugia* infection.[134,138] Chronic, recurrent eosinophilic pneumonitis associated with wheezing, cough, chest pain, pulmonary infiltrations, and hypereosinophilia (tropical pulmonary eosinophilia) is an IgE-mediated hypersensitivity reaction to microfilariae trapped in the lungs and, if left untreated, leads to debilitating interstitial pneumonitis.[135]

DIFFERENTIAL AND SPECIFIC DIAGNOSES

The differential diagnosis of lymphatic obstruction in children should rule out other more likely conditions before focusing on

filariasis. In older children and adults, familial lymphedema (Milroy disease) can mimic filariasis.

In endemic regions, LF typically is diagnosed on the basis of appropriate clinical findings in a region with known endemicity for the disease. In young children living in endemic areas, however, early infection is largely subclinical.[139] A definitive diagnosis of LF still relies on detecting adult parasites in the lymphatics through ultrasonography or by recovering microfilariae from the blood. In view of the circadian periodicity of the appearance of numerous microfilariae in blood, a specimen should be collected at the appropriate time, in many regions of the world between 10 P.M. and 2 A.M., for microscopic examination by a staining or concentration technique. Increasingly, an immunochromatographic card test that measures specific filarial antigen is being used, especially in amicrofilaremic individuals.[133]

TREATMENT

New agents or drug regimens are needed that would be more effective against the adult filarial worm and at the same time elicit minimal immunopathologic damage. Currently, the major drugs used are especially effective against microfilariae. Diethylcarbamazine is the treatment of choice and typically is given in a 12-day course (6 mg/kg/day) for a total dose of 72 mg/kg. In the United States, it is common practice to administer first small doses of 1 to 2 mg/kg (maximum of 50 to 100 mg) before beginning this regimen. More recently, a single dose of 6 mg/kg has been recognized to produce a similar therapeutic result.[133] Diethylcarbamazine is available under an Investigational New Drug Protocol from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, Georgia, 30333; 404-639-3670 (evenings, weekends, or holidays: 404-639-2888).

Side effects of specific antifilarial therapy include allergic and febrile reactions that are caused by the inflammatory response to dying microfilariae rather than by the drug itself, and that occur primarily in patients with high levels of circulating microfilariae. These systemic manifestations can be treated symptomatically with antihistamines or corticosteroids. Some of the allergic manifestations also may be avoided by administering diethylcarbamazine in a graded, stepwise manner. This drug also is the treatment of choice for tropical pulmonary eosinophilia, a syndrome caused by circulating microfilariae. Ivermectin also may have a role in the medical treatment of LF because it is very effective in clearing circulating microfilariae.[136] Albendazole, in high doses, is effective in killing adult worms and, in lower doses, inhibits microfilarial production, but it is not registered for use in LF in the United States.[132]

The difficulty in management of filariasis by drugs is that late symptoms, such as elephantiasis, do not abate. The main usefulness of chemotherapy is in cases recognized early, before the anatomic abnormalities develop. Hydrocele can be treated surgically. Of critical importance to the management of lymphedema and elephantiasis are attention to hygiene, wearing shoes to prevent injury, and reduction of lymphostasis with exercise and elevation of the lower extremity.

The more recent discovery that *W. bancrofti* harbors bacterial endosymbionts has led to efforts to use tetracycline and related antimicrobial agents as part of the therapeutic regimen for LF.[138] The therapeutic use of such regimens is under active investigation. As of this writing, the Centers for Disease Control and Prevention (see earlier) and the Clinical Center of the National Institutes of Health (Bethesda, MD) have extensive experience and expertise in the management and treatment of human filarial infections, including *W. bancrofti*, *Loa loa*, and *Onchocerca volvulus* infections.

PREVENTION

Prevention in the past depended principally on vector control, which was unsatisfactory, primarily because of the difficulty in developing effective insecticides that also would be nontoxic to the rest of the environment. Successful experience in China has shown that large-scale chemoprophylaxis approaches to prevention are possible in endemic countries. Currently, through the Global Alliance to Eliminate Lymphatic Filariasis, the international community is directing a large-scale LF control campaign on this principle. Typically, this control is being accomplished through single-dose combination of albendazole (400 mg) with either ivermectin (200 μg/kg) or diethylcarbamazine (6 mg/kg). On this basis, long-term targets for the elimination of LF have been proposed.[131,132] The finding of extensive subclinical infection among children living in endemic regions highlights the importance of targeting this group for mass drug administration as well as adults.[139]

LOA LOA

L. loa infection is limited to a small area of western and central Africa and is spread by *Chrysops* flies. Periodicity in *L. loa* microfilariae is diurnal. The parasite elicits numerous allergic inflammatory responses that are most evident in expatriates.[140,141] Infection leads to high eosinophilia and recurrent angioedema, which when localized develop into painful, pruritic, subcutaneous swellings on the extremities and the face known as Calabar swellings. Rarely, some cases of lymphatic obstruction of the lower extremities and hydroceles have been reported.

The most dramatic manifestation of this infection is the occasional appearance of a migrating *L. loa* adult under the conjunctiva of the eye. It does not damage the eye and can be removed surgically. Treatment with diethylcarbamazine, as indicated earlier, effectively destroys the adults, but reactions may be more intense than in the treatment of *Wuchereria* and *Brugia* infections. Diethylcarbamazine should be administered in a gradual, stepwise manner as described earlier, particularly in patients with high levels of circulating microfilariae. Co-administration of corticosteroids often is required during treatment. Encephalopathy has been described in patients receiving diethylcarbamazine, especially when heavily infected.[140] Ivermectin elicits fewer inflammatory symptoms during treatment and may be less toxic in general, but still encephalopathy can occur in patients with heavy *Loa* infections.[142]

ONCHOCERCA VOLVULUS

Onchocerca volvulus infection is acquired through the bite of a *Simulium* fly, which tends to breed along rivers and streams (hence the name of the disease—river blindness).

EPIDEMIOLOGY

Disease is limited to sub-Saharan Africa, where approximately 99 percent of the world's 18 million cases occur (approximately half of the cases occur in Nigeria and Congo), and focal pockets in Central America (primarily Guatemala and Chiapas State, Mexico), and the northern parts of South America (near the border between Venezuela and Brazil and in Ecuador). In view of human dependence on water and the establishment of settlements along rivers, the frequency of infection tends to be high in areas where *Simulium* prevails. The development of hydroelectric power based on the construction of large dams can increase

the breeding sites of *Simulium* and increase the incidence of *Onchocerca* infection.

PATHOPHYSIOLOGY

Larvae deposited by a *Simulium* bite remain in the subcutaneous tissue and develop into adult worms there. Adult worms tend to become coiled, and worms of both sexes become enveloped by fibrous tissue and form nodules within which they reproduce. The larvae produced by fertilized females invade the skin, where they remain until they are picked up by a *Simulium* bite, or they die about 30 months later. In addition to the skin, microfilariae penetrate the eye and affect every layer from the conjunctiva to the optic nerve. In African onchocerciasis, chorioretinitis and optic atrophy occur commonly; in the Central American disease, iritis is the primary lesion.

The probability of the development of eye disease is related to the location of the adult worms. When the nodules are situated around the head, eye lesions are common; when they are in the lower parts of the body, eye lesions occur less frequently. In Africa, the nodules tend to be distributed primarily in the lower parts of the body, but because of the high prevalence of the infection, onchocercal blindness is common. In Central America, the lesions tend to be on the upper part of the body.

CLINICAL MANIFESTATIONS

The appearance of the skin nodules and the presence of live microfilariae within the eye (readily seen with a slit-lamp ophthalmoscopic examination) are the manifestations of early and intermediate disease. Later, the eye involvement includes keratitis, iridocyclitis, chorioretinitis, and, eventually, blindness. Microfilariae in the skin cause an inflammatory reaction that includes acute papular onchodermatitis and chronic changes such as edema, lichenification, atrophy, and depigmentation.

DIFFERENTIAL AND SPECIFIC DIAGNOSES

Because the skin invasion is associated with itching, the pruritus of onchocercal infection must be differentiated from contact dermatitis, prickly heat, insect bites, and scabies. Onchocerciasis is identified by examination of a skin snip. Examination of sectioned and stained tissue or a stained impression smear reveals microfilariae.

TREATMENT

Surgical removal of all visible nodules may radically extirpate the source of new microfilariae that invade the eye. The routine use of nodulectomy is still controversial, however. Chemotherapy with ivermectin (single oral dose of 150 μg/kg administered every 6 to 12 months) until asymptomatic is the treatment of choice. Ivermectin reduces the number of microfilariae in the skin within days, and subsequently the number of microfilariae in the eye, and prevents the onset of blindness.[143] Ivermectin also can be used in mass treatment to diminish transmission by the vector and control the incidence of this infection.[131,143,144]

PREVENTION

Vector control, periodic treatment of infected individuals, and possibly surgical removal of subcutaneous nodules all are means of prevention, and when carried out effectively, can be remarkably successful.[143]

MANSONELLA PERSTANS AND *MANSONELLA OZZARDI*

Neither *Mansonella perstans* nor *Mansonella ozzardi* is known to cause significant human pathology, but the microfilariae present in blood must be distinguished morphologically from the microfilariae of the other more pathogenic filariae. *M. ozzardi* is found throughout the Caribbean (especially Haiti) and Central America. It has been suggested as a cause of chronic arthritis in these regions. *M. perstans* also is found in Africa, where it has been identified as a cause of painless nodules in the conjunctiva and secondary eyelid swelling. For that reason, it sometimes is called the Kampala or Ugandan eye worm.[145] Albendazole, mebendazole, or ivermectin is the treatment of choice for *M. perstans* infection.

DIROFILARIA IMMITIS

Dirofilaria immitis is a filarial worm commonly found in dogs, in which it occupies the right ventricle of the heart. The microfilariae produced circulate in blood and are transmitted to new animals through the bite of culicine mosquitoes. Fewer than 100 cases of human infection have been reported, none of them in children. Most human hosts infected with *Dirofilaria* were asymptomatic, but individuals who had symptoms complained of chest pain, wheezing, and cough. All infected individuals had coin lesions detected on pulmonary radiographs.[146,147] Human infection is transmitted through a mosquito bite. As with visceral larva migrans and the zoonotic *Brugia* infections, *D. immitis* cannot complete its life cycle in humans. No microfilariae of this worm have ever been shown in human peripheral blood.

All patients evaluated for pulmonary dirofilariasis have had mild peripheral eosinophilia, usually not exceeding 10 percent. Because the radiographic picture is not diagnostic, and in view of the potential seriousness of a coin lesion,[146] the lesion must be examined histologically. If a worm is found, the diagnosis of dirofilariasis can be made; if it is not found, the diagnosis is still tenable. In the presence of eosinophilia and pneumonitis, however, a whole range of other diagnostic possibilities must be considered, including eosinophilic pneumonia, polyarteritis nodosa, Wegener granulomatosis, and histiocytosis X. No treatment is necessary for this infection in humans.

DRACUNCULUS MEDINENSIS

Infection by *Dracunculus medinensis* (guinea worm) also is limited largely to sub-Saharan Africa, with the greatest number of cases occurring in Sudan, Ghana, and Nigeria. Currently, fewer than 50,000 cases are thought to remain in these regions, and the disease is slated for elimination. The adult female worm lies in subcutaneous tissue and can extend over a length of 50 to 120 cm. No information about the fate of the male exists. The adult lives for 18 months. At the end of the first year of infection, the adult female migrates to subcutaneous tissue, where it produces an indurated papule that tends to vesiculate and ulcerate. When the surface of the ulcer comes in contact with water, the worm discharges motile larvae. These larvae are ingested by a crustacean, *Cyclops*, in which they undergo additional maturation and development.

Humans become infected by swallowing *Cyclops* in drinking water. The larvae penetrate through the gut into subcutaneous tissue by a route not fully understood. Multiple infections occur

commonly. In Nigeria, this disease previously was reported to be responsible for 25 percent of absenteeism in schoolchildren.[149] Secondary bacterial infections leading to cellulitis are common, as are secondary arthritis and contractures that can lead to permanent disability.[149]

Stagnant water is necessary for maintenance of the infection, which tends to be infrequent when running water and properly constructed wells are available. The diagnosis is established readily by observing the adult worm emerging from a cutaneous ulcer. The outline of the worm can be seen easily under the skin.

The classic treatment of this infection involves incision of the skin and tying the end of the worm to a small piece of wood. By turning the wood daily, the worm can be extracted over several weeks. This therapy is unsatisfactory and often results in failure of complete extraction. If the worm tears, an intense inflammatory reaction with skin sloughing develops. Treatment with chemotherapeutic agents such as metronidazole is controversial. Some investigators report that treatment with these agents helps decrease inflammation and facilitate removal of the worm.

Because filtering of drinking water can prevent this infection effectively, authorities are optimistic that this parasite can be eradicated through appropriate control measures.[148-150] Through an initiative led by the Carter Center (Atlanta), success has been achieved in eradicating guinea worm infection in many parts of Africa and Asia. The highest rates of infection still exist in the Sudan because of the difficulty encountered in implementing public health control measures in this war-torn region.

SUBSECTION 3

Cestodes

CHAPTER 238

CESTODES

A. Clinton White, Jr. ❂ Philip R. Fischer ❂ Andrea P. Summer

OVERVIEW OF CESTODES AND THEIR IMPORTANCE FOR CHILDREN

Cestodes are multicellular helminth parasites.[228] Children may harbor the adult worms (tapeworms) or larval stages (e.g., cysticercosis or hydatid disease). The adult tapeworms are segmented worms that contain a scolex (attachment organ), a neck region where the segments are formed, and segments termed *proglottids*. The scolex contains either sucking grooves (*Diphyllobothrium*, *Spirometra*) or round suckers (other species). In some species

(e.g., *Taenia solium*), the scolex is armed with rows of hooks, which also aids in attachment. The proglottids develop in the neck region and move distally as they are displaced by newer proglottids. Eventually, chains of proglottids form and compose the body of the adult worm. The external surface of the proglottid forms an absorptive surface, which functions as the parasite gut. As the proglottids are displaced from the scolex, they gradually mature, with both male and female sexual organs developing in each proglottid. The terminal proglottids contain the uterus, which are full of ova. The ova of *Spirometra* and *Diphyllobothrium* are shed into water, where they infect a series of aquatic intermediate hosts. The ova of other species infect the immediate host after being ingested. Both larval and adult forms of *Hymenolepis nana* live in the human intestines, and the entire life cycle can take place in a single host. Humans are dead-end hosts for numerous zoonotic tapeworms, including *T. solium* (cysticercosis), *Echinococcus* spp. (hydatid disease), and *Spirometra* (sparganosis). The term *cysticercosis* (literally bladder-tail) refers to infection of tissues with an intermediate form of the parasite containing a cystic parasite with one (or a small number) invaginated scolex. Human cysticercosis usually is caused by *T. solium*. However, human cysticercosis is also rarely caused by *Taenia crassiceps* or *Taenia multiceps*. *Hydatid disease* refers to infection of tissues with the intermediate form of the parasites of the genus *Echinococcus*, which form cystic lesions filled with innumerable protoscolices, each of which can turn into a tapeworm or another hydatid lesion, depending on the tissues. Infections with cestodes have been common human infections since antiquity and have been found in mummies.[18,91] Currently, approximately 200 million people worldwide are infected by cestodes.

TAENIA SAGINATA (BEEF TAPEWORM) INFECTION

The different life cycle forms and designation of species of the beef tapeworm were identified in the 18th and 19th centuries.[227] Although other species names have been used in the past, *Taenia saginata* is accepted now as an inclusive term for all of the species of tapeworms acquired from beef. In recent years, however, *Taenia asiatica* has been identified as a distinct species similar to *T. saginata* but acquired from pork. Differentiation of these species morphologically, however, is difficult, and identification of species is aided by DNA analysis.[31,91]

THE ORGANISM

The scolex of *T. saginata* measures 1 to 2 mm in diameter and has four muscular suckers but bears no hooks. The length of the parasite usually varies from 4 to 10 m but may reach 25 m. The size of the proglottids depends on their stage of development and their state of muscular relaxation. Gravid proglottids typically are 16 to 20 mm in length and 5 to 7 mm in width. The linear, central uterine stem has 12 to 30 main lateral branches on each side. The eggs measure 30 to 40 μm in diameter. The six-hooked embryo is surrounded by a brown, radially striated embryophore. When the bovine host ingests the ova, embryos hatch and burrow through the intestinal mucosa, where they gain access to the circulation. After lodging in capillaries, the embryo develops into a larval cysticercus. This cystic, ovoid structure measures 7 to 10 mm by 4 to 6 mm and contains an invaginated scolex.

Cattle are the principal intermediate hosts. Humans are the only definitive host. Ingestion of *T. saginata* eggs is of no particular danger to children because humans are not susceptible to development of the cysticercus stage.

TRANSMISSION

The life cycle of *T. saginata* requires transmission of the infection to the intermediate host and subsequently to humans, who in turn transmit the organism to other intermediate hosts. Contamination of pastures or feed lots with human feces or untreated sewage leads to bovine cysticercosis. When humans ingest raw or poorly cooked beef containing viable cysticerci, the scolex evaginates from the cysticercus and attaches to the intestinal wall. Proglottids develop from the neck region and gradually enlarge to form the adult tapeworm. Gravid proglottids, which are at the distal end of the worm, appear only 84 to 120 days after infection.[204] Infection may persist for years. In most geographic areas, parasitism is with a single worm, but in highly endemic areas, multiple infections may be found.[204]

Ova may be found within feces. However, eggs are shed more frequently when gravid proglottids actively migrate from the anus. As these muscular proglottids crawl about, eggs are expressed from the anterior margin. The ova of *T. solium* and *T. saginata* are not distinguishable on morphologic grounds.

EPIDEMIOLOGY

Worldwide, 45 to 60 million people are thought to be infected with *T. saginata*. Infection is most important in tropical and subtropical cattle-raising areas of Africa, the Middle East, Europe, Asia, and South America.[31,117,227] The prevalence of human taeniasis caused by *T. saginata* is poorly understood. In general, the prevalence of human infections is less than 1 percent of stool examinations in all but highly endemic areas, but because of the poor sensitivity of the assays, this figure may understate the prevalence. In recent studies, prevalence rates of more than 20 percent have been noted in East Africa, Bali, and Tibet.[31] Although the incidence of taeniasis in the United States is low, transmission does occur. However, less than 0.1 percent of fecal specimens examined in state health laboratories were positive for *Taenia* eggs.[102] With socioeconomic changes, improvements in the cattle industry, and decreasing instances of ingestion of undercooked beef, the prevalence of intestinal taeniasis likely will continue to drop in much of the world.

PATHOLOGY AND PATHOGENESIS

Little is known of the pathology or pathogenesis of intestinal taeniasis. Speculation about local mucosal trauma, irritation, production of toxic substances, or induction of clinically significant hypersensitivity has scant documentation. Rare, ectopic localization of worms or proglottids may stimulate local inflammatory reactions. Because adult worms "rob" the infected host of nutrients, malnutrition could result from the child's incomplete uptake of ingested food, but little evidence exists to support this possibility.

CLINICAL MANIFESTATIONS

A variety of symptoms have been attributed to *T. saginata*, but the parasite infection likely is often merely coincidental to the concurrently observed symptoms in the child.[31] The most common complaint is the discomfort caused by the migration of gravid proglottids from the anus. The patient's awareness of the infection frequently causes a preoccupation with gastrointestinal function. Some studies of *T. saginata* infection revealed abdominal pain, nausea, weakness, and loss of weight as the most common symptoms recorded.[31,227] Alterations in appetite and bowel habits were reported inconsistently. Intestinal obstruction and

symptoms related to ectopic localization of proglottids are extremely rare. Although taeniasis usually is not associated with significant eosinophilia, some patients occasionally have significant eosinophilia between the sixth and ninth weeks after the initial infection occurs. One study reported that by the time the patients first began passing proglottids, the eosinophil counts had returned to normal or nearly normal.[80] Another series of observations showed a syndrome of marked eosinophilia and severe colicky abdominal pain that occurred approximately 1 month before the patients passed *Taenia* proglottids.[8] A single experimental infection produced symptoms of nausea, headache, and disturbed sleep at approximately the time that gravid proglottids appeared in the stool, 84 days after infection. A 10.5 percent increase in the number of eosinophils and a 13 percent increase in the number of lymphocytes were noted.[204]

DIAGNOSIS

The scolex of *T. saginata* lacks hooks and is differentiated easily from the scolex of *T. solium*, which bears a circle of hooks. However, the scolex usually is not recovered, even after successful treatment. Studies suggest that use of polyethylene glycol salts as a purgative may improve recovery of proglottids.[101] Eggs may be seen on routine fecal wet mounts, but the likelihood of their being detected is enhanced by concentration methods. Even then, ova are shed only intermittently, and the yield of a single stool examination is low. Cellulose tape swabs applied to the anal and perianal skin, as used for the diagnosis of *Enterobius* infection, have been found to be even more efficient than is fecal concentration.[208]

The eggs of *T. saginata* and *T. solium* cannot be differentiated morphologically. Thus, examination of gravid proglottids is the usual method for determining species. The patient is instructed to collect proglottids in a vial of saline and to deliver the specimen to the laboratory as soon as possible. Fixatives such as alcohol and formalin tend to render the proglottids rigid and opaque. The proglottid should be compressed between two microscope slides. If the uterus contains enough ova, counting the main branches of the uterine stem is relatively easy. The uterus is more readily identified by injecting a small amount of India ink into the midportion. Counts of 13 or fewer branches on one side of the stem are considered diagnostic for *T. solium*. If the count is 14 or more, the species is designated *T. saginata*. Because of morphologic variations, this method has been criticized, particularly when the decision is based on gravid proglottids with counts in the range of 12 to 15. Analysis of many specimens of *Taenia*, as identified by their scolex, showed that mature proglottids with fully developed sex organs could be differentiated by several characteristics. The most prominent features are a vaginal sphincter seen only in *T. saginata* and a third ovarian lobe that is present only in *T. solium*. To define these and other features, the proglottids require painstaking staining and clearing as well as examination by a skilled parasitologist.

Antigen detection tests are becoming increasingly useful for the identification of *T. saginata*. Tests for *T. solium* currently are more specific than are tests for *T. saginata*.[3] Polymerase chain reaction testing has been useful in diagnosis of *T. saginata* in field situations.[31] On occasion, the diagnosis of tapeworm is established when larger portions of a worm appear as a ribbon-like defect in the barium column during contrast studies of the gastrointestinal tract. In plain films of the abdomen, a tapeworm may be seen as a linear density in a gas-filled loop of bowel.

TREATMENT

Praziquantel, a pyrazinoisoquinoline derivative, is the primary medication used to treat *T. saginata*. It is given as a single oral dose of 5 to 10 mg/kg. An alternative to praziquantel for treatment of intestinal taeniasis is niclosamide (marketed as Yomesan in parts of Europe but not consistently available in the United States); this agent is given as a single oral dose of 50 mg/kg (up to 2 g for large children or for adults). Nitazoxanide, a newer thiazolide agent approved for use in children with other parasitic infections, has been effective in treating taeniasis that has been incompletely responsive to both praziquantel and niclosamide.[117]

Because infection with *T. saginata* is not contagious, no routine follow-up is needed after treatment. If, however, proglottids are noted through the anus or in the stool more than a week after treatment is completed, subsequent therapy may be considered, perhaps with an alternative agent.

PROGNOSIS

Symptoms, when present, may be annoying but do not usually alter health significantly. Treatment is highly effective, and the prognosis is excellent.

PREVENTION

T. saginata infection can be prevented by avoiding the ingestion of raw or undercooked beef. In addition, visual meat inspection is effective in detecting all but light infections. Cooking beef to a temperature of 56° C kills cysticerci. Education of workers in the cattle-raising industry, coupled with detection and prompt treatment of human infection, may reduce the incidence of transmission. Vaccines to prevent bovine *T. saginata* cysticercosis are feasible, but development has been slowed by limited commercial interest.[122]

TAENIA ASIATICA (ASIAN PORK TAPEWORM)

T. asiatica was identified in East and Southeast Asia, where humans become infected by eating small cysts contained in raw porcine liver. The proglottids are morphologically similar to those of *T. saginata*, such that it was not recognized as a separate species until 1993.[31,98]

THE ORGANISM

Although adult tapeworm proglottids of *T. asiatica* are morphologically similar to those of *T. saginata*, the scolex contains a rostellum (like *T. solium*) but no hooks (like *T. saginata*). Proglottids usually contain 16 to 21 uterine branches, similar to *T. saginata*. The larval cysticercus stage is also similar to that of *T. saginata*, but the cysticerci generally are smaller. The cysticerci also are located primarily in the liver, not generally in muscle. *T. asiatica* cysticerci are found mainly in pigs but have been identified in cattle, goats, monkeys, and wild boar.[98]

TRANSMISSION

Pigs (but also cattle, wild boar, and goats) become infected by ingesting *T. asiatica* eggs, which hatch, releasing the larvae, which in turn invade and develop into the cysticercal stage primarily in the liver. Animals, including humans, become infected when they ingest cysticerci (usually in raw porcine liver) and then develop the intestinal adult forms of infection. An experimental human infection demonstrated that a period of 76 days transpired

between ingestion of the cysticercus and the appearance of gravid proglottids.[53]

EPIDEMIOLOGY

Asian taeniasis has been identified in Taiwan, Korea, China, Philippines, Vietnam, Thailand, Indonesia, and Malaysia.[31,53] It may be that other parts of the Asia-Pacific region are also endemic for *T. asiatica* but that previous surveys incorrectly identified the offending organism as *T. saginata*. The prevalence of infection varies among regions, probably related to religious and cultural choices about food; 0 to 21 percent of people in various parts of Indonesia are infected.[221]

PATHOLOGY AND PATHOGENESIS

Observations in humans and studies in mice suggest that the pathogenesis of infection by *T. asiatica* is similar to that of *T. saginata*.[99] No human cysticercal form has been identified.

CLINICAL MANIFESTATIONS, DIAGNOSIS, TREATMENT, AND PROGNOSIS

The clinical manifestations, diagnosis, treatment, and prognosis of *T. asiatica* have not been described completely, but they appear to be similar or identical to those of *T. saginata*.

PREVENTION

Human *T. asiatica* infection can be prevented by avoiding ingestion of undercooked liver and other viscera (especially porcine).

TAENIA SOLIUM

Cysticercosis was first described in ancient Greece, where cysticerci (literally bladder-tails) were noted in infected pork.[75] The life cycle was clarified by the 19th century. The main clinical manifestation results from infection of the central nervous system (CNS) and is termed neurocysticercosis. Large case series describing most of the clinical manifestations were published in the early 20th century.[47] Neurocysticercosis, however, was diagnosed only rarely until the late 1970s. Subsequent advances in neuroimaging led to a dramatic increase in recognition.[165] Neurocysticercosis is now recognized as among the more common causes of disease worldwide.[14,69,75,176,222]

THE ORGANISM

T. solium, referred to as the pork tapeworm, takes two distinct forms in the human host: taeniasis (tapeworm infection of the gut lumen) and cysticercosis (infection of tissues with the larval cysticercus form).[69,75] Neurocysticercosis refers to cysticercosis involving the CNS (including the subarachnoid space, spinal cord, and eyes). Humans develop the adult tapeworm after ingesting undercooked pork containing the cysticercus. The scolex evaginates in the intestines, attaches, and develops chains of proglottids. The tapeworms can be several meters long. Eggs and gravid proglottids are shed intermittently into stool. The off-white proglottids appear as flattened segments 1 mm thick and up to 2 cm in length and 1 cm in width. Pigs are infected after ingesting eggs or proglottids from human fecal material. Once ingested, the larval oncospheres emerge from the eggs, penetrate the wall of the gut, enter the bloodstream, and migrate to the tissues, where they develop into cysticerci during a period of a few weeks.

TRANSMISSION

Field studies of both taeniasis and cysticercosis are associated with tight clustering.[66,67,119,175] Taeniasis is acquired by ingestion of undercooked pork and is closely tied to pig-raising areas in endemic countries. Most carriers are from families that raise pigs and butcher them informally in the household. Cysticercosis is acquired from the human tapeworm carriers, who not only shed eggs into the environment but also harbor eggs on their hands and fingernails. These eggs can then autoinfect the tapeworm carrier or infect other people. Thus, most transmission occurs among close contacts of tapeworm carriers. Human cysticercosis is not always acquired directly from pork, as illustrated by outbreaks noted among vegetarians in India and orthodox Jews in the United States.[178,188,216] In both cases, transmission has been associated with domestic servants who are tapeworm carriers, a factor also seen in urban areas lacking infected pigs.[93]

EPIDEMIOLOGY

The global prevalence of human cysticercosis is not clearly defined. Between 50 and 100 million people are thought to be infected with cysticercosis, but far fewer with intestinal taeniasis. Nearly all areas where pigs are raised that have access to human fecal material are endemic for cysticercosis.[176] In endemic areas, pigs often are reared on small farms, where they are allowed to forage for food rather than being fed. Improved sanitation, meat inspection, and animal husbandry led to the eradication of cysticercosis from western Europe, which previously was highly endemic. However, similar approaches have not proved sustainable in poorer countries. Currently, porcine cysticercosis remains highly endemic in Latin America, sub-Saharan Africa, and South and Southeast Asia as well as parts of Korea, China, Indonesia, and Papua New Guinea.[14,98,128,188]

In the United States, porcine cysticercosis is a very rare occurrence. By contrast, human neurocysticercosis is widespread among immigrants from endemic countries.[46,146,185,197,198,213] Limited transmission occurs in the United States, mainly linked to tapeworm carriers infected in endemic areas.[38,199,220]

PATHOLOGY AND PATHOGENESIS

Cysticerci can develop in a wide range of tissues. In most tissues, the cysticerci cause few symptoms, and their survival appears to be limited. For example, many of those infected have cigar-shaped calcifications noted on radiographs of skeletal muscle, despite the absence of musculoskeletal symptoms. By contrast, infection of the CNS often lasts for years and can cause severe symptoms.

Cysticerci mature to their full size (typically 10 to 20 mm in diameter) within a few weeks after infection occurs; but as illustrated in studies of British subjects returning from India and Hispanic immigrants to the United States, symptoms do not develop for several years.[46,47] This delay may reflect the parasites' complex array of molecules used to modulate the host inflammatory response.[75,223] When the parasites lose the ability to evade immune attack, the cysticerci are attacked by a granulomatous response with a mixed cell population, including lymphocytes and mononuclear cells, with variable numbers of eosinophils and neutrophils.[87,123,163,164,182] This granulomatous host response to the parasite, when it is present in the brain parenchyma, is thought

to be the cause of seizures, the characteristic clinical feature of parenchymal neurocysticercosis.[201] During the course of several months, the inflamed parasite is invaded by inflammatory cells, the cyst cavity collapses, and the parasite material is replaced by the host granulomatous response.[87] The lesion eventually either resolves or is replaced by a small calcified granuloma. The calcified lesions contain a mixture of fibrosis and residual parasitic debris. An inflammatory response to persistent parasitic antigen may be the cause of recurrent seizures in patients with cerebral calcifications. Rarely, massive infection is accompanied by a diffuse cerebral edema.[162,207]

Extraparenchymal neurocysticercosis is associated with a poorer prognosis, largely because of production of hydrocephalus.[10,64,65,75] Parasites can cause obstructive hydrocephalus by lodging in the outflow tracks of the cerebral ventricles. Cysticerci in the basilar cisterns often are associated with chronic arachnoiditis. This basilar inflammation may lead to chronic meningitis (with headache and nuchal rigidity but usually without fever), vasculitis and strokes, or communicating hydrocephalus. Less frequently, cysticerci in fissures enlarge to 5 cm or larger (termed giant cysticerci). The parasites, along with accompanying cerebral edema, may cause a mass effect. In patients with multiple cysticerci, several forms of the disease can be present at the same time.

CLINICAL MANIFESTATIONS

Taeniasis

Taeniasis typically causes few symptoms. Cases have been associated with vague abdominal complaints and occasionally pruritus. The most specific symptom is the passage of proglottids in the stool. The proglottids appear flattened (typically 0.3 to 0.5 cm wide by 1 to 2 cm long and 1 mm thick). Each segment has 13 or fewer uterine branches. Unlike *T. saginata*, the proglottids usually are single and seldom are noted to be motile.

Cysticercosis

The clinical manifestations of cysticercosis are extremely variable, depending on the location of the parasites and the host inflammatory response. Experts now group neurocysticercosis into a range of syndromes that differ in pathogenesis, clinical manifestations, prognosis, and management.[64,65,75,144,183]

SINGLE ENHANCING LESIONS. The most common presentation of children with neurocysticercosis is with seizures and a single enhancing lesion on neuroimaging studies.[113,136,168,169,172,190,192,207,219] Onset typically occurs in those 5 to 40 years old, but it has been noted in infants. Most cases are manifested with seizures, which can be isolated or recurrent. The seizures typically are focal with secondary generalization, although they may be focal or generalized.[190,219] Some children will complain only of severe headaches,[156] which can resemble either tension headaches or migraines. Imaging studies of children reveal either a focal area of enhancement or a ring of enhancing lesions, often with surrounding edema. Lesions typically are found within the cortex.

MULTIPLE CYSTIC (VIABLE) LESIONS. Similar to children with single enhancing lesions, patients with multiple parenchymal cysticerci also present with seizures. The seizures more often are generalized or focal with secondary generalization but may also be focal.[21,22,45,74,192] Neuroimaging studies demonstrate edema or contrast enhancement or both for one or more parasites,[186,222] and symptoms are thought to result from the host inflammatory response. Noninflamed cysts cause few symptoms, even when they are numerous,[62] but they pose a risk for development of recurrent symptoms when they degenerate.

Other symptoms include headaches. Infected children may develop learning disabilities,[120,169] but in many cases they may be the result of either poorly controlled seizures or hydrocephalus.[203] An association of cysticercosis with depression and occasionally psychotic episodes also may exist.[59]

CYSTICERCAL ENCEPHALITIS. Some children present with diffuse cerebral edema from large numbers of inflamed cysticerci, termed cysticercal encephalitis. The clinical presentation includes symptoms or signs of raised intracranial pressure, seizures, and altered mental status.[162,207] Cysticercal encephalitis is thought to result from a brisk inflammatory response to a massive infection and is seen more frequently in children and women than in adult men. This pathogenesis is the direct result of the host inflammatory response, and the key to management is to address inflammatory and cerebral edema. Antiparasitic drugs are contraindicated because they can worsen the cerebral edema.

PARENCHYMAL CALCIFICATIONS. Resolution of neurocysticercosis can be associated with the formation of calcified granulomata within the brain parenchyma.[142] The calcifications appear as well-defined calcified nodules measuring 2 to 10 mm. The calcified lesions contain fibrotic reactions, parasite debris, and calcium deposits, with variable degrees of inflammation. Patients frequently present with seizures.[189] The most common imaging finding from neurocysticercosis in population-based studies in endemic villages is with focal calcifications.[44,57,139,160] Few patients will have focal abnormalities on electroencephalographic studies.[24,45] Among patients with seizures, calcified lesions are a risk factor for having recurrent seizures.[39,78,159] Patients with seizures and calcifications should be treated with antiepileptic therapy indefinitely. Some patients with neurocysticercosis and seizures have calcified lesions and associated enhancement and edema on magnetic resonance imaging (MRI) studies.[7,86,143,187] Rather than revealing viable parasites, the enhancement may result from breakdown of the calcified granulomata, with release of antigen resulting in restimulation of the host inflammation.[86]

VENTRICULAR NEUROCYSTICERCOSIS. Approximately 10 to 20 percent of adult patients with cysticercosis have cysticerci in the ventricles,[75,64,144,173,222] but the numbers often are lower than those in children.[172] Cysticerci are found in any of the ventricles, but symptoms are particularly associated with obstruction of the outflow of the third or fourth ventricle at the cerebral aqueduct or foramina of Luschka and Magendie. In contrast to parenchymal disease that largely results from the host inflammatory response, symptoms of ventricular disease result from mechanical obstruction typically caused by viable parasites.[104] Within the thin-walled viable cysticerci, the cyst fluid often is isodense with cerebrospinal fluid (CSF), rendering them difficult to detect. Computed tomography (CT) scanning may show only obstructive hydrocephalus or distortion of the shapes of the involved ventricle. Even on MRI, the findings may be subtle and can be missed by inexperienced observers unless the patients have concomitant parenchymal cysticerci.[89,233,234]

Symptoms from ventricular neurocysticercosis usually result from raised intracranial pressure and include headache, nausea or vomiting, altered mental status, papilledema with visual changes, or dizziness. The onset is extremely variable from chronic intermittent headache to sudden loss of consciousness.

SUBARACHNOID CYSTICERCOSIS. Subarachnoid cysticercosis can also be quite variable. Small cysticerci in the gyri have a clinical presentation and prognosis similar to that of parenchymal cysts, although they are associated more often with

CSF pleocytosis, may be slightly larger, and respond less well to antiparasitic drugs.[173] Cysticerci in the basilar cistern can cause arachnoiditis, leading to CSF outflow obstruction, communicating hydrocephalus, vasculitis, and strokes.[10,63,200] In the era before antiparasitic drugs were available, this form carried a high case-fatality rate.[200] By contrast, more recent case series have been characterized by low mortality rates.[40,144]

Most patients with cysticerci in the basilar cisterns are infected with large numbers of parasites, and they frequently have coexisting ventricular or parenchymal as well as subarachnoid disease. Symptomatic cysticerci in the basilar cisterns typically are accompanied by chronic arachnoiditis. This arachnoiditis may present as meningitis with headache, stiff neck, and CSF pleocytosis, but it usually is not accompanied by fever. Patients often develop communicating hydrocephalus (headaches, nausea, vomiting, and dizziness). Basilar cysticercosis frequently involves the basilar vasculature either by direct invasion or by inducing vasculitis. Thus, patients may present with cerebrovascular accidents, which may involve either small vessels with lacunar infarctions from vasculitis or large-vessel strokes (associated with invasion of the vessel wall by the parasite).[11,41,64]

GIANT CYSTICERCI. Cysticerci, termed giant cysticerci, can develop in the fissures (especially the sylvian fissure) and may enlarge to more than 5 cm in diameter.[151] In some cases, the cysticerci can lose the scolex and may grow as clusters of cyst walls (termed racemose cysticercosis). Giant cysticerci not only are associated with symptoms of parenchymal inflammation but also can cause mass effects such as midline shift. Frequently, giant cysticerci are accompanied by cysticerci in the parenchyma or basilar cisterns. Giant cysticerci are readily visualized by CT or MRI, but the accompanying basilar cysticerci may not be seen as easily.

OTHER FORMS OF CYSTICERCOSIS. Neurocysticercosis rarely involves the spine.[10] Most patients present with radicular pain and less frequently myelitis. In most cases, cysticerci are in the spinal fluid, but they can also be intramedullary cysticerci.[118] The intramedullary form typically presents with myelitis. Orbital involvement includes subconjunctival cysticerci and involvement of the extraocular muscles.[155,181] Intraocular disease may be subretinal, intravitreal, or within the anterior chamber. Skeletal muscle involvement typically is asymptomatic, but it may result in pseudohypertrophy or weakness with massive infection. Subcutaneous lesions typically present as one or more painless mobile cystic lesions. Subcutaneous disease is more commonly noted in Asia and Africa than in the Western Hemisphere.

DIAGNOSIS

Taeniasis

Taeniasis has been diagnosed traditionally by examination of the stool for proglottids, ova, or both. The ova and proglottids are shed only intermittently, and collection of stool specimens from children can prove difficult. Furthermore, the sensitivity of stool microscopy for ova is only 26 percent,[5] and the ova of *T. solium* and *T. saginata* are indistinguishable, which limits the specificity of the assay. Identification of species requires collection of the proglottids, which can be facilitated by treating the patient with polyethylene glycol.[101] The proglottids of the two species can be distinguished by counting the number of uterine branches, which are lower for *T. solium*.

More sensitive and specific techniques are available only as research tools. Antigen-detection assays have a specificity of 99.2 percent and a sensitivity of 70 to 92 percent,[4,5,166] but they cannot distinguish *Taenia* spp. Enzyme-linked immunosorbent assay (ELISA) to identify serum antibodies to *T. solium* tapeworm-stage antigens may be more sensitive than are stool-based tests and seem to be specific for the *T. solium* tapeworm stage.[88,121] However, the antibody may persist after treatment. Polymerase chain reaction assays also can be used to improve sensitivity and specificity.[133]

Neurocysticercosis

Establishing the diagnosis of neurocysticercosis is more difficult than with many other parasitic infections. The major clinical presentations are nonspecific, and the location of the parasites within the CNS usually precludes their being observed directly. Serologic tests using crude antigens (including a number of commercially available ELISAs) are plagued by poor sensitivity and specificity. However, computerized imaging methods (e.g., CT and MRI) have led to a dramatic increase in the ability to recognize cases and are now the mainstay of diagnosis (Figs. 238–1 to 238–3), although even these techniques cannot always distinguish neurocysticercosis from other neurologic processes.

An expert group proposed diagnostic criteria based on neuroimaging studies, serologic tests, clinical history, and exposure.[42] The presence of either a single absolute criterion or two major criteria along with two minor or epidemiologic criteria is considered diagnostic. One major criterion plus two other criteria or three minor criteria along with exposure define a probable diagnosis.

Direct visualization of the parasite on ophthalmoscopic examination or histology is considered diagnostic of neurocysticercosis.[42] However, biopsy or autopsy material demonstrating *T. solium* parasites rarely is available, and parasites seldom are visualized in the eye. The neuroimaging pattern of a cystic lesion with

a mural nodule measuring 1 to 3 mm (consistent with a scolex) is thought to be pathognomonic for cysticercosis.[232,234] However, rare cases have been reported in which similar findings have been noted in other diseases, and even in neurocysticercosis, the scolex cannot be visualized in most cases.

The main major diagnostic criterion for neurocysticercosis is one or more lesions on neuroimaging studies highly suggestive of neurocysticercosis.[42] Viable cysticerci appear on CT or MRI scans as rounded fluid collections typically 1 to 2 cm in diameter. The cyst fluid is isodense with CSF (hypodense compared with brain tissue on CT or T1 imaging). The scolex sometimes is visible as a small nodule found attached to the cyst wall. The wall of the cysticercus initially is isodense with the parenchyma and not easily visualized. On T2-weighted and fluid attenuated inversion recovery images, the fluid is seen as hyperintense. Inflamed cysticerci are characterized by perilesional edema and contrast enhancement.[201] Subsequently, the cyst fluid increases in density and becomes infiltrated by host inflammatory cells. The cyst cavity eventually collapses, forming a solid area of focal enhancement. At that point, the granulomatous inflammation either resolves or leads to the formation of a calcified nodule typically measuring 2 to 6 mm in diameter.

Although enhancing lesions are typical of neurocysticercosis, similar lesions can be noted with tuberculomas, brain abscesses, and tumors. Rajshekhar and Chandy[158] noted that cysticercal lesions typically have a diameter smaller than 20 mm and rarely cause midline shift. A single, round, enhancing lesion less than 20 mm in diameter without midline shift on imaging studies in patients lacking signs or symptoms of systemic disease, focal neurologic deficits, or increased intracranial pressure was highly suggestive of neurocysticercosis in a prospective study of 401 patients in southern India.[160] However, the results are less specific in areas with a lower prevalence of cysticercosis. Spontaneous resolution or resolution achieved with antiparasitic drugs is another major criterion.[157]

Serodiagnosis has proved problematic for cysticercosis. ELISAs employing unfractionated antigens, such as cyst fluid, have poor sensitivity and specificity.[152,161] The preferred serodiagnostic test is the enzyme-linked immunotransfer blot employing semi-purified parasite glycoproteins.[214] A positive reaction to any one of seven glycoprotein bands is considered positive. ELISAs using recombinant versions of these antigens are being developed.[64] Studies have confirmed a specificity of nearly 100 percent in suspected cases, but the sensitivity is limited in subjects with either a single lesion or with only calcified lesions.[81,152,179,226] For this assay, tests of serum are more sensitive than are tests of CSF.[226] Assays to detect parasite antigens may prove to be important diagnostic studies.[37,54,70,72,73,148] Although several different antigen detection tests are in development, none is widely available commercially.

Minor criteria include (1) lesions on neuroimaging studies consistent with neurocysticercosis but less suggestive (e.g., isolated basilar meningitis, hydrocephalus without demonstration of cystic lesions, or filling defects in the spinal subarachnoid space without discrete cysticerci), (2) symptoms suggestive of seizures or hydrocephalus, and (3) cysticercosis outside the nervous system (e.g., cigar-shaped muscle calcifications or subcutaneous nodules).[42] Epidemiologic criteria include residence or prolonged visits to endemic areas and contact with a tapeworm carrier.

Numerous other tests may prove useful in excluding other illnesses but are not diagnostic of neurocysticercosis. These tests include blood counts, lumbar puncture for testing of CSF, and stool studies. Lumbar CSF frequently has elevated protein levels and may show hypoglycorrhachia. Cell counts are variable and may demonstrate a predominance of lymphocytes, neutrophils, or eosinophils.

TREATMENT

For patients with seizures caused by neurocysticercosis, initial management should focus on control of the seizures, which usually can be accomplished with a single antiepileptic drug. Most published studies describe use of phenytoin or carbamazepine. Newer agents (e.g., valproate, lamotrigine, levetiracetam, topiramate, oxcarbazepine, or clobazam) may be more effective, but they are not affordable in endemic areas.[103] Breakthrough seizures usually occur with subtherapeutic antiepileptic drug levels, often from poor adherence to medication therapies.[74] Seizure therapy can be tapered off for many patients after they have a seizure-free period if radiographic resolution of the lesion is seen. However, a substantial risk exists for recurrence of seizures if residual inflamed or calcified lesions are present.[22,74,159,219] Antiepileptic drugs should be continued indefinitely if calcifications develop.

Patients with obstructive hydrocephalus usually require surgery.[65,144,183] For patients with mild or intermittent symptoms (e.g., a cysticercus in the lateral ventricles not associated with midline shift), elective endoscopic removal of the cysticercus is the treatment of choice. Cases with altered mental status or impending herniation should undergo emergency CSF diversion by a ventriculostomy or placement of a ventriculoperitoneal shunt. A high rate of shunt failure exists if shunting is not followed by administration of antiparasitic therapy or corticosteroids.[75,104,200] Patients with communicating hydrocephalus often require placement of a ventriculoperitoneal shunt.[104] In some patients, cysticerci and associated edema may lead to mass effects. If the symptoms are life-threatening or if the cysticercus is easily approachable (e.g., in the sylvian fissure), surgical decompression of the cysticercus is the preferred approach.

A consensus is emerging among experts about the proper role of antiparasitic drugs and corticosteroids in the management of neurocysticercosis.[144,183] Experts agree that neurocysticercosis represents a spectrum of diseases that differ in optimal management.

SINGLE ENHANCING LESIONS. The most common presentation of children with neurocysticercosis is seizures and a single enhancing lesion. Seizures generally can be controlled with antiepileptic medications.[103,159,219] Controlled trials of antiparasitic drugs in patients with single enhancing lesions have demonstrated a favorable prognosis with symptomatic therapy. However, the length of time until radiologic resolution is achieved and the duration of time for risk of experiencing seizures appear to be somewhat shorter with antiparasitic drug treatment.[43,191,209] By contrast, these treatments do not appear to affect the formation of calcified lesions or development of chronic epilepsy. The role of steroids is better defined; several studies showed clear benefit in reducing seizure activity and faster resolution of the lesion on CT when steroids were used in conjunction with antiepileptic medications.[77,79,112,130,150] Overall, the best evidence points to a small benefit achieved from use of antiparasitic drugs (e.g., albendazole, 15 mg/kg/day for 8 days) and a short course of corticosteroids (e.g., prednisone, 1 mg/kg/day for 8 to 10 days).

MULTIPLE PARENCHYMAL LESIONS. Patients presenting with seizure activity with multiple cysticerci usually will have one or more lesions in the process of degenerating (e.g., edema or contrast enhancement on imaging studies). However, other cysticerci may be in the viable stage, posing a prolonged risk for having seizures. A placebo-controlled trial from Peru showed a modest reduction in the number of generalized seizures in patients treated with albendazole and corticosteroid,[74] but no decrease occurred in the development of chronic calcifications. A meta-analysis of trials also supported this approach.[43] One recent trial suggested a worse outcome with this treatment,[36] an effect not seen in any other study. Overall, the current expert consensus is that patients with multiple parenchymal cysticerci usually should be treated with a course of an antiparasitic agent (albendazole, 15 mg/kg/day in two daily doses for 8 days) and a simultaneous course of corticosteroids.[144] Even so, symptomatic therapy (e.g., antiepileptic drugs) remains a key to management.

CYSTICERCAL ENCEPHALITIS (NUMEROUS CYSTICERCI WITH CEREBRAL EDEMA). In this context of diffuse cerebral edema (cysticercal encephalitis), antiparasitic drugs are contraindicated because of their potential to exacerbate host inflammatory responses.[65,162,207] Most cases will resolve spontaneously with anti-inflammatory medications.

CALCIFIED PARENCHYMAL CYSTICERCI. Parenchymal brain calcifications can be seen in more than 10 percent of residents in some neurocysticercosis endemic areas.[142,160] These parenchymal calcifications are a significant risk factor for having continued seizure activity.[76,159,219] If a patient with a history of seizures has a calcified lesion, that patient should be treated with antiepileptic therapy indefinitely. Recurrent seizures may be due to concomitant mesiotemporal sclerosis.[218] Antiparasitic medications and anti-inflammatory drugs are not indicated. Surgical removal of the calcified focus has been used in some cases of intractable seizures.[225] By contrast, most cases can be managed with a single antiepileptic medication.

VENTRICULAR NEUROCYSTICERCOSIS. Patients with obstructive hydrocephalus usually require surgery. For mild or intermittent symptoms (e.g., a cysticercus in the lateral ventricles not associated with midline shift), elective endoscopic removal of the cysticercus is the treatment of choice.[12,65,94,144,154,202] Cases with altered mental status or impending herniation should undergo emergency CSF diversion by a ventriculostomy or placement of a ventriculoperitoneal shunt. A high rate of shunt failure exists if shunting is not followed by administration of antiparasitic therapy. Cysticerci in the lateral and third ventricles usually can be removed through a rigid endoscope. A flexible endoscope is required to approach the fourth ventricle or basilar cisterns.[95,212,235] Endoscopic foraminotomy and third ventriculostomy often can be used to treat residual hydrocephalus. Antiparasitic medications should not be given before the procedure is performed as they can cause the cysticerci to be friable or to adhere to the ventricular wall. The cysticerci frequently rupture during removal, but this rupture has not been associated with any adverse effects. Endoscopic third ventriculostomy has been used as an alternative to shunting procedures.[12,94,114,153]

A ventriculoperitoneal shunt may be used to treat hydrocephalus. The rate of shunt failure is high in patients treated only with ventriculoperitoneal shunting. However, shunt failure appears to occur less frequently when patients receive adjunct therapy with corticosteroids and antiparasitic drugs.[12] Although some patients have been treated with only chemotherapy and steroids, a substantial risk exists for development of acute hydro-

cephalus from cysticerci or accompanying inflammation causing obstruction of the foramina.[13]

SUBARACHNOID NEUROCYSTICERCOSIS. Basilar subarachnoid cysticercosis is perhaps the most severe form of infection and carries risks for communicating hydrocephalus, vasculitis, and strokes.[64,75,144] Data on how best to treat this form are limited, but most experts agree that patients should be treated with antiparasitic drugs, corticosteroids, and, in most cases, CSF diversion procedures.[151] Most experts recommend treatment with albendazole (typically 15 mg/kg/day in divided doses for at least 28 days), but cure rarely is achieved with a single course of albendazole. Repeated courses, prolonged therapy, higher doses, switching to praziquantel, and combination of the two drugs have been tried in some cases.[131] Improved responses with endoscopic debulking of a number of parasites are anecdotal,[85,144] and this approach has not yet been studied systematically.

Inflammation seems to drive much of the pathogenesis, and the residual symptoms may reflect a chronic inflammatory response to cysticercal antigens rather than viable cysticerci. Prednisone (doses up to 60 mg per day) or dexamethasone (doses up to 24 mg per day) should be used along with the antiparasitic drugs.[63] After 2 to 4 weeks, the dose often can be tapered. In cases that require more prolonged steroid therapy, methotrexate has been used as a steroid-sparing agent.[137]

GIANT SUBARACHNOID NEUROCYSTICERCOSIS. Some cysticerci, particularly in the sylvian fissure or basilar cisterns, may enlarge to more than 5 cm in diameter, causing mass effect either directly or by surrounding edema. If mass effect cannot be reversed quickly by corticosteroids and even mannitol, surgical decompression may be required. In the absence of symptomatic mass effect, however, giant cysticerci can be treated similarly to other subarachnoid cysticerci.[144,151]

OTHER FORMS OF NEUROCYSTICERCOSIS. Cysticercosis of the eye, spine, or subcutaneous tissue generally is treated by surgical removal.[75] There are, however, anecdotes of medical therapy.

PROGNOSIS

The prognosis of neurocysticercosis is extremely variable, depending on the sort of infection. Patients with single enhancing lesions generally do well and often are seizure free and discontinue therapy within 1 to 2 years. Patients with calcified lesions may require chronic antiepileptic therapy. Patients with numerous subarachnoid cysticerci often require repeated courses of therapy and even repeated surgeries. However, with optimal management of hydrocephalus, cases are rarely fatal.

PREVENTION

Cysticercosis was eliminated from western Europe by improved sanitation, animal husbandry, and meat inspection.[68,83] For example, porcine cysticercosis can be prevented by not allowing pigs access to human feces.[217] However, confined pigs must be fed, which is not affordable for peasant farmers. Human infection with adult tapeworms also can be prevented by adequate cooking or freezing of infected pork, but meat inspection has not been successful in areas where pigs are slaughtered informally.[205] Mass chemotherapy of endemic populations for carriage of the human tapeworm or porcine cysticercosis has resulted in significant short-term decreases in prevalence,[4,35,71,83,174] but prevalence rates rapidly return unless mass treatment is continued. Development of an effective vaccine against cysticercosis may provide the best potential tool for eradication of the disease. There are promising studies that this will be possible for human and porcine cysticercosis.[58,84]

COENUROSIS (*TAENIA MULTICEPS,* OTHERS) AND CYSTICERCOSIS CAUSED BY *TAENIA CRASSICEPS*

Several species of *Taenia* have a larval stage called a *coenurus* that consists of a cystic membranous structure measuring up to 6 cm in diameter from which multiple scolices bud internally or externally.[87,97] On the basis of this morphologic appearance, the parasite was given the species name *multiceps*. Currently, the preferred genus name is *Taenia* because of the morphology of the adult worms and the inability to justify a genus designation based solely on the form of larvae. The following species generally are accepted for purposes of discussion. The adult tapeworm of *Taenia multiceps* is found in dogs, and the larval stages occur in herbivores. The larvae often develop in the CNS in sheep. In sheep-raising areas of Europe and Asia, the infection is still endemic in animals. *Taenia serialis* adult worms are found in dogs and other canids, but common intermediate hosts are rabbits, hares, and rodents. The coenurus develops in subcutaneous and intramuscular tissue. *T. serialis* has been reported from the United States, Canada, France, and Africa. *Taenia brauni* is the name given to the tapeworms of dogs, jackals, foxes, and genets found in tropical Africa. The larvae develop in gerbils and other rodents. Humans are a rare accidental host for the larval stages of these worms. Fewer than 100 human infections have been recorded. Most infections are from Africa, with many occurring in children. Giving a species designation based solely on the morphologic features of organisms recovered from human tissue is nearly impossible. The infection is presumed to be acquired by the ingestion of eggs excreted by the definitive hosts, usually dogs. Because of the subcutaneous and subconjunctival locations of cysts in infections in tropical Africa, some researchers have suggested that direct contact of the eggs on skin or the conjunctiva is a mode of transmission. A review of the six human infections in North America has been published.[87,97]

The clinical manifestations of coenurosis are related to the location of the parasite. Involvement of the CNS produces a spectrum of illness that resembles that of cysticercosis (discussed earlier), including meningeal reactions. Larvae have been seen in the subconjunctival and subretinal tissue, the extraocular muscles, the anterior chamber, and the vitreous. Subcutaneous and intramuscular lesions occur most commonly in the abdomen and chest wall. A definitive diagnosis is made by demonstrating the characteristic morphologic features of the larva recovered at surgery. The multiple scolices that bud from the delicate cyst membrane have double rows of hooklets of a typical shape, size, and number. In instances in which no scolices are found, differentiation of a coenurus from a cysticercus of *T. solium* is impossible. The diagnosis of intramuscular coenurosis has been made by examination of fine-needle aspirates.[87,97] Radiographic studies such as CT are useful in cerebral coenurosis but do not differentiate the parasite from other cystic lesions. Treatment is surgical. Mortality rates in cerebral disease are high. Organisms in other locations, with the exception of subretinal lesions, are removed easily. A combination of praziquantel and a corticosteroid administered to a patient with a subretinal coenurus caused death of the parasite, which resulted in a severe inflammatory reaction, retinal detachment, and permanent loss of vision.[96] Severe reactions were reported in the two additional cases described in this review. Praziquantel should be used with great caution, if at all, in cases

of human coenurosis. Although the exact mode of infection in humans has not been identified, avoidance of close contact with dogs and dog excreta, which are the most likely sources of infection, is prudent.

Taenia crassiceps cysticerci usually are found in field mice, with the tapeworm found in foxes, other canids, and felines. A limited number of cases have been noted to cause ocular disease or mass lesions in compromised hosts (e.g., patients with acquired immunodeficiency syndrome).[25,28,61,90,129] Diagnosis and management require surgery.

DIPHYLLOBOTHRIUM SPECIES (FISH TAPEWORM)

Diphyllobothriasis can occur in children who ingest raw or undercooked fresh-water fish. The prevalence of infection increases with age in endemic areas. Nonspecific gastrointestinal complaints may occur in infected individuals, and megaloblastic anemia has resulted.[31,227]

Several species of *Diphyllobothrium* have been reported in humans. *Diphyllobothrium latum* was described first in 1592 from specimens found in Switzerland; it is now estimated to infect approximately 9,000,000 individuals worldwide, with most cases occurring in Europe and some in South America and Asia.[49] *Diphyllobothrium pacificum* is a similar fish tapeworm found infecting humans in Japan and South America, and *Diphyllobothrium nihonkaiense* has been found in Pacific salmon (and, hence, in humans) in Japan and Europe.[31] The *Diphyllobothrium* spp. typically have fish-eating birds, marine mammals, bears, dogs, and foxes as definitive hosts, but children living in endemic areas may be infected when they eat raw or undercooked fish.

THE ORGANISM

The scolex of *D. latum* possesses neither discrete suckers nor hooks but has two deep grooves. The worm may be as long as 15 m. The gravid proglottids have a characteristic rosette-shaped central uterus. Eggs measure 55 to 61 μm by 37 to 56 μm and have light brown, operculated shells. The eggs are shed in an unembryonated state from a uterine pore into the fecal stream. The embryos develop within the eggs in fresh water. The ciliated embryos hatch and are ingested by copepods to develop further. After the fish have ingested the infected copepod, the larval stages develop into the plerocercoid stage in the muscles of fish. As the smaller fish are eaten by larger species, the larvae parasitize the muscles of the new host. Eventually, the larvae are found in fish that are sources of food for humans, such as species of pike, perch, turbot, lake trout, and whitefish. The plerocercoid larvae or spargana are white, ribbon-like worms approximately 5 cm in length.

TRANSMISSION

Children can be infected by ingesting the plerocercoid forms in raw or undercooked fish muscle that are infectious when ingested by people. Cooking and freezing kill the larvae. The cycle of infection is perpetuated by the discharge of untreated human sewage into fresh-water lakes and streams. Some fish-eating mammals also may serve as definitive hosts for *D. latum* and maintain the cycle of infection in the absence of humans. Because *D. latum* requires intermediate hosts, direct transmission cannot occur, and no techniques of isolation or special precautions are required for infected patients.

EPIDEMIOLOGY

The prevalence of infection increases with age in endemic areas. However, infections have been reported in children younger than 1 year.[31] The disease is worldwide in distribution, but higher endemicity is associated with eating fresh-water fish raw, lightly salted, or pickled without cooking. Infection occurs frequently in the Baltic countries and Russia; South America; Scandinavia; Switzerland and the adjacent lake regions of Italy, France, and Germany; the Danube River delta; the lake areas of the northern United States; Canada; and the river deltas of Alaska. Five decades ago in northern Canada, 83 percent of Eskimos older than 2 years were infected with *D. latum*. Pediatric infection by *D. latum* has been identified recently in school-age children in India, Taiwan, Korea, Argentina, and Hawaii. Salmonid fish (salmon, trout, whitefish) transmit *D. nihonkaiense* to humans in Japan. Infection of humans with a tapeworm parasite of seals, *D. pacificum*, has been reported from Peru.

PATHOLOGY AND PATHOGENESIS

Little is known about the direct effects of parasitization, with the exception of megaloblastic anemia.[1] The following factors may be significant: (1) the strains of *D. latum* found in Finland, where anemia occurs, absorb seven times more vitamin B_{12} than do strains from North America, where anemia has not been reported; (2) interference with absorption of vitamin B_{12} occurs in nonanemic carriers as well as in those with anemia, and deficient stores of vitamin B_{12} plus malabsorption of vitamin B_{12} may contribute to the anemic state; (3) dietary intake of vitamin B_{12} may be low in anemic patients, and oral vitamin B_{12} has been shown to cause reticulocytosis in the presence of the worm; (4) worms found in anemic patients take up more of an oral dose of vitamin B_{12} than do worms in asymptomatic carriers, and worms are attached more proximally in the small intestine in anemic patients; and (5) secretion of intrinsic factor is reduced in anemic patients.

CLINICAL MANIFESTATIONS

Most infections are asymptomatic, but patients may notice proglottids or chains of segments in the stool. In Finland, comparison of nonanemic infected patients with uninfected controls revealed an increase in the symptoms of fatigue, weakness, craving for salt, lack of well-being, dizziness, and numbness of the extremities in the infected group.[170] Significant gastrointestinal symptoms occur infrequently. However, an experimental infection with seven larvae produced nausea, severe periumbilical pain, and marked weight loss. Episodes of intestinal obstruction associated with the vomiting of masses of tapeworms have been reported. Eosinophilia is an uncommon finding. Patients with *D. pacificum* complained of abdominal pain, vomiting, diarrhea, and flatulence.[125] Megaloblastic anemia caused by *D. latum* infection is extremely rare outside Finland and neighboring endemic areas. Usually, it is seen in patients older than 50 years (and may occur in as many as 2 percent of adult tapeworm carriers), but it has been reported in children as young as 9 years.

DIAGNOSIS

Identification of the characteristic eggs (oval, operculated, approximately 60 μm across) or proglottids provides the

diagnosis. The parasite produces nearly 1 million eggs per day, and ova usually are detected easily by fecal examination.

TREATMENT AND PREVENTION

Treatment with praziquantel (5 to 10 mg/kg as a single oral dose) is highly effective. An alternative medical treatment is niclosamide (50 mg/kg as a single oral dose). Tapeworm-related anemia is reversible by treatment of the infection, but the affected child should receive supplementation initially with vitamin B_{12}.

A significant reduction in the transmission of *D. latum* has been accomplished in many areas through the introduction of sewage treatment and targeted drug treatment of human infections. Raw and undercooked fish should not be consumed in areas where a possibility of larval infection exists. Larvae do not survive in fish that is either cooked for 5 minutes or more at temperatures of at least 55° C or frozen at temperatures of at least –10° C for 8 to 72 hours.[49]

DIPYLIDIUM CANINUM (DOG TAPEWORM)

Dipylidium caninum, the common tapeworm of dogs and cats, also infects infants and young children.[31,227] Transmission occurs through the accidental ingestion of infected fleas (*Ctenocephalides* spp.) or body lice (*Trichodectes* spp.). Although it usually is asymptomatic, infection may be associated with decreased appetite, abdominal discomfort, or, perhaps, diarrhea.

THE ORGANISM

D. caninum adult worms have a scolex with four cup-shaped suckers and a rostellum that bears one to seven rows of small hooks. The worm ranges from 10 to 50 cm in length. The gravid proglottids resemble cucumber seeds in size and shape. The proglottids have two pairs of sex organs, and a genital pore opens on each lateral margin. The eggs measure 35 to 65 µm in diameter and appear in packets of 5 to 30 enclosed in a membrane. The gravid proglottids are excreted in feces or migrate actively from the anus. The eggs are liberated as the proglottid disintegrates. Several species of flea serve as intermediate hosts. The larval flea ingests the egg of *D. caninum*. Development of the tapeworm's larval stages takes place as the flea metamorphoses into an adult. When the flea is ingested by the definitive host, the adult worm develops in the small intestine.

TRANSMISSION AND EPIDEMIOLOGY

Humans acquire the infection by the accidental ingestion of infected fleas. Dogs may transfer infective larvae to humans by licking children after crushing fleas orally. Because of the motility of the proglottids, eggs may be disseminated widely in the environment of animal hosts. Fleas are so ubiquitous that transmission to the intermediate host is accomplished readily.

Infection of dogs and cats is a common occurrence worldwide. *D. caninum* also has been found in a variety of wild canines and felids. Reports of dipylidiasis in humans in the United States, however, are uncommon.[23,138]

CLINICAL MANIFESTATIONS, DIAGNOSIS, PROGNOSIS, AND TREATMENT

Although the incubation period in humans is unknown, infection has been seen in infants aged 5 weeks. Frequently, the only evidence of infection is the finding of proglottids in stool or in an infant's diapers. Varying degrees of abdominal pain, diarrhea, irritability, and even pruritus have been recorded in symptomatic children.

The characteristic proglottids must be differentiated from other parasites. A frequent error is to assume, from the parents' description, that the small, motile proglottids that migrate from the anus are pinworms. Proglottids also may be mistaken for fly larvae. Examination findings of stool specimens may be spuriously negative because proglottids tend to migrate from the fecal mass and disintegrate on the walls of the specimen container. Treatment with praziquantel (5 to 10 mg/kg as a single oral dose) is effective. An alternative treatment is niclosamide (50 mg/kg as a single oral dose).

Infected dogs and cats also should be treated. Flea control requires the use of appropriate insecticides on pets. In addition, particular attention must be given to carpets and areas where pets sleep because these are the sites of development of the larval fleas.

HYMENOLEPIS NANA (DWARF TAPEWORM)

Infection with *Hymenolepis nana*, the dwarf tapeworm, occurs worldwide and probably is maintained by direct fecal-oral transmission from person to person.[31,227] Insects may serve as intermediate hosts. Infection may be asymptomatic, but gastrointestinal, neurologic, and allergic symptoms have been reported.

THE ORGANISM

Adult worms of *H. nana* measure 1 to 5 cm in length and are less than 1 mm in maximal width. The tiny scolex has four cup-shaped suckers and a rostellum with a circle of 20 to 30 small hooks. Gravid proglottids disintegrate within the intestine, and eggs are found in the feces. The oval eggs measure 30 to 50 µm in diameter and contain a six-hooked embryo within two envelopes. The space between the two envelopes contains filaments that extend from two small polar protrusions on the inner envelope. Larval stages develop in insect intermediate hosts after they have ingested the eggs. However, if the definitive host ingests eggs, larval stages develop in the intestinal villi in 4 to 5 days and then break into the lumen and develop into adult worms. Ova appear in feces 2 to 4 weeks after infection occurs. A morphologically identical organism found in rodents may be a separate species. The rodent strains are alternatively called *Hymenolepis fraterna* or *H. nana* var. *fraterna*.[31,127] The rodent strain occasionally infects humans.

TRANSMISSION

Human infection is acquired most commonly by the ingestion of eggs from the feces of infected persons. Humans serve as both intermediate and definitive hosts in this direct cycle. Poor hygienic habits, overcrowding, lack of running water, and any other factor that fosters fecal-oral transmission enhance transmission through this route. The rodent strains of *H. nana* are infectious for humans, and food contaminated by rodent feces is a possible source of infection. Eggs may be produced for periods longer than 1 year, but the possibility of recurrent autoinfection obscures determination of the duration of the initial infection. Internal autoinfection may occur when ova from gravid proglottids are exposed to appropriate conditions within the intestinal lumen. Hatching occurs, and the embryos penetrate the mucosa, undergo larval development, and eventually emerge as adult worms.

EPIDEMIOLOGY

H. nana is a common parasite of rats and mice worldwide, and 50 to 75 million people are thought to be infected.[31,227] The distribution of infection in humans is worldwide, with an increased prevalence in some urban areas. Stool surveys from endemic areas commonly show prevalence rates of 5 to 25 percent, which may approach 50 percent in children aged 4 to 10 years.[34]

PATHOLOGY AND PATHOGENESIS

Little is known of the pathogenesis and pathology of *H. nana* infection in humans. The larval stage of *H. nana* is a cystlike structure called a *cysticercoid* that is approximately 250 μm in diameter. Local reactions consisting of mucosal inflammation or atrophy may occur at the site of attachment of the adult worms in the small intestine. Rare cases of disseminated infection in children with depressed cellular immunity have been reported.[124]

CLINICAL MANIFESTATIONS

A wide variety of symptoms have been ascribed to *H. nana* infection, but few well-controlled clinical studies have been presented. Heavy burdens of worms have been associated with abdominal pain, diarrhea or loose stools, malnutrition, retardation of growth, and lethargy, whereas children with low burdens did not have significant symptoms.[26,27,193]

DIAGNOSIS

Detection of the characteristic eggs in fecal material by examination of direct saline wet mounts or by concentration techniques usually is not difficult. However, a single examination is not always adequate to rule out infection.

TREATMENT AND PROGNOSIS

Praziquantel (25 mg/kg as a single oral dose) is effective in treating *H. nana* infection. Nitazoxanide (100 mg by mouth twice daily for 3 days for children 1 to 3 years of age, 200 mg by mouth twice daily for 3 days for children 4 to 11 years of age, and 500 mg by mouth twice daily for 3 days for older children) is a reasonable alternative therapy; efficacy is approximately 75 to 82 percent.[26,147] Family members should be examined and treated if they are infected. Infection with *H. nana* rarely is severe and responds well to appropriate treatment.

PREVENTION

Transmission of *H. nana* infection largely could be eliminated if proper methods of personal hygiene and disposal of human waste could be invoked throughout the world. Infected food handlers always should be treated and monitored to ensure that treatment has been successful. Stored food should be protected from rodents and insects.

HYMENOLEPIS DIMINUTA (RAT TAPEWORM)

Hymenolepis diminuta is a rat tapeworm that only rarely presents as a human infection. Adult worms are 20 to 90 cm long; eggs are round.[31,227] Children become infected after ingesting larva-infected insects. Infection often is asymptomatic, but abdominal discomfort and pruritus have been reported. Treatment is with praziquantel (25 mg/kg in a single oral dose) or niclosamide.

SPARGANOSIS (INTERMEDIATE-STAGE *SPIROMETRA* SPECIES INFECTION)

Sparganosis is a zoonotic infection seen most frequently in eastern Asia.[87,227] It occurs when humans are infected with a metacestode larval stage of *Spirometra* spp.

THE ORGANISM

Evidence indicates that the amorphous, thin, ribbon-like spargana recovered from human infections belong to the genus *Spirometra*.[87,227] The adult tapeworms are found in dogs, cats, raccoons, and a variety of wild carnivores. Eggs passed in the feces of these definitive hosts hatch in fresh water. The embryo that emerges from the egg is ingested by a copepod, where it undergoes larval development. When a second intermediate host ingests the infected copepod, the larva develops into a sparganum (plerocercoid). The range of second intermediate hosts includes amphibians, reptiles, birds, and mammals. When the second intermediate host is eaten by the definitive host, the sparganum attaches to the intestinal mucosa and develops into the adult tapeworm. The designation of species found in humans is based largely on epidemiologic relationships to species described in local animals. The species found in Africa, Asia, Europe, and South America usually is called *Spirometra mansoni* or *Spirometra erinacei*, and the species infecting humans in the United States is called *Spirometra mansonoides*. A rare form of sparganosis that buds, branches, and multiplies asexually to massive numbers in humans is called *sparganum proliferum*.[141]

TRANSMISSION

In parts of Asia, application of poultices of amphibian or reptile flesh to wounds or sores is a common practice, and children can be infected when the spargana migrate from the poultice into human tissues. Human sparganosis in the United States often is associated with drinking well water or untreated surface water that could contain the minute copepods containing the procercoid form. Transmission by ingestion of the raw or inadequately cooked flesh of second intermediate hosts has been demonstrated experimentally in humans. Animal sources that have been incriminated in human infection are snakes, frogs, chickens, and pigs.

EPIDEMIOLOGY

Human infection is an uncommon occurrence. In the United States, almost all reports have come from the southern or southeastern states and from Puerto Rico or were reported in persons who had been in these areas. The only report of infection in a child in the United States came from southern California.[30] Reports of human infection have come mainly from China, Korea, Southeast Asia, Japan, India, Indonesia, the Philippines, Australia, Africa, Italy, South America, and the former Soviet Union.[87,227,229]

PATHOLOGY, PATHOGENESIS, AND CLINICAL MANIFESTATIONS

Ocular sparganosis, usually acquired by contact, may involve conjunctival, retro-orbital, or palpebral tissues and cause

conjunctivitis, periorbital and palpebral edema, exophthalmos, chemosis, and corneal ulceration.[87,227,229] Subcutaneous sparganosis is the most common form of the infection, with the trunk frequently being involved. The lesion usually is nodular. Tenderness and inflammation may be absent, intermittent, or constant. Some lesions are migratory. Eosinophils may or may not be present. Some infections have had an associated peripheral eosinophilia, but it is not a constant finding. Spargana have been identified in a wide range of other tissues. Sparganosis of the CNS may be associated with a variety of neurologic manifestations.[87,111,196,227,229] Brain imaging of patients with cerebral sparganosis shows edema and degeneration of cerebral white matter commonly with a "tunnel sign" of hypodensity and ring enhancement.[196] Sequential MRI imaging has revealed migration of larva between various regions of the brain in some children. The disease caused by sparganum proliferum consists of progressive replacement of host tissues by the multiplying organisms. Eleven cases reported from the world literature were reviewed in 1990.[141]

DIAGNOSIS

The diagnosis may be suspected in persons with typical subcutaneous lesions and a suggestive epidemiologic background. Usually, however, the diagnosis is made during surgical removal of a painful or cosmetically disturbing lump without anticipation of the parasitic etiology. Spargana vary considerably in width and length. They usually are several centimeters in length, whitish, and opaque, and they may have the grooved indentations on the anterior end that are precursors of the bothria or suckers of the scolex of the adult worm. Small portions of spargana are difficult to distinguish grossly or microscopically from cysticerci and other less common larval cestodes. Neuroimaging may yield characteristic findings in cerebral sparganosis.[111,196] Obtaining an ELISA for serum and CSF antibody appears to be useful in endemic areas, but this test is not generally available.[227]

TREATMENT AND PREVENTION

Surgical removal is the only known form of therapy. Praziquantel has been used in some cases, but no convincing evidence of clinical activity exists. Filtration of water prevents the ingestion of copepods from wells or ponds. Proper cooking of meat eliminates second intermediate hosts as sources of infection. Educational effort should be made to warn of the dangers of applying raw flesh poultices in areas where it is a cultural practice.

ECHINOCOCCUS GRANULOSUS AND RELATED SPECIES (CYSTIC HYDATID DISEASE)

Humans may be infected with the larval stages of parasites of the genus *Echinococcus*.[32,33,51,52,100,177] Humans acquire the infection by the ingestion of ova from the feces of carnivorous definitive hosts. The disease in humans and intermediate hosts is called hydatid disease and is characterized further according to the morphologic features of the larval stages: cystic echinococcosis caused by *Echinococcus granulosus* and related organisms, alveolar echinococcosis caused by *Echinococcus multilocularis*, and polycystic echinococcosis caused by *Echinococcus vogeli* or *Echinococcus oligarthrus*. Most cases in children present with cystic hydatid disease, which is the focus of this section of the chapter.[32,33,51,52,100,177]

THE ORGANISMS

Cystic hydatid disease is caused by *E. granulosus* and related species. On the basis of morphologic features, all cases initially were considered to belong to a single species. However, genetic studies have demonstrated 10 separate genotypes that infect different intermediate hosts.[51,100,177] Significantly different strains are found in sheep, Tasmanian sheep, cattle, pigs, horses, camels, and cervids (deer, reindeer, moose, elk). Most human infections are caused by the sheep strain. However, Tasmanian sheep, cattle, camel, and cervid strains also can cause human infection. The life cycles of the species of *Echinococcus* are similar, but the geographic distributions, types of hosts, and morphologic features of the parasites differ significantly. Adult tapeworms of the sheep strain are found in dogs. The cervid strain involves primarily wolves, but dogs also may be infected. The adult tapeworm is only 3 to 8 mm long and has two to five segments. Dogs often are hosts to thousands of adult worms. When sheep or humans ingest eggs from the feces of infected dogs, the embryos hatch in the intestine and burrow through the intestinal wall to gain access to the portal circulation. The embryos that survive are able to develop in many tissues, but they do so most commonly in the liver or lungs, where they become the cystic larval structures called *hydatid cysts*. A hydatid cyst is composed of an outer laminated, acellular membrane that is lined by a thin, cellular germinal membrane. Spherical structures called *brood capsules* grow from the germinal membrane. Protoscolices develop within the brood capsules. Each protoscolex has suckers and hooks and the potential to become the scolex of an adult worm if it is eaten by a dog. Compression and reaction from growth of the cyst produce a "pericyst" of compact, collagen-rich host tissue around its exterior. In older cysts, so-called daughter cysts may develop within the primary cyst cavity.

TRANSMISSION

Humans acquire cystic hydatid disease by ingestion of ova shed by the definite host, typically dogs.[33,51,135,140,171,177] Close contact with dogs can result in infection because tapeworm eggs can be found on the dog's perianal hair, muzzle, and paws. Contaminated food, drink, or fomites (e.g., flies and other insects) may disseminate the eggs from dogs' feces. However, most cases occur in pastoral families and are associated with close contact with infected dogs.

EPIDEMIOLOGY

The sheep strain of *E. granulosus* is found worldwide in most areas where sheep are raised.[33,51,100,135,140,177] Studies of the global burden of disease and economic impact of cystic hydatid disease suggest that the impact is significantly underestimated compared with other illnesses.[19] The disease is endemic in the sheep-raising areas of South America, the Middle East, the Mediterranean basin, China, and the former Soviet Union.[33,51,100,135,140,171,177] One of the highest morbidity rates is seen in rural Africans in Kenya and Uganda, where people live in close association with their dogs. The custom of feeding sheep viscera to sheepdogs maintains foci of infection. In the United States, Basques in central California, Mormon ranchers in Utah, and Native Americans in Arizona and New Mexico have been infected. The cervid strain of *E. granulosus* is found in northern parts of the Western Hemisphere. In Alaska and Canada, human infection usually is limited to Eskimos and Native Americans who have working dogs that are fed moose and reindeer viscera.[206] The strain found in this region often is manifested as giant pulmonary cysts.

PATHOLOGY AND PATHOGENESIS

In cystic hydatid disease, the pathologic process is related to compression or displacement of the host's tissue.[51,149,177] Cyst growth is variable but probably averages approximately 1 cm in diameter per year. Rates of up to 4 to 5 cm a year have been reported, but growth may be more rapid in the lung. The cyst may exceed 35 cm in diameter in the abdominal cavity. When rupture or leakage of a cyst occurs, an allergic reaction caused by the antigenic cyst contents may develop. Cysts may calcify after many years, which usually signifies death of the parasite. Hydatid cysts may form foci for secondary bacterial infection.

CLINICAL MANIFESTATIONS

Most children with *E. granulosus* infection have a single unilocular cyst, but multiple cysts are seen in 15 to 30 percent of patients, usually in a single organ system.[51,149,177] The most common site of the cysts is in the liver. In clinical series, approximately one in five children with a pulmonary cyst also has a concurrent liver cyst, but the proportion outside the liver is lower in population-based screening.[116] Approximately 10 percent of cysts are found in sites other than the liver or lung, including spleen, kidney, peritoneum, genitourinary tract, bone, muscles, heart, eye, and brain. The cervid strain of *E. granulosus* found in Canada and Alaska characteristically produces pulmonary cysts.[51,149,177] CNS hydatid disease occurs much more commonly in children than in adults.[29,108] Bone cysts, which may be seen in preschool children, occur most frequently in vertebral and long bones.[149,177] Unlike cysts in other sites, bone cysts characteristically are multilocular and contain little fluid. Eye, bone, and brain cysts typically are small when they are discovered, whereas cysts in other sites may exceed 35 cm in diameter before being detected. Cysts grow approximately 1 to 3 cm in diameter each year, but growth may be more rapid with pulmonary cysts.[116] Complications usually occur only if cysts become large and include secondary bacterial infection of hydatid cysts and leakage or rupture with resultant hypotension, urticaria, and eosinophilia. Rupture may occur spontaneously or secondary to trauma or surgery, but it generally is considered to be an uncommon complication of hydatid disease in children.

The wide spectrum of symptoms in cystic hydatid disease depends on the number, size, and location of the cysts.[51,149,177] Slowly growing cysts in liver or lung often are asymptomatic for years. Symptomatic intrahepatic cysts cause constant or intermittent right upper quadrant or epigastric pain, enlargement of the liver, or nausea and vomiting. Unruptured cysts rarely cause fever. Rupture of a cyst may be precipitated by a traumatic event and may cause a range of symptoms, including fever, abdominal pain, hypotension, and allergic manifestations, including eosinophilia, urticaria, and anaphylaxis. Rupture into the biliary tract may cause cholangitis with fever and right upper quadrant pain. Some children with hydatid disease also have retarded growth patterns.[134]

Intact pulmonary cysts typically do not cause symptoms.[51,149,177,184,211] Rupture or leakage, however, may cause cough, chest pain, dyspnea, and hemoptysis. Fever may be present, but it is often a marker for secondary bacterial infection. As many as a third of pulmonary cysts rupture into the pleural space or into a bronchus. In the latter case, the patient may describe coughing up portions of the membranes, which may resemble grape skins, or noting a characteristic salty taste. Bone cysts are seen in patients with bone pain or pathologic fracture. Vertebral hydatid disease causes signs and symptoms of spinal cord and radicular compression; severe pain on palpation of the affected portion of the spine is characteristic. Fifty to 75 percent of intracranial cysts are seen in children.[29,82,108,215] Increased intracranial pressure with headache, vomiting, and focal neurologic complaints are common findings. Seizures also may occur.

DIAGNOSIS

The diagnosis of cystic echinococcosis usually is suspected on the basis of clinical or radiologic findings plus a history of residence in an endemic area. Physical examination rarely is definitive. Only half of patients with hepatic cysts have abnormal liver enzyme results. Eosinophilia typically is low grade or absent. The initial diagnosis of cystic hydatid disease often is based on imaging findings. An unruptured pulmonary hydatid cyst has a sharply demarcated, round or oval smooth border. It has a homogeneous cannonball appearance and sometimes is surrounded by a layer of atelectatic lung.[51,149,177] After the cyst has ruptured into a bronchus, a crescent-shaped air layer may be seen that is virtually diagnostic. In addition to the arc of air between the parasite and the host cyst wall, air in the cyst lumen also may be present. The membrane of a collapsed cyst floating on the surface of the fluid in a ruptured pulmonary cyst has a characteristic "water lily" appearance.

Cysts in the liver usually are visualized easily and measured with ultrasonography, CT, or MRI. Ultrasound techniques are useful for defining most cysts within the abdomen and can differentiate fluid-filled cysts from solid tumors. Because ultrasonography is portable and relatively inexpensive, it has been the main technique used in epidemiologic studies and clinical cases in developing countries. A World Health Organization staging system has been developed that has been used to define management (Fig. 238–4).[6,167,224] Stage CL cysts are unilocular collections without a discrete wall and with uniform anechoic contents. This appearance is not specific for *Echinococcus*. Stage CE1 cysts have a dense wall and may have internal echoes. This so-called hydatid sand is caused by protoscolices within the cyst. CE2 cysts have internal septa or daughter cysts, forming honeycomb patterns, that are highly characteristic of hydatid cysts. CE3 cysts demonstrate detachment of the cyst wall or early collapse. CE4 cysts demonstrate inhomogeneous material instead of a cyst cavity. CE5 cysts demonstrate a thick rim of calcification. Radiographically apparent cyst wall calcification occurs only in liver or spleen cysts and generally takes more than 5 to 10 years to develop. Bone cysts typically produce radiolucencies without periosteal reaction. MRI offers little advantage over CT for the imaging of cysts except in the CNS.

Fine-needle aspiration of cysts for establishment of the diagnosis can be dangerous if it is not performed carefully because of the risk of spillage of hydatid fluid, which can induce anaphylactic shock and possibly secondary cyst development. However, the percutaneous route has been used for both diagnosis and treatment, with few untoward events (see later). The fluid obtained should be examined for evidence of protoscolices, hooks, or antigen.

Serologic tests can be useful in confirmation of the diagnosis.[51,149,177] Antibody tests using crude antigen of either *E. granulosus* or *E. multilocularis* tested by ELISA, indirect hemagglutination, and fluorescent antibody assays are positive in 50 to 90 percent of cases. False-negative results are more common in patients with pulmonary, brain, and splenic cysts. Because the tests available may cross-react with cysticercosis or other parasitic infections, positive results should be confirmed by a more specific test, either an immunoblot assay or a gel diffusion assay looking for the specific arc 5.

TREATMENT AND PROGNOSIS

The treatment of cystic hydatid disease is in evolution. Surgery was the traditional treatment of choice for nearly all cases of

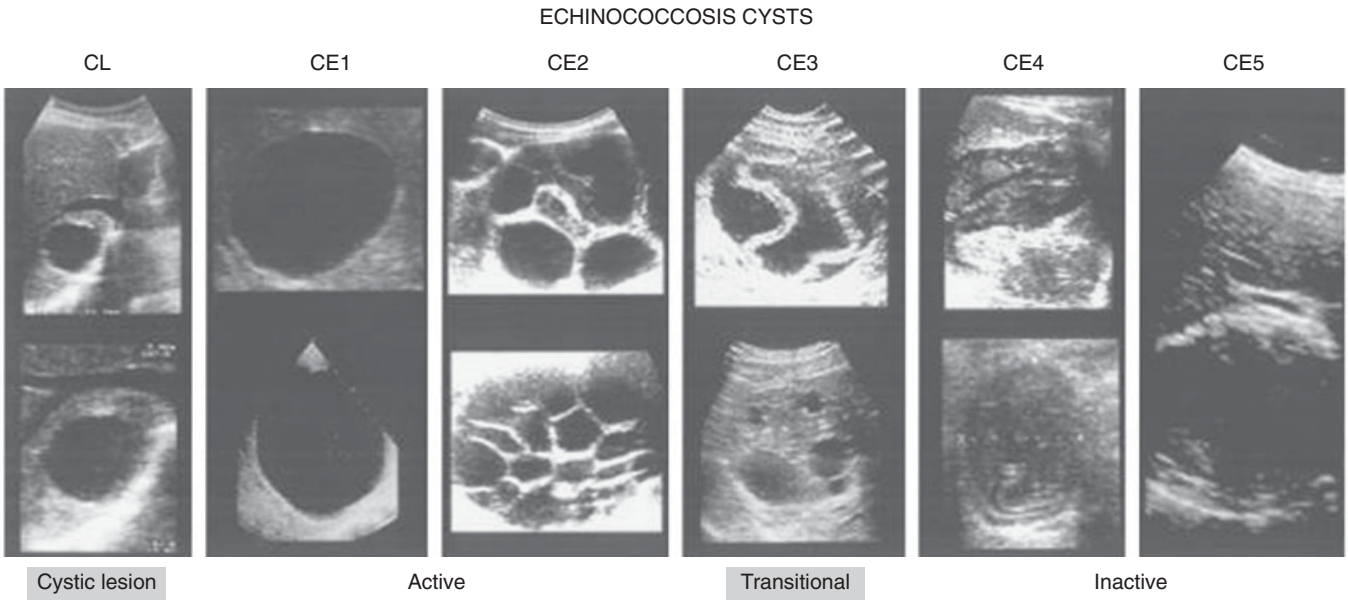

Figure 238–4 Staging of echinococcosis. *(From World Health Organization Informal Working Group on Echinococcosis: International classification of ultrasound images of cystic echinococcosis. Reproduced with the permission of the World Health Organization.)*

cystic hydatid disease, but that approach has given way gradually to a range of approaches including surgery, antiparasitic chemotherapy, percutaneous drainage termed PAIR (*p*ercutaneous *a*spiration, *i*ntroduction of scolicide, and *r*easpiration), and "watch and wait."[51,177] Currently, expert opinion suggests that treatment should vary on the basis of the location of the cyst or cysts, the nature and size of the cysts, the condition of the patient, and the available expertise with surgery required by only a minority of cases. For example, in a prospective study, only 10 percent of children with hepatic cysts detected in a population-based ultrasound survey required surgery during the subsequent 5 years.[115]

The benzimidazoles albendazole and mebendazole have been used for chemotherapy.[51,55,60,92,107,115,177,210] Approximately a third of hepatic cysts will resolve in response to benzimidazoles, and 30 to 50 percent improve. Many of the residual lesions considered treatment failures were shown subsequently to be nonviable. The response to chemotherapy is better with smaller lesions. It is now thought to be the treatment of choice for small (<5 cm) CL, CE1, and perhaps CE3 lesions.[51,177] Chemotherapy also has proved to be successful for treatment of small pulmonary cysts.[48] However, a high failure rate exists with chemotherapy alone for larger lesions in either the liver or the lung. Albendazole is thought to be more effective than is mebendazole. Albendazole typically is dosed at 10 to 15 mg/kg/day in two daily doses continued for 3 to 6 months. Side effects may include neutropenia, elevated liver enzymes, and alopecia. Prospective studies of surgically removed specimens show that protoscolices can remain viable for as long as 3 months, which is the minimum duration of chemotherapy.[15,55] Treatment failures have been successfully managed by further chemotherapy, PAIR, or surgery. In some cases, PAIR may demonstrate that protoscolices no longer are viable, even with persistent lesions. Because chemotherapy can be associated with relapses or treatment failure, children should receive follow-up imaging studies for years after receiving chemotherapy. Chemotherapy also is an important adjunct to surgical therapy.

The PAIR technique offers a less invasive option than the traditional surgical approaches do.[17,56,110,145,177,195,230,231] Results have been similar to those with surgery, but with fewer perioperative complications. PAIR is thought to be the treatment of choice for uncomplicated CL and CE1 lesions larger than 5 cm and CE3 lesions. CE2 lesions can be treated with a modification of PAIR that employs a larger bore catheter and drainage.[17,180] Although the data comparing different treatments are limited, PAIR was associated with similar efficacy and less morbidity than was surgery in one randomized trial. PAIR should be performed after initiation of albendazole chemotherapy for at least 4 hours but preferably for several days. In a controlled trial, PAIR plus chemotherapy was superior to either chemotherapy or PAIR alone.[109,145] Aspiration generally should go through solid tissue (e.g., liver) rather than directly into the cyst (to limit spillage). The cyst fluid should be examined for protoscolices or hooks (to confirm the diagnosis). Before scolicidal agents are injected, the cyst fluid should be checked for bile staining (by dipstick or, preferably, by injection of contrast medium) because these agents can cause sclerosing cholangitis if they are injected into the biliary tract. Alcohol and hypertonic saline have been used as scolicidal agents in this procedure. Contraindications to PAIR include communication with the biliary tract, inaccessibility, superficial cysts, and cysts that are free in the abdomen, heart, brain, or spine. If the cyst is found after puncture to communicate with the biliary tract, contrast media can be used to further define the communication. Contrast material also is mildly scolicidal.

Surgery has been the traditional approach to therapy for hydatid disease and remains the treatment of choice for complicated infections and some CE3 lesions.[51,149,177] The goal of surgery is to remove the entire cyst without spilling its contents. Rupture of the cyst contents at the time of surgery carries a risk of causing disseminated echinococcosis and a small risk of anaphylaxis occurring at the time of operation. Surgical approaches have included pericystectomy (removal of the entire cyst and a rim of surrounding tissues), resection of the involved organ, simple drainage, omentoplasty, and capitonnage. In general, the more radical procedures have been associated with fewer relapses, but at the cost of more perioperative complications. However, laparoscopic approaches have been reported recently to be associated with a high success rate and less morbidity.[20,50,126,231] Chemotherapy with albendazole with or without praziquantel is performed routinely.[9,55,177] With administration of chemotherapy, pressure within the cyst may be reduced, and removal of cyst membranes and contents will be facilitated. In addition, treat-

ment decreases the likelihood of development of secondary cysts. With albendazole alone, cysts remain viable for as long as 3 months.[15] The preoperative administration of praziquantel combined with a benzimidazole has been suggested because of the scolicidal properties of praziquantel.[9] The practice of injecting the cyst with scolicidal drugs before removing it is associated with complications and is not thought to be necessary in the setting of preoperative and postoperative chemotherapy.[177]

Pulmonary cysts have been treated successfully surgically, medically, and with PAIR.[2,48,105,132,194] No controlled trials of these different strategies have been performed. However, retrospective series suggest that smaller cysts often respond to antiparasitic chemotherapy.[48] Larger cysts may be treated with PAIR or surgery. The cervid strains of *E. granulosus* from Alaska and Canada do not produce anaphylaxis on rupture, and pulmonary cysts spontaneously resolve after evacuating into bronchi. If the cyst wall remains in place after the patient has undergone chemotherapy or PAIR, residual parasite material can serve as a nidus for bacterial superinfections.[2]

The prognosis of hydatid disease varies widely from self-limited asymptomatic infection to fatal infection associated with rupture of the cyst. All of the modes of therapy are associated with relapse during the first few years of treatment. Thus, careful follow-up is essential. With appropriate therapy, however, few cases are fatal.

PREVENTION

Control programs for cystic hydatid disease have met with variable success.[32,33,177] *E. granulosus* was eliminated from Iceland by banning home slaughter of sheep. Banning of home slaughter, education, arecoline purging of dogs, and treatment of infected dogs with praziquantel have led to eradication in New Zealand and Tasmania. However, these eradication programs required significant resources and have been less successful elsewhere. A recombinant vaccine has proved to be highly effective in field studies but awaits implementation.[33,122] Other tools in developmental stages include coproantigen tests to detect infected dogs and improved therapy for ovine infection.

OTHER *ECHINOCOCCUS* SPECIES

Echinococcus multilocularis is the cause of alveolar hydatid disease.[51,100,106,149,177] Humans are an incidental host in a life cycle that typically involves foxes as definitive hosts (but also wolves and occasionally domestic dogs) and rodents as intermediate hosts. The larval parasite does not form a large cystic structure but grows by progressive external budding. The laminated membrane and host pericyst are thin. The larval mass slowly enlarges and replaces liver tissue much as a malignant neoplasm does. *E. multilocularis* is endemic in arctic and alpine areas, including western China, central Europe, and scattered foci in North America. In recent years, disease is emerging in much of central Europe. The larvae may invade contiguous structures and rarely metastasize. Human infection almost invariably involves the liver, but it may spread to adjacent tissues or metastasize to the brain. Because the larval mass grows slowly, with a typical latent period of 5 to 15 years before clinical presentation, clinical disease is a rare finding in children. Diagnosis involves imaging studies with serologic confirmation. Management requires surgical resection along with prolonged chemotherapy. Comprehensive reviews of epidemiology, clinical manifestations, diagnosis, and management are available.[16,51,100,106,149,177]

Echinococcus vogeli is a parasite of bush dogs and feral dogs in South America.[177] The intermediate hosts are rodents (pacas, agoutis, spiny rats). When humans are infected, the germinal membrane grows externally to form additional cysts, and septa develop within the original cyst. This manifestation is the "polycystic" variety of hydatid disease. A rare polycystic hydatid disease in humans has been attributed to *E. oligarthrus*, a fourth species that is found as adult tapeworms in wild felids such as pumas and jaguars. The intermediate hosts are the same as those for *E. vogeli*. Most infections occur in Central and South America. Polycystic hydatid disease is limited to South and Central America, where fewer than 100 human infections have been reported. Initial management should include administration of albendazole.

SUBSECTION 4

Trematodes

CHAPTER 239

TREMATODES

Andrea P. Summer ❂ A. Clinton White, Jr. ❂ Philip R. Fischer

Humans are infected with a number of trematode parasites, which are also referred to as flukes. In fact, an estimated 40 to 50 million people are infected with food-borne trematode infections, and approximately 10 percent of the world's population is at risk of acquiring infection.

Flukes are flatworms (members of the phylum Platyhelminthes and of the subphylum Trematoda). Although schistosomes are trematodes, they differ from other flukes in morphology, biology (e.g., separate sexes), and clinical manifestations, so they are discussed separately. Trematodes other than schistosomes share common characteristics. The adult worm usually is flat and leaf shaped, with an oral and ventral sucker and a bifurcated, blind-ended gastrointestinal tract. Unlike schistosomes, other trematodes are hermaphroditic, producing operculated eggs that typically are passed in host feces. Eggs possess an operculum at one end, the opening through which a ciliated larva will hatch. Fresh-water snails are intermediate hosts for all trematodes and are infected by either direct penetration by the ciliated larva or by ingestion of the unhatched egg. Complex larval development and multiplication occur within the snail host, with large numbers of larvae called cercariae ultimately produced. In most trematode life cycles, the cercariae emerge from the snails and swim about until they attach to the appropriate second intermediate host, which may be fish, crustaceans, mollusks, or aquatic vegetation, depending on the species of fluke. After attachment occurs, the larvae develop into metacercariae within protective cyst walls. Humans are infected by ingestion of the metacercariae. In Southeast Asia and the western Pacific region, food-borne trematodiasis has become an emerging public health problem, probably because of the exponential growth of aquaculture.[22] Many of the medically important flukes have a wide range of definitive hosts. Diagnosis of fluke infections typically is accomplished by examination of fecal specimens for characteristic ova. Immunodiagnostic tests are available to aid in establishing the diagnosis of some flukes and are becoming the preferred method of diagnosis for certain species. Common nonschistosomal intestinal, liver, and lung flukes are reviewed in this chapter.

INTESTINAL FLUKES

FASCIOLOPSIASIS

LIFE CYCLE

Fasciolopsiasis is a food-borne, intestinal zoonotic parasitosis that is caused by *Fasciolopsis buski*, the giant intestinal fluke. The fluke attaches to the proximal end of the small intestine and, in its adult form, measures up to 7.5 cm in length. The life span of the adult worm is approximately 6 months. Eggs, usually produced about 3 months after infection occurs, are oval and measure 130 to 150 µm in length by 80 to 85 µm in breadth. A single parasite may excrete 25,000 eggs daily. The eggs are released in the feces, and after several weeks in fresh water, ciliated larvae hatch from the eggs and penetrate snails, where they undergo further larval development. Cercariae emerge from the snail approximately 1 to 2 months later and encyst on a wide variety of aquatic vegetation and debris as well as on the water surface. The infective larvae cause infection when ingested. Water chestnuts, caltrop, and water bamboo are common vegetative sources of infection. Ingestion of larvae also can occur through drinking of untreated water or handling or processing of water-derived plants (e.g., peeling water chestnuts that have encysted larvae attached to the outer surface of the nut with the teeth).

EPIDEMIOLOGY

Fasciolopsiasis occurs most often in Asia and the Indian subcontinent. Pigs are the reservoir host, and fasciolopsiasis is particularly prevalent in areas where pigs are raised and aquatic plants are commonly consumed. Human infection has been reported most frequently in China, Bangladesh, Southeast Asia, and parts of India. Fasciolopsiasis is most prevalent in school-age children, in whom high worm burdens are not uncommon findings.

PATHOLOGY

The parasites usually are found in the duodenum and jejunum, but heavy infections also have been observed to migrate to the stomach, ileum, and colon. Inflammation, ulceration, and small abscesses sometimes develop in the intestinal mucosa where the parasite is attached. Increased mucus secretion and mild bleeding can result. Massive infections can lead to intestinal obstruction. Light infections typically are asymptomatic. Systemic manifestations, including malabsorption and protein-losing enteropathy, are common occurrences in heavy infections and can lead to generalized edema and ascites. Toxic and allergic metabolites of the parasite also are thought to contribute to the edema.

CLINICAL MANIFESTATIONS

The severity of symptoms usually is correlated with the number of parasites. Epigastric pains resembling "hunger pains" or peptic ulcer disease have been reported as early as 30 days after exposure. Diarrhea and abdominal pain may be intermittent and may occur separately or simultaneously. In heavy infections, nausea and vomiting may develop. Facial edema, anasarca, and ascites are encountered in advanced, severe infections. Eosinophilia with counts greater than 30 percent is not an uncommon occurrence. Leukocytosis and mild anemia may be noted.

In endemic areas, it is not unusual for a child to have multiple intestinal parasites and a borderline nutritional status. Fasciolopsiasis adds an additional burden to the host defense mechanisms and may be responsible, in concert with the other stresses, for significant morbidity.

DIAGNOSIS

The eggs of *Fasciolopsis* are demonstrated easily by routine fecal examination, but they are virtually indistinguishable from those of the liver fluke *Fasciola hepatica* and the echinostomes. Epidemiologic information, such as travel history and exposure to sources of infection, may be helpful in determining the diagnosis. Because the life span of the adult worm is short, anyone who has been out of an endemic area for longer than 9 months is not likely to have persisting infection with *Fasciolopsis*. Therefore, eggs present in stool long after a potential exposure would be attributable to the longer-lived *Fasciola*.

TREATMENT AND PROGNOSIS

Praziquantel, 75 mg/kg divided into three doses given in 1 day, is effective therapy and has few side effects. Although this drug is approved by the U.S. Food and Drug Administration, it is considered investigational for *Fasciolopsis* infection.

Infections treated early and most light infections, even when they are untreated, have an excellent prognosis. Heavy infections in children, especially when they are complicated by intestinal obstruction, edema, or concomitant secondary infections, portend a much poorer prognosis.

PREVENTION

The most practical method to prevent fasciolopsiasis is to avoid eating raw, water-derived food. Cooking aquatic vegetation or immersing the plants or nuts briefly in boiling water usually is sufficient to prevent infection. Also, discouraging the use of human feces as fertilizer and promoting the institution of modern pig farming both can aid in the control of fasciolopsiasis. Successful efforts in health education have reduced the transmission of this parasite in some endemic areas, such as Taiwan[25]; however, in areas where fasciolopsiasis was presumed controlled, such as Uttar Pradesh, re-emerging infection has been reported.[3]

HETEROPHYIASIS

More than 10 different species of the family Heterophyidae have been reported to cause human infection. Except for two species, *Heterophyes heterophyes* and *Metagonimus yokogawai*, these infections are relatively uncommon occurrences and are incidental to the prevalence in other mammals and birds.

THE ORGANISMS

H. heterophyes and *M. yokogawai* adult worms attach to the mucosa of the small intestine. The parasites are minute, measuring 1 to 2.5 mm long and less than 1 mm wide. They often burrow deeply into the mucosa. The eggs measure 26 to 30 µm in length and 15 to 17 µm in width. The eggs of the two species are essentially identical. Eggs excreted in the stool are fully embryonated. The snail intermediate host becomes infected by ingesting the trematode egg. After multiplication in the snail, cercariae emerge and encyst under the scales or in the skin or flesh of a variety of freshwater fish. After being ingested by the definitive host, the metacercariae are freed from their cysts and develop into adults in as little as 5 days.

TRANSMISSION AND EPIDEMIOLOGY

Humans acquire the infection by eating fresh-water fish that is raw, inadequately cooked, pickled, or salted. Heterophyiasis occurs worldwide. Areas of endemic infection are Southeast Asia, the Middle East, the Nile Delta, China, Japan, Taiwan, the Philippines, and parts of the former Soviet Union. Many reservoir hosts, such as dogs, cats, and fish-eating birds, may play an important role in maintenance of infection in some endemic areas.

PATHOLOGY

The small heterophyid flukes cause variable degrees of inflammatory reactions, including superficial inflammation and erosions at the sites of mucosal attachment and granulomatous lesions that contain eosinophils due to eggs deposited beneath the mucosa. Eggs may invade the circulatory system through the intestinal capillaries or lymphatics and embolize to distant sites such as the heart, brain, and spinal cord, causing significant disease that can be fatal. The complications of embolic heterophyiasis appear to be particularly frequent in the Philippines, where heart disease often is attributed to heterophyiasis. The embolized eggs induce a granulomatous response, with the eventual production of fibrosis in the infected areas.

CLINICAL MANIFESTATIONS

Light infections without the deposition of ectopic eggs usually are asymptomatic, although eosinophilia may be noted. In heavier infections, epigastric pain, diarrhea, malabsorption, and weight loss may occur. Seizures may result from eggs carried to the brain. Congestive heart failure or arrhythmias may occur after cardiac involvement.

DIAGNOSIS

Routine fecal examination demonstrates eggs, but because the eggs closely resemble the eggs of the liver flukes, establishing a specific diagnosis of these flukes often is difficult. Eggs recovered from biliary drainage or from persons who have been out of endemic areas for more than 2 years can be assumed to be those of the liver flukes *Opisthorchis* or *Clonorchis*. The heterophyid worms have a relatively short life span compared with that of the liver flukes.

TREATMENT AND PROGNOSIS

Praziquantel, 75 mg/kg/day in three divided doses for 1 day, is the recommended treatment. With the exception of the complication of egg emboli to distant organs, the prognosis is excellent.

LIVER FLUKES

FASCIOLIASIS

Fascioliasis is a parasitic disease caused by the flukes *Fasciola hepatica* and *Fasciola gigantica*. With 91 million people at risk of acquiring infection,[1] human fascioliasis is an important public health problem with increasing incidence of human cases in 51 countries.[12,30] Fascioliasis is primarily a zoonosis of ungulates (e.g., cattle and sheep), and humans are an incidental host.

THE ORGANISM

The adult *Fasciola hepatica* measures up to 30 mm in length and 13 mm in width. The surface has scalelike spines, and the anterior portion of the worm is cone shaped. The worms reside in the bile ducts, and eggs appear in the bile and eventually are excreted in feces. Eggs measure approximately 130 μm in length and up to 90 μm in width. The eggs are indistinguishable from those of *Fasciolopsis buski*. After being incubated in water for several days, the ciliated larva hatches from the egg and swims about in search of the snail intermediate host. The larva penetrates the snail and undergoes a complex cycle of asexual multiplication. Cercariae, which are the final stage of this asexual cycle, leave the snail and encyst on fresh-water vegetation, including watercress and alfalfa. These encysted metacercariae initiate infection when the mammalian host ingests the raw aquatic vegetation or drinks water contaminated with metacercariae. The metacercariae excyst in the intestine, penetrate the intestinal wall, and migrate in the peritoneal cavity to the liver. The developing worms penetrate the liver capsule and slowly burrow through the parenchyma to the bile ducts, where they mature into the adult worms. The adult worms feed on liver cells and duct epithelium. The life span of the adult fluke in humans ranges from 9 to 13.5 years.

TRANSMISSION AND EPIDEMIOLOGY

Ingestion of infected raw aquatic plants, such as watercress, is the most frequent cause of infection in humans. In a study from Peru, alfalfa juice seemed to be the major food source.[29] Water from ponds or marshes with infected vegetation may contain metacercariae. Infections occur in humans who have no history of eating watercress but have ingested water from sources that potentially are infected. The distribution of fascioliasis is worldwide, with the highest numbers of infected humans in Andean countries (Peru, Bolivia, Ecuador, Chile), the Caribbean, western Europe, northern Africa, and the Caspian Sea.[31] The reservoir host range is broad and includes herbivorous mammals, the most common or which are sheep, cattle, and goats. Intermediate hosts are fresh-water snail species. *F. gigantica* infections are predominantly infections in cattle. Human infection with *F. gigantica* has been reported in Africa, the former Soviet Union, Vietnam, Hawaii, and Iraq.

PATHOLOGY AND PATHOGENESIS

Fascioliasis includes an acute phase as the juvenile forms migrate through the liver and a chronic phase associated with the adult worms and eggs in the biliary tract. The pathogenesis of acute fascioliasis is related to damage occurring to liver tissues as the juvenile worms migrate through the liver tissue to the bile ducts. Linear necrotic lesions containing eosinophils form as worms progress through the liver parenchyma. Flukes that die before reaching the bile ducts may produce necrotic cavities that eventually evolve into fibrous scar tissue. Juvenile flukes that fail to migrate into the liver may wander about and cause ectopic fascioliasis. They may appear in the intestine, pancreas, subcutaneous tissue, brain, eye, and other locations. During the chronic stage, adult worms in the bile ducts cause inflammation and adenomatous changes in biliary epithelium, leading to duct thickening and dilatation. Ductal and periductal fibrosis occurs. The gallbladder and extrahepatic ducts may be invaded and undergo similar

inflammatory and fibrotic reactions. Adult worms may migrate back into liver parenchyma through eroded biliary epithelium and cause formation of abscesses.

CLINICAL MANIFESTATIONS

The first symptoms of fascioliasis occur approximately 4 to 6 weeks after infection develops, but this period varies widely, depending on host response and the number of parasites. The acute stage of infection occurs during the migration of worms in the liver. Children often have severe symptoms of right upper quadrant or generalized abdominal pain, tender hepatomegaly, fever, and anemia. Patients typically have marked eosinophilia. Sweating, dizziness, wheezing, and urticaria may occur. This stage may last 1 to 3 months. The chronic form of the disease is defined less well and includes a variety of symptoms related to the biliary system. These symptoms frequently are identical to those of gallbladder disease, cholangitis, and pancreatitis caused by nonparasitic conditions. Elevation in alkaline phosphatase levels is a common manifestation. Patients often endure years of having biliary tract symptoms before the diagnosis of fascioliasis is considered. Heavy infections eventually may cause sufficient liver damage to produce cirrhosis with all of the classic complications of this condition. Chronic infections with *F. hepatica* also may be asymptomatic but often are associated with eosinophilia. If ectopic localization of immature *F. hepatica* flukes occurs, it usually is in the subcutaneous tissues of the thorax, back, and extremities but has also been observed in lungs, heart, brain, and intestinal wall. A detailed review of the clinical aspects of human fascioliasis has been published.[2] The clinical manifestations of fascioliasis in a series of 16 Egyptian children included fever, abdominal pain, and a marked peripheral eosinophilia.[11]

Because the acute manifestations of human fascioliasis may precede the appearance of eggs in the stool by 7 to 12 weeks, immunodiagnostic tests are required to identify early infections. Obtaining a history of eating raw watercress or drinking surface water from an area that may be contaminated by domestic animals is helpful. The syndrome of fever, hepatomegaly, and eosinophilia is consistent with the diagnosis. Radiologic imaging of the liver may demonstrate findings of tracklike small abscesses, subcapsular lesions, and slow evolution of the lesions on follow-up examinations.[15] Computed tomography detects parenchymal lesions, and ultrasonography effectively evaluates the biliary tract and gallbladder. Magnetic resonance imaging findings also have been described.[6] A variety of immunologic tests have been developed. Presently, the tests used most frequently are enzyme immunoassays with excretory-secretory antigens combined with confirmation of positive results by immunoblot. *Fasciola*-specific antibodies may be detected within 2 to 4 weeks after infection or several weeks before eggs appear in stool. The reported sensitivities of the FAST-ELISA (the Falcon assay screening test–enzyme-linked immunosorbent assay) format of enzyme immunoassay and the confirmatory immunoblot are 95 percent and 100 percent, respectively.[17] Serologic tests are also useful in the diagnosis of ectopic fascioliasis.

During chronic infection, routine stool examination with use of a formalin–ethyl acetate concentration should reveal ova of *Fasciola* in established infections. As discussed previously, *Fasciola* eggs are indistinguishable from those of *Fasciolopsis buski*. False-positive stool examinations may occur if the patient recently ingested infected livers containing eggs. To avoid false-positive results in this situation, keep the patient on a liver-free diet several days before the stool specimen is collected. Chronic fascioliasis may be detected during radiographic studies of the biliary tract or gallbladder. Adult worms may be seen on ultrasonography or appear as curvilinear lucent areas in the contrast medium at cholangiography. Endoscopic retrograde cholangiopancreatography may directly visualize the adult worms, which are leaf shaped and bile stained. Eggs also may be identified in bile.

TREATMENT AND PROGNOSIS

Unlike other trematode infections, fascioliasis is relatively resistant to praziquantel. The drug of choice is triclabendazole at a dose of 10 mg/kg with a meal once or twice. The formulation manufactured for human use as Egaten is currently not available in the United States. Triclabendazole (Fasinex) has been used for many years by veterinarians for treatment of livestock in endemic areas. Anecdotally, it has been used safely in humans. However, resistance is emerging in isolates from domestic animals. Triclabendazole has been used successfully in a variety of open clinical trials in adults and children for both acute and chronic fascioliasis.[10,21] It is effective against both migrating worms and established infections. Treatment with bithionol also is effective. Bithionol no longer is manufactured, but a small supply is available in the United States for investigational use only from the Centers for Disease Control and Prevention (CDC). Bithionol usually is administered in a dose of 30 mg/kg given either daily for 5 days or on alternate days for a total of five doses. More intense courses of 30 to 50 mg/kg of bithionol on alternate days for 10 to 15 doses have been recommended as well. After successful treatment, the eosinophilia resolves slowly and immunologic test results become negative. Nitazoxanide was effective in two trials in chronic fascioliasis.[14,35]

In one study, children with severe acute infections were treated with 5 to 10 mg of prednisone before receiving specific fasciolicidal drugs.[13]

Heavy infections in children may be fatal during the acute stage of the disease. However, most heavy infections become chronic or, possibly, asymptomatic. The variable reaction of the human host and the number of parasites determine the outcome. In heavy infections, hepatic damage may be significant, with fibrotic scarring or abscess formation. Chronic or recurrent biliary tract problems are common.

PREVENTION

Watercress grown for human consumption should be protected from human and animal fecal contamination. Animal fascioliasis can be targeted for chemotherapeutic control, and control of the snail intermediate hosts with molluscicides can be attempted. Effort should be made to educate the population at risk about the danger of eating raw watercress and other metacercariae-carrying aquatic plants harvested from unprotected waters and the hazard of drinking untreated or filtered surface water.

CLONORCHIASIS AND OPISTHORCHIASIS

Three similar trematodes of the genus *Opisthorchis* infect the bile ducts of humans. Although the name *Opisthorchis sinensis* is proper parasitologically, this organism more commonly is called *Clonorchis sinensis*, and the name of the infection, clonorchiasis, is well entrenched in the clinical literature. This organism also is called the Chinese or Oriental liver fluke. *Opisthorchis viverrini* and *Opisthorchis felineus* have similar life cycles and produce similar lesions and illnesses in humans.

THE ORGANISMS

The adult flukes measure 4 to 25 mm in length by 2 to 5 mm in breadth and have an anterior oral sucker. The life cycle involves

mammals (primarily humans, dogs, and cats) as definitive hosts, snails, and fresh-water fish or shrimp. In the definitive hosts, they are found mainly in the intrahepatic biliary ducts and occasionally in the extrahepatic and pancreatic ducts. The small operculate eggs, similar to those of the heterophyid flukes, appear in bile and are excreted in feces. The snail intermediate host ingests the embryonated egg, and free-swimming cercariae emerge from the snail approximately 6 to 8 weeks later. The cercariae encyst under the scales or in the musculature of a variety of fresh-water fish. When the raw, inadequately cooked or pickled fish is eaten, the larvae excyst and migrate to the intrahepatic bile ducts, usually through the ampulla of Vater and the common duct. Juvenile flukes attach themselves to the bile duct epithelium with their suckers and travel along the biliary tree against bile flow. Adult worms begin producing eggs approximately 4 weeks after ingestion of metacercariae. The worms probably survive for as long as 30 years.

TRANSMISSION AND EPIDEMIOLOGY

Infection is initiated by the ingestion of raw, inadequately cooked, cured, or pickled fresh-water fish that have encysted larvae in their tissues. *C. sinensis* is endemic in China, Japan, Korea, Taiwan, and Vietnam. The high prevalence in Hong Kong is attributed to the importation of fish from mainland China. Natural reservoir hosts are cats, dogs, pigs, and rats. *O. viverrini* is localized to the northern areas of Thailand, Laos, and Cambodia. In northern Thailand, where a dish prepared from chopped raw fish, called *koi pla*, is popular, researchers have estimated that more than 7 million residents are infected. Cats, civet cats, dogs, and other fish-eating mammals serve as reservoirs. In China and other Asian countries, edible fish often are raised in ponds that are fertilized with human feces, thus providing perfect conditions for the entire life cycle of the parasite.

O. felineus is endemic in central Siberia and in eastern and southeastern Europe. Cats, dogs, and foxes serve as major reservoirs. Human infection is limited to groups that habitually consume raw, dried, or freshly salted fish or fish lightly pickled in garlic juice. Sporadic infections with *O. felineus* have been reported from several Asian countries.

The distribution of infection by all species in human infections depends on the eating habits of the population. In most areas, patterns of infection are similar. Typically, the lowest prevalence and intensity of infection is found in the youngest age groups; intensity of egg excretion often increases with age and reaches a plateau by the late teens. Prevalence is usually highest in older persons.[41]

PATHOLOGY AND PATHOGENESIS

The epithelium of infected bile ducts reacts with desquamation, adenomatous hyperplasia, and metaplasia of goblet cells, accompanied by an increase in mucus production. The pathogenesis of the hepatobiliary damage may be due to mechanical irritation from the fluke suckers or metabolites from the worms. Other proposed mechanisms include immunopathologic processes, especially those involving host immune responses.[16] Ductal dilatation and bile stasis probably increase susceptibility to bacterial cholangitis. Inflammation of the bile duct wall usually indicates secondary infection. Numerous factors determine the severity of these changes and include the duration and intensity of infection, host susceptibility, and number of reinfections. Chronic infection may lead to extensive periportal and periductal fibrosis.[38] The presence of the parasites in addition to other factors appears to render the host susceptible to cholangiocarcinoma. Experiments in hamsters have shown that repeated infection with *O. viverrini* induces overproduction of nitric oxide, which may play a significant role in the development of cholangiocarcinoma through oxidative and nitrosative DNA damage to the bile ducts.[32] An extensive analysis of the available data concerning cancer and liver flukes has concluded that infection with *O. viverrini* is carcinogenic to humans and that infection with *C. sinensis* probably is carcinogenic.[39] Data were not sufficient to determine the status of *O. felineus* infections. *O. viverrini* infections frequently involve the gallbladder and may lead to complications such as gallbladder sludge, cholecystitis, and formation of gallstones.[28] The parasites often are found in the pancreatic ducts, where reactions of the epithelium are similar to those in the bile duct. Pancreatitis occurs infrequently in these liver fluke infections and is usually mild.

CLINICAL MANIFESTATIONS

The occurrence of symptoms probably correlates with the intensity of infection but is variable. In endemic areas, infections may begin early in life and often are asymptomatic. Patients with heavy infections may complain of a dull pain or discomfort in the right upper quadrant, weakness, or malaise, and they may have significant hepatic enlargement. An uncontrolled study of patients with *O. viverrini* infections in Thailand showed general improvement in well-being after treatment.[33] Symptoms of abdominal distress and epigastric pain declined significantly. A community study showed significant improvement in the infected population after treatment based on symptoms, laboratory test results, and ultrasound abnormalities.[34]

Acute symptoms starting 2 to 3 weeks after exposure have been reported with *C. sinensis* and *O. felineus* infections and include fever, malaise, anorexia, diarrhea, tender hepatomegaly, and eosinophilia. The eosinophilia of acute infection gradually decreases and in chronic infection disappears.

Complications are more likely to occur in heavy infections. Relapsing cholangitis, cholecystitis, bilirubin gallstones, pancreatitis, and cholangiocarcinoma all have been associated with infection. Clonorchiasis often is cited as a cause of pancreatitis in individuals from endemic areas.[23,36] Cholangiocarcinoma, which may result from chronic or repeated infections, accounts for only approximately 7 to 8 percent of liver cancer in the United States but is presumed to be responsible for more than 60 percent of liver tumors in northeastern Thailand.[39]

DIAGNOSIS

Symptoms of acute infection may develop 3 to 4 weeks before eggs appear in the stool. The diagnosis may be suggested by the epidemiologic information. Serologic tests are sometimes used to establish the diagnosis in some endemic areas[1,18,40] but are not always readily available or practical to perform. Ultrasonography has been shown to be a useful diagnostic tool. Sonographic findings consist of the pathologic changes of the bile duct or gallbladder that result from infection with *Clonorchis* or *Opisthorchis* species and include intrahepatic bile duct dilatation, increased periductal echogenicity, and gallbladder sludge.[8] In chronic infections, eggs should be evident in routine fecal examinations. Filtration of fluid obtained at duodenal intubation is claimed to be diagnostically more sensitive than is examination of two fecal specimens. A monoclonal antibody–based ELISA has been developed for the demonstration of *O. viverrini* antigen in fecal specimens.[19] This test appears to be specific and highly sensitive.

Cholangiography often shows multiple cystic dilatations of the ducts, elliptic or filamentous filling defects within the peripheral intrahepatic ducts, and intrahepatic duct haziness.[7] A combination of large cystic dilatations and small cystic ectasias or

mulberry-like dilatations is considered diagnostic. The flukes may be evident as linear radiolucencies on cholangiography. The adult worms or eggs also may be visible on endoscopic retrograde cholangiopancreatography.

The eggs of *O. viverrini* and *C. sinensis* are virtually identical. *O. felineus* is reported to have a narrower egg, as determined by the ratio of length to width. Differentiation between the eggs of these species of liver flukes and the eggs of small heterophyid flukes is difficult. Fortunately, treatment with praziquantel is identical for all these parasites.

TREATMENT AND PROGNOSIS

These liver fluke infections respond well to treatment with praziquantel, 75 mg/kg divided into three doses given in a single day. Side effects of headache and dizziness are common occurrences. Although untreated light and moderate infections appear asymptomatic and may have little if any clinical significance, the availability of a safe, easily administered drug renders treatment an appropriate approach, especially for those who have left an endemic area. Treatment also may decrease the risk for development of cholangiocarcinoma in those infected. Albendazole also has been found to be effective in treating clonorchiasis. A dose of 10 mg/kg is given daily for 7 days. Effective treatment has reversed the biliary tract abnormalities in *O. viverrini* infections and would be expected to have a similar salutary effect in clonorchiasis and *O. felineus* infections.

The prognosis of heavy infections depends on the complications. Superimposed bacterial infections are the most common cause of morbidity and mortality.

PREVENTION

Education of the population at risk concerning the consumption of raw fish in its various forms (dried, pickled, salted, or smoked) is about the only hope for reducing prevalence in humans. A large reservoir exists in domestic and wild animals; therefore, attempts to eliminate infection in humans by mass treatment are unlikely to succeed. Prohibiting the fertilization of fishponds with raw human sewage surely would reduce the incidence of transmission. In Thailand, control programs for opisthorchiasis have included examinations of stools with treatment of positive cases, health education to discourage the consumption of raw fish, and promotion of hygienic defecation.[20]

METORCHIS INFECTION

Metorchis conjunctus, the North American liver fluke, is a member of the Opisthorchiidae family and has a life cycle similar to that of the other opisthorchids described earlier. A wide variety of fish-eating mammals may serve as definitive hosts. This infection is a significant cause of morbidity and mortality in sled dogs in Canada. It is an occasional incidental finding on fecal examination in native communities in northern Canada. An outbreak of 19 cases of *Metorchis* infection was related to fish prepared raw as sashimi.[26] The symptoms began 1 to 15 days after the infected fish were ingested. The severity and duration of the symptoms correlated with the amount of fish eaten. Symptoms were fatigue, upper abdominal tenderness, fever, epigastric abdominal pain, headache, weight loss, anorexia, nausea, diarrhea, vomiting, muscle pain, backache, cough, and rash (in descending order of frequency). The degree of eosinophilia and elevation in liver enzyme levels were proportional to the amount of fish ingested. Eggs were noted in stool 10 days after infection developed. All symptoms resolved after treatment with the standard course of praziquantel. Serologic testing indicates that a similar liver fluke, *Metorchis bilis*, is a frequent parasite of residents of the Novosibirsk areas of Russia.

LUNG FLUKE

PARAGONIMIASIS

Many species of *Paragonimus* have been identified, at least 10 of which have been recovered from humans and in some instances have been found in distinct endemic foci. Of these, *Paragonimus westermani* is the species of lung fluke that causes most human infections.[4]

THE ORGANISM

The adult forms of *Paragonimus* measure about 15 mm long by about 6 mm wide. They are nearly as thick as they are wide. The worms typically are located in the lungs. Eggs measuring 80 to 118 μm by 48 to 60 μm are discharged into the bronchi and are either expectorated or swallowed and excreted in feces. The larva hatches from the egg after at least 2 weeks of development in water. The free-swimming larva penetrates the snail intermediate host and undergoes development and multiplication for several weeks. Cercariae emerge and encyst in the tissues of fresh-water crabs and crayfish. When humans or reservoir hosts ingest the flesh of these second intermediate hosts, the larvae penetrate the wall of the intestines and migrate through or around the diaphragm to reach the lungs. In some instances, the worms may lodge in ectopic sites within the abdomen, in subcutaneous tissue, or in the central nervous system. The worms usually are found singly or in pairs within a capsule or cyst of reactive host tissue. Approximately 2 to 3 months are required from the time of ingestion until the worms are fully mature. In most infections, the worms die within 10 years; however, production of eggs for 20 years after the individual has left the endemic area has been reported.

TRANSMISSION AND EPIDEMIOLOGY

The infection is acquired by eating fresh-water crabs, crayfish, or shrimp that are raw, inadequately cooked, salted, pickled, or soaked in wine. Cooked foods may be contaminated with viable larvae from the hands, utensils, or cutting boards used in the preparation of crabs or crayfish.

Paragonimiasis is a zoonotic disease that is estimated to affect 20 million people worldwide.[27] Significant reservoir hosts for *P. westermani* include cats, civet cats, wild felids, foxes, wolves, dogs, pigs, and mongooses; main endemic foci are in China, Taiwan, Korea, Japan, eastern India, Sri Lanka, Southeast Asia, Indonesia, and some areas of the former Soviet Union. Instances of paragonimiasis being acquired in North America are extremely rare.

More than nine different species of *Paragonimus* infect humans. In many areas, the distribution of these species often overlaps that of *P. westermani*. Endemic areas with other species can be found in Central Africa (Cameroon and Nigeria), East Asia (China, Japan), and the Pacific coast of Latin America (Mexico, Peru, Ecuador, and Central America). The potential exists for transmission of paragonimiasis in the United States.[9]

PATHOLOGY AND PATHOGENESIS

After penetration of the pleura occurs, the worms reside near larger bronchioles or bronchi, where an exudate of neutrophils

and eosinophils forms around them. In time, this inflammatory response around the parasite organizes into a fibrotic wall that may measure up to several millimeters thick. The cysts usually are 1 to 2 cm in diameter and often are filled with a brownish material that likely contains hematin. The cyst may communicate with a bronchiole or bronchus, which provides a route for discharge of the eggs into sputum. Complications of paragonimiasis include bronchiectasis, fibrosis, interstitial pneumonia, and secondary bacterial infections.

The central nervous system is a common location for extrapulmonary involvement. All areas of the brain and meninges are susceptible to invasion. The adult worms and the eggs cause areas of central necrosis and granuloma formation with dense collagenous walls surrounded by lymphocytes, plasma cells, eosinophils, and Charcot-Leyden crystals. The lesions vary in size and may be several centimeters in diameter and may appear cystic. Eventually, the wall may calcify. Spinal cord lesions are similar. Other sites at which worms may cause cysts or abscesses are the intestinal wall, mesentery, peritoneal cavity, liver, diaphragm, myocardium, and subcutaneous tissue.

CLINICAL MANIFESTATIONS

Migration of the worms from the intestinal tract to the lungs usually causes no symptoms, but diarrhea, abdominal pain, and urticaria may occur in the first 3 weeks after exposure. These symptoms may be followed by fever, chest pain, dyspnea, cough, malaise, and night sweats.

The pulmonary clinical manifestations are mainly a chronic cough that is productive of mucus, and rust-colored or blood-streaked sputum is present. Hemoptysis usually is intermittent and occasionally may be severe. Eosinophilia is a common finding in the early stages of infection but may return to normal during a period of months or years. Heavy infections may be associated with complications such as pneumothorax, pleural effusion, empyema, and pneumonia. The presence of hemoptysis and cavitary lung lesions can be confused with tuberculosis, but tuberculosis typically has more systemic symptoms (e.g., fevers, night sweats, and weight loss).

Cerebral paragonimiasis occurs most commonly in endemic areas of Asia and may result in serious morbidity and often death.[24] Cerebral involvement is more common in children, with more than half the infections occurring before the child reaches 10 years of age. This form of paragonimiasis may present initially as a mass lesion, a seizure disorder, meningitis, or a cerebrovascular accident. Seizures often begin as the focal motor type but may generalize. Visual disturbances, headache, and elevated cerebrospinal fluid pressure are common events. Pleocytosis with eosinophilia in the cerebrospinal fluid may be noted. The variety of neurologic manifestations depends on the number, location, and size of the lesions. Spinal cord lesions often are extradural and mimic mass lesions caused by tumors or infection.

Cutaneous paragonimiasis is identified by the appearance of subcutaneous nodules, which may be fixed or migratory. In China, species of *Paragonimus* found in the northern region often cause subcutaneous, migratory lesions associated with fever and eosinophilia. Worms recovered from these lesions are immature.

DIAGNOSIS

Normal results on chest radiographs are found in 10 to 20 percent of patients. Radiographic abnormalities may develop as the worms enter the lungs. Initially, the chest film shows poorly defined basilar pneumonic infiltrates. These areas may evolve into cysts or nodules within a few weeks. Other radiographic findings include cavitations, fibrosis, and pleural thickening, which occasionally can be associated with a pleural effusion. Although the nodules and cysts of the chronic stage of infection may develop in any area of the lung, including the apices, they tend to localize in the periphery of the middle and lower lung fields. A common radiographic diagnostic feature is a "ring shadow." This finding represents the circular or oval thin-walled cyst with a crescent-shaped opacity along one side.

Cerebral paragonimiasis may be seen as an avascular mass on computed tomography. In long-standing cerebral infections, the cystlike structures may calcify and be seen as a cluster of "soap bubbles." The individual oval or spherical bubbles may measure 2 to 40 mm in diameter, and a cluster of these structures may extend 10 cm. Magnetic resonance imaging is not as effective in demonstrating calcification, but it is a useful supplement in defining the lesions of cerebral infection. Magnetic resonance imaging of infected children can show hemorrhage and irregular, conglomerated lesions.[42]

Pulmonary paragonimiasis is diagnosed definitively by finding the characteristic eggs in sputum or stool from a patient with symptoms suggesting the infection. Eggs are not present until 2 to 3 months after infection develops. Concentration techniques may help identify eggs in patients with light infections. Several immunodiagnostic tests, complement fixation, ELISA, DNA probes, and immunoblotting have been developed, which may assist with confirming the presence of infections and with monitoring responses to treatment. Immunodiagnosis is especially useful in infections in which eggs are not demonstrated easily, such as in cerebral paragonimiasis. The immunoblot assay performed with a crude antigen extract of *P. westermani* has a sensitivity of 96 percent and specificity of 99 percent and is the serodiagnostic test of choice.[37] The complement-fixation test and enzyme immunoassay tests also have been used. Antibody levels detected by enzyme immunoassay and immunoblot decline slowly after successful treatment, so antigen-detection systems may be a more useful approach to monitor treatment efficacy.[43] Intradermal testing cannot distinguish between past and current infections, but it has been useful in performing epidemiologic studies.

TREATMENT AND PROGNOSIS

Praziquantel, 75 mg/kg divided into three doses, is given daily for 2 days. Bithionol is no longer manufactured, but a small supply is available in the United States through the CDC in Atlanta. Bithionol is given in single doses of 30 to 50 mg/kg on alternate days for a total of 10 to 15 doses. Side effects occur much more commonly with bithionol than with praziquantel. Data from case reports and clinical trials have revealed the potential usefulness of triclabendazole as an alternative treatment for humans infected with *Paragonimus* species.[21] One study demonstrated 84 to 90 percent efficacy with single-day regimens of triclabendazole for the treatment of pulmonary paragonimiasis, indicating possible value for use of this regimen in community-based treatment programs.[5]

The prognosis is good in most pulmonary infections, even if they go untreated, although symptoms may persist for many years. Treatment effectively resolves the pulmonary lesions and symptoms. The prognosis for central nervous system involvement depends on the location and extent of the lesions but is usually grave.

PREVENTION

The key in prevention is education of the population in endemic areas concerning the source of infection. Crabs and crayfish,

prepared in a manner that transmits paragonimiasis, are delicacies in many parts of the world. Changing attitudes about food habits is not an easy task, and the likelihood of eliminating the occurrence of human infections by mass treatment and improved sanitation is doubtful because of animal reservoirs.

CHAPTER 240

SCHISTOSOMIASIS

Philip R. Fischer ❂ Andrea P. Summer ❂ A. Clinton White, Jr.

Approximately 200,000,000 individuals are infected with parasites of the genus *Schistosoma*.[28,66,113,148] Many are unaware of their infection, although approximately 20 million people have severe disease with potentially fatal portal hypertension, urinary tract involvement, renal failure, and bladder cancer. Initial infection usually occurs during childhood. The prevalence typically peaks in the teen years, and although most of the morbidity occurs in adults, symptomatic disease develops in millions of children.

There is historical evidence of schistosomiasis occurring as early as the second millennium B.C.E.[130,132] For example, *Schistosoma* eggs have been found in mummies from the 20th Dynasty in ancient Egypt and in ancient China. In 1851, Theodor

Bilharz identified the parasitic etiology of endemic hematuria. At the same time, the association between *Schistosoma* and Katayama fever was recognized in Japan. The complete life cycle was identified during the first decades of the 20th century. Before the development of effective curative medication in the 1970s, schistosomiasis was considered to be the "most dreadful of the remaining plagues of Egypt."[66,67] Efforts to control the disease continue, and eradication measures are still in the early stages of being implemented.

EPIDEMIOLOGY

Schistosomiasis is caused by helminth parasites of the class Trematoda, which includes the flukes. Schistosomes differ from other human flukes in that they live within the vascular system and have separate male and female sexes. Humans are the definitive host for five species within the *Schistosoma* genus.[130,132] *Schistosoma haematobium* is the cause of urinary schistosomiasis. *Schistosoma japonicum* and *Schistosoma mansoni* are common causes of disease resulting from infection of the intestinal vasculature. *Schistosoma mekongi* and *Schistosoma intercalatum* also cause infection along the intestinal tract but are restricted geographically. Other mammalian *Schistosoma* spp. occasionally infect humans.

Each species of *Schistosoma* uses fresh-water snails as obligate intermediate hosts,[130,132] and the geographic distribution of *Schistosoma* is limited by the habitat of these snails (Fig. 240–1). Updated World Health Organization figures on the prevalence and distribution of schistosomiasis are available at *http://www.who.int/wormcontrol/en/*. *Oncomelania* snails transmitting *S. japonicum* live in the moist soil along slow-flowing streams and irrigation canals, limited primarily to parts of China, the Philippines, and Indonesia. The *Bulinus* snails associated with *S. haematobium* and the *Biomphalaria* snails associated with *S. mansoni* live in shaded, slow-flowing, shallow water. *S. haematobium* is seen primarily in tropical Africa, along the Nile River, and in the Middle East. *S. mansoni* is found across tropical Africa, along the Atlantic coast of South America, and on some Caribbean islands. *Tricula*, the snail host for *S. mekongi*, is limited to the Mekong River in Laos and Cambodia. *S. intercalatum* and its snail host *Bulinus* are found only in Cameroon and the Democratic Republic of Congo. In the United States, schistosomiasis occasionally is diagnosed in immigrants and travelers from endemic regions.

Most human infections occur when children come into contact with fresh-water streams, rivers, or lakes inhabited by infected snails (Fig. 240–2).[132] Thus, for most of the world, transmission of disease occurs during routine activities such as obtaining water for household use, bathing, fishing, and irrigating fields. Humans are infected by the fork-tailed schistosomal cercariae. Cercariae penetrate the skin with the aid of secretory serine proteases.[88,118] During penetration, the parasites lose their tails and modify their tegument to form the schistosomula stage. Schistosomulae enter the bloodstream and then migrate to the lungs. They move from the pulmonary arterial to the venous circulation without exiting the vessels. The parasites then travel through the systemic circulation until they reach splanchnic vessels and gain access to the portal system.

During the course of a few weeks, the schistosomulae develop into mature male and female adults that mate continuously.[131,132] Adult worms are 1 to 3 cm in length and usually live for 3 to 7 years. *S. haematobium* localizes to the venules of the urinary bladder, *S. japonicum* goes to the superior mesenteric vessels, and *S. mansoni* goes to the inferior mesenteric vessels. The gravid females migrate upstream to lay eggs near the bladder or intestines. Each adult female can produce hundreds (in the case of African species) to thousands (for Asian species) of eggs per day.[57] Most of the eggs become embedded in the walls of the peripheral vessel, where they were laid. However, some of them flow with the blood and can stimulate reactions and cause disease at other sites. A localized granulomatous response allows the eggs to pass through the wall of the bladder (for *S. haematobium*) or the intestine (for other species) to be released in urine or stool. Released eggs mature in a week's time and then hatch to release miracidia. The miracidia penetrate the snail to continue their life cycle and eventually develop into hundreds of cercariae.

Infection is seen in children as young as 6 months; exposure to cercariae often is greatest in boys between the ages of 5 and 10 years.[66,71,130] In some lakeside African villages, however, nearly half the children are infected during the first 3 years of life.[101] The peak intensity of infection, as measured by excretion of eggs, occurs in children as young as 8 to 12 years in heavily infected areas and takes place during the teenage years in more lightly infected areas. The intensity and the incidence of excretion of eggs decline after the adolescent years, and hormonal changes during puberty are associated with increased resistance to infection.[76]

PATHOGENESIS AND IMMUNITY

Within hours of penetration of the skin, local erythema and inflammation may result from the activity of parasite proteases.[87,117,136] In individuals previously sensitized, a delayed immune reaction may cause papular or vesicular lesions.[74,130] Infiltration of the epidermis and dermis with a mixture of mononuclear cells and eosinophils causes papules. This reaction (termed *swimmer's itch*) is more pronounced for avian schistosomes, which are unable to penetrate into the human circulation and die in situ. During the initial migration of schistosomes through the lungs, patients may develop fever, pneumonitis, pulmonary infiltrates, and eosinophilia. However, these reactions resolve spontaneously.

Acute schistosomiasis typically begins 4 to 8 weeks after exposure, at the time that the female parasites begin to produce eggs.[39] This condition is recognized more commonly with *S. japonicum* than with *S. mansoni* and rarely is described with *S. haematobium*.[74,130] Patients characteristically have marked eosinophilia along with IgE and IgG antibodies to the parasites, consistent with an active T_H2 response.[74,130] However, studies suggest that proinflammatory cytokines play an important role.[36,97] The antibodies react with egg antigens, which cross-react with antigens from the cercaria or schistosomula stages.[8,62,63] During early production of eggs, the quantity of antigen exceeds that of antibody, and soluble immune complexes are formed. Immune activation and immune complex deposition lead to the clinical manifestations, including fever, myalgia, urticarial rash, and bloody diarrhea. Pulmonary nodules and infiltrates may be noted during acute infection.[30,119] In addition, acute infection can be complicated by ectopic egg production. Patients with acute *S. mansoni* or *S. haematobium* infection occasionally can have neurologic involvement.[23,45,108] Interestingly, acute disease occurs rarely in endemic populations, perhaps because of modulation of the immune response from exposure to parasite antigens in utero.

CHRONIC SCHISTOSOMIASIS

Despite the fact that the adult worms live within the bloodstream, they cause little host response. The parasite surface incorporates blood group glycoproteins and major histocompatibility antigens and down-regulates expression of its own surface proteins, which may help the adults evade immune system attack.[55,106,123]

Chronic infection is characterized by localized granulomata surrounding the parasite eggs.[74,113,130] Excretory products of the eggs (termed *soluble egg antigens*) are the major antigens. The egg antigens are cytotoxic to host cells, such that infection of

mice lacking T cells results in increased localized necrosis surrounding the eggs; the granulomata help protect the host from the ravages of the eggs. The granulomata also facilitate transit of the eggs into stool and urine as illustrated by the fact that immunodeficient hosts tend to have lower rates of shedding of eggs despite having high concentrations of eggs in tissues.[38,70,99]

The granulomata also contribute to the pathologic process. They are composed of a mixture of eosinophils, lymphocytes, macrophages, and granulocytes.[16] Late-stage granulomata also contain fibroblasts, collagen, and giant cells. Initially, antigen-presenting cells stimulate $CD4^+$ T cells to produce interleukin (IL)-2, tumor necrosis factor–α (TNF-α), and interferon-γ.[98] Early expression of TNF-α plays a key role in the initial formation of granulomata.[4] A subsequent shift occurs toward production of T_H2 cytokines (e.g., IL-4, IL-5, IL-10, and IL-13) along with antibody.[107] This event is accompanied by eosinophil recruitment. IL-4 and IL-13 also play a primary role in the development of hepatic granulomata, and IL-13 expression is linked closely to the development of fibrosis in murine models.[26,27] Subsequent immunomodulation, largely mediated by IL-10 and transforming growth factor–β (TGF-β), results in downsizing of the granuloma and suppression of the inflammation.[7,42,47,64,90,97,122,145] When granulomata are limited to the intestines, the cytokine response is dominated by anti-inflammatory cytokines (e.g., IL-10 and TGF-β), and patients have few symptoms.[32] By contrast, patients with granulomata in the liver are more likely to be symptomatic. They express more inflammatory cytokines, including IL-13 and TNF-α. TGF-β also is associated with fibrosis in primate models,[42] whereas T_H1 cytokines (e.g., interferon-γ and IL-12) suppress fibrosis.[17,149,154]

IL-13 in particular stimulates the formation of fibrosis in the portal tracts.[26] Portal fibrosis, in turn, leads to the development of portal hypertension (i.e., hepatosplenomegaly, ascites, and esophageal varices).[74] Death from hepatic schistosomiasis typically results from gastrointestinal bleeding. Overt bleeding is an uncommon occurrence in children, but it can occur in adolescents and young adults. In patients with isolated schistosomiasis, hepatocellular function is surprisingly normal.[16] Patients are thought to tolerate even gastrointestinal bleeding better than cirrhotic patients do. By contrast, progressive hepatocellular damage and rapid progression to liver failure develop in patients co-infected with hepatitis viruses, particularly hepatitis C.[5,29,69] The immunomodulation that develops in response to schistosomiasis is thought to suppress immune control of the hepatitis virus. Whether schistosomiasis-associated immune changes alter susceptibility to or expression of human immunodeficiency virus is unknown.[142]

Interestingly, patients with schistosomiasis are less susceptible to allergies.[141] Evidence indicates that asthmatics with schistosomiasis produce lower levels of IL-5 and greater levels of IL-10 than do asthmatics without schistosomiasis, and it is this suppression of T_H2 responses that might modulate the expression of asthma and atopic disease in patients with schistosomiasis.[6] Alternatively, it is possible that a common genetic predisposition alters the risk of subsequent development of both atopic disease and schistosomiasis.[10] Similarly, parasite-induced changes in the T_H1/T_H2 balance are hypothesized to explain how young children with underlying schistosomiasis are less likely to develop malaria.[89]

Several means exist by which schistosomiasis might be related to anemia, and the exact pathologic mechanisms are not fully understood.[49] At least sometimes, however, the anemia is due to inflammation rather than to iron deficiency.[79] Generalized undernutrition is associated with schistosomiasis; proinflammatory

cytokines (IL-1β) and generalized inflammation (as manifested by elevated levels of C-reactive protein) are contributing factors.[34] Even without acute inflammation, schistosomal infection and periportal fibrosis are associated with reduced vitamin A status and high oxidative stress (increased serum hydroperoxides).[14]

Approximately 40,000,000 women of child-bearing age are infected with schistosomes. Although mechanisms are not clear, some evidence indicates that schistosomiasis during pregnancy is associated with decreased birth weight and a higher risk of preterm delivery.[50]

URINARY SCHISTOSOMIASIS

Genital and urinary schistosomiasis also is the result of granuloma formation. Severity of disease correlates with increased production of TNF-α and decreased production of IL-10.[75] Direct inflammatory responses to eggs along the ureters or from obstruction to ureteral drainage caused by space-occupying granulomata in the bladder wall block ureteral emptying.[72,124] Abnormal ureteral flow, dilatation, and hydronephrosis develop.[124] In some communities where *S. haematobium* is common, ureteral deformities demonstrable on intravenous pyelography are noted in half of affected children, and hydronephrosis develops in more than 10 percent.[73] Eventually, scarring and calcifications form and may be associated with chronic hydronephrosis, even with resolved or light chronic infection.[75,124] The hydronephrosis and urinary stasis predispose patients to chronic bacteriuria and urinary tract infections.

In *S. mansoni* infection, immune complexes may mediate glomerulonephritis, as evidenced by the finding of schistosome-derived immune complex deposits in glomeruli.[11,125] Nephrotic syndrome has been reported in association with chronic schistosomiasis.[91,92] Amyloid deposits have been found in the kidneys of children with chronic schistosomiasis, and this condition probably is caused by immune responses that are altered by the chronic parasitic infection.[12,143]

Squamous cell carcinoma of the bladder is a common occurrence in areas of heavy infection with *S. haematobium*, but otherwise, it is a rare form of bladder cancer.[75,124,130] The prolonged irritation of bladder epithelium by schistosome eggs and the resulting immune response are thought to trigger hyperplasia and subsequent malignant disease.[80] This condition could be aggravated by urinary stasis in the bladder with secondary increases in pH that favor malignant transformation of epithelial cells. Carcinogenic tryptophan metabolites also have been postulated to link the nutritional activities of parasites near the bladder with subsequent carcinogenesis.

CLINICAL MANIFESTATIONS

The main clinical manifestations of schistosomiasis vary with the stage of the parasite's life cycle and also differ among species. Many patients remain asymptomatic. Patients with asymptomatic schistosomiasis may be identified during community screening programs in an endemic area, through immigrant or returned traveler evaluations in a nonendemic area, or when diagnostic tests such as urine or stool microscopy are performed to evaluate other, seemingly unrelated symptoms. The minority of children with heavy infections are most likely to develop early symptoms and also are at greatest risk for subsequent major health complications.

CERCARIAL PENETRATION

Within a few minutes of coming into contact with cercariae, some children develop pruritus. This response to initial contact with the parasite occurs more commonly in nonimmune visitors to endemic areas than it does in indigenous residents of endemic areas, but it seems to be more pronounced after repeated exposure to cercariae than on the first exposure. It may occur after contact with any of the human *Schistosoma* spp. but more commonly results after contact with the cercariae of avian schistosomes. An erythematous and, sometimes, papular rash may develop.[74,130] The rash usually subsides during a period of 2 to 10 days without scarring, regardless of whether specific treatment is given.

ACUTE SCHISTOSOMIASIS (KATAYAMA FEVER)

Acute schistosomiasis, referred to as Katayama fever, typically begins 4 to 8 weeks after exposure, when the adult worms begin to produce eggs.[6,39,65] Clinical manifestations of acute schistosomiasis usually include high fever, chills, myalgia, headache, and a general ill appearance.[36,39] An urticarial rash, which may include giant urticaria, and diffuse lymphadenopathy may be seen.[112,156] Cough, rales, and pulmonary infiltrates may be noted, even in the absence of fever.[30,119] Gastrointestinal symptoms of anorexia, abdominal pain, and loose stools sometimes are observed. Bloody diarrhea may be seen acutely with heavy infections by *S. japonicum* and *S. mansoni*. Tender hepatomegaly and mild splenic enlargement develop in approximately 30 percent of children with Katayama fever. Some reports suggest that myelopathies are a common accompaniment of acute schistosomiasis.[45,108] Genital symptoms (primarily hematospermia) also are frequent initial symptoms.[31,110] Marked eosinophilia often is seen with acute schistosomiasis.

URINARY SCHISTOSOMIASIS

Hematuria is the classic finding of *S. haematobium* infection.[20,37,72,130,147] In some highly endemic areas, for boys nearing puberty not to display this evidence of "male menstruation" is considered abnormal. Typically, hematuria results from the release of blood from irritated, inflamed areas around granulomata in the bladder wall as the bladder contracts during micturition.[124] Thus, the blood is most obvious at the end of the urine stream ("terminal hematuria"). The hematuria usually is not associated with pain or discomfort, but dysuria can be present.[1,20] With chronic infection in children who either were not treated initially or were re-infected, obstructive uropathy can develop. In community surveys in endemic areas, as many as 40 percent of children were found to have significant renal or ureteral abnormalities (or both).[1,61,144] Hematuria and dysuria occur more commonly in children than in adults, presumably because they have heavier parasite loads. However, hydronephrosis, which develops more slowly, is seen more often in adults.[72,73,96,124]

Bacterial urinary tract infection may coexist with urinary schistosomiasis, probably secondary to obstruction of urinary outflow.[124] Chronic infection can lead to renal failure. Obstructive uropathy, with or without incident or recurrent urinary tract infections, can lead to loss of renal function. Children with schistosomal infection also can have glomerulonephritis and nephrotic syndrome. Bladder cancer, when it occurs, typically develops in the setting of untreated, heavy chronic urinary schistosomiasis.

GENITAL SCHISTOSOMIASIS

Studies have emphasized the genital tract as an important site of schistosomiasis in both men and women.[22,81,108,109] In women, egg granulomata may be found in the cervix, uterus, or fallopian

tubes.[43,81,82,109] Cervical irritation and ulceration, vaginal bleeding, or ectopic pregnancy may develop. Genital schistosomiasis can be confused with cancer.[134] Adolescent boys may have involvement of the prostate and seminal vesicles.[81,110] Eggs were noted in semen from 43 percent of men in an area endemic for *S. haematobium*.[81] The main clinical finding is hematospermia,[81,94] which may occur with acute infection or during chronic disease. In Africa in particular, genital schistosomiasis may be a cofactor in transmission of human immunodeficiency virus infection.

INTESTINAL DISEASE

Most children with intestinal schistosomiasis do not have intestinal symptoms.[128,130] Thus, even finding eggs in stool does not mean that symptoms are related to the schistosomiasis.[59] Nonetheless, both the small and large intestines may be involved with schistosomal disease. Irritation of the bowel wall from inflammatory reactions induced by eggs may lead to diarrhea that sometimes contains blood or mucus.[24,25,128-130] Crampy abdominal pain and generalized malaise may occur. Endoscopy can reveal granular inflammation with hyperemic areas, ulceration, and hemorrhage. Polyps, which may develop around granulomata, may be identified by contrast radiography or endoscopy. Protein-losing enteropathy and blood loss can result in malnutrition and iron deficiency, especially in cases with significant small bowel disease. The role of schistosomiasis in malnutrition was illustrated by studies of mass chemotherapy, which resulted in improved nutrition and a lower prevalence of anemia.[9,102,135]

HEPATOSPLENIC DISEASE (HEPATOMEGALY, SPLENOMEGALY, AND PORTAL HYPERTENSION)

The life-threatening complications caused by *S. japonicum* and *S. mansoni* are the result of eggs that remain in the venous vasculature and migrate back to the liver.[16] Egg burden seems to be the greatest predictor of hepatic involvement with schistosomiasis, but some link with HLA type has been suggested.[93,94,121,146]

Children with compensated disease initially have few symptoms. These symptoms may include anorexia, malaise, and abdominal fullness.[16,25,77,103,110,147] Children have hepatomegaly even without significant portal hypertension. The hepatomegaly generally is firm and either minimally tender or nontender. Splenic enlargement usually is noted as well. Liver function is affected only late in the course of hepatic schistosomiasis, so jaundice and liver enzyme elevations are unusual findings.

As fibrosis develops around eggs in the liver, portal hypertension ensues. Liver function usually remains intact, but esophageal varices can cause death during the late adolescent and early adult years.[16,25,103] Ascites gradually develops during a period of years, and the spleen may become very large. Bleeding esophageal varices are a common cause of demise in individuals who had heavy schistosomal infections in childhood. Such patients may come to medical attention for melena or hematemesis. Initial episodes are well tolerated. However, with progressive liver decompensation, variceal bleeding can be fatal.

Children with severe hepatosplenic schistosomiasis do not grow as well as do other children. Debate has ensued about whether this deficiency is due to a direct effect of the parasitic infection or poor nutritional intake caused by poor general health. Some recent data suggest that a decrease in insulin-like growth factor–1 activity is linked to hepatic schistosomiasis.[105] Extensive formation of hepatic granulomata may hinder the liver's structure and function in such a way that growth-promoting factors are not produced normally.

PNEUMONITIS AND COR PULMONALE

Sometimes, children initially have low-grade fever and cough as schistosome larvae migrate through their lungs. This condition can occur with an initial heavy infection (when eggs will not be detectable) or with a heavy re-infection (when eggs will be detectable in urine or stool from the preceding underlying infection). This larval pneumonitis can be manifested on lung examination as basilar rales and wheezing.[30,119] Radiographs may show basilar mottling in the lung fields. Eosinophilia is a common occurrence with this type of pneumonitis. Resolution, even without treatment, usually occurs in 2 to 4 weeks. Similar symptoms also may be seen as a reactive pneumonitis when patients with heavy parasite burdens are treated.

In children with advanced hepatosplenic schistosomiasis and portal hypertension, eggs may bypass the liver and flow from the abdominal and pelvic veins into the small lung vessels. Localized granulomata form around eggs lodged in the lungs. During the course of time, children may be subject to fatigue, cough, and right-sided heart failure. Medical therapy stops the progress of disease and may decrease the ongoing inflammatory responses, but right-sided heart failure, once it is established, is not fully reversible.

CENTRAL NERVOUS SYSTEM INVOLVEMENT

Neurologic manifestations of schistosomiasis often are dramatic, even if not common.[45,100,108,120] Worms do not always follow the typical routes described for urinary and intestinal schistosomiasis. On occasion, worms migrate to cerebral blood vessels. Production of eggs in that location can cause seizures and headaches in children.[108,120] Sometimes, optic field defects and dysarthria are noted; these findings seem to result from localized space-occupying inflammatory reactions that develop around worms or eggs. Spinal fluid pressure may be elevated, and both protein concentrations and lymphocyte counts in spinal fluid may be increased. This cerebral schistosomiasis occurs more commonly with *S. japonicum* infection and is thought to develop in as many as 2 percent of infected children.

S. mansoni infection and, to a lesser extent, *S. haematobium* infection can produce eggs that embolize to the spinal cord. The eggs or associated granulomata can cause transverse myelitis. Paraplegia along with urinary and fecal incontinence often is the initial problem in children with spinal schistosomiasis.[45,120]

CHRONIC OR RECURRENT SALMONELLOSIS

In endemic areas, some children have salmonellosis and schistosomiasis concurrently. Children present with chronic low-grade fever, fatigue, malaise, and poor growth.[54,77,111,116,152] Blood cultures frequently demonstrate *Salmonella* bacteremia, but stool may not contain these bacteria. Some children have chronic *Salmonella* bacteriuria. Sepsis and mortality are unusual findings despite these persistent bacterial infections. Relapse of the *Salmonella* infection occurs commonly unless the coexisting schistosomal infection is treated. The bacteria are thought to hide within the parasitic worms, where antibiotic penetration is poor, and thereby evade host defenses.

DIAGNOSIS

A clinical diagnosis of schistosomiasis should be entertained in the presence of typical clinical features. These features might be as obvious as painless hematuria in a child in a region endemic for *S. haematobium*, or portal hypertension may be noted late in

the second decade of life in an otherwise healthy adolescent from an area known to be endemic for *S. mansoni* or *S. japonicum*.[110,118] The other clinical findings described also should prompt the clinician to consider a diagnosis of schistosomiasis when the child has resided in or traveled through a *Schistosoma*-endemic area.[133] In traveling children, the index of suspicion must be particularly high because patients may be asymptomatic or have atypical symptoms, they may not have clear history of exposure to contaminated water, and parasitologic examination findings often are negative.[15,110]

Outside endemic areas, re-infection is not expected. Thus, a reasonable approach is to test all children, including asymptomatic children, who have returned or emigrated from an endemic area where they had potentially significant exposure to fresh water. Such testing would involve all travelers who swam in, waded in, or even touched suspicious water, and it could involve immigrants who have spent long periods in endemic areas. Certainly, any child outside an endemic area who has even a remote history of having had possible contact with cercariae and clinical findings suggestive of any form of schistosomiasis should be tested. Testing is appropriate because even late therapy can favorably alter the course and outcome of schistosomiasis. In some highly endemic areas, diagnostic testing is of limited feasibility or questionable reliability (or both), and curative medications are readily available. In such settings, establishing a proven diagnosis might be less necessary. For example, in a highly endemic setting, a urine paper strip test result positive for hematuria could provide sufficient suspicion of infection to warrant administration of specific antischistosomal therapy. In populations with known high rates of infection, mass treatment (without expensive diagnostic testing) is reasonable.

In established heavy infections, eggs usually are readily apparent on microscopic examination of urine or stool. For lighter infections, concentrating techniques are useful. Urine can be centrifuged and filtered to increase the yield of eggs. The result of urine examination is most likely to be positive when urine is voided at midday and when it is collected at the end of the urine stream. In the event of high suspicion and negative urine findings, bladder wall biopsy can be performed. The procedure usually is not necessary, however, because urine microscopy, especially with filtered or concentrated samples, generally is positive. Examination of multiple samples increases the yield.

The eggs of *S. haematobium* and *S. mansoni* are approximately 90 mm in diameter, whereas the eggs of *S. japonicum* and *S. mekongi* are somewhat smaller. As demonstrated in Figure 240–3, identification of species is aided by observation of the spine—small for *S. japonicum* and *S. mekongi*, at one end for *S. haematobium*, lateral for *S. mansoni*, and broad at each end for *S. intercalatum*. Eggs usually are detectable in voided urine. Plain radiographs might demonstrate some calcification in the bladder wall around chronic granulomata. Cystoscopy, if it is performed, reveals bladder wall hyperemia and, subsequently, nodular lesions and fibrosis that give rise to "sandy patches" on the bladder wall. Granulomata may protrude from the bladder wall into the lumen. Both edema and granulomata may be seen obstructing ureteral orifices.

In light infections, examination of stool or urine samples may not reveal ova because of intermittent or low-volume shedding. Thus, negative stool or urine test results do not adequately rule out intestinal schistosomiasis.[15,110] When stools repeatedly are negative for ova, rectal biopsy may be performed. Samples may be obtained by random punch biopsy, but the yield is increased when samples are taken from inflamed sites under direct visualization. Eggs are detected in unstained smears made by pressing the tissue sample between a coverslip and a glass slide, but eggs also can be seen with standard histologic stains.

Nonviable eggs may be excreted for months or years after therapy has been successful. With good medical treatment, eggs usually are not viable when they are passed more than a week after the initiation of therapy. With ineffective treatment or re-infection, however, viable eggs may continue to be passed. On microscopic examination, living ova contain transparent miracidia within the egg, which often are motile. For further documentation of their viability, the eggs may be hatched by placing them in fresh water exposed to light for 20 minutes; observation with a hand lens then can reveal swimming miracidia.

Serologic tests may be needed in acute infection, which may occur before the eggs are excreted or with eggs in ectopic locations.[60,137] For travelers with limited exposure and the likelihood of having either an acute or a limited chronic infection, serology is the main diagnostic tool. Currently, the most common screening serologic test is the FAST-ELISA (the Falcon assay screening test–enzyme-linked immunosorbent assay) using *S. mansoni* adult worm microsomal antigen.[138] It also cross-reacts with *S. haematobium* but is less sensitive for *S. japonicum* or *S. mekongi* infection. Species can be confirmed by use of an immunoblot assay (enzyme-linked immunotransfer blot).[137] An immunoblot assay also is available for *S. japonicum*. Antigen-detection assays may be helpful, but they are not available in the United States.[2]

Ultrasonography is the main imaging procedure used in schistosomiasis.[61] It can document involvement of the portal and urinary tracts and, in selected cases, be diagnostic of schistosomiasis. Ultrasonography can identify bladder polyps, ureteral dilatation, hydronephrosis, and calcifications within the urinary tract. When resources are available, an ultrasound evaluation of the urinary tract should be performed in any child found to be

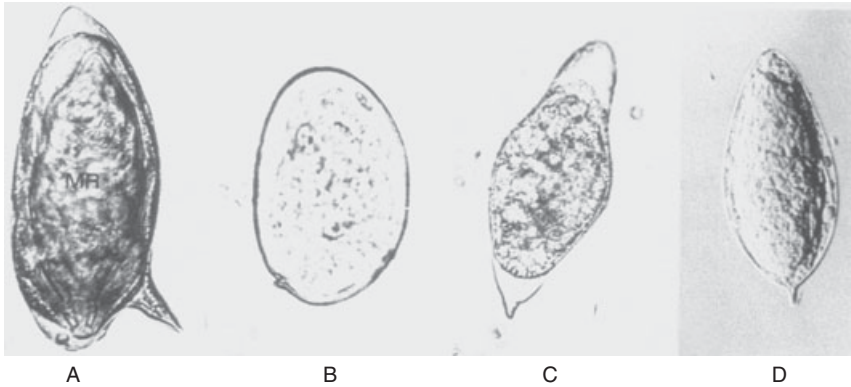

Figure 240–3 Human schistosome eggs. **A,** *S. mansoni.* **B,** *S. japonicum.* **C,** *S. intercalatum.* **D,** *S. haematobium.* *(From Mahmoud, A. A. F. [ed.]: Schistosomiasis. London, Imperial College Press, 2001. Reprinted with permission.)*

infected with *S. haematobium*. For children with persistent urinary symptoms (dysuria, suprapubic pain, hematuria) despite having received good medical treatment, cystoscopy should be considered, in part to screen for bladder cancer. Other radiographs and tests of renal function and excretion generally are not indicated unless the ultrasound evaluation reveals significant urologic disease.

Portal ultrasonography is the imaging study of choice for hepatic involvement. The presence of periportal fibrosis with thickening of the portal tracts and vein walls (so-called clay-pipe stem or Symmer fibrosis) correlates with parasite burden and hepatic disease. In experienced hands, schistosomiasis can be distinguished reproducibly from cirrhosis and other chronic liver diseases.

TREATMENT

Optimal treatment of schistosomiasis varies with the stage of the disease. Cercarial dermatitis resolves spontaneously and requires no antiparasitic treatment. Oral antihistaminic agents, however, may be given for severe itching. Medical therapy for schistosomiasis caused by the human schistosomes is effective and well tolerated without significant complications. No good medical reason exists to allow schistosomiasis to go untreated. The cost of therapy, however, is a limiting factor in resource-poor areas of the world. Several different medications can be considered for curative treatment.

Praziquantel, a mixture of stereoisomers of pyrazinoisoquinoline ring structures, is a broad-spectrum oral anthelmintic agent that is effective against each of the five human schistosome species. The mechanism of action was thought to involve unmasking of parasite antigens with subsequent killing by the host immune response.[19] However, patients with acquired immunodeficiency syndrome respond well to praziquantel, raising questions about this hypothesis. Praziquantel is given in divided doses on a single day as full curative treatment. For infection with *S. haematobium*, *S. mansoni*, and *S. intercalatum*, the dose is 40 mg/kg in two divided doses given on the same day. For children infected by *S. japonicum* or *S. mekongi*, the dose is 60 mg/kg in three divided doses given on the same day.[3,40] Heavily infected children sometimes experience some nausea, vomiting, and abdominal cramping with treatment. Rare side effects, including headache, pruritus, bloody stools, and fever, are transient and resolve within 1 to 2 days after the initiation of treatment. Because praziquantel primarily kills mature adult worms, a second course is recommended for the treatment of acute infection. Praziquantel is effective in more than 90 percent of treated children. Some studies suggest that resistance may be emerging.[84,85] However, those studies were performed in areas with frequent re-infection and with high parasite burden. Thus, the poor response may be due to the fact that juvenile forms are not as susceptible to praziquantel. Studies from nonendemic areas, however, continue to demonstrate excellent efficacy.[147] In addition to curing infection, treatment with praziquantel is associated with improved growth and reduction in anemia.[33] In endemic areas with high rates of infection, school-based and community-based (when many children in the area do not regularly attend school) treatment strategies (without confirmatory diagnostic testing) are effective; cost issues, however, raise concerns of program sustainability.[51]

An alternative treatment effective only against *S. mansoni* is oxamniquine, a tetrahydroquinoline compound.[127] The mechanism by which this agent acts is unknown. The effective dose has varied with the geographic origin of the schistosomal infection, but some resistance has been reported. Current recommendations are that children treated with oxamniquine be given 40 to 60 mg/kg divided into two doses administered on 1 day or four separate doses given during the course of 2 days. Mild side effects include nausea, headache, and fever. Seizures are a rare side effect, so administration of this medication should be avoided in children with seizure disorders. Cure rates of more than 90 percent are reported with oxamniquine.

Metrifonate is an organophosphate compound that causes paralysis of the parasite. It is 70 to 80 percent effective against *S. haematobium* when it is used at a dose of 10 mg/kg orally once every 2 weeks for 6 weeks. It does decrease the child's own plasma and erythrocyte cholinesterase activity, but actual cholinergic symptoms seldom occur. This medication is less expensive than the other options, but it generally is not used when praziquantel is available.

Medical therapy usually is effective for children with schistosomiasis, even with advanced disease.[86,115,126,153] Clear improvement in the patient's disease burden occurs when treatment is given. Even established uropathy and portal hypertension often are reversible.[88,115,126] Surgical procedures usually are reserved for children with complications related to long-term infection, such as persistent portal hypertension. Propranolol prophylaxis and sclerotherapy or banding can reduce rebleeding from esophageal varices.[41] Some cases require surgical decompression of portal hypertension. Splenorenal shunts are associated with high rates of hepatic encephalopathy. Comparative studies suggest that in experienced hands, esophagogastric devascularization with splenectomy is the procedure of choice.[46,53]

Systemic steroids may be useful for severely ill children with Katayama fever or severe larval pneumonitis. They also may be helpful in cases with granulomata in the central nervous system.[45,48] However, corticosteroids have not been proved effective treatments in other forms of the disease.

PREVENTION

Travelers and expatriates in endemic areas can prevent disease by limiting exposure to infectious fresh water. In endemic areas, they should avoid swimming in fresh-water streams and lakes. In addition, the cercaria can be eliminated by chlorination or by allowing water to settle for 24 hours before bathing or washing.

The use of effective medical therapy coupled with improved urine and stool hygiene has the potential to eradicate schistosomiasis from endemic areas.[148] Elimination of the snails that serve as intermediate hosts also would be effective, but attempts at implementation of programs administering molluscicides have been unsuccessful to date. Historically, national control programs in China focusing on snail control, sanitation, and improved water supplies have led to sustained reductions in infection rates, even apart from the influence of chemotherapy.[140,150] For specific populations, health education can lead to significant favorable changes in knowledge about the illness, water-exposure activities, and re-infection rates in school-age children.[58] Recently, control efforts have focused on mass chemotherapy, with particular emphasis on school-based therapy.[9,59,102,104,148] Treatment programs in which the entire school-age population is treated, typically with praziquantel, have resulted in overall improvement in levels of nutrition and in a reduction in the prevalence of anemia. In areas where re-infection commonly occurs, however, the effects of mass treatment programs are of limited duration, and treatment must be repeated every 6 months to 1 year. Sustainability of national control programs and of favorable outcomes remains challenging in Africa.[52,68,44]

Several studies suggest that artemisinin derivatives can prevent development of infection and decrease the worm burden in those exposed to *S. mansoni* and *S. japonicum*.[83,113,139] However, they are less effective for chemotherapy than is praziquantel,[18,35] probably because parasitologic activity is limited to the juvenile forms.

Furthermore, the public health role of chemoprophylaxis in the prevention of infection has not been established.

Immunization of experimental animals with irradiated cercariae can prevent experimental schistosomiasis. Thus, development of a vaccine to prevent human schistosomiasis is theoretically possible. Several potentially protective antigens have been identified on schistosomes, and they are being used as targets for vaccine development. However, the correlates of protective immunity in humans are not well defined. Currently, vaccines using combinations of antigens are being studied for *S. mansoni*.[151] Early-stage clinical trials have been performed for *S. haematobium* glutathione *S*-transferase–containing vaccines.[21] Vaccines related to several *S. japonicum* antigens also are being studied in animals, but efficacy is limited.[95,114,155] Whether development of a vaccine to prevent human infection is a real possibility remains far from certain, and no vaccine is likely to be ready for clinical use in the near future.[13,56]

SUBSECTION 5

Arthropods

CHAPTER 241

ARTHROPODS

Jan E. Drutz

Arthropods comprise nearly three fourths of the world's animal species. Although some arthropods are capable of producing damage to agriculture and homes and others serve as reservoirs, hosts, and vectors of human and animal pathogens, the majority have no significant impact in causing human disease.[59] However, among the more significant diseases transmitted to humans by arthropods are Chagas disease, malaria, dengue, and bubonic plague. In the United States, ticks transmit more vector-borne diseases caused by bacteria, rickettsia, viruses, and protozoa than do any other species.

TICKS

Ticks, mites, spiders, and scorpions all belong to a class of arthropods known as Arachnida. Two of three families of ticks belonging to this class contain species capable of transmitting pathogens to humans. Ixodidae, the hard tick family, and Argasidae, the soft tick family, serve as both vectors and reservoirs for many rickettsiae (Table 241–1). By use of a fluorescent technique, these rickettsiae can be identified in the tick hemolymph.

Hard ticks are so named because of their scutum, a dorsal sclerotized shield. Owing to the limited scutum coverage of the female, she is more capable of becoming engorged with blood than is the male, a factor significant in the reproductive process. During feedings, these ticks remain attached to the host for hours or days at a time.[15,52] Three genera of Ixodidae are known to transmit disease to humans in the United States: *Amblyomma*, *Dermacentor*, and *Ixodes*.[51]

Soft ticks have no scutum and tend to live for long periods of time, often surviving for years without eating. Both the nymph form and the adult tick have a tendency to eat often but for brief periods often lasting less than 30 minutes.[15,52] Of the family Argasidae, only ticks of the genus *Ornithodoros* are known to transmit pathogens to humans in the United States.[51] Specifically, they are the vectors of tick-borne relapsing fever.

Local reaction from tick bites appears to be mediated by complement. The reaction from these bites may persist and subsequently develop into a so-called tick bite granuloma. Systemic reactions such as fever, chills, nausea, vomiting, abdominal pain, and headache can be associated with tick bites.

As noted, tick-borne diseases can result from infection with pathogens that include bacteria, rickettsia, viruses, and protozoa.[53] The major tick-borne diseases occurring in the United States include tick paralysis (discussed here) as well as tularemia (Chapter 144), tick-borne relapsing fever (Chapter 152), Lyme disease (Chapter 153), Colorado tick fever (Chapter 184), Rocky Mountain spotted fever (Chapter 207), ehrlichiosis (Chapter 207), and babesiosis (Chapter 230).

Tick-borne rickettsial diseases are clinically similar yet epidemiologically and etiologically distinct illnesses. In the United States, they include Rocky Mountain spotted fever, human monocytotropic (or monocytic) ehrlichiosis, human granulocytotropic (or granulocytic) anaplasmosis (formerly known as human granulocytotropic ehrlichiosis), *Ehrlichia ewingii* infection, and other emerging tick-borne rickettsial diseases.[10] Mediterranean spotted fever, a tick-borne disease caused by *Rickettsia conorii* (Chapter 207), is found almost exclusively in the Mediterranean area.

TABLE 241–1 Human Infectious Diseases for Which Ticks Are a Vector

Disease	Agent
Relapsing fever	*Borrelia duttonii*
Q fever	*Coxiella burnetii*
Tularemia	*Francisella tularensis*
Queensland tick typhus	*Rickettsia australis*
Fièvre boutonneuse	*Rickettsia conorii*
Rocky Mountain spotted fever	*Rickettsia rickettsii*
Asian tick typhus	*Rickettsia sibirica*
Colorado tick fever	Arbovirus
Encephalitis	Arbovirus
Lyme disease	*Borrelia burgdorferi*
Human monocytic ehrlichiosis	*Ehrlichia chaffeensis*
Human granulocytic ehrlichiosis	*Ehrlichia* species
Babesiosis	*Babesia microti*

TICK PARALYSIS

Tick paralysis is a neurologic syndrome characterized chiefly by an ascending flaccid paralysis in association with the attachment of certain species of ticks. A well-known disease of animals, it was reported to occur in humans in North America first in 1912.[56] Most cases have occurred in the Pacific Northwest and Rocky Mountain states, in spring and summer.[53] It has been reported to occur more frequently in children, especially in girls between 2 and 5 years of age, than in adults. Numerous genera of ticks are known to be associated with tick paralysis. In North America, *Dermacentor andersoni* (wood tick) and *Dermacentor variabilis* (dog tick) are the primary species responsible for tick paralysis.[36] In Australia, ticks implicated most commonly are *Ixodes holocyclus* and *Ixodes cornuatus*. Both adult female and male as well as immature ticks have been implicated in this nervous system disorder.

Pathogenesis

Tick paralysis is thought to be caused by a neurotoxin (holocyclotoxin) produced in the tick's salivary glands.[34] It usually is released by gravid female ticks at the site of attachment, usually the scalp. The neurotoxin is a protein with temperature-dependent activity.[13] The exact mechanism and location of the

toxin's action are not known but may include decreased entry of calcium into motor nerve terminals or interference with presynaptic excitation-secretion coupling, which leads to a reduction of acetylcholine release at the motor end-plate.

Investigations in children with tick paralysis have implicated primarily peripheral nerve dysfunction, as nerve conduction velocities were noted to be diminished somewhat.[28,54] Compound muscle action potentials that are abnormally low or low-normal in amplitude when the patient has maximal neurologic deficits generally are reversed rapidly once the tick is removed.[36] Swift and Ignacio[54] postulated that the major effect of the toxin is to prevent depolarization in the terminal portions of the motor neurons.

Clinical Manifestations

Onset of tick paralysis usually occurs 5 to 7 days after the female tick attaches to the skin. Until mating occurs with the male, engorgement of the female tick is relatively limited. Mating leads to rapid engorgement, fertilization of the eggs, and production of the neurotoxin. In turn, production of neurotoxin coincides with initial paralytic symptoms, and continual feeding accelerates production of toxin, accounting for rapid clinical deterioration. Once the female becomes engorged, she disengages from the skin to deposit her eggs.[22]

Symmetric weakness of the lower extremities progresses to an ascending flaccid paralysis during the course of several hours or days. Sensory function usually is spared, and the sensorium is clear.[53] Alternatively, the disease can present as acute ataxia without muscle weakness.[37] If the paralysis involves the cranial nerves, the patient may have changes in voice and have difficulty in swallowing and handling secretions. Nystagmus, strabismus, and convulsions may occur as well.[28] Temperature elevation generally is not present. After tick removal, symptoms tend to resolve within several hours or days. Left untreated, tick paralysis can be fatal, with reported mortality rates of 10 to 12 percent.[48]

Routine laboratory tests are not helpful in establishing the diagnosis. The white blood cell count, urine analysis, cerebrospinal fluid, and erythrocyte sedimentation rate usually are normal.

Diagnosis

The diagnosis of tick paralysis can be established when the patient shows the typical clinical picture and improves when a tick is removed. A fine-toothed comb can aid in the detection of ticks attached to the scalp. The differential diagnosis of tick paralysis includes Guillain-Barré syndrome, botulism, poliomyelitis, myelitis, spinal cord neoplasm, syringomyelia, and porphyria. Botulism is characterized by slow, descending paralysis involving cranial nerves first, usually with extraocular palsy and large, poorly reactive pupils.[22]

The neurologic impairment caused by *I. holocyclus* ticks in Australia is more severe than that caused by *Dermacentor* spp. in North America. With exposure to *I. holocyclus* neurotoxin, the weakness and bulbar symptoms often intensify during the first 24 to 48 hours after tick removal. Clinical recovery is much slower than with *Dermacentor*-related paralysis. *I. holocyclus* antitoxin must be administered before removal of the ticks, and a longer observation period is required.[22]

Treatment

The earlier the tick is removed in the course of the syndrome, the more promptly the syndrome will clear. Forceps, not fingers, should be used to remove the tick. The tick's head should be gently but firmly grasped, and slow, reverse traction should be applied to remove all body parts. Recovery generally is complete within 1 to 5 days. In one reported case, weakness did not resolve for several months.[16] Intensive supportive care is required if the patient has cranial nerve dysfunction. Ineffective ventilation and ensuing respiratory failure require assisted ventilation.

MYIASIS

Myiasis is the invasion of a host's tissues by the larval stage (maggot) of nonbiting flies. Because of the immaturity of maggots, differentiating the various species is difficult. Myiasis can be classified according to the anatomic site of infestation (i.e., aural myiasis, ophthalmomyiasis, or cutaneous myiasis) or on the basis of the clinical syndrome (i.e., furuncular cutaneous myiasis, migratory cutaneous myiasis, or wound myiasis).[50] In the past, parasitic diseases were limited to their endemic areas. With the relative ease of worldwide travel, however, they are appearing with increasing frequency in the United States and other developed countries.[27]

ETIOLOGY

The true flies of the order *Diptera* undergo metamorphosis in four stages: egg, larva, pupa, and adult. Some larvae of the suborder *Cyclorrhapha* have adapted to a parasitic relationship with humans to different degrees. Some are classified as obligate, facultative, or accidental parasites in humans. In each case, the larval stage of the fly is able to invade the tissues of the host and progress in the stages of metamorphosis.

EPIDEMIOLOGY

The occurrence of human myiasis has been linked to humid and warm climates that favor the breeding of flies. Epizootics in livestock, marginal housing, poor disposal of refuse, and undernutrition also are important factors in the development of human myiasis.[40] In the United States, myiasis has been reported both from flies native to North America and from the larvae of flies acquired during foreign travel. More than 50 species of flies have been reported to cause human myiasis.

PATHOGENESIS

The pathogenesis of human myiasis differs with the degree of parasitic adaptation of each fly. *Dermatobia hominis* (the human botfly) uses a bloodsucking insect as a vector to deposit its eggs on a warm-blooded host. The larvae emerge from the eggs and then penetrate the host's skin, frequently using the puncture site of the carrier insect. The larvae develop within the dermal layer of skin, which leads to a boil-like swelling. During this period, the human host develops clinical symptoms. *D. hominis* and *Cochliomyia hominivorax*, the primary screwworm, are examples causing obligate myiasis.[40] *C. hominivorax* can be responsible for aural or nasal myiasis.

The genus *Sarcophaga* (flesh flies) is capable of causing facultative myiasis. The adult fly is attracted to wounds or ulcers containing purulent and necrotic material. The adult fly deposits eggs in the open wound, where the larvae hatch.

Maggots seldom are found in the human intestinal or urinary tract.[50] Accidental myiasis can occur when humans ingest eggs or larvae and the larvae remain in the intestinal tract. Genitourinary myiasis is thought to occur by the deposition of eggs around the external urethral orifice. The larvae then may migrate into and up the urethra. Such situations should be called *pseudomyiasis*[62] because the maggots are not living parasitically.

CLINICAL MANIFESTATIONS

The lesions of cutaneous myiasis generally are located over the exposed area of the body. Early in the course of cutaneous myiasis, pruritus is the predominant symptom. As the larvae grow after the first week of infestation, a serous exudate may drain from the penetrating site. At this point, pain and pruritus are prominent symptoms and the lesion appears as a small furuncle (furuncular myiasis). Tissue destruction by the larvae may continue, and secondary bacterial infection can occur. *Staphylococcus aureus* and group A streptococci, as well as gram-negative organisms, have been isolated from infected cutaneous myiasis wounds.

Abdominal pain, diarrhea, and anal bleeding are the symptoms of intestinal myiasis, which is self-limited and may last 2 to 6 weeks. Larvae within the genitourinary tract may lead to proteinuria, dysuria, hematuria, and pyuria. Nasal myiasis can extend into bone, sinus cavities, and even the meninges.[3] Aural myiasis has been described in a child without underlying disease.[14] Ophthalmomyiasis is characterized by an acute catarrhal conjunctivitis.[17] Penetration into the brain has been associated with intracerebral hematomas.[35]

DIAGNOSIS

A careful history of travel, occupation, and exposure is necessary to establish the diagnosis when the physician is confronted with unusual skin lesions that are pruritic and have not resolved with usual local care.[26,32] Myiasis is confirmed if larvae are demonstrated within the wound. A parasitologist or entomologist may be able to identify the species of larvae responsible.

TREATMENT

The removal of the larvae is necessary in any of the forms of myiasis. Endoscopic removal of nasal infestation is recommended. Surgical intervention may be required to expose the larvae in the wound. Forceps are used to pick out the larvae; the application of 5 percent chloroform in olive oil may facilitate removal. Occlusive coverings of the wound opening are helpful in extruding *Dermatobia* larvae because this maneuver diminishes the oxygen supply to the larvae. A thick layer of petroleum jelly (Vaseline) effectively interrupts air flow to larvae. Local or systemic antibiotics may be required if secondary bacterial infection is present.

The prevention of human myiasis requires good wound care, adequate personal hygiene, screening to protect against flies, and the prevention of myiasis in domestic animals.

MITES

As mentioned earlier, mites belong to the same class of arthropods (Arachnida) as do ticks, spiders, and scorpions. They, too, can be vectors for infectious agents. The house mite, *Liponyssoides sanguineus*, serves as the vector for rickettsialpox (Chapter 207) agent. Chiggers, which are larvae of mites (family Trombiculidae), transmit to humans the agent responsible for scrub typhus, *Rickettsia tsutsugamushi* (Chapter 207).

Some mites transmit no specific disease but can cause an annoying pruritic rash. In 2004, the microscopic itch mite (*Pyemotes herfsi*) was identified as a likely cause of an intensely pruritic skin reaction in individuals living in several Midwestern states as well as Texas and Oklahoma. Skin lesions were papular and erythematous and occurred primarily on the face, neck, and limbs.[11]

Scabies, an extremely pruritic skin infestation, has been known for more than 2500 years. The etiologic agent for this condition, *Sarcoptes scabiei*, is an obligate human parasite that burrows into the epidermis, no deeper than the stratum granulosum.[12] Scabies appears to have an increased incidence in 15-year cycles[49] and is transmitted person to person through direct and usually prolonged contact.

PATHOGENESIS

Mites of all developmental stages tunnel into the stratum corneum and deposit feces (scybala) behind them. Characteristically, the gravid female lays eggs in the tunnels. Clothing and bed items are thought to be less important in the transmission of the *Sarcoptes* mite. Because scabies is transmitted by skin-to-skin contact, sexual transmission occurs commonly, as does nonsexual spread in family settings.[12] Epidemic outbreaks of scabies have been reported in hospitals and other institutions where people were living closely together and especially where poor sanitation predominated.[4]

Hypersensitivity of both immediate and delayed types has been implicated in the development of lesions other than burrows.[12] Papulovesicular scabies is characterized by perivascular lymphohistiocytic infiltrates with eosinophils. The papillary dermis is edematous. The histologic appearance of nodular scabies is one of a dense, superficial, and deep perivascular lymphohistiocytic infiltrate with many plasma cells and eosinophils. Various vascular changes also may be apparent. Norwegian scabies (crusted scabies) is distinguished by numerous mites that are found in histologic sections of the stratum corneum, and hyperkeratosis is noted.[23] This form of scabies occurs most commonly in debilitated individuals, such as institutionalized retarded children or immunosuppressed children, including children with human immunodeficiency virus (HIV) infection.

CLINICAL MANIFESTATIONS

Scabies is characterized by moderate to severe pruritus that starts several weeks to months after infestation, at which time the host has become hypersensitive to the mite or its products. Itching, most evident at night, is the primary symptom of infection. A papular or vesicular eruption with pustules and linear burrows occurs and classically involves the webs between the fingers, flexures of the arms, axillae, and genital regions. In infants and children, scabetic lesions more typically occur on the palms, soles, head, and neck in the form of vesicles, pustules, or nodules. In this age group, scabies often is not suspected because of the atypical skin lesions that result from vigorous scratching and secondary infections.[31]

Acute glomerulonephritis may be associated with pyoderma in scabies. A careful history may reveal that other family members or child caretakers have pruritus and skin lesions consistent with scabies. Examination of the skin of family members for signs of scabies frequently is helpful. Norwegian scabies may be manifested with a nonspecific hyperkeratosis that may be generalized or localized to the hands or feet rather than with the typical pruritic papules.[18]

DIAGNOSIS

Definitive diagnosis can be made by microscopic identification of the mites, eggs, or mite feces.[32] To obtain this material, skin scrapings should be taken from papules or the end of a burrow or from underneath the surface of fingernails. In some cases, a variety of biopsy techniques can be useful.[7]

The diagnosis should be considered when the physician is faced with an unusual papular or bullous rash. The differential diagnosis of scabies in children includes impetigo, atopic eczema, seborrheic or contact dermatitis, psoriasis, histiocytosis, and chickenpox.[30,31]

TREATMENT

The management of scabies involves the application of a topical scabicide to all areas of skin (except the face) and subsequent removal in 8 to 24 hours, depending on the product applied. Effective scabicides are gamma benzene hexachloride (lindane), permethrin 5 percent, and 10 percent crotamiton.

The agent of choice for infants and young children is permethrin topical cream, which can be applied to the entire head, neck, and body of the infant.[31] All family members should be treated simultaneously.[44] Antibiotics may be necessary if secondary bacterial infection is present.

Ivermectin has proved to be highly efficacious as an oral therapy for scabies in a single dose for otherwise healthy or HIV-infected adults.[41] It works against several different parasites by interrupting GABA-induced neurotransmission.[12] Approval has not been granted for use of ivermectin in children, especially for those weighing less than 15 kg.

Articles of clothing and bed sheets should be machine washed in hot water at 60° C. Insecticidal powder or aerosol should be reserved for materials that cannot be washed.[12] Some evidence exists indicating that gamma benzene hexachloride may not be safe for use in infants and young children because of transcutaneous absorption and subsequent adverse central nervous system effects.[31,38] These adverse effects possibly may be prevented by a careful explanation of the application and removal of lindane after 8 to 12 hours.[16,22] Pruritus often persists for some time after successful treatment with a scabicide and may be relieved by an oral antihistamine or mild to moderate topical steroids.[8,44] In hospitalized patients, contact isolation is recommended to lessen the potential for nosocomial transmission.

Management of the intensely pruritic rash caused by the itch mite (*Pyemotes herfsi*) may include DEET-containing insect repellents to prevent the bites, Calamine lotion, an oral antihistamine, and an over-the-counter topical hydrocortisone preparation.[11]

PEDICULOSIS

Arthropods of the order Anoplura (sucking lice) are important as vectors of rickettsial or spirochetal illnesses. The body louse, *Pediculus humanus humanus*, is the vector for epidemic typhus (*Rickettsia prowazekii*), trench fever (*Bartonella quintana*), and louse-borne relapsing fever (*Borrelia recurrentis*). The body louse, head louse *(Pediculus humanus capitis*), and crab louse (*Phthirus pubis*) all are capable of achieving human infestation. Pediculosis has been a problem for humans for more than 10,000 years.[12]

PATHOGENESIS

Head lice are the most common type of louse. Tiny, they measure no more than 1 to 4 mm in length. They have six legs, each with powerful claws allowing firm attachment. Mouth parts consist of stylets (retracted when not in use) modified for piercing and sucking. When they are not feeding, lice are translucent with grayish white bodies; but when they are engorged with blood, they become red. Each female is capable of laying as many as 300 eggs (nits) in a brief lifetime of 1 to 3 months. These eggs are less than 1 mm in diameter and hatch in 6 to 10 days, giving rise to nymphs. During a period of 10 days, the nymphs become adults. School children of all socioeconomic groups are affected, with head-to-head contact being the most common means of transmission.

CLINICAL MANIFESTATIONS

Children or adults with head lice usually present with white or opalescent nits attached to individual strands of hair. The lice themselves firmly adhere to the base of the hair shaft, millimeters from the scalp. Once a louse pierces the skin, a poisonous salivary secretion is exuded, resulting in pruritic dermatitis. Itching is the primary symptom in acute cases.

Body lice occur when socioeconomic conditions are poor. Infestation occurs when people fail or are unable to wash their clothes regularly, such as those living in refugee camps. Intense itching is a major problem, with noticeable excoriations and occasional secondary infections.

Pubic lice are transmitted primarily through sexual contact, although not exclusively so. In children, pubic lice generally occur from nonsexually transmitted contact with an infected parent. Again, itching is a major presenting symptom. Pubic lice may become attached to other hairy areas of the body, such as the axillae of adolescents, the eyelashes of children, and the scalp hair of any age group.[12]

As mentioned, body lice can function as vectors for the transmission of several diseases. One of these is trench fever caused by *B. quintana*. Although some patients may have no symptoms, others may present with fever, myalgias, headache, meningoencephalitis, transient maculopapular rashes, or chronic adenopathies. Another disease is epidemic typhus caused by *R. prowazekii.* Symptoms of this infection may include fever, headache, rash, or confusion. Relapsing fever caused by *B. recurrentis* is the third group of louse vector–transmitted diseases.[12]

DIAGNOSIS

Head, body, and pubic lice are visibly recognizable. Nits are attached firmly to hair shafts and are distinguished readily from dandruff flakes, lint, and other debris easily removed from the hair. Viable nits, located close to the scalp, are oval and grayish to yellow-white. Empty nonviable nits, attached at some distance from the scalp, are almost completely clear. Although difficult to see with the naked eye, nits visibly fluoresce yellow-green under Wood's lamp. Polymerase chain reaction allows the identification of host DNA from lice through their blood meal, providing valuable information for rape, homicide, and child abuse cases.[39]

The body louse only lately has been demonstrated by polymerase chain reaction detection of *B. quintana* DNA in lice from infected patients as the true vector of trench fever.[6] Detection of rickettsial DNA in lice indicates current human typhus.

TREATMENT

Head Lice

Numerous forms of treatment for the eradication of head lice have been used. Gamma benzene hexachloride (lindane) shampoo was used almost exclusively until the early 1970s. Because of concern about potential neurotoxic effects for the patient, it no longer is recommended as a first-line medication for children. Subsequently, a 1 percent permethrin cream rinse used as a single treatment became the preferred form of therapy. This biodegradable and generally very safe product is recommended to be applied to wet hair and left in place for about 10 minutes before

rinsing. To remove the firmly adherent nits, a fine-toothed stainless steel comb (LiceMeister) has been recommended.

During the course of time, resistance to several forms of therapy has developed. Additional therapeutic intervention has included pyrethrin plus piperonyl butoxide, ivermectin, malathion, trimethoprim-sulfamethoxazole, and smothering agents (including olive oil, margarine, and petroleum jelly). Some success has been reported with use of a 5 percent permethrin preparation and wearing a shower cap overnight.[46]

Malathion, an organophosphate, when it is applied to hair and left in place for 8 to 12 hours, provides residual protection. A combination of 0.5 percent malathion and 78 percent isopropanol has been approved for use by the Food and Drug Administration. Because it is hydrolyzed and detoxified by plasma carboxylesterases much more rapidly in mammals than in insects, it is considered safe.[1] However, it is flammable and is not recommended for use in children younger than 6 months.[12]

Ivermectin has been used when other medications have failed. A dose of 200 μg/kg given on days 1 and 8 appears to be effective. Concern exists when the drug is used in patients weighing less than 15 kg, or those who are pregnant or breastfeeding.[8]

The antibiotic combination trimethoprim-sulfamethoxazole works by destroying essential gut bacteria in the louse. These bacteria, responsible for the production of vitamin B, are essential for life.

A nonchemical approach to treatment has been the application of a topical lotion (Cetaphil Skin Cleanser) to the hair with subsequent use of a blow drier to "shrink-wrap" and ultimately suffocate the lice.[43] Although this approach may result in significant success, the original study was not rigorous enough to prove its effectiveness.

The use of a high-volume, hot air blow drier alone has been reported to have killed 94 to 98 percent of lice eggs and 76 to 80 percent of hatched lice.[25] When examined 1 week later, virtually all of the patients were completely cured. Although it is promising, this approach necessitates further testing by independent investigators. If it is proved to be efficacious, it could eliminate the use of chemicals, to which some lice have become resistant.

Body Lice

A general recommendation has been thorough washing of the body with soap and water followed by the application of a pyrethrin or pyrethroid or malathion for 8 to 24 hours. Again, caution should be taken in the use of these preparations in children. Decontamination of clothing and bed linens is essential by either washing them in hot soapy water at a temperature of 130° F for 10 minutes or placing them in a hot clothes drier for 20 minutes.

Pubic Lice

Treatment should be similar to that used for managing head lice. Clothes and bed linen should be decontaminated. In the case of children, parents also should be treated; and in the case of adolescents, sexual partners require treatment.

BEDBUGS

There are numerous recent reports of the re-emergence of bedbugs (*Cimex lectularius*) as a cause of pruritic, erythematous papules.[55] Although they are known to harbor pathogens (e.g., plague and hepatitis B), bedbugs are considered to be incapable of transmitting these diseases to humans[33,57] and, therefore, are not thought to pose a medical threat. Secondary skin infections, however, can develop as a result of persistent scratching.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

Bedbugs tend to be nocturnally active and are attracted to humans by warm body temperature and the exhalation of carbon dioxide. Survival is dependent on blood extracted from their respective hosts, which is achieved by piercing the skin with their beak-like proboscis containing a set of two hollow tubes. Through one of these tubes, they inject saliva, containing both anticoagulants and anesthetics; through the other one, blood is withdrawn.[55] Although they can live for up to 18 months without feeding, bedbugs typically seek blood every 5 to 10 days.

Total feeding time can range from as short as 5 minutes to as long as 30 minutes, after which the insect abandons the skin surface and seeks seclusion among bed sheets, blankets, mattresses, floorboard cracks, or other crevices.[55] The host generally does not experience itching or skin irritation until several minutes or hours after the insect has fed. In some cases, no skin reaction occurs at all.

DIAGNOSIS

Suspicion for the possible presence of bedbugs occurs when the host awakens with itching and visible bites not present before going to sleep. Clues to the presence of bedbugs include discrete reddish brown bloodstains on sheets and mattresses as well as flecks of excrement at the portals of hiding places.[55] Confirmation requires finding and identifying these bugs.

TREATMENT

Treatment of bites is relatively conservative, directed toward symptomatic relief of itching, irritation, and secondary infection. Antipruritic medication, either topical or oral preparations, may be considered. First-generation antihistamines can help alleviate the itching but may be sedating. Topical corticosteroids can help reduce the erythema and itching. Oral antibiotics alone are sufficient to treat secondary bacterial skin infections. To rid the living environment of bedbugs, a professional exterminator should be consulted.

SPIDERS

Of the thousands of species in the United States, only a few pose a threat to humans. Species of the genus *Loxosceles* are the spiders predominantly responsible for necrotic arachnidism in the United States. The two most common species are the black widow spider (*Loxosceles mactans*) and the brown recluse spider (*Loxosceles reclusa*). Both prefer dark, undisturbed habitats, such as outdoor lavatories, woodpiles, underside of stones, or dark corners of garages and attics. The black widow has a characteristic red hourglass shape on its ventral surface. The brown recluse has a violin-shaped marking over its dorsal surface. In the Pacific Northwest area of the United States, the hobo spider (*Tegenaria agrestis*) produces an envenomation similar to that of the brown recluse spider.[9]

PATHOGENESIS

Venom from the black widow contains a neurotoxin (α-lactotoxin), not a tissue toxin. The main effect is at the presynaptic membrane of the neuromuscular junction. Venom from the brown recluse spider contains sphingomyelinase D, a phospholipase that induces dermal necrosis and also causes system effects through its interaction with red blood cells,

platelets, and endothelium.[47] The necrosis caused by the venom is dependent on neutrophils, but the neutrophils are not activated by the venom itself. Rather, the venom is a potent stimulus for the inflammatory response of endothelial cells, which in turn activates the polymorphonuclear neutrophils to cause tissue destruction.[42]

CLINICAL MANIFESTATIONS

The bite of the black widow spider generally is painless, but a target lesion may develop. Within 30 to 120 minutes, some patients complain of regional lymph node tenderness.[61] The primary symptom that follows the bite is muscle cramping, generally involving the abdomen, chest, or back, depending on the location of the bite. Autonomic symptoms including profuse sweating, nausea, vomiting, and tachycardia may occur.[47] Hypertension can be a significant problem. The degree of systemic symptoms depends on the amount of venom injected and the number of bites. Severe cases may progress to internal hemorrhage, paralysis, and, rarely, even death.

The brown recluse spider bite may produce a mild or sharp stinging sensation. After several hours, the pain intensifies and itching occurs.[2] Eventually, a blister with surrounding erythema forms at the site. In the course of time, the lesion becomes larger, and central necrosis develops. Systemic signs developing in the first 24 to 48 hours may include headache, fever, nausea, vomiting, and joint pain. Disseminated intravascular coagulation, multiorgan failure, and death have been reported in children.[24,60]

Like that of the brown recluse spider, the bite of the hobo spider may result in a central necrotic area. The most common systemic symptom is a severe headache. Protracted systemic effects, including aplastic anemia, intractable vomiting, and profuse secretory diarrhea, are rare occurrences but may be associated with death.[58]

TREATMENT

For the patient who has been bitten by a black widow spider, analgesia is the mainstay of care.[47] An antivenin is available but only for the most severe cases of envenomation that are unresponsive to other measures.[5]

For bites of brown recluse spiders, numerous treatments have been used and include hyperbaric oxygen therapy, early excision, antibiotics, dapsone, and corticosteroids. Careful supportive care, including monitoring of electrolytes and renal function, is required if symptoms are severe.[47] Systemic corticosteroid therapy may be of some benefit if the patient has systemic symptoms. Dapsone, an inhibitor of neutrophil function, appears to decrease the development of wound complications and subsequent need for surgical excision.[45]

SCORPIONS

Scorpions, like ticks, mites, and spiders, belong to the Arachnida class of arthropods.[19] The striped bark scorpion (*Centruroides vittatus*) is the most common type of scorpion found in the United States.[20] The most dangerous and perhaps the most lethal scorpion in this country is *Centruroides exilicauda* (former species name, *sculpturatus*), occasionally referred to as the bark scorpion.[21,47] It is indigenous to the Desert Southwest, particularly Arizona. Depending on the species, scorpions tend to reside in cracks and crevices, in cupboards and closets, or under loose tree bark. They inject their venom when disturbed or threatened.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

C. vittatus produces a neurotoxic venom stored in poison glands in the tip of the tail. The venom of these scorpions is deadly to insect prey and produces a painful sting for humans. For those allergic to the sting, it may produce an anaphylactic reaction.[20] The venom from the *Vaejovis carolinianus* (plain eastern stripeless scorpion) is considered to be mild, similar to that of a honeybee sting. Anecdotal reports indicate that on occasion, a severe reaction may occur.[19]

The *C. exilicauda* scorpion produces a neurotoxic venom that can lead to cardiac failure, respiratory paralysis, agitation, paresthesias, hypersalivation, hypertension, and gastrointestinal symptoms. Although tachycardia and hypertension are frequent reactions, opposite effects are a possibility when the venom activates the parasympathetic nervous system.[47] The absence of local tissue reaction is helpful in distinguishing *C. exilicauda* stings from those of other scorpions found in Arizona.[21] Children and elderly adults are most at risk as a result of envenomation from *C. exilicauda*.[20]

TREATMENT

Most scorpion stings necessitate only nonprescription analgesic medication. For the management of *C. exilicauda* envenomation, atropine can be used to control hypersalivation, although it could be contraindicated when the sting has been produced by scorpions foreign to the United States. In some of those cases, the use of atropine can exacerbate an adrenergic toxicity reaction created by the sting of the scorpion. Treatment of *C. exilicauda* envenomation with an antivenin (available in Arizona only; not approved by the Food and Drug Administration) has been reported to provide relief from the neurotoxic effects. It has the unfortunate potential of causing both immediate and delayed hypersensitivity reactions.[21,47]

SECTION XXIII

Health Information for International Travel

CHAPTER 242

International Travel Issues for Children

Michelle Weinberg ✪ Susan A. Maloney

During the past half-century, the number of persons traveling internationally has increased tremendously. Between 1950 and 2006, the number of international arrivals worldwide grew from 25 million to 806 million, an annual growth rate of 7 percent. In 2006, travel to Africa increased by 10 percent, more than travel to any other region of the world, whereas travel to Asia and the Pacific was the world's second fastest growing region, with growth of 8 percent. In 2005, more than 38 million trips overseas were taken by U.S. residents. Approximately 55 percent of these trips were to destinations other than Europe or Canada; these destinations included almost 5 million trips to Asia, 5.6 million trips to Mexico, 2.4 million trips to South and Central America, 700,000 trips to Oceania, 500,000 trips to the Middle East, and more than 200,000 trips to the African continent.[148,174]

International travelers may be exposed to a variety of health risks, depending on the travel destination, trip itinerary, duration of stay, planned travel activities (i.e., business versus adventure), individual risk factors, and preventive measures taken. For persons from industrialized countries visiting developing countries, travel may expose them to a variety of infectious pathogens and environmental hazards, some of which they may rarely encounter at home. An estimated 15 to 70 percent of adult travelers report health problems during international travel; 1 to 8 percent of travelers seek medical care during travel, 0.1 to 1 percent are hospitalized abroad, 0.01 to 0.1 percent require emergency evacuation, and 1 in 100,000 dies.[55,142,144]

Infectious diseases are a major cause of morbidity among international travelers. Numerous authors have studied and estimated the incidence of infectious diseases in international travelers.[39,40,45,125,144] The most common illnesses are diarrhea, respiratory tract infections, malaria, and skin infections.[82-84,110,123] In a review of 917 travelers receiving treatment at two Australian Infectious Disease Units for illnesses acquired overseas, 19 percent had malaria, 15 percent had gastroenteritis or diarrhea, and 7 percent had upper respiratory tract infections.[110] Malaria is a potentially life-threatening problem for travelers; an estimated 30,000 North American and European travelers contract malaria annually.[87] Diarrhea has been estimated to occur in as many as 40 percent of persons traveling annually from industrialized to developing countries.[39,40,43,49,81,125,139,144] In a review of patients at GeoSentinel surveillance sites, a network of globally dispersed sentinel clinics providing care for international travelers, 7.8 percent of all infections in returned travelers were respiratory tract infections. Among the 1719 persons with respiratory tract infection, 1100 patients had upper respiratory tract infection, most of which were unspecified upper respiratory tract infection (47.2%) and pharyngitis (13%), and 680 had lower respiratory tract infection, primarily bronchitis (20.3%). Influenza was diagnosed in 96 patients (5.6%). Influenza was associated with travel to the Northern Hemisphere during December through February, travel involving visits to family or relatives, and trip duration of more than 30 days. Lower respiratory tract infections were associated with male sex and increasing age, whereas the risk of pharyngitis, sinusitis, or otitis media was significantly greater in younger persons.[83]

Infectious disease risks vary with destination. In a review of 17,353 travelers who returned ill from 30 GeoSentinel Surveillance Network sites, significant regional differences were detected. Systemic febrile illness without localizing features occurred disproportionately among travelers returned from sub-Saharan Africa or Southeast Asia, acute diarrhea among those returning from south central Asia, and dermatologic problems among those returning from the Caribbean or Central or South America.[55]

Other infectious diseases reported in travelers include parasitic infections, such as amebiasis, cutaneous larva migrans, giardiasis and schistosomiasis, hepatitis A and B, typhoid, sexually transmitted diseases, animal bites with a risk of rabies, cholera, legionellosis, human immunodeficiency virus (HIV) infection, and meningococcal disease.* Approximately 13 percent of the cases of hepatitis A reported in the United States, 42 percent of cases in Switzerland, and 40 percent of cases from Quebec, Canada, are associated with international travel.[24,105,122] Among Swiss travelers, the incidence of hepatitis A in travelers to countries of high or intermediate risk of transmission was 3.0 to 11.0 per 100,000 person-months abroad for all travelers and 6.0 to 28.0 per 100,000 for those presumed to be nonimmune; the highest risk was for children 0 to 14 years of age who were visiting family and friends.[105] In a review of 2445 cases of typhoid fever reported in the United States between 1985 and 1994, 72 percent were associated with international travel within 30 days of onset of illness.[99] Drug-resistant typhoid infection also is associated with international travel. Among 293 persons with symptomatic typhoid fever reported in the United States between 1996 and 1997, 81 percent were associated with international travel; patients with multidrug-resistant *Salmonella typhi* and nalidixic acid–resistant *S. typhi* were more likely to have traveled outside the United States, particularly to the Indian subcontinent (Bangladesh, India, and Pakistan).[1]

Fewer data have been collected on the incidence of noninfectious health problems among adult travelers, but those available suggest that injuries (especially from motor vehicle and sporting accidents and drowning) and complications from preexisting

*See references 10, 14, 48, 56, 65, 78, 80, 89, 98, 99, 103, 118, 130, 135, 140, 143, 144, 151.

medical conditions are substantial causes of serious morbidity and mortality.[113] Noninfectious health problems also are more common causes of mortality among adult travelers than infectious diseases are. In separate studies of deaths in adult international travelers from the United States, Australia, and Scotland, the most common cause of death was cardiovascular disease; among U.S. travelers, cardiovascular disease in men older than 60 years accounted for 50 percent of all deaths.[58,60,114,121,138]

Despite the well-documented health risks associated with international travel, surveys have shown that many travelers do not seek pre-travel health advice or obtain appropriate travel-related preventive medications or vaccinations. Surveys of U.S., European, and Australian travelers have shown that only 31 to 52.1 percent of the travelers sought travel advice before the trip. In an airport survey of 203 U.S. passengers traveling to high-risk, malaria-endemic areas, only 46 percent were carrying antimalarial medications with them,[59,156,162] and few were vaccinated for their travel: only 11 percent for tetanus, 14 percent for hepatitis A, 13 percent for hepatitis B, and 5 percent for yellow fever.[59]

Travelers who are visiting family and friends are at high risk for acquiring a variety of illnesses and are less likely to seek pre-travel medical advice.[6-8,84] In a review of travelers seeking medical care for travel-related illnesses in the GeoSentinel Surveillance Network, only 16 percent of those who were immigrants and were visiting family and friends sought pre-travel medical advice.[84] Systemic febrile illnesses (including malaria), nondiarrheal intestinal parasitic infections, respiratory syndromes, tuberculosis, and sexually transmitted diseases were more commonly diagnosed among immigrants visiting family and friends, compared with other travelers, whereas acute diarrhea was less frequent. Compared with other travelers, the immigrants who were visiting family and friends were more likely to travel to sub-Saharan Africa or Latin America and to take a trip of longer than 30 days in duration.[84] In a review of travelers presenting at one GeoSentinel Surveillance Network clinic site, the proportion of travelers with malaria who had been visiting family and friends was eight times greater than among tourists (16.9% versus 2.1%).[82]

PEDIATRIC TRAVELERS AND HEALTH RISKS ABROAD

Less specific information is available on the number of children traveling internationally or living abroad. By extrapolation from overseas travel data for U.S. residents, a conservative estimate is that at least 2.6 million trips overseas are taken by children traveling overseas annually (i.e., 7% of the 38 million U.S. residents traveling internationally in 2005 reported traveling with children). Information also is more limited on the causes of serious morbidity and mortality among pediatric travelers, and efforts to collect these data should be undertaken to direct prevention measures so that morbidity and mortality rates in pediatric travelers can be decreased.[12,64,120] In a review of 1743 patients in Belgium with fever after international travel, 117 (6%) of the fever cases occurred in children younger than 15 years, and 15 children required hospitalization. Among all patients (adults and children), a definitive diagnosis was established in 76 percent of the cases of fever. Tropical diseases accounted for 39 percent of all causes of fever, and the most common pathogen was malaria.[11] The data available include a 1-year prospective hospital-based study in the United Kingdom of children admitted with fever who had traveled recently to the tropics.[77] In this study, 31 children with a median age of 4 years (range, 5 months to 15 years) met the study entry criteria. Fourteen of these children had nonspecific, self-limited illnesses of presumed viral origin, and 17 children had conditions requiring hospital management and antimicrobial therapy. Conditions requiring hospital management included four cases of malaria (three of *Plasmodium falciparum* malaria and one of *Plasmodium vivax* malaria), three cases of bacillary dysentery, two cases each of dengue and typhoid fever, and one case each of acute hepatitis A infection, pneumonia (unspecified), *Pneumocystis jiroveci* pneumonia (in a child with newly diagnosed HIV infection), bacterial lymphadenitis, streptococcal throat infection, and acute myeloid leukemia; no deaths occurred. In another retrospective study of traveler's diarrhea in Swiss children who had visited the tropics or subtropics, Pitzinger and colleagues[120] found incidence rates of 40, 8.5, 21.7, and 36 percent in children aged 0 to 2, 3 to 6, 7 to 14, and 15 years and older, respectively. Other authors have reported substantial health risks for pediatric travelers from noninfectious causes such as injuries. Most deaths are associated with swimming or automobile accidents.[64,85] One study of British children drowning abroad while traveling showed that an average of eight British children drown each year abroad, primarily in swimming pools without adequate lifeguards.[38]

Although data from adult travelers can be extrapolated to use in the management of pediatric travelers, infants and children have special vulnerabilities and needs when preparing for travel abroad. These needs include (1) up-to-date and appropriate vaccinations (at times through accelerated or altered routine childhood vaccine schedules and also including special travel-related vaccines); (2) appropriate malaria and other chemoprophylaxis regimens tailored for use in pediatric travelers; (3) prevention counseling, particularly in the areas of insect barriers, food and water safety, and injury prevention; and (4) anticipatory guidance for the management of potential illness and successful location of medical resources overseas. This chapter provides recommendations for conducting a pediatric pre-travel assessment to ensure that the child has received the appropriate vaccination and chemoprophylaxis regimens, pre-travel prevention counseling, and means of accessing additional sources of travel information about health risks and the availability of medical resources at specific travel destinations.

GENERAL APPROACH TO PRE-TRAVEL ASSESSMENT FOR CHILDREN

Before embarking on international travel, children should have a pre-travel health assessment performed by a health care provider. The number of physicians who specialize in travel medicine for children is relatively limited, and most pre-travel assessments are performed by general pediatricians or pediatricians who specialize in infectious diseases. The visit should be conducted with the goal of preventing travel-related illnesses. Depending on the destination and the vaccinations recommended or required, the assessment should be conducted optimally up to 6 months before travel. Because families may not be aware of the need for multiple vaccinations, health care providers should be proactive and routinely ask patients and their families if they are anticipating any international travel in the next 6 months, especially before holiday periods.

During the pre-travel assessment, the provider should do the following:

1. Review the child's current and past medical history, including the status of routine childhood vaccinations.
2. Obtain specific details about the travel itinerary and planned activities.

Then, after review of endemic diseases and recent outbreaks in travel destinations:

3. Administer indicated routine and travel-related vaccinations.
4. Prescribe antimalarial and other prophylactic medication (based on risk assessment from the medical history, travel itinerary, and planned activities).

5. Counsel about prevention of travel-related illnesses.
6. Provide guidance about seeking medical assistance for travel-related illness.

The age, immunization status, and medical history of the child are important information to have in conducting the pre-travel assessment. The provider should consider three categories of vaccinations: routine childhood vaccinations, required travel-related vaccinations, and recommended travel-related vaccinations. Some routine vaccinations should be administered at an earlier age or after an accelerated schedule in preparation for international travel. In addition, the provider should review and administer travel-related vaccinations that are required for entry by various countries to prevent the importation of disease and development of outbreaks as well as vaccinations recommended for the prevention of illness in the individual traveler. Currently, only two vaccines, yellow fever and meningococcal, are required for entry by selected countries; however, these requirements may change in the future. In addition, some countries require documentation of HIV testing before allowing entry of long-term travelers (see the section on international travel information resources). Guidelines for standard and accelerated schedules for routine childhood immunizations and for required and recommended travel-related vaccinations by specific travel destinations are summarized in this chapter in the section on vaccination for international travel. A review of medical conditions and contraindications is critical before vaccinations are administered or medications such as antimalarial chemoprophylaxis are prescribed.

The pre-travel assessment should include a detailed review of the trip itinerary. The health care provider should ask about sources of water and food (homes versus hotel restaurants), type of accommodations (e.g., camping, hotel chains, or residing with local families), amount and type of contact with the local population, and planned activities during travel (adventure travel with exposure to animals, water, high altitude, or any combination of these factors). A template of a pre-travel assessment questionnaire for children that can be completed by the family at the visit is shown in Figure 242–1. Recommendations to prevent vector-borne diseases, including malaria, should be determined by a comprehensive review of the travel itinerary and planned activities. Guidance for determining appropriate regimens for antimalarial chemoprophylaxis in pediatric travelers is provided in this chapter in the section on malaria prevention. In addition, the risk of acquiring an infectious disease differs and is probably greater for an adolescent who is participating in a rural home-stay program for 3 months than for a 5-year-old child traveling with parents to a beach resort. Furthermore, expatriates who live abroad and foreign-born persons, especially immigrants, refugees, and their children visiting friends and relatives in their home country, have health risks different from those of short-term travelers who are visiting tourist destinations. These differential risk profiles should be taken into account during the pre-travel assessment because such knowledge is essential for devising a specific pre-travel management plan.

On the basis of risk assessment, preventive health counseling should include information about prevention of vector-borne illnesses, food and water safety, and prevention of other infectious and noninfectious illnesses, such as automobile accidents. General and specific prevention counseling recommendations are addressed later in the chapter. In addition, families should clarify with their health insurance company whether they are covered for health care provided abroad. If not, insurance can be purchased from several companies; such insurance may include coverage for health care providers in a specific country and airlift medical evacuation. If assistance for illness acquired abroad is needed, the U.S. embassy or consulate can provide names and addresses of English-speaking health care providers at the travel destination. This information can be obtained before departure by accessing embassy Internet sites or by calling the embassy. In addition, names of physicians abroad also can be obtained from some worldwide directories (see the section on international travel information resources). Parents should be told to carry all health-related documents with them for easy retrieval, including written prescriptions for medications, health insurance information, and medical contacts abroad. Counseling on ensuring the use of sterile needles and the safety of the local blood supply also should be included in pre-travel prevention counseling topics; blood screening and infection control practices may not be as stringent in some countries as in the United States.

Special consideration must be given to children who have chronic diseases. Children with medical conditions should take a summary of their medical history and treatment record. If the child has cardiac disease, the family should consider taking a copy of the child's recent electrocardiogram and echocardiography report. Children with diabetes who are traveling through more than one time zone should consult their pediatrician or endocrinologist for guidance on the need for altering insulin dosing. Prescription medications should be carried in original bottles, and a sufficient supply for the length of the planned trip should be taken. Required medications should be carried on the plane rather than packed in luggage because bags may be lost or exposed to unfavorable environmental conditions. Families should be counseled about the potential hazards of obtaining medications in pharmacies in developing countries, where many medications can be purchased over-the-counter without a prescription and where the names, content, and concentration of medications may be different from those of U.S. products. Parents carrying medical equipment (such as nebulizers) should remember to take adaptors for foreign electric current and bring a letter from a physician that documents the need for the equipment.[41] Similar documentation is encouraged for anaphylaxis kits that include syringes. Additional information on travel considerations for immunocompromised children is provided later in the chapter.

VACCINATION FOR INTERNATIONAL TRAVEL

Vaccination before international travel is among the most critical and complex components of the pre-travel assessment for children. The pre-travel assessment should include a review of both recommended routine childhood vaccinations and required and recommended travel-related vaccines. Vaccination recommendations change rapidly. Whereas this section provides guidance as of publication date, clinicians should obtain the most current recommendations available on the Centers for Disease Control and Prevention (CDC) Web site (see the section on international travel information resources).

ROUTINE CHILDHOOD VACCINATIONS FOR PEDIATRIC TRAVELERS

For children who will be traveling internationally, having their routine immunizations brought up to date is essential because many vaccine-preventable diseases are more prevalent in developing countries than in the United States. In particular, children who have nonmedical exemptions to routine vaccinations may be at high risk of acquiring vaccine-preventable diseases, such as measles and rubella, that no longer are endemic in the United States but still occur frequently in other countries. The pre-travel visit also may give the health care provider a unique opportunity to update the routine vaccination status of a patient who has fallen behind schedule. In certain cases, routine vaccinations may need to be accelerated to maximize protection, particularly against polio, diphtheria-tetanus-pertussis, and measles (e.g.,

measles vaccination may be recommended for children younger than 12 months).[119] The management plan for routine vaccinations will be determined by the travel destination and itinerary. For example, diphtheria and pertussis are prevalent in eastern Europe and many developing countries, and measles is still endemic in the developing world; therefore, if travel to developing countries is planned, ensuring immunity is imperative, and accelerated schedules should be considered. In addition, parents should check their own immune status because traveling with children can increase their risk of exposure to measles and other vaccine-preventable diseases. Trip activities also may increase the risk of acquiring infectious diseases such as measles; recently, numerous cases of serologically confirmed measles in internationally adopted children and their new parents and siblings who

had traveled to China to accompany them home have been reported. Data suggest that the exposure to measles occurred in China, probably at the orphanage, where an outbreak of measles was occurring.[95,96,104] In 2005, importation of measles by an unvaccinated U.S. traveler led to the largest outbreak of measles in the United States since 1996 and involved 34 confirmed cases. The index case was a 17-year-old student who had a nonmedical vaccination exemption and was working as a missionary in an orphanage in Romania, where a large measles outbreak subsequently was reported.[116] Travel in large groups on conveyances such as cruise ships can facilitate the transmission of infectious and vaccine-preventable diseases.[91] The CDC has provided consultation on managing outbreaks of varicella and meningococcal disease in pediatric travelers on international cruise ships (CDC, unpublished data).

Worldwide polio eradication efforts have decreased the number of countries where travelers are at risk for acquiring polio. In 2005, 1979 cases of wild poliovirus were reported from 16 countries; however, wild poliovirus is considered endemic in only four countries: Afghanistan, India, Nigeria, and Pakistan. These four countries never completely interrupted transmission of wild poliovirus and, through exportation, account for approximately 92 percent of all reported cases of poliomyelitis globally. Nigeria accounts for 65 percent, and India accounts for 25 percent. As of late 2006, eight countries, Angola, Bangladesh, Democratic Republic of Congo, Ethiopia, Namibia, Nepal, Niger, and Somalia, have ongoing transmission after importation.[166,167] In July 2000, an outbreak of vaccine-derived poliovirus type 1 was reported in the Dominican Republic and Haiti.[154] To ensure protection, pediatric travelers visiting countries where polio is epidemic or still endemic should be fully immunized, and clinicians should obtain up-to-date information about areas of transmission from the World Health Organization (WHO) or the CDC (see the section on international travel information resources).

Respiratory tract infections caused by influenza are a major cause of illness among travelers.[83] Influenza can occur throughout the year in tropical countries. Peak influenza rates in temperate regions of the Southern Hemisphere occur from April through September. In North America, influenza vaccine may not be available during the summer months. Although all children between the ages of 6 and 59 months and children older than 6 months with certain risk factors should have routine influenza vaccination annually, some pediatric travelers older than 59 months also should receive influenza vaccine (see Table 242–1). Travelers to the Southern Hemisphere should be vaccinated by the spring, if possible. Influenza vaccinations should be considered for travelers who are at high risk for complications from influenza for travel to (1) tropics any time of year, (2) Southern Hemisphere from April through September, (3) any destination with large groups of tourists at any time of year, or (4) any destination where influenza outbreaks are occurring.[23]

Avian influenza A (H5N1) has become a panzoonotic infection affecting regions of Asia, Africa, and the Middle East. As of December 2006, the WHO had reported 261 human cases and 157 deaths caused by avian influenza from 10 countries. Most of these cases were associated with direct contact with infected poultry.[27,168] The risk to travelers is low. However, clinicians should obtain up-to-date information about affected countries and counsel travelers going to those areas. Persons visiting areas with reports of outbreaks of H5N1 among poultry or of human H5N1 cases can reduce their risk of infection by (1) avoiding direct contact with poultry, including touching well-appearing, sick, or dead chickens; (2) avoiding poultry farms and bird markets; (3) avoiding handling surfaces contaminated with poultry feces or secretions; (4) practicing frequent and careful handwashing; and (5) consuming all foods from poultry, including eggs and poultry blood, only if they have been thoroughly cooked. Because influenza viruses are destroyed by heat, the cooking temperature for poultry meat should be 74° C (165° F).[27]

Hepatitis A, hepatitis B, *Haemophilus influenzae* type b, rotavirus, *Streptococcus pneumoniae*, and varicella are endemic in many developing countries, and vaccination should be ensured, particularly for young pediatric travelers to these regions. For detailed information about accelerating routine childhood vaccinations and indications for use in pediatric travelers, see Table 242–1.

COMMON TRAVEL-RELATED VACCINES FOR CHILDREN

An important consideration in determining travel vaccination needs is "required" versus "recommended" vaccinations. The most recent travel requirements and recommendations for vaccinations can be obtained from the CDC Travelers' Health Internet site (see the section on international travel information resources). Few vaccinations are required. The United States does not require arriving travelers to have any vaccinations for entry or return to the United States. However, immigrants, refugees, asylum seekers, and internationally adopted children migrating to the United States for permanent residence have different requirements. Some other countries may require proof of vaccination against yellow fever for entry, especially if the traveler is arriving from a country where yellow fever is present. Yellow fever vaccine is available only from certified yellow fever vaccination centers; providers can contact their state public health department to locate certified centers in their areas. Saudi Arabia requires meningococcal vaccine for travelers visiting Mecca for the Hajj or for the Umrah.[18,171] Some countries previously have required cholera vaccination, but currently no countries require vaccination as a condition of entry.[171] However, non-U.S. customs officials who "unofficially" request proof of vaccination have been reported. Cholera vaccine is not available in the United States.

Tables 242–1 and 242–2 provide general guidelines and indications for the use of routine and selected travel-related vaccines based on U.S. recommendations.[17,18,25,66,67,119] WHO recommendations may differ.[171] Depending on the complexity of the travel itinerary and the patient's medical history, the vaccination plan may need to be developed in consultation with a travel medicine or infectious disease specialist. Travel-related vaccine recommendations should be tailored carefully to the trip itinerary and based on the travel destination, season when the travel will occur, duration of the trip, and activities to be undertaken. For example, hepatitis A is endemic in most of the world, and travelers are at risk in any area where sanitation is poor. In 2006, hepatitis A vaccination became part of routine childhood recommendations in the United States for all children at 1 year of age (12 through 23 months), supplementing recommendations in 1999 for vaccination of children 2 to 18 years of age residing in states and communities with high incidence of disease and other high-risk groups. Vaccination is recommended for pediatric travelers aged 1 year or older who will be visiting countries with intermediate to high endemicity, such as Mexico, Central and South America, Asia (except Japan), Africa, and eastern Europe.[17,24,25] Intramuscular immune globulin is recommended for immunoprophylaxis against hepatitis A in children younger than 1 year. In addition, for children 1 year of age or older who will be departing sooner than 4 weeks after the pre-travel visit (and therefore may not have sufficient time for immunity to develop after hepatitis A vaccination), both immune globulin and vaccine can be given concurrently at different sites to ensure more immediate protection. Shortages of immune globulin have occurred recently, so obtaining it for hepatitis A prophylaxis may be difficult. In practice, some clinicians choose to administer hepatitis A vaccine rather than immune globulin to children who have 14 days but less than 1 month before their departure. Limited data are available about the timing of the appearance of neutralizing antibody. Among a

TABLE 242–1 Routine Childhood Vaccinations and Accelerated Schedules and Modifications for Pediatric Travelers

Vaccine	Minimum Age	Routine Schedule*	Accelerated Schedule and Modifications†	Indications for Use and Other Information‡
DTaP, DTP, DT	6 weeks	5 doses at ages 2, 4, 6, 15-18 months and 4-6 years	5 doses MI from dose 1 to dose 2: 4 weeks MI from dose 2 to dose 3: 4 weeks MI from dose 3 to dose 4: 6 months Minimum age for dose 4: 12 months MI from dose 4 to dose 5: 6 months Minimum recommended age for dose 5: 4-6 years Dose 5 is not necessary if dose 4 was administered after the 4th birthday	Use for children 6 weeks to 7 years of age. Use DT for children <7 years of age for primary series (instead of DTaP or DTP) when pertussis vaccination is contraindicated.
Tdap	11 years	One dose		Only 1 dose of Tdap is recommended. All subsequent doses of tetanus-diphtheria booster should be administered as Td. If vaccination to prevent tetanus or diphtheria disease is required for children 7-9 years old, Td should be administered. The preferred interval between Tdap and a previous dose of Td is 5 years.
Td	7 years	1 booster dose every 10 years Children ≥11 years should receive 1 dose of Tdap, followed by booster doses of Td every 10 years.	MI for booster for travel: 5 years	Td should be used rather than Tdap if Tdap is not available and for: Anybody who has already received Tdap Children 7-9 years of age See information for Tdap regarding timing of Td versus Tdap.
Haemophilus influenzae type b (Hib)	6 weeks	4 doses at ages 2, 4, 6, and 12-15 months *or* 3 doses at ages 2, 4, and 12-15 months (PRP-OMP vaccines only) Unvaccinated child >15 months: 1 dose	Accelerated schedule is available but varies by vaccine brand; see package insert for vaccine used. MI between doses: 4-8 weeks	Minimum interval between doses depends on age. Children receiving the first dose of vaccine at age ≥7 months require fewer doses to complete the series. See M. M. W. R. Morb. Mortal. Wkly. Rep. *54*:Q1-Q4, 2005, for indications. Vaccinate all children <5 years of age and children >5 years of age with special indications (e.g., asplenia, immunodeficiency).
Hepatitis A	1 year	2 doses at ages 12 and 18 months	MI from dose 1 to dose 2: 6 months	Recommended for all children at 1 year of age (12-23 months). Recommended for (1) international travelers to Mexico, Central and South America, Asia (except Japan), Africa, and eastern Europe; (2) all children residing in states, counties, and communities with existing hepatitis A vaccination programs based on high disease incidence and other high-risk groups.§ Immunogenicity: limited data are available for the timing of the appearance of neutralizing antibody. Among a sample of vaccinated persons, 54-62% were positive for neutralizing antibody 14 days after the first dose, and 94-100% were positive at 1 month.‡

TABLE 242–1 Routine Childhood Vaccinations and Accelerated Schedules and Modifications for Pediatric Travelers—cont'd

Vaccine	Minimum Age	Routine Schedule*	Accelerated Schedule and Modifications†	Indications for Use and Other Information‡
Hepatitis B¶	Birth	3 doses at ages 0-2, 1-4, 6-18 months For children 11-12 years: 3 doses at 0-, 1-, and 4-month intervals For unvaccinated adolescents 11-15 years: 2-dose vaccine series (only Recombivax HB, adult dose) at 0, 4-6 months or 3 doses of other vaccine brands as for children 11-12 years	3 doses (except 2 doses of Recombivax HB, adult dose for adolescents) MI from dose 1 to dose 2: 4 weeks MI from dose 2 to dose 3: 8 weeks MI from dose 1 to dose 3: 16 weeks Minimum age for dose 3: 6 months	Use for travelers to endemic areas, including Africa, Asia, Latin America, who plan to: Travel abroad for ≥6 months Have intimate or sexual contact with local population Work in health care setting or may have contact with blood, blood products, or body fluids Count all doses; do not restart series even if time lapse between doses is greater than recommended interval. **Accelerated schedules that may be associated with decreased immunogenicity:** 4 doses at 0, 1, 3 weeks and 6-12 months *or* 4 doses at 0, 7, 21 days and booster at 1 year
Human papillomavirus vaccine (HPV)	9 years Approved only for female patients 9-26 years	3 doses at 11-12 years at 0-, 2-, and 6-month intervals	Recommended interval dose 1 to dose 2: 2 months MI dose 1 to dose 2: 4 weeks Recommended interval dose 1 to dose 3: 6 months Recommended interval dose 2 to dose 3: 4 months MI dose 2 to dose 3: 3 months	
Influenza, trivalent inactivated vaccine (TIV) or live attenuated vaccine (LAIV)	TIV: 6 months; however, check product as minimum age varies by vaccine manufacturer LAIV: 2 years, approved for use only for persons aged 2-49 years	Recommended annually for healthy children aged 6-59 months and children aged >59 months with certain risk factors. See M. M. W. R. Recomm. Rep. *55*(RR-10):1-48, 2006. Children ≤8 years of age who are receiving influenza vaccine for first time: 2 doses Children >8 years of age and persons who previously received influenza vaccine: 1 dose	TIV: MI dose 1 to dose 2: 4 weeks LAIV: MI dose 1 to dose 2: 6 weeks	Influenza can occur throughout the year in tropical countries. Peak influenza in temperate regions of the Southern Hemisphere occurs from April through September. In North America, influenza vaccine may not be available during the summer months. Travelers to the Southern Hemisphere should be vaccinated by the spring, if possible. Consider for travelers who are at high risk for complications from influenza for travel to Tropics any time of year Southern Hemisphere from April through September Any destination with large groups of tourists at any time of year Any destination where influenza outbreaks are occurring
Measles, mumps, rubella (MMR)	6 months	2 doses at ages 12-15 months and 4-6 years	Children 6-11 months: 1 dose, then revaccinate at 12-15 months of age and 4-6 years of age Children >12 months vaccinated with 1 prior dose: 1 additional dose at least 4 weeks after dose 1 Unvaccinated children >12 months: 2 doses separated by 4 weeks MI between doses: 4 weeks	Do not administer MMR for 3 months after immune globulin for hepatitis A prophylaxis; see M. M. W. R. Morb. Mortal. Wkly. Rep. *54*:Q1-Q4, 2005, for deferral times for blood products and immune globulin administered for other indications. Defer immune globulin administration for 2 weeks after MMR vaccination. Monovalent vaccines are available for measles, mumps, and rubella. Combination MMRV (measles-mumps-rubella-varicella vaccine) can be used for children 12 months-12 years.

TABLE 242–1 Routine Childhood Vaccinations and Accelerated Schedules and Modifications for Pediatric Travelers—cont'd

Vaccine	Minimum Age	Routine Schedule*	Accelerated Schedule and Modifications†	Indications for Use and Other Information‡
Meningococcal (quadrivalent A, C, Y, W135) Conjugate vaccine (MCV4) Polysaccharide vaccine (MPSV4)	MCV4: 11 years MPSV4: 3 months for serogroup A protection, standard recommended minimum age: 2 years (see indications)	MCV4: routine vaccination, 1 dose for children at age 11-12 years MCV4: 1 dose for high-risk populations and selected travelers ≥2 years MCV4 for children >2 years	MCV4: no booster dose recommended MPSV4: every 3-5 years for high-risk persons¶	Meningococcal vaccination is required for travelers to annual Hajj in Mecca, Saudi Arabia. Vaccination is recommended for travel to sub-Saharan Africa during dry season (December through June) or for travel to any countries where epidemic is occurring. Recommended for all children at age 11-12 years, unvaccinated adolescents at high-school entry (15 years of age), all college freshmen living in dormitories, and certain high-risk children ≥2 years of age with terminal complement deficiencies or anatomic or functional asplenia and certain other high-risk groups. See M. M. W. R. Recomm. Rep. *54*(RR-7):1-21, 2005. For children ≥3 months of age traveling to risk areas (sub-Saharan Africa): Serogroup A meningococcal polysaccharide vaccine, given as MPSV4, can be immunogenic in children as young as 3 months. Responses to other serogroup components are poor or unknown in children ≤2 years of age. For children younger than 18 months, it is administered as 2 doses separated by a 3-month interval. See *Red Book 2006*.
Pneumococcal conjugate 7-valent (PCV)	6 weeks	4 doses at ages 2, 4, 6, and 12-15 months	MI between doses: 4-8 weeks, depending on age Number of doses varies with age at first dose administered and current age.	Minimum intervals between doses depend on age. Children receiving the first dose of vaccine at age ≥7 months require fewer doses to complete the series. See M. M. W. R. Morb. Mortal. Wkly. Rep. *54*:Q1-Q4, 2005. Pneumococcal polysaccharide vaccine (PPV23) is routinely recommended for high-risk persons aged ≥2 years. See M. M. W. R. Morb. Mortal. Wkly. Rep. *54*:Q1-Q4, 2005.
Polio-inactivated poliovirus vaccine (IPV)	6 weeks	4 doses at ages 2, 4, 6-18 months and 4-6 years	Previously unvaccinated children: 3 doses MI between doses: 4 weeks Preferred interval between dose 2 and dose 3: 2 months Minimum age for dose 2: 10 weeks Minimum age for dose 3: 14 weeks Minimum age for dose 4: 18 weeks Previously unvaccinated children <4 years at completion of dose 3: 4 doses Previously unvaccinated children ≥4 years at completion of dose 3: 3 doses Previously vaccinated adult (≥18 years): 1 booster recommended for travel to risk area MI between doses: 4 weeks	Primary series is recommended for all travelers; booster dose for adults is recommended for international travelers to Africa or Asia; not routinely recommended for travel to Latin America except to Haiti or Dominican Republic, where an outbreak occurred in 2001. Single booster of IPV for previously vaccinated adults confers lifetime immunity. Oral poliovirus vaccine (OPV) is no longer recommended or available in the United States. For use in other countries, the World Health Organization recommends birth as the minimum age of administration. The minimum interval between doses is 4 weeks. OPV can be used for children younger than 6 weeks traveling to areas with polio transmission.

TABLE 242–1 Routine Childhood Vaccinations and Accelerated Schedules and Modifications for Pediatric Travelers—cont'd

Vaccine	Minimum Age	Routine Schedule*	Accelerated Schedule and Modifications†	Indications for Use and Other Information‡
Rotavirus (RV)	6 weeks	3 doses at ages 2, 4, 6 months	First dose must be administered at age 6-12 weeks Maximum age of any dose: 32 weeks MI between doses: 4 weeks Minimum age for dose 2: 10 weeks Minimum age for dose 3: 14 weeks	Vaccine series should not be started at age 13 weeks. RV should not be administered to children aged 33 weeks regardless of the number of doses received at age 6-32 weeks. If possible, defer rotavirus vaccination for 6 weeks after receipt of antibody-containing product such as immune globulin. However, if the 6-week deferral would cause the first dose of RV to be scheduled for age ≥13 weeks, a shorter deferral should be used to ensure that the first dose of RV is administered no later than 13 weeks.
Varicella	12 months	2 doses at 12-15 months of age and 4-6 years	MI between dose 1 and dose 2 for children <13 years: 12 weeks MI between dose 1 and dose 2 for persons ≥13 years: 4 weeks Minimum age for dose 2: 15 months	Do not administer varicella vaccine for 3 months after immune globulin for hepatitis A prophylaxis; see M. M. W. R. Morb. Mortal. Wkly. Rep. *54*:Q1-Q4, 2005, for deferral times for blood products and immune globulin administered for other indications. Defer immune globulin administration for 2 weeks after varicella vaccination. Combination MMRV (measles-mumps-rubella-varicella vaccine) can be used for children aged 12 months-12 years.

**Number of doses and recommended ages. Minimum age is the U.S. recommendation unless otherwise noted. Recommendations in the U.S. schedule may be different from those of the World Health Organization and other countries.*

†Number of doses and minimum interval (MI) between doses. Note: interval represents time to dose.

‡Contraindications: anaphylactic reaction to prior dose or to any vaccine component or moderate to severe acute illness is a contraindication for all vaccines.

§See M. M. W. R. Recomm. Rep. 55(RR-7):1-23, 2006.

¶Combination hepatitis A–hepatitis B (TWINRIX) is available for use in persons 18 years of age and older. The vaccine, which is composed of inactivated viral components, is administered intramuscularly. The schedule involves 3 doses at 0, 1, and 6 months. It can be administered at an accelerated schedule of 4 doses at 0, 7, and 21 days and 1 year.

¶A second dose of meningococcal vaccine is recommended for persons previously vaccinated with MPSV who remain at high risk for meningococcal disease. MCV4 is preferred for revaccination of persons aged 2 to 55 years, but a second dose of MPSV is acceptable. Certain experts recommend a second dose of MPSV 3 years after the first dose for persons at increased risk for meningococcal disease.

sample of vaccinated persons, 54 to 62 percent were positive for neutralizing antibody 14 days after the first dose, and 94 to 100 percent were positive at 1 month.[24] If the first dose of hepatitis A vaccine is administered less than 30 days before departure, patients should be counseled that they may not be fully protected against hepatitis A virus and that they should take extra precautions with food and water to reduce exposure risk (see Table 242–4).[24]

Meningococcal disease occurs sporadically worldwide. Epidemic disease has been reported in India, Saudi Arabia, and sub-Saharan Africa; indeed, recurrent epidemics of meningococcal disease occur in sub-Saharan Africa, mainly from December to June (the dry season). Serogroup A is the most common cause of epidemics outside the United States, but serogroup C and other serogroups also have been associated with epidemics. Serogroup W-135 meningococcal infection has been reported recently in travelers returning from Saudi Arabia after visiting the Hajj.[151] Two meningococcal vaccines, a polysaccharide vaccine (MPSV4) and a conjugate vaccine (MCV4), are available in the United States. Both vaccines are quadrivalent and effective against serogroups A, C, Y, and W-135. MCV4 is expected to provide better, longer lasting protection. In the United States, routine MCV4 vaccination is recommended for all children at the 11- to 12-year-old visit, unvaccinated adolescents at high-school entry (15 years of age), and college freshmen living in dormitories. Meningococcal vaccination is recommended for pediatric travelers 2 years of age or older who are visiting sub-Saharan Africa during the dry season or any country where an epidemic caused by a vaccine serogroup is occurring. MCV4 is the preferred vaccine for children 2 years of age and older. MCV4 is also recommended for children 2 to 10 years old who are at risk. Although it is less immunogenic than when it is administered to older children and adults, MPSV4 also can be used in children as young as 3 months to 2 years of age to provide protection against serogroup A, such as travelers to areas with an epidemic or during seasonal transmission. These children should have two doses, 3 months apart.[22,25,120]

Yellow fever occurs year-round in the predominantly rural areas of sub-Saharan Africa and South America; however, outbreaks have been increasing in incidence, particularly in Africa.[173] The resurgence of yellow fever in Brazil has raised concern about increased risk in other areas of Latin America and the possibility of urban yellow fever transmission.[157,158] Although a rare disease, yellow fever continues to be reported in travelers, particularly unvaccinated travelers, and it usually is fatal. Preventive measures taken against yellow fever should include the use of personal protection against mosquitoes and vaccination. As discussed previously, some countries require yellow fever vaccination for travelers arriving from endemic regions; current requirements and recommendations for vaccination based on travel destination can be obtained from the CDC Travelers' Health Internet site. Yellow fever vaccine is largely considered to be a safe and effective vaccine. However, the vaccine has been found to be associated with an increased risk for development of encephalitis and other severe reactions in young infants.[119] The vaccine should not be used in children younger than 6 months. It should be used with caution in children 6 to 9 months of age after discussion with a travel medicine expert to weigh the risks and benefits.[18] Medical waivers can be given to children who are too young for vaccination and to those who have other contraindications to

TABLE 242–2 Common Travel-Related Vaccines and Immune Globulin for Children

Vaccine*	Vaccine Type	Route	Minimum Age	Primary Series†	Booster or Revaccination‡	Accelerated Schedule	Protection After	General Indications for Use§
BCG	Live attenuated bacteria	ID, SC	Birth	1 dose	None	None	2 months after dose (WHO)	Consider for children <1 year who will be long-term travelers residing in high-risk areas to protect against meningeal and miliary tuberculosis.
Immune globulin (IG)	Antibody from pooled human plasma	IM	Birth	1 dose	3-6 months	None	Immediate	Use to prevent hepatitis A infection in children <2 years of age who are traveling to risk areas or for persons departing within 4 weeks. Defer MMR and varicella vaccination for 3 months after IG administered for hepatitis A prevention; defer the administration of IG for hepatitis A prevention for 2 weeks after MMR or varicella vaccination. Defer rotavirus vaccine (RV) administration for 6 weeks if possible. However, if 6-week deferral would cause the first dose of RV to be scheduled for age ≥13 weeks, a shorter deferral interval should be used to ensure that the first dose of RV is administered no later than age 13 weeks. Defer immune globulin administration for 2 weeks after MMR or varicella vaccination. See M. M. W. R. Morb. Mortal. Wkly. Rep. *54*:Q1-Q4, 2005.
Japanese encephalitis	Inactivated virus	SC	1 year	3 doses at 0, 7, and 14 or 30 days	2-3 years Booster: 1 dose	None	10-14 days after dose 3	Use for travelers to selected areas of Asia, Oceania (Australia and Papua New Guinea), Russia, especially long-term travelers to rural, agricultural endemic areas or epidemic regions during seasonal transmission (usually May to September). Allergic reactions (urticaria, angioedema, respiratory distress, anaphylaxis) occur in approximately 0.6% of persons. Anaphylaxis can occur up to 10 days after vaccination; therefore, all doses of vaccine should be administered at least 10 days before departure. Persons vaccinated should remain in areas with access to health care. Observe for 30 minutes after vaccine administration and counsel about possible delayed hypersensitivity reactions. Persons with history of urticaria are at greater risk for development of allergic reactions. Mild adverse reactions (headache, fever, local reactions) occur in approximately 20% of vaccinees.

Rabies Human diploid cell vaccine (HDCV) Rabies vaccine adsorbed (RVA) Purified chick-embryo cell culture vaccine (PCEC)	Inactivated virus; cell culture derived	IM, ID (HDCV only)	US: None WHO: 1 year	3 doses at 0, 7, and 21 or 28 days	6 months-3 years, depending on risk or serologic tests Continuous risk: check antibody titer every 6 months Frequent exposures: check antibody titer after 2 years WHO: 1 year after primary series, then every 2-3 years Booster: 1 dose	None	14 days after dose 3	Use for travelers to rabies-endemic countries. Vaccination is recommended for long-term travel in rural areas or in areas with limited access to health care. Travelers with extensive unprotected outdoor, evening, and nighttime exposure in rural areas, such as backpacking, should consider vaccination even for trips of short duration. Widespread worldwide rabies distribution. See Health Information for Travelers for list of countries that have not reported cases of rabies recently. Complete intradermal rabies vaccine series at least 7 days before starting chloroquine or mefloquine. Postexposure vaccination is required even for persons who receive vaccination before exposure. After exposure in vaccinated person: 2 doses at 0, 3 days (no rabies immune globulin required) After exposure in unvaccinated person: rabies immune globulin (20 IU/kg) plus vaccination with 5 doses at 0, 3, 7, 14, and 28 days
Typhoid (ViCPS)	Capsular polysaccharide	SC	2 years	1 dose	2 years	None	14 days after dose	Use recommended for travelers to Africa, Asia, and Latin America for long-term stays, travel outside usual tourist destinations, or travelers who desire maximal protection. Patients should be counseled about protective efficacy of vaccine (approximately 50-74% when studied in endemic areas) and importance of other preventive measures.
Typhoid oral (Ty21a)	Live attenuated bacteria	Oral	6 years	4 doses at 0, 2, 4, 6 days	5 years	None	7-10 days after last dose	See indications for typhoid ViCPS. Patients should be counseled about protective efficacy of vaccine (approximately 60-85% when studied in endemic areas) and importance of other preventive measures. Must be swallowed (cannot be chewed) 1 hour before meal, and vaccine must be refrigerated until administration. Do not administer within 24 hours of mefloquine, atovaquone-proguanil, doxycycline, or any other antibiotic. Contraindicated for immunocompromised patients
Yellow fever	Live attenuated virus	SC	4 months	1 dose	10 years	None	10 days after dose	Use for travelers to selected areas of Africa and South America. Yellow fever has not been reported in Asia; however, some countries require proof of vaccination if the traveler is arriving from a yellow fever–endemic country. Yellow fever vaccination for children 4-9 months should be discussed with an expert to weigh risk of adverse events against risk of yellow fever. Reports of rare serious adverse events of multiorgan system failure after vaccination. Contraindicated for patients who are immunocompromised or have allergy to eggs.

**Cholera vaccine is no longer available in the United States. It is administered as a 2-dose series at 1- to 4-week intervals. It had limited efficacy and was associated with frequent adverse effects. Tick-borne encephalitis vaccine is not available in the United States. It is administered as a 4-dose series at 0, 28-day, 42-day, and 1-year intervals, with booster doses required every 3 to 5 years. The vaccine is available in Europe.*

†Number of doses and recommended ages and intervals. Note: interval represents time from dose.

‡Number of doses and recommended ages and intervals.

§Contraindications: anaphylactic reaction to prior dose or to any vaccine component or moderate to severe acute illness is a contraindication for all vaccines.

BCG, bacille Calmette-Guérin; MMR, measles, mumps, rubella; WHO, World Health Organization.

vaccination, such as immunodeficiency. More recently, life-threatening severe illness with major organ system failure has been reported in association with yellow fever vaccination. The syndrome usually consists of fever, jaundice, and multiple organ system failure, and more than half of the people who have developed these adverse effects have died. The risk is thought to be approximately 1 per 200,000 to 300,000 doses in persons younger than 60 years and 1 per 40,000 to 50,000 doses in persons 60 years of age and older. The risk is greater in persons with a history of thymectomy, thymoma, myasthenia gravis, or DiGeorge syndrome.[30] Further studies are being conducted.[33,92,157] In the interim, the CDC has recommended that given the risk of serious illness and death from yellow fever,[94] evidence of increasing transmission of the disease,[129] and the known effectiveness of the vaccine, clinicians should continue to use yellow fever vaccine to protect travelers.[18] Health care providers should carefully review travel itineraries to ensure that only people traveling to areas endemic for yellow fever or areas where yellow fever activity is reported receive yellow fever vaccine.[18,50,52,171]

Japanese encephalitis (JE) is a viral infection transmitted by *Culex* mosquitoes that bite from dusk to dawn. JE occurs year-round in tropical regions and primarily from May through October in temperate zones. The risk is greatest for travelers to rural Asia, where the mosquito breeds in rice fields and other agricultural areas. JE is associated with high rates of case fatalities and severe neurologic sequelae, especially in young children and the elderly. Vaccination should be considered for pediatric travelers 1 year of age or older who will visit and reside in areas where JE is endemic or epidemic, especially during the transmission season, or for pediatric travelers whose activities include trips to rural farming areas. Short-term travelers (<30 days) who visit only major urban areas are at lower risk for acquiring JE and generally do not need to be vaccinated.[18]

Rabies occurs worldwide except in Antarctica. In certain areas of the world, including (but not limited to) parts of Brazil, Bolivia, Colombia, Ecuador, El Salvador, Guatemala, India, Mexico, Nepal, Peru, the Philippines, Sri Lanka, Thailand, and Vietnam, canine rabies remains highly endemic. Rabies also occurs in other wild animals, including bats. Rabies vaccine should be considered for children visiting rabies-endemic countries for longer than 1 month, those undertaking extensive outdoor activities such as backpacking or camping in endemic countries, or children traveling to areas where access to health care is limited. To reduce the risk of acquiring rabies, children and their families should be counseled to stay away from stray dogs and other animals, especially if traveling to Latin America, Asia, or Africa.[18]

Typhoid vaccine is recommended for pediatric travelers visiting developing countries, especially for prolonged periods, or traveling outside the usual tourist destinations. Two vaccines are available in the United States: (1) an attenuated, live oral vaccine that can be administered to children aged 6 years and older and (2) an injectable Vi capsular polysaccharide vaccine that can be administered to children, starting at 2 years of age. Parents should be cautioned, however, that vaccination is not 100 percent effective, and precautions regarding safe food and water should be followed.[18]

Finally, bacille Calmette-Guérin (BCG) vaccine is a live vaccine prepared from attenuated strains of *Mycobacterium bovis;* BCG is used primarily in young infants to prevent disseminated and other forms of life-threatening disease caused by tuberculosis, such as tuberculous meningitis. BCG is recommended by the WHO for administration at birth; in the United States, BCG is recommended in only limited circumstances, such as unavoidable risk of exposure to *Mycobacterium tuberculosis.* Vaccination of a young pediatric traveler (non–HIV infected and with a negative tuberculin skin test response) might be considered, therefore, if long-term stay (such as children of missionaries or expatriates) is planned in a country with a high prevalence of tuberculosis and prolonged contact with active tuberculosis cases is thought to be a potential problem.[3,119,146] A rate of tuberculin skin test seroconversion of 1.8 percent was reported among travelers to areas endemic for tuberculosis.[34] More recently, 10 percent of 357 travelers to the Hajj for pilgrimage had evidence of seroconversion when tested with use of QuantiFERON, a whole-blood assay for tuberculosis antigens.[161] Multidrug-resistant tuberculosis has been increasing in incidence worldwide. Cases of extensively drug-resistant tuberculosis have been reported from several countries, including Estonia, Latvia, Lesotho, Peru, the Philippines, South Africa, Swaziland, and the United States.[169,170] From 2000 to 2004, a survey of an international network of tuberculosis laboratories determined that of 17,690 isolates, 20 percent were multidrug resistant and 2 percent were extensively drug resistant.[47] BCG vaccine can be obtained from the Canadian subdivisions of Sanofi Pasteur *(http://www.sanofipasteur.ca)*. More generally, children traveling to countries with a high prevalence of tuberculosis should be skin tested before and after travel to document possible exposure to tuberculosis. According to reports, U.S. children who had traveled to countries with a high prevalence of tuberculosis within the previous 12 months were 3.9 times more likely to have positive tuberculin skin test results than were children who lived in the same U.S. areas but had not traveled.[86] Additional information about preventing other infectious diseases is provided in this chapter in the section on preventing other infectious diseases in pediatric travelers.

One limitation to performing adequate travel-related vaccination is that patients may not seek medical assessment in sufficient time to complete vaccination and acquire protective immunity. Providers should ask patients routinely whether they are planning any travel in the future, particularly in the months before holidays and summer vacations. Multiple doses are required for some travel-related vaccines. In addition, other time-related vaccination issues also should be considered; for example, a patient who receives JE vaccine should complete the series of three doses at least 10 days before travel so that the patient can be observed for delayed allergic reactions.

PREVENTION OF MALARIA

EPIDEMIOLOGY OF MALARIA

Malaria is a parasitic infection caused by one of four species of *Plasmodium: Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, or *Plasmodium malariae*. It is transmitted by the bite of an infective female *Anopheles* mosquito. Malaria is endemic in more than 100 countries on five continents; transmission occurs primarily in the tropic and subtropical regions of sub-Saharan Africa, Asia, Latin America, the Caribbean, the Middle East, and Oceania. Globally, malaria is responsible for 300 to 500 million clinical infections and 1.5 to 2.7 million deaths annually, with most caused by *P. falciparum*, principally in young children and pregnant women.[172]

An estimated 10,000 to 30,000 travelers from industrialized countries are thought to contract malaria each year, but these numbers probably are underestimated because they do not include travelers in whom malaria was diagnosed and treated abroad.[70,71,87] Of 5794 cases of malaria in U.S. civilians reported to the CDC from 1992 through 2000, 976 (17%) of the cases occurred in children younger than 18 years. Among children with malaria, 343 (35%) were 1 month to 5 years old, 215 (22%) were 6 to 9 years old, 226 (23%) were 10 to 14 years old, and 192 (20%) were 15 to 17 years old (CDC, unpublished data).

In 2003, 1268 imported malaria cases and seven deaths due to malaria among persons in the United States were reported to the CDC. Of 1201 imported cases in which the region of acquisition was known, the majority (70.0%) were acquired in Africa, 14.7

percent were acquired in Asia, 12.3 percent were acquired in the Americas, and 3.1 percent were acquired in Oceania. *P. falciparum* species was identified in 53.4 percent and *P. vivax* was identified in 22.9 percent of infected persons, with the species identified in blood films. Approximately 82.7 percent of imported cases of malaria among U.S. civilians occurred among persons who were either not taking prophylaxis or were taking nonrecommended prophylaxis for the region to which they were traveling. Reviews of deaths attributed to malaria in the United States indicate that failure to take or to adhere to recommended antimalarial chemoprophylaxis, to promptly seek medical case for post-travel illness, and to promptly diagnose and treat suspected malaria contributed to fatal outcomes.[46,90,108]

The majority (53.9%) of the malaria cases occurred among persons visiting family or relatives, whereas 12.5 percent occurred among tourists and 9.2 percent occurred among missionaries or their dependents. Retrospective reviews of malaria in children also have found that a substantial proportion of cases occurred in recent immigrants and the children of former immigrants who had traveled to visit their family's country of origin.[12,46,63,128] These data highlight the importance of pre-travel assessment and counseling, particularly for foreign-born persons, who may assume that they are protected by natural immunity or do not perceive the risk of acquisition of malaria by their children who accompany them on returning to visit their home country.

PREVENTING MALARIA IN PEDIATRIC TRAVELERS

The substantial proportion of U.S. civilian malaria cases reported in children younger than 18 years underscores the importance of pre-travel counseling and strategies for malaria prevention. Young children and nonimmune persons of any age are at greater risk for development of severe complications from malaria. Prevention of malaria in pediatric travelers depends first on obtaining current and accurate information about the risk of acquiring malaria in proposed travel destinations and determining whether planned activities, such as rural versus urban travel, and the season of travel place the traveler at increased risk of exposure. Information on the geographic- and country-specific risks of acquiring malaria is available from multiple sources. Selected Web sites with information about the country-specific risk of acquiring malaria are listed in this chapter in the section on international travel information resources.

After a thorough assessment of the risk of acquiring malaria has been made, prevention strategies for pediatric travelers are twofold: personal protection measures against contact with mosquitoes and antimalarial chemoprophylaxis. The first mainstay of prevention of malaria is appropriate and effective use of personal protection measures. All travelers to malaria-endemic areas should be counseled on recommended measures to avoid bites from *Anopheles* mosquitoes, which typically are evening and nighttime feeders. Such measures include wearing clothing that reduces the amount of exposed skin (such as long-sleeved shirts, long pants tucked into socks, hats, stroller nets) and, whenever possible, remaining in well-screened or enclosed air-conditioned areas. Travelers staying overnight in facilities without air conditioning or screens should use insecticide-treated mosquito nets over the beds. Stroller nets can be used for children in strollers. Bed nets that have been treated with insecticide such as permethrin are more effective in preventing malaria than are untreated bed nets and are safe for children.[109] Travelers can purchase permethrin to spray on the bed nets or purchase pretreated (or impregnated) bed nets. Permethrin also can be sprayed on clothing, but it should not be applied directly to skin. During the evening, insecticide also can be sprayed inside rooms. Another important focus of counseling for personal protection measures is appropriate use of insect repellent on exposed skin.

The CDC recommends the use of repellent products with active ingredients registered with the U.S. Environmental Protection Agency (EPA). In scientific studies, two registered products, DEET (*N*,*N*-dimethyl-*m*-toluamide) and picaridin (KBR 3023), have been demonstrated to have a higher degree of efficacy than that of products containing other repellents. In recent studies, repellent products containing oil of lemon eucalyptus were tested against mosquitoes in the United States and were found to provide protection similar to that of low concentrations of DEET. Other products have been evaluated for repellent activity. However, they have not been studied as well as has DEET and may not be safe for use in children. Most botanical products provide relatively limited or no protection.

Some controversy has occurred regarding the recommended concentration of DEET for pediatric use. In 1998, the EPA conducted an extensive review of DEET safety. The agency concluded that no evidence indicates that DEET is toxic to infants or children. Additional evaluations have not demonstrated a link between seizures and topical use.[18,21] DEET formulations of up to 50 percent can be used for children older than 2 months. The concentration of DEET affects the duration of protection. Higher concentrations provide longer protection; however, the duration of protection reaches a plateau at approximately 30 to 50 percent. Therefore, most clinicians recommend products having up to 30 percent for children. In a laboratory study, a product with 23.8 percent DEET provided an average of 5 hours of protection (range, 3 to 6 hours), and a product with 6.65 percent DEET provided an average of 2 hours of protection (range, 1.5 to 2.8 hours). Duration of protection may be affected by the environmental temperature, sweating, and wind conditions.[21,53] DEET should not be used on children younger than 2 months.

The EPA recommends the following precautions in use of insect repellents:

- Apply repellents only to exposed skin or clothing.
- Never use repellents over cuts, wounds, or irritated skin.
- Do not apply to eyes or mouth, and apply sparingly around ears. When using sprays, do not spray directly on face—spray on hands first and then apply to face.
- Do not allow children to handle the product. When using on children, apply to your own hands first and then put it on the child. You may not want to apply to children's hands.
- Use just enough repellent to cover exposed skin or clothing. Heavy application and saturation generally are unnecessary for effectiveness. If biting insects do not respond to a thin film of repellent, then apply a bit more.
- After returning indoors, wash treated skin with soap and water or bathe. This procedure is particularly important when repellents are used repeatedly in a day or on consecutive days. Also, wash treated clothing before wearing it again. (This precaution may vary with different repellents; check the product label.)
- If you or your child gets a rash or has other reactions from an insect repellent, stop using the repellent, wash the repellent off with mild soap and water, and call a local poison control center for further guidance. If you go to a physician because of the repellent, take the repellent with you to show the physician.[21,53]

Products that contain repellents and sunscreen generally are not recommended because of the need to reapply sunscreen more frequently than repellent.[5] Mosquito coils should be used with extreme caution in the presence of children to avoid burns and inadvertent ingestion.[29]

Clinicians are encouraged to stress to parents and children alike the importance of using personal protection measures. Despite the demonstrated efficacy of these measures, studies have found that only 17 percent of adult travelers with malaria reported

using insect protection methods and only 11 percent took the recommended chemoprophylaxis.[70]

The second mainstay of malaria prevention is chemoprophylaxis. Selection of the appropriate drug for antimalarial chemoprophylaxis must be based on numerous factors: the most recent information available about malaria in the proposed travel destinations; the trip itinerary; the age, weight, and medical history of the traveler; the personal preference for the frequency of dosing and the duration of chemoprophylaxis on return from the trip; and the cost of medication. These decisions can be challenging for primary care providers and clinicians with limited experience in infectious disease and travel medicine, so when in doubt, clinicians should seek the advice of a travel medicine or infectious disease expert. In addition, the CDC provides resources with guidance on appropriate use of and recommended regimens for antimalarial chemoprophylaxis (listed in the section on international travel information resources).

Figure 242–2 outlines an algorithm for determining appropriate antimalarial chemoprophylaxis regimens for pediatric travelers. Maps of malaria-endemic areas and zones of drug resistance, which can be used as visual aids, are presented in Figures 242–3 to 242–5. Because data on the distribution of drug-resistant malaria are evolving constantly, in addition to using the information in this chapter, clinicians always should obtain the most recent information about the risk of malaria and zones of drug resistance before prescribing malaria chemoprophylaxis.[19,137] For example, in November 2006, an outbreak of malaria caused by *P. falciparum* was reported in Kingston, Jamaica, an area not considered endemic for malaria. As of December 2006, 107 cases had been confirmed, and the CDC recommended malaria chemoprophylaxis for all travelers staying overnight in Kingston. Although the recommendation is expected to be temporary, it highlights the importance of obtaining current information about malaria for any overseas destination.[28]

The first decision point in selecting appropriate antimalarial chemoprophylaxis is whether travel is occurring in a region of chloroquine-sensitive or chloroquine-resistant malaria. For travel to areas with chloroquine-sensitive malaria, chloroquine is the drug of choice for antimalarial chemoprophylaxis. *P. ovale*, *P. malariae*, and most *P. vivax* are widely sensitive to chloroquine; however, chloroquine-resistant *P. vivax* is an emerging problem and has been reported from Guyana, Papua New Guinea, India, Burma (Myanmar), and areas of Indonesia.[19,72] In addition to chloroquine-resistant *P. vivax*, chloroquine-resistant *P. falciparum* has been reported from these areas, and consequently chloroquine would not be recommended as chemoprophylaxis for travelers to these regions.

If the traveler is visiting a region with chloroquine-resistant malaria, the next decision point is whether travel will include regions with chloroquine-resistant malaria only or both chloroquine- and mefloquine-resistant malaria. Chloroquine-resistant *P. falciparum* is widespread and exists in all malaria-endemic areas except Mexico, the Caribbean, Central America west of the former Panama Canal Zone, Argentina, and parts of the Middle

Atlanta, U.S. Department of Health and Human Services, Public Health Service, 2007.)*

East and China.[72] In some regions, *P. falciparum* may be resistant to both chloroquine and mefloquine; these areas currently are limited to the borders of Thailand with Myanmar (Burma) and Cambodia, the western provinces of Cambodia that border Thailand, and the eastern states of Myanmar (Burma), including the states of Shah, Kayin, and Kayan.[18,72] For travel to areas with chloroquine-resistant malaria, three current antimalarial chemoprophylaxis options are mefloquine (Lariam), atovaquone-proguanil (Malarone), and doxycycline. The CDC no longer recommends the use of chloroquine-proguanil for chemoprophylaxis in chloroquine-resistant areas. For travel to areas with chloroquine- and mefloquine-resistant malaria, either atovaquone-proguanil or doxycycline can be used. Primaquine can be used as an option for primary prophylaxis in special circumstances. Clinicians should contact the CDC Malaria Hotline (770-488-7788) for additional information. Primaquine also can be used for terminal prophylaxis to prevent relapses of *P. vivax* or *P. ovale*. In general, terminal prophylaxis is indicated only for persons who have had prolonged exposure to malaria-endemic areas (missionaries, expatriates).[18] Tafenoquine, a long-acting primaquine analogue, is being investigated and may be approved for malaria chemoprophylaxis in the future.[32,72,79,136,137]

In evaluating options for antimalarial chemoprophylaxis, physicians should review each medication for contraindications and weight and age restrictions (Table 242–3). Chloroquine is relatively well tolerated in children. In the United States, chloroquine is available in tablet form; in Europe and other countries, it is also available as a syrup. Mefloquine can be used safely in children weighing less than 15 kg and may be useful for longer trips because it is administered once weekly.[88] However, it must be continued for 4 weeks after leaving the malarious area, and no liquid preparation is available. Doses for children are one fourth, one half, and three fourths of a tablet, depending on weight. No data are available on the use of atovaquone-proguanil in children weighing less than 11 kg; however, studies are in progress. For children who weigh more than 11 kg and are at risk of acquiring chloroquine-resistant *P. falciparum* infection, atovaquone-proguanil can be advantageous for short trips because it is started 1 to 2 days before the trip commences and can be stopped 7 days after the trip. However, the patient or parent must remember to take or to administer the medication daily. It is available in pediatric tablet form. Doxycycline is contraindicated in children younger than 8 years because of concern about the propensity of tetracyclines to stain growing teeth or to potentially affect developing bones. For older children, doxycycline must be administered daily and continued for 4 weeks after departing the malaria-endemic area.[18,72,79]

The importance of determining appropriate antimalarial chemoprophylaxis regimens for travelers and counseling to improve compliance cannot be overemphasized. In retrospective reviews of pediatric malaria cases, between 75 and 100 percent of infected children had received no or inadequate chemoprophylaxis.[46,128,159] Finally, effective pre-travel malaria prevention counseling includes anticipatory guidance for parents about recognition of and response to symptoms of malaria infection in young pediatric travelers. Parents should be counseled that although compliance with personal protection measures and chemoprophylaxis will decrease the risk, it cannot guarantee prevention of malaria infection. They should be instructed about the symptoms of malaria infection, such as fever, headache, vomiting, diarrhea, and myalgia, and be counseled to seek immediate medical attention if symptoms occur. Delay in recognition and treatment of malaria is associated directly with an increase in rates of morbidity and mortality; therefore, prompt and appropriate initiation of effective therapy is paramount.[18,57,70,71,145,165] Parents also should be advised that some types of malaria can become symptomatic several weeks to months after exposure, and therefore prompt medical attention should be sought even if illness develops in a child months after international travel to malaria-endemic areas.

PREVENTION OF OTHER INFECTIOUS DISEASES IN PEDIATRIC TRAVELERS

Because the epidemiology of many diseases is evolving, prevention hinges on the clinician's being knowledgeable about information on current outbreaks and risk in planned travel destinations, evaluating risk based on planned activities and the season of travel, and providing appropriate counseling and vaccination, if available. Information about specific infectious disease risks can be obtained from numerous sources listed in the section on international travel information resources. More detailed information about specific vaccinations is included in the section on vaccination for international travel.

A variety of pathogens increasingly are being recognized as emerging infectious diseases in travelers. In addition to malaria, other vector-borne infectious diseases are among the important diseases for consideration in travelers. Dengue is one of the most significant vector-borne viral infections worldwide and is endemic in Asia, the South Pacific, Africa, Latin America, and the Caribbean. Worldwide, an estimated 50 to 100 million cases of dengue fever occur annually; of these cases, 200,000 to 500,000 are dengue hemorrhagic fever. Dengue fever has been reported among 2 to 14 percent of ill travelers.[11,55,110,163] Epidemics of dengue hemorrhagic fever, the more severe clinical form of dengue fever, occur every 3 to 5 years in Southeast Asia and are an emerging problem in Latin America.[115] Epidemics caused by all four serotypes (1 to 4) have become progressively more frequent and larger in the past 25 years. As of 2004, dengue fever is endemic in most tropical countries of the South Pacific, Asia, the Caribbean, the Americas, and Africa. In addition, most tropical urban centers in these regions have multiple dengue virus serotypes co-circulating (hyperendemicity), which increases the risk of dengue transmission and the risk for dengue hemorrhagic fever.[18] Outbreaks of dengue fever also have occurred in Hawaii and along the United States–Mexican border.[26,124,150] Dengue is transmitted primarily by day-biting *Aedes aegypti* mosquitoes, which breed in flower vases, barrels, and discarded tires that collect water. Transmission occurs in rural and urban areas, but the risk is greatest in urban areas. Prevention should focus on protection against mosquito bites. Travelers to areas of risk should be counseled to apply repellent during the day, even while visiting cities. No vaccine is available, and previous infection with one of the four serotypes does not protect against infection with another serotype. The risk of contracting dengue hemorrhagic fever increases after subsequent infection with a different serotype.[147]

Chikungunya virus is an alphavirus that exists in tropical Africa and is transmitted by the bite of infected mosquitoes. Because chikungunya fever epidemics are sustained by human-mosquito-human transmission, the epidemic cycle is similar to those of dengue and urban yellow fever. Infection is associated with fever, headache, severe joint pain, and, in approximately half of the cases, a generalized maculopapular rash similar to that of dengue virus infection. Large outbreaks of chikungunya have been reported recently on several islands in the Indian Ocean and in India. During 2005 to 2006, 12 cases were reported in travelers who arrived in the United States from areas known to be epidemic or endemic for chikungunya virus.[16] No vaccines or specific preventive medications are available; therefore, prevention measures should focus on personal protection against mosquito bites and awareness of local epidemics.

African trypanosomiasis (sleeping sickness), a parasitic infection transmitted by the bite of a tsetse fly, occasionally has been reported in travelers, including children. Infection can result in

TABLE 242–3 Antimalarial Chemoprophylaxis Regimens for Pediatric Travelers

Medication	Regimen	Dose	Contraindications and Precautions	Side Effects	General Indications and Information for Use
Chloroquine (Aralen)	Weekly starting 1-2 weeks before trip Continue weekly during trip and for 4 weeks after trip	5 mg base/kg (8.3 mg salt/kg) up to 300 mg base (500 mg salt) Tablets: 300 mg base (500 mg salt)	Prior retinal or visual field changes Psoriasis (may be exacerbated by chloroquine) Do not administer with intradermal human diploid cell rabies vaccine (intradermal rabies vaccine series must be completed at least 7 days before starting chloroquine)	Gastrointestinal symptoms, seizures, rash headache, dizziness, pruritus (especially in dark-skinned persons), blurred vision, decreased hearing, tinnitus, retinal damage at high cumulative doses* High toxicity in overdoses, keep out of reach of children	Use only in areas of chloroquine-sensitive malaria Limited usefulness because of widespread chloroquine resistance Bitter taste
Mefloquine (Lariam)	Weekly starting 1 week before trip Continue weekly during trip and for 4 weeks after trip	≤15 kg: 4.6 mg/kg base (5 mg/kg salt) 15-19 kg: 1/4 tablet 20-30 kg: 1/2 tablet 31-45 kg: 3/4 tablet ≥46 kg: 1 tablet Tablets: 228 mg base (250 mg salt)	Psychiatric conditions, cardiac conduction disorders, seizure disorders, persons with known hypersensitivity to mefloquine Should not take with quinine-like drugs Do not administer with intradermal human diploid cell rabies vaccine (intradermal rabies vaccine series must be completed at least 7 days before starting mefloquine) Do not administer oral typhoid vaccine within 24 hours of mefloquine	Gastrointestinal symptoms, dizziness, insomnia Occasional serious adverse effects: seizures, nightmares, depression, anxiety, psychosis, especially in persons with these preexisting medical conditions	Use in areas with chloroquine-resistant malaria Advantageous for long-term travelers because of weekly dosing and less costly than atovaquone-proguanil Bitter taste
Atovaquone-proguanil (Malarone)	Daily starting 1-2 days before trip Continue daily during trip and for 7 days after trip	11-20 kg: 1 pediatric tablet (62.5 kg/25 mg) 21-30 kg: 2 pediatric tablets (125 mg/50 mg) 31-40 kg: 3 pediatric tablets (187.5 mg/75 mg) ≥40 kg: 1 adult tablet (250 mg atovaquone and 100 mg proguanil hydrochloride) Pediatric tablets: 62.5 mg atovaquone and 25 mg proguanil hydrochloride Adult tablets: 250 mg atovaquone and 100 mg proguanil hydrochloride	Contraindicated in severe renal failure Not recommended or use with caution for children <11 kg, pregnant or lactating women Do not take with tetracycline, metoclopramide, rifampin, or rifabutin (all reduce concentrations of atovaquone) Do not administer oral typhoid vaccine within 24 hours of atovaquone-proguanil	Gastrointestinal symptoms, headache, loss of appetite, dizziness, pruritus	Use in areas with chloroquine-resistant or mefloquine-resistant malaria Advantageous for short-term travelers because prophylaxis can be stopped 1 week after leaving malaria area Available in pediatric tablets Take with food or milk
Doxycycline	Daily starting 1-2 days before trip Continue daily during trip and for 4 weeks after trip	2 mg/kg up to 100 mg daily Tablets: 50 mg, 100 mg	Do not use for children <8 years, pregnant or lactating women Do not give simultaneously with antacids or Pepto-Bismol Do not administer oral typhoid vaccine within 24 hours of doxycycline	Gastrointestinal symptoms, photosensitivity, increased blood urea nitrogen level, hypersensitivity reactions, blood dyscrasias, vaginal candidiasis May decrease the effectiveness of oral contraceptives	Use in areas with chloroquine-resistant and mefloquine-resistant malaria (borders of Thailand with Myanmar (Burma) and Cambodia, the western provinces of Cambodia that border Thailand, and the eastern states of Myanmar (Burma), including the states of Shah, Kayin, and Kayan Take with food; taking with food or milk can decrease gastric irritation (absorption of doxycycline is not significantly decreased by simultaneous administration of milk or food)

**Despite the use of chloroquine as an antimalarial chemoprophylaxis agent for decades and the use of high-dose chloroquine for certain chronic diseases, the literature is inconclusive about the potential risk of retinopathy associated with long-term use of chloroquine for antimalarial prophylaxis. Retinopathy has rarely been reported in patients receiving weekly prophylaxis. Retinopathy appears to be related to dosage and accumulated dosage.*

severe neurologic sequelae and is 100 percent fatal if untreated. In 2001, significant increases in cases were reported among U.S. and European travelers to game parks in Tanzania and Kenya. Between 1967 and 2000, an imported case occurred on average every 1 to 2 years; however, in 2001, seven cases were reported in U.S. travelers.[51,100-102,154]

Schistosomiasis, another parasitic infection caused by flukes that live part of their life cycle in fresh-water snail hosts, affects more than 200 million people worldwide. Schistosomiasis has been reported in travelers to endemic areas of Africa, Asia, South America, and the Caribbean who participated in high-risk activities such as swimming and wading in fresh water.[18,31,37,49] Because most acute infections are asymptomatic, preventive counseling is critical. Children and their families should be counseled against swimming or wading in fresh water in risk areas.

Tick-borne encephalitis is transmitted primarily by the bite of *Ixodes* ticks. It also can be transmitted by the ingestion of unpasteurized dairy products from infected livestock. Transmission occurs during the summer months in western and central Europe, Scandinavia, and parts of the former Soviet Union. Persons who will be traveling for longer than 3 weeks in endemic rural areas or travelers who will be engaging in high-risk activities, such as camping, should be considered for vaccination. The vaccine is not available in the United States but can be obtained in Europe.[18]

Adventure travel can increase the risk of acquiring a variety of infectious diseases. Examples of recent outbreaks or cases of unusual pathogens affecting adventure travelers include fungal organisms (such as histoplasmosis and coccidioidomycosis), leptospirosis, and leishmaniasis. Histoplasmosis is a fungal infection acquired by the inhalation of spores, usually through exposure to bat, bird, or chicken droppings in barnyards and caves. The organism is endemic in the United States, Latin America, eastern Asia, parts of Europe, Africa, and Australia. Coccidioidomycosis, a fungal infection associated with the inhalation of organisms in soil from high-risk areas, is endemic in the southwestern part of the United States and Latin America. Both infections can cause a spectrum of illness from asymptomatic infection to acute pulmonary infection to severe, disseminated disease, especially in immunocompromised persons. Several outbreaks of histoplasmosis have been reported in groups of U.S. visitors who entered a cave with bats in Costa Rica[15] (CDC, unpublished data), Ecuador,[155] Peru,[14] and Nicaragua.[160] More than 200 college students became infected with histoplasmosis during a spring break trip to Acapulco, Mexico.[112,153] Two outbreaks of coccidioidomycosis have been reported in youth missionary groups involved in construction work in Mexico.[13,35] Most of these fungal outbreaks have two common features: high-risk group activities and high attack rates, even in young, nonimmunocompromised individuals. Because no vaccine is available, prevention involves counseling travelers to avoid exposure or to use special masks for high-risk individuals who cannot avoid exposure.[20]

Leptospirosis is a zoonotic infection that is transmitted by exposure to water or soil contaminated with organisms excreted by domestic and wild animals. Outbreaks have been reported in white-water rafters in Costa Rica[113] and in athletes from 26 countries who participated in the Eco-Challenge multisport expedition race in Borneo, Malaysia, in 2000.[111,152] Because no vaccine against leptospirosis exists, persons engaging in high-risk activities should be counseled to avoid exposure to water that may be contaminated or to wear protective clothing. The CDC recommends that persons engaging in high-risk activities consider the use of doxycycline (200 mg orally, once a week), begun 1 to 2 days before exposure and continuing through the period of exposure for prophylaxis; doxycycline should not be used routinely for children younger than 8 years.[18]

Leishmaniasis, a parasitic infection transmitted by the bite of a sandfly, can lead to cutaneous or visceral infection. It has been reported in students who traveled to the rain forest in Costa Rica and other travelers.[61,62,97,164] The appropriate use of insect repellent and other personal protection measures against sandfly bites is the only prevention tool available.

Finally, studies of sexual practices among travelers have shown that 5 to 50 percent of short-term travelers engage in casual sex while abroad; 40 to 60 percent of long-term travelers have reported engaging in casual sex while abroad.[93,126] A study of British travelers reported that 18.6 percent had had new sexual partners, two thirds of those who were sexually active did not use condoms on every occasion, and 5.7 percent contracted sexually transmitted diseases.[125] Adolescents should be counseled about the risks and prevention of sexually transmitted diseases, hepatitis B, and HIV infection associated with sexual contact, sharing needles, or receiving acupuncture or tattoos.

PREVENTION OF TRAVELER'S DIARRHEA IN CHILDREN

EPIDEMIOLOGY OF TRAVELER'S DIARRHEA

One of the most difficult tasks faced by international travelers of any age is ensuring the safety of food and water. Traveler's diarrhea, caused by the ingestion of contaminated food and water, typically is defined as the occurrence of four or more unformed stools in a 24-hour period or three or more unformed stools in an 8-hour period with at least one of the following signs or symptoms: temperature higher than 38° C, abdominal cramping, nausea, vomiting, fecal urgency, tenesmus, or blood or mucus in stools.[44,49,117] Traveler's diarrhea affects between approximately 20 and 50 percent of adult travelers and is the health problem most frequently reported by travelers to developing countries.[43,44] It can occur any time during travel but typically occurs within the first week or two of the trip. The illness usually is self-limited, and for adults the average duration of illness has been reported to be 3 to 5 days.[49] Less information about traveler's diarrhea in children is known. A retrospective study conducted by Pitzinger and associates[120] of Swiss children who had visited the tropics or subtropics reported finding similar incidence rates of traveler's diarrhea in children: 40, 8.5, 21.7, and 36 percent in children aged 0 to 2, 3 to 6, 7 to 14, and 15 years and older, respectively. In this study, the authors also found that small children (0 to 2 years old) most frequently were affected with traveler's diarrhea and that the clinical course tended to be more severe and prolonged than in older pediatric age groups. Overall, children were found to have longer lasting illness than that noted in adults, with an average duration of 11 days for all children combined and 29 days for small children.

Enteric pathogens typically are isolated from approximately 50 to 75 percent of stool specimens from adult travelers with diarrhea; in the remainder, usually no pathogen is isolated. *Escherichia coli*, especially enterotoxigenic *E. coli*, is the most common overall cause of traveler's diarrhea (although the incidence can vary by destination), followed by *Campylobacter*, *Salmonella*, and *Shigella*. Other etiologic agents include pathogenic bacteria, such as *Aeromonas* and *Plesiomonas*; protozoa (e.g., *Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium* spp., and *Cyclospora cayetanensis*); viruses, such as rotavirus and Norwalk-like viruses; and, rarely, helminths.[117] Numerous risk factors for traveler's diarrhea, including the consumption of certain high-risk foods (raw foods such as meats, seafood, and vegetables; unpasteurized dairy products; ice and tap water) and travel to certain destinations, also have been identified.[139] Other authors previously categorized destinations by high, intermediate, and low levels of risk for acquiring traveler's diarrhea. Destinations generally considered to have the highest associated risk for contraction of traveler's diarrhea include Latin America, Africa, Asia, and the Middle East; destina-

tions with intermediate risk include southern Europe and the Caribbean; and low-risk travel destinations include North America, northern Europe, Australia, and New Zealand.[18] The location of food preparation also is a recognized risk factor for acquiring traveler's diarrhea, with a higher risk shown for travelers eating from street vendors and in local restaurants and a lower risk in luxury hotels and private homes. Although fewer data on traveler's diarrhea in children are available, children (especially toddlers) are probably more vulnerable to food- and water-borne pathogens for many reasons, including their propensity to touch multiple surfaces and to mouth objects. Of note, one study found that only 40 percent of parents said that they had practiced dietary prevention measures consistently, and only 5 percent reported using oral rehydration solutions (the mainstay of treatment of diarrhea in children).[120]

PREVENTIVE COUNSELING FOR TRAVELER'S DIARRHEA

Counseling parents of pediatric travelers about appropriate preventive behavior to avoid traveler's diarrhea and anticipatory guidance to ensure successful management of diarrhea are important aspects of the pre-travel assessment.

Food and Beverage Precautions

The most important aspect of preventive counseling for parents of pediatric travelers is appropriate food and beverage precautions (Table 242–4). In addition to preventing the diarrheal diseases already listed, compliance with food and water precautions also will decrease the risk of contracting other food-borne diseases such as hepatitis A. Parents should be counseled that in areas where chlorinated tap water is not available or where hygiene and sanitation are poor, tap water (including ice cubes) should be considered contaminated and hence should be avoided. In addition, travelers also should be advised to avoid brushing their teeth with tap water. Breast-feeding, boiled or bottled water, and bottled carbonated beverages are recommended as typically safe beverages for children; powdered drink mixes made with boiled water (e.g., formula, tea, Kool-Aid) also generally can be considered safe. Parents should dry wet cans and bottles before opening and wipe drinking surfaces clean before serving.[69]

In areas where access to bottled water is poor, water may be boiled for 1 minute (or for 3 minutes at altitudes above 2000 m [6562 feet]). These procedures will kill bacterial, parasitic, and viral pathogens. Chemical disinfection with iodine is an alternative method for water treatment when the water cannot be boiled; however, this method cannot be trusted to kill *Cryptosporidium* unless the water stands for 15 minutes after boiling before drinking. Two well-tested methods are tincture of iodine and tetraglycine hydroperiodide tablets (e.g., Globaline, Potable Aqua, or Coghlan's); these tablets are available at pharmacies, sporting goods stores, and camping outfitters. Chlorine also can be used for chemical disinfection, but its germicidal activity varies with pH, temperature, and organic content of the water; therefore, it can provide less consistent levels of disinfection in many types of water. Portable filters are available and provide various degrees of protection against microbes. Reverse-osmosis filters afford protection against viruses, bacteria, and protozoa, but they are large and expensive, and the small pores can be plugged by cloudy or muddy water. Microstrainer filters with pore sizes in the 0.1- to 0.3-μm range can remove bacteria and protozoa from drinking water, but they do not remove viruses. To kill viruses, parents using microstrainer filters should be advised to chemically disinfect water with iodine after filtration. Data are inadequate at present to evaluate the efficacy of specific brands or models of filters, and therefore the CDC cannot recommend specific brands or models of filters most likely to remove bacteria, viruses, and parasites.[18]

Parents of pediatric travelers also should be counseled on the importance of advance planning for food and beverage items, especially for infants and young children. Breast-feeding infants are considered relatively safe from contracting traveler's diarrhea because they are not exposed to local food and water; therefore, traveling mothers should be encouraged to continue breast-feeding for as long as practical. For infants receiving formula, formula concentrate and powdered forms are the most convenient for travel, but a clean water supply must be available or water must be boiled or chemically disinfected before preparation. For feeding toddlers and older children, the travel adage of "boil it, cook it, peel it, or forget it" applies. In general, unless beverages and food come from a can or can be completely cooked or peeled, they should be considered unsafe (including raw fruits and vegetables). Travelers should avoid unpasteurized dairy products, including cheese and ice cream. In addition, travelers should be advised to not consume raw seafood, shellfish, and meats. Freshly prepared steaming hot food, breads and cereals, hot pasta (including rice and noodles), and well-cooked meat or fish generally can be considered safe for consumption. Bringing crackers and peanut butter is a good suggestion for parents of hungry children when the availability of safe foods is uncertain. The incidence of traveler's diarrhea in children also can be reduced potentially by advising parents to encourage or to supervise frequent handwashing, including the use of alcohol-based hand sanitizer, and to try to prevent children from placing objects in their mouths.

Some species of fish and shellfish can contain poisonous biotoxins, such as ciguatoxin and scombrotoxin, even when they are well cooked. Ciguatera poisoning is a potential risk in all subtropical and tropical regions of the West Indies and the Pacific and Indian oceans where the implicated fish are consumed; such fish include barracuda, red snapper, grouper, amberjack, and sea bass. Symptoms of ciguatera poisoning include gastroenteritis and neurologic manifestations such as dysesthesias and weakness.

TABLE 242–4 Food and Beverage Precautions for International Travel

Generally Safe Food and Beverages	Generally Unsafe Food and Beverages
Boiled or chemically disinfected water	Tap water and ice
Powdered drink mixes made with boiled water (e.g., formula, teas, Kool-Aid)	Unpasteurized milk and dairy products (including cheese and ice cream)
Canned or bottled water or beverages	Cooled, standing, or reheated foods
Fruits and vegetables that can be peeled	Raw fruit and vegetables, including salads
Breads and cereals	Undercooked or raw meats
Hot, fully cooked pasta, vegetables, meat, or fish	Undercooked or raw fish and shellfish; fish with suspected biotoxins

Modified from Jenista, J. A.: The International Child Traveler. In *Jensen, H. B., and Baltimore, R. S. (eds.): Pediatric Infectious Diseases: Principles and Practice. Norwalk, CT, Appleton and Lange, 1995, p. 1518.*

Scombroid poisoning occurs in tropical as well as in temperate regions and is caused by high levels of histidine in the flesh of fish such as bluefin, yellowfin tuna, mackerel, bonito, mahi-mahi, herring, amberjack, and bluefish; if improperly refrigerated, histidine is converted to histamine, which can cause flushing, headache, nausea, vomiting, diarrhea, and urticaria.[18]

MANAGING TRAVELER'S DIARRHEA IN CHILDREN

Adults traveling with children should be counseled about the signs and symptoms of dehydration and the proper use of WHO oral rehydration solution (ORS). Immediate medical attention is required for an infant or young child with diarrhea who has signs of moderate to severe dehydration (Table 242–5), bloody diarrhea, temperature higher than 38.5°C (>101.5°F), or persistent vomiting. ORS should be provided to the infant by bottle or spoon while medical attention is being obtained.

Assessment and Treatment of Dehydration

The greatest risk to the infant with diarrhea and vomiting is dehydration. Fever or increased ambient temperature increases fluid losses and speeds dehydration. Parents should be advised

TABLE 242–5 Anticipatory Guidance for Management of Traveler's Diarrhea in Children

Signs	Minimal or No Dehydration (<3% loss of body weight)	Mild or Moderate Dehydration (3%-9% loss of body weight)	Severe Dehydration (>9% loss of body weight)
Mental status	Well; alert	Normal, fatigued or restless, irritable	Apathetic, lethargic, unconscious
Thirst	Drinks normally; might refuse liquids	Thirsty; eager to drink	Drinks poorly; unable to drink
Breathing	Normal	Normal; fast	Deep
Eyes	Normal	Slightly sunken	Deeply sunken
Tears	Present	Decreased	Absent
Mouth and tongue	Moist	Dry	Parched
Skin fold	Instant recoil	Recoil in <2 seconds	Recoil in >2 seconds
Capillary refill	Normal	Prolonged	Prolonged; minimal
Extremities	Warm	Cool	Cool; mottled; cyanotic
Urine output	Normal to decreased	Decreased	Minimal

1. Include oral rehydration solution (ORS) packets in travel kit. Products can be obtained from Jianas Brothers Packaging Company, 2533 Southwest Boulevard, Kansas City, Missouri 64108, USA (1-816-421-2880) for WHO ORS packets (glucose-based formula) or Cera Products, 9017 Mendenhall Court, Columbia, Maryland 21045, USA (1-410-309-1000 or 1-888-Ceralyte; *www.ceraproductsinc.com*) for CeraLyte, a rice cereal–based product.
2. Recognize the signs and symptoms of mild, moderate, and severe dehydration.
3. Begin ORS with first episode of watery stools or vomiting.
4. Mix 1 ORS packet with 1 liter of bottled or boiled water in a clean container or as instructed on the packet label; discard after 12 hours at room temperature.
5. Treatment should include two phases: rehydration and maintenance. In the rehydration phase, the fluid deficit is replaced quickly (i.e., during 3-4 hours). This is followed by a maintenance phase with the provision of calories and fluids.

   Rehydration

   During the rehydration phase, administer ORS as follows:

   In a nondehydrated child: 1 mL of fluid for each gram of output. When losses are not easily measured, 10 mL of additional fluid can be administered per kilogram of body weight for each watery stool or 2 mL/kg body weight for each episode of emesis. Alternatively, children can be hydrated with the same amounts as specified for children with mild too moderate dehydration as below.

   In mildly to moderately dehydrated child

   <10 kg body weight: 60-120 mL ORS for each diarrheal stool or vomiting episode

   ≥10 kg body weight: 120-240 mL ORS for each diarrheal stool or vomiting episode

   For children with vomiting, it may be necessary to start rehydration with small volumes of ORS (5 mL) every 5 minutes, with a gradual increase in the amount consumed. Administration with a spoon or syringe under close supervision can help guarantee a gradual progression in the amount taken.

   Feeding

   Continue normal, unrestricted feeding throughout illness if possible. Rapid realimentation should follow rapid rehydration with a goal of quickly returning the patient to an age-appropriate unrestricted diet. Gut rest is not indicated. The diet should be increased as soon as tolerated to compensate for lost calorie intake.

   In infants: Formula or breast-feeding. For formula-fed infants, diluted formula is not recommended, and special formula usually is not necessary.

   In older children: Encourage the intake of the usual diet. Foods high in simple sugars (carbonated soft drinks, juice, gelatin desserts) should be avoided because the osmotic load might worsen diarrhea. The practice of withholding food for ≥24 hours is inappropriate. Highly specific diets (e.g., the BRAT [bananas, rice, applesauce, and toast] diet) are unnecessarily restrictive and provide suboptimal nutrition for the patient's nourishment and recovering gut.

   In a severely dehydrated child: Intravenous or intraosseous therapy is required for severe dehydration. Severe dehydration is a medical emergency. Oral or nasogastric rehydration should also be provided.
6. Antimotility agents (i.e., Lomotil [active ingredient, diphenoxylate] and Imodium [active ingredient, loperamide] are not recommended.
7. Empiric treatment with antimicrobials is not generally recommended.
8. Seek urgent medical attention for diarrhea with high fever, bloody stools, moderate to severe dehydration, lethargy, severe vomiting, or diarrhea lasting more than 3 days.

Modified from Duggan, C., Santosham, M., and Glass, R. I.: The management of acute diarrhea in children: Oral rehydration, maintenance, and nutritional therapy. M. M. W. R. Recomm. Rep. 44(RR-16):1-20, 1992; Jenista, J. A.: The international child traveler. In *Jensen, H. B., and Baltimore, R. (eds.): Pediatric Infectious Diseases: Principles and Practice. Norwalk, CT, Appleton & Lange, 1995, p. 1520; King, C. K., Glass, R., Bresee, J. S., and Duggan, C.: Managing acute gastroenteritis among children: Oral rehydration, maintenance, and nutritional therapy. M. M. W. R. Recomm. Rep. 52(RR-16):1-16, 2003; Sandhu, B. K.: Practical guidelines for the management of gastroenteritis in children. J. Pediatr. Gastroenterol. Nutr. 33(Suppl. 2):S36-S39, 2001; World Health Organization: The Treatment of Diarrhea: A Manual for Physicians and Other Senior Health Workers. Geneva, World Health Organization, 1995.*

that dehydration is best prevented and treated by use of ORS, in addition to the infant's usual food. Rice-based and other cereal-based ORS, in which complex carbohydrates are substituted for glucose, also are available and may be more acceptable to young children. Adults traveling with children should be counseled that sports drinks, which are designed to replace water and electrolytes lost through sweat, do not contain the same proportions of electrolytes as those of the solution recommended by WHO for rehydration during diarrheal illness.

ORS packets are available at stores or pharmacies in almost all developing countries. (See information later about ORS availability in the United States.) ORS is prepared by adding one packet to boiled or treated water. Travelers should be advised to check packet instructions carefully to ensure that the salts are added to the correct volume of water. ORS should be consumed or discarded within 12 hours if it is held at room temperature or 24 hours if it is kept refrigerated. A dehydrated child will drink ORS avidly; travelers should be advised to give it to the child as long as the dehydration persists. An infant or child who vomits the ORS usually will keep it down if it is offered by spoon, oral syringe, or straw in frequent small sips.[19,76,132]

Children weighing less than 10 kg who have mild to moderate dehydration should be administered 60 to 120 mL of ORS for each diarrheal stool or vomiting episode. Children who weigh 10 kg or more should receive 120 to 240 mL of ORS for each diarrheal stool or vomiting episode. Severe dehydration is a medical emergency that usually requires administration of fluids by intravenous or intraosseous routes.[19,42,76,132]

Dietary Modification

Breast-fed infants should continue nursing on demand. Formula-fed infants should continue their usual formula during rehydration. They should receive a volume that is sufficient to satisfy energy and nutrient requirements. Lactose-free or lactose-reduced formulas usually are unnecessary. Dilution of formula may slow resolution of diarrhea and is not recommended. Older infants and children receiving semisolid or solid foods should continue to receive their usual diet during the illness. Recommended foods include starches, cereals, yogurt, fruits, and vegetables. Foods that are high in simple sugars, such as soft drinks, undiluted apple juice, gelatins, and presweetened cereals, can exacerbate diarrhea by osmotic effects and should be avoided. In addition, foods high in fat may not be tolerated because of their tendency to delay gastric emptying. The practice of withholding food for 24 hours or longer is inappropriate. Early feeding can decrease changes in intestinal permeability caused by infection, reduce illness duration, and improve nutritional outcome. Highly specific diets (e.g., the BRAT [bananas, rice, applesauce, and toast] diet) frequently have been recommended; however, similar to juice-centered and clear fluid diets, such severely restrictive diets used for prolonged periods can result in malnutrition and should be avoided.[76]

ORS packets are available in the United States from Jianas Brothers Packaging Company, 2533 Southwest Boulevard, Kansas City, Missouri 64108, USA (1-816-421-2880). In addition, Cera Products, 9017 Mendenhall Court, Columbia, Maryland 21045, USA (1-410-309-1000 or 1-888-Ceralyte; *www.ceraproductsinc.com*), markets a rice cereal (rather than a glucose-based product), CeraLyte, in different flavors. ORS packets also may be available at stores that sell outdoor recreation and camping supplies.

Other Measures

Parents should be particularly careful to wash hands well after changing diapers of infants with diarrhea to avoid spreading infection to themselves and other family members.

Oral syringes available in most pharmacies for oral medications can be useful for the administration of ORS and can be included as part of the traveler's health kit for young children. Straws also can be useful for older children.

The use of antimotility agents (e.g., Imodium, Lomotil) in children younger than 2 years is not recommended. Because overdoses of these types of drugs can be fatal, they should be used with extreme caution in children. Side effects of these drugs in adults include opiate-induced ileus, drowsiness, and nausea. Lomotil has been associated with fatal overdoses and other severe complications, including coma and respiratory depression. Antinausea medications, such as promethazine and prochlorperazine, are not recommended routinely. They are contraindicated for use in children younger than 2 years. Fatal respiratory depression in children has been reported with use of promethazine. Children with an acute illness, including gastroenteritis and dehydration, are more susceptible than are adults to neuromuscular reactions, especially dystonias, associated with prochlorperazine. The extrapyramidal side effects associated with these medications can be confused with symptoms of other undiagnosed primary diseases associated with vomiting, such as Reye syndrome. These medications should not be prescribed routinely for empiric treatment of children with possible traveler's diarrhea. Adults traveling with children should be fully counseled about the indications, dosage, frequency, and possible side effects if these medications are prescribed.[19,76]

Antibiotics

Few data are available for empiric administration of antibiotics for traveler's diarrhea in children. Furthermore, the antimicrobial options for empiric treatment in children are limited. Trimethoprim-sulfamethoxazole was used previously for empiric treatment of traveler's diarrhea in children; however, its effectiveness has been reduced by widespread drug resistance, and it is no longer routinely recommended. Fluoroquinolones are used frequently for the empiric treatment of traveler's diarrhea in adults. The use of fluoroquinolones generally is not recommended in children and adolescents younger than 18 years because of cartilage damage in animals tested. The only indication for fluoroquinolone use in children that has been approved by the Food and Drug Administration is for complicated urinary tract infections. The American Academy of Pediatrics suggests some special circumstances for fluoroquinolone use, including the treatment of gastrointestinal infection caused by multidrug-resistant *Shigella* spp., *Salmonella* spp., *Vibrio cholerae*, or *Campylobacter jejuni*. However, the routine use for empiric treatment of traveler's diarrhea is not recommended. Tetracyclines can cause teeth staining if they are used in children younger than 8 years.[19,119]

In some studies, azithromycin has been found to be as effective as fluoroquinolones in treating traveler's diarrhea in adults.[2] In practice, some clinicians prescribe azithromycin either as a single dose or at 10 mg/kg for 3 to 5 days for empiric treatment. Flavored oral suspension of azithromycin is available. The suspension does not require refrigeration; however, it should be used within 10 days of mixing. The unreconstituted form of azithromycin has a longer expiration period. In certain circumstances, the unreconstituted form can be provided with clear instructions for preparation and may be useful for children traveling for more than 10 days.

SPECIAL CONSIDERATIONS FOR IMMUNOCOMPROMISED PEDIATRIC TRAVELERS

Travel preparations for a child with an immunocompromising condition, including congenital immunodeficiencies and acquired

immunodeficiencies (such as HIV infection), need to be tailored to the specific underlying condition. Limited data are available on health risks in immunocompromised pediatric travelers, but data from adult travelers can be used to guide the management of children. Schuhwerk and colleagues[133] have published a comprehensive review of considerations for travelers with HIV infection. A key component of the pre-travel assessment is a careful review of routine and travel-related vaccinations. In addition, the child and family should receive individualized preventive counseling about how to reduce disease risk while traveling. The health care provider should ensure that parents of immunocompromised children are knowledgeable about the type of immune defect or condition, the types of infections to which their children will be more susceptible, and how these risks may be affected by planned travel and activities. As previously discussed, parents should be advised to carry the following items with them for easy retrieval: (1) a summary of their child's medical history and treatment record, (2) copies of all important health-related documents (i.e., written prescriptions for medications; health insurance information; and medical contacts abroad, including specialists in planned travel destinations), and (3) all required prescription medications (in original bottles and sufficient supply for the length of the trip). Physicians should stress the importance of bringing an adequate supply of prescription medications, especially for travelers with HIV infection, because many medications are unavailable outside the United States. At present, no countries require proof of a negative HIV test result for entry for tourism purposes; however, some countries require HIV testing for students and workers and for persons wishing to stay in the country longer than 3 months.[36]

VACCINATION OF IMMUNOCOMPROMISED PEDIATRIC TRAVELERS

The American Academy of Pediatrics, Committee on Infectious Diseases, reports that experience with vaccine administration in immunocompromised children is limited. In most situations, theoretical considerations are used to guide decisions about vaccine administration because data for specific vaccines in children with specific disorders are lacking.[119] Vaccination recommendations may change, so clinicians should obtain the most recent recommendations before vaccinating immunocompromised patients (see the section on international travel information resources and Advisory Committee on Immunization Practices general recommendations on immunization[17] for detailed recommendations). In general, children with immunocompromising conditions, including primary and secondary immune deficiencies, should receive all inactivated vaccines that are recommended for nonimmunocompromised pediatric travelers. The risk for development of complications from the administration of inactivated vaccines and immune globulin preparations has not been shown to be increased in immunocompromised persons; however, immune responses may vary and may be suboptimal (thereby substantially reducing vaccine immunogenicity). Children with a deficiency in antibody-synthesizing capacity usually are incapable of mounting an antibody response to vaccines and should receive regular doses of immune globulin to provide passive protection against many infectious diseases. Children with milder B lymphocyte and antibody deficiencies have an intermediate degree of vaccine responsiveness and may require monitoring of postimmunization antibody titers to confirm vaccine immunogenicity.[119] Consideration should be given to timing the dosing of intravenous immune globulin to coincide with the immediate pre-travel period.[36,119]

In general, immunocompromised children should not receive live vaccines, either viral or bacterial, because of the risk for development of disease from vaccine strains. The American Academy of Pediatrics, Committee on Infectious Diseases, notes, however, that some immunocompromised children may benefit from special-use as well as routinely administered immunizations.[119] In patients with primary immunodeficiencies, live vaccines are contraindicated for most individuals with B lymphocyte defects except immunoglobulin A (IgA) deficiency and for all patients with T lymphocyte–mediated disorders. Fatal poliomyelitis and measles vaccine virus infections have occurred in children with disorders in T-cell function after the administration of live viral vaccines. Children with phagocytic function disorders, including chronic granulomatous disease and leukocyte adhesion defect, can receive all immunizations except live bacterial vaccines (BCG and Ty21a *Salmonella typhi*). Live vaccines generally are contraindicated in patients with secondary immunodeficiencies (including children with HIV infection or acquired immunodeficiency syndrome [AIDS]), cancer, and organ transplants and in children receiving immunosuppressive or radiation therapy. Exceptions to this proviso are children with HIV infection who are not severely immunocompromised; measles-mumps-rubella vaccines are recommended in these children, and varicella vaccine should be considered if age-specific $CD4^+$ T-lymphocyte values are 15 percent or more. In the United States, BCG is contraindicated for HIV-infected children, although the WHO recommends giving BCG to asymptomatic HIV-infected children in regions with high tuberculosis prevalence. All HIV-infected children should, however, have tuberculin skin testing performed before and after traveling. Yellow fever vaccination is contraindicated in HIV-infected persons by the Advisory Committee on Immunization Practices, but it is recommended by the WHO for those with asymptomatic HIV infection who reside in endemic areas.[91,119,171]

PREVENTION OF MALARIA IN IMMUNOCOMPROMISED CHILDREN

No data have been published to indicate that immunocompromised travelers are at increased risk for acquiring malaria or having more severe disease if they are infected, except in persons who are HIV infected and pregnant.[18] Before prescribing malaria chemoprophylaxis, clinicians should check for possible drug interactions for immunocompromised children receiving other medications. Counseling should emphasize the importance of exercising personal protection measures against malaria and using recommended chemoprophylaxis. Immunocompromised patients may be at risk for acquiring a variety of infections that are manifested as febrile illnesses; parents should be advised to seek expert medical advice early in the course of a febrile illness to ensure that the child receives the appropriate diagnosis and effective treatment.[36]

PREVENTION OF TRAVELER'S DIARRHEA AND OTHER INFECTIOUS DISEASES IN IMMUNOCOMPROMISED CHILDREN

During travel to developing countries, immunocompromised children may be at higher risk for acquiring food- and water-borne diseases than when they are in the United States. At present, data are too limited to determine whether the risk and incidence of traveler's diarrhea are increased in this population; however, good evidence indicates that the disease is more severe or prolonged in immunocompromised travelers.[36] Intensive counseling on the effective use of food and beverage precautions for this population is essential to minimize and to prevent morbidity and mortality. Water-borne infections also can result from swallowing water during recreational water activities. To reduce the risk of acquiring diseases such as cryptosporidiosis and giardiasis, parents should be advised that children should avoid swimming in water that might be contaminated and that their children

should be encouraged to not swallow water during swimming. In addition, many tropical and developing countries have high rates of tuberculosis; some immunocompromised persons, such as HIV-infected travelers, may be at greater risk for acquiring tuberculosis, especially during long-term travel.[127] BCG vaccination is contraindicated in HIV-infected persons. Chemoprophylaxis may be appropriate for some individuals visiting or living in high-risk areas for a prolonged period. When immunocompromised children travel abroad, they may encounter new organisms not endemic in their own countries; these organisms will pose variable risks based on their degree of immunocompromise. Health care providers should identify travel-specific risks and instruct parents in ways to reduce the risk of contracting infection. Other pathogens that can lead to more severe infection in immunocompromised travelers include visceral leishmaniasis and fungal infections (including *Penicillium marneffei*, coccidioidomycosis, and histoplasmosis).[18] Leishmaniasis is endemic in the Mediterranean coastal regions of southern Europe and northern Africa. *P. marneffei* poses a risk for travelers to the Far East, and histoplasmosis affects those traveling to Latin America. Few data exist on the efficacy of primary prophylaxis for opportunistic infections such as leishmaniasis and penicilliosis; therefore, avoidance of areas of high prevalence may be prudent if the child has severe immunodeficiency or advanced HIV disease.[73]

GENERAL TRAVEL HEALTH COUNSELING FOR CHILDREN

During the pre-travel assessment, the clinician should provide the parents with general advice and preventive counseling to avoid health risks and injuries in children. Simple personal protection measures can prevent children from incurring many types of travel-associated injuries and conditions. The most common skin condition reported by travelers is sunburn. To prevent sunburn and the subsequent risk of skin malignant neoplasms later in life, children should avoid sun exposure during peak hours and use sunscreen appropriate for the child's age. When sunscreen and insect repellent are used concomitantly, the sunscreen should be applied first. Injuries, drownings, and motor vehicle accidents pose a great risk for morbidity and mortality among international travelers.[60,125] The risk of motor vehicle–related death generally is many times higher in developing countries than in the United States. Parents traveling with infants or young children should be advised to bring their own child safety restraint seats for use during travel. The use of car seats and seat belts for children, preferably sitting in the rear seat, should be emphasized. Unfortunately, in some developing countries, cars with seat belts may not be readily available. Night driving can be more hazardous, especially outside urban areas in developing countries, and should be avoided.[18] Use of a helmet is imperative for bicycle travel. Fire injuries can be prevented by advising parents to inquire whether hotels have smoke detectors and sprinkler systems (they also may consider bringing their own smoke detector). Other major causes of injury and trauma include drowning and boating accidents. Parents and children should be counseled to be aware of weather conditions and forecasts, and parents should be advised that an adult should accompany children at all times when swimming. Personal floatation devices should be used when boating or water skiing, regardless of the distance to be traveled or swimming ability.[131]

Swimming in contaminated water can result in skin, eye, ear, and some intestinal infections; for prevention of infectious diseases, generally only pools that contain chlorinated water can be considered safe. Parents also should be advised that swimming in fresh-water lakes and streams in developing countries carries a risk of contracting schistosomiasis, leptospirosis, and primary amebic meningoencephalitis.[18] In salt-water bodies, biting and stinging fish, corals, and jellyfish also can be a risk. Parents of pediatric travelers, especially to areas endemic for rabies, should be reminded to warn children that they should not attempt to pet, handle, or feed domestic or wild animals (including monkeys). Travelers also should avoid snakes because most bites are the direct result of handling, harassing, or trying to kill snakes. In general, children should wear covered footwear rather than sandals, including when wading on reefs and swimming.[18,131] Children should avoid walking barefoot, particularly in rural areas, to prevent cutaneous larva migrans, hookworm, and *Strongyloides* infections.

THE PEDIATRIC TRAVELER'S HEALTH KIT

Children traveling to developing countries may have unique exposures, particularly if they are traveling to remote locations or will have close contact with other children. Consideration should be given to inclusion of the following medications as part of the traveler's health kit: rectal preparations (suppositories) of selected medications, such as acetaminophen; topical treatments for lice and scabies for pediatric travelers to developing countries who may have extensive contact with local children; and a topical antibiotic, such as mupirocin, for bacterial skin infections.[19] Adults accompanying these children and teenagers should consider obtaining basic first aid and safety training before departure.

INTERNATIONAL TRAVEL INFORMATION RESOURCES

One of the most important functions that a clinician can fulfill in preparing a pediatric patient and parents for international travel is to provide up-to-date and accurate travel health information and recommendations for preventing illness. Many varied sources of information are available, including software packages and databases designed specifically for use in travel medicine and pre-travel care.[54,75] Increasingly, the Internet and computer-based travel resources are being used by practitioners and consumers alike because they provide current information to appropriately and effectively counsel and treat international travelers. Two reviews have provided comprehensive summaries of travel medicine resources.[54,75] Table 242–6 is a summary of some selected travel health resources that can be useful for providing health care professionals and parents with essential information on health risks in specific travel destinations (including endemic or epidemic diseases) and current travel health recommendations (including immunizations and chemoprophylaxis). Travelers also should be aware of the need for health insurance and emergency evacuation coverage during travel and medical assistance in the event of a travel-related illness; a variety of companies offer these services, and travelers should investigate options before making any purchases. This summary is not meant to be comprehensive; because resources are constantly changing, clinicians are advised to review and to compare sites for availability and updated information and recommendations.

CHAPTER 243

Infectious Disease Considerations in International Adoptees and Refugees

Margaret K. Hostetter

More than 20,000 internationally adopted children enter the United States each year to begin life with their new families. The demographics of this process have changed considerably since the mid-1980s, when approximately 70 percent of internationally adopted children spent their infancy in two-parent foster homes in Korea. Since 1991, China, Russia, and eastern Europe are the countries of origin for more than 70 percent of internationally adopted children; most of these children spend weeks to years in orphanages and other state-run institutions, variably called nurseries, baby homes, or hospitals. Although all internationally adopted children present special health considerations, the institutionalized child is particularly at risk for acquisition of numerous infectious diseases as well as for developmental and emotional handicaps ascribable to institutional care.

PRE-ADOPTION ENVIRONMENTS IN THE COUNTRIES OF ORIGIN

Children coming from the state-subsidized foster homes of Korea receive optimal nutrition, nurturing, and preventive health care. The Korean foster home system chooses only two-parent families who have successfully reared their own children. Foster parents must meet defined dates for medical follow-up, continuity of care, and immunizations. Both boys and girls may be adopted, but the Korean procedure has numerous stipulations about age, physical condition, and household income of the prospective adoptive parents. Korean infants typically are adopted when they are between 6 and 13 months of age.

Because Chinese culture stipulates that the son must care for his aging parents, most infants surrendered for adoption under China's "one child" policy are girls. These girls typically are adopted in the United States when they are between 8 and 15 months of age. The standard of care in Chinese orphanages is certainly acceptable in terms of nutrition, but hygiene and immunization practices can be variable. At times, the child's stated age may be younger than the actual age because growth parameters and developmental attainments then appear more favorable.

Children coming from Russian or eastern European orphanages have highly variable lengths of stay in pre-adoption care. A substantial number of Russian adoptees have remained in institutions for more than 2 years. Children can be removed from their biologic families at any time, and it is not uncommon to find sibling groups who have been separated because of parental abuse or alcoholism. Immunizations may be erratic and, although recorded, may not have been administered. Anecdotal reports of caseworkers filling out immunization sheets as the child is leaving with the parents are not unusual. The varying backgrounds of Russian or eastern European adoptees, the variable ages at the time of adoption, and the unpredictable nature of the pre-adoption environment carry implications not only for medical but also for developmental health.

TABLE 243–1 Screening Tests for Internationally Adopted Children

Hepatitis B virus surface antigen (HBsAg) and antibodies to hepatitis B surface and core antigens
Hepatitis C virus antibody
Human immunodeficiency virus (HIV) antibodies by ELISA and DNA PCR
Varicella-zoster virus antibody
Fecal examination for parasite ova and *Giardia* antigen
VDRL (or RPR) and FTA-ABS
PPD (Mantoux) skin test with control for adequacy of the delayed hypersensitivity response
Complete blood count with erythrocyte indices
Serum lead level
Thyroid-stimulating hormone level
Urinalysis
Hearing screening
Vision screening
Developmental evaluation

ELISA, enzyme-linked immunosorbent assay; FTA-ABS, fluorescent treponemal antibody absorption assay; PCR, polymerase chain reaction; PPD, purified protein derivative; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratory.

TABLE 243–2 Prevalence of Hepatitis B and C by Country of Origin

Country	Hepatitis B[16]	Hepatitis C[1,14,25]
Central and South America	2-7%	1-1.9%
China	8-10%	2-2.9%
Eastern Europe	2-7%	2-2.9%
Russia (former USSR)	2-10%	2-2.9%
South Korea	8-10%	1.7%

TABLE 243–3 Interpretation of Hepatitis B Profile

Status	HBsAg	Anti-HBc	Anti-HBs	AST and ALT
Carrier	+	–	–	Normal
Acute infection	+	IgM	–	Elevated
Chronic infection	+	IgG	–	Normal to elevated
Past infection	–	IgG	IgG	Normal
Passive transfer	–	IgG	IgG	Normal
Vaccination	–	–	IgG	Normal

ALT, alanine aminotransferase; AST, aspartate aminotransferase; IgG, immunoglobulin G.

Other countries also serving as sources of international adoptees include Central and South America, India, Vietnam, Cambodia, and Ethiopia. Often, little or no information about the child's birth circumstances, maternal health, or pre-adoption environment is available. In Guatemala, approximately 50 percent of adoptees spend time in foster homes for which subsidies are paid by the potential adopting parents. The remainder reside in orphanages or mixed-care environments before adoption.[17] Orphanages run by religious groups in Central America and Colombia frequently provide prenatal care for single mothers and excellent postnatal care for their infants. Most children from India come from orphanages where limited resources may impair the ability of the orphanage workers to meet all the needs of the children in their care. Children from Vietnam and Cambodia often are adopted at an early age, which mitigates the effects of less than optimal nutrition and truncates potential time of exposure to cases of tuberculosis among caregivers.

To my knowledge, screening for tuberculosis is not required in any of the countries in which children are adopted from orphanage settings, nor have standards of sanitation in orphanages been mandated or accepted worldwide. As a result, the highly varying environments from which these children come carry substantial implications for their health. This chapter addresses many of the issues with which the infectious disease specialist must be familiar.

SCREENING TESTS

Screening tests currently recommended by the American Academy of Pediatrics should be applied to internationally adopted children without regard to age, sex, or country of origin (Table 243–1). Many pre-adoption referrals will report results of medical testing done in the country of origin, but any test done in the country of origin should be repeated when the child arrives in the United States. In my experience, results of testing done in the country of origin are wrong at least 10 percent of the time, especially with regard to hepatitis B.

As shown in Table 243–2, the reported prevalence of hepatitis B and hepatitis C may vary widely, depending on the country of origin. The remainder of this section discusses specific infectious diseases of particular importance to children, parents, and physicians.

VIRAL INFECTIONS

Hepatitis A, B, and C

Because hepatitis A is endemic in the developing world, routine testing for hepatitis A immunity is not recommended. If the adoptee is involved in a situation in which vaccination for hepatitis A is a possibility (e.g., daycare outbreak, travel to a country in which the virus is endemic), antibody testing should be done to determine the need for vaccination.

The prevalence of hepatitis B among internationally adopted children varies with the carriage rate for this virus among women of child-bearing age (see Table 243–2). As a result, parents planning to adopt from most countries in Asia (Cambodia, China, India, or Vietnam) should be informed that the chance of the child's having hepatitis B infection may be as high as 10 percent in unvaccinated children; parents planning to adopt from Russia or eastern Europe should know that the prevalence of hepatitis B ranges from 2 to 20 percent, the latter in some regions of Romania.[13]

Accurate testing for hepatitis B infection, past infection, or vaccine-induced immunity involves the hepatitis B profile. Table 243–3 delineates common patterns of serologic responses to the three components of the hepatitis B profile: hepatitis B surface antigen (HBsAg) and antibodies to hepatitis B surface and core antigens (anti-surface and anti-core antibodies). The use of all three tests is essential to determine which category best fits the child's serologic pattern. A substantial proportion of hepatitis B infections in internationally adopted children is misdiagnosed as "carrier state" when HBsAg is present but testing for immunoglobulin G (IgG) anti-core antibodies is omitted.[12] The child who is positive for HBsAg and IgG anti-core antibodies for more than 6 months meets the definition for chronic hepatitis B; approximately 90 percent of children exposed to hepatitis B during the first 12 months of life will develop chronic infection, and approximately 10 percent of these children will go on to develop cirrhosis or hepatocellular carcinoma. Therefore, the finding of a positive HBsAg response never should be dismissed as indicative of the "carrier state" in the absence of testing for IgG anti-core antibodies. Treatment with interferon α-2b may be beneficial in cases of chronic infection. Interferon α-2b and ribavirin in combination or lamivudine alone is approvid for children older than 2 years of age.

Additional testing in children positive for HBsAg should include the hepatitis Be antigen, aspartate and alanine aminotransferases, and hepatitis D antibodies. The coexistence of hepatitis Be antigen increases the risk of infectivity. Hepatitis D (delta virus) occurs only in conjunction with hepatitis B and typically is acquired in countries such as southern Italy, parts of eastern Europe, South America, Africa, and the Middle East. Co-infection with hepatitis D enhances the development of chronic liver disease and the rate of cirrhosis in patients infected with hepatitis B. Practitioners should be aware that administration of the hepatitis B vaccine can lead to a brief period of antigenemia if testing for HBsAg is performed within 2 or 3 days of vaccination.

Hepatitis B immunization is given appropriately in Korea, and this national policy has virtually eliminated hepatitis B infection in Korean adoptees.[12] However, although the Korean government has practiced universal immunization for hepatitis B since 1989, premature infants or the rare abandoned child may not have been vaccinated within the first week of life. Hepatitis B immunizations are given erratically if at all in every other country from which internationally adopted children come. Health care providers should review the timing of hepatitis B immunizations: optimally, the first is given within the first week of life; the second, 1 month later; and the third, 6 months after the first. In many countries, the administration of the initial hepatitis B immunization is delayed for several weeks or months. This delay of course means that the child is not protected from the acquisition of hepatitis B either by vertical transmission from the mother or by horizontal transmission in the orphanage during this time.

Most children who have received at least two hepatitis B vaccines should have anti-surface antibodies (anti-HBs). Vaccination does not elicit anti-core antibodies (anti-HBc). Children who do not have anti-surface antibodies after receiving two or more recorded vaccines probably have not received the immunizations indicated on their certificates, and the entire hepatitis B series should be repeated.

Hepatitis B vaccination also is essential for household contacts, including family members and home daycare contacts. Although most infants in the United States will have received hepatitis B vaccine and thereby are protected from horizontal transmission in a daycare center, daycare mothers or other daycare workers themselves often are not immunized. The primary caregiver is the one to whom hepatitis B is transmitted most frequently; therefore, the physician should provide counseling to the adoptive parents as to the necessity of immunizing household contacts and home daycare providers who will be caring for any child who is HBsAg positive.

On the basis of prevalence rates determined by the World Health Organization (see Table 243–2), the risk of hepatitis C being present in internationally adopted children is thought to be significantly lower, perhaps around 1 percent,[21] although no study of the prevalence of this infection in internationally adopted children has been published. Between 2 and 8 percent of infants born to infected mothers will acquire the virus; data on transmissibility from breast milk are somewhat more controversial. Numerous studies have documented the presence of hepatitis C RNA in breast milk, but studies looking for infection after breastfeeding typically have found little if any evidence that breastfeeding is a major source of infection.[24,26]

The hepatitis C enzyme immunoassay is the screening test of choice. If the result is positive, the physician may choose either the recombinant immunoblot assay or a direct measure of viral RNA by polymerase chain reaction for confirmation. The polymerase chain reaction test is preferred by many adoption medicine specialists because it is specific for infection and helpful for identifying infection in infants in whom passive transfer of maternal antibody may confound the clinical picture. Documentation of aspartate and alanine aminotransferase levels for those children who are positive by antibody test also is important.

The prognosis of children with hepatitis C infection is unclear. Although the disease is thought to be benign in many children, there are anecdotal reports of internationally adopted children with more aggressive presentations. Children with bridging necrosis or active cirrhosis on liver biopsy or with persistently elevated serum transaminase concentrations exceeding twice the upper limits of normal should be referred to a gastroenterologist for further management, which typically includes tests for alpha-fetoprotein concentration and abdominal ultrasonography. Eight studies of interferon α-2b therapy have been undertaken in children, and one pediatric study has used combination therapy with interferon α-2b and ribavirin.[9]

Human Immunodeficiency Virus Infection

Detection of unsuspected human immunodeficiency virus (HIV) infection in internationally adopted children after arrival in the United States is quite rare. However, because the results of the HIV enzyme-linked immunosorbent assay (ELISA) may be confounded by the presence of passively transferred maternal antibodies in children younger than 18 months, some experts recommend testing for HIV DNA by polymerase chain reaction on arrival. A secondary advantage to this test is that horizontal transmission ensuing within the previous 1 to 2 months theoretically will be detected, even though the length of time has not been sufficient for the child to develop an antibody response. Other experts recommend a repeated ELISA for HIV 6 months after the child arrives in the United States. When the diagnosis is confirmed, management by a pediatric HIV infection specialist is essential.

BACTERIAL INFECTIONS

Helicobacter, Salmonella, Shigella, Campylobacter, and *Yersinia*

In a single retrospective study, colonization with *Helicobacter pylori* as assessed by antibodies to this organism was found in 31 percent of 226 adopted children from 18 countries.[19] Seropositive children were more likely to be older at the time of adoption and to have co-infection with intestinal parasites, but no significant differences in height, weight, anemia, or diarrhea among seropositive versus seronegative adoptees were found.[19] Interestingly, all seropositive children reported having spent some time in an orphanage; none of the 25 children who resided completely in foster care was seropositive. Because no prospective, controlled studies in adoptees have assessed the long-term effects of colonization or the utility of pediatric treatment in preventing resumption of colonization or progression to ulcers or cancer, neither routine testing for *H. pylori* nor presumptive therapy is indicated.

Although routine testing for ova and parasites is recommended for all international adoptees (see Table 243–1), the utility of stool culture for identifying bacterial pathogens in asymptomatic children is controversial. Prospective series put the rate of bacterial gastroenteritis between 2.5 and 7 percent.[12,18,23,27] Because of transmissibility, some practitioners test for salmonellae; although this organism may be present in asymptomatic children, treatment prolongs excretion and therefore is not recommended for otherwise normal children older than 3 months. Children with diarrhea should be evaluated for a number of pathogens, including *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia*; rotavirus and caliciviruses, such as *Norovirus;* and intestinal parasites (see later).

Syphilis

Maternal syphilis is a major problem in Russia, eastern Europe, and Guatemala. Treatment in these countries often is erratic or inadequate; foreshortened courses, use of oral agents, and poor documentation of treatment are common findings in pregnant women. Referral paperwork on many adoptees states that "preventive treatment for syphilis was given," but these regimens can vary dramatically from a few days of oral antibiotic therapy to the more appropriate 21-day course of intramuscular penicillin.

As a result, testing for syphilis with both a non-treponemal (Venereal Disease Research Laboratory [VDRL] or rapid plasma reagin) test and a treponemal test (fluorescent treponemal antibody absorption [FTA-ABS]) is essential for internationally adopted children, even in the face of purportedly negative test reports from abroad. The combination of the VDRL and FTA-ABS tests is extremely useful, especially in infants young enough to have experienced passive transfer of maternal antibodies. Mothers infected with syphilis before the child's birth will have a positive FTA-ABS assay response, and the antibody will be passed to the young infant, even if the VDRL test result in the child has been confounded by partial therapy in the nursery or orphanage. When the FTA-ABS or the VDRL test result is positive, consideration should be given to obtaining spinal fluid, long bone films, and hepatic transaminase values before the initiation of parenteral penicillin therapy. Because syphilis is an entirely curable disease and the complications of untreated or partially treated congenital syphilis involve not only intellectual impairment but disfiguring physical complications such as Hutchinson incisors, saber shins, and gummata, accurate determination of the adoptee's syphilis status is essential.

For the child found to have congenital infection, treatment with 10 days of intravenous penicillin G (100,000 to 150,000 units/kg/day) should be followed by repeated VDRL levels at 3- to 6-month intervals for up to 24 months to ensure a fourfold reduction in titer. Children with a positive VDRL test result in the spinal fluid will require a repeated lumbar puncture 6 months after receiving treatment.

Although congenital syphilis is by far the most common presentation, my experience also has included cases of primary and secondary syphilis acquired in situations of abuse. Differentiation among these causes of positive serologic results has important implications for treatment.

Tuberculosis

The American Academy of Pediatrics has mandated that the purified protein derivative (PPD; Mantoux test) be used to test skin reactivity in children coming from areas in which tuberculosis is endemic. Despite this recommendation, many pediatricians still use the tine test or do not test at all if the adoptee has received bacillus Calmette-Guérin (BCG) vaccine. Both of these practices are incorrect. All internationally adopted children should be tested with PPD (and a *Candida* skin test or other control for delayed-type hypersensitivity) as soon after adoption as is feasible. As many as 30 percent of adoptees may be anergic within the first 1 to 2 months after arrival; when both skin test results are negative shortly after adoption, the PPD test and the control for delayed-type hypersensitivity should be repeated within 4 months.[11,12] Children who have received the vaccine by report and whose left (or more rarely right) deltoid shows the typical scar may be tested with the PPD approximately 12 months after application of the BCG vaccine without inducing a false-positive reaction. Prospective studies in Native American children given BCG at birth have demonstrated that cross-reactivity between BCG and PPD is maximal 6 months after vaccination and wanes thereafter.[15] Concerns about a sloughing reaction if PPD is placed after administration of BCG vaccine are exaggerated and should not stand in the way of placing a Mantoux skin test.

The Mantoux test should be read by trained medical personnel, not by parents. If the PPD response shows more than 10 mm of induration in the transverse diameter, chest radiography should be performed. If the chest radiograph is normal, the child should receive 10 mg/kg of isoniazid once a day for 9 months. The 6-month course of isoniazid for latent tubercolosis is no longer recommended. Parents should be instructed that isoniazid as prepared by many commercial pharmacies may be poorly tolerated from the standpoint of taste and gastrointestinal complaints. Under those circumstances, physicians should instruct the pharmacist to prepare a low-sucrose formulation in an appealing flavor. A little extra work by the physician to ensure palatability of isoniazid goes a long way toward maintaining compliance.

A child with a positive PPD response and an abnormal chest radiograph should be managed by an infectious disease specialist. Acid-fast bacillus culture and stains should be performed on sputum or gastric aspirates, depending on the age of the child. Resistance to multiple antituberculous agents can be a problem in the countries of Southeast Asia and in some areas of Russia and eastern Europe; as a result, unusual regimens may need to be implemented for individual patients on the basis of the drug susceptibility of their isolates.

In children older than 5 years with a positive PPD reaction and a normal chest radiograph, consideration should be given to extrapulmonary disease of the spine or genitourinary tract. Standard evaluation in these cases should include a sedimentation rate, imaging of the lumbosacral spine with appropriate shielding, and three first-morning voided urine specimens as well as urinalysis to look for hematuria and sterile pyuria. Pulmonary or extrapulmonary disease requires at least three antituberculous agents for 2 months while awaiting sensitivity data.

Although transmission of tuberculosis to school or family contacts is rare in children younger than 6 years who cannot generate sufficient tussive force to spread respiratory droplets, household contacts of the child with a positive PPD reaction also should undergo PPD testing. Cavitary disease, although an unusual occurrence among children, is virtually always infectious for others, and failure to place a Mantoux skin test or to interpret it correctly can lead to widespread dissemination among multiple contacts.[8]

PARASITIC INFECTIONS

The presence of intestinal parasites is a common concomitant of orphanage confinement but is exceedingly rare in Korean adoptees raised in foster homes. A single stool sample for ova and parasites is informative approximately 85 percent of the time[7]; however, detection is improved when multiple specimens are examined.[10,22] Ova of *Ascaris lumbricoides* will not be found in the stool sample if the harbored worm is either a male or an unfertilized female, but the subsequent passage of the worm may cause great consternation for the parent. Apprising the parents of this possibility saves recriminations later.

Administration of albendazole before the child's arrival may limit the number of parasites found in internationally adopted children,[20] but certain parasites, such as *Giardia lamblia*, are not killed by this regimen. Because of the potential to transmit *Giardia* in the daycare setting, most children should be treated, even when they are asymptomatic. The drug of choice is metronidazole, although the liquid formulation of furazolidone typically is more palatable for children. Tinidazole and nitazoxanide also are appropriate. For symptomatic children in whom giardiasis is suspected, a stool antigen test, in addition to examination for ova and parasites, enhances the likelihood of establishing the diagnosis.[30]

Although not yet reported in internationally adopted children, *Cyclospora*, *Cryptosporidium* spp., *Isospora belli*, and *Microsporidia* spp. have caused diarrhea in immunocompetent children[30]; thus, these agents should be sought in diarrheal illness that does not yield other pathogens. Treatment of *Blastocystis hominis*, *Chilomastix mesnili*, *Trichomonas hominis*, *Trichomonas tenax*, *Entamoeba coli*, and *Iodamoeba buetschlii* is not necessary because these organisms are not pathogenic, although some experts recommend treating immunocompromised children with *B. hominis*. Repeated stool samples for ova and parasites should be performed at the close of a treatment course if the child remains persistently symptomatic or if more than one organism was isolated on the original screen.

LICE AND SCABIES

Scabies is a consequence of the orphanage environment and as such is found infrequently in Korean adoptees and more commonly (7% to 10%) in those from other countries.[21] Pruritic papules on the wrists, ankles, palms, or soles are the major diagnostic clues. Treatment entails the topical application of 5% permethrin cream; a second application one week later may be necessary. Head lice *(Pediculus capitis)* are found more frequently than are body lice *(Pediculus corporis)* or pubic lice *(Phthirus pubis)*. Topical 1 percent permethrin, 1 percent lindane, or 0.5 percent malathion is effective for most cases of head lice, but treatment failures due to emerging resistance may require two doses of oral ivermectin, spaced at a 10-day interval.

OTHER TESTS FOR INFECTIOUS DISEASES IN INTERNATIONAL ADOPTEES

The microcephalic child represents a perplexing dilemma. Studies have shown that head circumference may be inversely correlated with length of time in the orphanage setting,[13] and a downward trend of head circumference from the percentile recorded at birth is common in adoptees reared in orphanages. Microcephaly is a common feature of fetal alcohol syndrome, but testing for treatable causes, such as toxoplasmosis and syphilis, should be undertaken before the diagnosis of fetal alcohol syndrome is made. Although entities such as rubella, cytomegalovirus, and herpes simplex virus are prognostically highly important as a cause of microcephaly, routine testing of normocephalic adoptees for rubella, cytomegalovirus, herpes simplex virus, or toxoplasmosis is not recommended. Routine screening tests for malaria are not warranted in asymptomatic international adoptees.

Internationally adopted children from Mediterranean regions, Middle Eastern countries, and China should be tested for glucose-6-phosphate dehydrogenase deficiency if administration of nalidixic acid, nitrofurantoin, or sulfonamide is contemplated.

VALIDITY OF MEDICAL RECORDS AND MEDICAL TESTING IN THE COUNTRY OF ORIGIN

Parents may be inappropriately encouraged to accept "normal" results when screening is performed in the country of origin. Parents should be cautioned that many countries have no standard accreditation of laboratory personnel and that results may be haphazard, inaccurate, or falsified. For these reasons, medical testing should be repeated as soon as possible after the child arrives in the United States.

A major area of debate at present is the validity of immunization records from countries other than South Korea. A careful analysis of both the number of immunizations and the interval between them more often than not detects aberrancies. Immunizations that antedate a child's recorded birth date, that are given on the same day of the month (e.g., 8/7/00, 9/7/00, 2/7/01), or that are administered in orphanages without refrigeration are suspect.

DPT AND POLIO SERIES

In prospective studies, an evaluation of titers to diphtheria, tetanus, and polio in 98 Chinese orphans whose records indicated complete DPT and OPV series found that as many as 30 percent lacked detectable antibodies, as compared with less than 1 percent in age-matched Dutch children.[28] In a retrospective chart review, only 28 percent of 103 Guatemalan adoptees' vaccination records met U.S. standards.[17] Another retrospective study reviewed immunization records of 504 children from 16 countries; only 35 percent had documented vaccination for DPT (diphtheria, pertussis, tetanus), hepatitis B, or MMR (measles, mumps, rubella), and of these, only 62 percent were up to date with one or more series according to the U.S. schedule.[29]

On the basis of these reports, the Advisory Committee on Immunization Practices has recommended re-administration of the entire DPT series (and IPV) if any departure from the U.S. vaccination schedule is found in terms of the number of vaccinations, the interval between them, or the child's age at immunization. Table 243–4 presents some approaches to immunizations in international adoptees. In my 20 years of experience with reimmunization of children with questionable vaccination certificates, I have encountered not a single incident of toxicity with this approach. At issue here is not so much the infant who may have received one immunization abroad and will certainly receive a protective complement here in the United States; rather, the focus of concern should be the older child, age 2 years and older, whose immunization certificate may be inaccurate. If not reimmunized, such a child is at risk for acquiring tetanus in the United States or other diseases such as polio or diphtheria that may be acquired during international travel.

IMMUNIZATION FOR MEASLES, MUMPS, AND RUBELLA

Countries other than Korea either omit the MMR vaccine entirely or give only the measles component, typically when the child is 6 to 12 months of age. Two outbreaks of measles in Chinese adoptees and caregivers traveling to the United States impugn the reliability of vaccination certificates from orphanages. The first outbreak encompassed 14 cases: 10 among adoptees and 4 secondarily transmitted to siblings and caregivers aged 28 months to 47 years.[2] The second outbreak among 12 Chinese adoptees resulted in 10 cases across three states (Washington,

TABLE 243–4 Approaches to Immunizations in Internationally Adopted Children

Accept all appropriate pre-adoption records of immunization.
Measure serum antibodies against diphtheria, tetanus, poliovirus (serotypes 1, 2, and 3), hepatitis B, varicella, measles, mumps, and rubella. If antibody levels are appropriate for age, accept all corresponding pre-adoption records of immunization.
Measure serum antibodies against vaccine-preventable diseases (above); if normal for age, consider the child to have received one immunization in the series.
Accept no pre-adoption records of immunization; immunize the adoptee with all vaccinations appropriate for age.

Modified from Murray, T. S., Groth, M. E., Weitzman, C., et al.: Epidemiology and management of infectious diseases in international adoptees. Clin. Microbiol. Rev. 18*:510-520, 2005.*

Maryland, and New York); nine of these cases occurred in adoptees aged 12 to 18 months and the tenth in an exposed, unvaccinated adult aged 19 years.[3-6] In both outbreaks, the infected adoptees were old enough to have been vaccinated under Chinese policy. For children coming from countries other than Korea, MMR vaccine should be given when the child is 12 to 16 months old, 4 to 6 years of age, and again in middle school.

POLYSACCHARIDE VACCINES

Polysaccharide conjugate vaccines for *Haemophilus influenzae* type b and *Streptococcus pneumoniae* serotypes are not administered routinely in any countries other than the United States and western Europe. These vaccines should be given to internationally adopted children as part of the immunization series in the United States.

TRAVEL MEDICAL KIT

Many parents are encouraged by adoption agencies or by information on the Internet to take antibiotics to the country of origin. Although this action may seem prudent, no antibiotic known to the author is a panacea for all infectious diseases. A child with a fever whose parents are carrying a third-generation cephalosporin may have needed treatment delayed if the real cause of the illness is methicillin-resistant *Staphylococcus aureus* or tuberculosis. For these reasons, in our clinic, we instruct parents that fever should prompt medical attention, not random dosing with an antibiotic. Teaching parents how to take a rectal temperature accurately is more important than supplying them with an antibiotic that may be outdated, inefficacious, or contaminated with nonsterile water on dilution.

INTERNET RESOURCES

Informative Web sites for prospective adoptive parents can be found at *eeadopt.org* and *www.adopting.com*. A plethora of Web sites also provides first-hand information from parents, but subjective reports should not be confused with objective information. Physicians may find the Web site *www.adoptmed.org* of value if questions arise with regard to individual patients.

INFECTIOUS DISEASES IN REFUGEE CHILDREN

The widely varying conditions from which internationally adopted children come are no more predictable for refugee children. Some will have experienced only recent disruption, whereas other children may have been displaced from parents for months to years. An accompanying parent oftentimes is helpful in providing information about immunizations and illnesses in the past medical history, but refugees from war or persecution may arrive without a knowledgeable adult.

Except in the most chaotic circumstances, refugee children who have spent some time in a camp supervised by responsible international health organizations have many advantages over internationally adopted children, for whom there are no globally accepted screening protocols (Table 243–5).

TABLE 243–5 Comparison of Refugees and Adoptees

Refugees	Adoptees*
Organized screening in camps	No organized screening
Most diseases already identified	Many medical illnesses unidentified
Medical testing accurate in camps	Medical testing inaccurate
Preventive health care under way	Preventive health care delayed

**From countries other than South Korea.*

SCREENING TESTS

No universally accepted recommendations exist for medical evaluation of refugee children. In general, in the absence of documentation of immunizations or screening undertaken in refugee camps, the most prudent course is to screen for transmissible infectious diseases that are found more commonly in the child's country of origin or that may have been transmitted during the period of displacement. Such entities include but are not limited to hepatitis B, hepatitis C, HIV infection, tuberculosis, and diarrheal pathogens such as *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia*. Illnesses such as melioidosis, typhoid fever, malaria, filariasis, and flukes may be found more commonly in refugees than in adoptees because of regional prevalence. In refugees or immigrants from regions such as Asia, the Middle East, sub-Saharan Africa, eastern Europe, Latin America and the Caribbean, the frequency of intestinal parasitosis may be high; therefore, some experts recommend presumptive treatment with albendazole as a more cost-effective strategy than screening. The pediatric dosage is 400 mg given once. Practitioners should be aware that such treatment is not effective against *G. lamblia*.

A careful history and physical examination may suggest diseases caused by geographically circumscribed entities such as leprosy, schistosomiasis, and other rarely encountered parasitic diseases. Many travel medicine clinics find it particularly useful to have a parasitologist on staff or at least to have ready access to informed consultation. Last, consideration is indicated for both refugees and adoptees of sickle hemoglobinopathies in Africa, India, and Central and South America; hemoglobin E in Southeast Asia; glucose-6-phosphate dehydrogenase deficiency in Africa, the Mediterranean, the Middle East, and China; and delta hepatitis (hepatitis D) in hepatitis B–infected individuals from southern Italy, eastern Europe, South America, Africa, and the Middle East.

SECTION XXIV

HEALTH CARE–ASSOCIATED INFECTIONS

CHAPTER 244

HEALTH CARE–ASSOCIATED INFECTIONS

W. Charles Huskins ❂ Donald A. Goldmann

Health care–associated (nosocomial) infections traditionally have been defined as infections that develop in hospitalized patients and are neither present nor incubating at the time of the patient's admission to the hospital.[208] A more inclusive view is that health care–associated infections are infections that occur as a consequence of health care, regardless of whether they arise during hospitalization. This definition includes a surgical-site infection that occurs after an outpatient surgical procedure or a case of varicella acquired during an emergency department visit. Infections in hospital personnel caused by microorganisms acquired in the hospital also are health care–associated infections. This expanded view of health care–associated infections fits well with the increased delivery of medical care in ambulatory settings, the more comprehensive assessment of outcomes of medical care, and the occupational risk medical personnel face of acquiring infections.

In some cases, determining whether an infection is a consequence of health care may be difficult. Infections with long or variable incubation periods, such as hepatitis C or late-onset prosthetic valve endocarditis, may not be manifested until long after patients have undergone medical procedures, raising doubt about their causation. Infections in immunocompromised patients occurring during hospitalization, such as cytomegalovirus enteritis, hepatitis, or pneumonia, and even aspergillosis, often are perceived as being attributable to the patients' underlying risk of acquiring infection, to previous infection, or to colonization, although the use of immunosuppressive medications may contribute directly to the occurrence of these infections.

Despite these ambiguities, defining health care–associated infections as infections that occur among persons who are exposed in the health care environment makes sense because doing so identifies the population at risk. This definition affords us the opportunity to understand the mechanisms leading to these infections better and to design and to evaluate interventions to prevent their occurrence. This chapter discusses the general epidemiology of health care–associated infections (including those that are introduced into the hospital from the community); infections related to invasive devices, procedures, and treatments; and infections in special populations. Programmatic approaches to the prevention and control of nosocomial infections are discussed in Chapter 245.

HISTORICAL ASPECTS

The history of health care–associated infections and their control is linked tightly to developments in institutional medical care. Two publications describe this history in considerable detail.[335,540] Unfortunately, historical data of health care–associated infections in children are relatively limited. Nonetheless, ample evidence indicates that efforts to study and to prevent infection among hospitalized children have contributed significantly to the development of infection control and prevention efforts in general.

Hospitals in Europe during the Middle Ages and the Renaissance were notorious for their overcrowding and unsanitary conditions, and one can imagine that children suffered greatly from the epidemics of contagious diseases that spread through hospitals during this period. The Sanitarian movement in England in the 19th century included a focus on the egregious conditions in many hospitals. Florence Nightingale and William Farr noted the high mortality rates in hospitals and campaigned tirelessly to improve hospital design and hygiene. By the 18th and 19th centuries, sketchy information about the impact of infections in hospitalized pediatric patients began to emerge. These data, summarized in a report presented in a landmark seminar on nosocomial infections in pediatric patients at the Sixth Northern Pediatric Congress in Stockholm in 1934,[198] provide dramatic evidence that health care–associated infections were the cause of considerable morbidity and mortality in hospitalized children.

Semmelweis' classic studies of puerperal fever in the Vienna Lying-In Hospital in the mid-1800s provided insights into the etiology of perinatal infections in newborn infants, not just their afflicted mothers.[541] Semmelweis noted that rates of mortality in infants born to women in the First Division of the hospital (the division where medical students who had come from the autopsy table cared for women in labor) were several-fold higher than those in infants born to women in the Second Division of the hospital (the division where midwives cared for women in labor). In support of his theories about the infectious etiology of puerperal fever, he noted that rates of infant mortality closely paralleled rates of maternal mortality from puerperal fever and that autopsy findings were remarkably similar in infants and mothers. The opening of wards and entire hospitals designated for the treatment of patients with infectious diseases in the early 20th century stimulated interest in the study of "cross-infection" with measles, chickenpox, scarlet fever, whooping cough, diphtheria, and invasive meningococcal disease.[540] The potential for cross-infection with these classic contagious diseases on pediatric wards, especially wards caring for infants, was well recognized in the leading hospitals of the day and stimulated a number of interventions to minimize this problem. Quarantine areas for new admissions, confinement of each child in an individual cubicle, cohorting of patients admitted during community epidemics, use of masks by persons caring for patients, exclusion of visitors, and strict control of the health of nurses and physicians caring for the patients were employed to minimize the spread of contagious diseases.[59,69,261,349,362] Some hospitals even used closed cubicles with outside exhaust of air for patients with measles or varicella.[261] Analysis of the effectiveness of these interventions contributed to a better understanding of how contagious diseases are spread in hospitals.

Undoubtedly because of this vigilance, the first systematic surveys of infections in pediatric patients in hospitals in Europe

and the United States published in the 1930s and 1940s demonstrated that spread of the classic contagious diseases in hospitals occurred but was relatively uncommon.[261,349,396,471,620] However, respiratory infections of various types were encountered frequently; gastrointestinal and skin infections also were relatively common occurrences.[261,349,396,620]

Although infections caused by beta-hemolytic streptococci had been a scourge of obstetric and surgical wards for centuries, advances in diagnostic microbiology and serotyping of streptococci in the mid-1900s led to greater appreciation of the etiologic role of this organism in hospital-acquired scarlet fever, postpartum infection, postoperative infection, and secondary infection in patients with burns, measles, and influenza.[530,540] The decline of this organism as a major hospital-acquired pathogen coincided with the introduction of antibiotic therapy in the 1940s and 1950s, although a causal link between these events has not been established.[530]

Outbreaks of *Staphylococcus aureus* infection in hospitalized newborn infants had been documented in late 1800s and early 1900s,[79,314] but the pandemic of *S. aureus* infections that plagued hospitals in the 1950s and 1960s drew special attention to the impact of infections caused by this organism. Outbreaks of staphylococcal disease were particularly devastating in newborn nurseries, where epidemics caused by specific phage types caused substantial morbidity and mortality.[530,533]

The seriousness of the problem of hospital-acquired staphylococcal infection spawned more comprehensive efforts to document the impact and consequences of hospital-acquired infections and served as the impetus for development of organized infection-control programs, particularly in Great Britain (with its tradition of infection control sisters) and North America. A 1-year study of nosocomial infections in pediatric patients at The Hospital for Sick Children in Toronto was conducted in 1959.[511-513] The cumulative incidence of these infections was 6.5 percent; respiratory and gastrointestinal infections occurred most commonly. *S. aureus* caused infection in only 2.6 percent of patients overall, but it accounted for most of the surgical-site infections. Even this early study recognized the important consequences of nosocomial infections, reporting that 16 deaths and 2070 extra hospital days were the result of these infections.

In 1970, a surveillance and control program for nosocomial infections was established at Children's Hospital in Boston, and data were reported to the nascent National Nosocomial Infections Study at the Centers for Disease Control and Prevention (CDC).[201] The cumulative incidence of infection was 4.6 percent. *S. aureus* was the pathogen encountered most frequently, but more than 60 percent of the pathogens were gram-negative bacilli, including *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella* spp., *Enterobacter* spp., *Proteus* spp., and *Serratia* spp. Study of the epidemiology of specific pathogens in this period was hampered because few clinical laboratories performed extensive speciation at the time. Moreover, the detection of hospital-acquired viral infections was hindered by the limited availability of suitable diagnostic techniques. The Children's Hospital study emphasized the association of nosocomial infections with exposure to invasive devices and procedures (e.g., surgical-site infections in patients undergoing surgery, urinary tract infections in patients with indwelling urinary catheters, bloodstream infections and septic phlebitis associated with intravascular catheters, and ventriculitis associated with cerebrospinal fluid shunts). Additional epidemiologic studies of infections in newborn infants and children cared for in intensive care units (ICUs) during the 1970s and early 1980s strengthened the association between the use of invasive devices and procedures and hospital-acquired infections.[229,267,272,372]

Advances in viral diagnostics in the 1970s led to greater appreciation of the importance of viruses as a significant cause of nosocomial infections, particularly in pediatric patients.[610,632] Spread of respiratory and gastrointestinal viruses, especially respiratory syncytial virus (RSV) and rotavirus, was documented to be a severe problem on pediatric wards.[148,253,404,519,634]

The past 30 years have witnessed several major new developments. Gram-positive bacteria, including coagulase-negative staphylococci, *S. aureus*, enterococci, and streptococci, have re-emerged as significant pathogens in hospitalized patients.[181,236,294,424,577] Antimicrobial-resistant bacteria, such as methicillin-resistant *S. aureus* (MRSA), vancomycin-resistant enterococci, and gram-negative bacilli resistant to third-generation cephalosporins, aminoglycosides, carbapenems, and quinolones, have become especially problematic.[211,424,607] Although MRSA has received the most attention in the media and peer-reviewed literature, gram-negative pathogens, such as *Burkholderia*, *Stenotrophomonas*, and *Acinetobacter*, are potentially even more problematic because they are resistant to most (or even all) available antibiotics, and the pipeline of new active agents is virtually nonexistent. Overuse of antibiotics is partly responsible for the continued increase in the incidence of *Clostridium difficile* infections; the clonal spread of new, more virulent stains of *C. difficile* (NAP-1) is particularly alarming. As the number of severely ill and immunosuppressed children receiving care in hospitals has increased, the incidence of fungal infection, especially infection caused by *Candida* and *Aspergillus*, has increased dramatically.[1,181,191] Health care–associated acquisition of common respiratory viruses, such as RSV, parainfluenza virus, and adenovirus, can lead to severe, sometimes lethal pneumonia in these patients. Finally, the potential for health care–associated infections caused by blood-borne pathogens, such as the human immunodeficiency virus (HIV), hepatitis B, and hepatitis C, to occur among patients as well as health care providers is well recognized.[58,94,444,462,638]

In summary, the history of health care–associated infections in children is tied closely to the progress of medicine itself. New therapies and invasive procedures have had the unwanted side effect of increasing the risk of acquiring infections. Longer survival from conditions formerly causing early death and increasing numbers of immunocompromised children have resulted in a growing population of children with impaired host defenses who are at increased risk for development of infections. The selective pressure of widespread use of new, broad-spectrum antimicrobial agents has resulted in the development of previously unknown forms of antimicrobial resistance and the emergence of fungi as serious health care–associated pathogens.

GENERAL EPIDEMIOLOGY OF HEALTH CARE–ASSOCIATED INFECTIONS

Perhaps more than any other area of infectious disease epidemiology, the methodology used to study the epidemiology of health care–associated infections has itself been subjected to intense investigation and validation. This section describes the epidemiology of health care–associated infections in pediatric patients in general terms, highlighting important methodologic issues. The epidemiology of specific health care–associated infections and pathogens is discussed in later sections.

RATES OF HEALTH CARE–ASSOCIATED INFECTION

During the 1960s to 1980s, numerous hospital surveys examined rates of nosocomial infections in pediatric patients.[116,181,201,294,398,511-513,632] These surveys were useful in documenting the nature and frequency of these infections and in illustrating trends in infections caused by various pathogens (see the section on historical aspects). However, methodologic differences rendered evaluation and comparison of infection rates among these studies difficult. The types of infections studied and the definitions used to identify infections varied considerably.

TABLE 244–1 Pooled Means of Device-Associated Infection Rates by Type of Intensive Care Unit in Hospitals Participating in the National Nosocomial Infection Surveillance System

Type of Intensive Care Unit	Pooled Mean		
	Central Line–Associated Bloodstream Infections/1000 Central Line Days	Ventilator-Associated Pneumonia/1000 Ventilator Days	Catheter-Associated Urinary Tract Infections/1000 Urinary Catheter Days
Adult ICUs			
Coronary	3.5	4.4	4.5
Cardiothoracic	2.7	7.2	3.0
Medical	5.0	4.9	5.1
Medical-surgical			
Major teaching	4.0	5.4	3.9
All others	3.2	5.1	3.3
Neurosurgical	4.6	11.2	6.7
Respiratory	4.8	4.9	6.4
Surgical	4.6	9.3	4.4
Trauma	7.4	15.2	6.0
Burn units	7.0	12.0	6.7
Pediatric ICUs	6.6	4.9	4.0

Data are from January 2002 to June 2004.
Modified from National Nosocomial Infection Surveillance System: National Nosocomial Infection Surveillance (NNIS) System Report, data summary from January 1992 through June 2004, issued October 2004. Am. J. Infect. Control 32:470-485, 2004.

The sensitivity of the case-finding techniques employed and the vigor with which viral infections were sought and confirmed also varied greatly. In most cases, there was insufficient adjustment for length of hospitalization, exposure to invasive devices and procedures, case mix, and severity of illness, all of which increase the risk of acquiring health care–associated infection.

Many but not all of these methodologic concerns have been alleviated by examining rates of health care–associated infection in pediatric patients provided by the National Nosocomial Infections Surveillance (NNIS) system, now called the National Healthcare Safety Network (NHSN),[606] coordinated by the Division of Healthcare Quality Promotion at the CDC. Similar methods have been used in other countries for surveillance of health care–associated infections in pediatric patients.[490] As of 2000, more than 320 U.S. acute-care hospitals, including 70 pediatric ICUs and more than 120 high-risk nurseries (the term used by the NNIS system for newborn ICUs), were reporting data to the NNIS on the incidence of health care–associated infections.[576] Participating hospitals follow NNIS/NHSN surveillance methods, which include use of published definitions of health care–associated infections,[208] standardized coding of data, structured data collection sheets, and a microcomputer surveillance software program designed to report data to the NNIS system.[167,274] Case-finding methods are not specified in the NNIS/NHSN methodology, although most hospitals identify health care–associated infections by reviewing microbiology result reports and patient charts.[167] Post-discharge surveillance for infections such as surgical-site infection is highly variable among participating hospitals.

The accuracy of data reported to the NNIS has been evaluated in a small subset of ICUs, which did not include any pediatric ICUs or high-risk nurseries.[166] The accuracy of reports of infection varied by the site of infection. The sensitivity of surveillance for bloodstream infection, pneumonia, surgical-site infection, urinary tract infection, and other sites of infection was 85, 68, 67, 59, and 30 percent, respectively; the specificity was 98, 98, 98, 99, and 99 percent, respectively. Consequently, although current surveillance procedures in these hospitals fail to identify some infections, those infections that are reported are very likely to be true infections.

The invasive devices that are a routine part of modern hospital care are especially important risk factors for health care–associated infection, and additional adjustment of infection rates is necessary to accurately reflect these risks. Central venous catheters increase the risk of acquiring bloodstream infection, mechanical ventilation increases the risk of developing pneumonia, and indwelling urinary catheters increase the risk of developing a urinary tract infection. To adjust for exposure (as well as the duration of exposure) to these devices, infection rates can be expressed as the number of infections among individuals exposed to the device per 1000 device-exposure days. Table 244–1 contains data on the device-associated incidence density of bloodstream infections, pneumonia, and urinary tract infections for adult and pediatric ICUs in hospitals participating in the NNIS system.[424] Table 244–2 contains data on device-associated incidence density of bloodstream infections and pneumonia stratified by birth weight for high-risk nurseries in hospitals participating in the NNIS system.[424] More recent data for adult and pediatric ICUs and high-risk nurseries have been reported from the NHSN, but they include only a subset of the facilities that previously reported data to the NNIS system.[159] For this reason, NNIS system data are discussed in this chapter. The NNIS system data illustrate that the pooled mean rate of bloodstream

TABLE 244–2 Pooled Means of Device-Associated Infection Rates by Birth Weight Category in High-Risk Nurseries in Hospitals Participating in the National Nosocomial Infection Surveillance System

Birth Weight Category	Pooled Means	
	Umbilical and Central Line–Associated Bloodstream Infections/1000 Umbilical or Central Line Days	Ventilator-Associated Pneumonia/1000 Ventilator Days
≤1000 g	9.1	3.5
1001-1500 g	5.4	2.4
1501-2500 g	4.1	1.9
>2500 g	3.5	1.4

Data are from January 2002 to June 2004.
The number of participating high-risk nurseries in each of the birth weight classes ranged from 94 to 104 for umbilical and central line–associated bloodstream infections and 86 to 102 for ventilator-associated pneumonia.
Modified from National Nosocomial Infection Surveillance System: National Nosocomial Infection Surveillance (NNIS) System Report, data summary from January 1992 through June 2004, issued October 2004. Am. J. Infect. Control 32:470-485, 2004.

infection is higher in pediatric ICUs and high-risk nurseries, particularly for lower birth weight categories, than in adult ICUs (except for adult trauma and burn ICUs). Conversely, the pooled mean rate of pneumonia is substantially lower in pediatric ICUs and high-risk nurseries than in adult ICUs. The pooled mean rate of urinary tract infections in pediatric ICUs is comparable to that in adult ICUs.

On the basis of seminal studies by Freeman and others, birth weight has long been recognized as an important risk factor for health care–associated infection in newborn infants.[186,267] For this reason, rates of device-associated bloodstream infections and pneumonia from high-risk nurseries participating in the NNIS system are stratified into four birth weight strata (see Table 244–2): 1000 g or less, 1001 to 1500 g, 1501 to 2500 g, and 2500 g and more.[424] In the future, the NHSN will stratify data for the lowest birth weight category into two categories: 750 g or less and 751 to 1000 g.[159] As seen in Table 244–2, there is a progressive and marked increase in rates of bloodstream infections in sequentially lower birth weight categories such that the rate of infection in infants weighing 1000 g or less is nearly threefold higher than the rate in infants weighing more than 2500 g. Higher rates of pneumonia also occur in lower birth weight categories, but this trend is much less marked than for bloodstream infections.

Despite adjustment made for length of hospitalization, exposure to invasive devices, and birth weight (for neonates), health care–associated infection rates still vary considerably among ICUs. Boxplots of the distribution of device-associated infection rates reported by pediatric ICU and high-risk nurseries in hospitals participating in the NNIS system are displayed in Figures 244–1 and 244–2, respectively.[424] These figures illustrate that device-associated infection rates vary as much as 10-fold among units.

A portion of this variability likely is due to differences in the nature and severity of patients' underlying illnesses. Simple systems for classifying severity of illness, such as the system proposed by McCabe and Jackson[389] and the American Society of Anesthesiologists Physical Status Classification (ASA score), have been in existence for decades.[309] In the 1980s and 1990s, investigators developed and refined severity-of-illness scoring systems for adult, pediatric, and newborn ICUs. The use of these measures to adjust rates of nosocomial infections in pediatric and newborn ICUs is discussed in the following paragraphs.

The Physiologic Stability Index (PSI) was developed and validated as a measure of severity of illness for pediatric ICU patients.[650] The Pediatric Risk of Mortality (PRISM) score subsequently provided a streamlined scoring system by reducing the number of variables in the PSI through regression analysis and weighting of physiologic variables to better reflect their contribution to the risk of mortality.[466] Although the utility of this score and its subsequent modifications in predicting mortality in pediatric ICU patients has been studied extensively,[464-466] only three studies have examined the use of the PRISM score as a predictor of the development of health care–associated infection.[467,565,567] The most recent study developed a multivariable model, including the PRISM III-24 score, for assessing the risk of acquiring a health care–associated infection.[565] The model consisted of three factors assessed on the day of admission: the use of invasive devices (i.e., central venous catheter, mechanical ventilation, indwelling urinary catheter), the administration of parenteral nutrition, and an interaction of the PRISM III-24 score and postoperative care. As a whole, the model predicted the risk of acquiring a health care–associated infection well. However, the datasets used to develop and to validate the model were limited in size and derived from only one pediatric ICU. In addition, the most common health care–associated infection was tracheitis, which accounted for more than a third of all health care–associated infections analyzed; bloodstream infections and pneumonia accounted for only 25 percent and 7 percent, respectively, of the infections analyzed. The implication of these observations on the generalizability of model is not clear.

Another score, the Paediatric Index of Mortality (PIM), and a second-generation index (PIM2) are used widely[545,570] but in limited investigation have not been found to be good predictors of health care–associated infections.[24]

Several severity-of-illness measures have been developed for newborn ICU patients.[233,279,498-500,603,655] The most extensively tested and applied score, the Score for Neonatal Acute Physiology (SNAP), was shown by Gray and colleagues[232] to be a strong predictor of health care–associated coagulase-negative staphylococcal bacteremia among infants of very low birth weight

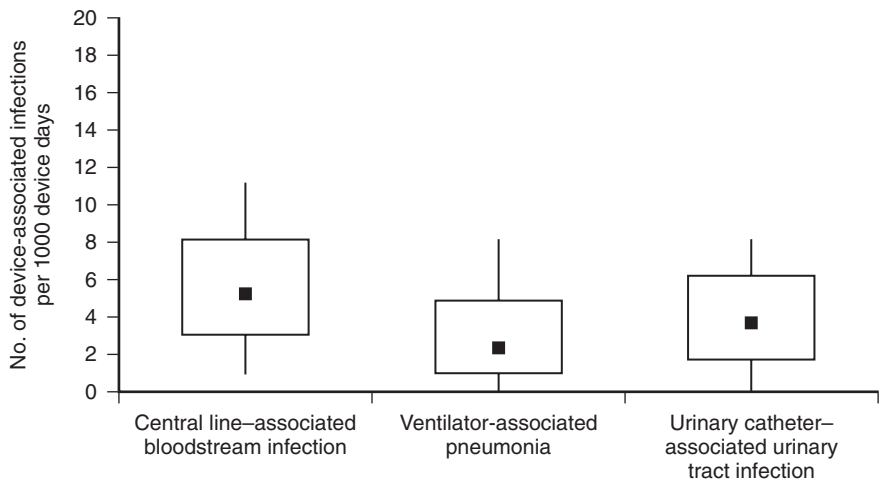

Figure 244–1 Distribution of device-associated infection rates in pediatric intensive care units in hospitals participating in the National Nosocomial Infection Surveillance system. Boxplots of the distribution of device-associated infection rates in pediatric intensive care units indicate the following: the solid square (■) represents the 50th percentile (median). The lower and upper bounds of the open vertical rectangle (□) represent the 25th and 75th percentiles, respectively. The lower and upper bounds of the lines extending above and below the open vertical rectangle represent the 10th and 90th percentiles, respectively. The number of participating pediatric intensive care units was 54 for central line–associated bloodstream infections and 52 each for ventilator-associated pneumonia and urinary catheter–associated urinary tract infections. *(Modified from National Nosocomial Infection Surveillance System: National Nosocomial Infection Surveillance [NNIS] System Report, data summary from January 1992 through June 2004, issued October 2004. Am. J. Infect. Control 32:470-485, 2004.)*

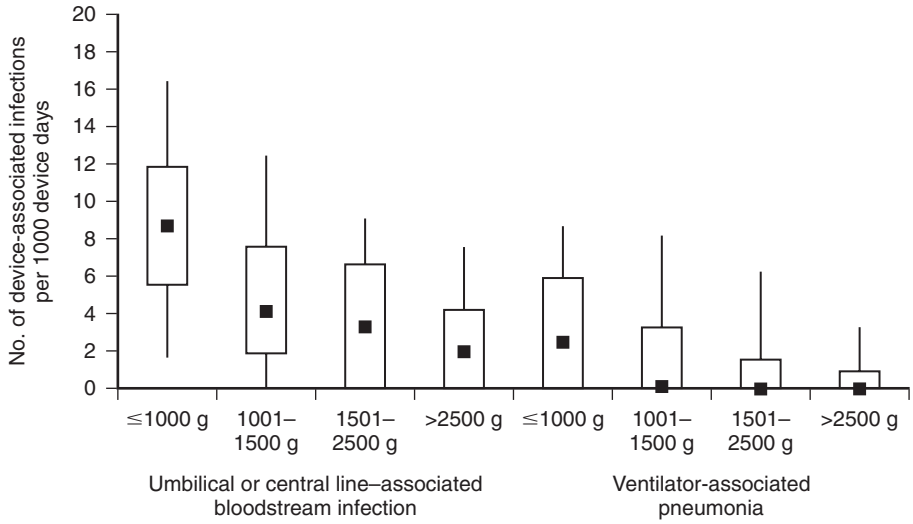

Figure 244–2 Distribution of device-associated infection rates in high-risk nurseries in hospitals participating in the National Nosocomial Infection Surveillance system. Boxplots of the distribution of device-associated infection rates in pediatric intensive care units indicate the following: the solid square (■) represents the 50th percentile (median). The lower and upper bounds of the open vertical rectangle (□) represent the 25th and 75th percentiles, respectively. The lower and upper bounds of the lines extending above and below the open vertical rectangle represent the 10th and 90th percentiles, respectively. The number of participating neonatal intensive care units in each of the birth weight classes ranged from 94 to 104 for umbilical and central line–associated bloodstream infections and 86 to 102 for ventilator-associated pneumonia. *(Modified from National Nosocomial Infection Surveillance System: National Nosocomial Infection Surveillance [NNIS] System Report, data summary from January 1992 through June 2004, issued October 2004. Am. J. Infect. Control 32:470-485, 2004.)*

(<1500 g) in an early study. However, rates of infection in this study were not adjusted for exposure to central or umbilical lines, and information about other significant risk factors, such as the administration of lipid emulsions, was not available. Two subsequent studies have examined SNAP as a predictor for development of bacteremia in more detail. In a follow-up case-control study conducted in the same units used by Gray, Avila-Figueroa and colleagues[30] found that SNAP on day 7 of hospitalization was not associated with coagulase-negative bacteremia, after adjustment for birth weight, length of hospital stay, and nearest date of discharge. In addition, Brodie and colleagues[70] conducted a cohort study in six newborn ICUs and found that after adjustment for birth weight and the presence of small-for-gestational age, SNAP was not a significant predictor of bloodstream infection. Therefore, in these two studies, SNAP did not add to adjustment by other intrinsic (i.e., host) risk factors. Consistent with a prior work,[185] both studies identified administration of parenteral nutrition with lipid emulsion as a highly significant risk factor for infection.[30,70] Interestingly, the study by Brodie found substantial variability in infection rates among newborn ICUs, even after applying rigorous methods of risk adjustment, suggesting that other patient care practices also may play a role in the observed variability in infection rates among newborn ICUs.[70] Although not explored in Brodie's study, higher nurse-to-patient staffing ratios have been linked to higher rates of health care–associated infections in various inpatient settings, including ICUs.[25,193,241,243,259,429,504]

Another approach to risk adjustment—use of a composite risk index calculated by several individual risk factors—has been applied to analysis of surgical-site infections by the NNIS system. Developed by analysis of 4 years of surgical-site infection data reported to the NNIS, the NNIS Basic Surgical-Site Infection (SSI) Risk Index is an example of a composite risk index that has been incorporated into routine surveillance in many hospitals.[125,213] This risk index is calculated by counting one point for each of the following three risk factors: a preoperative ASA score of 3, 4, or 5; an operation classified as either contaminated or dirty infected; and an operation with a duration of more than *T* hours, where *T* depends on the operative procedure performed.[125] The duration of a particular procedure is thought to reflect the complexity of the procedure. As seen in Table 244–3, this risk index provides a much better assessment of risk than does traditional wound classification alone. This index has not been applied to pediatric patients undergoing surgery. Moreover, although the NNIS Basic SSI Risk Index works well across a broad range of different surgical procedures, it does not work as well for some specific procedures, such as cardiac surgery, neurosurgery, and cesarean section.[165,214,275,495,510] Procedure-specific composite risk indices are being developed with use of NNIS data and multivariable modeling techniques.[212,273] The standardized infection ratio (a ratio that compares the observed rate of infection to the expected rate of infection generated with use of the regression

†Calculated by counting one point for each of the following three risk factors: a preoperative American Society of Anesthesiologists Physical Status Classification (ASA) score of 3, 4, or 5; an operation classified as either contaminated or dirty infected; and an operation with a duration of more than T hours (T is the 75th percentile for the duration of surgery rounded to the nearest hour for procedures included in the NNIS database; see reference 125).

Modified from Culver, D. H., Horan, T. C., Gaynes, R. P, et al.: Surgical wound infection rates by wound class, operative procedure, and patient risk index. Am. J. Med. 91:152S-157S, 1991.

equation developed by multivariable modeling) has been proposed as a means of using procedure-specific composite risk indices for benchmarking SSI rates.[212,273] A similar approach could be applied to other infections.[565] Other risk-adjustment methods may be useful in benchmarking SSI rates. For example, the National Surgical Quality Improvement Program uses a robust risk-adjustment method to calculate expected versus observed rates of complications in the 30 days after surgery; this method, which was validated in adult patients in Veterans Administration hospitals, has not been studied systematically in pediatrics.

In summary, the methodology for meaningful comparison of rates of health care–associated infection among ICUs or hospitals has advanced remarkably in the past 2 decades. Hospitals have used risk-adjusted infection rates, such as those provided by the NNIS system, to benchmark their institution-specific rates and to target areas for improvement. They likely have achieved some success in this effort because rates of device-associated bloodstream infections, pneumonia, and urinary tract infections declined in adult and pediatric ICUs participating in the NNIS system during the 1990s.[95,576] In high-risk nurseries during the same period, rates of catheter-associated bloodstream infections declined among infants in all birth weight categories, and rates of ventilator pneumonia declined among all but the smallest infants.[576] More recently, requirements for public reporting of health care–associated infection rates and national patient safety and quality improvement initiatives are reshaping the focus of surveillance of health care–associated infections from refinements in risk adjustment and benchmarking to a perspective of "zero tolerance" and complete elimination of health care–associated infections.[52,292,397,654] Application of evidence-based care bundles appears to be especially effective in reducing rates of central venous catheter–associated bloodstream infection and ventilator-associated pneumonia.[127,475,492]

SITES OF HEALTH CARE–ASSOCIATED INFECTIONS

Figures 244–3 and 244–4 illustrate the site distribution of health care–associated infections among patients in pediatric ICUs and

high-risk nurseries in hospitals participating in the NNIS system.[215,497] Bloodstream infection, pneumonia, urinary tract infection, other types of lower respiratory tract infection (e.g., tracheitis), and surgical-site infection represent the majority of health care–associated infections among patients in pediatric ICUs (see Fig. 244–3). The distribution of infections does not vary substantially by age group, although bacteremia is found more frequently and urinary tract infection less frequently among the youngest children (≤2 months). The majority of health care–associated infections among patients in high-risk nurseries are the following: bloodstream infection; pneumonia; eye, ear, nose, and throat infections; gastrointestinal infection; and skin and soft tissue infection (see Fig. 244–4). As noted previously, bloodstream infection occurs most frequently in lower birth weight categories of infants (≤1000 g and 1001 to 1500 g). A point prevalence survey conducted in pediatric and newborn ICUs in 29 U.S. hospitals participating in the Pediatric Prevention Network (PPN), a research collaboration between the National Association of Children's Hospitals and Related Institutions and the CDC, confirmed these general conclusions.[236,577]

The site distribution of health care–associated infections among children and newborns differs substantially from that among adults. Bloodstream infection represents a considerably greater proportion of health care–associated infections in children and newborns; conversely, urinary tract infection and, to a lesser extent, pneumonia and surgical-site infection represent lower proportions of infections in children and newborns.

Some of these differences are due to differences in exposure to invasive devices, but others are not. For example, urinary catheters are used much less frequently in pediatric and newborn ICUs than in adult ICUs,[424] decreasing the overall frequency of urinary tract infection, although the per-day risk of acquiring infection is probably similar. In contrast, the greater frequency of bloodstream infections in children and newborns is not attributable to catheter exposure because central lines (including central venous and umbilical catheters) are used less frequently

in pediatric and newborn ICUs than in most adult ICUs.[424] Indeed, as discussed previously (see the section on rates of infection), rates of bloodstream infections are higher among children and newborns than among adults even after adjustment for catheter exposure.[424] Mechanical ventilation is used roughly as frequently for children in pediatric ICUs and for very-low-birth-weight infants (≤1000 g) in newborn ICUs as in adult ICUs, indicating that other factors must play a role in the lower proportion and rates of pneumonia in children and newborns. Other factors playing a role in these differences are discussed in greater detail in other portions of this chapter (see the sections on health care–associated infections related to invasive devices, procedures, and treatments and health care–associated infections in special populations).

Health care–associated respiratory and gastrointestinal infections caused by seasonal pathogens circulating in the community, especially viruses such as RSV, influenza virus, and rotavirus, are important because of their impact on children and newborn infants. These infections are discussed in detail in other portions of this chapter (see the section on health care–associated infections due to spread of infections common in the community).

PATHOGENS CAUSING HEALTH CARE–ASSOCIATED INFECTIONS

Tables 244–4 and 244–5 list the distribution of pathogens for major sites of health care–associated infections among patients in pediatric ICUs and high-risk nurseries participating in the NNIS system.[215,497] *S. aureus*, coagulase-negative staphylococci, *Enterococcus* spp., a variety of gram-negative bacilli, and *Candida* spp. are responsible for most infections. Pathogens responsible for specific infections are discussed in more detail in other portions of this chapter (see the sections on health care–associated infections due to spread of infections common in the community; health care–associated infections related to invasive devices, procedures, and treatments; and health care–associated infections in special populations).

Several general trends in the microbial etiology of health care–associated infections that are relevant for children should be emphasized. The number of infections caused by coagulase-negative staphylococci has increased dramatically in the past 2 decades, almost entirely as a result of an increase in the frequency of bloodstream infections caused by these microorganisms.[215,497] This trend is particularly impressive in newborns, which is explained at least in part by the increased survival number of very-low-birth-weight infants who have long hospital stays and are highly dependent on intravascular catheters and parenteral nutrition.[185,186,188,558] Several studies using molecular epidemiologic techniques indicate that specific strains of coagulase-negative staphylococci may become endemic in newborn ICUs and may be transmitted by the hands of caregivers.[75,283,365,447,571,616] The frequency of *Candida* spp., especially *Candida albicans*, has increased for all major sites of infection.[191] Infections caused by these fungi have had a major impact among critically ill and immunocompromised children and premature infants.[191,293,486,527] The frequencies of infections caused by *S. aureus*, *Enterococcus* spp., *P. aeruginosa*, and *Enterobacter* spp. also have increased.

More alarming is the dramatic increase in antimicrobial resistance among common health care–associated pathogens. Project ICARE (Intensive Care Antimicrobial Resistance Epidemiology) studied the prevalence of antimicrobial resistance in adult and pediatric ICUs in more than 40 U.S. hospitals during 1996 to 1997.[192] This surveillance project subsequently became a part of the NNIS system and NHSN.[424] In its 2004 report, NNIS

**Group B streptococcal bloodstream infections and pneumonia occurred more frequently in infants weighing more than 2500 g.*
†Rotavirus constitutes 96.4% of viruses isolated from gastrointestinal infections.
Modified from Gaynes, R. P, Edwards, J. R., Jarvis, W. R., et al: Nosocomial infections among neonates in high-risk nurseries in the United States. National Nosocomial Infections Surveillance System. Pediatrics 98:357-361, 1996.

reported that the overall prevalence of methicillin resistance among *S. aureus* causing health care–associated infections was 60 percent (an increase of 11% in 2003 compared with 1998 to 2003), and the prevalence of vancomycin resistance among enterococci was 29 percent (an increase of 12% in 2003 compared with 1998 to 2003).[424] Resistance to methicillin is now virtually ubiquitous among coagulase-negative staphylococci. Resistance to third-generation cephalosporins is a common finding among gram-negative rods such as *E. coli*, *Klebsiella pneumoniae*, *Enterobacter* spp., and *P. aeruginosa*, and resistance to imipenem and quinolones is a rapidly growing problem among *P. aeruginosa* and other gram-negative pathogens.[424]

Hospitals caring for children have not escaped these trends, although the frequency of specific problems of resistance differs somewhat between pediatric and adult ICUs.

Infections caused by MRSA in pediatric patients have been recognized in children's hospitals since the 1980s.[295] However, data from the Project ICARE in the late 1990s indicated that the prevalence of MRSA in pediatric and neonatal ICUs is far less than in adult ICUs.[426] Similarly, a study of the prevalence of colonization with antimicrobial-resistant bacteria among patients in eight U.S. pediatric and newborn ICUs participating in the PPN found that colonization with this microorganism was uncommon.[560] Reasons for this difference are not known, but they may relate to the fact that a greater proportion of adult patients are transferred to the ICU from long-term care facilities, where colonization occurs more frequently, and the greater success of various control measures in containing or eradicating MRSA from an individual unit when the overall prevalence rate in the unit is relatively low. In recent years, the threat posed by MRSA has become accentuated by genotypically distinct strains of MRSA that have become widely disseminated in communities across the United States[415] and are an increasing cause of health care–associated infections.[319,320,544] Studies have documented that these strains also are a common cause of health care–associated MRSA infection in children at major pediatric referral centers.[284,653] Outbreaks of infection also have been described in otherwise healthy neonates and their mothers.[67,91,182,289,523]

The first reported infection with *S. aureus* with reduced susceptibility to vancomycin occurred in a child with a wound infection after undergoing cardiac surgery in Japan.[271] The experience thus far in the United States has involved infections in only a handful of adults.[103,563]

As previously noted, methicillin resistance among coagulase-negative staphylococci encountered in the hospital setting is now nearly universal in all inpatient care settings. Infections caused by *S. epidermidis* with reduced susceptibility to vancomycin also have been reported in adults.[209,562]

Viridans streptococci have emerged as a major cause of bloodstream infections among neutropenic patients, and the prevalence of resistance to penicillins and cephalosporins is increasing among these bacteria.[158,550]

Resistance among enterococci has become a particularly alarming problem, especially given the increasing frequency of health care–associated infections caused by these organisms. Enterococci are intrinsically resistant to many antimicrobial agents, including all cephalosporins, clindamycin, and trimethoprim-sulfamethoxazole.[98] In addition, enterococci, especially *Enterococcus faecium*, always have been relatively resistant to penicillin, but high-level resistance due to mutations in penicillin-binding proteins is now a relatively common finding.[98] High-level resistance to aminoglycosides emerged in the 1970s and became widespread in the 1980s; enterococci resistant to both streptomycin and gentamicin are resistant to the synergistic activity of all known antimicrobial combinations.[98] Penicillin resistance due to β-lactamase production in conjunction with high-level gentamicin resistance also has been reported.[494,633] As alarming as these trends were, the rapid increase in the rate of colonization and infection with vancomycin-resistant enterococci (VRE) observed across the United States during the 1990s was truly astounding.[86,425] Treatment of VRE-colonized adults with anti-anaerobic antibiotics promotes high-density colonization with VRE, which may facilitate dissemination of these bacteria.[151] Although colonization and infection with VRE have been demonstrated in pediatric patients,[56,57,234,356,382,514,566,608] data from Project ICARE and the PPN colonization study indicate that the problem is much less widespread among hospitalized children than among adults.[426,560]

In contrast, antimicrobial-resistant, gram-negative bacilli are both a common and serious threat to hospitalized children. The

introduction and widespread use of third-generation cephalosporins in the 1980s was followed quickly by the emergence and dissemination of gram-negative bacilli with mutations resulting in constitutive expression of chromosomally encoded AmpC β-lactamases.[355] In the late 1980s and throughout the 1990s, plasmid-borne, extended-spectrum β-lactamases capable of inactivating third-generation cephalosporins were identified in gram-negative rods from around the world and included *Klebsiella* spp., *Enterobacter* spp., *E. coli*, *Citrobacter* spp., *Morganella morganii*, and *P. aeruginosa*.[64,355] These pathogens often carry genes for resistance to aminoglycosides and other front-line antibiotics on their plasmids.[64,355] More recently, some gram-negative rods have been demonstrated to produce both an AmpC β-lactamase and an extended-spectrum β-lactamase, with both enzymes encoded on a plasmid.[456] Gram-negative rods producing AmpC β-lactamases or extended-spectrum β-lactamases have caused a number of outbreaks involving pediatric patients,[27,189,427,546] and data from Project ICARE and the PPN colonization study indicate that these bacteria, especially *Enterobacter* spp., are a significant and widespread problem in pediatric and newborn ICUs.[426,560] CTX-M extended-spectrum β-lactamases are now widespread in *E. coli* and *Klebsiella* both in the community and in hospitals in many countries and generally are associated with resistance to multiple antibiotics and reduced susceptibility to quinolones.[459] OXA-40 β-lactamase–producing *Acinetobacter* have caused outbreaks in Illinois and Indiana,[419] and carbapenemase-producing, gram-negative bacteria (both plasmid and chromosome mediated) are reducing the utility of this important class of antibiotics.[477] Aminoglycoside resistance due to production of aminoglycoside-inactivating enzymes by gram-negative rods has been a persistent but less pervasive problem. Resistance to imipenem and fluoroquinolones is a newer and growing concern, particularly among *P. aeruginosa*,[424] although the impact of these problems in pediatric patients has been limited thus far. Other gram-negative bacilli, including *Stenotrophomonas maltophilia*, *Acinetobacter* spp., *Citrobacter* spp., *Alcaligenes* spp., and *Burkholderia cepacia*, infrequently cause health care–associated infection but are notable because they usually exhibit multiple drug resistance.

Fluconazole resistance among *Candida* spp. is well documented; however, resistance is largely confined to non-albicans species of *Candida*, especially *Candida glabrata* and *Candida krusei*.[455] Although these species have become a more common cause of infection in patients undergoing treatment for cancer, they have not become widespread in other populations.[191]

ANTIMICROBIAL USE

The emergence, selection, amplification, and dissemination of antimicrobial-resistant microorganisms are closely related to the use of antimicrobial agents, although this connection may be easier to demonstrate at a population level than in an individual patient. Data regarding the use of antimicrobial agents in hospitals providing care to pediatric patients are very limited, although two multicenter studies provide general descriptive information.

Project ICARE tracked the use of antimicrobial agents in adult and pediatric ICUs. The initial Project ICARE report provided data from only a small number of pediatric ICUs,[192] but the 2001 NNIS system report included data from 16 pediatric ICUs.[425] Antimicrobial use in this report is quantified as the number of defined daily doses per 1000 patient days. The defined daily dose is a metric designed to quantify medication use in adult patients and does not make any adjustment for weight (e.g., the defined daily dose for cefotaxime is 3 g/day, whereas the usual dose prescribed for a child is 150 mg/kg/day). Consequently, the data in the NNIS system report probably underestimate the use of antimicrobial agents in children versus adults. Despite this caveat, these data provide a qualitative assessment of the frequency of use of specific agents in pediatric ICUs. In the participating units, third-generation cephalosporins are by far the most commonly used agents, followed by parenteral vancomycin, first-generation cephalosporins, ampicillin- or amoxicillin-containing agents, second-generation cephalosporins, antistaphylococcal penicillins, trimethoprim-sulfamethoxazole, antipseudomonal penicillins, fluoroquinolones, carbapenems, penicillins, oral vancomycin, and aztreonam.

The PPN point prevalence survey cited earlier found somewhat different results.[235] In this study, the antimicrobial agent most commonly used in pediatric ICUs was a first-generation cephalosporin, followed by third-generation cephalosporins and vancomycin. Most of the patients receiving cefazolin had undergone surgery recently. The agent most commonly used in neonatal ICUs was gentamicin, followed by ampicillin and vancomycin.

The reason for the discrepant results between the NNIS system report and the PPN study are not clear and may relate to differences in the ICUs and their patient populations or methodologic differences in measuring antimicrobial use. Although these two studies provide data on the relative frequency of use of specific antimicrobial agents, the determinants or the appropriateness of antimicrobial use in hospitals providing care to children in the United States has not been described in any detail. Moreover, a standardized approach to the measurement of antimicrobial use in children has not been defined and validated.

INTERACTIONS BETWEEN HOSTS AND PATHOGENS

In general, newborns begin life devoid of microbial flora, but they quickly become colonized with a broad array of microorganisms. Most of these microorganisms will not produce disease unless their human host's natural defenses against infection are compromised. In contrast, exposure to microbial pathogens may lead to infection unless the host has effective innate or specific immunity to these microorganisms. In hospitalized children, weakened host defenses coupled with the aggressive medical care required to sustain critically ill children tend to be more important factors than is the pathogenic potential of the specific microorganisms that happen to be circulating in the institution at any given moment.

Neonates are at particular risk for acquiring infection because of the relative immaturity of their immune systems, especially if they are born prematurely. A full review of the deficits in newborn immune function is available in other texts,[348] but a few of the most important problems deserve emphasis. Infants born before approximately 28 weeks of gestation do not have the benefit of transplacentally acquired maternal antibody, and even more mature newborns lack specific antibodies to many of the pathogens they can expect to encounter early in life. The alternative pathway of complement activation is designed to protect the host in the absence of specific antibody, but it may not function adequately against pathogens in the newborn infant. Neonates have limited neutrophil reserves, which may be exhausted quickly in the face of aggressive pathogens. In addition, migration of neutrophils is decreased, phagocytosis is less effective, and production of antibiotic proteins and peptides, such as bactericidal/permeability-increasing protein, is decreased.[347] Not surprisingly, opsonophagocytosis is compromised by the combination of inadequate specific antibody, suboptimal complement activation, and qualitative defects in recruitment, migration, and function of neutrophils. Immature cellular immunity also compromises the response of neonates to viral and other intracellular pathogens. Moreover, the neonate's lack of an established normal bacterial flora provides no natural "colonization resistance" against pathogens entering the upper respiratory or alimentary tracts, and the

fragile skin of premature infants is less resistant to trauma and the resulting microbial invasion.

Even after their immune system has matured and they are capable of mounting their own vigorous immune response to infection, infants and young children remain susceptible to communicable diseases that may be spread in hospitals, such as varicella, measles, and parvovirus, if they lack specific immunity. Some pathogens, such as RSV, provoke such a limited immune response that infants become susceptible again a short time after infection develops. Others, such as influenza virus, change their antigenic presentation so rapidly that immunity acquired in one year is of limited value in the next.

Underlying diseases, especially those that compromise the immune system, predispose the host to infections caused by a wide array of microorganisms that ordinarily do not cause disease in normal hosts. For instance, neutropenic children are particularly susceptible to filamentous fungal infections, such as invasive pulmonary aspergillosis, that rarely affect other children.[1,617] Immunocompromised children also may suffer more severe consequences from infections that would be relatively trivial in normal hosts. For example, RSV and adenovirus may cause prolonged lower respiratory tract infection or even fatal pneumonia in transplant recipients; rotavirus and *Cryptosporidium* may cause chronic diarrhea in children with acquired immune deficiency syndrome (AIDS). Pathogens that remain well localized in normal hosts may disseminate widely in compromised children (e.g., disseminated candidiasis in neutropenic children).

Medical treatment also has an important impact on the risk for development of an infection. Common features of modern medical care include the use of intravascular catheters and infusions, indwelling urinary catheters, and mechanical ventilation. Many pediatric patients require much more sophisticated care, including invasive hemodynamic monitoring, extracorporeal membrane oxygenation, intensive chemotherapy, bone marrow and solid organ transplantation, hemodialysis, plasmapheresis, and monitoring of intracranial pressure. Aggressive surgical procedures, such as reconstructive surgery and sophisticated cardiovascular surgery, not only are performed more frequently but also are performed on children at a very young age. Overuse of antibiotics in critically ill children predisposes them to colonization and infection with antimicrobial-resistant bacteria or fungi.

Although considerable knowledge exists about the host factors that influence the risk of acquiring a health care–associated infection, substantially less is known about the properties of specific microorganisms that render them more or less pathogenic in hospitalized patients. For the most part, reasons why some microorganisms do not disseminate widely in a hospital whereas others do, and why some microorganisms colonize many patients but produce few infections whereas others cause devastating epidemics of infection, are unclear. Why, for example, did the *S. aureus* phage type 80/81 cause a worldwide pandemic of staphylococcal disease, especially in nurseries, whereas other phage types have a much more limited range, appear to disseminate less readily on hospital wards, and produce serious infections less frequently?[530] Why have genotypically distinct strains of MRSA (USA 300 and USA 400) disseminated rapidly across the United States, causing both community and health care–associated infections?[319,320,415,544]

Contemporary laboratory techniques gradually are unraveling the pathogenic properties of specific microorganisms. For example, the genomes of nosocomial and community-acquired MRSA have been sequenced and analyzed, providing better insights into the origins and pathogenesis of virulent strains.[34,310,328] Interestingly, both phage type 80/81 and community-acquired MRSA strains have genes mediating production of a putative virulence factor, Panton-Valentine leukocidin. The genetic make-up of community MRSA strains may favor colonization of the skin. Studies of coagulase-negative staphylococci have determined that this bacterium produces a capsular polysaccharide that facilitates its adherence to prosthetic materials and "slime" that protects it from clearance by host defense mechanisms.[282,323,395] *Citrobacter diversus* (now classified as *Citrobacter koseri*) produces a surface protein that contributes to its propensity to produce destructive meningitis and cerebral abscesses[321,322]; *E. coli* with the K1 capsular serotype are more likely to invade the meninges[291]; group A streptococci that produce an exuberant hyaluronic acid capsule are more likely to evade opsonophagocytosis[636]; and *E. coli* that produce P pili, are hemolytic, and have specific capsular serotypes and colicin types are more likely to produce urinary tract infections.[300] Nonetheless, we are a long way from understanding the factors that govern the ecology and pathogenic potential of most microorganisms and using this knowledge to prevent infections caused by these microorganisms.

MODES OF TRANSMISSION OF HEALTH CARE–ASSOCIATED INFECTIONS

Modes of transmission are the general mechanisms involved in the transfer of microorganisms from the reservoirs where they live and replicate to susceptible hosts. Table 244–6 lists the important modes of transmission. Examples of specific health care–associated infections are listed, as are the relevant reservoirs, sources, and modes of transmission of microorganisms causing these infections. Because reservoirs often cannot be eliminated, strategies must be designed to interrupt modes of transmission. These strategies are discussed in detail in Chapter 245.

The three basic types of airborne transmission are dissemination of droplet nuclei, "shedding" of skin squames (or "rafts") by colonized or infected individuals, and aerosolization of fungal spores. Droplet nuclei are small particles (<5 μm) generated by the desiccation of larger droplets expelled by coughing, sneezing, or speaking letters such as *t* or *p* forcefully. Because they are extremely light, droplet nuclei can travel over very long distances on air currents. If ventilation is poor and the microorganisms in the droplet nuclei are hardy, these infectious particles may remain suspended in the air of enclosed spaces for relatively long periods in concentrations sufficient to cause infection even if the index patient is no longer present. Because they are so small, droplet nuclei can remain suspended in inhaled air, evading the mechanical host defenses of the upper respiratory tract, and reach the lungs.[417] Classic diseases spread by respiratory droplet nuclei included measles, tuberculosis, smallpox, and, in certain circumstances, influenza and varicella.[128,343,418,491,626] Legionnaires' disease may be spread by small aerosolized droplets generated by devices such as cooling towers, showerheads, and even bedpan cleaners.[595]

Certain individuals are heavy "shedders" of skin squames contaminated by staphylococci or, more rarely, group A streptococci and other skin microorganisms (e.g., *Rhodococcus*).[530] Shedders may have obvious dermatitis or a clinical infection, but they often are asymptomatic. Shedders have been implicated in outbreaks of infection, especially in operating rooms, but most personnel who are colonized with potential pathogens do not dispense large numbers of bacteria and do not pose a threat to patients.[530]

Spores of filamentous fungi, such as *Aspergillus* and Zygomycetes, are ubiquitous in the environment, especially where there is decaying organic matter and moisture. Their small size (<3 μm) and aerodynamic shape permit dispersion over long distances and facilitate penetration of hospital air-handling systems and the respiratory tract of susceptible individuals.

Aerosolization of other organisms, such as *Coxiella burnetii*, can occur in hospitals under special circumstances. For example, an outbreak of Q fever among personnel occurred when sheep were transported through the corridor of a university hospital for a research study.[399]

TABLE 244–6 Modes of Transmission with Examples of Specific Health Care–Associated Infections and the Reservoirs and Sources Involved in the Transmission of These Infections

Mode of Transmission	Health Care–Associated	Reservoir	Source
Airborne	Measles, varicella,* pulmonary tuberculosis	Infected persons	Airborne droplet nuclei
Contact			
Direct	Neonatal staphylococcal skin infection	Infected or colonized caregiver	Drainage from infected wound on the hand of a caregiver
Indirect	RSV infection	Infected persons	Hands of caregivers, fomites
	Infection with antimicrobial-resistant bacteria	Infected or colonized persons	Hands of caregivers, fomites
Droplet	Pertussis, invasive meningococcal disease, group A streptococcal infection	Infected or colonized persons	Large respiratory droplets
Endogenous (autoinfection)†	Coagulase-negative staphylococcal bacteremia associated with a central venous line	Skin at the site of the catheter insertion	Intravascular catheter
	Escherichia coli urinary tract infection associated with an indwelling urinary catheter	Periurethral skin and mucus membranes	Indwelling urinary catheter
Common vehicle	Gram-negative bacteremia associated with intravenous infusion	Liquid substances in the environment	Intrinsically or extrinsically contaminated intravenous fluids
	Post-transfusion infection with blood-borne pathogen (HIV, hepatitis B virus, hepatitis C virus, CMV)	Infected persons	Blood products from infected donors
	Salmonellosis	Infected or colonized persons	Contaminated food
Vector	Enteric infection	Infected persons or infectious material	Flies, pharaoh ants

**Varicella-zoster virus may be transmitted by airborne, direct contact, and droplet contact transmission.*
†See text.
CMV, cytomegalovirus; HIV; human immunodeficiency virus; RSV, respiratory syncytial virus.

Contact transmission is the principal mode of transmission for most nosocomial infections. Direct contact transmission involves physical contact between a person harboring the microorganism, such as a caregiver with a staphylococcal infection on a hand, and the host. Indirect contact transmission involves transfer of microorganisms through an intermediary person or object. The hands of caregivers are the most common source for indirect contact transmission, but fomites also are important for certain pathogens (e.g., RSV, *C. difficile*). Droplet contact transmission involves transfer of microorganisms by large respiratory droplets, such as those generated by coughing or sneezing, which typically travel short distances in the air before settling. Important pathogens spread by this route include *Bordetella pertussis*, *Neisseria meningitidis*, and group A streptococci.

Endogenous infection (or autoinfection) is caused by a patient's own flora. These generally harmless commensals cause disease when the patient's host defenses are compromised by severe underlying disease, immunosuppressive therapy, or invasive devices and procedures. Microorganisms that produce endogenous infections are not always part of a patient's normal flora that he or she brought into the hospital from the community. Commonly, these microorganisms are transferred from other patients by the hands of caregivers and become part of a patient's colonizing endogenous flora. Consequently, these infections can be considered a special case of contact transmission.

Common vehicle (common source) transmission involves the widespread dissemination of a microorganism to many persons through a contaminated item or substance. Many outbreaks of infection in hospitals have been caused by nonenteric, gram-negative bacilli, such as *P. aeruginosa*, which thrives in medications, solutions, or wet equipment and is relatively resistant to antimicrobial preservatives, antiseptics, and disinfectants.

Vector transmission of microorganisms either on (extrinsic) or within (intrinsic) insects is a rare occurrence in hospitals. Extrinsic vector transmission of enteric pathogens may occur when these microorganisms are transported on the legs of flies, roaches, or ants.[42,99,183] Intrinsic vector transmission, such as transmission of malaria or dengue, involves more than physical transfer of the microorganism because a portion of the life cycle of the microorganism is completed in the vector. Whereas intrinsic vector transmission in the hospital is possible theoretically, to the authors' knowledge, no cases have been reported.

Some infections may be spread by more than one mode of transmission. For example, varicella-zoster virus may be spread by airborne and direct contact transmission.

CONSEQUENCES AND COSTS OF HEALTH CARE–ASSOCIATED INFECTIONS

Valid, well-controlled studies of the consequences and costs of health care–associated infections in pediatric patients are limited, partly because of the difficulty in determining whether the consequences or costs are directly attributable to the patient's infection as opposed to the patient's underlying disease. To attribute a consequence to health care–associated infection, investigators must match infected and noninfected patients carefully, using criteria such as age, sex, presence of underlying conditions, severity of illness, operative procedures, and length of stay, or adjust for these potential confounding factors using multivariable statistical analyses. In addition, studies must quantify hospital costs, as opposed to hospital charges, which may be difficult to do precisely.[520]

Pediatric studies that have made a rigorous effort to measure attributable risk indicate that health care–associated infections have a substantial adverse impact on hospitalized children. For example, appropriately designed cohort studies of coagulase-negative staphylococcal bacteremia in newborn ICUs (including adjustment for birth weight and severity of illness) have found increased length of stay (approximately 14 days), increased use of antibiotics, and increased hospital charges (about $25,000) but no increased mortality from this infection.[185,232] More recent data from the Vermont Oxford Network, a network of neonatal ICUs in the United States, indicate that attributable excess costs and

increased length of stay for neonates are somewhat lower than these estimates and vary by birth weight categories.[449] The attributable cost of bloodstream infections in a pediatric ICU was estimated at approximately $39,000,[163] a cost similar to that reported previously in adult ICUs.[460]

HEALTH CARE–ASSOCIATED INFECTIONS DUE TO SPREAD OF INFECTIONS COMMON IN THE COMMUNITY

Health care–associated infections that occur as a result of the in-hospital transmission of infections common in the community are a major concern for all facilities providing health care to children. Several principles about the general epidemiology of these infections, modified from those initially published by Hall[247] in relation to the epidemiology of health care–associated respiratory virus infections are summarized here.

First, their appearance and spread on the wards parallel closely the activity of disease in the community. Second, significant exposure to these pathogens generally results in infection in any host that lacks specific immunity; consequently, a susceptible child is at risk regardless of the nature or severity of the underlying disease or specific medical treatment. Third, these infections often are more severe in hospitalized patients who have underlying diseases (e.g., pulmonary or cardiac disease) or who are immunocompromised. Fourth, children hospitalized as a result of the community-acquired infections are the most important reservoir for microorganisms causing these infections, but mildly symptomatic or asymptomatically colonized adult caregivers may be important reservoirs for some agents (e.g., RSV, pertussis). Fifth, prevention depends primarily on the timely implementation of and compliance with isolation precautions specifically designed to interrupt transmission of the microorganisms involved. In the case of some infections, other interventions also are indicated, such as antimicrobial therapy to reduce the risk of transmission from children with pertussis and passive immunization with varicella-zoster immune globulin to protect high-risk individuals exposed to varicella. Finally, unless post-discharge surveillance is performed, reports of the frequency of these infections are likely to be gross underestimations, especially given recent trends toward shorter lengths of hospital stay, as many of these infections may be in the incubation period at the time of discharge and become manifested only after the child returns home.

RESPIRATORY INFECTIONS

Respiratory Viruses

RSV infection is the most common health care–associated respiratory virus infection, especially among children in the first 2 years of life. Community outbreaks occur every year in the late fall or winter, although the precise timing, intensity, and duration of these outbreaks may vary.[244] Population-based studies indicate that RSV infection may account for a substantial number of hospital admissions in young children during epidemic periods, especially children with underlying medical conditions.[63,548]

Children admitted to the hospital with community-acquired RSV infection represent a substantial reservoir for transmission of RSV to other hospitalized children and health care providers. In a study conducted during a community outbreak in the 1970s, 45 percent of children who were hospitalized for 1 week or longer on an infant ward and 40 percent of the caregivers on this ward acquired RSV infection.[253] A study actively surveyed the frequency of health care–associated RSV infections in all children admitted to eight leading Canadian children's hospitals during the mid 1990s.[340] The percentage of health care–associated RSV cases among all RSV cases in the hospital varied from 2.8 to 13.0 percent among the participating hospitals. As demonstrated in several studies, risk factors for health care–associated infection are prematurity, heart and lung disease, and immunocompromising conditions.[246,251,340,367,461] Outbreaks in newborn ICUs have been reported, some in association with other viruses.[251,400,575,609,642]

In the absence of effective control programs, attack rates tend to be high because immunity after infection is short-lived and because inoculation of virus into the nose or eyes reliably leads to infection.[244,245,248] Moreover, RSV survives for relatively long periods in the environment, and infected children excrete high titers of virus in their copious secretions.[244,245,250] Not surprisingly, duration of hospitalization (and thus the duration of potential exposure) correlates strongly with the risk for development of infection because a greater opportunity exists for direct or indirect contact transmission to occur.[253] One study used polymerase chain reaction to detect RSV nucleic acid in air samples of patient rooms, including samples taken as far as 7 meters from the bedside.[8] However, the implication of this finding on infectivity is unclear.

Scrupulous attention given to hand hygiene and the use of barriers (gloves and gowns) when touching patients or their immediate inanimate environment can reduce markedly the transmission of RSV.[342] Goggles or masks or both may be effective in reducing the attack rate of RSV in personnel,[6,200] which in turn can reduce transmission of virus to patients. However, whether masks and eye protection are effective because they prevent direct deposition of respiratory droplets on the eyes or nose or merely because they reduce the likelihood that staff will rub their eyes or noses with contaminated hands remains unclear. Covering only the nose and mouth with a mask probably is not very effective.[249] The CDC's Healthcare Infection Control Practices Advisory Committee recommends Standard and Contact Precautions for care of hospitalized patients with RSV and does not require use of a mask.[559,594] Some investigators have demonstrated that cohorting of infected patients, combined with the use of barriers, can reduce spread of RSV.[149,327,370] However, it is not clear whether cohorting by clinical symptoms alone is effective or whether all admitted patients must be screened for RSV infection to identify children with minimal symptoms who may be excreting the virus. Moreover, the added value of strict cohorting, which may be expensive or difficult to implement, as opposed to the rigorous use of a barrier technique, has not been demonstrated. Various multidisciplinary programs to promote awareness of the potential for transmission of RSV and to optimize use of prevention measures have been described.[305,342,366] Two studies estimated that the cost savings associated with their programs were substantial.[305,366]

One group of investigators used a screening approach to reduce the frequency of RSV infection among children undergoing cardiac surgery.[11] They screened all children aged 16 days to 4 years admitted for cardiac surgery between September and March with RSV enzyme-linked immunoassay. Surgery was delayed in patients with symptomatic diseases as well as in asymptomatic patients with positive RSV test results (the majority of whom developed symptoms in the subsequent days after having the positive test result). Although this procedure was not a controlled trial, the incidence of postoperative infections with RSV and the attendant complications were reduced substantially during the screening period.

Treatment of RSV infection with ribavirin reduces shedding of RSV,[147] which may decrease the potential for transmission. However, the use of this agent has been limited because of a lack of clear evidence of its clinical benefit.[16] Palivizumab, a humanized murine monoclonal antibody, has demonstrated efficacy in preventing or reducing the severity of RSV infection in high-risk patients,[17] but it is unlikely to have a profound effect on nosoco-

mial transmission. Palivizumab has been used to help control an outbreak of RSV in a neonatal unit.[119] The development of vaccines against RSV may lead to more effective prevention strategies in the future.[244]

Health care–associated infections caused by parainfluenza virus and human metapneumovirus are similar to RSV infection in their epidemiology and prevention.[244,412,594]

Population-based studies indicate that rates of hospitalization in young children are substantially lower for influenza than for RSV infection.[63,287,430,548] Yet the potential for transmission of influenza virus to occur remains significant. Health care–associated influenza is a common cause of intercurrent fever in hospitalized children during epidemic periods,[253] and outbreaks in neonatal ICUs have been described.[126,420]

Although the modes of transmission of influenza have not been defined precisely, direct, indirect, and droplet contact are likely to be most important in health care settings. Nonetheless, data from animal models and the rapid spread of influenza in confined human populations suggest that airborne transmission may occur in some situations.[225,418] In addition to the precautions described for RSV, masks should be worn during close contact because of the potential for droplet transmission to occur. The need for isolation rooms with negative air pressure relative to hallways has not been established.[594] Placement of a patient in a private room without special air handling and cohorting of patients with proven influenza are recommended control strategies.[594]

Annual influenza vaccination of high-risk individuals and hospital staff limits the potential for large outbreaks of influenza to occur if the vaccination is offered at the appropriate time and is well accepted by patients and staff. Antiviral medications are an adjunct to vaccination for treatment and chemoprophylaxis after an exposure to influenza virus.[177] Oseltamivir and zanamivir are the only antiviral medications currently recommended for use in the United States.[177] These agents may reduce the risk for occurrence of transmission, but it has not been demonstrated.

Health care–associated adenovirus infections occur sporadically throughout the year, and outbreaks of respiratory infection and pharyngoconjunctival fever among hospitalized children are well described.[176,219,422,457,470,568,591,635] Outbreaks in ICUs have been associated with severe disease and substantial mortality rates.[568,635] Children undergoing liver transplantation also are at high risk for development of severe disease in the immediate post-transplantation period.[403] In addition to direct and indirect contact, adenovirus may be spread by droplet contact, necessitating the use of masks with eye protection during close contact.

Health care–associated rhinovirus infections generally are mild, although serious lower tract disease has been documented in children with underlying disorders.[105] The mode of transmission of rhinovirus infection remains controversial. Some studies suggest direct and indirect contact transmission as the primary modes of transmission; others suggest that droplet contact may be more important.[225] Hand hygiene is sufficient as a control measure in most situations.

Pertussis

Outbreaks of pertussis in hospitals and chronic care institutions are well documented.[178,329,353,549,583,599,611] In many situations, health care providers were responsible for spreading pertussis to hospitalized children.[104,329,353,611] Indeed, two studies have demonstrated that infection among health care providers is a relatively frequent occurrence, even in the absence of a defined outbreak.[146,647]

Prevention of health care–associated pertussis depends on the appropriate isolation of children in whom the infection is suspected, use of masks to prevent droplet contact transmission, antimicrobial treatment of confirmed cases to minimize the potential for transmission, and prophylactic treatment of exposed individuals. In addition, hospital staff who present with symptoms suggesting pertussis (upper respiratory tract infection with severe, prolonged cough) must be evaluated and treated promptly. The availability of clarithromycin and azithromycin has enhanced treatment of exposed individuals because most adults tolerate these agents much better than erythromycin.

The beneficial impact but relatively high cost of aggressive steps to control the intrahospital spread of pertussis was illustrated during a large community-wide epidemic of pertussis in Cincinnati in 1993.[106]

The availability of acellular pertussis vaccine enhances the potential to enhance immunity among health care providers to prevent spread of pertussis in health care settings. Acellular pertussis vaccine was used as an adjunctive control measure in a hospital outbreak of pertussis.[548] The vaccine was reasonably well tolerated, but no data about its efficacy were reported.

Diphtheria

The potential for health care–associated transmission of diphtheria has been emphasized by a large outbreak in Russia and the Ukraine in the 1990s. Diphtheria acquired during travel to these regions has been reported in U.S. citizens, and imported cases have been documented in other European countries.[84] An imported case of diphtheria in a child from Haiti resulted in exposure of a large number of hospital contacts in Florida. Secondary cases were reported among household contacts but not among hospital contacts.[171] Health care providers should wear masks while providing care of patients with pharyngeal diphtheria. Investigation and prophylaxis of contacts should be pursued aggressively.[171]

GASTROINTESTINAL INFECTIONS

Gastrointestinal Viruses

Rotavirus is a common cause of endemic and epidemic health care–associated gastrointestinal virus infections.[223,488,505] Risk of acquiring infection is closely associated with the duration of hospitalization.[114,144] Infection usually is self-limited, although prolonged duration of diarrhea may occur in immunocompromised patients. One study associated an outbreak of necrotizing enterocolitis in a newborn nursery with concurrent rotavirus infection.[508]

Patients infected with rotavirus in the hospital or community may shed the virus in their stools for many days after symptomatic infection occurs.[637] Asymptomatically infected patients also may shed virus.[114,640] Together, these patients represent a substantial reservoir of virus that may be transmitted easily to other patients. In addition, rotavirus can be transferred by hands and can survive for extended periods on environmental surfaces.[23,531] The primary mode of transmission is indirect contact through the contaminated hands of caregivers, and the scrupulous use of barriers (gowns and gloves), hand hygiene, and appropriate disinfection of environmental surfaces is critically important.[559] An experimental study suggests that rotavirus infection also can be spread by the respiratory route,[473] although this finding has not been demonstrated clinically.

The development and licensure of the rotavirus vaccine likely will reduce the number of hospitalizations due to rotavirus infection, which in turn will reduce the risk of spread of this virus in health care settings.

Hospital outbreaks of norovirus infection, most often due to a new genogroup II.4 variant that emerged earlier this decade in the United States and Europe, have become a major problem, although wards with elderly populations have been affected more significantly than have pediatric wards.[298,302] A variety of other gastrointestinal viruses, including enteric adenoviruses,[325] Norwalk-like viruses,[579] calicivirus,[580] astrovirus,[143,330] and torovi-

rus,[290] also have been documented to cause endemic and epidemic gastrointestinal infection.

Clostridium difficile

Although toxin-producing *C. difficile* is a well-recognized cause of antimicrobial-associated diarrhea in adults, investigation of the role of this organism as a cause of health care–associated diarrhea in hospitalized children and infants has been limited.

Studies conducted in the 1980s illustrated that toxin-producing *C. difficile* often can be found in the stools of neonates and young infants.[111] Because *C. difficile* seldom is found in the stools of healthy women and because clusters of colonized infants often can be detected in nurseries,[111] a presumption is that health care–associated transmission, as opposed to vertical transmission, plays a role in the acquisition of this microorganism by neonates. Nonetheless, *C. difficile* rarely produces significant disease in newborns or young infants,[111] although one study has reported that infants whose stools are positive for *C. difficile* toxin A have more stools per day than do infants whose stools are negative.[168]

On the other hand, numerous reports indicate that older children and even infants can develop symptomatic *C. difficile*–associated diarrhea and that some children may develop severe disease, including pseudomembranous colitis.[73,82,174,260,392,438,441,476,656] Disease usually occurs in association with antimicrobial therapy, and several reports have described the occurrence of the disease in children with cancer.[73,82,476,656] A prospective study of health care–associated diarrhea in hospitalized children and adolescents found that as a group, viral causes were most common; however, *C. difficile*–associated diarrhea was the most frequent single cause and was found more frequently in older children.[338]

An epidemic strain of *C. difficile* (NAP-1) emerged and disseminated in Canada and the United States during mid-2000 and involved patients in the community and health care facilities.[360,390] This strain has caused severe disease in populations thought to be at low risk, including peripartum women and children.[92]

Two studies have explored the relationship of humoral immunity and *C. difficile*–associated diarrhea in elderly hospitalized adults.[331,332] In one study, hospitalized adults who became asymptomatically colonized with *C. difficile* but did not develop disease had significantly higher serum levels of immunoglobulin G (IgG) antibody against toxin A than did those who developed disease.[332] A second study of patients who developed an initial case of *C. difficile*–associated diarrhea found that patients with higher serum concentrations of IgM and IgG antibodies against toxin A were less likely to develop recurrent disease than were patients with lower concentrations of antibody.[331] The implications of these findings on the epidemiology of this disease in children have not been investigated.

C. difficile can be found on the hands of personnel and in the patient's immediate environment,[221] where *C. difficile* spores can survive for prolonged periods and are relatively resistant to disinfectants. Therefore, direct or indirect contact is responsible for the spread of this microorganism from patient to patient. Barriers (gowns and gloves) and hand hygiene may reduce the risk of transmission. Vigorous environmental cleaning is important because *C. difficile* spores can heavily contaminate the environment and survive for long periods. Conventional cleaning agents may not be sporicidal, and some authorities recommend using dilute bleach to disinfect rooms of patients with *C. difficile* infection, particularly while they have diarrhea.[221]

If possible, antibiotic therapy should be discontinued. Diarrhea resolves spontaneously in 15 to 25 percent of patients without further intervention, although predicting which patients will respond to conservative management is difficult. Oral metronidazole and vancomycin are equivalent in terms of response and relapse rates,[600] although metronidazole is considerably less expensive. Vancomycin should be used for treatment of severely ill patients.[220]

Other Bacteria

Bacterial pathogens are rare causes of endemic health care–associated diarrhea in U.S. hospitals.[154] Consequently, in the absence of an outbreak, the yield of routine stool cultures in the evaluation of health care–associated diarrhea is extremely low.[65,120,652] One study developed and evaluated simple screening criteria for rejecting stool bacterial cultures for patients who were hospitalized for more than 3 days.[652] The reduction in volume of tests processed by the laboratory led to cost savings of $25,082 in the 6-month trial period.

Outbreaks of health care–associated salmonellosis have been documented throughout the world, although they are reported more frequently from developing countries.[239,255,313,373,416,569,589,648] Neonates are particularly susceptible to infection by *Salmonella* spp., and invasive disease, such as bacteremia, meningitis, and osteomyelitis, is a common occurrence.[239,255,313,373,569,589,648] Transmission occurs through a variety of means, including contaminated food, direct contact between patients, and indirect contact transmission by contaminated hands or instruments.

Outbreaks of health care–associated shigellosis occur much less frequently. Only one hospital outbreak has been reported in the United States,[45] although shigellosis can be a major problem in institutions caring for disabled children.[36,155] A study in a hospital in Kenya cultured *Shigella* spp. from the stools of 2.5 percent of patients with health care–associated diarrhea.[446] *Shigella* is transmitted easily by direct or indirect contact, and only a small inoculum is required to establish infection.[154]

Health care–associated cholera has been documented in developing countries.[402,518] One of these reports is notable because it provides evidence that acquisition of *Vibrio cholerae* by children who were discharged to home before becoming symptomatic was instrumental in initiating and sustaining an outbreak of cholera in the surrounding community.[402] The mechanism involved in transmission of cholera in these studies is not clear, but direct or indirect contact transmission, as opposed to transmission by contaminated water, was suspected.

Other bacterial pathogens, including *Campylobacter* spp.,[77,269,306,613] *Yersinia* spp.,[80,487] and various types of *E. coli*, have caused outbreaks of diarrhea.[217,542]

Protozoa

Health care–associated infections caused by protozoa are rare findings. An outbreak of cryptosporidiosis was reported from a pediatric hospital in Mexico.[428] The index case was a patient with AIDS who had chronic diarrhea caused by infection with *Cryptosporidium*. Although giardiasis is a common cause of diarrhea in institutionalized children,[601] infections in hospitalized children or neonates have not been reported. Given the large number of severely immunocompromised children in U.S. hospitals and the relative ease of transmitting protozoa by direct or indirect transmission in families and daycare centers, it is somewhat surprising that health care–associated gastroenteritis caused by *Giardia*, *Cryptosporidium*, *Microsporidium*, and other intestinal protozoa has not been reported more frequently.

VARICELLA-ZOSTER VIRUS

Outbreaks of health care–associated varicella in hospitals have been documented in numerous reports.[197,240,343,534] These reports demonstrate conclusively that varicella can be transmitted by the airborne route, although spread by direct and droplet contact may well be more efficient. In these outbreaks, secondary infections occurred in patients who had no face-to-face contact with the index patients and who were separated from the index patient by considerable physical distances (in some cases more than 30

meters).[240,343] Air flow studies indicated that air in the rooms of index patients flowed into the hallway and into other patient rooms.[240,343] In one report, contaminated air flowed through an open window in the index patient's room, traveled along the exterior of the building, and entered other patient rooms by through-the-wall ventilation units.[343] The majority of secondary infections in each of these outbreaks occurred in patients who had been discharged and were detected only by telephone contact or home visit.[240,343] Several susceptible hospital staff members also were infected.

These clinical observations of airborne spread of varicella-zoster virus (VZV) are supported by a study that used polymerase chain reaction to detect airborne virus in hospital rooms of patients with active infection.[532] VZV was detected in air samples collected 1.2 to 5.5 meters from patients' beds for 1 to 6 days after the onset of rash. VZV DNA also could be detected in some air samples obtained in the hallway just outside the patient's negative-pressure isolation rooms.

Transmission of varicella can be minimized if infected patients have single rooms with separate exhaust systems and negative air pressure relative to the hallway.[19] Because infected persons are infectious for 24 to 48 hours before distinctive symptoms and signs appear, prompt recognition and isolation of patients and visitors who may be in the contagious phase of varicella also are critical. Barriers to prevent direct and indirect contact transmission (gloves and gowns) can reduce the spread of this infection dramatically. In addition, caregivers who are not immune to varicella should not care for such patients. Varicella-zoster immune globulin (VZIG) can prevent infection or mitigate the consequences of infection in high-risk, exposed, susceptible individuals if it is administered within 96 hours, but preferably within 48 hours, of exposure.[12] Intravenous acyclovir should be administered to these individuals to limit the replication of virus if infection develops.[12] Hospitalized exposed children should remain in isolation from day 8 to day 21 after being exposed. If VZIG is administered, isolation should be continued until day 28 after the exposure occurs.[12] Management of exposed health care providers is discussed in Chapter 245.

The use of VZV vaccine should diminish the risk of transmission of health care–associated varicella by decreasing the number of children hospitalized with varicella, reducing the size of the pool of susceptible children in hospital wards, and providing protective immunity to health care providers who do not have a history of prior infection. However, data demonstrating these effects have not been published. The use of this vaccine in health care pro-viders is discussed in Chapter 245.

CYTOMEGALOVIRUS

Perhaps no issue is the subject of as much concern and misinformation among health care providers as is the risk of acquiring health care–associated cytomegalovirus (CMV) infection. Concern among caregivers undoubtedly has been heightened by reports of CMV infection occurring among staff at daycare centers. Daycare centers provide optimal conditions for CMV transmission because many children are excreting CMV in their saliva or urine, and abundant opportunities exist for sustained contact with contaminated secretions. However, even in the daycare setting, transmission of CMV to susceptible care providers occurs slowly.[5] This delay reflects the relative inefficiency of direct or indirect contact transmission of CMV, a virus that is inactivated easily by soaps, detergents, and disinfectants and is not stable on environmental surfaces for long periods.[5]

In hospitals, the risk to staff appears to be very low. A meta-analysis of numerous studies that have examined the risk of CMV being acquired by pediatric nurses indicates that CMV infection in this population occurs at a rate comparable to that in control populations (persons of comparable age and sex who are not nurses).[5] A subanalysis of these data suggests that nurses who work in nurseries may have a slightly higher rate of infection than do control populations.[5] However, studies using restriction enzyme analysis of CMV isolates have shown that these nurses did not acquire CMV from the infants in their care,[5] and they presumably contracted their infections from children in their own households, through sexual contact, or from other community sources.

In conclusion, few if any data suggest that health care–associated transmission of CMV is a significant risk factor for health care providers. Given the frequency of asymptomatic CMV excretion in children (e.g., approximately 1% of newborns excrete the virus), health care providers should assume that any child may be excreting virus and should practice handwashing and use of Standard Precautions (see Chapter 245) as a part of routine patient care. Additional interventions are not indicated, and pregnant staff need not be given special assignments.

Two restriction enzyme studies have documented probable patient-to-patient spread of CMV in a newborn ICU and a chronic care unit.[142,578] In both situations, the infected children had been in proximity and were provided care by common caregivers for extended periods.

HERPES SIMPLEX VIRUS

Health care–associated transmission of herpes simplex virus (HSV) type 1 to newborn infants has been confirmed through the restriction enzyme analysis.[256,352,528,614] The mode of transmission is not clear in all of these cases. Direct contact with a hospital worker with herpes labialis was implicated in one case.[614] In the other cases, indirect contact transmission from one infected infant to another is most likely, although direct contact transmission from an asymptomatic parent or caregiver cannot be ruled out.[256,352,528] Health care–associated HSV infections among health care providers, patients, and family members also have been described in ICUs.[4,453] Herpetic whitlow has been observed among nurses, presumably as a result of direct transmission during suctioning of oral and respiratory secretions from infected patients.[4] The risk associated with this procedure is substantial, given recent data that indicate that HSV is found commonly in mucosal and orofacial cultures obtained from intubated patients, including those without obvious lesions.[258] When present, lesions often are atypical in appearance and frequently are found in the distribution of tape used to secure endotracheal tubes.[258] Substantial risk of transmission from immunocompromised patients, in whom reactivation of latent HSV infection is a common occurrence, also exists.[619,644] The use of Standard Precautions (see Chapter 245), particularly the use of gloves during contact with oral and respiratory secretions and hand hygiene, will prevent transmission of HSV.

Surveys of health care–associated infections in pediatric wards indicate that HSV infections are uncommon occurrences.[181,610,632] When documented, these infections usually are attributed to reactivation of preexisting endogenous infection rather than to primary infection.[610] However, as with patients in ICUs, subclinical infection in other hospitalized children may be a more common occurrence than is recognized presently.

MEASLES, MUMPS, AND RUBELLA VIRUSES

Efforts to control measles worldwide have reduced markedly or eliminated endemic measles transmission in many developed

countries.[90] However, as past history indicates, transmission of measles in health care facilities remains a threat, and hospitals have the potential to serve as niduses for community-wide infection.[89a,394,481,503,582b]

Measles is transmitted by airborne droplet nuclei, as is demonstrated by a report of an outbreak in a pediatrician's office.[491] Four susceptible children visiting the office on the same day as the index child subsequently developed measles, even though none of these children had face-to-face contact with the index child or was even in the same room at the same time. Three children visited the office 60 to 75 minutes after the index case had left.

Prevention of health care–associated measles hinges on the prompt recognition of infected or potentially infected patients and placement of these patients in isolation rooms with negative air pressure relative to the hallway.[559] Prophylactic vaccination of exposed susceptible individuals within 3 days of the exposure reliably prevents measles, whereas administration of immune globulin within 3 days attenuates disease but does not guarantee that the exposed individual will not develop contagious infection.[14] Outbreaks of measles among health care providers can be avoided by having health care facilities require new employees involved in patient care to provide evidence of immunity or appropriate vaccination or to receive vaccination with either measles vaccine or MMR (measles, mumps, rubella) as a condition of employment (see Chapter 245).

Outbreaks of health care–associated mumps and rubella have been reported less commonly than has measles.[270,463,590,637] The primary concern with regard to spread of both of these infections relates to potential complications in health care providers. Mumps orchitis in adult men can cause sterility; rubella in pregnant staff can result in fetal infection and the congenital rubella syndrome. Information about the transmission of both of these viruses is limited, but it probably occurs primarily by droplet contact. Masks should be worn during close contact with infected patients.[559] Patients with congenital rubella syndrome may excrete large amounts of virus in their urine and respiratory secretions, and excretion of virus in the urine may persist for months or even years. Consequently, gowns and gloves should be worn for contact with these patients for their first year of life unless nasopharyngeal and urine cultures are negative by the time they are 3 months old.[559] No effective post-exposure prophylaxis for exposed individuals is known. As with prevention of measles, health care facilities should require new employees involved in patient care to provide evidence of immunity or appropriate vaccination or to receive vaccination with MMR (measles, mumps, rubella) as a condition of employment (see Chapter 245).

PARVOVIRUS B19

Parvovirus B19 causes the relatively benign syndrome of erythema infectiosum (occasionally accompanied by arthritis, particularly in older children and adults), acute aplastic crisis in children with hemoglobinopathies, and chronic infection and anemia in immunocompromised children. Some reports have suggested that an association exists between vasculitis and other immunologically mediated diseases.[175,645]

An experimental study of acute parvovirus B19 infection in normal adults detected virus in respiratory secretions in three of four patients during a period of viremia and systemic symptoms that developed 6 to 13 days after the patients were inoculated.[22] Detectable virus in respiratory secretions disappeared as viremia and systemic symptoms diminished, and virus was not demonstrable in respiratory secretions when rash, arthralgias, and arthritis occurred several days later.[22]

Recognition of the wide spectrum of disease caused by parvovirus, coupled with well-documented health care–associated outbreaks of infection, has fueled efforts to understand the transmission and control of this virus in hospitals.[46,169,326,363,458,489] These studies indicate that parvovirus B19 infection can be transmitted by acutely infected patients, probably as a result of the high levels of virus in their blood and in their respiratory secretions. The risk of transmission occurring from chronically infected, immunocompromised patients is less clear; however, one report indicates that these patients do transmit infection.[363] The mode of transmission is not clear but probably involves direct or indirect contact with respiratory secretions or droplet contact. Therefore, gloves and gowns should be worn during contact with infected patients or fomites contaminated with respiratory secretions, and a mask should be worn during close contact.[559] The description of a play therapist who acquired parvovirus despite her lack of close contact with an infected patient has led to concern about possible airborne transmission, but the need for use of isolation rooms with negative air pressure has not been established and currently is not recommended.[559]

Limited data in one of the outbreaks suggest that standard immune globulin preparations may be useful in mitigating the consequences of infection in high-risk, exposed, susceptible contacts.[458] However, data at present are sufficient to recommend the routine use of immune globulin for postexposure prophylaxis.

HEPATITIS A VIRUS

Although health care–associated outbreaks of hepatitis A seldom occur, this pathogen can cause major epidemics before infection is detected and contained. The largest outbreak of hepatitis A occurred as a result of a blood transfusion from a single donor who was viremic but had not yet developed symptomatic disease; 11 newborns received contaminated transfusions and 55 secondary cases occurred in two hospitals.[433] Other transfusion outbreaks have been described,[32,318] as have outbreaks traced to asymptomatic excretion by an infected child[152] and vertical transmission from mother to infant.[621]

Controlling an outbreak of health care–associated hepatitis A is difficult and usually requires the assistance of the local health department, especially if nonhospitalized contacts or more than one institution is involved. To limit the potential for indirect contact transmission, hospitalized infected children should be cohorted. Hand hygiene and use of barrier precautions should be emphasized to prevent direct contact transmission to caregivers and indirect contact transmission to other children.[559]

Immune globulin should be administered to all exposed, susceptible individuals.[60] Symptomatic health care providers should be furloughed until 1 week after the onset of symptomatic infection or until all susceptible persons have received immune globulin.[60] Tracing of contacts is necessary to prevent additional secondary cases. Hepatitis A vaccine can be administered concurrently with immune globulin to patients who have not been immunized if vaccination is indicated for these individuals.[60] Hepatitis A vaccination is not recommended routinely for health care providers.[60]

ENTEROVIRUSES

Numerous outbreaks of health care–associated enterovirus have been reported, most occurring in newborn nurseries.[37,101,266,299,317,483,596] In most cases, adult caregivers infected in the community transmitted the virus to one or more hospitalized children through direct contact, with subsequent indirect contact transmission from one child to another occurring. In one nursery outbreak, the virus was introduced by a perinatally infected

child.[483] Newborns with severe underlying illness were more likely to be infected, presumably because the prolonged and intensive care these infants required provided more opportunities for transmission.[317,483] Enterovirus infections in newborn infants can be severe—even fatal—but mild and subclinical illnesses also may occur.[410,483] The presence of maternally derived antibody may play a role in limiting the severity of disease in some infants.[410,483]

Surveys of infections in pediatric wards indicate that health care–associated enterovirus infections are uncommon occurrences,[181,610,632] yet the potential for transmission of these viruses is substantial. Large community outbreaks of echovirus and coxsackievirus infections occur predictably every summer and fall. Because virus is excreted in stool for long periods, a large number of hospitalized children and caregivers certainly are excreting virus during these periods. Detection of infection may be compromised because viral cultures may not be readily available, some enteroviruses are difficult to cultivate in tissue culture, and infection may not become manifested until after the patient is discharged.

Like hepatitis A, enteroviruses are picornaviruses, and the use of hand hygiene and barrier precautions are of paramount importance to prevent transmission, and cohorting of infected infants is prudent.[559] A report has demonstrated the value of early diagnosis by use of polymerase chain reaction and aggressive control measures.[29] The upper respiratory tract may be involved in acute enteroviral infection, but most authorities do not recommend the use of masks during the care of infected patients.[559] These same principles should be applied to confirmed or suspected enteroviral infections in children, especially young diapered children, although the need for cohorting is debatable and may not be feasible during summer and fall epidemics. The efficacy of immune globulin as treatment prophylaxis for individuals exposed during the course of an outbreak is unclear, but it may be helpful if the preparation used has significant titers of antibody to the outbreak strain, especially in newborn infants who are at risk for development of severe disease.[2] An antiviral agent, pleconaril, may be useful in treating serious infection.[507]

RABIES

Rabies has been transmitted by corneal and solid organ transplants,[21,581] but spread through contact with infected patients has not been reported.

TUBERCULOSIS

The number of new cases of tuberculosis in the United States has reached an all-time low.[89b] The proportion of cases of multidrug-resistant *Mycobacterium tuberculosis* has remained stable in recent years; rare cases of extensively drug-resistant *M. tuberculosis* have been reported. However, the threat of health care–associated transmission of tuberculosis remains real, heightened by the increasing proportion of cases of tuberculosis in the United States that occur in foreign-born persons and continuing problems with multidrug-resistant and extensively drug-resistant *M. tuberculosis* in many regions of the world.[89b]

This risk was demonstrated dramatically by outbreaks of multidrug-resistant *M. tuberculosis* among adult patients and health care providers in several hospitals in New York and Florida in the 1990s.[43,117,157,194,297,450] One of these outbreaks involved transmission of multidrug-resistant *M. tuberculosis* in the hospital nursery and resulted in infection among infants, mothers, and health care providers.[432] This outbreak and others illustrated that tuberculosis in hospitals caring for pediatric patients occurs almost exclusively as a result of transmission of *M. tuberculosis* from infected adults—parents, visitors, and health care providers—to other children and adults.[33,216,432,585,627] Probable transmission from infected children in health care settings has been described.[388,482] However, the risk of transmission from a child is very small because children infrequently have cavitary disease and consequently have fewer tubercle bacilli in their endobronchial secretions and because young children do not tend to generate aerosols of airborne droplet nuclei.[582a] Nonetheless, transmission from children can occur as evidenced by extensive transmission from a 9-year-old child with bilateral cavitary disease.[128]

The risk of health care–associated tuberculosis occurring in adult hospitals has been minimized by prompt recognition and treatment of pulmonary tuberculosis, adequate isolation of infectious patients in rooms with negative air pressure relative to the hallway, and proper use of personal protective equipment.[296] If rooms with appropriate ventilation are unavailable, alternative engineering solutions, such as well-placed and well-maintained ultraviolet lights, may be useful.[296] Personnel entering the rooms of infected patients should wear respiratory protection devices. Particulate respirators with a National Institute for Occupational Safety and Health certification of N95 or better satisfy the CDC specifications for these devices.[296] These devices must be fit tested on the individuals using them according to the standards of the Occupational Safety and Health Administration.[296] Prompt identification of tuberculosis in parents, visitors, and health care providers in hospitals caring for pediatric patients is an integral part of reducing the risk of transmission of tuberculosis. Screening of health care providers for latent or active tuberculosis is discussed in Chapter 245.

INVASIVE BACTERIAL INFECTIONS

Health care–associated transmission of *Neisseria meningitidis* is a rare occurrence and has been demonstrated in hospitalized patients only when the index patient has meningococcal pneumonia,[112,506] an uncommon clinical presentation of disease in children. Other situations in which transmission has occurred have involved special circumstances. For instance, a mother became infected after nursing her infant who was hospitalized with meningococcemia,[381] and several microbiology laboratory providers developed fatal disease after working with cultures of this microorganism.[87] Hospital personnel caring for patients, on the other hand, appear to be at minimal risk unless they have extensive face-to-face contact and fail to wear a mask.

Health care–associated transmission of *Haemophilus influenzae* or *Streptococcus pneumoniae* also has been regarded as a rare phenomenon but may be more common than previously recognized. A few reports from the 1980s documented transmission of *H. influenzae* type b among pediatric patients,[35,41] and cases among elderly adults and even hospital staff were reported in the late 1980s and early 1990s.[280,393,448,573] Widespread immunization of infants with *H. influenzae* type b conjugate vaccine has reduced considerably the risk of transmission of this microorganism in pediatric patients. Numerous outbreaks of health care–associated infection caused by nonencapsulated *H. influenzae* in elderly patients and hospital staff also have been reported.[20,280]

Numerous outbreaks of health care–associated infection caused by penicillin-resistant *S. pneumoniae* among hospitalized adults and residents of nursing homes have been documented in North America and Europe.[141,383,405,435,630] There are fewer reports of health care–associated multidrug-resistant pneumococcal infections in pediatric patients,[107,136] although this problem has been well documented among hospitalized children in South Africa for many years.[195]

N. meningitidis, *H. influenzae*, and *S. pneumoniae* are spread by droplet contact transmission. Masks should be worn by health care providers while caring for patients with suspected invasive meningococcal disease until the patient has completed 24 hours of parenteral antimicrobial therapy.[559] In the past, the use of masks during care of patients with infections caused by *H. influenzae* type b was variable in many hospitals. However, the CDC Healthcare Infection Control Practices Advisory Committee guideline recommends use of masks to prevent droplet contact transmission from patients infected with *H. influenzae* until the patient has completed 24 hours of parenteral antimicrobial therapy.[559] The guideline does not recommend the use of a mask in caring for patients with *S. pneumoniae* or even penicillin-resistant *S. pneumoniae* unless there is evidence of transmission within a patient care unit or facility.[559] However, given the reports of health care–associated transmission of *S. pneumoniae*, the authors recommend use of masks in caring for patients with infections caused by penicillin-resistant *S. pneumoniae*. Antimicrobial prophylaxis should be administered to persons with close, unprotected contact with patients infected with *N. meningitidis*, but it is not recommended for exposure to patients infected with *H. influenzae* or *S. pneumoniae* unless an outbreak clearly is in progress.

Invasive bacterial infections in neonates, including infections caused by *S. aureus*, group B streptococci, *Citrobacter* spp., and *Enterobacter sakazakii*, are discussed in another section of this chapter (see the section on health care–associated infections in special populations, newborn infants).

ECTOPARASITES

Scabies and pediculosis are common infections in children, and incidental diagnosis of these infections among hospitalized children is not an uncommon occurrence. A large number of outbreaks of scabies have been reported from a variety of health care institutions.[344] The presence of crusted scabies, which is associated with defects in cellular immunity, including HIV infection, increases the risk of transmission because of the large number of mites in these lesions.[344] Although health care–associated transmission of pediculosis can occur, the direct or indirect contact necessary to spread this infection (i.e., head-to-head contact or sharing of combs) is less likely to happen in medical settings than at home.

INTESTINAL HELMINTHS

Person-to-person transmission of four intestinal helminths, *Enterobius vermicularis* (pinworm), *Strongyloides stercoralis*, *Hymenolepis nana*, and *Taenia solium*, is possible because these microorganisms do not require an intermediate host and because the eggs or larvae excreted in the stool are infectious.[345] However, evidence for health care–associated transmission of these microorganisms is limited.[345]

UNUSUAL INFECTIONS INCLUDING INFECTIONS CAUSED BY AGENTS OF BIOLOGIC WARFARE

A variety of unusual, potentially fatal infections may be in transmitted in health care settings. Because international air travel has increased the mobility of the world's population, persons may travel long distances during the incubation period of infections acquired in remote settings.[622] In addition, some of the potential agents of bioterrorism are highly transmissible (e.g., smallpox virus, *Yersinia pestis*, hemorrhagic fever viruses) and could result in secondary health care–associated cases after a primary bioterrorism attack.[26,61,145,268,285,414] A high index of suspicion for these infections and prompt institution of appropriate isolation precautions as indicated are necessary to reduce the risk of health care–associated transmission.

Smallpox is the most feared of the potential agents of biologic warfare because it can be transmitted through droplet nuclei over large distances, the case-fatality ratio is approximately 30 percent, no effective treatment exists, and much of the world's population is either nonimmune or was immunized in the distant past.[268] Even a very limited number of cases of smallpox would be a global public health emergency, and detailed plans for containment would be needed. Hospitalized patients must be cared for with airborne and contact isolation precautions, and health care providers caring for these patients must be vaccinated.[268,592]

Plague is endemic in portions of the western United States and in other countries. No person-to-person transmission of plague has been identified in the United States for more than a half-century,[285] but an outbreak in India illustrated the potential for plague to be imported into other countries.[85] Droplet transmission of *Y. pestis* from persons with pulmonary involvement is well documented. Health care providers should wear masks while caring for patients with signs or symptoms of pulmonary involvement.[285] Tetracycline, doxycycline, sulfonamides, chloramphenicol, and perhaps fluoroquinolones can be used for prophylaxis of contacts.[285]

Ebola, Marburg, Lassa, and Crimean-Congo viruses and the New World arenaviruses have been spread in hospitals because of close contact with infectious body fluids or reuse of contaminated needles.* Health care–associated transmission of hantavirus in the United States has not been reported but has occurred with Andes virus, another cause of hantavirus pulmonary syndrome.[443] Ebola, Marburg, Lassa, Rift Valley fever, yellow fever, Omsk hemorrhagic fever, and Kyasanur Forest disease viruses and New World arenaviruses have been proposed as potential biologic weapons.[61] Of these, only Ebola, Marburg, and Lassa viruses and the New World arenaviruses are spread from person to person (see earlier).[61] The bulk of evidence suggests that airborne transmission of these viruses does not occur in clinical settings, although epidemiologic data are insufficient to exclude this possibility.[83] Health care providers, as well as family members and visitors, providing care to these patients should use airborne isolation precautions as well as additional viral hemorrhagic fever–specific precautions, which emphasize enhanced barrier precautions to avoid contact with the copious amounts of infected material typically encountered in the care of these patients.[61]

HEALTH CARE–ASSOCIATED INFECTIONS RELATED TO INVASIVE DEVICES AND PROCEDURES

This section reviews health care–associated infections related to intravascular catheters and infusion respiratory therapy, instrumentation of the urinary tract, and surgical procedures. Infants, children, and adolescents are at risk for acquiring other health care–associated infections in association with medical treatments, including infections associated with receipt of blood products or immunosuppressive treatments. Readers are referred to chapters in this text related to common bloodborne pathogens (i.e., HIV, hepatitis B and C viruses, and *Trypanosoma cruzi*). In addition, health care–associated infections may occur in relation to invasive procedures other than surgery, such as various endoscopic procedures and interventional radiographic procedures.

*See references 39, 61, 308, 311, 413, 454, 496, 572, 593, 622.

INFECTIONS RELATED TO INTRAVASCULAR CATHETERS AND INFUSIONS

Local infections related to the use of intravascular catheters include infection at the site where the catheter exits the skin (exit-site infection), infection along the subcutaneous track of a tunneled catheter (tunnel infection), and infection in the subcutaneous pocket containing an implanted catheter (pocket infection).[401,436,484] Phlebitis is a common local complication related to the use of intravascular catheters, but it usually is caused by chemical or mechanical irritation and is seen less frequently in children than in adults.[206] Suppurative thrombophlebitis is a rare finding in children.[312]

Systemic infections related to the use of intravascular catheters include bloodstream infections occurring as a result of microbial colonization of the catheter (catheter-related bloodstream infection) and contamination of fluids or medications infused through the catheter (infusate-related bloodstream infection).[401,436] Endocarditis, septic thrombophlebitis, and infection at other body sites as a result of hematogenous seeding (e.g., meningitis, pyelonephritis, hepatic or splenic abscesses, osteomyelitis, septic arthritis, and endophthalmitis) are serious complications of bloodstream infections.

The risk for development of endemic local and systemic infections associated with intravascular catheters varies by the type of catheter in use.[374] Percutaneously inserted peripheral intravenous catheters, especially catheters made with modern pliant, nonthrombogenic materials, are associated with a very low rate of local infection in children, and bloodstream infections are rare occurrences.[206,207,374,554] Rates of local and bloodstream infection associated with peripheral intravenous catheters also are low in newborn infants,[205] but infusion of parenteral nutrition with lipid emulsion through these catheters significantly increases the risk of acquiring bloodstream infection with coagulase-negative staphylococci and *Candida*.[30,70,187,527] Peripheral arterial catheters generally also have a low rate of endemic local and systemic infectious complications; two reports studying a total of more than 400 arterial catheters did not identify any catheter-related bloodstream infections.[153,199]

Most endemic catheter-related bloodstream infections in pediatric patients are associated with central venous catheters.[374] As shown in Tables 244–1 and 244–2, rates of bloodstream infection associated with central venous catheters in pediatric ICUs and central venous and umbilical catheters in newborn ICUs are higher than in adult ICUs participating in the NNIS system.[424] Rates of infection among low-birth-weight infants (<1000 g) in newborn ICUs are higher than those of any other ICU population.[424] These data do not distinguish rates of infection associated with specific catheter types, nor do they distinguish whether a specific catheter is the source of the infection in patients with multiple catheters in place at the same time.

Comparisons of bloodstream infection rates associated with different types of central venous catheters in pediatric patients are confounded by numerous factors.[636] Patient populations in whom these catheters are used have diverse underlying diseases (e.g., cancer, cystic fibrosis, prematurity, short bowel syndrome, AIDS) with widely variant intrinsic risk of bloodstream infection. Even among pediatric oncology patients, risk varies considerably with the type of cancer and the intensity of chemotherapy,[286] and younger children have a higher risk of acquiring infection even when the underlying disease and the type of catheter used are similar.[286,649] Use of the catheter for multiple purposes and infusion of parenteral nutrition with lipid emulsion also increase the risk of acquiring infection.[30,70,315]

With these caveats, rates of bloodstream infection appear lower in totally implanted than in tunneled catheters.[374,639] This conclusion is supported by several studies directly comparing rates of infection between these two types of catheters[334,407,543,649] as well as by a comprehensive review of the literature.[374] These studies demonstrated lower rates of infection with implanted catheters, although statistically significant differences were not seen in every report.

Among adults, rates of bloodstream infection associated with percutaneously inserted central venous catheters are at least several-fold higher than rates associated with either tunneled or implanted catheters,[374] and this observations appears to hold for infants and children as well.[281,584] Rates of infection associated with hemodialysis catheters or intracardiac catheters in pediatric patients who have undergone cardiac surgery have not been reported. Peripherally inserted central venous catheters are now used commonly in newborn ICUs, pediatric ICUs, and pediatric wards. A randomized trial comparing peripherally inserted central venous catheters with peripheral intravenous catheters in very-low-birth-weight infants found no difference in rates of bloodstream infection associated with these two types of catheters. A study of umbilical catheters in neonates found that bloodstream infection occurred in 5 percent of neonates with umbilical artery catheters and 3 percent of neonates with umbilical venous catheters (rates of infections per 1000 catheter days were not reported).[337]

In contrast to endemic infections, which are closely associated with the type of catheter used, epidemics of bloodstream infection generally are related to other factors.[44] In the past, improperly disinfected pressure transducers were the most frequent cause of epidemics of bloodstream infection.[44] Detailed investigation of practices often is necessary to identify and to eliminate causes of bloodstream infection outbreaks, as illustrated by an outbreak of candidemia in a newborn ICU related to retrograde administration of medications into intravenous tubing.[551] Several recent reports have associated the introduction of new mechanical valves in Luer lock catheter caps and hubs with increased infection rates.[386,515]

The principal risk factors for catheter-related bloodstream infection in adults have been identified.[122,123,436,479] Heavy colonization of the skin at the catheter exit site is an important risk factor for colonization of the external surface of catheters of all types and is correlated with increased risk of bloodstream infection.[122,123,436] Colonization of the catheter hub also is an important risk factor for development of bloodstream infections, especially disease occurring late in the course of central venous catheterization.[140,351] Other risk factors related to central venous catheters include longer duration of insertion (>3 days), insertion into the internal jugular vein as opposed to the subclavian vein, use of catheters with multiple lumens as opposed to single lumens, and presence of a mural or atrial thrombus.[122,123,436] Both the level and composition of nurse staffing have been associated with bloodstream infections in adult surgical ICUs—a low nurse-to-patient ratio and a low regular (as opposed to pool nurse) nurse-to-patient ratio were associated with a higher risk of acquisition of a bloodstream infection.[193,504]

Information about general risk factors in children and newborn infants is far more limited than in adults. Two studies of peripheral intravenous catheters in pediatric patients found that the likelihood of colonization occurring on the external surface of the catheter was slightly greater with increasing duration of insertion, but bloodstream infections were extremely uncommon occurrences, even in patients with colonized catheters.[206,207] A study of catheter colonization in patients in newborn ICUs found that duration of insertion longer than 3 days was a significant risk factor for colonization of peripheral intravenous catheters and umbilical catheters.[124] A similar trend was seen with central venous catheters in this patient population, although the number of catheters studied was limited and no conclusions could be drawn with regard to the risk of acquiring a bloodstream infection.[124] Current information is not sufficient to state whether the site of insertion of central venous catheters has an impact on

the risk of acquiring infection, although one study in pediatric ICU patients found similar rates of infection between catheters inserted in the femoral vein and catheters inserted into veins at other sites.[582a] A more recent study of risk factors for acquiring a bloodstream infection in a pediatric ICU identified a higher number of arterial catheter days and packed red blood cell transfusions as well as the presence of an underlying genetic syndrome as independent predictors.[162] Severity of illness, underlying illnesses, and medications were not independently associated with increased risk. As in adult patients, a higher risk for development of infection exists with the use of larger catheters (i.e., multiple-lumen versus single-lumen catheters).[108]

More detailed information is available about risks factors for specific pathogens. A series of studies of coagulase-negative staphylococcal bloodstream infection in patients in newborn ICUs found that length of stay, birth weight, and administration of lipid emulsions were significant risk factors.[30,185,186] Given the potential use of fluconazole for prophylaxis against candidemia, several studies have explored risk factors for development of candidemia in newborn ICUs. Two studies examined risk factors other than birth weight.[172,553] One study identified intravascular catheter use, previous bacterial bloodstream infection, and a history of gastrointestinal disease as risk factors.[172] Another study identified gestational age of less than 26 weeks, vaginal delivery, and abdominal surgery as risk factors.[553] A third study, which did not match or restrict the analysis by birth weight, identified birth weight of 400 to 750 g, receipt of cephalosporin antibiotics, male sex, and lack of enteral feeding as risk factors.[47]

Microorganisms associated with catheter-related bloodstream infections in pediatric and newborn ICUs participating in the NNIS system are displayed in Tables 244–4 and 244–5.[215,497] In both populations, the most common cause of bloodstream infections is coagulase-negative staphylococci. Other gram-positive bacteria, including *S. aureus*, *Enterococcus* spp., and various streptococci, are also relatively common. Ten to 20 percent of infections are caused by gram-negative bacteria, including *E. coli*, *P. aeruginosa*, *K. pneumoniae*, *Enterobacter* spp., *Acinetobacter* spp., *Serratia marcescens*, *Citrobacter* spp., and other aerobic gram-negative bacilli. *C. albicans*, other *Candida* spp., and other fungi together cause 5 to 10 percent of infections. A study from the NNIS system from 1995 to 2004 found that the incidence of *Candida* bloodstream infections in low-birth-weight infants declined during this period, and infection with species commonly resistant to azoles was extremely rare.[190] Atypical mycobacteria occasionally cause bloodstream infection.

A large number of studies in adults, including studies using molecular typing of isolates, have demonstrated that most infections arise from microorganisms that colonize the skin at the insertion site and migrate along the external surface of the catheter through its subcutaneous track and into the blood vessel (extraluminal contamination).[122,123,436,522] Colonization of the interior surface of the catheter occurs through contamination of the catheter hub (intraluminal contamination).[122,123,436,522] The relative contributions of these two mechanisms may depend on the duration of catheterization.[480] Detailed microbiologic studies and scanning electron microscopy have demonstrated that colonization of the external surface predominated in the first 10 days after insertion, whereas colonization of the internal surface increased with the length of catheterization and was significantly more common in catheters in place for more than 30 days.[480] Microorganisms on the hands of health care providers can contaminate the catheter, the insertion site, or the hub during insertion and maintenance of the infusion system.

There are few similarly detailed studies in pediatric patients. However, several studies in neonates suggest that intraluminal contamination is the most common source of organisms causing bloodstream infection. The catheter hub appears to be a common source of bloodstream infections acquired through the intraluminal route.[202,529]

A variety of microbial and host factors play roles in the pathogenesis of bloodstream infections. For example, capsular polysaccharide adhesin, which is a component of the capsule of coagulase-negative staphylococci, facilitates adherence of these bacteria to prosthetic material, formation of biofilm (slime), and intercellular adhesion.[282,395] *Candida* spp. also may produce slime, particularly in the presence of glucose-containing fluids.[66] Interactions among organisms in mixed biofilms also may contribute to colonization of catheter surfaces.[3]

Catheter materials are important factors in catheter colonization and associated infection. Catheters made of polyvinyl chloride or polyethylene are less resistant to colonization in vitro than are catheters made of Teflon, silicon elastomer, or polyurethane. Trauma to blood vessels is more likely to occur with use of stiff plastics (e.g., polyvinyl chloride) than with newer plastic materials (Teflon, silicon elastomer, or polyurethane), predisposing to development of phlebitis and infection. Other factors, such as surface irregularities and the thrombogenicity of catheter material, also may play roles. Catheters that are coated or impregnated with anti-infective agents (e.g., benzalkonium chloride, chlorhexidine–silver sulfadiazine, minocycline-rifampin, silver) to resist bacterial colonization have been developed (see additional discussion later).[122]

Contaminated intravenous infusions,[380,552] medications,[48,237] narcotics (as a result of criminal tampering),[378,442] blood products,[96] and hemodynamic monitoring systems[44] have resulted in serious outbreaks of infection. Purposeful contamination of infusates as a form of child abuse also has been reported.[354] The frequency of hematogenous seeding of the catheter from a distant site of infection is unknown but is likely to be uncommon.

Table 244–7 lists clinical criteria for establishing the diagnosis of infections related to intravascular catheters and infusions.[436] The utility of these definitions has been affirmed for pediatric patients.[484] Definitions used by the NNIS system are similar but do not specifically define separate local infections and include two subcategories of bloodstream infection (laboratory-confirmed bloodstream infection and clinical sepsis).[436] These definitions were revised in early 2008 to require two positive blood cultures within 48 hours for infections caused by common skin microorganisms.[88]

Potential bloodstream infections should be evaluated with at least two blood cultures, including at least one blood culture drawn by venipuncture, before antimicrobial therapy is instituted.[401] If there are indications for catheter removal (see additional discussion later), the catheter should be removed by an aseptic technique and cultured to determine whether it is colonized. Non-tunneled central venous catheters may be changed over a wire or removed and cultured. The semiquantitative roll-plate culture technique is the traditional and most widely available method for culturing the catheter.[379] More than 15 colony-forming units (CFU) is regarded as evidence of colonization of the external surface of the catheter but does not reliably predict risk for development of bloodstream infection; more than 100 CFU has greater positive predictive value for development of bloodstream infection.[379] However, the roll-plate technique does not detect colonization of the catheter hub or the intraluminal surface of the catheter. Quantitative cultures of catheter segments (i.e., catheter tip, subcutaneous segment, or hub), which involve flushing the segment with broth culture media or sonicating the segment in broth followed by serial dilutions of the broth and plating on blood agar, are more sensitive than is the roll-place technique because they detect colonization of both the external and internal surfaces of the catheter.[479,521,551,561] One study suggests that sonication is the most important procedure for increasing the recovery of bacteria from removed catheters.[550]

TABLE 244–7 Clinical Criteria for Infections Related to Intravascular Catheters and Infusions

Infection	Diagnostic Criteria
Catheter colonization	Significant growth of a microorganism (>15 CFU) from the catheter tip, subcutaneous segment of the catheter, or catheter hub
Exit-site infection	Erythema or induration within 2 cm of the catheter exit site, in the absence of concomitant bloodstream infection and without concomitant purulence
Tunnel infection	Tenderness, erythema, or site induration >2 cm from the catheter site along the subcutaneous track of a tunneled (e.g., Hickman or Broviac) catheter, in the absence of concomitant bloodstream infection
Pocket infection	Purulent fluid in the subcutaneous pocket of a totally implanted intravascular catheter that might or might not be associated with spontaneous rupture and drainage or necrosis of the overlying skin, in the absence of concomitant bloodstream infection
Bloodstream infection	
Infusate related	Concordant growth of the same organism from the infusate and blood cultures (preferably percutaneously drawn) with no other identifiable source of infection
Catheter related	Bacteremia or fungemia in a patient with an intravascular catheter with at least one positive blood culture obtained from a peripheral vein, clinical manifestations of infections (i.e., fever, chills, or hypotension), and no apparent source for the bloodstream infection except the catheter One of the following should be present: a positive semiquantitative (>15 CFU/catheter segment) or quantitative (>10^3 CFU/catheter segment catheter) culture whereby the same organism (species and antibiogram) is isolated from the catheter segment and peripheral blood; simultaneous quantitative blood cultures with a ratio ≥5:1 central venous catheter versus peripheral; differential period of central venous catheter culture versus peripheral blood culture positivity of >2 hours

CFU, colony-forming units.
Modified from O'Grady, N. P., Alexander, M., Dellinger, E. P., et al.: Guidelines for the prevention of intravascular catheter–related infections. Centers for Disease Control and Prevention. M. M. W. R. Recomm. Rep. 51(RR-10):1-29, 2002.

Unfortunately, quantitative catheter cultures are time-consuming and expensive, and they are not universally available.

Because these techniques require removal of the catheter, some investigators have attempted to diagnose catheter-related bloodstream infection by comparing quantitative blood cultures drawn through the catheter and by venipuncture (paired cultures) or by comparing multiple cultures drawn through the catheter only (unpaired cultures). A meta-analysis found that the paired quantitative blood culture technique was the most sensitive technique.[521] The differential time to positivity technique, which compares information (time to positivity) provided by existing automated systems between blood cultures drawn through catheter with those drawn peripherally, is nearly as sensitive as the paired quantitative blood culture technique and is less labor-intensive.[521] However, consistent volumes of blood must be inoculated into each of the paired culture bottles.

Other investigators have examined rapid techniques. The acridine orange leukocyte cytospin test is nearly as sensitive as the paired quantitative blood culture technique and the differential time to positivity technique.[521] In a study of infants, the Gram stain and acridine orange leukocyte cytospin test of blood drawn through a central venous catheter had 87 percent sensitivity and 94 percent specificity for the diagnosis of catheter-related bloodstream infections compared with quantitative blood cultures drawn from the catheter and by venipuncture.[517] An advantage of this test is that it can be completed in less than 1 hour. Buffy coat Gram stain of a blood sample drawn from the catheter may reveal yeast forms in some patients with candidemia. If the catheter is removed, Gram staining of adherent material also may facilitate rapid diagnosis.

In practice, several difficulties arise in establishing the diagnosis of catheter-associated bloodstream infections. Physicians' designation of microorganisms isolated from blood cultures as pathogens or contaminants may be confounded by the patient's age and underlying condition and the presence of an intravascular catheter, particularly a central venous catheter. For example, in one study, physicians were more likely to interpret the coagulase-negative staphylococci in blood cultures drawn from very-low-birth-weight infants as clinically significant.[188] Obtaining cultures by venipuncture is difficult in young children, and clinicians may be reluctant to obtain blood for more than one culture in low-birth-weight infants. Central venous catheters often are not removed for culture because of potential complications associated with reinsertion of a new catheter and the fact that many catheter-related bloodstream infections can be treated with the catheter in place. Finally, unless infusate-related bloodstream infection is suspected, obtaining cultures of intravenous fluids or medications often is overlooked.

The terminology used to describe the clinical manifestations of bloodstream infection in pediatric patients has been standardized recently.[231] Consensus definitions of the systemic inflammatory response syndrome (a condition that arises from a variety of processes including bloodstream infection), sepsis, severe sepsis and septic shock, and multiple organ dysfunction in neonates and children have been reported[231] but have not been validated.

Empiric antimicrobial therapy for suspected bloodstream infection instituted while awaiting culture results should be based on the severity of the patient's clinical disease, the nature and severity of the patient's underlying condition, and local knowledge of the relative frequency and susceptibility patterns of pathogens causing this infection. The guideline cited previously contains detailed recommendations for the management of these infections.[401] In most situations, empiric therapy should include an agent effective against gram-positive bacteria, such as nafcillin, oxacillin, or vancomycin, and an agent effective against most gram-negative bacteria including *Pseudomonas*, such as ceftazidime, cefeprime, or an aminoglycoside. MRSA has become such a common problem that many clinicians now prefer to initiate therapy with vancomycin until culture and sensitivity results are available. Gentamicin generally is equivalent to ceftazidime in its activity against gram-negative rods, is synergistic with vancomycin against susceptible *Enterococcus* spp., and is much less costly. Unless renal toxicity or ototoxicity is a major concern, gentamicin may be appropriate empiric coverage against gram-negative rods if the patient has no evidence of meningitis. Empiric use of two agents with activity against gram-negative rods (e.g., ceftazidime plus gentamicin) is appropriate in a severely ill patient or when infection with a resistant gram-negative rod is suspected because even a short delay in instituting appropriate therapy is associated with an increased risk of mortality. In settings where extended-spectrum β-lactamase–producing gram-negative rods are prevalent, choosing a carbapenem for empiric therapy may

be prudent. Empiric antifungal therapy also may be necessary, for instance, in situations when suspicion of fungemia is high (i.e., a severely ill patient who is colonized with *Candida* spp. or a neutropenic patient who is already receiving broad-spectrum antibacterial therapy). Once culture information is available, the treatment regimen can be tailored accordingly or discontinued if no infection is identified.

The aforementioned management guideline also reviews the efficacy of the "antibiotic lock" technique for treatment of tunneled catheter–related bacteremia.[401] The concept behind this approach is that organisms embedded in biofilms on the luminal surfaces of long-term, tunneled catheters may be killed more effectively by antibiotic concentrations 100 to 1000 times higher than standard concentrations of therapeutic parenteral antibiotics.[401] An antibiotic solution (usually vancomycin or gentamicin) in a concentration of 1 to 5 mg/mL with an appropriate concentration of heparin (usually 50 to 100 units) is infused into the catheter in sufficient volume (2 to 5 mL) to fill the lumen and is left in place while the catheter is not being used.[401] The volume of instilled antibiotic is removed before the next dose of antibiotic or intravenous medication or solution is infused. This treatment approach may be used with or without concomitant systemic therapy in carefully selected patients with tunneled catheter–related bacteremia caused by intraluminal colonization of the catheter.[401] Preliminary studies suggest that alcohol locks may provide an additional approach to treatment of recalcitrant catheter infections, although data are insufficient to support this approach.[479]

No evidence suggests a benefit for the use of thrombolytic agents for adjunctive treatment of catheter-related bloodstream infection. Two noncontrolled studies reported good responses to treatment of catheter-related bloodstream infections using a combination of antimicrobial therapy and low-dose urokinase.[303,537] However, two subsequent randomized, controlled trials found no benefit from the combination of urokinase and antimicrobial therapy.[28,333] Recombinant tissue plasminogen activator has proved effective in restoring flow to occluded central venous catheters,[288,469] but this agent has not been studied as adjunctive therapy for catheter-related bloodstream infection.

Most uncomplicated bloodstream infections associated with central venous catheters can be treated effectively without removal of the catheter.[401,639] However, treatment of catheter-associated fungemia without removal of the catheter has a relatively low success rate and may be associated with higher mortality rates as well as with other complications.[135,401] Strong consideration also should be given to removal of catheters associated with difficult-to-treat bacteria, such as antimicrobial-resistant enterococci or gram-negative rods. In the authors' experience, in situ treatment is not as likely to be successful with implanted catheters, but few published data specifically address this issue. Percutaneously inserted central venous catheters may be changed over a wire and the catheter tip sent for culture. If the culture of the tip is negative, the replacement catheter can be left in place. If the culture of the tip is positive, the replacement catheter should be removed and a new catheter inserted at a new site. Catheters should be removed immediately if evidence of embolic phenomena, septic thrombophlebitis, or endocarditis is present or the patient is hemodynamically unstable.

Few data address the optimal duration of therapy for bloodstream infections if the catheter remains in place, but experience suggests that 10 to 14 days usually is adequate. If the catheter is removed, shorter courses of therapy (5 to 7 days) are appropriate for uncomplicated infections caused by less virulent pathogens such as coagulase-negative staphylococci.

Persistently positive blood cultures despite antimicrobial therapy or recrudescence of infection shortly after therapy is completed should prompt removal of the catheter. The need to remove catheters from patients with persistent fever but no positive culture results and no evidence of infection at another site is controversial and should be approached on a case-by-case basis.

Some success has been reported in treating uncomplicated exit-site infections with the catheter in place.[401,639] A trial of a combination of local therapy and systemic antimicrobial treatment is warranted before a decision to remove the catheter is made. In contrast, treatment outcomes of tunnel or pocket infections generally are poor if the catheter is left in place.[401,639]

A guideline for preventing the development of infections related to intravascular catheters and infusions has been published.[436] In addition, several reviews have focused on the role of novel technologies in the prevention of these infections.[122,123,479] Key aspects of the prevention of these infections are emphasized in the following.

Intravascular catheters and infusions should be used only when necessary and only for as long as necessary. Caregivers should monitor catheterized patients closely for signs of local and systemic infection. Interventions directed at minimizing contamination of the catheter during insertion include use of an effective skin antiseptic (chlorhexidine-based agents are more effective than povidone-iodine or alcohol-based agents but are not approved by the Food and Drug Administration for use in neonates).[100,122,205,378] Hand hygiene should be performed before the procedure, and full sterile barrier precautions (e.g., sterile gowns, gloves, and large drapes) should be used while central venous catheters are being inserted.[478] Rigorous application of an "insertion bundle," which includes these interventions with a central line "cart" (to ensure that all necessary supplies and equipment are easily accessible) and a checklist to monitor compliance, has been associated with significant reductions in the incidence of bloodstream infections in several studies, including a statewide observational study in Michigan.[49,475,618] The impact of this type of bundled intervention has not been studied as extensively in pediatric patients, but it has been used in a quality improvement collaborative sponsored by the Child Health Corporation of America and the National Association of Children's Hospitals and Related Institutions.

Several studies, including a study involving neonates, have examined the efficacy of a chlorhexidine-impregnated sponge placed at the catheter insertion site.[204,257,346,376] This device reduced cutaneous colonization at the insertion site and colonization of the catheter tip; however, only one study demonstrated that use of the device resulted in lower bloodstream infection rates.[376] In the neonatal study, 15 percent of the neonates weighing less than 1000 g developed localized contact dermatitis from the device.[204] Routine application of topical antimicrobials to the catheter exit site is not recommended.[123,436] Transparent semipermeable dressings facilitate inspection of the catheter site. However, some studies suggest that they may increase microbial proliferation at the site of insertion and predispose the patient to development of bloodstream infection, whereas others have shown no difference in colonization of the site or infection rates in comparison to gauze and tape dressings.[436] Despite the controversy, transparent dressings are in widespread use, often in combination with a small piece of gauze placed at the site of the insertion to absorb moisture.

Several publications have reviewed the data on the effect of central venous catheters impregnated with antimicrobials and silver-impregnated subcutaneous catheter cuffs on the incidence of catheter-related bloodstream infection.[123,436,479] These studies have not involved any pediatric patients. Catheters impregnated with chlorhexidine–silver sulfadiazine (coating the external surface only) or minocycline-rifampin (coating both the internal and external surfaces) significantly reduce rates of bloodstream infection compared with unmedicated catheters.[122] The minocycline-rifampin catheter was associated with lower rates of bloodstream infection than was the chlorhexidine–silver sulfadiazine catheter in a head-to-head trial.[134] However, a new chlorhexi-

dine–silver sulfadiazine catheter designed with a higher level of antiseptic in the catheter material and with coating of the internal and external surfaces has been demonstrated to reduce catheter colonization.[516] Silver-impregnated catheters and catheters using active iontophoresis have been tested, but the results have been mixed.[479] The long-term impact of these catheters on antimicrobial resistance has not been evaluated.[123,479] These types of catheters have not been evaluated systematically in pediatric patients. In general, these catheters should be considered only if the conventional methods for prevention of infections as described before have been implemented in a highly reliable fashion and have failed (e.g., in high-risk patients prone to recurrent infections).

Catheter caps containing antiseptic agents also have been tested. A randomized controlled trial of a central venous catheter cap with a chamber containing 3 percent iodinated alcohol demonstrated a fourfold reduction in the rate of catheter-related bloodstream infection,[539] although these results were not confirmed in a subsequent study performed by a different group.[364] A small randomized controlled trial of a povidone-iodine–saturated sponge to encase the hub demonstrated significant reduction in the incidence of bloodstream infections.[254] These devices have not gained widespread acceptance, and the amount of iodine that may enter the bloodstream if these devices are used routinely remains unclear.

Needle-less connectors for intravenous tubing are important to reduce the risk of needle-stick injury among health care providers. However, increased rates of bloodstream infection have been observed when these devices have been used incorrectly.[115,130,391]

Reports associating increased rates of bloodstream infection with introduction of new mechanical valves in Luer lock catheter caps are cause for concern because they may indicate a design defect that facilitates contamination of the interior surfaces of the device.[386,515] However, because these reports do not document adherence with optimal cap care, incorrect practice may be a contributing factor.

Studies of the use of "prophylactic" vancomycin or other antibiotics added to intravenous fluids and flush solutions to prevent development of catheter-related infections have shown some promise.[436] A randomized, placebo-controlled trial of a vancomycin-heparin lock solution found that this intervention reduced the incidence of catheter-related bloodstream infections in high-risk neonates with long-term central catheters.[203] No vancomycin-resistant organisms were identified. Vancomycin was not detected in the blood of infants who did not receive systemic vancomycin therapy. A substantial proportion of infants in each arm of the study had asymptomatic hypoglycemia at the end of a catheter-lock period, but these episodes resolved promptly when glucose-containing intravenous fluids were restarted. The intervention appears to be safe, although with asymptomatic hypoglycemia in the infants receiving the lock. This type of intervention warrants further study.

Manipulation of the catheter and infusion sets should be minimized, and these sets should be maintained as closed systems whenever possible. When manipulation is necessary, hand hygiene and use of aseptic technique should be practiced and hubs should be disinfected with an alcohol swab. Infusion sets used for standard intravenous fluid administration need not be changed more frequently than every 72 hours.[436] If parenteral nutrition or blood products are administered, infusion sets should be changed at least every 24 hours.[436]

The apparatus for hemodynamic monitoring should be maintained as a closed system, and manipulations of this system should be kept to a minimum.[436] When manipulation is necessary, hand hygiene and use of aseptic technique should be practiced. Disposable domes and transducers used for hemodynamic monitoring should be changed every 96 hours.[436] Reused transducers should be reprocessed appropriately between uses.[436]

Stopcocks are common components of intravenous infusion and hemodynamic monitoring systems and are used as portals for injection of medications, infusion of fluids (e.g., parenteral nutrition), and collection of blood samples. These devices can become contaminated during use, although their role in bloodstream infections has not been studied well. Manipulation of these devices should be kept to a minimum, and the access port should be disinfected before it is entered.

Two randomized controlled trials have found fluconazole to be effective in preventing candidemia among low-birth-weight infants in neonatal ICUs,[307,385] although the rates of candidemia in both trials were substantially higher than those reported in a large network of newborn ICUs.[585] A survey of prescribing practices conducted between the publication of these two trials indicated that use of prophylactic fluconazole was not widespread.[76]

INFECTIONS RELATED TO RESPIRATORY THERAPY

Most cases of health care–associated pneumonia are caused by bacteria and are associated with mechanical ventilation. Pneumonia also can be caused by respiratory viruses, but these infections are caused by intrahospital transmission of common community infections rather than by exposure to medical devices or ICUs (see the section on health care–associated infections due to spread of infections common in the community, respiratory infections, respiratory viruses). *Legionella* and filamentous fungi also cause pneumonia, but these infections occur almost exclusively in immunocompromised patients and are related to inhalation of contaminated aerosols or fungal spores, not respiratory therapy.

Tables 244–1 and 244–2 display rates of pneumonia associated with mechanical ventilation in pediatric ICUs and newborn ICUs in U.S. hospitals participating in the NNIS system.[424] Rates of pneumonia are considerably lower in pediatric and newborn ICUs than in adult ICUs.[424]

Aside from these rates, very limited data exist on the epidemiology, pathogenesis, treatment, and prevention of ventilator-associated pneumonia in infants and children. The information discussed here draws largely from studies in adult patients. This same general information can be found in several reviews.[180,474,646]

Health care–associated pneumonia related to the use of equipment generating contaminated mists has not been reported recently in pediatric patients, although numerous outbreaks caused by "water bacteria" (e.g., *Flavobacterium meningosepticum*, *P. aeruginosa*, *Achromobacter* spp.) in pediatric patients in the 1950s and 1960s were linked to the use of centrifugal, Venturi, and ultrasonic mechanical nebulizers.[411] Such devices can aerosolize droplets that are small enough to reach the distal airways, so contamination of their fluid reservoirs is extremely hazardous. Most large-volume, mechanical nebulizers have been replaced by heated humidifiers. These devices are considerably less dangerous because they do not generate small-particle aerosols and are less prone to heavy contamination because heating of the reservoir retards the growth of most potential pathogens. Mist tents used today for patients with bronchiolitis and croup do have mechanical nebulizers, but they generate larger particles that are deposited in the environment, mouth, and pharynx and do not generally reach the lower respiratory tract. Nonetheless, an effective cleaning and disinfection program is required to minimize the likelihood for development of infection.

On the other hand, small-volume, hand-held nebulizers used commonly for inhalation therapy in pediatric patients are designed intentionally to generate particles small enough to reach the distal airways, and the potential for pneumonia related to the use of these devices is underappreciated by most caregivers. An outbreak of *Legionella* pneumonia caused by contaminated

medication administered with use of small-volume nebulizers has been reported.[387] In addition, the small-volume medication nebulizers used in conjunction with mechanical ventilators can become contaminated by bacteria colonizing the ventilator circuit and thus generate bacteria-laden aerosols.[121]

Mechanical ventilation is a major risk factor not only for health care–associated pneumonia but also for sinusitis and otitis media because the nasotracheal tube interferes with normal drainage of the ostia of the sinuses and the eustachian tube.[50,238] Detection of these infections requires a high index of suspicion because they often are "silent," with little in the way of symptoms other than fever.

Risk factors for ventilator-associated pneumonia in adults have been summarized in a review.[594] This review groups risk factors into several categories: host factors, such as chronic pulmonary disease and immunosuppression, which increase general susceptibility to pneumonia; factors that enhance bacterial colonization of the oropharynx and stomach with pathogenic bacteria, such as severe underlying disease, administration of antimicrobials, and, possibly, agents that raise gastric pH (e.g., antacids, H_2 blockers); factors that increase the likelihood of reflux of gastric contents and aspiration into the lower airway, such as depressed mental status, supine positioning, nasogastric tubes, and enteral feeding; conditions that require prolonged ventilation and hence increase potential exposure to contaminated respiratory equipment and contact with contaminated hands of caregivers; and factors that hinder adequate pulmonary toilet, such as thoracic or abdominal surgery and immobilization.[594] At least some of these risk factors are likely to be important in children as well. A study in a pediatric ICU found that the presence of a genetic syndrome, repeated intubation, and transport from the pediatric ICU independently predicted development of ventilator-associated pneumonia.[164]

Microorganisms associated with ventilator-associated pneumonia in pediatric and newborn ICUs participating in the NNIS system are displayed in Tables 244–4 and 244–5.[215,497] Not reflected in the tables is the fact that the majority of cases of pneumonia are polymicrobial in nature and often include both gram-positive and gram-negative bacteria.[594] Gram-negative bacilli, including *P. aeruginosa*, *Enterobacter* spp., and *Klebsiella* spp., are major pathogens, as is *S. aureus*. *S. pneumoniae* and *H. influenzae* have been recognized increasingly as causes of early-onset ventilator-associated pneumonia in adults.[591] *Moraxella catarrhalis* is an occasional pathogen. Anaerobic bacteria seldom are implicated as a cause of pneumonia,[594] but they may play a role in some polymicrobial infections, especially when pneumonia is caused by aspiration. Although *C. albicans* and other *Candida* spp. are isolated in some cases, they rarely if ever are the primary cause of pneumonia. The distribution of microorganisms causing sinusitis and otitis media in nasotracheally intubated patients is similar to that of pneumonia, although anaerobic bacteria may play a greater role.[71]

The pathogenesis of ventilator-associated pneumonia is complex but can be reduced to two general mechanisms: (1) aspiration of microorganisms colonizing the stomach and oropharynx and (2) inhalation of contaminated aerosols.[594] Aspiration is responsible for most cases of endemic pneumonia, whereas inhalation of contaminated aerosols tends to occur in the context of outbreaks of infection from common sources.

A variety of factors facilitate colonization of the oropharynx and upper respiratory tract with pathogenic bacteria. Adherence of gram-negative organisms to mucosal cells is enhanced in severely ill or debilitated patients by exposure of epithelial bacterial receptors and by changes in the amount and character of respiratory secretions.[594] Bacterial factors, such as the presence of pili in *P. aeruginosa*, also play a role.[594] Antimicrobial therapy reduces the concentration of normal flora, thereby reducing "colonization resistance" and allowing antimicrobial-resistant microorganisms to gain a foothold. Bacteria may reach the pharynx by the hands of caregivers or from contaminated equipment or aerosols, or they may be regurgitated into the pharynx from the stomach. Normal gastric pH prevents heavy contamination of stomach contents, but bacteria proliferate to high levels when stomach acid is neutralized by antacids or H_2 blockers.[594] Although the roles of these agents in fostering gastric colonization are supported by most studies, the degree to which they are associated with an increased risk of acquiring pneumonia is less clear.[591] Factors that increase reflux of gastric contents into the upper airway, such as bolus enteral feedings, nasogastric tubes, and supine position, probably increase the risk substantially, but they have not been studied extensively.

Regardless of how microorganisms reach the upper respiratory tract, contaminated secretions can be aspirated into the lower respiratory tract of mechanically ventilated patients during changes in position or deflation of the endotracheal tube cuff. Uncuffed endotracheal tubes are used in most pediatric patients, so the potential for aspiration is constant.

Pneumonia associated with inhalation of contaminated aerosols is much less common than is colonization of the oropharynx and aspiration.[591] As noted previously, such infections are likely to be caused by *P. aeruginosa*, *Legionella*, and a variety of other nonenteric gram-negative bacilli that are capable of surviving and proliferating in medications and solutions used in respiratory therapy.[594]

Once microorganisms have entered the lower airway, the status of normal defense mechanisms is extremely important in determining whether infection results. Diseases that compromise the mucociliary clearance system (i.e., cystic fibrosis, chronic lung disease) and the ability of the immune system to contain and to inactivate these microorganisms (i.e., chemotherapy, HIV infection) increase the risk of infection dramatically.

Methods used to diagnose community-acquired pneumonia, such as auscultation of the chest, examination of sputum, and chest radiography, are helpful but much less precise tools for establishing the diagnosis of ventilator-associated pneumonia. Auscultation often is hindered by sounds of the ventilation system itself and is virtually impossible in patients on high-frequency ventilation. Furthermore, a variety of underlying pulmonary diseases (e.g., bronchopulmonary dysplasia, adult respiratory distress syndrome, cystic fibrosis) and conditions (e.g., fluid overload) may produce sounds indistinguishable from those present in pneumonia. Cultures of tracheal aspirates may be misleading because the endotracheal tube often is colonized with potential pathogens, especially in patients ventilated more than a few days.[224] A Gram stain of the tracheal aspirate can semiquantitatively assess both the number of neutrophils and the number and type of microbial flora, but localized irritation or superficial infection of the trachea related to the endotracheal tube may produce purulent secretions that are laden with bacteria on Gram stain. Finally, the presence of new radiographic findings consistent with pneumonia may be extraordinarily difficult to assess in patients with underlying lung disease or patients recovering from thoracic or complicated cardiac surgery. Viral pneumonia requires demonstration of the pathogen by direct detection, culture, or serology.

A variety of techniques to improve the diagnosis of ventilator-associated pneumonia in adults have been evaluated. Bronchoscopic techniques (e.g., quantitative culture of protected brush specimens, bronchoalveolar lavage, and protected bronchoalveolar lavage) have been studied in detail. A meta-analysis and a recent randomized controlled trial failed to show a benefit in terms of clinical outcomes from the use of a bronchoscopic technique.[555,602] The utility of blind catheterization of the distal airway (i.e., mini–bronchoalveolar lavage) to obtain specimens for Gram stain and quantitative culture of the endotracheal aspirate also

has been investigated, albeit less rigorously.[72] Neither technique has been studied rigorously in ventilated children or infants.

Evaluation of fever in a mechanically ventilated patient should include examination for otitis media. If a cause of the fever is not established, consideration should be given to radiographic studies of the sinuses (e.g., sinus films or a computed tomographic scan), especially if the child has a nasotracheal tube. If otitis media or sinusitis is diagnosed, tympanocentesis or a tap of the sinuses for culture should be considered to guide antimicrobial therapy.

Administration of empiric antimicrobial therapy for ventilator-associated pneumonia while awaiting culture results should be based on the severity of the patient's clinical disease, the nature and severity of the patient's underlying condition, and local knowledge of the relative frequency and susceptibility patterns of pathogens causing this infection. Therapy with a broad-spectrum agent with good activity against gram-negative bacilli, including *P. aeruginosa*, possibly with inclusion of an agent active against MRSA as guided by local patterns of susceptibility, generally is appropriate. On the basis of the patient's clinical status and culture results, the treatment regimen can be tailored accordingly or discontinued (i.e., de-escalated). Prolonged treatment of patients in whom the diagnosis is questionable should be avoided because it often leads to endotracheal colonization with antimicrobial-resistant bacteria. Duration of treatment has not been studied in children. Uncomplicated cases may be treated with 7 to 10 days of therapy. If a necrotizing gram-negative pneumonia is diagnosed (rare in pediatric patients), therapy should be administered for at least 14 days.

Nasotracheally intubated patients with otitis media or sinusitis should have the nasotracheal tube changed to an orotracheal tube. Short-term treatment with a decongestant and lavage of the sinuses (often performed at the time of the sinus tap) may be beneficial in the treatment of sinusitis. Treatment of these infections also has not been studied extensively, but the authors generally use approximately 10 days of therapy for otitis media; extensive sinusitis warrants administration of therapy for at least 14 days.

A comprehensive guideline for the prevention of health care–associated pneumonia has been developed by the CDC and the Healthcare Infection Control Practices Advisory Committee.[594] Key features of this guideline are emphasized here.

Noninvasive approaches to enhance ventilation should be used as much as possible. Mechanical ventilation should be used only when necessary and for only as long as necessary. Care should be taken to avoid accidental extubation. Caregivers should monitor ventilated patients carefully for signs of pneumonia, otitis media, and sinusitis. New approaches to weaning of patients from mechanical ventilation can reduce the length of the period of mechanical ventilation significantly.[605] However, a randomized controlled trial in pediatric ICUs did not demonstrate reduced time to extubation with the use of a volume support weaning protocol, in part because most of the children were weaned from mechanical ventilator support in 2 days or less.[485]

The importance of prevention of cross-colonization with "hospital flora," especially antimicrobial-resistant bacteria, should be stressed. Hand hygiene and use of gloves during contact with respiratory secretions or objects or surfaces contaminated with respiratory secretions are important, especially in busy ICUs caring for many sick patients. Data are insufficient to recommend sterile rather than clean, nonsterile gloves.

A cuffed endotracheal tube with subglottic or in-line suctioning is recommended in adults. Cuffed endotracheal tubes are not used routinely in all children, especially younger children, and in-line suctioning has not been studied in a pediatric population. Suctioning should be performed gently with a sterile, single-use catheter, and sterile fluids should be used to loosen secretions and to clear the suction catheter. Several procedures to prevent reflux of gastric contents during enteral feeding, such as elevating the head of the bed, avoiding rapid infusion of large fluid volumes, and avoiding external pressure on the stomach, are simple to implement and probably helpful. Use of continuous rather than intermittent bolus feedings and duodenal rather than gastric placement of the feeding tube have not been studied in sufficient detail. Avoiding the use of agents that elevate gastric pH is prudent unless the patient is viewed as being at risk for stress-induced gastric bleeding. A retrospective study of ventilated children found that the strategy used to prevent gastrointestinal bleeding was not associated with the risk for development of ventilator-associated pneumonia.[361] Regular oral care should be performed. A recent randomized trial found that perioperative decontamination of the nasopharynx and oropharynx with 0.12 percent chlorhexidine gluconate reduced the incidence of lower respiratory tract infections and deep surgical-site infections in adult cardiothoracic surgery patients.[538] This strategy has not been tested in infants and children.

The experience of a children's hospital implementing a ventilator-associated pneumonia prevention bundle, derived from the interventions discussed before, is discussed in a recent review.[127]

Endotracheal tubes and ventilator circuits become contaminated with the patient's own oropharyngeal flora very quickly, and repeatedly changing this equipment does not reduce the risk for development of infection. Ventilator circuits and humidifiers should be changed no more frequently than every 48 hours. The maximum "permissible" period of use has not been established.[594] Care should be taken to prevent condensate that collects in the ventilator tubing from draining into the endotracheal tube because this fluid can be contaminated with a very large number of microorganisms. Tubing should be maintained in a dependent position relative to the endotracheal tube, and condensate should be discarded routinely. The impact of various innovations, such as traps to collect condensate, bacterial filters, hygroscopic condenser-humidifiers, or heat exchange humidifiers, on the risk for development of pneumonia has not been determined.

Large-volume, mechanical nebulizers should not be used unless they are scrupulously cleaned and reprocessed on a daily basis. Only sterile water should be used in these devices. Small, hand-held medication nebulizers should be rinsed with sterile water and allowed to air dry between uses. These devices should be reprocessed before use in another patient. Only sterile, aseptically dispensed medications should be used in these devices. Other respiratory therapy equipment should be reprocessed between uses in different patients.

Development and application of effective procedures for reprocessing of all reused respiratory therapy and ventilator equipment have played a major role in reducing the risk for development of serious gram-negative pneumonia. Items that have direct or indirect contact with the mucus membranes or respiratory secretions should be cleaned thoroughly and either sterilized or disinfected in a manner consistent with high-level disinfection.

INFECTIONS RELATED TO INSTRUMENTATION OF THE URINARY TRACT

Urinary tract infections (UTIs) are the most common health care–associated infection in hospitalized adults, accounting for approximately 40 percent of all infections in this group.[242] In contrast, UTIs represent a much smaller proportion (10% or less) of health care–associated infections in hospitalized children.[181,294,339,632] This difference can be explained in part by differences in urinary tract catheterization in these two populations. Data from the NNIS system indicate that indwelling urinary catheters are used approximately half as frequently in pediatric

ICUs as they are in adult ICUs.[424] Indwelling urinary catheters are used infrequently in newborn ICU patients. On the other hand, the infectious risk associated with the use of indwelling urinary catheters is similar in adults and children. As shown in Table 244–1, rates of UTIs associated with indwelling urinary catheters are only slightly lower in pediatric ICUs than in adult ICUs in U.S. hospitals participating in the NNIS system.[424]

The descriptive epidemiology of UTIs in pediatric patients has been examined in several studies.[138,339,357,358,440] In a prospective cohort study, catheterized patients were identified and prospectively observed for symptoms and signs of UTIs (in which case a urinalysis and culture were performed) and by weekly urinalyses and urine cultures regardless of symptoms.[357] Health care–associated UTIs in noncatheterized patients also were studied. UTIs were detected in 11 percent of all catheterized patients, including 11 percent of those in whom only indwelling catheterization was used, 9 percent with both indwelling and intermittent catheterization, and 12 percent with intermittent catheterization alone. The incidence density of infection was not reported. The median duration of catheterization preceding infection was 7 days (range, 2 to 77 days). Three quarters of the infections identified were symptomatic. No definite cases of secondary bacteremia were detected.

Additional information about the spectrum of health care–associated UTIs in this study was provided by combining data from catheterized and noncatheterized patients.[357] Catheterization and female sex were identified as risk factors for development of UTIs; 77 percent of all infections occurred in catheterized patients, and 75 percent of all infections occurred in female patients. The majority of infections in noncatheterized patients occurred in the newborn ICU and the preschool-age ward. A wide range of underlying diagnoses were reported, but neurologic, renal, oncologic, orthopedic, or trauma-related diagnoses accounted for 50 percent of cases.

No data have been published on rates of UTIs associated with different types of indwelling catheters (e.g., urethral, suprapubic, ureteral, nephrostomy) in pediatric patients. In the authors' experience, infection (or at least bacteriuria or candiduria) frequently occurs when catheters remain in place for long periods (i.e., more than 1 to 2 weeks), regardless of the type of catheter used. Data on the incidence of infection developing after cystoscopy, renal transplantation, or other types of urinary tract instrumentation in pediatric patients are not available. In the authors' experience, infections seldom develop after cystoscopy alone or urologic surgery in which preexisting infection or bacteriuria is not present and long-term use of indwelling catheters is not necessary. Bacteriuria and UTIs appear to occur more frequently among patients undergoing renal transplantation, although it is difficult to determine whether this is due to the use of urinary catheters in this population or to inherent risks of the transplantation procedure itself.

Outbreaks in adult patients in the 1970s and 1980s were attributed to contamination of the urinary collecting system by pathogens on the hands of hospital personnel, contaminated drainage pans and measuring containers, and use of inadequate or contaminated antiseptics.[74] Several outbreaks demonstrated that use of urinary catheters contributed to the emergence of antimicrobial resistance among gram-negative bacilli.[74] Antibiotics excreted in the urine provide selective pressure for the emergence of resistant populations of bacteria colonizing urine collection systems, and the large numbers of different types of bacteria present in these systems facilitate transfer of resistance plasmids between species.[74]

Microorganisms causing catheter-associated UTIs in pediatric ICUs participating in the NNIS system are displayed in Table 244–4.[497] Roughly a fifth of infections are caused by *E. coli* alone, and another quarter are caused by various other gram-negative bacteria. *Enterococcus* spp. and various *Candida* spp. account for 10 and 14 percent of infections, respectively. These data are similar to those reported from individual studies.[138,357,358] The rate of UTIs attributed to coagulase-negative infections in newborn ICU patients has been reported to be in excess of 30 percent.[138,358]

Microbial colonization of the urine is the first step in the pathogenesis of UTIs. A detailed culturing study of catheterized patients suggests that roughly two thirds of infections are caused by microorganisms that migrate up the extraluminal surface of the catheter, and the other third of infections arise from microorganisms that gain access to the bladder through the internal lumen of the catheter.[598] In addition, numerous studies in catheterized adults have correlated microorganisms colonizing the urethral meatus with those most frequently causing infection.[74] These microorganisms can be carried into the bladder during insertion of a catheter, or more commonly, once the catheter is in place, they can migrate along the external surface of the catheter into the bladder. The shorter length of the urethra in women has been suggested as an explanation for their increased risk of causing infection in women. However, meatal colonization with pathogenic microorganisms, which also is more common in women, also may be important.[74] Distention of the urethra by the catheter, obstruction of periurethral glands, adherence of pathogenic microbes to the uroepithelium and the external surface of the catheter, and formation of a biofilm composed of host proteins and microbial exopolysaccharide on the external surface of the catheter all play a role in initiation of infection, although the relative contributions of each of these factors are poorly understood.[74]

Microorganisms also may be introduced into the bladder from exogenous reservoirs. Although modern catheters and urine collecting systems are "closed" systems, microorganisms may be introduced into the interior of the catheter collecting system at three points: the junction between the urinary catheter and the collecting system, the port used to aspirate urine specimens and to irrigate the catheter, and the drainage spigot attached to the collection container. Some urinary catheters are fused to the collection system during manufacture, eliminating the possibility of junction disconnection, but such catheters are not in widespread use. Improper technique in the use of the aspiration and irrigation port or the spigot also may result in contamination of the interior surfaces of the system. Once microorganisms gain access to the interior of the catheter or collecting system, they can multiply quickly, reaching concentrations in the collection container exceeding 10^5 CFU/mL of urine in a matter of a few days. Encrustations on the interior surface of the system may serve as sites for microbial attachment and proliferation. Movement of microorganisms into the bladder is facilitated by obstruction of the urine flow and reflux of urine into the bladder (i.e., raising the collection system above the level of the bladder), but many gram-negative bacteria are motile and can "swim" upstream even if the system is maintained properly.

Microorganisms that reach the bladder multiply in the small, but persistent, reservoir of urine that is not completely drained by the catheter.[74] Infection (i.e., symptoms and signs of tissue invasion) is not an inevitable result of colonization of the bladder, and many chronically catheterized patients go for long periods with gross urine colonization but no clinical evidence of infection. Because many young children have vesicoureteral reflux, ascending infection involving the kidneys is a significant concern, but the epidemiologic studies discussed before have not demonstrated pyelonephritis and secondary bacteremia to be common problems.

The diagnosis of a health care–associated UTI depends heavily on the result of a quantitative urine culture. Urine specimens from noncatheterized patients should be obtained aseptically by one of three techniques: midstream, clean-catch collection; "straight" catheterization of the bladder; or suprapubic aspira-

tion. Cultures of urine specimens obtained from external bag collectors are of dubious value because they frequently are contaminated. Specimens from patients with indwelling urinary catheters should be obtained from the aspiration port because urine collected from the collection container may reflect colonization of this reservoir rather than infection.

Although diagnostic criteria for catheter-associated UTIs vary, several definitions established for surveillance purposes generally are well accepted.[208] Symptomatic UTI is defined as the presence of symptoms or signs of infection (e.g., fever, urgency, frequency, dysuria, or suprapubic tenderness) and a quantitative urine culture with more than 10^5 CFU/mL of urine of no more than two different species. Asymptomatic bacteriuria or candiduria (also termed asymptomatic urinary tract infection in some studies, including the cohort study discussed before[357]) is defined as the absence of symptoms or signs of infection and a quantitative urine culture with more than 10^5 CFU/mL of urine of no more than two different species.[208] The diagnosis of asymptomatic bacteriuria is complicated by the fact that approximately 5 percent of healthy school-aged and adolescent girls in the community have asymptomatic bacteriuria that may be detected only after they have been hospitalized. A urinalysis showing evidence of pyuria (e.g., dipstick positive for leukocyte esterase or ≥10 white blood cells/mL^3 of urine) or nitrate provides corroborating evidence of infection. Pyuria is a reasonably good predictor of the presence of significant concentrations of gram-negative rods in the urine of catheterized patients, but it is a poor predictor for the presence of significant concentrations of enterococci or *Candida*.[597] A Gram stain of an unspun urine specimen is useful in guiding initial treatment decisions. However, patients with indwelling catheters and low-level bacteriuria (<10^5 CFU/mL) tend to progress to frank bacteriuria with 10^5 CFU/mL or more within a few days if antibiotics are not administered.

The diagnosis of symptomatic UTI in patients with urinary catheters often is complicated by the fact that these patients do not have symptoms such as urgency, frequency, or dysuria, and the abdominal pain and tenderness may be difficult to assess in newborns and severely ill children in ICUs. Consequently, fever is the sign of infection most frequently identified in these patients, emphasizing the importance of a quantitative urine culture in the evaluation of a new fever in a hospitalized child.

Therapy for health care–associated UTIs is similar to that for community-acquired infections, although parenteral therapy usually is used initially until secondary bacteremia is excluded. Empiric antimicrobial therapy for urinary tract infection while awaiting culture results should be based on the severity of the patient's clinical disease, the nature and severity of the patient's underlying condition, and local knowledge of the relative frequency and susceptibility patterns of pathogens causing this infection. Therapy with a broad-spectrum agent with good activity against gram-negative bacilli, possibly including an agent or agents active against *P. aeruginosa* and enterococci, is generally appropriate. If the Gram stain reveals only gram-negative bacilli, enterococcal infection is unlikely. If renal toxicity from the use of an aminoglycoside is a serious concern, use of a third-generation cephalosporin, carbapenem, aztreonam, or a quinolone in older children is appropriate. Antifungal therapy generally can be withheld, unless yeast elements are identified on a urinalysis or Gram stain of the urine. On the basis of the patient's clinical status and culture results, the treatment regimen can be tailored accordingly or discontinued (i.e., de-escalated).

Whenever possible, indwelling urinary catheters should be removed. Cases of asymptomatic bacteriuria (or asymptomatic candiduria) often resolve with removal of the catheter alone.

Few data are available on the appropriate duration of therapy for health care–associated UTIs. Although simple community-acquired cystitis in older children and adolescents often can be treated successfully with 1 to 3 days of oral therapy, it is prudent to treat uncomplicated hospital-acquired UTIs for at least 7 days. If the infection is uncomplicated and the child has responded to therapy, oral therapy can be used to complete the course. Even pyelonephritis may be treated with oral agents if the pathogen is susceptible, but therapy should be extended to at least 14 days. Secondary bacteremia usually is treated parenterally. Treatment of asymptomatic candiduria with a short course (i.e., 5 days) of therapy is sufficient, but infection is likely to recur unless the catheter is removed. Likewise, infections involving nephrostomy or suprapubic catheters often recur if these catheters must remain in place. In cases in which nephrostomy tubes must be used for extended periods, suppressive antimicrobial therapy may be used after treatment is completed, although this approach involves a risk for development of secondary infection with resistant bacteria or yeast.

The prospective cohort study discussed previously examined the consequences of health care–associated UTIs during the 6 months after infection occurs.[357] Four patients (7.8%) suffered relapses and one patient (2.0%) suffered a re-infection. No deaths occurred, and no additional complications were identified. The need for evaluation of vesicoureteral reflux or anatomic abnormalities of the kidney or urinary collecting system after a health care–associated UTI in infants or young children has not been evaluated. The authors do not perform these studies routinely if the infection appears related to a urinary catheter.

A guideline for the prevention of health care–associated UTIs was published in the mid-1980s.[643] Key features of the prevention of these infections are emphasized here.

Reducing unnecessary use of urinary catheters is the most effective preventive measure. Davies and colleagues[138] reduced the rate of urinary tract infection in a pediatric ICU by 90 percent during the course of an 8-month period simply by instituting a policy whereby nurses automatically removed urinary catheters from patients after 48 to 72 hours unless a physician indicated that continued catheterization was necessary. Urinary catheters should be inserted by trained personnel using careful aseptic technique after the meatus has been cleansed and an effective antiseptic (e.g., povidone-iodine) applied to the meatus and surrounding skin.[643] Contamination of the interior surfaces of the catheter and collection system can be minimized by maintaining a closed system (i.e., avoiding disruption of the connection between the catheter and the collection system), disinfecting the aspiration and irrigation port before accessing this port, and minimizing contamination of the spigot on the collection container.[643] The collecting system should be examined regularly to ensure that urine flow is not impeded, and care always should be taken to maintain the collection system in a dependent position relative to the bladder to prevent reflux of urine.[643] Treatment of preexisting UTIs is important, especially among patients with underlying renal, urologic, or neurologic disease, in whom these infections are frequent occurrences.[643] Systemic antibiotics are effective in preventing UTIs for short periods (5 days or less)[74]; however, routine use of antibiotics for this purpose is likely to facilitate emergence of resistant pathogens. A wide variety of other interventions have been studied, most with limited or variable benefit.[74,375] Manufacturers continue to attempt to design a catheter that will resist adherence of microorganisms or minimize urethral trauma. A silver-hydrogel catheter that inhibits adherence of microorganisms to the catheter surface and antibiotic-impregnated catheters have been studied in adults with mixed results. No studies of novel urinary catheters have been performed in pediatric patients.

INFECTIONS RELATED TO SURGICAL PROCEDURES

Patients undergoing surgical procedures are at risk for a variety of health care–associated infections. A 1-year study of more than 600 pediatric patients undergoing surgical procedures found that

surgical-site infection was the most common infection after surgery, occurring in 3.5 percent of patients.[53] Bloodstream infection occurred in 2.3 percent of patients, with half of these infections occurring in patients whose surgical procedure was insertion of a tunneled central venous catheter. Other reported infections included pneumonia (1.6%), UTI (0.8%), gastrointestinal infection caused by rotavirus (0.3%), and necrotizing enterocolitis (0.2%). A report of health care–associated infections in pediatric patients undergoing cardiovascular surgery found that surgical-site infection and bacteremia accounted for 28 and 27 percent of all infections, respectively.[468]

A handful of reports have described the epidemiology of surgical-site infections in general pediatric surgery patients, although these reports are now dated.[54,137,139,150,369,547]

As expected, wound class was a powerful predictor in these studies of the likelihood for development of surgical-site infection. Considerable variability exists in infection rates within wound class categories among the pediatric studies, suggesting that other factors must have a strong impact on the risk for development of infection. A composite risk index developed through the analysis of data from the NNIS system, which includes measures of severity of illness (the ASA score) and duration of surgery in addition to wound class, is a much better predictor of risk of surgical-site infection than is wound class alone (see Table 244–4).[125] Children undergoing surgery were not included in the original development of this risk index.[125] Other risk factors for development of surgical-site infection are longer duration of surgery,[53,137,139,150] younger age,[150,369,547] prolonged preoperative hospital stay,[137,139,150] emergency surgery,[54,150] longer length of incision,[137,150] and presence of underlying diseases.[54] The experience of the surgeon (i.e., resident versus attending surgeon) performing the surgery was not found to be a risk factor for development of infection, although unnecessary trauma and cautery as well as residual hematoma probably do increase risk.

Two types of surgical procedures—cardiovascular procedures and neurosurgical procedures—are discussed because of the particularly serious nature of surgical-site infections associated with these procedures.

A prospective study of more than 300 children undergoing cardiovascular surgery found an infection rate of 7.1 percent.[468] Surprisingly, infection rates in this study were lower among patients undergoing open heart surgery with cardiopulmonary bypass (6.7%) than among patients undergoing closed heart surgery without bypass (8.1%), but this difference was not statistically significant. Infection rates were higher among patients in whom the sternum was left open after surgery (27.6% in patients with open sternums versus 5.0% in patients with closed sternums, $p < .001$) and among patients with higher PRISM scores (10.7% in patients with PRISM scores ≥10 versus 2.3% in patients with PRISM scores <10, $p < .01$). It is not clear from the data presented in this study whether an open sternum after surgery was an independent risk factor for development of infection or whether the increased risk in patients with open sternums was attributable entirely or in part to increased severity of illness (i.e., higher PRISM score). Subsequent studies documented prolonged duration of surgery and younger age as risk factors.[9,304,423] However, a study that examined the performance characteristics of a risk index specific for children undergoing cardiovascular surgery failed to identify a set of factors that adequately predicted the risk for development of surgical-site infection.[304]

Rates of infection after cerebrospinal fluid shunting procedures vary widely, but many studies are dated, and reported rates of infection related to ventriculoatrial and ventriculoperitoneal shunts (which now are used infrequently) involved small numbers of patients or did not routinely incorporate perioperative antimicrobial prophylaxis into the regimen of care.[651] A large pediatric series from the 1980s with more than 500 patients undergoing ventriculoperitoneal shunting procedures, most of whom received perioperative antimicrobial prophylaxis, reported an infection rate of 11 percent.[437] Rates of infection were higher among patients with myelomeningocele and patients who had undergone previous shunting procedures. Half of the infections occurred in the 2 weeks after surgery and were not commonly associated with simultaneous incisional infection.

Microorganisms causing surgical-site infections in pediatric ICUs participating in the NNIS system are displayed in Table 244–5.[497] Gram-positive cocci account for nearly half of the isolates. *S. aureus* is the most common isolate, but coagulase-negative staphylococci and *Enterococcus* spp. also are common findings. Gram-negative bacilli of various types represent approximately 40 percent of isolates. *Bacteroides fragilis* and other anaerobic bacteria are isolated infrequently, but how frequently anaerobic cultures were performed is unclear. *C. albicans* and other *Candida* spp. are isolated from a minority (4%) of surgical-site infections. This distribution of microorganisms is similar in the several studies of surgical-site infection in general pediatric surgery patients cited previously.[53,137,547] Studies of pediatric patients who undergo cardiovascular surgery have described a similar distribution of microorganisms.[160,468] Gram-positive bacteria more frequently are the cause of cerebrospinal fluid shunt infections. In the large study cited previously, gram-positive bacteria accounted for three fourths of the infections; coagulase-negative staphylococci were the cause of 40 percent of the infections.[437]

The pathogenesis of surgical-site infection relates to the degree of microbial contamination of the wound, the condition of the host (both resistance to infection and the ability to heal the wound), and the conduct of the procedure itself. Microbial contamination of the surgical site occurs almost exclusively during the time the incision is open, which likely is the reason that longer duration of surgery is associated with increased risk of infection, although longer procedures also may be reflective of other factors that influence risk (i.e., complexity of the surgery, skill of the surgeon, care in dissection). If the incision is closed primarily, subsequent contamination of the site from external sources (i.e., use of contaminated antiseptics or dressings) seldom occurs. Most of the microorganisms contaminating open wounds are endogenous in origin (i.e., microorganisms colonizing the skin and respiratory, gastrointestinal, and genitourinary tracts). Indeed, carriage of *S. aureus* in the anterior nares is associated with postoperative infection caused by this organism.[324,384] Infrequent outbreaks of surgical-site infection caused by *S. aureus*, group A streptococci, and group C streptococci have been traced to personnel in the operating room (but not necessarily participating in the surgery itself) who are heavy shedders of these microorganisms, usually as a result of rectal, vaginal, or nasal carriage.[230,502,530] The inanimate environment of the operating room (e.g., walls, floors, other surfaces, and surgical instruments) is an uncommon source of microorganisms causing surgical-site infections.[31] Postoperative hematogenous seeding of the surgical site can occur but seldom does. Airborne fungal spores can cause postoperative infections in immunocompromised patients and rarely in patients undergoing cardiovascular or neurosurgical procedures.

Host factors, such as underlying diseases (e.g., malignant neoplasm, uremia), the competence of the immune system, and nutritional status, are likely to be important, but the nature and degree to which these factors affect the risk for development of an infection are not well described. Hyperglycemia and frank diabetes have been demonstrated to be risk factors for development of infection in adults.

Even with careful preparation of the skin in clean surgery, small numbers of microorganisms are present at the surgical site of virtually every procedure, and careful surgical technique is necessary to avoid conditions that favor the growth of these microorganisms in the postoperative period. Damaged and devascularized tissue created by rough tissue handling and overuse

of electrocautery is less resistant to infection.[10] Hematomas and seromas, which provide optimal growth conditions for bacteria, may develop if dead spaces are not obliterated or if hemostasis is inadequate.[10] Low-pressure suction drains are indicated to facilitate drainage of blood and secretions and to facilitate adherence of tissues and surfaces to promote wound healing.[10] To the extent that they accomplish this goal, surgical drains are useful. However, unnecessary use of drains should be avoided because they provide a portal for entry of microorganisms and may inhibit healing.

Consensus criteria for surgical-site infections developed through the collaborative efforts of the CDC, surgeons, and infection control professionals have been published.[276] Surgical-site infections are subcategorized into superficial incisional infections (involving the skin or subcutaneous tissues), deep incisional infections (involving the muscle or fascia), and organ or space infections (involving visceral organs or deep body spaces or cavities). For the most part, these criteria rely on observations made by direct inspection of the surgical site. Cultures of wound drainage are useful to determine the microbial etiology of the infection, but these criteria rely on the results of wound cultures only when wound drainage is not clearly purulent (i.e., serosanguineous drainage must be culture positive for it to be considered evidence of an infection). Stitch abscesses are not considered surgical-site infections.

Principles of the treatment of surgical-site infections are described in other references.[10] Significant fluid collections, especially collections of purulent material, should be drained. Contemporary interventional radiology drainage techniques have revolutionized the approach to such collections. In some cases, fluid collections may be inaccessible or an attempt at drainage may seriously compromise the patient. In these cases, antimicrobial therapy alone may be successful in resolving the infection, although therapy needs to be chosen carefully to ensure adequate penetration into the area and to minimize the potential for emergence of antimicrobial resistance. Clinical response must be monitored closely. Devitalized tissue should be débrided, and any tension, pressure, or obstruction in the area should be relieved to allow adequate blood flow and drainage. Foreign bodies should be removed. For instance, cerebrospinal fluid shunt infections are not likely to resolve unless the shunt is removed.[651] In some special cases, antimicrobial therapy can successfully suppress infection with foreign bodies in place while postoperative healing takes place (i.e., plates and screws to stabilize bones during healing after orthopedic procedures). However, removal of these devices generally is required eventually to achieve complete cure. Systemic antimicrobial therapy should be prescribed for serious infections, but many superficial infections resolve with local care and application of topical antimicrobial agents.

A guideline for the prevention of surgical-site infections is available.[384] More recently, the Surgical Care Improvement Project has codified the most important prevention practices.[68] Key prevention measures that have the common goal of minimizing microbial contamination of the surgical site are summarized in the following paragraphs.

Preoperative interventions have a major impact on the nature and degree of microbial contamination of the surgical site; it is prudent to minimize the duration of preoperative hospitalization because hospitalized patients are more likely to become colonized with hospital flora (e.g., methicillin-resistant staphylococci). Treatment of preexisting infections is important because microorganisms causing these infections may contaminate the surgical site, but unnecessary therapy should be avoided as it increases the likelihood that colonization with antimicrobial-resistant microorganisms will occur.

Preoperative bathing with use of an agent with antimicrobial activity is a logical prevention measure. This practice does reduce colony counts of bacteria on the skin but has not been shown to reduce the rate of surgical-site infection definitively.[384] A study comparing chlorhexidine and iodophor shampoos before neurosurgical procedures in children demonstrated that chlorhexidine shampoos reduce the number of microorganisms on the scalp before surgery and the frequency of wound contamination; however, the number of patients studied was not sufficient to demonstrate any effect on infection rates.[341] A meta-analysis concluded that preoperative bathing with chlorhexidine is not beneficial in reducing the risk for development of an infection.[625]

A randomized trial examined the effect of topical mupirocin applied to the nares preoperatively to prevent surgical-site infections after general, gynecologic, neurologic, or cardiothoracic surgical procedures.[452] Children were not included in this trial. The overall rate of surgical-site infections was not different among patients receiving topical mupirocin versus those receiving placebo. However, the risk for development of infection with *S. aureus* at any site (surgical site, bloodstream, catheter, lower respiratory tract) among patients with nasal carriage of *S. aureus* was significantly lower among those who received mupirocin than among those who received placebo. Screening for colonization with *S. aureus* or MRSA in patients undergoing elective surgery remains controversial, but some authorities advocate MRSA screening for patients undergoing placement of prosthetic materials and devices in regions where the community prevalence of MRSA is high. If a carrier is detected, an attempt can be made to eradicate colonization before surgery, or the prophylactic antibiotic can be changed to an agent with activity against MRSA.

Although removal of hair appears to provide a "cleaner" operative site, shaving the skin, especially the day before surgery, has the paradoxical effect of increasing skin colonization by liberating resident skin flora from deeper skin structures and causing microscopic skin trauma that facilitates the growth of bacteria. If hair removal is necessary, hair should be clipped instead of shaved. If shaving is necessary, it should be done immediately before surgery.

Appropriately administered perioperative antimicrobial prophylaxis eradicates or at least retards the growth of bacteria that gain access to the surgical site. Numerous studies have examined the effectiveness of perioperative antimicrobial prophylaxis for various surgical procedures performed on adults, but few studies have been performed in pediatric patients. Consequently, recommendations for perioperative antimicrobial prophylaxis for pediatric patients undergoing surgery largely follow regimens recommended for use in adults.[13] Prophylaxis should be administered within 1 hour (2 hours for vancomycin) before the surgical incision is made.[110] If prophylaxis is administered outside this window period, effectiveness is greatly diminished; administration more than 6 hours after the incision is made has essentially no effect.[110] If the surgical procedure is prolonged, another dose should be administered after 2 half-lives of the administered agent have elapsed (i.e., 4 to 6 hours for cefazolin). Additional doses in the postoperative period are unnecessary. Ensuring appropriate use and timing of perioperative antimicrobial prophylaxis is an important quality of care issue; likewise, ensuring that prophylaxis is not used unnecessarily is important for containment of costs.

A variety of intraoperative practices and procedures are intended to prevent microbial contamination of the surgical site.[384] However, the effectiveness of many of these measures is either minimal or has not been studied rigorously. Cleaning of the skin and application of an antiseptic (e.g., alcohols, iodophors, chlorhexidine) reduce the number of viable bacteria at the surgical site. The surgical hand scrub performed by members of the operative team using an effective antiseptic (e.g., alcohols, iodophors, chlorhexidine) reduces the number of bacteria on the hands and the potential for contamination of the surgical site through visible or microscopic breaks in surgical gloves. Barriers worn by the surgical team (i.e., masks, caps, gowns) are logical

parts of operating room practice and provide protection for the operative team against exposure to blood and body fluids, but little evidence exists that they have a substantial impact on the risk for development of surgical-site infections. Traffic and activity in the operating room increase the bacterial count in the air, and limiting the number of persons and movement to a minimum is reasonable, but the effect on the risk for development of infection is likely to be minimal. Bacterial counts in the air also can be minimized by regularly servicing the operating room ventilation system and by maintaining adequate ventilation parameters (15 air changes with 3 changes of outside air per hour and use of a ventilation system with filters with at least 95% efficiency).[18] Laminar air flow and ultraviolet lights can decrease bacterial counts in the air to very low levels, but their effectiveness in reducing the incidence of infections remains controversial.

Proper surgical technique also is important in the prevention of surgical-site infections, as discussed previously. Many studies have demonstrated that confidential feedback of surgeon-specific rates of infection to individual surgeons reduces rates of infection.[601] This approach has been endorsed by the CDC, surgeons, and infection control professionals as a means by which individual surgeons may examine their own rates of infection and adjust their operative techniques accordingly.[604]

Other interventions that have been examined in adult patients include glycemic control, maintenance of normothermia, and supplemental oxygen. These interventions have not been investigated in infants and children undergoing surgery.

HEALTH CARE–ASSOCIATED INFECTIONS IN SPECIAL POPULATIONS

NEWBORN INFANTS

Healthy newborns are thrust into the world quickly, becoming colonized with microorganisms derived from their mothers and the immediate environment within several days. Predominant colonizers are coagulase-negative staphylococci on the skin and umbilicus and in the nose and alpha-hemolytic streptococci in the mouth. Colonization of the gastrointestinal tract is more complex. Lactobacilli predominate in breast-fed babies, whereas more "adult" flora composed of *Bacteroides* spp., other anaerobes, and *E. coli* colonize formula-fed babies.[229] These commensals help resist colonization with pathogenic microorganisms. Because pathogens can spread quickly in crowded nurseries, rooming-in and early discharge reduce the potential for transmission to normal newborns. However, early discharge also renders detection of significant problems when they occur more difficult. For instance, the incubation period for *S. aureus* infection generally is longer than a newborn's stay in the hospital, and significant outbreaks can escape detection unless an aggressive reporting system is established.[265,368]

Premature and full-term infants requiring care in newborn ICUs face a far different fate. Colonization of these infants is delayed substantially, perhaps because of limited contact with their mothers, delayed enteral feeding, and administration of parenteral antimicrobial agents.[222,228] When colonization does occur, it is with markedly different microorganisms. Coagulase-negative staphylococci colonize the skin, umbilicus, and nose of these infants as well.[228] However, molecular typing studies have demonstrated that particular strains of coagulase-negative staphylococci can persist in newborn ICUs for extended periods, being transmitted on the hands of caregivers and causing bloodstream infection in some infants.[283,365,447] *S. aureus* may colonize a variety of sites, particularly the umbilicus and nose.[228] Although lactobacilli and anaerobes still colonize the gut, aerobic gram-negative bacilli, including *E. coli*, *Klebsiella* spp., *Enterobacter* spp., *P. aeruginosa*, *S. marcescens*, and *Citrobacter* spp., represent a much larger proportion of the intestinal flora than in normal newborns. Antimicrobial-resistant strains of these bacteria are a particular problem in many newborn ICUs. As these bacteria can reach concentrations in the stool of 10^6 to 10^8 CFU/g, one is not surprised that the hands of caregivers are easily contaminated, providing an important route for transmission. *Enterococcus* and *Candida* can become established on the skin and umbilicus and in the gut,[228] again by contamination of the hands of caregivers and selection pressure imposed by treatment with antimicrobial agents. Unfortunately, the medical devices that help sustain these infants, such as intravascular catheters and mechanical ventilation, provide portals of entry for these microorganisms to invade sterile sites and cause infection.

The preceding sections have described a variety of microorganisms generally regarded as community pathogens that often cause outbreaks of health care–associated infection in nurseries and newborn ICUs, including RSV and other respiratory viruses, rotavirus, *Salmonella* and other enteric bacterial pathogens,[648] herpes simplex virus, cytomegalovirus, hepatitis A virus, and enteroviruses, and infections related to the use of invasive devices in neonates (see the sections on health care–associated infections due to spread of infections common in the community and health care–associated infections related to invasive devices, procedures, and treatments). Other important pathogens in normal newborn nurseries and newborn ICUs are highlighted here.

S. aureus remains a significant pathogen in newborn infants, although not nearly to the extent that it was in the 1950s and 1960s. Staphylococcal skin and soft tissue infections, including superficial skin infections, mastitis, and omphalitis, are the most common infections; severe staphylococcal pneumonia is now a rare occurrence.[530] Direct contact with colonized caregivers is the predominant mode of transmission.[530] Indirect contact transmission from infected or colonized infants and droplet contact transmission from infants with coexisting viral respiratory tract infection (so-called cloud babies) are uncommon occurrences.[530] Colonization of the skin, nose, umbilicus, or rectum precedes development of infection, but the correlation between rates of colonization and development of infection is poor. Typically, the number of colonized infants far exceeds the number of infected infants; conversely, outbreaks of staphylococcal infection can occur in nurseries with low colonization rates.[530] For this reason and because of cost considerations, surveillance cultures to detect colonized infants are not recommended except under outbreak conditions.

MRSA has been a persistent if somewhat sporadic problem in newborn ICUs for many years. However, infants in newborn ICUs as well as otherwise healthy newborns are being affected by broader trends in the incidence of MRSA infection (see the section on pathogens causing health care–associated infections). Outbreaks of MRSA in newborn ICUs have become more commonplace, even involving multiple separate units in the same city.[218] In addition, genotypically distinct strains of MRSA commonly associated with staphylococcal infection in the community have been identified increasingly as a cause of serious infection in otherwise healthy newborns and their mothers.[67,91,182,523] Risk factors for these infections include cesarean delivery (likely due to the longer postnatal hospital stay), male sex, improper infection control practices associated with circumcision, and contact with an infected health care worker.[51,91,431] Management of these outbreaks includes emphasis on standard infection control practices such as hand hygiene, use of isolation precautions, and proper disinfection or sterilization of patient care equipment. Although screening for colonization during the course of an outbreak clearly is useful to identify asymptomatically colonized individuals, the role of routine screening of infants—and potentially health care providers—is less clear.[91,218]

The use of hexachlorophene (3%) for bathing is effective in reducing colonization,[226,263] but this agent was found to cause cystic degenerative changes in the white matter of premature infants,[472,556,557] although no evidence was found that this agent posed a hazard to full-term infants. A warning against use of hexachlorophene was issued by the Food and Drug Administration in 1972. The use of this agent for infant bathing remains an option during outbreaks of *S. aureus* infection, although it should be diluted by 1:4 or 1:5 in water and should not be used for bathing very low-birth-weight infants.[226] Chlorhexidine is a reasonable alternative because it has good antistaphylococcal activity, and studies in neonates have demonstrated negligible absorption after bathing or cord care and no recognized toxicity. However, chlorhexidine is not approved by the Food and Drug Administration for use in neonates, even as an antiseptic for the insertion of vascular catheters.[7,118,301] Use of iodophors may cause adsorption of iodine, and alcohols may cause chemical burns, so these agents should not be used for bathing. A variety of agents, including triple dye (an aqueous mixture of brilliant green, proflavine hemisulfate, and crystal violet), alcohol, bacitracin, chlorhexidine, and mupirocin, have been used for care of the cord, although extensive efficacy and safety data are not available for any of these compounds.[226,263]

Fifty to 75 percent of women with group B streptococcal vaginal colonization will transmit this microorganism to their newborn infants, although only 1 to 2 percent of colonized infants will become infected. The CDC defines these and other infections transmitted through the birth canal as health care–associated infections.[208,215] The logic behind this designation has not been stated explicitly, but because these infections occur after an event (i.e., delivery) usually associated with medical care, it is reasonable to consider them health care–associated infections. However, the impact of conventional infection control interventions on early-onset (i.e., within the first 7 days of life) invasive group B streptococcal infection is likely to be limited. Intrapartum prophylaxis of women is a far more effective intervention to reduce infection rates in newborns.[97,536] An important note is that group B streptococci can be associated with health care–associated infection, not just perinatal infection. Outbreaks of group B streptococcal infection due to indirect contact transmission in nurseries have been well documented.[156,227,434]

Preterm infants are particularly susceptible to infection caused by a variety of yeasts and, to a lesser extent, filamentous fungi. *Candida* spp. are the most common pathogens. Infants probably become colonized in their gastrointestinal tracts because of carriage of *Candida*, especially *Candida parapsilosis*, on the hands of health care providers.[526] Cutaneous colonization also may lead to invasive infection.[509] Risk factors for colonization with *Candida* are treatment with H_2 blockers or third-generation cephalosporins and delayed enteral feeding.[526] Risk factors for development of bloodstream infections and the use of prophylactic fluconazole have been discussed previously (see the section on health care–associated infections related to invasive devices and procedures, infections related to intravascular catheters and infusions). Risk factors for development of *Malassezia furfur* infection are similar to those for *Candida*, but the association with lipid emulsion is particularly strong because this organism is obligately lipophilic.[129,359,501] Outbreaks of *Malassezia pachydermatis* infection have been reported, in one case in association with colonization of a health care provider's dogs.[102,628] Infections caused by filamentous fungi are rare and usually are associated with contaminated devices or practices that facilitate cutaneous invasion.[408,509]

Citrobacter diversus (now classified as *C. koseri*) has been responsible for numerous outbreaks of health care–associated infection in newborn infants.[350,445,641] Although most infants colonized with this microorganism do not develop clinical disease, infection almost always results in meningitis due to the particular neurotropism of this bacteria (see the section on general epidemiology of health care–associated infections, interactions between hosts and pathogens) and usually is accompanied by formation of one or more brain abscesses. Outbreaks of infection caused by this bacterium may occur sporadically for an extended time.[350,445,641] Transmission of this bacterium on the hands of caregivers has been implicated in several of these outbreaks.[445,641] On the other hand, molecular techniques have demonstrated that *C. koseri* also can be acquired perinatally by vertical transmission.[264]

Enterobacter sakazakii is a rare cause of health care–associated infection in neonates.[586] However, as is the case with infections caused by *C. koseri*, infections caused by this bacterium are usually severe, often involving meningitis and brain abscess.[55,93,109,336,564,612] Outbreaks of infection caused by *E. sakazakii* have been linked conclusively to consumption of intrinsically contaminated powdered milk formulas.[55,93,421,564,612] A variety of products have been implicated in these outbreaks.[93,336] Because powdered formulas are not marketed as sterile products, feeding practices in neonatal ICUs need to balance the relative nutritional benefits of particular products against the small but real risk of infection with *E. sakazakii* and other potential pathogens.

New obstetric practices, such as water birth, may pose infectious threats to infants, as demonstrated by the report of a case of *Legionella* pneumonia in an infant after a prolonged delivery in a pool with contaminated water.[184]

Hand hygiene is the most effective intervention to prevent spread of pathogenic microorganisms.[62] However, the hands of some staff may remain colonized with these microorganisms for prolonged periods despite scrupulous handwashing.[229] In addition, use of artificial nails or nail wraps has been associated with carriage of *P. aeruginosa* on the hands of health care providers in a neonatal ICU.[179] Use of these devices should be banned in these units.[524] Alcohol-based hand rubs are the most effective agents in reducing hand colonization with pathogenic bacteria and are the preferred method for hand hygiene when hands are not visibly soiled.[62]

Preceding sections contain specific recommendations for the prevention of health care–associated infections caused by community pathogens and infections related to the use of invasive devices (see the sections on health care–associated infections due to spread of infections common in the community and health care–associated infections related to invasive devices, procedures, and treatments). Other general references for the prevention of infections in normal nurseries and newborn ICUs, including recommendations for the design of facilities, appropriate staffing, and general infection prevention procedures, have been published.[15,263]

Several interventions designed specifically to prevent acquisition of health care–associated infections in high-risk infants deserve additional comment.

The Vermont Oxford Network Neonatal Intensive Care Quality Improvement (NIC/Q) Collaborative is a large multicenter network of neonatal units organized for the purpose of implementing evidence-based interventions to improve the quality of care of newborn infants *(www.nicq.org)*.[278] A subgroup of six units used quality improvement methods to implement 17 practices designed to reduce the incidence of health care–associated infections. The range of the number of these practices implemented per unit was 10 to 16. Compared with 65 units that did not participate in this initiative, overall rates of health care–associated infection and rates of coagulase-negative staphylococcal bacteremia declined more rapidly in the six units implementing these interventions.[277]

Many investigators have purposefully colonized infants in newborn ICUs with nonpathogenic microorganisms, including viridans streptococci and *Lactobacillus*, to "interfere" with colonization by potential pathogens.[226,406,493] Some of the studies using viridans streptococci demonstrated favorable results, but this approach has not been pursued in part owing to concern about

the potential for adverse events.[226] Studies using *Lactobacillus* have demonstrated little or no beneficial effect.[406,493]

Extremely-low-birth-weight infants have fragile skin, which is predisposed to drying and cracking and may be an inadequate barrier to prevent invasion by bacteria colonizing the skin. For this reason, products containing emollients that include fatty acids have been developed to reduce transepidermal fluid loss and to improve function of the skin barrier in very-low-birth-weight infants. A randomized controlled trial of the effect of an emollient ointment (Aquaphor) in infants with a birth weight of 501 to 1000 g and a gestational age of 30 weeks or less was conducted in 53 newborn ICUs participating in the Vermont Oxford Network.[161] The study found that treated infants had better skin condition on days 1 to 14 of life and fewer skin injuries on days 15 to 28 of life. However, the treatment group had a higher rate of late-onset bacterial sepsis, nearly entirely due to higher rates of bacterial sepsis infection in infants weighing 501 to 750 g. There was no effect on mortality rates. In contrast, two randomized controlled trials conducted in Bangladesh found that sunflower seed oil reduced the rates of late-onset infection and mortality in preterm infants with a gestational age of 33 weeks or less.[131,133] Interestingly, the second of these trials included Aquaphor as a comparator treatment and found a similar decrease in rates of mortality associated with application of this agent. An additional study conducted during the second trial provided indirect evidence that the effect of the treatment was mediated by decreased passage of skin pathogens into the bloodstream.[132]

Because premature infants lack sufficient levels of opsonizing antibodies, several well-designed trials have examined the efficacy of intravenous immune globulin in preventing health care–associated infection in premature infants.[38,170,316,371,628] Only one of these trials demonstrated any benefit in reducing overall health care–associated infection rates.[38] A systematic review of studies addressing the efficacy of intravenous immune globulin in preterm (<37 weeks) or low-birth-weight (<2500 g) infants found an overall 3 percent reduction in the incidence of sepsis and a 4 percent reduction in the incidence of serious infections associated with administration of immune globulin. However, no evidence of an impact on other outcomes, such as necrotizing enterocolitis, intraventricular hemorrhage, length of stay, or mortality, was noted.[439] An evaluation of commercially available intravenous immune globulin preparations found a large degree of variability in opsonic activity against common neonatal pathogens among lots produced by various manufacturers.[629] Individual lots also demonstrated variable levels of opsonic activity against different pathogens. This variability appeared to be a function of the donor pool rather than of the manufacturing method. Whether intravenous preparations with known pathogen-specific antibody content may be effective in reducing the rates of health care–associated infections with specific agents remains to be seen. Immunotherapy directed at antigens on the surface of staphylococci appeared promising in early clinical trials but failed to reduce the risk of development of *S. aureus* infections in premature neonates in a phase III trial.

Because preterm infants have limited neutrophil pools as well as limited neutrophil function, several randomized, controlled studies have examined the prophylactic and therapeutic effect of granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) on health care–associated infections in preterm infants. In all of these studies, infants receiving these agents had higher peripheral blood neutrophil counts than did infants receiving placebo. However, the benefits of treatment with these agents have been limited. A study of prophylactic treatment with GM-CSF for 5 days beginning shortly after birth found a trend toward decreased infection rates in treated infants, although the study was powered to address whether treatment reduced the incidence of neutropenia, not whether it reduced infection.[81] A second study of prophylactic treatment with GM-CSF during the first 28 days of life failed to demonstrate any benefit in terms of decreased health care–associated infection rates.[81] A study of the therapeutic effect of 3 days of treatment with G-CSF administered to infants with the clinical diagnosis of early-onset sepsis did not demonstrate any reduction in mortality rates but did find that infection rates were lower in treated infants in the 2 weeks after treatment was administered.[409]

Leukocytes present in stored blood products may have adverse effects on immune function, especially in preterm infants. However, a study examining the effect of universal pre-storage red blood cell leukoreduction programs found no effect on bloodstream infection and mortality rates, but it was associated with improvements in other clinical outcomes.[173]

Use of postnatal corticosteroids to prevent or to treat chronic lung disease in preterm infants has been associated with higher rates of health care–associated infection[588] as well as with other short- and long-term adverse outcomes.[113]

CHILDREN WITH BURNS

Information about the epidemiology of health care–associated infections in pediatric burn patients has been described in three reports.[210,535,624] The experience of a single pediatric burn facility that performed prospective surveillance using modified CDC definitions has been reported.[624] The definitions used in this study were modified to describe more accurately burn infections and secondary bloodstream infections in the burn population. On the basis of this and other studies, new definitions for burn infection have been proposed.[451] The overall frequency of infection in this unit was 14 percent or 16 infections/1000 patient days.[624] The frequency of burn infections was 10 percent or 5.6 burn infections/1000 patient days. Gram-positive cocci, including *S. aureus* and MRSA, were the most common causes of burn infections in patients with relatively small burns (<30% of body surface area). Gram-positive cocci and gram-negative bacteria (especially *P. aeruginosa*) were common causes in patients with extensive burns (>30% of body surface area). Rates of device-associated infections were 4.9 bloodstream infections/1000 central venous catheter days, 11.4 cases of ventilator pneumonia/1000 ventilator days, and 13.2 UTIs/1000 urinary catheter days. These rates are somewhat lower than the pooled means for adult burn units (see Table 244–1) and are roughly comparable to rates of infection in pediatric ICUs (see Table 244–1 and Fig. 244–1), although the incidence of UTIs is somewhat higher. When infection rates in this study were stratified by the extent of the burn, the incidence of bloodstream infection secondary to burn infection and catheter-associated UTIs increased with increasing size of the burn, although rates based on the number of patient days or device days reflected the risk of infection more accurately over time.

Interventions to reduce the incidence of health care–associated infections in burn patients include use of barrier techniques to reduce cross-colonization of patients, prevention of cross-colonization during hydrotherapy treatments, use of topical antibiotics to retard growth of microorganisms in the burn wound, appropriate use of systemic antibiotics, and early excision and closure of the burn wound. The success of the Shriners Burns Hospital in Boston in controlling infections in severely burned children by these methods and "bacteria-controlled nursing units" (a laminar air flow unit providing controlled temperature and humidity combined with barrier precautions) has been described.[623] A randomized, controlled trial of selective decontamination of the digestive tract using polymyxin E, tobramycin, and amphotericin B in severely burned children found no evidence of benefit.[40]

CHILDREN WITH CYSTIC FIBROSIS

Saiman and colleagues[525] reviewed the epidemiology of important pathogens in persons with cystic fibrosis in a document summarizing the conclusions of an international consensus conference convened to develop evidence-based guidelines for standardized microbiologic and infection control practices for these persons. They concluded that evidence of transmission of *Burkholderia cepacia* complex, *P. aeruginosa*, and MRSA among persons with cystic fibrosis in health care settings was substantial. They concluded that evidence was insufficient to determine whether *Stenotrophomonas maltophilia*, *Achromobacter xylosoxidans*, nontuberculous mycobacteria, or filamentous fungi could be transmitted from person to person.

The aforementioned guideline emphasizes standard infection control practices in the care of patients with cystic fibrosis, including appropriate hand hygiene and use of barriers by health care providers, proper use of isolation precautions, and effective procedures for cleaning and disinfection or sterilization of reused equipment contaminated with respiratory secretions.[525]

In inpatient settings, the guideline recommends contact isolation and a private room for patients who are colonized or infected with MRSA, *B. cepacia* complex, or multidrug-resistant *P. aeruginosa*. Patients who are not colonized with any of these bacteria may share a room with a patient who does not have cystic fibrosis and who is at low risk for acquiring infection with these bacteria. All patients, whether colonized with these bacteria or not, should avoid contact with other patients with cystic fibrosis.

The guideline makes no recommendation for the use of masks by patients with cystic fibrosis in either inpatient or outpatient settings because of lack of sufficient evidence for or against the efficacy of this practice.

In ambulatory settings, the guideline recommends that patients with cystic fibrosis who are colonized or infected with *B. cepacia* complex be segregated from other patients with cystic fibrosis and other patients colonized or infected with *B. cepacia* (to avoid replacement of one strain with another), that their visits be scheduled at the end of the clinic session or on another day, and that they be placed in an examination room immediately instead of sitting with other patients in the waiting room. Patients colonized or infected with multidrug-resistant *P. aeruginosa* also should be placed in an examination room immediately. For other patients, the guideline recommends a variety of clinic logistics to minimize the time that patients spend in waiting areas and emphasizes education of patients about appropriate waiting area behaviors to minimize contact among patients (e.g., discouraging handshakes and physical contact among patients, maintenance of at least 3 feet between patients, avoiding contact with common-use items). All patients should receive annual influenza vaccination and age-appropriate pneumococcal vaccination.

CHILDREN IN LONG-TERM CARE FACILITIES

Preceding sections have described a variety of microorganisms that have caused disease in long-term care facilities for children, including various viral infections and enteric pathogens. Specific interventions to prevent these infections have been discussed previously (see the section on health care–associated infections due to spread of infections common in the community).

A prospective, longitudinal study of infections in a pediatric long-term care facility illustrates the spectrum of endemic health care–associated infections in this population.[615] The cumulative incidence of infection was 40 percent among the more than 400 patients cared for in this facility during a 2-year period. Upper respiratory tract infections and UTIs accounted for 37 and 31 percent of infections, respectively. Nearly 80 percent of the UTIs occurred in a small group of patients with neural tube defects or neuromuscular disorders, but the study did not differentiate between symptomatic infections and asymptomatic bacteriuria. The rate of infection among children exposed to indwelling or intermittent catheterization also was not reported. Upper and lower respiratory tract infections were common findings among young children with tracheostomies. Skin infections accounted for 16 percent of infections, but the specific per-centage of decubitus ulcers was not reported. Gastrointestinal infections were remarkably uncommon (4% of all infections).

Similar findings regarding the overall distribution of infection have been described in a more recent report.[262] In addition, this report described the burden of device-related infections in this population. The incidence of catheter-associated UTIs was more than twice as frequent as in pediatric ICUs reporting data to the NNIS system, whereas the incidences of ventilator-associated pneumonia and central venous catheter–associated bloodstream infections were equivalent or slightly lower than those reported in pediatric ICUs.

Guidelines for the infrastructure and essential activities of infection control programs and key prevention practices in long-term care facilities have been published, although these documents do not deal with issues specific to the care of children.[196,574] Key prevention measures are effective hand hygiene, appropriate use of barriers and isolation precautions, proper care of patients who have indwelling devices (e.g., tracheostomies) or require invasive procedures (e.g., bladder catheterization), prevention of decubitus ulcers, age-appropriate immunization (including yearly influenza vaccine, conjugate or polysaccharide pneumococcal vaccine, hepatitis B vaccine, and hepatitis A vaccine, depending on local epidemiologic conditions), and early detection and control of outbreaks of infection.

CHAPTER 245

Programs to Prevent and Control Health Care–Associated Infections

W. Charles Huskins ❂ Donald A. Goldmann

The history of formal hospital programs to prevent and control hospital-acquired infections generally is traced to the organized efforts of hospitals in Great Britain and North America to control the pandemic of *Staphylococcus aureus* infections in the 1950s and early 1960s. However, programs to study and control the hospital spread of contagious diseases were well established in leading pediatric hospitals in several European countries and in North America even in the mid-1930s.[8,13,33,47,48,51]

Since the 1950s, the scope and complexity of programs to prevent and control hospital infections have expanded dramatically. Today, hospital inpatient populations include more severely ill children and children with compromised immune systems. Advances in medical care and technology have improved the survival rates of these vulnerable patients; however, this progress has gone hand in hand with an increased risk of health care–associated infection caused by a wide spectrum of microbial pathogens. These factors, in combination with the selective pressure of widespread use of broad-spectrum antimicrobial agents and suboptimal adherence to basic infection control practices, have resulted in the emergence and dissemination of antimicrobial-resistant bacteria, as well as in the rise of fungi as serious pathogens. The shift in the site of patient care from the inpatient to the outpatient setting has expanded the focus of infection control programs from the hospital to the entire health care system. The increased risk among medical professionals of acquiring an occupationally related infection has required infection control programs to work with employee health services to develop workplace policies and procedures to prevent these infections. Finally, many infection control professionals have assumed additional responsibility to address more general issues of health care quality and patient safety.

This chapter highlights key elements of a comprehensive program to prevent and control health care–associated infections in pediatric patients and health care workers. A detailed description of the development, implementation, and maintenance of an effective program is beyond the scope of this chapter, and the reader is referred to several excellent and authoritative references on this topic.[1,50,77] Specific health care–associated infections are discussed in Chapter 244.

EXTERNAL GROUPS AND ORGANIZATIONS INFLUENCING HEALTH CARE–ASSOCIATED INFECTION PREVENTION AND CONTROL PROGRAMS

Many external groups and organizations have significant influence on programs for the prevention and control of health care infection. The most influential groups and organizations are discussed in this section.

The Division of Healthcare Quality Promotion (DHQP), formerly the Hospital Infections Program, is a part of the Center for Disease Control and Prevention's (CDC's) National Center for Infectious Diseases (*http://www.cdc.gov/ncidod/dhqp/about.html*). The DHQP plays a major role in providing information and guidance to health care infection control programs, as well as in conducting its own investigations. The DHQP has the single largest experience in the investigation of outbreaks of health care–associated infections and can provide assistance to individual health care institutions. In general, health care institutions should consult their state public health departments before asking for assistance from the CDC.

Coordinated by the DHQP, the National Healthcare Safety Network (NHSN),[75] previously known as the National Nosocomial Infection Surveillance (NNIS) System, collects and reports data on the incidence of health care–associated infections, including device-associated infections in pediatric and newborn intensive care units (ICUs).[18,54] In the future, the NHSN will also report data on key process measures that are tightly linked with prevention of health care–associated infections.[75]

The Healthcare Infection Control Practices Advisory Committee (HICPAC) was established in 1991 to provide advice and guidance to the DHQP and the CDC regarding the practice of infection control and strategies for surveillance, prevention, and control of health care–associated infections in United States health care systems (*http://www.cdc.gov/ncidod/dhqp/hicpac_charter.html*). The HICPAC has published numerous guidelines regarding prevention of these infections.[9,10,49,58,71,72,74]

Numerous professional and trade associations also develop recommendations and guidelines related to infection control. The most prominent among these in the United States are the Society of Healthcare Epidemiology of America (SHEA) and the Association for Professionals in Infection Control and Epidemiology (APIC). The SHEA and the Infectious Diseases Society of America (IDSA) have formulated concise guidelines on major health care–associated infections (*http://www.idsociety.org/Content.aspx?id=9088*), and these guidelines have been endorsed by the APIC.

During the past several decades, the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations), a private, not-for-profit organization, has had a major influence on the structure and activity of health care infection prevention and control programs (*http://www.jcaho.org*). Joint Commission standards regarding these programs have evolved to place greater emphasis on organizational performance regarding processes that have a significant impact on patient care. The Joint Commission has promulgated a set of annual National Patient Safety Goals that have included goals to prevent health care–associated infections (*http://www.jointcommission.org/PatientSafety/NationalPatientSafetyGoals*). These goals are revised or supplemented periodically. Currently, these goals involve optimizing hand hygiene practice and managing all identified cases of unanticipated death or major permanent loss of function related to a health care–associated infection as sentinel events.

The United States Department of Labor's Occupational Safety and Health Administration (OSHA) issues regulations to minimize the hazards of occupational exposure to bloodborne pathogens and tuberculosis (*http://www.osha.gov/SLTC/etools/*

hospital/hazards/bbp/bbp.html; *http://www.osha.gov/SLTC/etools/hospital/hazards/tb/tb.html*).

The Institute of Medicine issued a report in 2000, entitled *To Err Is Human*,[41] that helped launch a variety of national patient safety and quality improvement initiatives. These initiatives, combined with requirements for public reporting of health care–associated infection rates, are reshaping the focus of infection control and prevention programs from surveillance of infection rates and an emphasis on traditional infection prevention strategies to a perspective of "zero tolerance" and tactics that aim to eliminate these infections completely.[6,37,52,81] The Institute for Healthcare Improvement (IHI) conducted the 100,000 Lives campaign, from June 2005 to December 2006, that included application of evidence-based care "bundles" of interventions to reduce the incidence of central venous catheter–associated bloodstream infections, surgical-site infections, and ventilator-associated pneumonia. An additional "plank" on reducing infections caused by methicillin-resistant *S. aureus* (MRSA) was added when IHI launched the "Protecting 5 Million Lives from Harm Campaign" (*http://www.ihi.org/IHI/Programs/Campaign*). Programs using such care bundles appear to be effective.[16,63,64] Some of the most striking results were obtained in a collaborative of 108 ICUs in Michigan (the Keystone Project). The median rate of central venous catheter infections per 1000 central venous catheter days fell from 2.7 to zero 3 months after implementation.[63] Initiatives to reduce the incidence of bloodstream infections in newborn ICUs have been conducted by the Vermont Oxford Network (*http://www.vtoxford.org/*) and in pediatric ICUs by the National Association of Children's Hospitals and Related Institutions (*http://www.childrenshospitals.net*) and the Children's Hospital Corporation of America (*http://www.chca.com*). For adult patients, the Surgical Care Improvement Project (SCIP) has codified the most important prevention practices for surgical-site infections, and initiatives to reduce MRSA infections also have been launched by the Department of Veterans Affairs, the Voluntary Hospital Association, and the APIC. The Leapfrog Group is a voluntary group of large employers whose aim is to mobilize purchasing power improve health care safety, quality, and customer value (*http://www.leapfroggroup.org/*). These U.S. initiatives have their counterparts in other countries. For example, the National Health Service in the United Kingdom is engaged in an ambitious program to reduce bloodstream infections caused by MRSA by 50 percent. The effectiveness of these initiatives needs further study. Finally, prodded by consumer advocacy groups, legislators have entered the picture by considering and passing legislation related to public reporting of hospital-associated infection rates and MRSA control programs.[3]

ORGANIZATION AND ACTIVITIES OF HEALTH CARE INFECTION CONTROL PROGRAMS

The Study on the Efficacy of Nosocomial Infection Control (SENIC) project, conducted in U.S. hospitals in the mid-1970s, found that hospitals with a trained, effective infection control physician, 1 infection control nurse for every 250 acute care hospital beds, and a system for reporting surgical-site infection rates to surgeons could reduce their health care–associated infection rates by 32 percent compared with hospitals with no infection control program.[30] However, because relatively few hospitals had implemented these maximally effective programs, only 6 percent of the theoretically preventable infections nationwide were, in fact, prevented. In 1983, a repeat survey of a sample of the participating hospitals found the percentage of hospitals with 1 infection control nurse for every 250 acute care hospital beds had increased from 22 to 57 percent[31]; however, the percentage with a physician trained in infection control remained low (15%), and the percentage of hospitals performing surveillance of surgical-site infections and reporting these rates to surgeons actually decreased. The percentage of preventable infections that were avoided had risen to 9 percent. Apart from the landmark SENIC study, there has been little objective evaluation of the efficacy of various components of infection control programs.

Nonetheless, a large amount of practical experience has guided the development of health care infection control programs. In 1998, the report of a consensus panel of national experts on the requirements for infrastructure and essential activities of these programs was published with the endorsement of the SHEA, the APIC, and other key organizations (including the DHQP and the Joint Commission).[70] The report stated that the principal goals of these programs are to protect the patient, the health care worker, visitors, and others in the health care environment and to accomplish these goals in a cost-effective manner whenever possible.[70] The specific recommendations of the panel are listed in Table 245–1, accompanied by an indication of the strength of the recommendation. The recommendations are described in more detail in the published report.[70] A guideline for the prevention of health care infections in long-term care residents also has been published.[24,73] These publications do not deal specifically with pediatric issues, although the recommendations generally are applicable to facilities providing care to children.

SURVEILLANCE STRATEGIES

Surveillance of health care–associated infections is necessary to understand the specific infection-related problems of individual hospitals. Surveillance data can focus prevention and control efforts on the highest-risk patients and provide a means of evaluating the effectiveness of these interventions. By establishing endemic rates of health care–associated infections, surveillance also facilitates detection of outbreaks. For these reasons, surveillance has been regarded traditionally as an essential component of a hospital infection prevention and control program, a view validated by the SENIC study.[30] Recommended practices for surveillance have been defined and published.[46]

Prevalence surveys can be used for quickly gaining a perspective of the nature and scope of health care–associated infection problems. These surveys also can be used to validate the sensitivity and specificity of ongoing surveillance. For hospitals that focus surveillance efforts on high-risk patients, periodic prevalence surveys can provide reassurance that previously low-risk populations or low-priority problems have not become more problematic. In general, however, surveillance systems that measure the incidence of health care–associated infections provide a more detailed assessment risk of infection and are much more likely to detect outbreaks.

Hospital-wide surveillance, frequently performed in programs in the 1970s and 1980s, has largely been abandoned because of the substantial time commitment required for data collection, although some hospitals have developed computerized systems for case finding that have improved the efficiency of this approach considerably.[14,19] Most hospitals currently favor focused (or targeted) surveillance, which concentrates on specific high-risk groups (e.g., patients in ICUs, surgical patients), specific sites of infection (e.g., bloodstream infections, surgical-site infections), or specific pathogens (e.g., respiratory viruses, *Clostridium difficile*, multidrug-resistant microorganisms). This approach is designed to maximize the efficiency of surveillance and to focus on particularly problematic infections or pathogens.

A surveillance plan for an individual health care facility may incorporate various types of surveillance. A written plan for surveillance activity should be reviewed annually and modified as necessary. For each surveillance component, the plan should include a description of the following: (1) the rationale for surveillance; (2) the target population; (3) infection definition(s); (4) case-finding method(s); (5) source of denominators used for rate

TABLE 245–1 Consensus Panel Recommendations Regarding the Requirements for Infrastructure and Essential Activities of Infection Control and Epidemiology in Hospitals

From Scheckler, W. E., Brimhall, D., Buck, A. S., et al.: Requirements for infrastructure and essential activities of infection control and epidemiology in hospitals: A consensus panel report. Infect. Control Hosp. Epidemiol. 19*:114-124, 1998.*

calculations; (6) collection of additional data regarding risk factors; (7) calculation of infection rates (including stratification by risk factors, if planned); (8) frequency of reporting to specific target groups (e.g., clinicians, infection control committee, leadership); and (9) estimated time commitment of staff for data collection, analysis, and reporting.

When choosing a particular surveillance strategy, it is important to consider its sensitivity and specificity. For example, self-reporting by clinicians is notoriously insensitive, and surveillance that relies on microbiology culture results alone is likely to be both insensitive and nonspecific. Considerable research regarding case-finding methods has been performed.[25,59] In general, active, concurrent case finding (i.e., active searching for cases by trained persons) should be used. The gold standard for case finding includes bedside examination, interviews with ward staff, review of patient records, and verification of all related microbiologic information by a trained surveyor.[23] However, few programs have the staff for this labor-intensive effort. Many programs rely on positive microbiology culture reports as a starting point for the investigation of infections for which cultures are obtained routinely, such as bloodstream infections, with subsequent review of patient records to confirm or refute the presence of a health care–associated infection. Strategies for detecting infections that may not be associated with collection of a microbiology culture,

such as a surgical-site infection, require other approaches to case finding. Strategies for surveillance that use electronic information to enhance surveillance also have been developed.[14,19,20,62] Sands and colleagues performed detailed studies of the usefulness of this approach in performing surveillance of surgical-site infections.[69]

Calculations of infection rates should include appropriate adjustments whenever possible (see Chapter 244). The simplest technique is merely to adjust for exposure to a particular device or procedure (e.g., number of bloodstream infections per 100 patients with central venous catheters). Adjustment for the duration of exposure to the hospital (e.g., number of infections per 1000 patient-days) or to a device (e.g., number of bloodstream infections per 1000 central venous catheter days) is more useful if the necessary denominator data can be obtained. Surgical-site infections should be stratified by wound class and, in adults, preferably by the surgical-site infection risk index or other method of risk stratification.[15] Some investigators have used severity-of-illness measures to adjust for host risk factors, but this type of adjustment has yet to be incorporated widely into routine surveillance data analysis (see Chapter 244).

Feedback of infection rates to clinicians should be done regularly using an easy-to-understand format. Graphic displays of data, such as statistical process control charts, are most effective.[4,5] Surveillance data also should be used to target areas for further investigation, additional staff education, and specific interventions.

Data mining strategies may be helpful in identifying undetected problems (e.g., an organism with a particular susceptibility profile in multiple different units) or unrecognized associations (e.g., patterns of antimicrobial prescription and the prevalence of specific antimicrobial-resistant organisms).[55]

Surveillance efforts also should examine adherence to processes that are tightly linked to outcomes. For example, the SCIP has examined adherence to three measures related to the administration of perioperative antimicrobial prophylaxis for prevention of surgical-site infections: (1) prophylactic antimicrobial received within 1 hour before surgical incision, (2) prophylactic antimicrobial administration consistent with published guidelines, and (3) prophylactic antimicrobial discontinued within 24 hours of surgery end time (≤48 hours for patients undergoing cardiac surgery).[12] Measurement of adherence to recommendations for hand hygiene and to isolation precautions during patient care is critical for reducing the transmission of epidemiologically important organisms. These process measures should be used to guide and monitor process improvement efforts. Surveillance and reporting of communicable infections to state departments of health are duties retained by some hospital infection prevention and control programs, although others delegate this responsibility primarily to the microbiology laboratory.

OUTBREAK INVESTIGATION

Investigators have estimated that a community hospital can expect to experience at least one outbreak of a health care–associated infection per year[32]; teaching hospitals can expect to experience several outbreaks every year.[78] Because outbreaks of health care–associated infections often are associated with significant rates of patient morbidity and mortality, clusters of infection should be investigated promptly. A single, highly unusual infection, such as a postoperative group A streptococcal infection, is sufficient cause for an investigation. Clusters of health care–associated infections caused by an uncommon microorganism, a common microorganism with an unusual antimicrobial susceptibility pattern, or a series of infections at the same anatomic site (i.e., an outbreak of diarrhea) also are obvious indications for an investigation. However, some outbreaks are more difficult to recognize because they occur intermittently, involve multiple microorganisms, or involve infection at various anatomic sites.

TABLE 245–2 Approach to the Investigation of Clusters of Nosocomial Infections

1. Confirm the diagnosis.
2. Make a case definition.
3. Search for additional cases.
4. Plot the epidemic curve.
5. Compare pre-epidemic rates to current rates using statistical tests to prove that an epidemic exists.
6. Perform a literature review.
7. Open lines of communication with leaders of relevant departments, the microbiology laboratory, and the hospital administration.
8. Keep detailed records of events and conversations.
9. Review charts of all cases and compile a line listing of relevant information.
10. Formulate a hypothesis about a likely reservoir and mode of transmission.
11. Institute temporary control measures.
12. Perform a case control study to develop epidemiologic evidence to support or refute the hypotheses.
13. Update control measures.
14. Document the reservoir and mode of transmission microbiologically. Confirm the relatedness of isolates, using molecular genotyping techniques, if necessary.
15. Document the efficacy of control measures.
16. Write a report and distribute it to appropriate individuals.
17. Change policies and procedures, if necessary.

A guide for investigating a cluster of health care–associated infections is provided in Table 245–2. Detailed discussions of the methodology for investigating outbreaks are found in other sources.[38] Published outbreak investigations are an invaluable resource because they often provide insight into potential causes of the outbreak. For example, an outbreak caused by *Stenotrophomonas (Xanthomonas) maltophilia*, *Burkholderia (Pseudomonas) cepacia*, or *Pseudomonas* spp. should suggest the possibility of a common source outbreak resulting from a contaminated solution or medication or an inadequately disinfected piece of equipment. Conversely, jumping to conclusions regarding the cause of a particular cluster of infections based on the results of a prior investigation is hazardous. Careful investigation is necessary to establish or refute epidemiologic links between cases and potential causes. Molecular genotyping techniques are important adjuncts to traditional epidemiologic methods (e.g., cohort or case-control studies) and can serve as powerful tools to confirm or refute a particular source or mode of transmission of a particular microorganism.

POLICIES AND PROCEDURES

Policies and procedures are necessary to optimize and standardize hospital routines and patient care practices. Certain generic policies and procedures, such as handwashing, isolation precautions, prevention of transmission of infectious diseases from and to visitors and health care workers, reprocessing of reusable patient care items, and disposal of medical waste, apply to all departments. Other policies and procedures should be tailored to the potential infection risks relevant to specific departmental activities. Numerous guidelines have been published that can help hospitals develop policies and procedures.[9,10,49,58,71,72,74]

As evidenced by numerous studies documenting poor adherence to policies for handwashing and isolation precautions,[10] adherence to policies and procedures often is less than optimal. Unfortunately, relatively few studies have attempted to elucidate

the reasons for non-adherence or to investigate methods for modifying the behavior of staff.[44,56,80] To have any chance of improving performance in such critical aspects of prevention of infections, hospital and departmental leaders must make adherence an organizational priority. Staff members responsible for implementation should be included in the process of developing policies and procedures to ensure that the resulting documents are workable, as well as to develop their sense of ownership and responsibility for successful implementation and sustained adherence. Staff education is important but not sufficient in and of itself. Prompt feedback of data concerning key outcome and process measures also is critical in motivating staff, and barriers to improvement must be identified and removed. For example, clinicians cannot be expected to comply with an isolation precaution policy if gloves are not available or are located inconveniently. Additional investigation into engineering solutions, cognitive approaches, behavioral modification, and training strategies also is needed. These efforts should be guided by principles of behavioral science and quality improvement.[36,79]

HAND HYGIENE

Proper hand hygiene, which encompasses both handwashing using soap and water and hand antisepsis using a waterless (alcohol-based) agent, reduces carriage of potential pathogens on the hands of health care workers.[10] Hand hygiene is widely regarded as the quintessential infection prevention measure.

Indications and procedures for hand hygiene are reviewed in detail in a HICPAC guideline.[10] In general, hand hygiene should be practiced under the following circumstances: before and after contact with patients; after contact with body fluids and substances, mucous membranes, nonintact skin, and objects that are likely to be contaminated; before performing invasive procedures; and after removing gloves (see "Isolation Precautions"). Handwashing must be performed when hands are visibly soiled, to remove organic material and associated microorganisms. When hands are not visibly soiled, hand antisepsis is preferred because is it likely to reduce more effectively than handwashing the number of pathogenic bacteria that transiently colonize the hands.[10,61] Hand hygiene also is necessary after removing gloves—an indication that many health care professionals fail to appreciate fully—because gloves may have macroscopic and microscopic holes that lead to contamination of hands[42] and because hands may be contaminated in the process of removing soiled gloves.

Before alcohol-based agents became widely available, adherence to hand hygiene (accomplished solely by handwashing) was notoriously poor among health care workers.[10] However, the hope is that the wider use of alcohol-based agents will boost hand hygiene adherence because these agents are faster and more convenient to use (i.e., they can be placed near the patient's bedside and require less than 30 seconds to use), are less drying and irritating to the skin than is handwashing,[11] and are more effective in reducing the numbers of transient flora.[60] Programs that combine ready access to these products at the point of care (i.e., close to the patient's bedside) with active efforts to promote their use have demonstrated improved hand hygiene adherence.[7,61] For these reasons, a HICPAC guideline on hand hygiene in health care facilities strongly recommends that these agents should be used preferentially for hand hygiene (when hands are not visibly soiled) and that facilities should develop active programs to promote the use of these agents.[10] However, alcohol has minimal activity against the spores of *C. difficile*, and some experts recommend handwashing after caring for patients with *C. difficile*–associated diarrhea.[27]

Persons wearing artificial fingernails are more likely to harbor pathogenic gram-negative bacilli and yeast on their fingertips, and these organisms are cleared less effectively on artificial nails by use of an alcohol-based agent than on natural nails.[34,53] Use of artificial nails or nail wraps was associated with carriage of *Pseudomonas aeruginosa* on the hands of health care workers and infection among high-risk infants in a neonatal ICU.[22,29] For these reasons, the HICPAC guideline on hand hygiene recommends that health care workers not wear artificial fingernails or extenders when providing patient care and that natural nails should be kept less than 1/4 inch long.[10]

ISOLATION PRECAUTIONS

Proper utilization of isolation precautions is important for all health care facilities but is especially critical in facilities caring for pediatric patients. Children hospitalized as the result of infections acquired in the community represent a substantial proportion of pediatric admissions, and transmission of these infections to other susceptible patients is a significant problem (see Chapter 244). Effective use of appropriate isolation precautions markedly reduces transmission of these agents.[2,45] A HICPAC guideline recommends the use of two tiers of precautions, Standard Precautions and Transmission-Based Precautions, which are described in greater detail in the following subsections.[71,72]

Standard Precautions

Standard Precautions synthesize the goals of protecting health care workers from bloodborne pathogens and protecting health care workers and patients from transmission of microorganisms from moist body substances.[72] Standard Precautions apply to the following: any planned or potential contact with blood; all body fluids, secretions, and excretions except sweat, regardless of whether they contain visible blood; nonintact skin; mucous membranes; and supplies, equipment, or surfaces contaminated with these substances. Standard Precautions should be used in the care of all patients at all times regardless of the diagnosis or presumed infection status.[72] New components of Standard Precautions include the following: use of respiratory hygiene/cough etiquette by patients and family members and visitors to prevent spread of respiratory infections; safe injection practices by health care providers to prevent spread of bloodborne pathogens; and infection control practices for special lumbar puncture procedures to prevent infections associated with these procedures.

Transmission-Based Precautions

Other precautions are needed to prevent transmission of contagious diseases (e.g., varicella, measles, tuberculosis, and pertussis) and other epidemiologically important microorganisms (e.g., multidrug resistant microorganisms, *C. difficile*) from infected or colonized patients. Transmission-Based Precautions are designed to provide the necessary measures, in addition to those already specified by Standard Precautions, to interrupt known modes of transmission of these microorganisms (see Chapter 244).[72] The three types of Transmission-Based Precautions are Airborne, Droplet, and Contact Precautions.

Airborne Precautions are designed to prevent transmission of microorganisms spread by droplet nuclei (e.g., measles, varicella, tuberculosis) that can be carried on air currents over substantial distances.[72] Special air handling and ventilation are required.[72] Droplet Precautions are designed to prevent transmission of microorganisms spread by large respiratory droplets that travel only short distances before settling.[72] Special air handling and ventilation are not required. Contact Precautions are designed to prevent transmission of microorganisms spread by direct and indirect contact.[72] Some infections are spread by more than one mode of transmission, so precautions systems may need to be combined for these infections (i.e., varicella requires Airborne

Precautions and Contact Precautions). Patients infected or colonized with more than one microorganism also may require a combination of precautions systems (i.e., a patient with active pulmonary tuberculosis and *C. difficile* enterocolitis requires both Airborne Precautions and Contact Precautions).

The HICPAC guideline lists clinical syndromes and conditions warranting empiric use of Transmission-Based Precautions, in addition to Standard Precautions, to prevent transmission of epidemiologically important pathogens until infection with these microorganisms is excluded.[72] To ensure that appropriate empiric precautions are implemented promptly, hospitals must have systems in place to evaluate patients for these infections as a part of routine preadmission and admission care.

VISITORS

Visitors with communicable diseases can expose hospitalized patients and health care workers inadvertently unless procedures to identify and exclude these infections are in place. Varicella, measles, and tuberculosis are the most problematic infections because these diseases are spread by airborne transmission, thus enabling infected visitors to expose a large number of individuals in a short period of time. In addition, visitors with pertussis, viral respiratory and gastrointestinal infections, parvovirus B19 infection, rubella, and mumps can pose a significant hazard to patients and health care workers with whom they have close contact.

Procedures to identify potentially infected visitors should include children who are visiting because they are the most likely persons to be infected with these agents. Parents or guardians of all such children should be asked a set of screening questions regarding the presence of fever, rash, and respiratory and gastrointestinal symptoms in the visiting child, as well as any recent exposure to other children with chickenpox, measles, or whooping cough. Children without any significant symptoms or exposures should be allowed to visit with no restrictions. Children who are otherwise well but who have a history of a recent minor illness may be allowed to visit but potentially with restrictions, such as avoiding close contact (<3 feet) with any patient, not visiting the activity room, and not sharing food, drinks, or toys. Children with upper respiratory infections should not be allowed to visit children with congenital heart disease, bronchopulmonary dysplasia, cellular immunodeficiency, or other conditions that predispose these vulnerable children to development of severe infection with respiratory viruses. Children with significant exposures to chickenpox, measles, or pertussis who may be in the incubation period of the disease should not be allowed to visit the hospital. This screening process should be repeated each day the child visits the hospital. This procedure does not guarantee that a child may not be in the incubation phase of a contagious disease at the time of the visit—varicella is an obvious example—but can be useful in limiting potential exposures.

OCCUPATIONAL HEALTH

Health care workers require protection from the significant infectious risks inherent in patient care; conversely, patients and other health care workers need to be protected from exposure to health care workers with communicable diseases. Integrating management and prevention strategies to accomplish these two goals requires close collaboration between hospital infection prevention and control programs and employee health departments. A HICPAC guideline for infection control in health care workers contains comprehensive recommendations for evaluation of illnesses, post-exposure evaluation and management, and prevention of occupationally acquired infections in health care workers.[9]

Evaluation of Ill Health Care Workers

Hospital staff and volunteers with symptoms such as persistent fever, conjunctivitis, skin lesions or rashes, diarrhea, and persistent cough should be evaluated for the presence of a contagious disease. Possible cases of varicella, herpes zoster on an exposed area of the body, herpetic whitlow, adenoviral conjunctivitis, measles, mumps, rubella, pertussis, staphylococcal skin infection, enteric infection in a food service worker, and active pulmonary tuberculosis should be investigated promptly and confirmed with laboratory tests, if necessary. Although many health care workers choose to have these problems evaluated by their primary care provider, employee health departments have an interest in completing these assessments, especially if a question exists about whether the condition was acquired in the workplace, requires a furlough from work, or may have exposed patients or other health care workers. Infection control staff can provide assistance in these evaluations as needed and should be kept abreast of the results.

Post-exposure Evaluation and Management of Health Care Workers

A structured approach to the assessment and management of exposures of health care workers to patients with infectious diseases is critical to provide post-exposure prophylaxis promptly, if indicated, and to allay anxiety while avoiding unnecessary interventions and loss of workdays. The first step is to develop criteria for assessing the nature of the exposure because many reported encounters are not significant. Some exposures (e.g., varicella, hepatitis B) may require an assessment of the susceptibility of the health care worker to infection, and procedures should describe the indications for laboratory tests as well as the interpretation of results. Post-exposure prophylaxis regimens are discussed in Chapter 244, in a HICPAC guideline,[9] and through the DHQP Web site (*http://www.cdc.gov/ncidod/dhqp/worker.html*). Counseling regarding the risks and consequences of the exposure is an important component of this service.

Prevention of Occupationally Acquired Infections in Health Care Workers

Because vaccination against infectious diseases is a highly cost-effective prevention strategy, hospitals should offer vaccinations free of charge. Vaccination against measles is so effective that ensuring immunity to measles (either as the result of natural immunity or vaccination) among hospital staff is widely regarded as an appropriate quality-of-care indicator for occupational health programs.[43] Because the combined measles-mumps-rubella (MMR) vaccine is readily available,[76] immunity against mumps and rubella can be ensured in an analogous fashion. Annual influenza vaccination of health care workers is recommended by the Immunization Practices Advisory Committee and is considered an essential quality measure by the Leapfrog Group; annual updates provide the latest recommendations.[21] However, acceptance of this vaccine by health care workers often is suboptimal. Consequently, employee health departments need to consider aggressive and innovative strategies to encourage employees to have an annual influenza vaccination. Given the significant occupational risk of hepatitis B infection in hospitals, hepatitis B vaccination should be offered routinely to health care workers. The OSHA bloodborne pathogens standard requires hospitals to offer hepatitis B vaccination free of charge; workers who do not wish to be vaccinated must sign a specific "informed

refusal." Other vaccines, such as the varicella vaccine and acellular pertussis vaccine, can help eliminate or at least drastically reduce the rate of occupational acquisition of these diseases as well.

In addition to hepatitis B vaccination, the OSHA bloodborne pathogens standard mandates other specific prevention measures, including the following: (1) the development of an exposure control plan that identifies employees with occupational risk of exposure to bloodborne pathogens; (2) annual training for these individuals regarding the risk of acquiring bloodborne infection and prevention measures; (3) provision of personal protective clothing and equipment; (4) work practice controls, including equipment and procedures for the safe handling and disposal of sharps; and (5) procedures for identification, transportation, storage, and disposal of contaminated items and waste.[57] The CDC also has published a detailed guideline for prevention and control measures to prevent transmission of *Mycobacterium tuberculosis* to health care workers.[39]

REPROCESSING OF REUSABLE PATIENT CARE ITEMS

Large numbers of outbreaks of health care–associated infections have been related to the use of contaminated equipment. Consequently, hospital infection prevention and control programs must work closely with all hospital departments that reprocess reusable patient care items to ensure proper selection, implementation, and quality monitoring of reprocessing methods. An APIC guideline discusses the characteristics and efficacy of various classes of disinfectants and provides recommendations for methods used to reprocess specific patient care items.[65] Newer methods for sterilization and disinfection have been reviewed.[67,68]

REGULATED MEDICAL WASTE

Regulated medical waste refers to waste that has at least the potential to transmit infectious agents to humans. However, infections resulting from exposure to regulated medical waste (other that those related to percutaneous exposures within hospitals) have not been documented.[66] Moreover, waste from hospitals represents 1 percent or less of the total municipal waste generated annually and has been demonstrated to have a lower microbial burden than does common household waste.[66]

Nonetheless, numerous national, state, and local regulations pertain to the identification, packaging, transport, storage, and disposal of regulated medical waste.[28] A full discussion of this topic is beyond the scope of this chapter, but hospital infection prevention and control programs can provide valuable input into the design of rational approaches to complying with these regulations. Because the management of regulated medical waste is considerably more expensive than that of traditional waste, ensuring proper sorting of regulated medical waste from nonregulated hospital waste can result in considerable cost savings.

EDUCATION AND TRAINING OF HEALTH CARE WORKERS

Providing education and training in both general principles and specific aspects of hospital infection prevention and control is one of the primary responsibilities of program staff. Staff members need to be familiar with principles of adult learning, assessing the educational needs of the audience, defining learning objectives, determining optimal instructional formats, using effective teaching and communication skills, and weighing the merits of various educational tools.[35]

ANTIBIOTIC UTILIZATION AND ANTIMICROBIAL RESISTANT MICROORGANISMS

The rapid emergence of pathogens resistant to multiple antimicrobial agents (e.g., vancomycin-resistant enterococci [VRE] and gram-negative, bacteria-producing, extended-spectrum beta-lactamases) and the widespread dissemination of these resistant microorganisms constitute an unprecedented crisis for hospitals worldwide. The mechanisms involved in the emergence and spread of antimicrobial resistance are complex but no doubt are facilitated by intense selection pressure caused by overuse and misuse of antimicrobial agents in hospitals, particularly newer, broad-spectrum agents. Dissemination of resistant strains is facilitated by suboptimal compliance with hand hygiene and isolation precautions.

A HICPAC guideline provides a detailed discussion of interventions to reduce the spread of antimicrobial resistant organisms, including administrative support, education, surveillance for resistant organisms, judicious antimicrobial use, isolation precautions, adherence monitoring, environmental disinfection, and decolonization.[71] The guideline provides general recommendations applicable to all facilities and recommendations for intensified interventions when the incidence or prevalence of multidrug-resistant organisms is not decreasing despite the use of routine control measures or when outbreaks or new isolations of epidemiologically important multidrug-resistant organisms are detected. A consensus guideline for preventing transmission of MRSA in newborn ICUs by a group of infection control professionals in Chicago also has been published.[26] One of the most controversial aspects of efforts to control MRSA and VRE is whether to perform active surveillance to identify asymptomatically colonized patients. Although screening for colonization during the course of an outbreak clearly is important, the role of routine screening of hospitalized children and infants is not clear.

The IDSA and SHEA have collaborated to publish a guideline for institutional antimicrobial stewardship programs.[17] The evidence base for the interventions recommended in the guideline, particularly those related to improving patient outcomes or controlling antimicrobial resistance, remains relatively weak. Few interventions have been specifically tested in health care facilities providing care to children, but many recommendations are likely to be applicable.

PRODUCT EVALUATION

Large numbers of new medical products are introduced to the health care market every year. Although some of these products have the potential to reduce the risk of acquiring infections, data to substantiate the safety and efficacy claims of manufacturers often are limited. Many devices marketed to hospitals caring for children have never actually been tested in children. Because these products often are substantially more expensive than are existing products, a compelling rationale must exist for their use. Hospital infection prevention and control staff can provide valuable assistance to hospital committees evaluating new products and, in some cases, can design and conduct appropriate clinical trials.[40]

CHAPTER 246

Antibiotic Resistance

Philip Toltzis ✪ Jeffrey L. Blumer

Soil bacteria developed mechanisms of resistance to antibiotics millions of years ago as a means of protecting themselves against other antibiotic-producing microorganisms or their own antimicrobial products. The current crisis of antibiotic resistance, however, was prompted by the intense selective pressure posed by the worldwide use of antibiotics during the past half-century. The problem of antimicrobial resistance in humans has been exacerbated by the widespread administration of antibiotics to farm animals.[247,370,420] Resistant zoonotic bacteria selected by this practice contaminate the food supply and thereby spread to human consumers.

To understand antibiotic resistance fully, one must make a distinction between the in vitro phenomenon of resistance and the less frequently observed clinical consequences of this in vitro phenomenon. Much of the discussion of bacterial resistance to antibiotics derives from the apparent changes in susceptibility of pathogenic bacteria to the concentrations of antibiotic achieved in blood following standard antibiotic dosing.[163] These concentrations have been established as "breakpoints" based on an integration of data derived from both clinical and animal studies, along with the measurement of plasma and serum drug concentrations associated with successful outcomes. Unfortunately, such breakpoints are not absolute. Rather, they depend on an intricate interrelationship between the pharmacokinetics and pharmacodynamics of the drug in question.[58] As such, if one component of this complex interrelationship is changed, the apparent breakpoint distinguishing susceptibility from resistance possibly and most likely also will change. Consequently, in presenting information concerning the mechanisms of antibiotic resistance and their clinical contexts, one must remember that the discussion derives, in part, from certain artificial pretexts. Any changes in a drug-dosing paradigm (e.g., dose, infusion duration, formulation) may affect the clinical relevance of the in vitro observations dramatically.

Bacteria develop resistance to antimicrobial agents through three principal cellular mechanisms (Table 246–1). In some microorganisms, two or more mechanisms of resistance to a given agent exist simultaneously. Antibiotic-resistance genes may be encoded either on the bacterial chromosome or on extrachromosomal DNA. The spread of antibiotic resistance among bacteria has been facilitated by the inclusion of many resistance genes on transmissible extrachromosomal genetic elements. To date, three interrelated genetic elements have been implicated in the expression and spread of antibiotic resistance, namely, *plasmids*, *transposons*, and *integrons*.

Plasmids are composed of circular double-stranded extrachromosomal DNA. Although plasmids characteristically use bacterial DNA polymerase to replicate, their replication occurs autonomously.[390] Many different plasmids exist in nature; they vary in size, in the complexity of their genetic machinery, in their host range and ability to conjugate, and in their stability within the bacterium. Minimal plasmids (replicons) contain genetic sequences encoding the site at which their replication begins and sequences that determine the copy number produced per cell. However, many more genetic elements can be inserted into the replicon. Indeed, plasmids range in size from 1 kb to more than 400 kb; additional genetic machinery is required for conjugation, and, therefore, conjugative plasmids are at least 30 kb in size.[352] Groups of plasmids containing homologous replicative sequences generally are unable to be maintained in the same bacterial cell. This property has been exploited to categorize plasmids into different "incompatibility groups."

Recognition of the importance of plasmids to human disease increased substantially when researchers discovered that these elements could incorporate one or more antibiotic-resistance genes. These so-called resistance plasmids are found in a wide variety of gram-positive and gram-negative bacteria and encode determinants conferring resistance to many antibiotics. Resistance-conferring sequences producing resistance to several drugs may be included on the same plasmid, and multiple, different plasmids expressing different determinants can be included in the same microorganism.[31,390] Several additional classes of plasmid-borne determinants besides antibiotic-resistance genes can confer selective advantage to the bacterium. These determinants include genes rendering resistance to environmental heavy metals (e.g., mercury, antimony, arsenic, and silver) and a variety of toxic organic compounds (e.g., camphor and toluene), genes leading to the synthesis of virulence factors such as adhesion ligands promoting bacterial attachment to epithelial surfaces and those encoding exotoxins, and genes encoding compounds enabling acquisition of chemicals necessary for bacterial survival (e.g., siderophores).[390] The coexistence of these genes on plasmids carrying antibiotic-resistance determinants serves to maintain the plasmid, even in the absence of antibiotic exposure.

Plasmids are transmitted from microorganism to microorganism both vertically and horizontally.[390] Vertical transmission occurs during bacterial division as the plasmids segregate to each daughter cell. Horizontal transmission is affected through conjugation, the transmission of the plasmid from one bacterium to another. At a minimum, all conjugal plasmids encode a genetic sequence that serves as the origin of transmission, and most encode additional mobilization genes.[389] However, plasmids that are unable to conjugate on their own frequently are able to do so when a conjugal plasmid co-resides in the same cell.[390] Especially in gram-negative bacteria, the donor-recipient contact required for conjugation is effected through sex pili. Conjugation frequently is restricted to intragenus transfer, but conjugation across bacterial genera may occur, particularly in gram-negative organisms, and conjugation occasionally occurs across Gram-stain barriers.[242,389]

TABLE 246–1 Cellular Mechanisms of Antibiotic Resistance and Their Transfer

Mechanisms
Genes that encode enzymes that modify or degrade antibiotics
Genes that modify the molecular targets for antibiotics
Genes that code for changes in cell wall channels or active pumping mechanisms
Transfer
Plasmids: extrachromosomal genetic elements made of circular double-stranded DNA <10 to >400 kb pairs; autonomous, self-reproducing; may be conjugative or nonconjugative
Transposon: a mobile genetic element in the bacterial chromosome or plasmid that confers a recognizable phenotype characteristic; incapable of self-replication
Integrons: DNA sequences on bacterial chromosome or plasmid often linked to a resistance gene that facilitates recombination among nonhomologous DNA sequences

A second group of bacterial nucleic acid elements that carry antibiotic-resistance genes is termed *transposons*. Transposons move segments of nucleic acid from one location to another, such as from different sites on the bacterial chromosome or from chromosome to plasmid.[346,353] Unlike chromosomal and plasmid DNA, transposons do not replicate independently and therefore must be integrated into a molecule capable of replication to propagate. Antibiotic-resistance genes may be encoded on conjugative transposons, which, unlike nonconjugative transposons, are able to transfer from one bacterium to another.[353] Most antibiotic-resistant conjugative transposons characterized to date have been identified in gram-positive organisms, although transposons in *Bacteroides* have been well characterized, and transposons in some facultative gram-negative bacteria have been discovered as well.[341] Conjugative transposons are very promiscuous in two senses. First, they move easily from one species of bacterium to another.[341,353] Second, the integration of transposons into other nucleic acid elements is relatively sequence-nonspecific. Although a preference exists for integrating into host DNA sequences with long stretches rich in adenine and thymidine, integration of conjugative transposons targets no detectable consensus sequences.[341]

Intracellular shuttling of a transposon from DNA to DNA begins with the production of a staggered cut on either side of the transposon sequence to produce single-stranded overhangs. These overhang sequences (termed *coupling sequences*) join covalently to produce a circularized double-stranded intermediate that contains the non–base-paired coupling sequences derived from opposite ends of the transposon.[341,353] Integration of the circle into the target double-stranded DNA also results in flanking non–base-paired regions, which become complementary only after a round of replication occurs.[353] Conjugation of the transposon from cell to cell also begins with the circularized intermediate, which, after nicking at a presumed origin site, is transferred as a single strand from donor bacterium to recipient bacterium, whereupon it re-circularizes. Complementary strands then are added to both single strands in the donor and the recipient, and integration into target DNA in both cells ensues.[341]

Excision and integration of transposons are catalyzed by a transposon-encoded integrase.[341,353] The efficiency of excision varies widely and accounts for the differences in rates of transfer of transposons. Conjugation of many transposons appears to be regulated.[341] Unlike some plasmids, conjugative transposons do not exclude entry of other transposons.[341] Indeed, some transposons promote the conjugation of other transposons as well as co-resident plasmids; the result is the dissemination of resistance determinants that are not encoded on the transposon itself.[353]

Integrons, a third type of bacterial DNA important in antibiotic resistance, are composed of segments of DNA that are able to capture and excise gene cassettes coding antibiotic-resistance genes. Integrons are unable to transfer from bacterium to bacterium themselves. To disseminate, the integron first must insert into a plasmid or transposon.[101,309,317] So-called superintegrons, carrying more than 50 gene cassettes, have been identified on the chromosomes of some nonpathogenic environmental bacteria.[241] Superintegrons possess many of the organizational features of antibiotic-resistance integrons and may have been their progenitors. Integrons contain an integrase that catalyzes the incorporation and excision of the cassette into the integron, as well as a promoter that mediates the expression of the resistance determinant, both situated 5′ to the cassette. The cassettes themselves are small segments usually encoding a single antibiotic-resistance determinant. Cassettes have been identified that confer resistance to a broad range of antibiotics, including the β-lactam agents, the aminoglycosides, fluoroquinolones, trimethoprim (TMP), and choramphenicol.[101,309,317] At the 3′ end of each cassette is a variable region commonly termed the *attC site* or, alternatively, the *59-bp element*, although it varies in length from cassette to cassette from 57 bp to more than 100 bp.[241] This 3′ element contains the sequences recognized by the integrase for incorporation of the gene cassette into the integron.[241,317] Several classes of integrons have been defined, based on the sequence of the integrase and their preference for certain transposons. Most antibiotic-resistance integrons are derived from class 1.[241] A single integron may contain multiple antibiotic-resistance cassettes in tandem, all of which are controlled by the single integron promoter. Transcription of tandem cassettes may terminate prematurely, however, such that the cassettes closest to the integron promoter are transcribed at the highest level.[309,317]

The consequences of mobile resistance genes on plasmids and transposons cannot be overstated. They have given bacteria a profound replicative advantage in the age of antibiotics by enabling the instant acquisition of multiple, ready-made antibiotic-resistance genes without requiring each organism to independently undergo the same or similar resistance-conferring mutations again and again.[241] Hence, bacteria may become resistant almost immediately after exposure to antibiotics and may efficiently transmit this resistance to bacteria co-residing in the same host and to bacteria colonizing or infecting multiple hosts in the same community.

RESISTANCE TO SPECIFIC ANTIBIOTICS

β-LACTAM ANTIBIOTICS

The β-lactam antibiotics are a diverse, highly effective family of drugs with broad activity against a wide variety of hospital- and community-acquired pathogens. The β-lactams are composed of four subgroups, namely, the penicillins, the cephalosporins, the monobactams, and the carbapenems. Resistance to the β-lactams is mediated by one of two principal mechanisms: (1) production of enzymes capable of hydrolyzing the β-lactam ring and (2) alteration of the target bacterial molecules, the penicillin-binding proteins (PBPs).

β-Lactamase Production

CLINICAL RELEVANCE

The explosive development in antimicrobial therapeutics since the mid-20th century has been driven, to a great extent, by the impact of β-lactamase activity on the response to antibiotic therapy in the clinical setting.[320] Shortly after penicillin became incorporated into the clinical armamentarium for the treatment of systemic infections, clinical failures were reported in patients treated for infections caused by *Staphylococcus aureus*. On further analysis, these failures were attributed to the presence of an enzyme, "penicillinase," elaborated and excreted by the bacteria, that inactivated the antibiotic before it could manifest its clinical effect. This finding led to the development of numerous new antistaphylococcal penicillins (i.e., the isoxazolyl penicillins) that were not substrates for this enzyme.

At the same time, a newer class of β-lactam agents, the cephalosporins, was developed. One of the criteria employed in moving candidate drugs from this class to the clinic was their resistance to inactivation by the penicillinase elaborated by staphylococci. Further development of all four of the subgroups in the β-lactam family (i.e., penicillins, cephalosporins, monobactams, and carbapenems) was influenced significantly by the recognition that the penicillinase elaborated by staphylococci was representative of a larger class of enzymes that were also present in gram-negative organisms. In this regard, history repeated itself. As gram-negative organisms such as *Escherichia coli* emerged as important clinical pathogens, their emerging resistance to aminopenicillins on the basis of β-lactamase elaboration spawned the development

of a group of enzyme inhibitors including clavulanic acid, sulbactam, and tazobactam.[221,324] Moreover, even as it became necessary to expand the spectrum of both the penicillins and cephalosporins to include some of the more itinerant gram-negative organisms such as *Serratia* spp., *Enterobacter* spp., and even *Pseudomonas*, β-lactamase stability emerged as a necessary attribute for clinical success.[221,324] This expansion was accomplished either through the addition of one of the β-lactamase inhibitors to members of the carboxy and acylureido class of penicillins or through structural engineering such as that seen with the development of the second- and third-generation cephalosporins and carbapenems.

In pediatric practice, the importance of β-lactamase became apparent soon after the widespread use of antibiotics in hospitalized patients began. However, three sentinel clinical events were probably most responsible for establishing β-lactamase as a prominent pediatric clinical problem. In 1974, the first case of bacterial meningitis caused by ampicillin-resistant *Haemophilus influenzae* was reported.[270,388] This report resulted in marked changes in clinical practice. First, all infants and children with suspected bacterial meningitis were treated empirically with both ampicillin and chloramphenicol (a drug not susceptible to degradation by bacterial β-lactamase) instead of with ampicillin alone.[320] In addition, several newer antibiotics, particularly the second- and third-generation cephalosporins, were evaluated for their efficacy in this clinical setting. From these studies, ceftriaxone or cefotaxime emerged as the drug of choice for the empiric treatment of suspected or proven bacterial meningitis in children. This selection was based both on both greater potency against *H. influenzae* and β-lactamase stability.

The second circumstance resulting in the affirmation of β-lactamase as an important clinical problem in pediatrics was the recognition of *Moraxella catarrhalis*, a β-lactamase–producing organism, as the third leading cause of acute otitis media in infants and children, and the emergence of amoxicillin resistance among the nontypeable strains of *H. influenzae*. β-Lactamase production in *H. influenzae* was thought to be particularly associated with therapeutic failure, thus spawning the development of oral second- and third-generation cephalosporins and newer macrolides as therapeutic alternatives in childhood otitis media.

By the early 1980s, β-lactamase–producing bacteria garnered additional attention from pediatricians because of the role of these bacteria as nosocomial pathogens. These bacteria became prominent as children with severe but survivable conditions (e.g., hematologic malignancies and solid organ transplantation) required immunosuppressive therapy and prolonged hospitalization, both of which predisposed these children to acquisition of hospital-acquired infection. With each succeeding decade, the number and variety of β-lactamase–producing hospital-acquired bacteria increased. By the early 21st century, virtually all nosocomial *S. aureus*, coagulase-negative staphylococci, and enteric and nonenteric gram-negative pathogens elaborated β-lactamase. These organisms commonly encode multiple distinct β-lactamases and express them simultaneously. Consequently, many bacterial infections currently acquired in the hospital are resistant to all β-lactam agents except for the higher-generation β-lactam–β-lactamase inhibitor combinations, the advanced-generation cephalosporins, or the carbapenems. In the most extreme cases, particularly in *Pseudomonas* and *Acinetobacter* infections, the organisms are resistant to all available β-lactam drugs.[56,209,311]

MECHANISM OF RESISTANCE

The β-lactamases constitute a broad array of enzymes that hydrolyze the β-lactam ring of selected antibiotics (Fig. 246–1). Most β-lactamases are structurally similar to the PBPs, and the consensus is that at least some of the β-lactamases were derived evolutionarily from them.[252] β-lactamases can be identified in both gram-positive and gram-negative bacteria. In gram-positive bacteria, the enzyme is secreted into the cell-free environment, whereas in gram-negative organisms, most enzyme is confined and concentrated in the periplasmic space between the cell wall and the outer membrane.

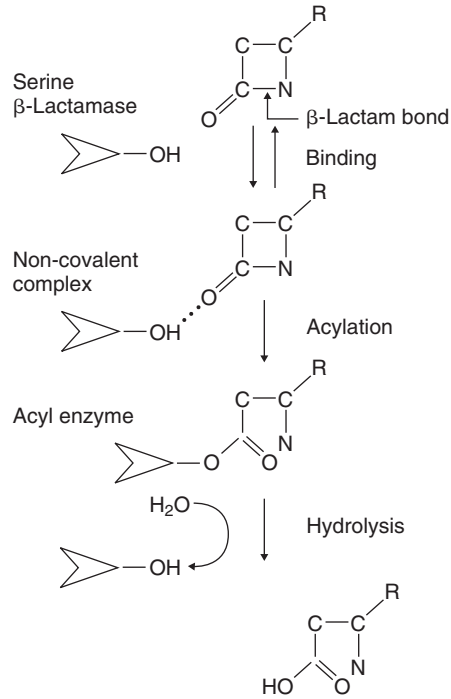

Figure 246–1 Mode of action of β-lactamases (classes A, C and D).

Hundreds of β-lactamases have been characterized,[170] and, doubtless, many more exist in nature. The β-lactamases have been categorized variously according to substrate preference, isoelectric focus, whether they are encoded on the bacterial chromosome or an episome, their ability to be inhibited by clavulanate, and their molecular structure. The molecular classification of Ambler[4] proposed in the 1980s is still widely employed. This classification divides the β-lactamases into four categories, A through D, although all but B, the metalloenzymes, have proved to have similar three-dimensional conformations.

The updated classification system of Bush, Jacoby, and Medeiros, proposed in 1995,[36] divides these enzymes into four groups (with subcategories) and uses virtually all the properties listed earlier to discriminate one class of enzyme from the others. The properties of the three most important groups proposed by Bush, Jacoby, and Medeiros are summarized in Table 246–2 and are described more fully here.

Group 1 AmpC β-Lactamases

The group 1 enzymes (also referred to as *AmpC* β-*lactamases*) hydrolyze virtually all β-lactam antibiotics except the carbapenems and are resistant to inhibition by clavulanate. These enzymes typically are chromosomally encoded on a sequence labeled *amp*C in a wide range of gram-negative bacteria; however, the AmpC β-lactamases are expressed in quantities sufficient to produce clinically important resistance only in selected species, including *Enterobacter cloacae*, *Serratia marcescens*, *Citrobacter freundii*, *Pseudomonas aeruginosa*, and *Morganella morganii*. In the absence of drug exposure, expression of the group 1 AmpC β-lactamases in these species is repressed by an upstream sequence labeled *amp*R (Fig. 246–2).[252,301] However, exposure of the bacteria to a β-lactam leads to the production and intraceullular incorporation of a bacterial cell wall metabolite that itself is pro-

TABLE 246–2 Properties of the Major Groups of β-Lactamases

BJM* group	1	2	3
Ambler class	C	A, D	B
Substrate preference	All but carbapenems	Variable†	Variable (carbapenems)
Chromosomal/plasmid	C	P	C/P
Distribution	Gram-neg	Gram-neg/gram-pos	Gram-neg
Clavulanate inhibition	No	Yes	No
Inducible‡	Yes	No	No

**Data from Bush, K., Jacoby, G. A., and Medeiros, A. A.: A functional classification scheme for beta-lactamases and its correlation with molecular structure. Antimicrob. Agents Chemother. 39:1211-1233, 1995.*
†May be divided into subgroups including penicillinases, cephalosporinases, cloxacillinases, and carbapenemases. Enzymes frequently can hydrolyze more than one group of β-lactam.
‡Indicates that normally repressed β-lactamase production can be induced by β-lactam exposure.

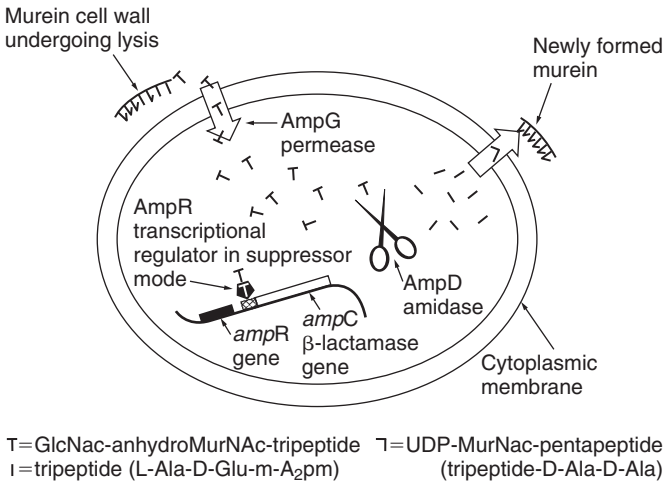

Figure 246–2 A model for peptidoglycan recycling and β-lacamase induction in enterobacteria. The lytic transglycosylases in the periplasm cleave the bond between *N*-acetylglucosamine (GlcNac) and *N*-acetylmuramic acid (MurNac) and form the peptidoglycan degradation product, *N*-acetylglucosaminyl-1,6-anhydro-*N*-acetylmuramyl-L-alanyl-D-glutamyl-meso-diaminopimelic acid (T). The AmpG permease transports T into the cytoplasm. The AmpD amidase recognizes specifically substrate containing anhydromuramic acid and cleaves the bond between it and L-alanine, releasing the stem tripeptide, L-Ala-D Glu-m-A_2pm (I). Unprocessed T activates the AmpR transcriptional regulator, thereby inducing β-lactamase production. The tripeptide, I, conversely, recycles to form new peptidoglycan. By regulating the relative amounts of T versus I, AmpD may control peptidoglycan composition. The regulatory function of the AmpC β-lactamase, if any, is unknown.

cessed by the enzyme AmpD.[165,219] In sufficient quantity, the AmpD substrate interacts with *amp*R, thus reversing the repression, and relevant quantities of the AmpC β-lactamase are thereby synthesized.

β-lactam antibiotics differ in their ability to induce AmpC β-lactamases by this mechanism. Ampicillin, cefoxitin, and imipenem are potent inducers, whereas most of the third-generation cephalosporins are weak. However, spontaneous mutations leading to a dysfunctional AmpD enzyme that occur at high frequency in nature result in permanent de-repression of the *amp*C gene, which, in turn, results in constitutive production of large quantities of the AmpC β-lactamase (see Fig. 246–2). De-repressed organisms are rendered highly resistant after this single mutational step. The third-generation cephalosporins are particularly prone to selecting such AmpD mutants, and the clinical emergence of resistant de-repressed isolates during the course of treatment with a third-generation cephalosporin has been documented.[49]

Group 2 β-Lactamases

The Bush, Jacoby, and Medeiros group 2 β-lactamases include a wide variety of enzymes that are encoded primarily on plasmids.[36,144,199,290,301] These plasmids commonly contain resistance determinants to other antibiotic classes as well. The plasmids are stable in nature and frequently are maintained within the bacteria even in the absence of antibiotic pressure. Moreover, they can be transmitted by conjugation from organism to organism and across species, sometimes leading to a "plasmid outbreak" in a confined environment (e.g., a nursing home or intensive care unit [ICU]) that is caused by different species containing the same plasmid. The group 2 enzymes have substrate preferences that have become increasingly broad with the introduction of each new class of β-lactam antibiotic. Characteristically, the group 2 enzymes are inhibited by clavulanate and are found in both gram-positive and gram-negative bacteria (see Table 246–2).[36,199,252]

The prototypical group 2 β-lactamases are included in the TEM and SHV families of enzymes, although large numbers of group 2 enzymes not belonging to either of these families also have been characterized. TEM-1, first identified in Europe in 1963, hydrolyzed ampicillin. During the ensuing decades, the TEM sequence mutated in a step-wise fashion (with each new iteration labeled sequentially: TEM-2, TEM-3, and so on), resulting in the ability of each new enzyme to degrade an ever-increasing number of β-lactam antibiotics.[88,169,252] Many of these mutations widen a critical cavity, formed by the three-dimensional configuration of the molecule, containing a serine-active site at its bottom that is key to hydrolysis of the β-lactam.[118,170] Although these mutations render the enzymes kinetically less efficient than their parents, they allow the entry of the newer β-lactams with their bulky side chains into the cavity, thereby enabling the serine-active site at the bottom to reach the β-lactam ring.[88,252]

Of increasing importance among the group 2 enzymes are the extended-spectrum β-lactamases (ESBLs). ESBL-producing organisms are distributed worldwide, but their incidence varies geographically.[299] Currently, bacteria elaborating ESBLs infect primarily critically ill, hospitalized patients,[291] although these enzymes are being reported in increasing numbers in the community.[53,256,307] Although they are molecularly diverse, ESBLs confer a common resistance phenotype, namely, reduced susceptibility to the third-generation cephalosporins, especially ceftazidime, and to aztreonam. Susceptibility to the carbapenems is preserved.[290] Common to other group 2 β-lactamases, hydrolytic activity typically is suppressed by the β-lactamase inhibitors. Most ESBLs are molecular descendents of TEM-1 and SHV-1 and are found in *E. coli*, *Klebsiella pneumoniae*, and to a lesser extent in *Proteus mirabilis*. Other families of ESBLs have been described. Among the more important ESBLs are the CTX-M enzymes, which are particularly active against cefotaxime, and some of the OXA-β-lactamases, the principal substrate of which is oxacillin but the spectrum of which has broadened to include

the advanced-generation cephalosporins.[290,299,307] Concomitant with their molecular evolution, ESBLs have been identified in an ever-widening range of bacteria, including *Pseudomonas*, *Salmonella*, and *Shigella* and *Enterobacter* spp.[290]

Although most ESBL-producing bacteria are overtly resistant, the third-generation cephalosporins have minimum inhibitory concentrations (MICs) against some ESBL-producing organisms that fall into the high end of the susceptible range. Consequently, the incidence of ESBL-producing bacteria is underestimated when conventional MIC breakpoints for resistance are used. Growing numbers of reports, however, indicate that infections caused by organisms expressing these "susceptible" MICs are clinically unresponsive to the third-generation cephalosporins.[315] Many hospital microbiology laboratories therefore screen all *E. coli*, *Klebsiella*, and *P. mirabilis* clinical isolates for reduced susceptibility to both ceftazidime and cefotaxime and alert the clinician accordingly. Although the optimal therapy for infection caused by ESBL-producing, gram-negative bacteria is not established, many authorities recommend a carbapenem.[170,290,315]

An additional family of group 2 β-lactamases, composed of carbapenemases, was identified first in the late 1990s.[26,154,367,426] These enzymes are found principally in hospital-acquired *K. pneumoniae*, and hence they are designated *K. pneumoniae* carbapenemases (KPCs).[26,154,368,426] By the early 2000s, they had become prominent in selected regions of the eastern United States. KPCs have been identified in a variety of other Enterobacteriaceae as well.[28] KPC enzymes are carried by conjugative plasmids expressing multiple other resistance genes. The carbapenem MICs for some KPC-containing organisms are at the high end of the susceptible range, whereas others are overtly resistant.

Group 3 Metalloenzymes

The Bush, Jacoby, and Medeiros group 3 β-lactamases are composed of the metalloenzymes (see Table 246–2).[35,411] These β-lactamases are genetically heterogeneous and structurally dissimilar to those of groups 1 and 2. The metalloenzymes are not suppressed by β-lactamase inhibitors. The active site requires the participation of zinc; hence hydrolysis of the β-lactam ring is inhibited by chelators such as ethylene diaminetetraacetic acid (EDTA). The active site itself is composed of a wide plastic groove that can accommodate many β-lactam substrates. Some metalloenzymes are chromosomal (e.g., in *Stenotrophomonas*), but many have been identified on integrons that are inserted on transferable elements.[411] These latter metalloenzymes, which characteristically encode aminoglycoside-resistance determinants as well, are identified primarily in *Pseudomonas* and *Acinetobacter* spp. and selected Enterobacteriaceae. During the latter 1990s and early 2000s, organisms harboring transferable metallo-β-lactamases, particularly those from the IMP and VIM family of metalloenzymes, were identified in many countries in eastern Asia, Europe, and South America. The substrate preference of the metallo-β-lactamases varies, but most organisms expressing these enzymes have reduced susceptibility or overt resistance to all the β-lactam antibiotics, including the carbapenems. Moreover, organisms encoding a metalloenzyme frequently express other chromosomal and plasmid-encoded β-lactamases as well, and this phenomenon, coupled with the coincident expression of resistance to other classes of antibiotic, often severely limits therapeutic options.

Although the properties summarized in Table 246–2 apply to most of the enzymes in each group, many exceptions have been noted. For example, enzymes that are genetically homologous to the group 2 family, typically plasmid-borne enzymes, have been identified on the bacterial chromosome in some isolates of *S. marcescens* and *E. cloacae*.[252] Conversely, group 1 AmpC enzymes, typically contained on the bacterial chromosome, have been identified on plasmids in genera such as *Klebsiella* and *Salmonella* that customarily do not express chromosomal *ampC* β-lactamase.[299-301] Some rare group 2–type enzymes are inducible.[252] TEM-type enzymes that are resistant to clavulanate have been identified (the so-called inhibitor-resistant TEMs [IRTs]).[42,192]

The degree of resistance exhibited by an organism encoding a β-lactamase frequently depends not only on the enzyme's in vitro substrate specificity and kinetics but also on the amount of enzyme produced. Hyperproduction of β-lactamase usually is the result of some alteration of a controlling sequence or an increase in number of copies of the β-lactamase gene within the bacterium.[117,287,431] High-level resistance results, and the susceptibility of the organism diminishes with increasing numbers of bacteria. Consequently, the organism may appear clinically unresponsive to a β-lactam antibiotic if hyperproduction occurs in the context of a high-inoculum disease. In some circumstances, hyperproduction operates in concert with other mechanisms to derive a resistant phenotype. Thus, some isolates of *E. cloacae* and *P. aeruginosa* have been rendered carbapenem-resistant through a combination of hyperproduction of an AmpC β-lactamase, which normally is ineffective in hydrolyzing the carbapenems, and the simultaneous loss of the outer-membrane poron through which imipenem traverses to reach the PBP.[45,182,266,311]

Alteration of Penicillin-Binding Proteins

CLINICAL RELEVANCE

Two species of clinical importance to pediatricians express resistance to β-lactam drugs through the alteration of PBPs, namely, penicillin-resistant *Streptococcus pneumoniae* and methicillin-resistant *S. aureus* (MRSA). Indeed, not until penicillin-resistant *S. pneumoniae* was recognized did pediatricians begin to realize that alterations in the PBPs in the bacterial cell wall could pose a major clinical problem.[186,244] The identification of patients with pneumococcal infections caused by organisms resistant to penicillin created tremendous consternation within the pediatric infectious disease community. However, to date, the precise clinical importance of these organisms remains unclear.

Part of the problem in assessing the clinical importance of altered penicillin binding among pneumococci is that, rather than simply conferring penicillin resistance, the genes coding for this altered enzyme activity often co-segregate with genes coding for resistance to other antibiotics, such as TMP-sulfamethoxazole (TMP-SMX) and the macrolides.[46,70,77,78,167,321,392] Thus, unlike resistance associated with the elaboration of β-lactamase, in which simply selecting a different class of antibiotic often will provide a reasonable solution, resistance associated with alteration in PBPs is multifarious and, if clinically important, may require significant alterations in clinical practice to provide an effective antimicrobial regimen. The more limited menu of antibiotic choices for the treatment of infections caused by these organisms led to some interesting therapeutic conventions. For example, because the basis for this type of resistance is akin to altered enzyme affinity, investigators recognized in the mid-1990s that overcoming the apparent decrease in efficacy could be possible by simply increasing the dose of β-lactam employed.[186,245,246] Of the available agents, only amoxicillin had the requisite therapeutic index to support the increased dosing strategy. On this basis (almost exclusively), the high-dose amoxicillin regimen (80 to 100 mg/kg/day) that is currently recommended was adopted. Additionally, the perceived need for a drug effective against antibiotic-resistant *S. pneumoniae* led to the widespread use of the parenteral third-generation cephalosporin, ceftriaxone, in the setting of common upper and lower respiratory tract infections because of its in vitro activity against most of these organisms.

As the clinical impact of the emergence of the antibiotic-resistant *S. pneumoniae* has been examined more carefully in recent years, several trends have emerged.[186,430] In immunocompetent patients with pneumonia and most other non–central

nervous system pneumococcal infections, no difference appears to exist in outcomes between patients infected with organisms that are susceptible to penicillin and those infected with organisms showing decreased susceptibility to penicillin.[286,298] Moreover, apparently no association exists between the intrinsic virulence of the organism and its antibiotic susceptibility. In contrast, in patients with pneumococcal meningitis caused by organisms with decreased penicillin susceptibility, there appears to be a delay in sterilization of cerebrospinal fluid in the presence of standard treatment.[225,429] For this reason, the current recommendation for empiric treatment of bacterial meningitis in infants and children consists of a combination of ceftriaxone or cefotaxime and vancomycin until the organism is identified and its antibiotic susceptibility is known.

S. pneumoniae remains the most prevalent bacterial cause of acute otitis media in infants and children. The clinical importance of the antibiotic susceptibility of these organisms in this clinical setting remains difficult to ascertain. The infection has a high rate of spontaneous resolution, and virtually all treatment is provided on an empiric basis. Consequently, any improved cure rate related to altered prescribing practices aimed at greater activity against organisms with decreased antibiotic susceptibility would be difficult to substantiate. Finally, the importance and virulence of these organisms in children who are either immunocompromised or immunosuppressed remain to be determined unequivocally.

The problem of penicillin-resistant *S. pneumoniae* has been at least partially addressed by the introduction of the conjugated heptavalent pneumococcal vaccine. The serotypes included in the vaccine account for most penicillin-resistant pneumococci in the United States.[393] Surveys conducted by the Centers for Disease Control and Prevention (CDC) indicated that the incidence of invasive *S. pneumoniae* infection caused by penicillin-resistant strains decreased by more than 50 percent in the years immediately following introduction of the vaccine.[206] The decrease was most pronounced in children younger than 2 years of age. This benefit has been mitigated in part by increases in disease caused by resistant serotypes not included in the vaccine, most notably serotype 19A.[17,206] Acute otitis media is caused by many pneumococcal serotypes not included in the heptavalent vaccine, and, consequently, the effect of immunization on reducing resistance in this and other noninvasive pneumococcal infection probably is marginal.

MRSA was isolated first from hospitalized adult patients in 1961 and became a prominent pathogen in critically ill patients during the ensuing decades. By the early 2000s, more than half of *S. aureus* infections in patients in ICUs in the United States were caused by MRSA.[267] Compared with those in adults, MRSA infections among hospitalized children occur relatively infrequently. In the mid-1990s, however, MRSA infections were identified among otherwise healthy children with no prior contact with hospitals or hospitalized patients.[145,161] These strains of community-associated MRSA (CA-MRSA) were molecularly distinct from MRSA infections previously identified in the hospital environment. By the mid-2000s, CA-MRSA had established a worldwide presence in both children and adults.[3] The infection causes primarily skin and soft tissue infection but occasionally bone and joint infection, severe necrotizing pneumonia, and other invasive, deep tissue disease. CA-MRSA infections are especially common in populations inhabiting close quarters and engaging in skin-abrading activities, including athletes participating in competitive sports, military personnel, and prison populations.[414]

Most MRSA isolates, both hospital and community-associated, are derived from a relatively small number of prominent, widely disseminated clones.[279] Several systems have been proposed to categorize the principal MRSA lineages. The system established by the CDC is based on *Sma*I macro-restriction patterns of bacterial DNA visualized after separation by pulse-field gel electrophoresis (PFGE). The PFGE types so defined have been labeled USA100 through USA800, in addition to two additional groups, named USA1000 and USA1100.[74,248] Currently, more than 90 percent of MRSA strains derived from patients in the United States fall within one of these PFGE types.[74,248] Most CA-MRSAs are included in the USA300 group, with a minority derived from the USA400 and USA1100 groups.[197,355]

MECHANISM OF RESISTANCE

β-Lactam antibiotics must bind to PBPs to confer their activity, and alteration of the structure of PBPs results in diminished affinity for drug and, consequently, antibiotic resistance. The PBPs are a heterogeneous group of compounds normally responsible for maintaining the peptidoglycan matrix supporting the bacterial cell wall. PBPs vary from species to species in number, size, copy number per cell, and affinity for β-lactam agents.[115,134,343] Typically, four to eight PBPs are present in any given bacterial isolate; they range in molecular weight from 35 to 120 kd.[115] PBPs possess two principal enzymatic activities. In general, the larger PBPs are responsible for peptidoglycan transpeptidase activity, whereas the smaller PBPs usually carry D,D-carboxypeptidase activity.[115] These activities constitute the final reactions in the formation of the peptidoglycan matrix and are responsible for the cross-linkage that significantly adds to the tensile strength of the bacterial cell surface.

Examination of PBP-mediated β-lactam resistance in *S. pneumoniae* and *S. aureus* serves to exemplify some of the features of this mechanism of resistance. Detailed investigations indicate that penicillin resistance in pneumococcus is associated with alternations in PBP 1A, 1B, 2A, 2X, and 2B; cephalosporin resistance has been correlated with structural abnormalities in PBP 1A, 2A, and 2X.[14,52,125,133,135,264] Confirmation that the resistant phenotype is related directly to structural abnormalities in various pneumococcal PBPs has been achieved through transformation experiments.[14,52,125,264] In these studies, penicillin-susceptible strains are converted to penicillin-resistant strains by addition of amplified DNA encoding the putative resistant PBPs. Patterns of PBPs from resistant pneumococci vary considerably from geographic location to location, a finding indicating that PBP-related pneumococcal resistance probably arose independently in various parts of the world.[133]

PBPs from penicillin-resistant *S. pneumoniae* contain blocks of amino acid sequences that are remarkably divergent from those seen in susceptible pneumococci. These sequences are homologous to those encoding for PBPs from other streptococcal species (e.g., *Streptococcus oralis* and *Streptococcus mitis*), a finding suggesting that the resistant pneumococci contain mosaic PBPs that arose after transformation and recombination of homologous genes from closely related bacteria.[84,85,132,208] These sequences then developed point mutations conferring resistance. A similar pattern of "resistance blocks" of amino acids has been identified in the PBPs of penicillin-resistant *Neisseria gonorrhoeae*, which appear to have originated from other *Neisseria* spp.[134] The degree of resistance conferred by a single mutated PBP is relatively small.[115,125] Acquisition of multiple abnormal PBPs results in incremental resistance and, ultimately, an organism that can survive routine β-lactam therapy.

Whether associated with the hospital or the community, all isolates of MRSA contain the *mecA* gene, a 2130-bp chromosomal sequence encoding the PBP 2A, which, unlike the other staphylococcal PBPs, has low affinity for β-lactam antibiotics.[62,63] The *mecA* gene is carried on a mobile element designated the *staphylococcal cassette chromosome mec (SCCmec) sequence*.[437] All MRSA strains contain an SCC*mec* complex, but their size and organization vary, thus allowing them to be grouped into five distinct SCC*mec* types, numbered I to V.[278,437] Hospital-acquired (HA)-MRSA strains contain SCC*mec* types I to III, whereas CA-MRSA

strains harbor type IV and, to a lesser extent, type V. In most HA-MRSA isolates, the SCC*mec* sequence contains resistance determinants additional to *mec*A, including those conferring resistance to clindamycin, the aminoglycosides, and the fluoroquinolones.[67,437] Hence, these organisms possess a selective advantage in ICUs, where exposure to multiple classes of antibiotics commonly occurs. By contrast, the CA-MRSA SCC*mec* type IV and V strains encode a smaller SCC*mec* sequence lacking the multiple antibiotic-resistance genes found in their hospital-associated counterparts.[67,437] These strains include certain virulence factors, however, most notably the Panton-Valentine leukocidin, possibly important for soft tissue breakdown and destruction. The smaller SCC*mec* sequences allow CA-MRSA to replicate more rapidly than does HA-MRSA,[277] because they can be maintained by the bacterium at a lower metabolic cost. The relatively small size of the CA-MRSA SCC*mec* sequences further enables efficient transfer to co-colonizing susceptible *S. aureus*.[437]

SCC*mec* elements likely originated in coagulase-negative staphylococci. Type IV SSC*mec* sequences, for example, have been identified in isolates of *Staphylococcus epidermidis* from the 1970s.[424] Additionally, sequences have been found in *S. epidermidis* and *Staphylococcus hominis* strains that contain the regulatory genes and insertion sequences of the SCC*mec* elements found in MRSA but that lack the *mecA* gene itself.[3]

The complexity of the genetics underlying PBP-associated β-lactam resistance is apparent in MRSA. In the presence of methicillin concentrations inhibitory to susceptible staphylococci, MRSA PBP 2A assumes virtually all responsibility for peptidoglycan synthesis, with the resultant production of a matrix of unusual muropeptide compositions. Some MRSA strains encode regulatory sequences for *mecA* termed *mecRI*, the product of which is a transmembrane sensor needed for induction of *mecA* expression in the presence of β-lactam, and an inhibitory controlling sequence (*mecI*).[134] However, the degree of methicillin resistance is not well correlated with the amount of expressed PBP 2A,[62,63] a finding indicating that other cellular factors are important for the production of the resistant phenotype. Transposon inactivation experiments have identified multiple additional sites on the staphylococcal chromosome critical for methicillin resistance. These sequences, termed *fem* (*f*actors *e*ssential for *m*ethicillin resistance) genes, express abundant substrate for PBP 2A that, in turn, is available to compete successfully with methicillin and other β-lactam antibiotics for the PBP 2A active site.[134] Dysfunction of the *fem* genes and absence of these peptidoglycan precursors result in reversion to the methicillin-susceptible phenotype, even in the presence of *mecA* encoded PBP 2A. Similar mechanisms appear to operate in methicillin-resistant, coagulase-negative staphylococci.

MACROLIDES, LINCOSAMIDES, AND SPREPTOGRAMINS

Clinical Relevance

The macrolides are compounds that contain 14-member (e.g., erythromycin and clarithromycin), 15-member (e.g., azithromycin), or 16-member (e.g., spiramycin) lactone rings. Their activity is directed primarily against gram-positive organisms and some gram-negative respiratory tract pathogens. In many bacteria, resistance to macrolides occurs concomitantly with that of the structurally unrelated lincosamides (including clindamycin) and streptogramin B families of antibiotics, two classes with activity also primarily against gram-positive bacteria. Because these three families of antibiotics interact competitively for ribosomal binding, they probably are associated with the same ribosomal site.

Resistance to the macrolides was noted in staphylococcal species soon after the introduction of erythromycin. More recently, however, macrolide resistance in streptococcal pathogens, particularly *S. pneumoniae* and *Streptococcus pyogenes*, emerged and assumed major clinical importance. Macrolide resistance among pneumococci is a result of both international dissemination of resistant clones and horizontal transmission of resistance determinants.[113,334] The late 20th century witnessed dramatic increases in the incidence of macrolide resistance in *S. pneumoniae* in many areas of the world.[146] In Southeast Asia, surveys indicated that nearly 40 percent of pneumococcal isolates were resistant to all macrolide antibiotics, and samplings of organisms from Europe and the Western Hemisphere showed similar but less extreme trends.[146,195] Perhaps most troubling, resistance to macrolides among pneumococci occurred particularly frequently in isolates co-expressing resistance to penicillin and other oral antibiotics.[78,162]

Similar to penicillin-resistant pneumococcus, the prevalence of macrolide-resistant *S. pneumoniae* has been reduced during the first decade of the 21st century by the introduction and widespread administration of the conjugated heptavalent pneumococcal vaccine, which includes serotypes that most commonly express both β-lactam and macrolide resistance.[393] Studies performed in Atlanta, Georgia, before release of the vaccine, for example, documented that 31 percent of pneumococcal isolates causing invasive disease were resistant to erythromycin.[112] Follow-up studies performed after the introduction of the vaccine recorded a drop in incidence of macrolide-resistant invasive pneumococcal disease by more than two thirds.[374] As in penicillin-resistant pneumococcus, this benefit has been partially offset by an increase in the incidence of invasive diseases by macrolide-resistant organisms derived from serotypes not included in the vaccine.[95]

Similar to *S. pneumoniae*, macrolide resistance in *S. pyogenes* has been unevenly distributed geographically.[191] By the start of the 21st century, most surveys in the Western Hemisphere, including the United States, indicated a prevalence of resistance less than 10 percent,[126,285,325,386,418] although the citywide clonal outbreak of macrolide-resistant group A streptococcus experienced in Pittsburgh, Pennsylvania, in 2001 underscored the potential for this phenotype to spread rapidly within a community.[234] Macrolide resistance in *S. pyogenes* is, on average, more prevalent in Europe, but the prevalence there also varies substantially from area to area, ranging (by 2007) from 3 percent in Norway,[220] to 13 percent in Belgium,[226] to more than 20 percent in Spain and France.[21,297] Molecular analysis of macrolide-resistant group A streptococcal isolates from geographically diverse regions suggested that the resistance genes were acquired multiple times by many lineages, some of which then disseminated worldwide.[330]

The increase in macrolide resistance has occurred concomitant with increased worldwide consumption of these compounds for respiratory tract infections beginning in the 1980s,[15,20,50,162,184,354] a finding suggesting a biologic association between these two phenomena. A nationwide survey of macrolide susceptibility among pneumococcal isolates in the United States, for example, documented an increase in erythromycin resistance from 10.6 percent in 1995 to 20.4 percent in 1999, a time when the number of prescriptions for macrolides increased by 13 percent across the board and by 320 percent in pediatric patients.[162] Seppälä and colleagues[354] reported an increase in resistance among *S. pyogenes* isolates in Finland from 5 percent in 1988 to 13 percent in 1990 after national macrolide consumption doubled during the 1980s. In response, a national campaign to reduce macrolide prescribing practices in Finland was launched in the early 1990s, after which macrolide resistance fell by half.[354] A similar campaign in Taiwan yielded similar results.[158]

Although the epidemiologic trends in macrolide resistance are alarming, the clinical consequences of the increases in macrolide resistance among streptococci are largely unknown. Current con-

vention employs an MIC of 4 μg/mL or greater to define resistance. The newer macrolide compounds, however, achieve tissue and intracellular concentrations that are many-fold higher than this designation.[93,276] Italian investigators, for example, noted a very high incidence of erythromycin resistance among group A streptococcal throat isolates, but neither clinical nor microbiologic failures were clearly associated with macrolide treatment.[404] The macrolides do not distribute in high concentrations to the blood compartment, however, and several reports document poor outcomes when this class of drugs is used for bacteremic pneumonia caused by macrolide-resistant pneumococcus.[194,222]

A newer group of related antibiotics, the ketolides, contain chemical modifications to the lactone ring. To date, they have proven in vitro activity against organisms that express high-level macrolide resistance.[94,260] Although the MICs of ketolides to macrolide-resistant organisms are higher than in macrolide-susceptible bacteria, they remain well within the range of concentrations achieved with standard dosing. A report suggesting a link between telithromycin, a prototypical ketolide, and severe hepatotoxicity in adults,[51] however, has slowed the development of this class of drugs for children.

Mechanism of Resistance

Two principal resistance phenotypes to macrolides and related antibiotics have been detected. The first, denoted the *MLS_B phenotype*, is characterized by resistance to all macrolides, regardless of the size of the ring, as well as to the lincosamides and the type B streptogramins. Most organisms expressing the MLS_B phenotype remain susceptible to the combination streptogramins (e.g., quinupristin-dalfopristin).[136,348] The second phenotype, denoted the *M phenotype*, is associated with resistance to the 14- and 15-member macrolides (including erythromycin, azithromycin, and clarithromycin), but not those with 16-member rings. The degree of resistance to the affected macrolides is lower, on average, compared with that seen with MLS_B resistance. Additionally, in organisms with the M phenotype, susceptibility to clindamycin is preserved.[239,380]

Most MLS_B resistance results from methylation of the 23S ribosomal RNA (rRNA) in the 50S subunit of the bacterial ribosome within the peptidyltransferase circle in domain V.[66,172,387,419] The methylases are encoded on transposons, with sequences found both on plasmids and in the bacterial chromosome.[120] Methylation of the 23S rRNA is encoded by a family of related genes labeled *erm* (*e*rythromycin *r*esistance *m*ethylases).[66,172,387,419] Historically, these methylases have been described and named in a haphazard fashion, although some investigators have proposed renaming many of these enzymes using a classification scheme based on genetic homology.[328]

Methylation is both inducible and constitutively expressed. Unlike many other inducible antibiotic-resistance factors, the mechanism of MLS_B resistance induction is at the level of translation, rather than transcription.[417] In the uninduced state, the leader sequence of the mRNA encoding ErmC, one of the methylases found in *S. aureus*, forms two stem loop structures that stall the ribosome's movement along the message, thereby preventing synthesis of the methylase enzyme. The attachment of erythromycin to the ribosome leads to a conformational alternation of this leader sequence that uncovers the appropriate ribosomal binding sites and allows the stalled ribosomes to proceed to translation.[417] Inducible macrolide resistance is detected in the clinical microbiology laboratory by the *double-disk D-test*. In this assay, an erythromycin disk and a clindamycin disk are placed side by side on a lawn of the test organism. Induction of clindamycin resistance in the presence of erythromycin is manifested by increased growth of bacteria on the erythromycin side of the clindamycin disk, producing a D-shaped zone of inhibition. Through the 1990s, greater numbers of *erm*-containing bacteria produced the rRNA methylase constitutively, a consequence of mutation of the leader sequence.[79,385]

In the mid-1990s, macrolide resistance mediated through a genetically transferable efflux pump was identified.[380] Most organisms expressing the M phenotype are resistant through this mechanism. Most macrolide-resistant pneumococci in North America express the macrolide efflux pump, and much of the expansion of macrolide resistance that occurred through the 1990s was the result of the appearance of organisms exhibiting this mechanism.[162,178,218,386] A family of related genes, termed *mef*, encodes the macrolide efflux pumps. The *mef* genes are included on transposons encoding associated functions, in particular an adenosine triphosphate (ATP)–binding protein.[112,113,120,239] As expected, ribosomes isolated from organisms resistant through *mef* genes bind to macrolide antibiotics as readily as do ribosomes from susceptible organisms. Radiolabeled erythromycin is excluded from the intracellular space in *mef*-positive bacteria, a phenomenon that is reversed by compounds that poison ATP-dependent pumps.[380]

Mechanisms of macrolide resistance besides rRNA methylation and efflux pumps have been identified but to date are uncommon. Some organisms modify the antibiotic by hydrolysis, acetylation, phosphorylation, or esterification.[328] Some evidence indicates that some erythromycin resistance is caused by altered ribosomal proteins and results in the production of ribosomes with diminished affinity for drug.[47]

TRIMETHOPRIM AND SULFAMETHOXAZOLE

Clinical Relevance

The combination antibiotic TMP-SMX inhibits bacterial folate synthesis at two successive steps. This mechanism accounted for its broad activity against a wide variety of gram-positive and gram-negative bacteria when it was first introduced in 1968. Despite the dual activity of this combination, resistance to TMP-SMX has risen steadily during the decades of its use and is now commonplace. Acquisition of resistance is potentiated by recent exposure to TMP-SMX.[96,373,428] When resistance occurs, the MIC expressed usually is very high,[159,160] and the affected organisms frequently are co-resistant to multiple other classes of antibiotics. Indeed, TMP-SMX resistance is sufficiently widespread that it precludes the use of the drug as a first-line antibiotic in clinical circumstances in which it was formerly the agent of choice, namely, respiratory tract infections and *Shigella*-associated dysentery. Its utility in urinary tract infection (UTI) also may be limited when the community prevalence of TMP-SMX resistance is sufficiently high. Ironically, its continued activity against CA-MRSA has rejuvenated the use of TMP-SMX among many practitioners as the incidence of infections caused by CA-MRSA organisms has mushroomed.

RESPIRATORY TRACT INFECTIONS (OTITIS MEDIA AND PNEUMONIA)

The frequency of TMP-SMX resistance in organisms causing respiratory tract infections has increased significantly. Among *S. pneumoniae* organisms, resistance to TMP-SMX was identified during the 1990s in many geographic locations, with resistance detected in 12 percent to more than 50 percent of isolates.[76,146,157,167,231,289,377] A worldwide survey conducted in the late 1990s noted the highest incidence of TMP-SMX pneumococcal resistance in the Asian Pacific region and in Latin America.[146] In surveys of U.S. isolates, TMP-SMX resistance is the most common resistance phenotype found in *S. pneumoniae*,[421] although the incidence of resistance varies widely from region to region.[76] TMP-SMX resistance is strongly associated with resistance to other classes of antibiotics commonly used in respiratory tract

infections, particularly penicillin and the macrolides. Among other organisms implicated in respiratory tract infections, TMP-SMX resistance also has been documented with increasing frequency in *H. influenza*, to which resistance ranges between 7 percent in Finland[231] and more than 50 percent in Taiwan.[157] The susceptibility of *M. catarrhalis* to TMP-SMX varies little from region to region. Although most *M. catarrhalis* organisms remain susceptible to TMP-SMX, the MICs cluster near achievable respiratory tract concentrations.[167]

The clinical consequences of TMP-SMX resistance in respiratory tract pathogens are not well defined. Direct evidence of the association between isolation of a TMP-SMX–resistant organism from the middle ear and failure of therapy by TMP-SMX in acute otitis media, for example, is lacking, but such an association is assumed to exist. The issue of the clinical relevance of TMP-SMX resistance in respiratory tract infections is particularly pressing in developing countries, where World Health Organization (WHO) guidelines recommend TMP-SMX as a first-line agent for pneumonia. A comparison of amoxicillin and TMP-SMX for treating pneumonia in Pakistan demonstrated superiority of amoxicillin in producing clinical cure, but treatment failure was not associated with resistance in the infecting organism.[378] These data and others[193,316,332] support the continued use of TMP-SMX therapy of pneumonia in the developing world, as least at present.

SHIGELLOSIS

Resistance of *Shigella* spp. to TMP-SMX rose dramatically during the 1980s in many parts of the world, including Bangladesh,[19] Thailand,[147] Somalia,[40] Israel,[10] and Canada.[138] In these surveys, the incidence of disease from TMP-SMX–resistant *Shigella* increased two- to threefold, to more than half the isolates; by 1998, more than 90 percent of *Shigella* organisms in Thailand,[147] as well as *Shigella* cultured from patients with acquired immunodeficiency syndrome (AIDS) in Kenya,[205] were resistant to TMP-SMX. Many of these *Shigella* organisms express extraordinarily high levels of resistance, with MICs to TMP exceeding 1000 μg/mL. In the United States, TMP-SMX resistance among *Shigella* isolates initially was confined to closed populations.[127] A more recent survey in Oregon, however, indicated that by the late 1990s, the incidence of TMP-SMX resistance among *Shigella* isolates in that state approached 60 percent. Resistant isolates were found disproportionately frequently in migrant workers traveling from Mexico and other areas of Latin America,[322] a finding emphasizing the importance of geographic spread of resistance in modern society. Subsequent surveys performed by the CDC in the early 2000s revealed that TMP-SMX–resistant *Shigella* had spread nationwide, with the prevalence highest in the East and West.[362] The incidence of TMP-SMX resistance in *Shigella* mirrors the increased TMP-SMX resistance among other enteric species as well,[127,401] notably *Salmonella*.[1,127]

TMP-SMX resistance in *Shigella* is virtually always borne on conjugative plasmids, and frequently these plasmids contain resistance determinants to several other antibiotic classes.[40,127,205,217,362,401] Co-resistance to four or more unrelated antibiotics, including β-lactams, chloramphenicol, tetracycline, and the aminoglycosides, is a common finding. Molecular analyses in a given geographic environment usually indicate fluid epidemiology, with multiple dominant chromosomal genotypes containing a variety of resistance plasmids.[27,217]

URINARY TRACT INFECTIONS

Through the 1990s and 2000s, TMP-SMX resistance in urinary tract isolates of *E. coli*, the most prominent pathogen implicated in UTIs, rose to 15 to 25 percent in the developed world and to as high as 60 percent in nonindustrialized countries.[129,130,190,229,438,439] Studies in the 1980s indicated that TMP-SMX–resistant *E. coli* can be transmitted to household contacts.[333] Indeed, one analysis suggested that TMP-SMX–resistant urinary tract isolates from geographically disparate areas of the United States may have emanated from a single clone.[229] Although urinary concentrations of both TMP and SMX are several-fold higher than concomitant concentrations in serum, resistance to TMP-SMX nonetheless is associated with treatment failure in UTIs. Bacterial and clinical response rates to TMP-SMX are approximately 80 to 95 percent in cystitis and pyelonephritis caused by susceptible organisms, but the response falls to approximately 50 percent when the infecting agent is TMP-SMX–resistant.[243,383] Considering all urinary tract pathogens together, however, the clinical and microbiologic response to TMP-SMX is nearly equivalent to comparator agents, and experts continue to recommend this drug as the first-line therapy for uncomplicated UTIs, based on its low cost.[98,153,413] Analyses have indicated that the total expense of treatment of UTIs with TMP-SMX begins to exceed that incurred by therapy with more expensive antibiotics, such as the fluoroquinolones, when the community TMP-SMX–resistance rates of urinary pathogens exceed approximately 20 percent, as a result of the additional expense of clinical treatment failure.[210,383] Alternatives to TMP-SMX also should be considered when the patient possesses risk factors for acquisition of infection with a TMP-SMX–resistant strain, namely, recent hospitalization, diabetes, or therapy with TMP-SMX within the previous 3 months.[153]

COMMUNITY-ASSOCIATED METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS*

Despite the explosive emergence of methicillin resistance in community-associated *S. aureus* infections in the latter half of the 1990s, these organisms have remained nearly uniformly susceptible to TMP-SMX.[29,185,259] Most infections caused by CA-MRSA are skin and soft tissue infections that can be treated without hospitalization, and TMP-SMX offers an inexpensive, oral therapeutic option in this setting. The clinical effectiveness of TMP-SMX in CA-MRSA infection relative to other oral agents is uncertain; indeed, whether any antibiotic is superior to incision and drainage is not clear.[254] Experiential reports, however, support the use of TMP-SMX as a principal or adjuvant therapy for CA-MRSA cellulitis.[382]

Mechanisms of Resistance

In susceptible bacteria, TMP-SMX inhibits sequential steps in the de novo synthesis of folate (Fig. 246–3). SMX inhibits the enzyme dihydropteroate synthetase (DHPS), which catalyzes the conversion of *para*-aminobenzoic acid to dihydrofolate. TMP inhibits the next enzyme in the pathway, namely, dihydrofolate reductase (DHFR), which catalyzes the conversion of dihydrofolate to tetrahydrofolate. The resulting depletion of folate within the bacterium interrupts the synthesis of critical cellular substrates, including purine nucleotides.[331] Eukaryotic DHFR is resistant to the activity of the sulfonamides, and eukaryotic cells do not express DHPS activity at all, thus accounting for the selective activity of these drugs against bacteria.[159,160]

The principal mechanism of resistance to TMP-SMX is alteration of the target enzymes. Altered genes for DHFR with reduced susceptibility to TMP have been identified on the chromosomes of intrinsically resistant organisms from a variety of species,[306] as well as on transferable elements. Many of the transferable resistance genes are encoded on transposons that can shuttle between plasmids and chromosomal DNA. Approximately 20 different transferable *dhfr* resistance genes have been identified.[160] Resistance usually is conferred by a single-point mutation

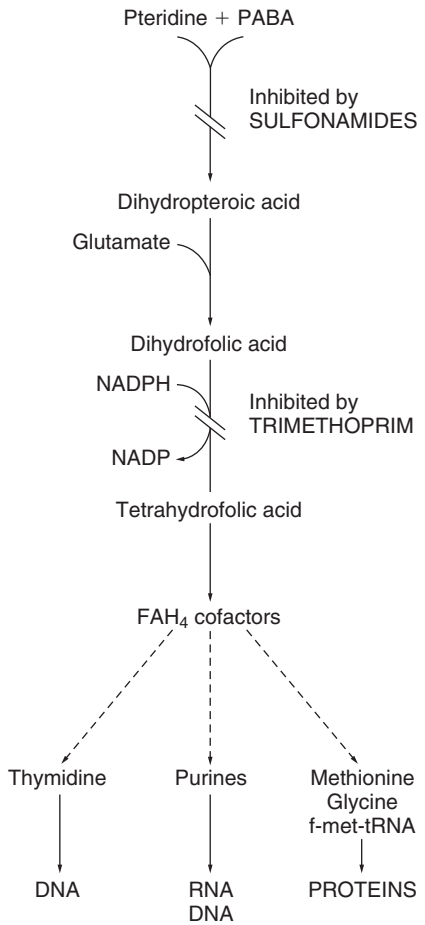

Figure 246–3 Trimethoprim-sulfamethoxazole inhibition of de novo folate synthesis. NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced form of nicotinamide adenine dinucleotide phosphate; PABA, para-aminobenzoid acid.

that results in a disruption of the three-dimensional conformation of DHFR, thereby interrupting a hydrogen bond normally available for binding the antibiotic but leaving the affinity for its natural substrate intact.[61,160,306] These structural changes may occur in concert with mutations of controlling sequences and lead to overproduction of the altered DHFR.[306] Similarly, sulfonamide resistance usually is the result of mutated *dhps* genes. In TMP-SMX–resistant *Neisseria meningitides*, the abnormal chromosomal *dhps* sequence is different compared with that found in susceptible isolates over a large portion of the gene, a finding implying that resistance resulted from a recombination event after horizontal transfer from an unrelated *Neisseria* spp.[313] Similar recombination events may account for sulfonamide resistance in pneumococcus. In other species, the abnormal *dhps* gene is the result of a single amino acid mutation, and the resistance gene is encoded on a transmissible transposon,[284] frequently linked to a *dhfr* resistance gene.[160]

Some organisms, particularly *P. aeruginosa*, are intrinsically resistant to TMP-SMX on the basis of the expression of multidrug efflux pumps.[200] The same pumps are responsible for resistance to a wide variety of other antibiotics, including fluoroquinolones, chloramphenicol, and β-lactams. Homologous pumps occasionally have been identified in other gram-negative species as well. Finally, in some isolates, the mechanism of resistance to TMP-SMX is not attributable to any of the previously listed mechanisms and remains undefined.[160,284]

AMINOGLYCOSIDES

Clinical Relevance

The aminoglycosides are parenteral antibiotics that are employed primarily for serious infections in hospitalized patients. Resistance to aminoglycosides is encoded on transmissible elements that have disseminated throughout the world, both among gram-negative and gram-positive pathogens. Among gram-negative species, resistance to the aminoglycosides varies widely according to geographic location.[347,349,402] Surveys recording longitudinal trends in susceptibility patterns of hospital-acquired isolates between the 1990s and 2000s, however, documented that, relative to other agents, the increase in resistance to the aminoglycosides has been slow, and resistance has decreased in some areas.[18,105,188] Surveys of hospital isolates conducted throughout Europe and North America in the late 1990s and early 2000s indicated resistance rates of 1 to 15 percent among enteric bacilli and 10 to 50 percent among non–lactose fermenters.[100,181,272,347,349,403] In almost all cases, the incidence of resistance was lowest to amikacin.[105,273,347,349,402] Aminoglycoside resistance occurs with much higher frequency among gram-negative organisms with coexisting resistance to other antibiotics.[13,181,261] Not surprisingly, fecal colonization with aminoglycoside-resistant bacilli is an uncommon finding among healthy persons. Although resistance to some of the older aminoglycosides, such as streptomycin and kanamycin, has disseminated into the community, carriage of organisms resistant to gentamicin is a rare finding in ambulatory populations.[214,281,312]

Few data exist recording the endemic incidence of aminoglycoside resistance in gram-negative organisms specifically among hospitalized children. In a survey of pediatric patients in an ICU in Cleveland in the mid-1990s, approximately 10 percent of patients were colonized with a tobramycin-resistant, gram-negative bacillus before discharge.[394] A survey in the neonatal ICU in the same institution, where gentamicin frequently was employed, recorded an approximate 5 percent endemic incidence of colonization with gentamicin-resistant bacilli.[391] However, outbreaks caused by gram-negative rods resistant to aminoglycoside have been reported from numerous neonatal ICUs since the early 1980s.[54,175,249]

Although the aminoglycosides have no utility in the treatment of infections with gram-positive organisms when used alone, they improve bacterial killing when they are employed in combination with cell wall–active agents. For this reason, these drugs frequently are added to β-lactam agents or vancomycin in the treatment of difficult or persistent infections caused by *S. aureus*, coagulase-negative staphylococci, or enterococci. However, resistance to aminoglycosides has been documented in all these gram-positive microorganisms. Surveys in Europe indicated 20 to 30 percent resistance to aminoglycosides among hospital isolates of *S. aureus*.[347] The occurrence of aminoglycoside resistance is many-fold higher among MRSA isolates than in bacteria that are methicillin-susceptible.[65,100] As with gram-negative bacilli, aminoglycoside resistance among *S. aureus* isolates varies greatly from region to region,[347] a finding correlating largely with the incidence of MRSA. Aminoglycoside resistance in coagulase-negative staphylococci also is a common finding. As with *S. aureus*, resistance is much more frequent among organisms that are methicillin-resistant (seen in more than half of the isolates tested from centers around the world), as opposed to the unusual hospital-acquired methicillin-susceptible, coagulase-negative staphylococci, for which resistance to aminoglycosides is recorded in fewer than 10 percent.[73,198,347]

Since the 1970s, proliferation of enterococci that express MICs to the aminoglycosides exceeding 2000 μg/mL has occurred, thus rendering the organisms resistant to all synergistic effects when the aminoglycosides are used with a cell wall–active

agent.[91,293] Such high-level aminoglycoside resistance has been recorded in approximately 30 percent of enterococcal samples from hospitals throughout the world.[223,361,436] Organisms expressing high-level aminoglycoside resistance frequently test highly resistant to ampicillin as well.[293] High-level aminoglycoside resistance also is a common finding in vancomycin-resistant enterococci, especially those identified in the United States.[223]

Mechanism of Resistance

The aminoglycosides are hydrophilic sugars composed of one to four rings, with amino groups substituting some of the hydroxyl groups at sites that vary from drug to drug. The amino groups render the drugs polycationic and allow them to bind with high affinity to selected sequences of nucleic acid.[319] The antibacterial activity of these drugs results from their binding to specific sites on the 16S ribosomal RNA that, in turn, interferes with the recognition of transfer RNA during translation and the translocation of tRNA to the peptidyl-tRNA site. Three-dimensional studies of the aminoglycoside-rRNA interaction suggest that this interference is the result of conformational changes in the shape of the rRNA.[204] The affinity of the aminoglycosides to ribosomal RNA is 10-fold higher in prokaryotes than in eukaryotes.[318]

The principal mechanism of resistance to the aminoglycosides is through the expression of aminoglycoside-modifying enzymes (Table 246–3). Many of these enzymes are encoded on transposons that reside in plasmids along with other resistance determinates. Three groups of modifying enzymes have been identified, namely, acetyltransferases (AAC), nucleotidyltransferases (ANT), and phosphotransferases (APH), each of which adds its respective moieties to selected side groups of the aminoglycoside sugar rings.[204,356] Researchers have hypothesized that these genes originated from bacterial housekeeping enzymes and then expanded to include aminoglycosides among their substrates through mutational evolution.[356] Transcription of these resistance genes is constitutive. Most members of each group of modifying enzymes share structural homologies, with minor amino acid variations resulting in specific substrate profiles.[356] The enzymes are subdesignated by the site they modify and by the resistance profile they confer (Fig. 246–4). Thus, for example, AAC(6′)-II denotes an AAC that substitutes an acetyl group for the amino group at the 6′-site of the aminoglycoside, with a resulting resistance pattern II (including, in this case, resistance to gentamicin, tobramycin, and sisomicin, but not amikacin). At least one enzyme has been discovered that possesses both AAC and APH activity [designated AAC[6′]-Ie-APH[2″]-Ia].[48,198,356,436] The modifications conferred by these enzymes result in altered electrostatic qualities of the antibiotic and consequent reduced ability to interact with rRNA.

The pharmaceutical industry has altered the structure of the aminoglycoside compounds to render them poorer substrates for the modifying enzymes. This exercise has been most successful in the development of amikacin, a kanamycin derivative with a relatively long amino hydroxybutyrate added at the 1 position.[255] This substitution does not interfere with rRNA binding but protects the compound from alteration by many of the modifying enzymes. Consequently, organisms resistant to gentamicin, for example, may remain susceptible to amikacin. Not all positions are protected, however, and amikacin-resistant phenotypes are conferred by certain modifying enzymes, most notably AAC(6′)-I.[255]

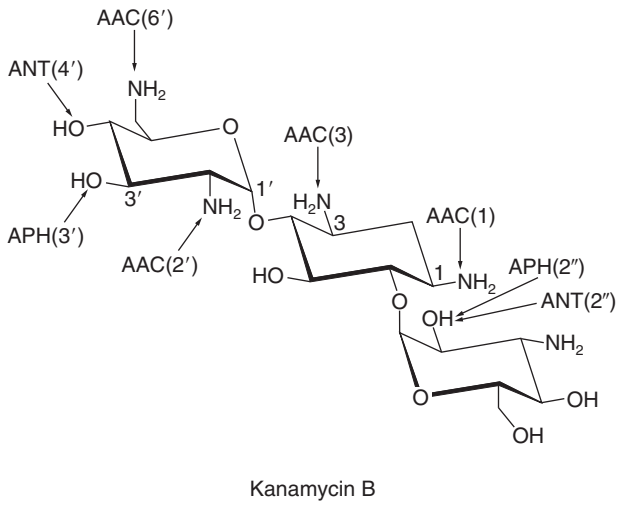

Figure 246–4 Sites of modification on kanamycin B by various aminoglycoside-modifying enzymes. The *arrows* point to the sites of modification by the specific enzymes, namely, acetyltransferases (AAC), phosphotransferases (APH), and nucleotidyltransferases (ANT).

Moderate-level resistance to the aminoglycosides has been achieved by some bacteria through decreased uptake of drug.[255] This mechanism has been noted most frequently in *Pseudomonas*. To date, modifications of the ribosomal binding sequences have been identified only rarely as a mechanism of resistance to the aminoglycosides.[255] The sequences involved in aminoglycoside binding likely are sufficiently critical to the survival of the organism that mutations within this site usually are fatal.[204]

GLYCOPEPTIDES AND OTHER ANTIBIOTICS DIRECTED AGAINST GRAM-POSITIVE BACTERIA

Clinical Relevance

Vancomycin is one of two glycopeptides available for clinical use. The second, teicoplanin, is licensed in Europe but not the United

States. Since the late 1980s, the prevalence of vancomycin resistance in organisms belonging to the genus *Enterococcus* (*vancomycin-resistant enterococci*, or VRE) has risen alarmingly. VRE frequently are highly resistant to many other antibiotics as well, and reported mortality from infection caused by these resistant organisms exceeds 30 percent.[71,262,359]

The appearance of VRE occurred coincident with an increased use of vancomycin in the United States and the use of the glycopeptide avoparcin as a growth promoter in animal feed in Europe, a practice banned by the European Union in 1997.[265] The incidence of VRE colonization and disease is much more prevalent in the United States than in other areas of the world,[72,223] but these organisms are present globally.[156,422] Approximately 10 to 20 percent of U.S. enterococcal isolates investigated in surveys in the late 1990s and early 2000s were resistant to vancomycin.[72,223] A disproportionate number of VRE in the United States are found in patients hospitalized in ICUs in large urban medical centers, especially among persons with prolonged hospitalizations and severe disease.[140,223,224,359] Additionally, a high incidence of VRE is seen among oncology patients,[90,238] transplant recipients,[89,251] and those with chronic renal failure who are receiving dialysis.[11,99,407] Some surveys have documented VRE among adults in chronic care facilities, who exported the organism into the community after acquisition in an acute care setting.[395] By contrast, the prevalence of VRE is relatively low in U.S. hospitals serving rural areas.[310,376]

Surveys of European centers also indicate a concentration of VRE in ICUs but in substantially smaller numbers compared with the United States.[350] A survey of resistance patterns among thousands of European hospital isolates collected during the early 2000s indicated that only 6 percent of enterococci expressed resistance to vancomycin.[337]

The genetic machinery conferring vancomycin resistance in *Enterococci* is complex, and resistance does not develop de novo by spontaneous mutation under antibiotic pressure.[265] The initial event in the appearance of VRE in a given unit is the importation of the resistant organism into the environment. The association between antecedent treatment with vancomycin and acquisition of VRE has been documented by many,[104,359] but not all, investigators.[38,81] Some researchers have established a stronger connection between the appearance of VRE and the use of extended-spectrum cephalosporins[24,283] and antibiotics with potent anti-anaerobic activity.[224] A study conducted in a Veteran's Affairs hospital reported that the stool density of VRE in patients who were treated with anti-anaerobic antibiotics increased exponentially, whereas the density decreased in those whose antibiotics had limited anaerobic activity.[80] The principal role of antecedent antibiotic exposure in VRE may be to open up ecologic niches in the gastrointestinal tract that allow a stable presence of VRE once the patient is exposed to the resistant organism.

Horizontal transmission of VRE is prominent in any closed environment and may outweigh antecedent antibiotic exposure as the principal determinant for acquisition.[24,140] Patient-to-patient spread in an ICU, presumably through the hands of caregivers, has been documented repeatedly, as has contamination of the immediate environment of the VRE-positive patient.[283,364] Indeed, perhaps the most significant risk factor for acquisition of VRE is the number of neighboring patients colonized with the organism at the same time.[12,24,60]

In many U.S. ICUs, multiple clones of VRE are present at any given moment, some imported into the unit and others spread after admission has occurred,[283] thus rendering control and containment very difficult to achieve. Extreme barrier isolation precautions, including surveillance for VRE on admission to a given unit, single-room isolation with dedicated medical instruments, and strict use of gowns and gloves, frequently are necessary to contain VRE once it has established an endemic presence, and even then these measures may not be entirely effective.[174,207,364]

With some exceptions,[124,250,396] to date VRE have been less a threat to pediatric patients than to adults, despite the wide use of vancomycin among hospitalized pediatric patients and their geographic proximity in many hospitals to sick adults colonized with the organism. Several outbreaks of VRE in the newborn nursery have been reported,[213,227] but they have resulted primarily from dissemination of a single clone within the unit and have been successfully eradicated with implementation of relatively simple barrier isolation and cohorting measures.

In the latter half of the 1990s, a second phenomenon involving reduced susceptibility to vancomycin was identified, namely, vancomycin-intermediate *S. aureus* (VISA).[103,367] These organisms express MICs to vancomycin in the intermediate range of approximately 8 μg/mL. Virtually all such isolates are coresistant to methicillin, but several have retained susceptibility to numerous other antimicrobial agents. To date, VISA isolates have been identified primarily in patients who have been treated with prolonged courses of vancomycin for MRSA infection. Disproportionate numbers of these patients have been undergoing dialysis.[367] Eradication of VISA has been difficult but achievable with high doses of vancomycin in combination with other antibiotics.[103,367] At present, infection with VISA is a rare occurrence, both in adults and in children.

In 2002, the first two cases of true vancomycin-resistant *S. aureus* (VRSA) in the United States were reported, one from Michigan and the other from Pennsylvania (MIC to vancomycin >128 μg/mL and =32 μg/mL, respectively).[398,399] Both patients were suffering from chronic foot ulcers from which the organisms were isolated. In both instances, the bacteria were susceptible to alternative agents, and the patients remained clinically stable. The potential for VRSA to emerge as a major public health hazard is substantial, but subsequent cases have been rare.[400]

Mechanisms of Resistance

By 2006, six genotypes for vancomycin resistance in *Enterococci* had been defined, labeled VanA through VanE and VanG, each associated with phenotypic nuances.[57,265] These genotypes differ in the species of enterococci affected, the relative resistance conferred to vancomycin and teicoplanin, and whether they are inducible or constitutively expressed (Table 246–4). The VanC phenotype is distinct from the others in that it is an intrinsically expressed, species-specific product of *Enterococcus gallinarum*, *Enterococcus casseliflavus*, and *Enterococcus flavescens*.[268] The other vancomycin phenotypes are acquired, although VanD resistance and VanE resistance are not readily transferable.

In susceptible bacteria, the glycopeptides are large molecules that interfere with cell wall peptidoglycan synthesis at a point proximal to that targeted by the β-lactam antibiotics. Specifically, the synthesis of peptidoglycan in vancomycin-susceptible bacteria includes the incorporation of a D-alanyl-D-alanine dipeptide onto the carboxyl end of the growing glycopeptide chain to form a pentapeptide precursor. The pentapeptide is translocated from the cytoplasm to the outer surface of the bacteria.[57] The D-Ala-D-Ala carboxy-terminal end of the pentapeptide is critical for the continued synthesis of the peptidoglycan chain and, ultimately, for peptidoglycan cross-linking and the formation of a stable cell wall. Vancomycin, which never enters the cell, binds to the D-Ala-D-Ala moiety of the pentapeptide through several hydrogen bonds along the outer surface of the cell wall,[16] thereby blocking synthesis of the remaining macromolecule.

The molecular basis for vancomycin resistance results from the complex, coordinated interactions of multiple genes usually encoded on a single genetic element. These interactions have been defined best for the VanA phenotype, although

genetic homologues are found in organisms expressing the other vancomycin-resistant phenotypes. The genetic machinery for VanA resides on the 10,851-bp transposon Tn*1546*.[7,409] The molecules central to conferring the resistant phenotype are encoded by the contiguous genes labeled *vanH*, *vanA*, and *vanX*, all of which are essential for expression of vancomycin resistance. The *vanA* gene encodes a ligase that, unlike the native enterococcal ligase, produces an abnormal D-alanyl-D-lactate dimer over the normal D-alanyl-D-alanine.[32] This process results in the formation of the peptidoglycan precursor uridine diphosphate–MurNAc–L-Ala-D-Glu-L-Lys-D-Ala-D-Lac, the C-terminus of which has profoundly reduced affinity for vancomycin.[33] The homologous ligase in VanC-, VanE-, and VanG–expressing organisms synthesizes D-Ala-D-Ser (see Table 246–4) with similar consequences.[57,265] VanH catalyzes the reaction taking pyruvate to D-Lac and increases the availability of this substrate to VanA for production of the D-Ala-D-Lac dimer.[33] *vanX* and a second gene labeled *vanY* encode a cleaving enzyme for the D-Ala-D-Ala dipeptide, thus reducing the natural cellular substrate for the D-Ala-D-Ala adding enzyme and resulting in greater relative incorporation of D-Ala-D-Lac into the peptidoglycan precursor.[57,323]

The *vanS* and *vanR* genes included on the same vancomycin-resistance transposon regulate expression of resistance. The products of these genes are homologous to other compounds of so-called two-component regulatory systems.[397] Ultimately, the result is transcription of the resistance genes in the presence of vancomycin.[57] The functions of the last two gene products, VanY and VanZ, are not essential for expression of the resistant phenotype.[8,9]

Between 2002 and 2004, five adult patients were described who had fully vancomycin-resistant MRSA infections from *S. aureus* harboring the TN*1546* transposon found in VRE.[8,9,398-400] This finding indicated that true VRSA could result from the conjugal transfer of the vancomycin-resistance transposon from VRE to MRSA, a phenomenon that can be replicated in vitro.[274] By contrast, VISA isolates do not contain the resistance genes found in VRE; rather, these isolates acquire unusual extracellular material around the cell wall as detected by electron microscopy.[34,367] This layer represents accumulated peptidoglycan with reduced levels of cross-linking, thereby exposing an excess of D-Ala-D-Ala moieties that bind to vancomycin before it can reach the cell wall.[410] Other vancomycin-resistance phenomena in *S. aureus* have been described and include those in which subpopulations express MICs two- to eightfold higher than those in the parent population (termed *heteroresistance*),[103,183] as well as those in which *S. aureus* can be inhibited but not readily killed by vancomycin (termed *tolerance*).[240] Some investigations indicated that isolates of *S. aureus* expressing vancomycin heteroresistance develop into VISA with continued exposure to the drug.[410]

RESISTANCE TO OTHER ANTIBIOTICS USED FOR GRAM-POSITIVE BACTERIAL INFECTIONS

Two antibiotics introduced in the early 2000s, namely, linezolid and daptomycin, were developed to address the increasingly important problem of antibiotic-resistant, gram-positive pathogens, especially VRE and MRSA. In both instances, the antibiotic represented a novel class of molecules, in the hope that resistance would be slow to develop.

Linezolid, the first of the oxazolidinone antibiotics, has activity against all important human gram-positive pathogens, including MRSA, VISA, and VRE. The molecular target of the oxazolidinones is domain V of the 23S rRNA of the 50S bacterial ribosomal subunit. Binding to this domain results in the inhibition of the initial steps of translation.[381] Linezolid's binding site is unique to the oxazolidinones, and cross-resistance to other antiribosomal antibiotics does not occur. Because the oxazolidinones are entirely synthetic, likely no significant natural resistance to this class of drugs existed before the introduction of linezolid.[253] To date, resistance to linezolid in vivo has been a rare occurrence. Multinational surveys conducted throughout the first decade of the 2000s have identified remarkably few linezolid-resistant organisms, despite the widespread use of the agent.[68,179,273] The few linezolid-resistant clinical isolates that have been encountered have been derived primarily from enterococci and *S. aureus*, usually after prolonged exposure to drug.[25,423] All linezolid-resistant organisms possess a mutation in the gene encoding domain V of the 23S rRNA.[253] Most bacteria have multiple copy numbers of this gene. The degree of resistance is gene-dose–dependent, such that the MIC of linezolid usually remains in the susceptible range after a single mutation occurs but increases incrementally as each allele is affected.[253]

Daptomycin, a fermentation product of *Streptomyces roseoporus*, is a unique antimicrobial with activity against a full range of gram-positive bacteria. The compound is a cyclic lipopeptide that inserts into the lipid bilayer on the bacterial cell surface. In the

presence of calcium, this event disrupts the transmembrane electrical potential with a secondary interruption of ATP and macromolecular synthesis.[136,372] As with linezolid, laboratory surveys of large numbers of gram-positive clinical isolates from many areas of the world indicate that daptomycin resistance is rare.[335,336] Soon after daptomycin was introduced in the early 2000s, however, several cases were reported documenting the emergence of *S. aureus* with reduced susceptibility to daptomycin during prolonged therapy.[141,230,236] In these cases, the infection emanated from a bony or endovascular focus into which penetration of the drug may have been limited. The mechanism of daptomycin resistance remains undefined. Some investigators mapped the resistance phenotype to selected genetic foci in *S. aureus*, at least one of which encodes a protein important in maintaining the bacterial cell membrane.[107] One report correlated vancomycin-intermediate resistance in *S. aureus* with reduced susceptibility to daptomycin,[59] and the investigators hypothesized that the accumulated molecules surrounding the cell wall in VISA protected the bacteria from the effects of daptomycin much as it does with vancomycin.

QUINOLONES

Clinical Relevance

The quinolone family of antibiotics possesses activity against a broad variety of microorganisms. As of the early 21st century, the quinolones had not been labeled for pediatric use. However, the safety profile in children of the more recently developed quinolones (i.e., the fluoroquinolones) is similar to that recorded in adults,[114,173,344] and this class of antibiotics has been effectively employed in selected children with serious infections caused by bacteria resistant to alternative agents. The following subsections discuss clinical circumstances in which quinolone resistance is relevant to pediatric practice.

CYSTIC FIBROSIS

The lungs of patients with cystic fibrosis (CF) are chronically infected early in life, primarily with *S. aureus* and later with *P. aeruginosa*. Exacerbations of pulmonary symptoms are treated effectively with antibiotics directed against these microorganisms. Ciprofloxacin represents the first oral agent with significant anti-*Pseudomonas* activity and manifests potency generally superior to that of the other fluoroquinolones.[304] As a result, experts in many centers treat patients with CF with ciprofloxacin, even when the recipients are younger than 18 years of age.[114] In most circumstances, pediatric patients with CF treated with ciprofloxacin have experienced improvement in their respiratory status.[345]

Pseudomonas surveys conducted with organisms derived from patients with CF as well as those without CF indicated susceptibility to ciprofloxacin in approximately 50 to 90 percent of strains; CF isolates tended to express resistance more frequently than did other isolates.[39,102,123,143,232,340,358] Several investigators documented that decreased susceptibility of *Pseudomonas* lung isolates to ciprofloxacin occurs frequently during the course of ciprofloxacin treatment in patients with CF.[82,371] Indeed, high proportions of *Pseudomonas* strains infecting the lungs of patients with CF are "hypermutators," particularly prone to spontaneous mutation resulting from defects in genetic repair mechanisms,[280] that allow the ready emergence of antibiotic resistance. However, as a general rule, patients who improve clinically during therapy for an acute pulmonary exacerbation do not eradicate the infecting organisms, and the importance of emergence of resistant bacteria during therapy versus any of the commonly employed antibiotics is uncertain, as long as the infecting organisms were susceptible initially.[365] Moreover, frequently the *Pseudomonas* reverts back to a quinolone-susceptible phenotype several weeks after treatment with ciprofloxacin has been completed.[75,82] As a result, ciprofloxacin currently appears to be a useful option for patients with CF who have worsening pulmonary disease, if at least one of the organisms in the initial sputum culture is susceptible.

The usefulness of ciprofloxacin in the patient with CF who is infected with *S. aureus* also probably depends on the susceptibility of the pre-treatment isolates. A worldwide survey conducted in the late 1990s indicated that most methicillin-susceptible strains of *S. aureus* also were susceptible to ciprofloxacin and other fluoroquinolones. However, the fluoroquinolone susceptibility among methicillin-resistant strains was less than 20 percent, and susceptibility was extraordinarily low to ciprofloxacin in particular.[102,128,151]

Enteric Gram-Negative Bacilli: Uropathogens, Nosocomial Bacteria, and Agents of Bacterial Enteritis

Quinolone resistance in enteric gram-negative rods, particularly among uropathogens, has been an uncommon occurrence in North America. Studies of enteric urinary tract isolates in the United States and Canada documented susceptibility rates to ciprofloxacin of 95 percent or greater during the 1990s and 2000s among nonelderly patients,[438] a finding supporting the effectiveness of quinolones for community-acquired cystitis and uncomplicated pyelonephritis.[86,98,129,130,210,243,383] In contrast, in some regions of Europe, the incidence of quinolone resistance among uropathogens has increased as administration of this class of antibiotics has become more widespread.[110,122,155] A 1998 survey of urinary tract isolates from Latin America indicated an even more dramatic occurrence of quinolone resistance: 22 percent of *E. coli*, 30 percent of *P. mirabilis*, and more than 35 percent of *Enterobacter* were ciprofloxacin-resistant.[110] Quinolone resistance in gram-negative urinary pathogens frequently is associated with resistance to other classes of antibiotics as well.[189] Consequently, several experts continue to recommend TMP-SMX over the fluoroquinolones as the first-line agent for uncomplicated UTIs, because clinical and microbiologic efficacy is nearly equivalent for the two classes of drugs, and routine use of quinolone will needlessly promote quinolone resistance.[98,153,413]

The quinolones traditionally have been mainstays of treatment for nosocomial infections in adult patients with severe illness. During the late 1990s and early 2000s, however, quinolone resistance in nosocomial gram-negative pathogens increased in many areas of the world among both Enterobacteriaceae and non–lactose fermenters.[105,181,188,261,273] In several instances, quinolone resistance in gram-negative bacilli increased more rapidly than any other resistance phenotype.[105,181] Many of these hospital-acquired pathogens co-express ESBLs and other resistance determinants.[6,30,292]

Antibiotic therapy, including treatment with quinolones, for bacterial enteritis usually is not indicated.[425] That said, with the exception of *Campylobacter*, most agents that cause bacterial enteritis have remained susceptible to the quinolones by in vitro testing,[121] although epidemic strains of both *Shigella* and *Salmonella* expressing quinolone resistance have been identified in Asia.[109,295,384] *Salmonella typhimurium* DT104, which spread rapidly throughout Europe and the United States in the late 1990s, is resistant to nalidixic acid, but most isolates (except for some identified in the United Kingdom) are susceptible to the newer fluoroquinolones.[108,121,142,257] Similarly, surveys of other non-*typhi Salmonella* conducted in the early 2000s indicated that few were ciprofloxacin-resistant, although as many as one fifth of the strains had reduced susceptibility to the drug.[131,233,375]

In contrast to resistance among other enteritis-associated bacteria, quinolone resistance among *Campylobacter* isolates from many parts of the world has become prominent and high level.[147,171,302,427] *Campylobacter* can acquire quinolone resistance

shortly after exposure to the antibiotic. Indeed, clinical relapse with quinolone-resistant organisms after therapy for *Campylobacter* enteritis is relatively common.[302,427] The introduction of quinolones into poultry feed for animals bred for food has exacerbated the spread of *Campylobacter* resistance in humans.[271,366] In chickens obtained from several different supermarkets in Minnesota in the mid-1990s, nearly 90 percent of samples were culture-positive for *Campylobacter*, and approximately 20 percent of these samples were resistant to ciprofloxacin.[366] These circumstances prompted a Food and Drug Administration ruling withdrawing the use of quinolone in poultry in 2005. It is likely, however, that quinolone-resistant *Campylobacter* has found a stable ecologic niche in both animals and humans and will continue to be encountered despite this intervention.[271] Unlike most other bacteria, *Campylobacter* becomes highly resistant to the quinolones after a single mutation,[119,412] so most quinolone-resistant clinical isolates demonstrate MICs of 32 μg/mL or more, much higher than the conventional cutoff for defining quinolone resistance.

COMMUNITY-ACQUIRED RESPIRATORY TRACT INFECTIONS

The applicability of quinolones to respiratory tract infections has been shadowed by the marginal activity of the first modern quinolones, namely, ciprofloxacin, ofloxacin, and norfloxacin, against *S. pneumoniae*. MICs of these antibiotics against most clinical isolates of *S. pneumoniae* average 1 to 2 μg/mL, concentrations that are close to those achievable in bronchial secretions.[304] Several reports of clinical treatment failures were reported in which ciprofloxacin was administered in pneumococcal disease in the respiratory tract.[201,211,296] Moreover, even when *S. pneumoniae* was the intended target of therapy, the wide use of the early quinolone agents in treating community-acquired infections during the 1990s resulted in the inadvertent exposure of respiratory tract colonizers, including *S. pneumoniae*, to these agents; the result was an even greater, albeit gradual, increase in the MICs of community-acquired *S. pneumoniae* isolates to ciprofloxacin.[43,97,177,339] By the mid-2000s, surveys recorded a prevalence of ciprofloxacin resistance (MIC ≥ 4 μg/mL) in *S. pneumoniae* of approximately 2.5 percent in the United States,[78,326] 4 percent in Canada,[2] and 15 percent in Italy.[69]

Most of the more recently introduced fluoroquinolones are substantially more potent against *S. pneumoniae* than is ciprofloxacin[203] and express MICs that are easily achieved in the respiratory tract. Usually, susceptibility is maintained, even in isolates resistant to the older quinolone agents.[180,304,327] However, MICs against the newer quinolones roughly correlate with those expressed against ciprofloxacin.[43,177,180,327] Consequently, clinically relevant resistance also has begun to emerge against these newer agents, particularly levofloxacin.[2,69,308,326] To date, susceptibility of other respiratory tract pathogens, including *H. influenzae*, *M. catarrhalis*,[22,166,304] and the bacterial agents causing atypical pneumonias, remains very good to all the fluoroquinolones, although exceptions, particularly in *Haemophilus* spp.,[269,435] have been reported.

Mechanisms of Resistance

The two principal molecular targets of the quinolone antibiotics are the topoisomerases DNA gyrase and topoisomerase IV. These enzymes mediate the three-dimensional topologic configuration of the bacterial duplex DNA ring during cell division and transcription and allow the repair and replication of nucleic acid and the separation of daughter chromosomes in the cramped intracellular environment to occur.[139,148] Several reactions have been identified that are mediated by these two bacterial DNA topoisomerases, including negative supercoiling and catenation.[149,379] Both DNA gyrase and topoisomerase IV are composed of two nonidentical subunits. In DNA gyrase, these subunits are labeled GyrA and GyrB, which are constructed into an A_2B_2 tetramer.[149,379] Quinolones bind to the GyrA subunit of the DNA gyrase-DNA-ATP complex and prevent further progress of the enzyme along the nucleic acid.[149] Bacterial cell death is enhanced by the release of toxic DNA ends from the quinolone-gyrase DNA complex.[139] Topoisomerase IV is composed of two equivalent subunits, labeled ParC and ParE, which share sequence homologies to GyrA and B, respectively.[150]

Quinolone resistance is conferred through several molecular mechanisms. Most organisms resistant to the fluoroquinolones demonstrate one or more mutations in DNA gyrase, topoisomerase IV, or both. Resistance to quinolones among gram-negative bacilli usually is mediated through mutations in DNA gyrase, whereas resistance in gram-positive organisms is the result of alterations of topoisomerase IV.[139,288,443] However, this pattern varies from organism to organism (e.g., the primary target in *S. pneumoniae* appears to be DNA gyrase) and from quinolone to quinolone.[139,150] In gram-negative bacilli, most first-step resistance-conferring mutations occur in *gyrA*, the gene encoding the GyrA subunit. These mutations are clustered in a segment termed the *quinolone-resistance determining region* (QRDR).[303,342,433,434] Hybrid DNA gyrase molecules composed of the A subunit from a resistant bacterial strain and the B subunit from a susceptible isolate confer quinolone resistance.[37] Within the QRDR, most mutations have involved the substitution of a serine for a bulkier, nonpolar amino acid at a single, specific site. This mutation, first identified in *E. coli*,[405,433] has been documented since in a variety of organisms.[64,164,202,258,314] Other amino acid substitutions near this site also have been described, with multiple-site mutations resulting in increased quinolone resistance compared with a single mutation alone.[405] Mutations of the GyrB subunit, which result in a quinolone-resistant phenotype, also have been identified. In general, mutations affecting the GyrB subunit result in lower levels of resistance than those noted with GyrA.[434] As with GyrA mutations, those affecting GyrB preferentially localize to specific amino acids.[434]

In most quinolone-resistant, gram-positive organisms, mutations of topoisomerase IV occur at locations that are the equivalent to those noted in DNA gyrase. First-step mutations most frequently are noted in *parC*, which, like *gyrA*, contains a hot-spot segment around which most resistance-conferring mutations occur.[149,150,303] *GyrA* mutations in these organisms frequently are clinically silent unless they occur concomitantly with a mutation in *parC*.[149]

Three additional mechanisms of quinolone resistance, which may appear together and in conjunction with a topoisomerase mutation in the same cell, have been identified. Two of these additional mechanisms result in diminished intracellular accumulation of drug. The first mechanism involves decreased entry of antibiotic into the cell secondary to alterations in porin composition, a mutation that generally results in only moderate drug resistance and that affects individual quinolones differentially, depending on their hydrophilicity.[342] Particular attention has centered on alterations in outer member protein F (OmpF).[152,440] This mutation, identified principally in *E. coli*, frequently is associated with resistance to other classes of antibiotics as well, including chloramphenicol, tetracycline, and some of the β-lactams. The diminished expression of OmpF in these resistant isolates does not appear to result from mutations in the corresponding structural gene or its regulatory sequences. Rather, the decreased expression of this outer-membrane protein is mediated through the enhanced expression of the gene *micF*, which transcribes an antisense RNA complementary to the 5′ end of the *ompF* message,[5] thereby destabilizing its binding to the ribosome. Occasional mutants involving additional strains of Enterobacte-

riaceae have demonstrated other alterations in outer-membrane porin composition.[37]

In the second mechanism, many quinolone-resistant species mediate their resistance through increased drug efflux.[215,216,235] Both bacterial and eukaryotic cells normally encode several efflux pumps that provide protection from a range of potential exogenous toxins.[294] The overexpression of an efflux pump resulting from the mutation of a controlling sequence accounts for reduced susceptibility to quinolones in many clinical isolates.[168,235] Individual efflux pumps select substrates based on their physical chemical properties (e.g., hydrophobicity and net charge), rather than their gross structural similarities; therefore, the various quinolone compounds, which differ from one another regarding these properties, may be differentially susceptible to organisms expressing these pumps.[294]

The gene encoding the quinolone efflux pump in *S. aureus*, labeled *norA*,[432] has been cloned and sequenced. Transformation of susceptible bacteria with the putative gene results in a resistant phenotype, for which resistance can be abolished by the addition of inhibitors of energy-dependent cellular pumps.[432] This pump, however, appears to be able to transport only hydrophilic quinolones; intracellular accumulation of the hydrophobic drug sparfloxacin, for example, is unaffected.

A range of additional genes encoding efflux pumps capable of producing quinolone resistance has been identified in other species, such as *prmA* in *S. pneumoniae*,[303] *acrAB* in *E. coli*,[168,228] and the *mexAmexB-oprM* complex in *P. aeruginosa*.[237] This third complex gene encodes components that transport the drug through both the cell wall and across the periplasmic space, as well as an outer-membrane protein.[294] Most of these pumps are able to extrude a wide variety of exogenous substances, such as detergents, dyes, and other antibiotics, from the bacterial cytoplasm.[168] Therefore, reduced susceptibility to quinolones may be selected by exposures unrelated to the quinolones themselves.

The first decade of the 2000s has witnessed the rapid emergence of transmissible plasmid-mediated quinolone resistance, the third mechanism. All previously defined mechanisms of quinolone resistance were chromosomal. Organisms exhibiting the transmissible mechanism have been identified in Asia, Europe, and North America.[329] The products encoded by these plasmids have been labeled *Qnr proteins*, a group of molecules that bind to topoisomerase and protect it from the inhibitory effects of the quinolones.[275,329] Although all the Qnr molecules described to date belong to the so-called pentapeptide-repeat family of proteins, a finding suggesting similar three-dimensional conformations, distinct families of Qnr proteins with largely nonhomologous amino acid sequences have been characterized.[275,329] These families have been named QnrA, QnrB, and QnrS, with subtypes identified within each. The variety of plasmid and integron structures carrying Qnr proteins and the multiplicity of sequences of the proteins themselves support the notion that Qnr-mediated resistance arose through many independent molecular events in geographically distinct regions of the world. The plasmids encoding the Qnr proteins have been found in multiple species belonging to the Enterobacteriaceae, but to date they have not been identified in nonenteric bacteria such as *Pseudomonas* and *Acinetobacter*.[329] Qnr plasmids frequently carry other antibiotic-resistance genes, most notable those encoding ESBLs and the aminoglycoside-modifying gene *aac(6′)-Ib-cr*, a gene that is able to acetylate selected quinolones as well.[329] The plasmids also may carry resistance determinants against rifampin, tetracycline, sulfonamides, and chloramphenicol.[275]

Quinolone resistance occurs incrementally as the organism acquires a series of topoisomerase mutations, altered outer-membrane proteins, overexpressed efflux pumps, and Qnr proteins.[92] Thus, in gram-negative species, mutations of *gyrA* usually occur in first-step mutants producing relatively small increases in the MIC and frequently result in bacteria that still are susceptible to the antibiotic. Additional mutations to *gyrA*, or added mutations to *parC* or the overexpression of an efflux pump, which may in themselves confer undetectable or only minor resistance to the quinolones, result in substantial quinolone resistance when they operate in concert.[150,342] Therefore, choosing a fluoroquinolone that can achieve a sustained concentration at the site of infection several-fold higher than the MIC may suppress the emergence of resistance, because this concentration is sufficient to suppress growth of both the parent organism and first-step mutants.[87,342] The propensity of a bacterial strain to emerge resistant to the quinolones can be quantified empirically by measuring the *mutant prevention concentration* (MPC), that is, the lowest concentration of quinolone required to suppress the emergence of resistant subpopulations among a high inoculum (10^{10}) of bacteria.[87,139] The acquisition of each resistance determinant results in an increase in MPC disproportionate to the increase in MIC, a finding indicating that ever-increasing concentrations of drug are required to halt the escalation of resistance as new resistance mechanisms are gained.[139,168]

CHLORAMPHENICOL

Clinical Relevance

In industrialized nations, chloramphenicol has been supplanted by other agents with similar or improved antibacterial potency and less toxicity. However, the antibiotic remains a staple for pediatric bacteremia and meningitis in the developing world because of its broad antibacterial activity, low cost, favorable achievable serum concentrations after oral or intramuscular administration, and excellent penetration across the blood-brain barrier. The incidence of resistance to chloramphenicol among the principal organisms causing bacteremia and meningitis in children, namely, *H. influenzae*, *S. pneumoniae*, *N. meningitidis*, and *Salmonella*, varies greatly by geographic location. Between the late 1980s and the early 2000s, surveys of *H. influenzae*, both type b and non–type b, were completed in several areas of the world. In vitro resistance to chloramphenicol ranged between 0 percent of isolates (from the Central African Republic and various locations in South America) and more than 50 percent (in India and Kenya).[41,116,176,196,282,332,338,351,363,416] Studies in 2001 and 2003 of *H. influenzae* isolates in Canada and the United States, where infection by these organisms is almost always treated with an alternative agent, indicated chloramphenicol resistance in fewer than 0.5 percent of tested bacteria.[146,441]

International surveys completed in the mid- to late-1990s that measured in vitro susceptibility of *S. pneumoniae* to chloramphenicol indicated resistance exceeding 10 to 20 percent in many areas of the world.[167,212,282,332] Chloramphenicol resistance was recorded in approximately 10 percent of European isolates of *S. pneumoniae* and in 5 percent of isolates identified in the United States and Canada.[146] Resistance to chloramphenicol is seen more commonly and is of a higher grade in penicillin-resistant pneumococci than in isolates that are penicillin-susceptible.[146] Even in penicillin-intermediate or resistant strains that retain in vitro susceptibility to chloramphenicol, the clinical response to chloramphenicol in meningitis is poor. Some investigators have suggested that such bacteria express high minimal bactericidal concentrations to chloramphenicol; as a result, concentrations of drug achieved in the cerebrospinal fluid with routine dosing are lower than those required for good outcomes in central nervous system infections.[106]

Chloramphenicol retains excellent activity against most strains of *N. meningitidis*. However, investigators described meningococcal strains from Vietnam, Paris, and Australia that possessed

high-level resistance to chloramphenicol.[111,360] Chloramphenicol resistance in *Salmonella* spp., a fourth group of organisms that causes disseminated disease and meningitis in pediatric patients, varies geographically. Resistance, with a prevalence frequently exceeding 50 percent, usually is detected in developing countries,[187] where chloramphenicol has been a readily available oral agent for typhoidal and nontyphoidal *Salmonella* infections for decades. In most *Salmonella* isolates, chloramphenicol resistance occurs coincident with resistance to multiple other antibiotics, particularly ampicillin, sulfonamides, tetracycline, and some of the older aminoglycosides. Chloramphenicol resistance has become increasingly common in industrialized nations as well.[55,369,415] In the United States, the strain *Salmonella typhimurium* DT104, which similarly co-expresses resistance to several classes of antibiotics including chloramphenicol, has become a widespread health hazard.[1,406]

Mechanisms of Resistance

The antibacterial activity of chloramphenicol is conferred by its interference with the peptidyl transferase region of the 50S prokaryotic ribosome. The principal mechanism of resistance is through the expression of the modifying enzyme chloramphenicol acetyltransferase (CAT), which catalyzes the acetylation of the C3-hydroxy group of the drug and thereby prevents its binding to the bacterial ribosome.[357] CATs actually represent a family of enzymes. Many CATs share chemical properties and structural homologies, especially around the active site.[357] CATs frequently reside on plasmids or transposons that carry other antibiotic-resistance determinants.[408] In *Salmonella* in particular, the chloramphenicol-resistance gene frequently is encoded on a class 1 integron incorporated in the so-called *Salmonella* Genomic Island 1 (SGI1), which includes multiple antibiotic-resistance cassettes.[83,263] SGI1 is transmissible and has been identified in many different *Salmonella* serovars.

Alternative mechanisms of resistance to chloramphenicol also have been identified in certain gram-negative species. In most of these organisms, resistance is linked to decreased intracellular accumulation of drug. In chloramphenicol-resistant *Pseudomonas*, this phenomenon has been associated with the overproduction of an approximately 50-kd outer-membrane protein,[216] which in the past led to the speculation that entry of drug into the bacterium was diminished by an abnormal porin. More recently, however, cell membrane proteins of this size have been identified as components of complex efflux apparatus that include both the pump itself and proteins that channel the extruded substance across the periplasmic space and through the outer membrane.[294] More direct evidence of such multidrug-resistance efflux pumps have been identified in chloramphenicol-resistant *E. coli*,[137] *Pseudomonas*,[216] *Stenotrophomonas*,[442] and *Salmonella*.[23,44,305] Usually, these pumps result in co-resistance to multiple other antimicrobial agents, including tetracycline, sulfonamide, aminoglycosides, quinolones, and selected detergents.

CHAPTER 247

The Pharmacokinetic-Pharmacodynamic Interface: Determinants of Anti-infective Drug Action and Efficacy in Pediatrics

Susan M. Abdel-Rahman ✪ Gregory L. Kearns

The success of anti-infective treatment of any infection depends wholly on proper drug selection and use. Without question, consideration of in vitro data that define the offending pathogen and provide information with regard to drug susceptibility is both valuable and vital. However, consideration of in vitro data in the absence of information that determines and governs drug exposure often can result in a therapeutic act of omission sufficient to bring about treatment failure. Thus, the conjoint consideration of drug action (i.e., pharmacodynamics) and drug disposition (i.e., pharmacokinetics) is of critical

importance in the selection and evaluation of any anti-infective drug regimen.

The *pharmacokinetic-pharmacodynamic interface* reflects an association between two determinants of drug effect, delivery of drug to the site of action and the intrinsic activity of a drug to alter cellular function once it reaches that site. In much of the contemporary literature in clinical pharmacology and therapeutics, *kinetics* generally is associated with a description of the rate processes associated with drug absorption, distribution, metabolism, and excretion (ADME). Although accurate in its definition concerning the movement of drugs into and out of the body, kinetics as a determinant of drug effect must be viewed in a much broader context, specifically, the sojourn and fate of a drug molecule in both the extracellular and intracellular milieu. Although understanding this facet of drug behavior admittedly is difficult because of a relative inability in the clinical context to track the intracellular fate of a drug in humans, achieving a high degree of control over anti-infective therapy by the application of well-characterized and understood kinetic principles is quite possible.

The focus of this chapter is the pharmacologic considerations necessary for the prudent use of anti-infective agents in pediatric patients, specifically, the pharmacokinetic and pharmacodynamic principles that, if embraced, can be the key to optimizing drug treatment and maximizing therapeutic efficacy and safety. The pediatric patient presents a particular challenge to the clinician. Although pediatric practitioners generally recognize that "children are not just miniature adults," one may not appreciate that the dramatic changes associated with normal human growth and development can, and many times do, exert a profound influence on drug disposition, drug action, and, ultimately, therapeutic outcome.[109] Failure to compensate for developmental differences in pharmacokinetics in the context of therapeutic drug use in pediatrics can increase the risk of occurrence of adverse drug effects associated with either overdose (i.e., drug toxicity) or underdose (i.e., lack of efficacy).[75,109]

The following sections of this chapter present the basic principles required to understand the pharmacokinetic-pharmacodynamic interface in pediatrics, namely, general principles in pharmacokinetics, the impact of development on drug disposition, the pharmacokinetic determinants of drug action, and methods to facilitate clinical integration of the pharmacokinetic and pharmacodynamic properties necessary to optimize anti-infective therapy.

PHARMACOKINETIC DETERMINANTS OF EXPOSURE

Implicit in the production of any pharmacologic effect is the association of a drug molecule with one or more receptors and the subsequent propagation of intracellular events that ultimately translate into drug action. In general terms, successful drug-receptor interactions are characterized by three principles: (1) *avidity*, the ability of a drug to combine with a receptor; (2) *affinity*, the physical combination of a drug with a receptor, and (3) *intrinsic activity*, the ability of the drug-receptor combination to generate one or more "impulses" or "signals" capable of activating biologic effector systems. The primary determinants of both avidity and affinity reside with the maintenance of structural specificity of both the drug and receptor to ensure that an association with one or more physicochemically distinct active sites can occur. Simply stated, a drug molecule must fit into a receptor as a key fits into a lock before intrinsic activity becomes a possibility. The receptor or receptors thus will function in the role of cellular targets for drug molecules when an effective combination is required for drug effect and, ultimately, therapeutic efficacy. The pharmacodynamic implications of these targets are discussed in the second half of this chapter and in other chapters in this textbook in the context of specific anti-infective agents.

The onset and offset of drug action are determined not only by receptor-modulated intrinsic activity but also by receptor occupancy. In almost all instances, these events are both concentration- and time-dependent. Hence, the disposition of a drug in the body (e.g., ADME) becomes the "driver" for its pharmacodynamics. This action is particularly true for anti-infective drugs when the therapeutic target, the infecting organism, must be exposed to a sufficient concentration of pharmacologically active (i.e., free) drug for a period sufficient for drug binding to critical cellular elements (e.g., penicillin-binding proteins [PBPs], intracellular enzymes) to occur and for subsequent disruption of normal cellular function (e.g., inhibition of protein biosynthesis, inhibition of cell wall synthesis) to result in cellular demise. Thus, the clinical determinants of drug efficacy (and safety), such as proper selection of both dose and dosing interval relative to the intrinsic sensitivity of the infecting pathogen or pathogens, and factors that determine delivery of the drug to the site or sites of infection embody the importance of pharmacokinetics in the selection and clinical use of anti-infective drugs.

BASIC TERMS

A complete discussion of pharmacokinetics is beyond the scope of this chapter because it would require a description of theory and a presentation of relatively sophisticated mathematic concepts. This information can be found in many excellent textbooks that provide both theoretical[74] and conceptual[109,181,225] presentations of pharmacokinetics and through Internet-based programmed instruction courses.[25] However, well within the scope of this chapter are a definition and glossary of pharmacokinetic terms sufficient to equip the reader with a conceptual, working knowledge of this pharmacotherapeutic tool. These definitions and concepts are presented as follows:

Absolute bioavailability (F) is the extent or fraction of drug absorbed after extravascular administration. It is determined by comparing the area under the plasma concentration versus time curve (AUC) after administration of an oral dose of a drug with the AUC after administration of an intravenous dose (e.g., $F = AUC_{PO} \times dose_{IV}/AUC_{IV} \times dose_{PO}$).

Absorption of drugs describes the process of drug uptake from a site of extravascular administration (e.g., oral, intramuscular, subcutaneous, intraperitoneal, intraosseous, intratracheal, intravaginal, intraurethral, sublingual, buccal, rectal, and dermal) into the systemic circulation. Drug absorption is conceptualized most accurately by considering both rate (e.g., absorption half-life, time to peak concentration) and extent (e.g., bioavailability), either of which can be influenced by biopharmaceutical (e.g., drug formulation), physicochemical (e.g., pH, solubility, hydrophilicity and lipophilicity, protein binding, complexation characteristics with food or drugs), and physiologic factors (e.g., barrier integrity, motility, volume and pH of body fluids at the absorptive site, protein-binding capacity, degradation/biotransformation potential).

Area under the curve (AUC) is, conceptually, a measure of both the extent of drug absorbed and its persistence in the body. It is the integral of drug blood levels over time from zero to either a predetermined post-dose time point (i.e., $AUC_{0\rightarrow tx}$) or extrapolated to infinity (i.e., $AUC_{0\rightarrow\infty}$) by using the apparent terminal elimination rate constant (similarly calculated from the observed plasma concentration versus time plot) (Fig. 247–1). AUC is therefore a pharmacokinetic parameter that is both time- and concentration-dependent.

Bioequivalence of a drug product is achieved if its extent and rate of absorption are not significantly different (i.e., within 80% to 125%) from those of a reference standard drug product when

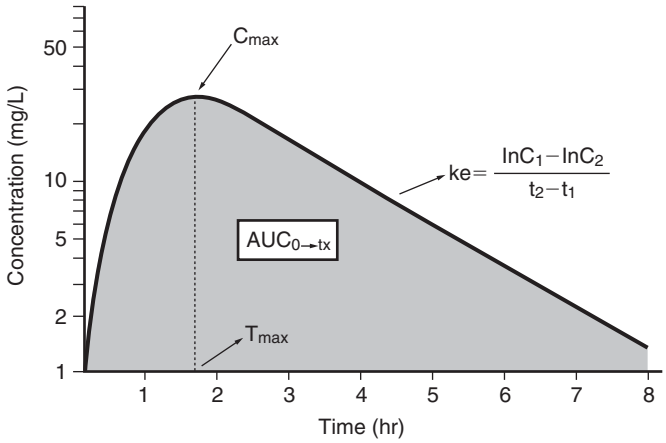

Figure 247–1 Representative plasma concentration versus time curve. Illustrated are commonly referenced pharmacokinetic parameters, including AUC, area under the curve; C_{max}, maximal plasma concentration; ke, elimination rate constant; and T_{max}, time to achieve maximal plasma concentration.

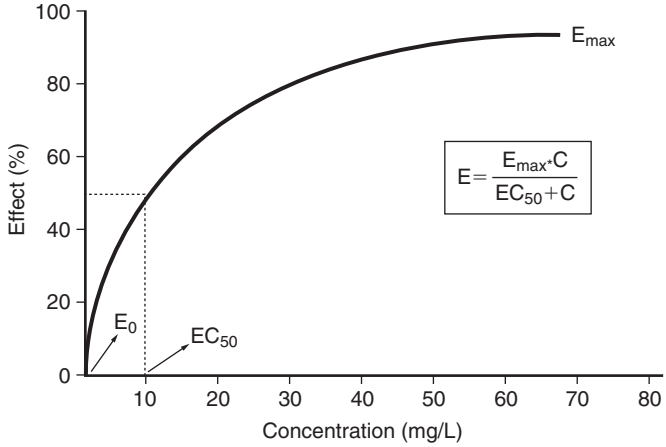

Figure 247–2 Representative nonlinear concentration (C) versus effect profile. Emax, maximal effect; EC50, drug concentration for which the observed effect is 50 percent of the maximal effect.

administered at the same molar dose. Bioequivalence is a pharmacokinetically determined parameter and does not entail a relative comparison of drug action or efficacy. Therefore, if a drug product (e.g., a generic drug) produces a rate and extent of absorption sufficiently similar to those of the reference formulation, the effect and toxicity profiles of the two drugs are assumed to be virtually identical.

Biopharmaceutics deals with the physical and chemical properties of the drug substance, the dosage form, and the body, as well as the biologic actions of a drug or drug product after administration. Biopharmaceutical considerations (e.g., rate and extent of the disintegration or dissolution of a dosage form, liberation of the active drug from a dosage form, solubility or binding of the drug at the site of absorption) can be rate-limiting for drug absorption or bioavailability, or for both, and thus may limit the efficacy of drug therapy.

Clearance (Cl) of a drug is represented conceptually by the volume of blood from which a certain amount of unmetabolized drug is removed (i.e., cleared) per unit of time by any and all pathways capable of drug removal (e.g., renal, hepatic, biliary, pulmonary, breast milk, sweat). In pharmacokinetics, clearance generally is represented as total-body (or plasma) clearance, renal clearance (Cl_{ren}), or nonrenal clearance (Cl_{nr}). Clearance is determined easily from knowledge of the drug dose and AUC and can be calculated as follows: Cl = Dose (mg/kg)/AUC (mg/L × hr), where AUC can represent either the $AUC_{0\rightarrow tx}$ for single-dose administration or the AUC from time zero to the end of the dosing interval at steady state (i.e., $AUCss_{0\rightarrow\tau}$). Calculation of renal clearance requires a complete, quantitative collection of urine (usually over the course of 24 hours) to determine the amount of drug excreted (Ae) unchanged. Nonrenal clearance generally is determined as the difference between total body clearance and renal clearance. For drug administration *by any extravascular route*, calculation of clearance yields an apparent value (e.g., Cl/F) in that it must be corrected for the extent of the drug dose absorbed (i.e., the bioavailability) from the site of administration.

A *compartment* in pharmacokinetics represents a *hypothetical space* into and out of which drug partitions as a function of time. *Compartment models* are used in pharmacokinetics to characterize the relationship between drug dose and concentration as a function of time. The most simple of all pharmacokinetic models is a *one-compartment open model* in which the only applicable rate processes represent drug ingress and egress from a single theoretical or central space. A *two-compartment model* has been used to characterize the disposition of many anti-infective agents in both pediatric and adult subjects. This particular model is composed of a central compartment and a peripheral compartment, both of which represent the various fluids and tissues where a drug may reside. Although a compartment often may not correspond to a true physiologic space that can be characterized by a specific volume of biologic fluid, compartment models can be used to conceptualize both drug distribution between physiologic spaces and elimination from the body. In the two-compartment model, for example, the central compartment often is used to represent a drug resident within the intravascular space and the highly exchangeable extracellular fluid of tissues and organs that are well perfused, whereas the peripheral compartment represents drug distribution to intracellular fluid and tissues and organs that are less well perfused and, in some instances, the association of the drug (e.g., binding) to specific tissues or tissue components. In all instances, compartmental models oversimplify the true processes of ADME. However, they have been demonstrated repeatedly to be useful as a reliable means to model, and therefore predict, the relationship between drug dose and concentration in both plasma and tissue.

Disposition refers collectively to the processes of ADME, all of which occur simultaneously after administration of a drug, as opposed to being discrete pharmacologic events.

Dose-response curve is a graphic representation of the pharmacologic effect as a function of either the drug dose or the concentration of the drug. A log dose-response curve is often sigmoidal, whereas a cartesian concentration-effect curve is hyperbolic (Fig. 247–2). Theoretically, a drug concentration of zero indicates no drug effect (i.e., E_0). As a drug travels to and interacts with a receptor, the effect (E) increases in a concentration-dependent manner (i.e., $E = [(E_{max} \times C)/(E_50 + C)]$) to a point at which a maximal effect (E_{max}) is attained and above which higher drug concentrations fail to enhance the effect. A pharmacologically important term that can be derived easily from a concentration-effect curve is the EC_{50}, or the drug concentration for which the observed effect is 50 percent of the E_{max}.

Elimination half-life of a drug is the time necessary to reduce the drug concentration (in blood serum or plasma) by 50 percent after absorption is complete and distribution between body compartments has attained equilibrium. Loss of drug from the body, as represented by the elimination half-life, reflects elimination of the administered parent drug molecule (i.e., not its metabolites)

by metabolism, urinary excretion, or other pathways capable of resulting in elimination of drug. Accordingly, many individuals use elimination half-life as a surrogate indicator of drug clearance. Such a determination should be made cautiously because this particular pharmacokinetic parameter is dependent on both clearance and the apparent volume of distribution (VD), as illustrated by the following equation: $t_{1/2}$ elimination = [(0.693 × VD)/Cl], where $t_{1/2}$ is half-life. Practically speaking, the elimination half-life is an important pharmacokinetic parameter because it can be used to determine the period of time required for a drug dosing regimen to produce steady-state plasma concentrations (e.g., 5 × $t_{1/2}$ elimination) and the dosing interval required to produce a desired excursion (i.e., peak and trough) in plasma drug concentrations.

First-pass effect describes a phenomenon whereby drugs may be metabolized or chemically degraded (or both) after extravascular administration before they reach the systemic circulation. Specific examples include biotransformation of selected drugs (e.g., cytochrome CYP3A4 substrates) in the enterocyte and nonenzymatic hydrolysis of an active drug (e.g., aspirin) in the lumen of the gastrointestinal (GI) tract (e.g., stomach, intestine, rectum). Drugs subject to a first-pass effect generally have a reduced rate or extent of relative bioavailability, or both, when compared with that achieved by parenteral administration.

Protein binding is the phenomenon that occurs when a drug (or metabolite) combines with plasma or extracellular or tissue proteins to form a drug-protein complex. In general, drug-protein binding usually is nonspecific and depends on the drug's affinity for the protein molecule (i.e., binding site), the number of protein-binding sites, and the drug and protein concentrations. With few exceptions, drugs that are bound to proteins are pharmacologically inactive and cannot be metabolized or excreted readily. The pharmacokinetic consequences of drug-protein binding can influence the drug dose versus the plasma concentration versus the effect relationship. For example, drugs with extensive tissue binding have apparent volumes of distribution that are far in excess of the total-body water space and, in general, have relatively long elimination half-lives. Conditions in which intravascular proteins escape to extravascular sites (e.g., nephrotic syndrome, severe burns, ascites) can increase the apparent volume (and elimination half-life) of drugs that are extensively (i.e., >70%) bound to albumin.

Relative bioavailability reflects the extent of drug absorbed from one dosage form given by an extravascular route of administration in comparison to a dose of a "standard" drug formulation administered by the same route. Generally, it reflects the relative extent of systemic availability (F) and is calculated by comparing the AUC of the test regimen relative to the standard formulation (e.g., $F = AUC_{test} \times dose_{standard}/AUC_{standard} \times dose_{test}$).

Steady state reflects the level of drug accumulation in the blood and tissue after multiple doses when input (i.e., the amount of drug placed into the systemic circulation) and output (i.e., drug clearance) are at equilibrium. When drugs are given at fixed doses and dosing intervals, the steady-state concentrations fluctuate between a maximum (C_{max}) and minimum (C_{min}) within a given dose interval that is identical between doses, provided that the size of the dose, method of administration, dosing interval, or drug pharmacokinetics (or any combination of these parameters) does not change. For drugs that follow first-order pharmacokinetics, steady-state plasma concentrations for a given dosing regimen are attained over a period of time that corresponds to four to five times the elimination half-life. In general, the pharmacokinetics of a drug at steady state provides the most accurate correlate for examining drug effect.

Volume of distribution (apparent volume of distribution) (VD) represents a hypothetic volume of body fluid that would be required to dissolve the total amount of a drug at the same concentration as that found in the blood and is illustrated by the following equation: $VD = Dose/Cp^0$, where Cp^0 represents the highest attainable plasma concentration after the administration of a single dose. As a proportionality constant, the VD is a determinant of plasma drug concentrations attained after administration of a given drug dose. For drugs that are not distributed extensively or that bind with great affinity to proteins and tissues, the apparent VD may correspond dimensionally to physiologic or anatomic body spaces (e.g., VD <0.1 L/kg approximates the intravascular space, 0.1 to 0.3 L/kg approximates the extracellular space, 0.6 to 0.7 L/kg approximates the total-body water space), which, when altered by disease or development, or by both, will influence the apparent VD and thus the achievable concentration for a given drug.

A working knowledge of these pharmacokinetic definitions allows one to have an understanding of the relationships among drug dose, concentration, and effect. The use of knowledge related to the physicochemical and pharmacologic properties of a drug, the impact of isolated or concurrent variables on drug disposition, and predictors of pharmacodynamics or drug response enables the clinician to optimize the selection of agents and dosing regimens and thus individualize drug therapy. To accomplish this goal, it is imperative that the relationship between drug pharmacokinetics and pharmacodynamics not be compartmentalized but rather, as illustrated in Figure 247–3, be conceptualized as multifactorial, in which the determinants of drug concentration and effect are dynamic and change as a function of a disease state and drug therapy.

IMPACT OF ONTOGENY ON PHARMACOKINETICS

Development represents a continuum of biologic events that enable adaptation, somatic growth, neurobehavioral maturation, and, eventually, reproduction. The impact of development on the pharmacokinetics of a given drug is determined, to a great degree, by age-related changes in body composition and the acquisition of function in organs and organ systems that are important in determining drug metabolism and excretion. Although classifying pediatric patients on the basis of postnatal age (e.g., neonates, ≤1 month of age; infants, 1 to 24 months of age; children, 2 to 12 years of age; and adolescents, 12 to 18 years of age) often is convenient for providing drug therapy, recognizing that the changes in physiology are not linearly related to age and may not correspond to these age-defined breakpoints is important. In fact, the most dramatic changes in drug disposition occur during the first 18 months of life, when the acquisition of organ function is most dynamic. Additionally, the pharmacokinetics of a given drug may be altered in pediatric patients as a result of intrinsic (e.g., gender, genotype, ethnicity, inherited diseases) or extrinsic (e.g., acquired disease states, xenobiotic exposure, diet) factors that may occur during the first 2 decades of life.

Selection of an appropriate drug dose for a neonate, infant, child, or adolescent requires an understanding of the basic pharmacokinetic properties of a given compound and how the process of development affects each facet of drug disposition. Accordingly, conceptualizing pediatric pharmacokinetics by examining the impact of development on the physiologic variables that govern ADME is most useful.

Drug Absorption

The rate and extent of GI absorption depend primarily on pH-dependent passive diffusion and motility of the stomach and small intestine, both of which control transit time. In full-term neonates, gastric pH ranges from 6 to 8 at birth and drops to 2 to 3 within the first few hours. After the first 24 hours of extrauterine life, gastric pH increases to approximately 6 to 7 as a result of immaturity of the parietal cells. A relative state of achlorhydria

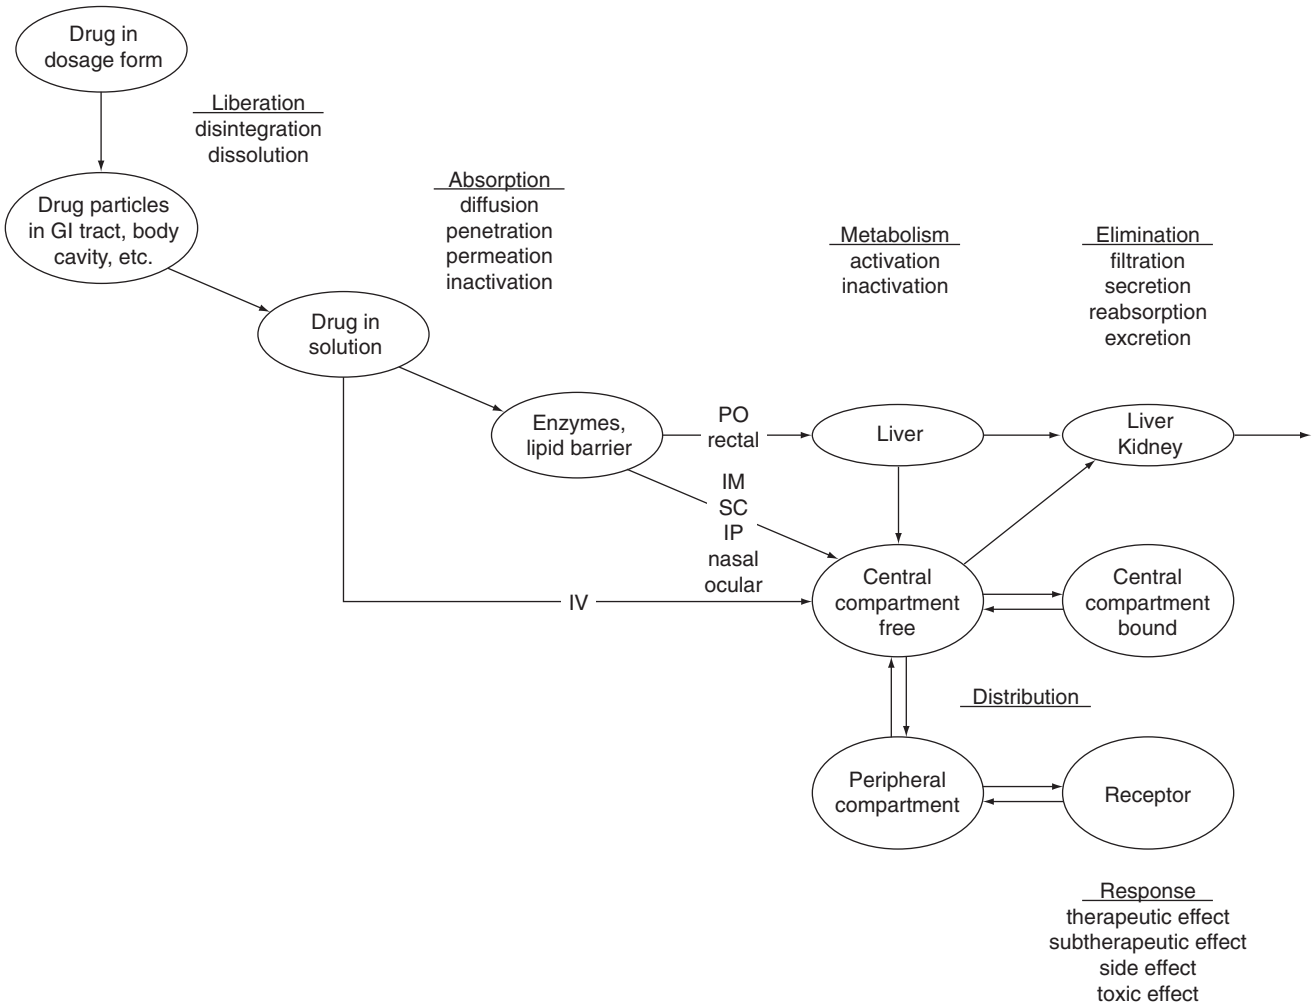

Figure 247–3 Graphic representation of the pharmacokinetic-pharmacodynamic interface. GI, gastrointestinal; IM, intramuscular; IP, intraperitoneal; PO, oral; SC, subcutaneous.

remains until adult values and diurnal patterns of gastric pH are reached at 20 to 30 months of age. Although basal gastric acid output can be quite similar in neonates, young infants, and adults, stimulated acid output can be three- to fourfold higher than that seen in adults.[52,53]

In neonates, GI transit time is prolonged as a result of reduced motility and peristalsis. Gastric emptying is both irregular and erratic and only partially dependent on feeding. Gastric emptying rates approximate adult values by the time the infant reaches 6 to 8 months of age. During infancy, intestinal transit time generally is reduced relative to adult values because of increased intestinal motility.[109] In contrast to developmental changes in motility, histologic examination of the luminal absorptive surface suggests that the adult pattern of architecture (and hence absorptive surface area relative to body size) is present at birth.[78,222] In neonates and young infants, additional factors, including diminished splanchnic blood flow, immature biliary function, variable microbial colonization, and an apparent reduction in the activity of intestinal drug-metabolizing enzymes, may play a role in intestinal drug absorption.[40,175]

These developmental changes in GI function and structure in the newborn period and early infancy produce alterations in drug absorption that are quite predictable. In general, the oral bioavailability of acid-labile compounds (e.g., β-lactam antibiotics) is increased, whereas that of weak organic acids (e.g., phenobarbital, phenytoin) is decreased. For orally administered drugs with limited water solubility (e.g., phenytoin, carbamazepine), the rate of absorption (i.e., T_{max}) can be altered dramatically as a result of changes in GI motility.[175] The pharmacokinetics of the antiviral agent pleconaril similarly provides an example of developmental differences in drug absorption. After administration of a 5-mg/kg dose, the AUC was much lower in neonates than either children or adults, thus demonstrating that the extent of pleconaril bioavailability in neonates was reduced. The reason for this difference may be attributed to the lipid-based pleconaril formulation and developmental differences in the ability to absorb lipids as a consequence of biliary immaturity and reduced lipase secretion in neonates.[112]

In newborns and young infants, both rectal and percutaneous absorption is highly efficient for properly formulated drug products. The bioavailability of many drugs administered by the rectal route is increased as a result of not only efficient translocation across the rectal mucosa but also a reduced first-pass effect caused by the immaturity of a number of drug-metabolizing enzymes in the liver. Both the rate and extent of percutaneous drug absorption are increased because of the thinner and better hydrated stratum corneum in young infants. As a consequence, systemic toxicity can occur with the percutaneous application of some drugs (e.g., hexachlorophene) to seemingly small areas of skin during the first 8 to 12 months of life. In contrast to older infants

TABLE 247–1 Summary of Drug Absorption in Neonates, Infants, and Children*

	Neonates	Infants	Children
Physiologic Alteration			
Gastric emptying time	Irregular	Increased	Slightly increased
Gastric pH	>5	4 to 2	Normal (2-3)
Intestinal motility	Reduced	Increased	Slightly increased
Intestinal surface area	Reduced	Near adult	Adult pattern
Microbial colonization	Reduced	Near adult	Adult pattern
Biliary function	Immature	Near adult	Adult pattern
Muscular blood flow	Reduced	Increased	Adult pattern
Skin permeability	Increased	Increased	Near adult pattern
Possible Pharmacokinetic Consequences			
Oral absorption	Erratic: reduced	Increased rate	Near adult pattern
Intramuscular absorption	Variable	Increased	Adult pattern
Percutaneous absorption	Increased	Increased	Near adult pattern
Rectal absorption	Very efficient	Efficient	Near adult pattern
Presystemic clearance	Less than adult	Greater than adult	Greater than adult (increased rate)

**The direction of alteration is given relative to the expected normal adult pattern.*

and children, the rate of bioavailability for drugs administered by the intramuscular route may be altered (i.e., delayed T_{max}) more than the extent of absorption in a neonate. This developmental pharmacokinetic alteration is the consequence of relatively low muscular blood flow in the first few days of life, the relative inefficiency of muscular contractions (useful in dispersing an intramuscular drug dose), and an increased percentage of water per unit of muscle mass.[175]

Developmental differences in drug absorption among neonates, infants, and older children are summarized in Table 247–1. The data contained therein reflect developmental differences that may be expected to occur in healthy pediatric patients. Certain conditions or disease states that could modify the function or structure, or both, of the absorptive surface area, GI motility, or systemic blood flow can further affect either the rate or the extent of absorption for extravascularly administered drugs in pediatric patients.

Distribution

Development is associated with marked changes in body composition as reflected by examination of total-body water, extracellular water, and stores of body fat (Fig. 247–4). The most dynamic changes occur in the first year of life, with the exception of total-body fat, which has a distinctly different pattern in male and female children. Furthermore, the adipose tissue of neonates may contain as much as 57 percent water and 35 percent lipids, whereas values in adults approach 26.3 percent and 71.7 percent, respectively.[175]

In addition to age-related alterations in body composition, several physiologic changes that occur during the neonatal period are capable of altering the plasma protein binding of drugs (Table 247–2). In neonates, the free fraction of drugs that are bound extensively to circulating plasma proteins is increased markedly, largely because of lower concentrations of drug-binding proteins, reduced binding affinity of these proteins, the presence of a relatively acidic plasma pH, and endogenous competing ligands (e.g., bilirubin, free fatty acids). This consideration is exemplified by ceftriaxone, a weak acid that is approximately 95 percent bound to albumin in adults but only 70 percent bound in neonates and thus is capable of producing significant displacement of bilirubin.[88,142] The reduced plasma protein binding in combination with absolute and relative differences in the size of various body compartments (e.g., total-body water, extracellular fluid,

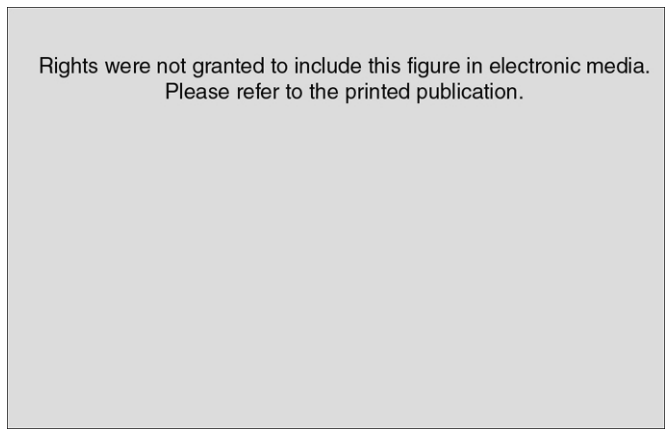

Figure 247–4 Body composition reflected as a percentage (y-axis) of total-body mass for total-body water (TBW), extracellular water (ECW), and body fat as a function of age (x-axis). *(From Ritschel, W. A., and Kearns, G. L.: Pediatric pharmacokinetics.* In *Ritschel, W. A., and Kearns, G. L. [eds.]: Handbook of Basic Pharmacokinetics. 6th ed. composition of body tissues) frequently influences (i.e., increases) the apparent VD for many drugs and also their localization (i.e., both uptake and residence) in tissue, which, in turn, can alter their plasma elimination half-life.

Renal Excretion

The renal excretion of many drugs is directly proportional to age-dependent patterns in the acquisition of renal function, primarily glomerular filtration and active tubular secretion. Accordingly, developmental differences in renal function may serve as a major determinant of drug clearance in neonates and young infants for compounds that are not metabolized extensively.[175]

In preterm infants, renal function is reduced dramatically because of the continued development of functioning nephron units (i.e., nephrogenesis). In contrast, the acquisition of renal function in a term neonate represents, to a great degree, the recruitment of fully developed nephron units. In both term neonates and preterm infants who have birth weights greater than

TABLE 247–2 Plasma Protein Binding and Drug Distribution*

	Neonates	Infants	Children
Physiologic Alteration			
Plasma albumin	Reduced	Near normal	Near adult pattern
Fetal albumin	Present	Absent	Absent
Total protein	Reduced	Decreased	Near adult pattern
Serum bilirubin	Increased	Normal	Normal adult pattern
Serum free fatty acids	Increased	Normal	Normal adult pattern
Blood pH	7.1-7.3	7.4 (normal)	7.4 (normal)
Possible Pharmacokinetic Consequences			
Free fraction	Increased	Increased	Slightly increased
Apparent volume of distribution			
Hydrophilic drugs	Increased	Increased	Slightly increased
Hydrophobic drugs	Reduced	Reduced	Slightly decreased
Tissue-to-plasma ratio	Increased	Increased	Slightly increased

Cl, total plasma clearance; $t_{1/2}$, half-life; VD, apparent volume of distribution.

1500 g, glomerular filtration rates increase dramatically during the first 2 weeks of postnatal life (Fig. 247–5). This particular dynamic change in function is a direct consequence of postnatal adaptations in the distribution of renal blood flow (i.e., medullary distribution to the corticomedullary border) and results in a dramatic recruitment of functioning nephron units.[109] In addition, a glomerular-tubular imbalance exists in which the maturation of the glomerular function is more advanced than is the proximal tubular secretion. This imbalance may persist for up to 6 to 10 months of age, when both tubular function and glomerular function approach values approximately equal to those observed in healthy, young adults.[175]

The impact of development on each of the components of renal function can be characterized by a definable pattern during the first year of life (see Fig. 247–5).[161] Accordingly, the renal handling and, hence, excretion and elimination characteristics of virtually any drug in neonates, infants, and children can be predicted largely by considering the ontogeny of renal function and the specific pharmacologic characteristics of a given drug with regard to its renal excretion (e.g., routes of renal excretion, the percentage of a given dose excreted unchanged in urine) in adults. For antimicrobial agents, the impact of the ontogeny of the renal function on pharmacokinetics is reflected largely by alterations in the plasma drug clearance. As summarized by van den Anker and Kearns,[213] the elimination half-life of antimicrobial agents from different classes that share predominantly renal pathways of excretion is increased substantially in neonates and young infants (Table 247–3). This increase is not the case for antimicrobial and other agents that are not excreted primarily by the kidneys (e.g., ceftriaxone; see Table 247–3).

Metabolism

Simply stated, drug metabolism (or biotransformation) involves the modification of a drug molecule by one or more enzymes such that the hydrophilicity of the product is increased relative to the parent drug, thus enhancing elimination and excretion. In most instances, drug metabolism creates products that are either less pharmacologically active than is the parent drug (e.g., desacetylcefotaxime) or devoid of pharmacologic activity altogether (e.g., cefotaxime lactone metabolites).[108] In other instances, metabolism can result in drug bioactivation and produce metabolites with pharmacologic activity from an inactive parent drug (i.e., prodrug) or generate metabolites that can result in cellular toxicity in the host (e.g., sulfamethoxazole's nitroso and hydrox-

ylamine reactive metabolites, acetaminophen's NAPQI reactive metabolite).

Virtually every tissue has some ability to carry out drug biotransformation reactions. Although the liver is quantitatively the most important organ capable of drug metabolism, the small intestine, lungs, skin, and kidneys also have substantial drug biotransformation activities. In infants, children, and adolescents, developmental variations in drug metabolism have been associated with age, sex, maturation, and genetic constitution. For compounds that are extensively metabolized, developmental differences in drug metabolism can serve as the primary determinant for age-appropriate dose selection.[127] Much of the existing information regarding the impact of ontogeny on drug metabolism has been derived as a byproduct of pharmacokinetic investigations designed, in part, to determine whether age-dependent differences in drug disposition were evident.[109] The following paragraphs highlight important general issues regarding drug metabolism and its relationship with development.

PHASE I PATHWAYS

Phase I biotransformation reactions include oxidation, reduction, and hydrolysis reactions that, in general, introduce or unmask a functional group (e.g., hydroxyl, amine, sulfhydryl) that renders a drug more polar. Quantitatively, the P-450 cytochromes are the most important of the phase I enzymes and represent a superfamily of heme-containing proteins that catalyze the metabolism of many lipophilic endogenous substances (e.g., steroids, fatty acids and fat-soluble vitamins, prostaglandins, leukotrienes, and thromboxanes) and exogenous compounds. In humans, the P-450 cytochromes can be divided functionally into two distinct classes: steroidogenic enzymes expressed in specialized tissues, such as the adrenal glands, gonads, and placenta; and enzymes involved in the metabolism of drugs, pesticides, and environmental contaminants. P-450 cytochromes that have been identified as important in human drug metabolism are found predominantly in the CYP1, CYP2, and CYP3 gene families.[127]

As reviewed by Leeder and Kearns,[127] considerable interindividual variability exists in the hepatic expression of P-450 enzymes, and, for a given individual, the pathway and rate of a compound's metabolic clearance constitute that individual's unique phenotype with respect to the forms and amounts of P-450 isoforms expressed. Of the cytochromes P-450 involved in drug biotransformation, CYP2C19, CYP2C9, and CYP2D6 are examples of isoforms that are polymorphically expressed in humans. Polymorphic expression of CYP1A2 and CYP3A4 has been reported in the literature but not definitively established with regard to functional consequences. Within a P-450 subfamily, several isoforms can exist (e.g., CYP3A4, CYP3A5, and CYP3A7), each of which can demonstrate substrate specificity and a distinct developmental pattern with regard to enzyme activity. In addition, certain P-450 cytochromes (e.g., CYP3A4) can work cooperatively with transporters (e.g., MDR-1 or P-glycoprotein) located in distinct cells or tissues to alter the availability of specific drugs to the systemic circulation (e.g., first-pass metabolism of CYP3A4 substrates in the enterocyte). Moreover, for certain polymorphically expressed P-450 cytochromes (e.g., CYP2C19, CYP2D6), enzyme activity has been shown to vary as a consequence of racial or ethnic origin[171] and, within a given phenotypic distribution (e.g., extensive metabolizers for CYP2D6), as a function of single nucleotide polymorphisms that exist in either the gene or its regulatory regions.[169] Finally, throughout development, the activities of the P-450 cytochromes can vary widely (e.g., 5- to 25-fold) among individuals of the same phenotype,[127] an important factor with respect to the ability for induction or inhibition and, thus, the prediction of drug-drug or drug-xenobiotic interactions in vivo.

PHASE II PATHWAYS

In general, phase II reactions involve the coupling of a drug or drug metabolite with an endogenous substance to enhance its hydrophilicity further and to facilitate drug excretion in either urine or bile. These reactions require the participation of specific transferase enzymes (e.g., epoxide hydrolase, glucuronosyltransferases, glutathione *S*-transferases, sulfotransferases, *N*-acetyltransferases, methyltransferases, transacylases) and high-energy, activated endogenous substances. Although most conjugation reactions result in drug detoxification, examples of bioactivation by phase II enzymes do exist.[174] Similar to what has been found for certain of the P-450 cytochromes, different isoforms of phase II enzymes also occur in humans. This finding is exemplified by the review of de Wildt and colleagues,[41] who described substrate specificity for 10 different glucuronosyltransferase isoforms in humans and known polymorphisms in 5 different isoforms of this enzyme. The impact of age on the disposition of several glucuronosyltransferase substrates (e.g., morphine, acetaminophen, zidovudine, chloramphenicol) suggests that isoform-specific, age-related differences in activity occur to a degree sufficient to produce profound effects on drug clearance that translate directly into age-specific differences in a drug dose.[41]

Normal growth and development can have a profound effect on the activity of drug-metabolizing enzymes. Traditionally, the impact of ontogeny for all enzymes was viewed as being extremely limited in newborn infants, rapidly increasing in the first year of life to levels in toddlers and older children that may exceed adult capacity, and declining to adult levels by the conclusion of puberty. Experimental and clinical data previously reviewed demonstrated that this theory is not accurate.[109,127] As illustrated by the summary data contained in Table 247–4, the impact of ontogeny on the activity of both phase I and phase II drug-metabolizing enzymes is very much a substrate- and isoform-specific event; development is one dynamic factor in a multitude of conditions (e.g., nutritional status, gender, diurnal variation, menstrual cycle, disease states/organ dysfunction, pregnancy, concomitant drug therapy) capable of altering the activity of drug-metabolizing enzymes and, thus, the clearance of drugs (and their metabolites) from plasma. Although discussion of the impact of ontogeny on the disposition (pharmacokinetics) of specific drugs is beyond the scope of this chapter, the clinician can use much of the information concerning specific enzymes provided in Table 247–4 as a tool to facilitate inquiry or clinical decision-making, or both. It can be done simply by using readily available, updated information describing which enzymes are responsible for drug metabolism and then searching the published or unpublished (e.g., information available from pharmaceutical companies for drugs under development) literature for information describing the pharmacokinetics of the drug being considered.[57]

Clinicians must recognize that age-dependent differences in the activity of enzymes that catalyze drug biotransformation are not limited solely to P-450 cytochromes or the host of transferase enzymes responsible for phase II drug metabolism, and, in many cases, these differences represent a critical determinant for successful anti-infective drug therapy. This factor is exemplified by considering the example of two antimicrobial agents that have unique places in pediatric therapy: cefotaxime and linezolid. In the case of cefotaxime, non–P-450 enzymes (probably an esterase) capable of generating the active desacetylcefotaxime metabolite appear to be present and fully active by the third trimester of gestation.[113] Nonetheless, the elimination half-life of cefotaxime in neonates is approximately threefold greater (i.e., ≈3 to 4 hours) than that observed in older infants and children (i.e., ≈1 to 1.5 hours), a difference that permits extension of the dosing interval for the use of cefotaxime in neonates. The reasons for this developmental difference reside not with the enzymes responsible for

TABLE 247–4 Developmental Patterns for the Ontogeny of Important Drug-Metabolizing Enzymes in Humans

Enzyme(s)	Known Developmental Pattern
Phase I Enzymes	
CYP2D6	Low to absent in fetal liver but present at 1 wk of age; poor activity (i.e., 20% of adult) by 1 mo; adult competence by 1 to 3 yr of age
CYP2C9	Apparently absent in fetal liver; low activity in first 2 to 4 wk of life, with adult activity reached by ≈6 mo; activity may exceed adult levels during childhood and declines to adult levels after conclusion of puberty
CYP1A2	Not present in appreciable levels in human fetal liver; adult levels reached by ≈4 mo and exceeded in children at 1 to 2 yr of age; adult activity reached after puberty
CYP3A7	Fetal form of CYP3A that is functionally active (and inducible) during gestation; virtually disappears by 1 to 4 wk of postnatal life when CYP3A4 activity predominates, but remains present in ≈5% of individuals
CYP3A4	Extremely low activity at birth, reaching ≈30% to 40% of adult activity by 1 mo, and full adult activity by 6 mo; may exceed adult activity between 1 and 4 yr of age and decrease to adult levels after puberty
Phase II Enzymes	
NAT2	Some fetal activity by 16 wk of gestation; poor activity between birth and 2 mo of age; adult phenotype distribution reached by 4 to 6 mo, with adult activity reached by 1 to 3 yr
TPMT	Fetal levels ≈30% of adult values; in newborns, activity ≈50% higher than in adults, with phenotype distribution approximating that of adults; exception is Korean children, in whom adult activity is seen by 7 to 9 yr of age
UGT	Ontogeny isoform-specific; in general, adult activity reached by 6 to 24 mo of age
ST	Ontogeny isoform-specific and appears faster than that for UGT; activity for some isoforms may exceed adult levels during infancy and early childhood

CYP, cytochrome P-450; NAT2, N-acetyltransferase-2; ST, sulfotransferase; TPMT, thiopurine methyltransferase; UGT, glucuronosyltransferase.

generation of an active metabolite; instead, age-associated reductions in the activity of enzymes appear to be responsible for the generation of inactive metabolites of cefotaxime (e.g., cefotaxime lactone) and pathways involved in the renal clearance of desacetylcefotaxime.[110] Linezolid, an oxazolidinone antimicrobial approved in the United States for use in pediatric patients, undergoes extensive biotransformation in humans, not through a cytochrome P-450 enzyme, but rather by nonselective chemical oxidation.[115] As demonstrated by Kearns and associates,[111] the mean plasma clearance of linezolid in children was approximately threefold higher than that observed previously for adults, with the greatest increase noted in infants younger than 1 year. Given the mechanism of action for linezolid and properties that reflect time-dependent killing,[115] the clinical implications of the age-dependent pattern of increased plasma clearance for this drug in young infants and children suggest that for infections with selected pathogens that have relatively high (90%) minimal inhibitory concentration (MIC_{90}) values for the drug, shorter dosing intervals (e.g., every 8 hours) may be necessary to ensure sufficient exposure of the organism in blood and tissue through most of a dosing interval.[111]

PHARMACOKINETIC DETERMINANTS OF EFFECT

Collectively, the most important determinants of efficacy for anti-infective agents are the pharmacokinetic profile of the drug, the physicochemical and biochemical characteristics of the local environment (i.e., site of infection), and the susceptibility of the infecting organisms under local growth conditions. As previously reviewed by Barza,[14] the mechanisms and pharmacokinetics of drug transport to and accumulation at the site or sites of infection, as well as the subcellular localization of drugs, are critical to success and are poorly understood. In many circumstances, plasma drug concentrations may not be reflective of those in tissue. Pathophysiologic processes related to the host, the infection, and the physicochemical properties of the drug work in concert to regulate distribution into and retention of active drug at the site of infection. Because these considerations should be embraced by the clinician when a particular anti-infective drug is selected for treatment and its therapy is monitored for clinical evidence of success, some general examples are presented as follows.

In addition to age (as discussed earlier), many disease processes (e.g., trauma, malignancy, renal or hepatic disease) have an impact on both the quantity of circulating plasma proteins (e.g., albumin, α_1-acid glycoprotein) and their affinity to bind anti-infective agents. Given that only free drug is available to enter tissue, the degree of binding to protein components in the blood will affect tissue concentrations. Thus, despite the presence of total (i.e., free and bound) plasma drug concentrations well in excess of the MIC, these concentrations may not be predictive of concentrations of highly bound (i.e., >70%) drug at the site of infection. Properties of the capillary bed feeding the site of infection also dictate drug penetration. Highly vascularized tissue with a large ratio of capillary surface area to volume can be expected to accumulate higher drug concentrations than can tissue that is poorly vascularized, principally because of the rate and extent to which drug can be delivered to the site. As with protein binding, variability in capillary density may be a function of disease (e.g., severe atherosclerosis, diabetes), infection (e.g., abscess, cardiac vegetation), and age, and it should be expected to have an impact on drug delivery. Similarly, tissues with tight junctions and few fenestrations (e.g., eye, central nervous system [CNS]) afford lower tissue concentrations, given that drug entry is restricted to transport across the lipid bilayer of the endothelial cell (i.e., transcellular versus paracellular transport). Here, adequate drug penetration is restricted to agents with a favorable lipid-water partition coefficient and ionization constant. As such, many infectious processes warrant direct instillation of antibiotic at the site of infection (e.g., intracisternal, intrathecal, intra-articular). Additionally, cellular transporters (e.g., P-glycoprotein at the blood-brain barrier, organic anion and cation transporters at the choroid plexus) capable of pumping drug from the cell can limit distribution and retention of drug at the tissue level. Finally, the pH at the site of infection (e.g., in tissue fluids, exudates, transudates) relative to the pH in plasma also can govern distribution of a drug. For example, in cases of bacterial meningitis, the pH that occurs in the CNS is lower relative to plasma. Weak acids (e.g., penicillin) are more highly ionized in plasma than in cerebrospinal fluid (CSF) and pass more readily from the CSF into plasma than in the reverse direction. Similarly, when the pH of

the local environment drops in the presence of infection, as occurs in lung abscesses, aminoglycoside efficacy is reduced because of chemical inactivation of the drug by ionization and the formation of stable adducts with high DNA concentrations found in purulent secretions. Finally, the physicochemical association of an intact (i.e., unmetabolized) drug with a particular physiologic fluid as part of its normal excretion profile can serve to localize drug at the site of infection (e.g., accumulation of drugs excreted by the biliary route in patients with cholangitis and in the urine in patients with nephritis).

PHARMACODYNAMIC DETERMINANTS OF EFFECT

The desired effect of any drug is realized when sufficient concentrations are achieved and maintained at the active site for an adequate period. In many models of disease for which the treatment targets of modern chemotherapy remain fixed, the concentration-effect (i.e., pharmacodynamic) relationships can be described with relatively modest effort. In contrast, evaluating the concentration-effect relationship for antimicrobials can be anything but straightforward, given the dynamic nature of infection. The intended target of the anti-infective agent is in constant flux as the number of organisms changes, the quantity and affinity of target receptors evolve, and the contribution of the host response adapts accordingly during the course of infection. Moreover, antimicrobials demonstrate variable effects at different concentrations and under different physicochemical environments. In fact, evaluating whether an organism survives in the presence of antibiotic is only one criterion by which to predict or define drug effect. Rather, a variety of effects related to antimicrobial concentration—from the extremes of complete eradication to complete survival—can be observed in the invading organism. The previous sections of this chapter review the principles of pharmacokinetics, specifically, factors that link dose to concentration. The sections that follow explore the pharmacodynamics of anti-infective therapy and detail the multitude of factors that link concentration with effect.

EFFECTS DESCRIBED BY PHARMACOKINETIC PARAMETERS AND CONVENTIONAL SUSCEPTIBILITY END-POINTS

Among the many decision-making tools that clinicians have at their disposal to guide in the selection of antimicrobial therapy are qualitative (e.g., breakpoints) and quantitative (e.g., MIC, minimal bactericidal concentration [MBC]) estimates of susceptibility. Although numerous studies and years of clinical evidence support the correlation between qualitative end-points and clinical outcome, their predictive power is diminished in the presence of immunocompromise, severe underlying disease, mixed infections, and infection with organisms demonstrating heterogeneic resistance patterns.[30,36,56,136,144] Quantitative end-points provide a better assessment of dose-effect relationships, with antibiotic concentration serving as a surrogate for the dose. However, these data alone do not reveal the complete picture relative to the anticipated bacterial response because laboratory-based quantitative tests contain a notable number of artificial aspects. Factors appreciated to influence the activity of antimicrobial agents in vivo (e.g., protein binding, fluctuating drug concentrations, serial drug exposure, inoculum size, immune defense status, physicochemical environment, compound stability) essentially are neglected when determining MIC values. As such, agents with comparable MIC values in vitro may, in fact, demonstrate markedly different effect profiles in a patient.[1,29,63,103,120]

In an attempt to move beyond reliance on quantitative tests as the sole marker for predicting antimicrobial activity in vivo, the integration of susceptibility information with population- and patient-specific pharmacokinetic data continues to be explored. Surrogate end-points, defined by a combination of pharmacokinetic parameters and quantitative susceptibility data, have been suggested to predict more reliably the efficacy of different antimicrobials. By far, pharmacodynamic determinants of antimicrobial effect most frequently link attainable drug concentrations or estimates of total-body exposure, or both, with in vitro estimates of pathogen sensitivity. For antimicrobials for which the mechanism of action is determined to be time-dependent (concentration-independent), the percentage of time that plasma or tissue concentrations remain above the MIC has been closely linked to therapeutic response (Fig. 247–6). By comparison, the ratio of C_{max} to MIC has demonstrated a similar relationship for drugs with concentration-dependent killing (see Fig. 247–6). Furthermore, the ratio of AUC to MIC, which reflects the concentration profile over the course of time, has been used with both classes of agents (see Fig. 247–6).

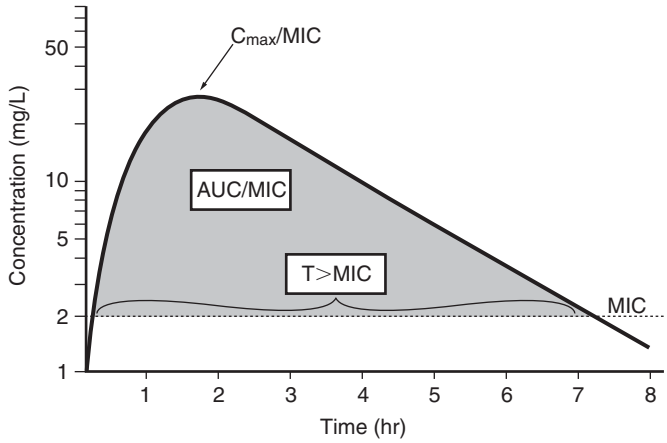

Figure 247–6 Representative plasma concentration versus time curve illustrating commonly referenced pharmacodynamic parameters. AUC, area under the curve; C_{max}, maximal plasma concentration; MIC, minimal inhibitory concentration; T, time.

Evidence to support the application of specific pharmacodynamic surrogates is reviewed in the following paragraphs. However, a large degree of interdependence exists among these pharmacokinetic parameters. With few exceptions, when the dose of a drug is increased, C_{max} and the total AUC increase, and with no change in clearance, so, too, does the percentage of time that plasma drug concentrations remain above the MIC. Accordingly, making distinctions among the various pharmacokinetic parameters in an attempt to determine the optimal pharmacodynamic end-point can be misleading. Given that many studies evaluate a limited number of doses or dosing intervals, restrict the number of pharmacokinetic parameters that are calculated, or neglect to perform multivariate analysis on the data, clear distinctions between parameters cannot always be made, and an appropriate degree of caution should be exercised when evaluating such data.[217]

Time Above the Minimal Inhibitory Concentration

Among the first class of antimicrobial agents to be discussed in the context of their concentration-effect relationships were the β-lactams, specifically penicillin. Although limited supporting evidence existed at the time, investigators were concerned with maintaining adequate blood levels of the drug in the host for a fixed period of time. This concern was reflected in their attempts to inhibit clearance pathways and formulate sustained-release preparations designed specifically for the purpose of extending

the time spent above some minimal concentration (T > MIC).[17,177] As it turns out, in vitro studies support the relative concentration independence of penicillin and demonstrate that a maximal rate of killing can be observed that is quickly saturated at reasonably low multiples of the MIC (Fig. 247–7A). As concentrations increase above this maximal level, no faster rates of kill can be demonstrated.[33] Rather, penicillin displays time-dependent killing in which the duration of time spent above some minimal concentration (typically ±1 to 2 dilutions of the MIC or MBC) appears to be the most important determinant of activity.[49] As newer antimicrobial agents with putative time-dependent activity became available for evaluation, those with longer plasma and tissue terminal elimination half-lives demonstrated enhanced bactericidal activity when compared with similar drugs. Those that simply resulted in higher maximal peak concentrations, with no extension of the time above the MIC, produced minimal if any differences in effect.[10,79,184,223] This time-dependent activity has been observed in vitro with virtually all β-lactams (e.g., cephalosporins, carbapenems, monobactams) against both gram-positive and gram-negative organisms.[58,79,197,229] Similarly, other drug classes, namely, the macrolides, azalides, glycylcyclines, glycopeptides, ketolides, and oxazolidinones, appear to possess this same characteristic.[8,85,139,214,215]

When evaluating whether the time-dependent activity observed in vitro can be reproduced in vivo by evaluating intrinsic antibiotic activity in the host (through restriction of observations to animals in which the element of both humoral and cell-mediated immunity has been removed), the strongest relationship between antimicrobial concentration and effect for the aforementioned agents remains the time spent above the MIC.[178] Elegant studies evaluating extensive numbers of dosing regimens and drug-microbe combinations demonstrated that β-lactam and macrolide efficacy correlates best with the percentage of time spent above the MIC, irrespective of whether gram-positive or gram-negative pathogens are involved.[217] Given the same total daily dose, therapy administered at more frequent intervals is required for a successful outcome.[12,128] Even when the drug-microbe interaction is such that only bacteriostatic activity results, a regimen consisting of more frequent doses is able to maintain an environment of no net growth, whereas positive net growth is observed with larger doses administered less frequently.[72] From such data, the efficacy of time-dependent agents appears to be maximized by maintaining antibiotic concentrations above the MIC for as much of the dosing interval as possible.

When evaluating whether these agents obey the same relationship in the presence of a competent immune system, animal models similarly demonstrate a significant correlation between antimicrobial efficacy and the percentage of time spent above the MIC.[2,64] In contrast to immunocompromised animals, animals with a functional immune system do not require that virtually 100 percent of the dosing interval be spent above the MIC to achieve adequate antimicrobial activity. Although the bactericidal activity of penicillin ceases when concentrations fall below the MIC, the remaining organisms do not resume multiplication for many hours, well in excess of the time observed for the same organisms in vitro.[51,104] This difference may reflect the time required for the organism to recover from the initial antibiotic insult, coupled with the complementary activity of subinhibitory antibiotic concentrations and the immune system (these pharmacodynamic principles are explored later in further detail).[69] Irrespective of the mechanism by which the protracted antimicrobial effect occurs, the pharmacodynamic goals for time-dependent agents are not as stringent in vivo as they are in vitro. However, the persistent suppression of bacterial growth is not indefinite, and a maximal amount of time can be spent below the MIC before a reduction in efficacy becomes apparent. Thus, a maximal dosing interval for these agents appears to exist in immunocompetent hosts, beyond which a decrease in efficacy can be expected.[50,189]

Clinical studies further confirm that for the agents discussed earlier, time above the MIC is a suitable pharmacodynamic endpoint in patients. In clinical studies of upper respiratory tract infection, the highest bacterial eradication rates for the β-lactams are observed when the time above the MIC exceeds 40 to 50 percent of the dosing interval.[37] For cefuroxime, cure rates drop from greater than 90 percent to approximately 75 percent when

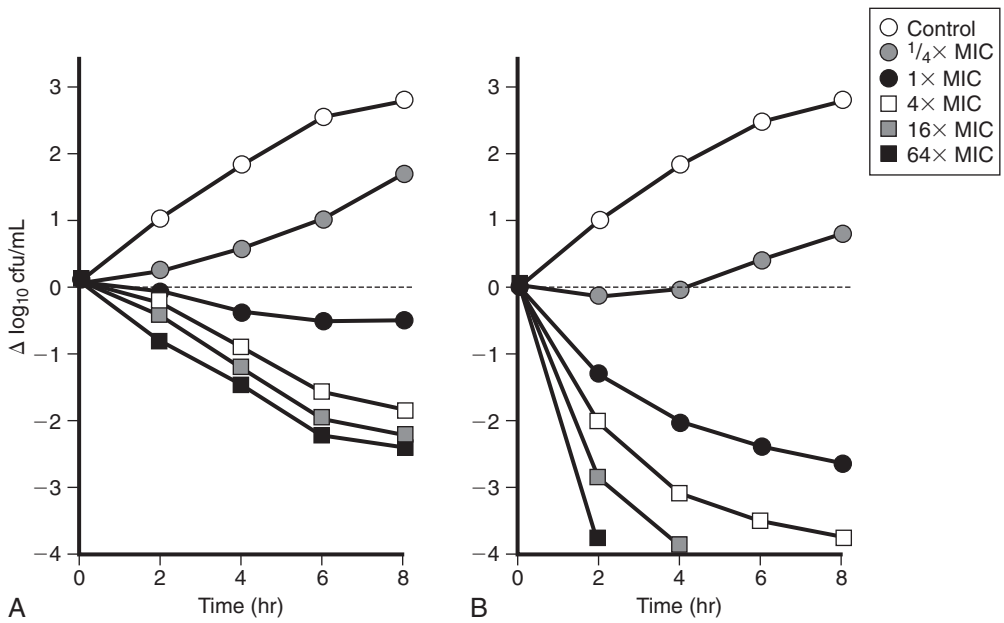

Figure 247–7 Representative log-kill curves. These curves illustrate the response to concentration-independent **(A)** (time-dependent) and concentration-dependent **(B)** antimicrobial agents. MIC, minimal inhibitory concentration. *(Adapted from Craig, W. A., and Ebert, S. C.: Killing and regrowth of bacteria in vitro: A review. Scand. J. Infect. Dis. 74[Suppl.]:63-70, 1991.)*

the time above the MIC falls to less than 40 percent.[67,76] Patients with a susceptible organism show 92 percent efficacy with a continuous-infusion regimen of cefamandole versus 63 percent efficacy with intermittent administration of the agent. Finally, in neutropenic patients, an overall efficacy rate of 65 percent was observed after continuous infusion of cefamandole as opposed to 21 percent efficacy in patients receiving intermittent administration.[24] For macrolide-susceptible pathogens, cure rates approaching 100 percent were observed when concentrations remained above the MIC for greater than 80 percent of the dosing interval.[37] As the MIC increases such that the percentage of time spent above the MIC falls, so too do cure rates. Macrolide concentrations rarely exceed the MIC for *Haemophilus influenzae*, and cure rates are comparable to those seen in placebo-treated individuals.[37] A few studies appear to contradict the aforementioned data, findings indicating that little difference in clinical response is observed when the same total daily dose of selected agents is administered as a continuous infusion or with increased frequency versus less frequent intermittent administration; however, a prolonged post-antibiotic effect (PAE) or protracted half-life, such that both of the regimens evaluated spend nearly 100 percent of the dosing interval above the MIC, may explain these discrepancies.[28,123,218]

Concentration Above the Minimal Inhibitory Concentration

In contrast to the aforementioned agents, a smaller group of agents demonstrate concentration dependence, with the magnitude of antimicrobial effect increasing in direct proportion to increasing drug concentrations (see Fig. 247–7B).[16,141] The aminoglycoside and fluoroquinolone antibiotics are the prototypic drugs of this pharmacodynamic class; however, concentration-dependent activity also has been observed with the lipopeptides and metronidazole.[5,39,168,196,212] Unlike the time-dependent agents, for which shortening the dosing interval results in increased efficacy, extending the dosing interval for concentration-dependent drugs affords an ability to increase the dose and results in a greater reduction in bacterial inoculum and, for some agents, a diminution in adaptive resistance.[38] Though highly variable, optimal ratios of peak plasma concentration to MIC that result in complete killing have been defined for many drug-microbe combinations. Similarly, ratios of C_{max} to MIC (C_{max}/MIC) can be defined, below which the organism is afforded the opportunity to regrow with increased selection of resistant subpopulations.[22,44,45]

Concentration-dependent killing for many of these agents has been demonstrated in both animal models and human clinical trials. In neutropenic mice with pseudomonal soft tissue infection, dosing schemes that deliver larger aminoglycoside doses less frequently result in greater killing than do schemes with the same total daily dose administered more frequently, even though all regimens achieved serum concentrations in excess of the MIC.[72] In patients receiving quinolone therapy for the treatment of respiratory tract, urinary tract, and skin and soft tissue infections, several pharmacodynamic parameters proved to correlate with clinical response; however, the best correlation was observed with the C_{max}/MIC ratio.[166] In clinical trials in which patients received aminoglycoside therapy for gram-negative infections, the strongest association between pharmacokinetic indices and clinical response was observed with the C_{max}/MIC ratio. In fact, the relationship between the C_{max}/MIC ratio and clinical response appeared to be linear over the range of clinically relevant plasma concentrations. No significant difference occurred in the time to achieve C_{max} between responders and nonresponders; therefore, the improved response rates in patients achieving higher peak plasma concentrations were not simply an artifact of drug accumulation as a result of longer duration of therapy.[148,149]

In addition to the absolute peak plasma concentration, the time that optimal peak levels are achieved appears to play a critical role in the response to concentration-dependent antimicrobial agents. A significant correlation with clinical improvement and reduction in mortality is observed if therapeutic peak plasma concentrations are reached early during the course of treatment.[150,153] The probable reason for this effect is that the response of the bacterial population to the same antibiotic concentration can change with subsequent doses. As alluded to earlier, subtherapeutic peak plasma concentrations serve to select out fewer susceptible variants within the population.[22,23,71] Based on these data, a key goal of therapy (i.e., in addition to proper drug selection) for concentration-dependent agents appears to be the attainment of high peak plasma concentrations early in therapy to afford rapid initial killing and minimize adaptive resistance.

Although prolonging the dosing interval affords the luxury of increasing the dose to optimize killing, the law of diminishing returns applies even for concentration-dependent agents, and it is possible to increase the dosing interval to excess and decrease efficacy. Despite the clear concentration dependence with escalating doses of fluoroquinolones, a simulated every-12-hour regimen was less effective than was a regimen using the same total daily dose administered every 8 hours.[15] Similarly, animal models of gram-negative lung and soft tissue infection suggest that delayed clearance of the infecting organism is observed in response to aminoglycoside and fluoroquinolone therapy when administered in protracted dosing regimens (e.g., dosing interval much greater than the half-life) as opposed to shorter dosing intervals.[128,152,178] Again, scattered studies appear to contradict these findings; however, they use agents with a longer half-life, and therefore the dosing interval may, in fact, not exceed the time spent above the MIC plus the residual PAE.[42] Thus, despite their concentration dependence, an element of time appears to be involved in the response to these agents. Unless peak concentrations are achieved in excess of those necessary to obtain maximal kill rates and the dosing interval does not markedly exceed time above the MIC plus the PAE, the efficacy of such agents is not only dose-dependent but also dose interval–dependent.

Total-Body Exposure Above the Minimal Inhibitory Concentration

The AUC, a reflection of total-body exposure, is a pharmacokinetic parameter that integrates both time and drug concentration. Estimates of AUC reflect the magnitude of the dose received and the drug half-life relative to the dosing interval. Accordingly, researchers have proposed that the ratio of AUC to MIC (AUC/MIC ratio) may serve as a better surrogate of pharmacodynamic activity for both time- and concentration-dependent agents. In several studies, the AUC/MIC ratio serves as the best correlate of the reduction in number of organisms for aminoglycosides, quinolones, streptogramins, rifamycins, isoniazid, evernimicin, and azole antifungals.* Because of the interdependence between AUC and the pharmacokinetic parameters previously noted, studies also can be identified that demonstrate a relationship between clinical or microbiologic outcome and the AUC/MIC ratio for agents with time-dependent activity (e.g., the β- lactams and glycopeptides). Often, however, these studies fail to evaluate multiple pharmacokinetic parameters.[147,188]

In an elegant study evaluating certain aminoglycoside dosing regimens against *Pseudomonas aeruginosa* and *Escherichia coli* infection, the log-normalized AUC provided the best correlation with efficacy. However, as was observed with concentration-dependent agents, when the dosing interval exceeded the time above the MIC plus the residual PAE, the best correlation with

*See references 4, 6, 7, 43, 54, 105, 106, 122, 132, 178.

efficacy was the percentage of time spent above the MIC, thus reaffirming that the dosing interval can be too long with the aminoglycosides.[217] A meta-analysis of 19 studies evaluating 8 quinolones and 6 different organisms in experimental endocarditis similarly demonstrated a correlation between the AUC/MIC and reduction in $\log_{10}$ colony-forming units (CFUs) per vegetation. However, given the relationship between the pharmacokinetic parameters, C_{max}/MIC and time greater than MIC also proved to correlate with a decrease in the size of the inoculum.[3] In human investigations, AUC/MIC appears to serve as the best predictor of clinical response, microbiologic response, and bacterial eradication for the fluoroquinolones. Nonetheless, C_{max}/MIC and time greater than MIC can be linked similarly to bacterial eradication for this class of agents.[61,62,163]

Clearly, the optimal AUC/MIC ratio will be different for different organisms despite sharing a similar quantitative susceptibility end-point. Similarly, optimal AUC/MIC ratios are highly variable and depend on the antimicrobial agent being evaluated. For example, effective eradication of organisms implicated in nosocomial pneumonia is observed with an AUC/MIC ratio of 540 for cefmenoxime, 34 for tobramycin, and 23 for ciprofloxacin.[187] Consequently, attempts have been made to standardize this pharmacodynamic end-point, and investigators have proposed a value of 125 as the cutoff below which a reduction in efficacy and increase in resistance may be expected.[96,186] However, optimal AUC/MIC ratios may differ, depending not only on a given organism and agent but also on the desired outcome and the disease state. A ratio greater than 125 resulted in bacterial eradication roughly 7 days after the initiation of β-lactam and quinolone therapy; however, an AUC/MIC ratio of 250 resulted in eradication of the pathogen within 1 to 2 days after initiating quinolone therapy.[186] For patients with acute exacerbations of chronic bronchitis who are receiving fluoroquinolones, an AUC/MIC ratio less than 276 was associated with longer time to clinical success, whereas a ratio greater than 576 was associated with a reduction in coughs per day and a ratio greater than 212 with decreasing days to a reduction in the volume of sputum.[145] In an animal model of bacterial endocarditis, significantly lower numbers of organism were found in the vegetation after 3 to 6 days of therapy when the AUC/MIC ratio exceeded 100.[3] Moreover, a value of 100 appeared to be the cutoff below which an increased risk of resistance was observed in a retrospective review of 107 acutely ill patients with lower respiratory tract infection.[207] Furthermore, in vitro models evaluating fluoroquinolone activity against *Streptococcus pneumoniae* demonstrated effective eradication with an AUC/MIC ratio between 30 and 65, much lower than the value of 125 reported as optimal for other pathogens.[122,132]

Although this hybrid parameter bridges concentration and time (i.e., extent of systemic drug exposure from a given dose) and has been demonstrated to correlate with efficacy for numerous drug classes, optimal criteria appear to vary with the organism, agent, disease state, and desired outcome. In addition, established relationships no longer may hold for some agents when a protracted dosing interval is used in therapy. As such, a general classification and standard outcome are not straightforward, and agents need to be evaluated with respect to known mechanisms of activity and the specific clinical and microbiologic situations in which they are used.

Optimal Surrogates for Drugs in Combination

Combination antimicrobial therapy is initiated in numerous circumstances: to ensure broad-spectrum coverage early in therapy, to treat polymicrobial infections, and to combat organisms that require multiple agents for effective eradication. Often, combination therapy entails the use of agents from different classes or agents that have different mechanisms of action (or both). This particular situation raises the question of how one applies the aforementioned pharmacodynamic principles to selecting or evaluating the efficacy of drug therapy when confronted with the combined use of agents that do not share similar pharmacodynamic targets. Although optimization of combination therapy may be possible by choosing the interval for one agent,[73] efficacy appears to be explained best when a combination of both pharmacodynamic properties is considered.[72,151]

Reasonable models of a concentration-effect relationship have been proposed for numerous agents alone and in combination; however, optimal ratios remain to be defined for many drug-microbe combinations. Moreover, it is probably more complex than simply defining the optimal ratio for specific combinations. Even though one can define the best correlate, killing rates, in fact, may vary with the site of infection because penetration of a drug into or clearance from tissue varies from site to site. For example, logAUC proves to be the best predictor for clearance of organisms from the lung regardless of the dosing interval used. In contrast, given faster drug clearance from the thigh, the time above the MIC was a more important predictor of eradication when a longer dosing interval was used, whereas the logAUC was the best predictor of clearance of organisms with the use of shorter dosing intervals.[129] Similarly, in animal models of bacterial meningitis, greater kill rates were observed as time greater than MBC increased. However, when concentrations remained above the MBC for the entire dosing interval, which may not be unexpected in situations in which the antibiotic half-life is longer in CSF than in plasma, kill rates were directly proportional to both peak/MBC and AUC/MBC ratios.[140] These data suggest that we may need to expand the characterization of pharmacodynamic surrogates to look at the pharmacokinetic-pharmacodynamic interface at the site of infection rather than simply defining dosing strategies based on in vitro susceptibility data and the disposition characteristics of drugs in plasma. Without question, many data need to be collected and verified in the human host. The maximal dose and dosing regimen ideally are selected so that the resultant pharmacokinetic profile affords optimal pharmacodynamic activity without causing unnecessary adverse events, therapeutic failure, or both, as may be observed with inappropriate dosing. Development of a successful therapeutic strategy requires the following: incorporation of knowledge regarding the infecting pathogen; the physicochemical, pharmacologic, and pharmacokinetic properties of the anti-infective agent; and specific factors of the host or disease that are capable of altering either drug disposition or action. Such an approach enables the clinician to make clearer distinctions among agents with similar susceptibility profiles, yet different mechanistic or pharmacokinetic profiles and to select an optimal drug regimen that will be most likely to result in successful therapy.

EFFECT OF SUPRAINHIBITORY ANTIMICROBIAL CONCENTRATIONS (EAGLE EFFECT, PARADOXICAL ZONE PHENOMENON, CONCENTRATION QUENCHING)

In simplest terms, one typically thinks of anti-infective activity's increasing with increasing antimicrobial concentration. More sophisticated models describe increasing activity with increasing drug concentration to a maximal effect until activity reaches a plateau and remains relatively constant despite further increases in drug concentration (see Fig. 247–4). However, for many antibiotics, an increase in drug concentration can, in fact, result in a reduction in antimicrobial activity (Fig. 247–8).[92] This paradoxical effect was observed as early as 1945 and described 3 years later by Eagle and Musselman, who reported the existence of antibiotic concentrations above the maximally effective concentration at which the killing rate of bacteria is paradoxically reduced.[48,118]

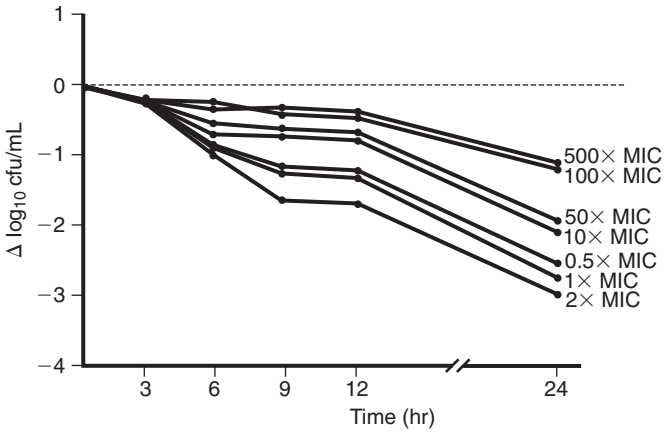

Figure 247–8 Representative log-kill curve demonstrating the paradoxical effects that can be observed with suprainhibitory antimicrobial concentrations. MIC, minimal inhibitory concentration. *(Adapted from Holm, S. E., Odenholdt-Tornqvist, I., and Cars, O.: Paradoxical effects of antibiotics. Scand. J. Infect. Dis. Suppl. 74:113-117, 1991.)*

This phenomenon has been described with a host of organisms and, although originally observed with penicillin, has been confirmed with other β-lactams, glycopeptides, aminoglycosides, and fluoroquinolones.[138,155,164,202,226] Given the diversity of agents that demonstrate a paradoxical reduction in activity with increasing drug concentration, this phenomenon probably cannot be explained by a single mechanism, and although they are not definitively elucidated, numerous mechanisms have been proposed to explain these observations.

For certain β-lactam antimicrobials, induction of β-lactamase may be responsible for the paradoxical effects observed in selected organisms. In vitro experiments performed with *Proteus vulgaris* suggested that the greatest paradoxical response seen with β-lactams was observed with agents that demonstrated the highest β-lactamase–inducing capacity and the poorest stability to degradation by this enzyme. When a mutant strain of this organism that was unable to induce β-lactamase production was evaluated, no paradoxical effect was noted.[98] In animal models of peritoneal infection, antibiotics with strong dose-dependent induction of β-lactamase similarly demonstrated a paradoxical effect against β-lactamase–positive strains of *P. vulgaris*. However, no paradoxical effect was observed against β-lactamase–negative strains. Agents that were only weak inducers of β-lactamase demonstrated no evidence of a paradoxical effect, regardless of whether the *P. vulgaris* strains produced β-lactamase.[99]

Because this paradoxical effect can be demonstrated with the β-lactams against organisms that do not produce β-lactamase, other mechanisms must also be responsible. One such mechanism may involve dysregulation of the bacterial autolytic system, which often confers tolerance to an organism but also may uncover an Eagle-type effect.[87] A paradoxical reduction in antimicrobial activity at high doses may be related to differences in regulation or expression of these autolytic enzymes. In *Enterococcus* strains that fully express only one of two recognized autolytic enzymes, diminished or deficient production of the second enzyme resulted in a paradoxical response to penicillin. Strains in which both enzymes were produced remained susceptible to the antibiotic irrespective of concentration, thus suggesting that a proportional dose-response relationship may require the synergistic activity of both enzymes.[59,60] Further investigation into the paradoxical effect observed in tolerant organisms suggests that organisms in the exponential growth phase demonstrate this response more consistently than do those in the stationary phase.[165,167] Animal models of *Staphylococcus aureus* endocarditis provide in vivo confirmation of the paradoxical response observed with tolerant organisms in vitro. Administration of continuous-infusion cloxacillin to animals infected with a nontolerant strain produced a dose-proportional reduction in bacterial density ($\log_{10}$CFUs/g) within the vegetation, whereas animals infected with a tolerant strain demonstrated a reduction and subsequent paradoxical increase in bacterial density with increasing dose. No statistical difference was observed in bacterial density within other organs or in overall survival, which raises questions regarding the in vivo significance of these observations.[219]

For antibiotics that demonstrate polyfunctional activity at supratherapeutic concentrations, a paradoxical response may occur as a result of secondary alterations in cellular functions that are requisite for antimicrobial activity. Despite a principal mechanism of action for the fluoroquinolones at the site of DNA gyrase, these agents appear to be bactericidal only in cells able to synthesize protein. As quinolone concentrations increase above those that are bactericidal, RNA synthesis and therefore protein synthesis are progressively inhibited, thus explaining the reduced rate of bactericidal activity observed at high quinolone concentrations.[176] Incompletely characterized genetic modifications also may confer a paradoxical response to antibiotics. β-Lactam resistance in methicillin-resistant *S. aureus* (MRSA) is mediated by de-repressing the production of a low-affinity PBP. However, because the modified PBP serves as an inefficient transpeptidase, it is regarded as an internal selective pressure in the bacterium, and a countermutation has arisen. Although it is not completely understood, the phenotypic expression of this countermutation is manifested as an Eagle-type resistance to methicillin.[119,183] Finally, an observed paradoxical response may not be a result of the drug-microbe combination alone but a result of the chemical environment as well. A paradoxical effect with penicillin, in which both cell count and the rate of killing were affected, was demonstrated in *Streptococcus agalactiae* when the pH was reduced under in vitro conditions.[100]

Most studies investigating the Eagle effect have been conducted in vitro, and the clinical implications of the paradoxical phenomenon have yet to be fully elucidated. However, anecdotal evidence appears to suggest that the clinical efficacy of antimicrobials can be compromised by high-dose antibiotic therapy. Case reports of β-lactam–susceptible streptococcal endocarditis and staphylococcal pneumonia describe patients who failed to respond to high-dose β-lactam therapy (plasma concentrations >100 times the MIC in one case), with subsequent improvement in each case when the dose was lowered.[70,80,205] For many agents, it is clearly advantageous to establish high peak drug concentrations early, the benefits of which include increasing log kill, preventing the selection of resistant mutants, overcoming refractoriness, and enhancing penetration of tissue. However, the relative safety of many drug classes (e.g., the β-lactams) often results in the use of doses that may be higher than necessary. When clear evidence is lacking for enhanced bactericidal activity at higher concentrations and the potential for diminished efficacy exists, escalation of antibiotic doses should be considered judiciously.

EFFECTS OF SUBINHIBITORY ANTIMICROBIAL CONCENTRATION

Individuals may be exposed to subtherapeutic antimicrobial concentrations for many reasons, including underdosing, poor compliance, and, perhaps most commonly, the inability of the pharmacokinetic profile of the agent in question to afford adequate penetration to the site of infection. Exposure of bacteria to antibiotic concentrations below the MIC can have variable effects, depending on the organism and the antimicrobial agent. In fact,

the effects observed with subinhibitory levels are not simply a milder extension of those observed at inhibitory concentrations but, instead, are qualitatively different from the effects observed at concentrations that equal or exceed the MIC.[134] Subinhibitory concentrations can have the following effects: enhance or impair opsonization and phagocytosis; affect the virulence of the bacteria by modifying the bacterial cell surface; alter adherence properties, antigen expression, or the excretion of enzymes and toxins (or any combination of these effects); and inhibit bacterial growth.[157,158,210] The result can be an increase or decrease in responsiveness to therapy, both of which are discussed later in this section. Before reviewing the current data, however, one should note that this discussion does not refer to subinhibitory concentrations occurring after initial suprainhibitory drug levels. These particular effects are distinguished as PAE and are addressed separately.

Even though antibiotic concentrations may fail to reach or exceed the MIC, these agents still can affect the growth of an invading organism adversely.[134,135,137] In fact, the term *minimal antibacterial concentration* (MAC), usually a fraction of the MIC, was coined to describe the lowest concentration of antibiotic required to produce either structural changes in the bacterium, a 1 $\log_{10}$ decrease in the number of organisms present, or a 10 percent delay in turbidimetric growth in vitro.[68,201] Rather than resulting in treatment failure, subinhibitory antimicrobial concentrations in concert with defenses in an immunocompetent host may be sufficient to clear the infection.[210] Many effects have been observed to occur as a result of exposure to subinhibitory antimicrobial concentrations, and they are mediated by a variable number of mechanisms.

Increased susceptibility to phagocytosis may be seen with subinhibitory antibiotic concentrations and can occur in many ways. Subinhibitory concentrations may induce morphologic changes in the bacterium such that its size and shape are altered markedly, and, as a result, the immune system is signaled to clear the bacterium.[11,201,220] However, subinhibitory concentrations of drugs that share a common intracellular target cannot be expected to have the same effects on bacterial morphology. Even though both penicillins and cephalosporins act through PBPs, subinhibitory concentrations of penicillins induce filaments in *Proteus mirabilis*, whereas cephalosporins induce the formation of globules.[135,137,205] A likely explanation lies in their different affinity for the various PBPs, whereby they can be expected to bind selectively at low concentrations and rather nonspecifically at therapeutic or supratherapeutic concentrations. The preferential binding of ceftibuten to PBP-3 of *E. coli* at subinhibitory concentrations results in filamentation because this PBP allows crosswall but not sidewall synthesis.[26] Similarly, subinhibitory concentrations of the same drug applied to different organisms can produce different morphologic changes. In *S. aureus*, subinhibitory concentrations of loracarbef induce no morphologic changes, whereas similar concentrations lead to elongated forms and short-chain forms in *E. coli* and elongated and filamentous forms in *H. influenzae*.[211]

Although size may be one factor stimulating enhanced clearance of the organism, increased uptake by the immune system can be demonstrated even for cells with little gross morphologic alteration. Subinhibitory antibiotic concentrations can impair the synthesis of antiphagocytic surface factors or liberate their release, thereby enhancing complement binding, opsonization, phagocytosis, and, ultimately, bacterial killing.[89,94,124] Production of the antiphagocytic A protein of *S. aureus* can be repressed by subinhibitory concentrations of selected protein synthesis inhibitors and fluoroquinolones.[143,195] Subinhibitory concentrations of β-lactam agents, but not vancomycin or protein synthesis inhibitors, increase the susceptibility of *S. agalactiae* to uptake by polymorphonuclear leukocytes (PMNs) because of the loss of antiphagocytic capsular material.[93] Carbapenems and cephalosporins at subinhibitory concentrations increase the serum sensitivity of K1-positive *E. coli* by reducing expression of the K1 capsular polysaccharide.[203]

Even drugs with no inherent bacteriostatic or bactericidal activity against a specific organism can induce sufficient changes in the cell surface to affect serum sensitivity. Pre-incubation of *P. aeruginosa* with subinhibitory concentrations of certain macrolides decreases cell surface hydrophobicity and enhances the sensitivity of the organism to human serum bactericidal activity.[206] Subinhibitory β-lactam concentrations are capable of sufficiently altering the peptidoglycan structure in MRSA to enhance susceptibility of the organism to the lysozyme present in sputum, even though the organism, because of altered PBP production, is no longer susceptible to the bactericidal activity of these agents.[97] Although most effects stimulating bacterial clearance by the host occur as a direct result of cellular changes in the organism, immune cells also can be altered by subinhibitory antibiotic concentrations. Erythromycin does not affect the generation of serum-derived leuko-attractants, nor does it increase PMN cell numbers, yet it appears capable of stimulating the migration of PMNs. Researchers suggested that this effect probably results from the ability of erythromycin to sustain cellular migration by reducing the level of leuko-attractant–induced auto-oxidation mediated by the myeloperoxidase–hydrogen peroxide–halide system.[55]

In addition to enhancing bacterial clearance, subinhibitory antibiotic concentrations also can impair bacterial virulence mechanisms. For many organisms, pili, fimbriae, and fimbriae-associated adhesins are responsible for the initial events surrounding adherence and colonization at the site of entry or infection.[185] Subinhibitory quinolone and clindamycin concentrations are capable of decreasing the adherence of nosocomial pathogens (e.g., *Staphylococcus epidermidis)* to the synthetic materials of implantable catheters.[31,193] Subinhibitory concentrations of penicillins, cephalosporins, azalides, and quinolones all have demonstrated the ability to decrease the formation of fimbriae or alter structures that mediate adherence. Specific examples include decreased adherence to oral and urinary tract epithelial cells for organisms such as *Porphyromonas gingivalis*, *E. coli*, *Salmonella typhimurium*, and *P. aeruginosa*.[26,133,195,204,220] Moreover, these effects do not appear to be growth phase–specific for select drug-microbe combinations.[27]

Subtherapeutic antibiotic concentrations also can have an impact on virulence by down-regulating bacterial toxin production. Subinhibitory concentrations of clindamycin can inhibit toxin production in *S. epidermidis* markedly without appreciably altering bacterial growth.[193] *Pseudomonas* exoenzymes that facilitate disease pathogenesis (e.g., exotoxin A, exoenzyme S, phospholipase C, total protease, elastase) are suppressed after exposure to subinhibitory concentrations of ciprofloxacin, tobramycin, and ceftazidime.[81] Finally, given the ability of subinhibitory fluoroquinolone concentrations to disrupt DNA structure sufficiently to interfere with effective mRNA production, continuous exposure of *S. aureus* to fluoroquinolones at subinhibitory concentrations decreases the production of nuclease and hemolytic alpha-toxin production.[195]

Although discerning which of these effects, alone or in combination, are responsible for the subinhibitory effects is difficult, one may see in vivo that the impact of the sum total of these effects can be observed at the level of the host. In a non-neutropenic rat model of *Klebsiella pneumoniae* pneumonia, a continuous infusion of ceftazidime resulting in steady-state concentrations of 0.06 mg/L protected all the animals from death, despite an MIC for the pathogen of 0.2 mg/L. The same could not be said, however, for immunocompromised animals, which required steady-state concentrations of 0.38 mg/L for adequate protection.[179,180] In a similar model of intraperitoneal *K. pneumoniae* infection, subinhibitory clindamycin concentrations resulted in an increase in bacterial clearance and a decrease in the

$\log_{10}$CFUs in blood at 72 hours.[9] In humans, low-dose ampicillin (such that concentrations in urine were no greater than one fourth to one half times the MIC) combined with large water intake was demonstrated to clear documented *E. coli* urinary tract infection in 16 of 20 patients within 2 days of initiating therapy, whereas none of the 18 control subjects receiving the fluid intervention alone demonstrated resolution of the infection.[173] Despite the resistance of *Pseudomonas* in patients with cystic fibrosis, the fluoroquinolones remain capable of eliciting a significant reduction in sputum colony counts and improvement in clinical signs and symptoms.[191,194]

Subinhibitory antimicrobial concentrations can be as potentially disadvantageous to the host as they can be beneficial. These concentrations can impair the ability of the host to respond to the bacterial inoculum, can augment bacterial defenses, and can serve to inactivate the antibiotic. For organisms that are susceptible to β-lactamase induction, strong inducers can up-regulate β-lactamase synthesis at concentrations below the MIC. Although β-lactamase induction typically is a reversible phenomenon, many antibiotics demonstrate the ability to select out genetically de-repressed mutants at subinhibitory concentrations.[192,198] Irrespective of whether this induction is phenotypic or genotypic, many antibiotics to which the organism originally may have been susceptible no longer retain their efficacy in light of β-lactamase production. This type of adaptive resistance, observed in response to sublethal antibiotic concentrations, also can be nonenzymatic. A single, one-time exposure of *P. aeruginosa* to subinhibitory concentrations of chlorhexidine results in unstable resistance, and repeated exposure leads to stable expression of altered cell surface macromolecules or efflux systems responsible for resistance.[208] In a clinical strain of this same organism exposed to subinhibitory concentrations of fluoroquinolones and carbapenems for 5 days, a 16- to 32-fold increase in MIC was observed in concert with an alteration in overall protein expression.[32]

Sublethal antibiotic concentrations also can stimulate the production of toxins that may be detrimental to the host. Exposure of enterohemorrhagic *E. coli* to subinhibitory concentrations of fluoroquinolones, cephalosporins, tetracyclines, and inhibitors of folic acid synthesis induces enhanced expression of a *Shiga*-like toxin (SLT-1), which is proposed to mediate events surrounding the development of hemolytic-uremic syndrome. Subinhibitory fluoroquinolone concentrations also can stimulate the production of verotoxins in this same organism.[221,227] Lincomycin and tetracycline at subinhibitory concentrations stimulate the production of heat-labile enterotoxin in enterotoxigenic *E. coli*, as well as *Vibrio cholerae* enterotoxin, even though these agents are principally protein synthesis inhibitors. Prior data suggest that the copy number of plasmids does not increase and proposed that the rate of enterotoxin liberation is enhanced as a result of antibiotic inhibition of the synthesis of proteins responsible for degrading the toxin.[131,228] The alpha-toxin of *S. aureus* is demonstrated to be hemolytic, dermonecrotic, and antichemotactic and appears to be up-regulated in the presence of subinhibitory nafcillin concentrations, irrespective of whether the isolate is susceptible to the agent. Greater hemolytic activity and increased lethality of the broth filtrate in a murine intraperitoneal model are observed, and this activity is ablated when incubated with anti–alpha-toxin antibody.[116] Other β-lactams (with the exception of aztreonam), ofloxacin, and trimethoprim are similarly capable of inducing alpha-toxin expression at subinhibitory concentrations.[159]

The up-regulation of protein expression by subinhibitory antibiotic concentrations not only is responsible for contributing to antibiotic and cellular destruction but also can enhance the binding of pathogens to host proteins and implantable devices. Subinhibitory concentrations of ciprofloxacin increase the transcription of fibronectin-binding proteins in *S. aureus* isolates and thereby result in greater adhesion to immobilized fibronectin and fibronectin-coated polymers, a particular concern with subcutaneously implanted devices that have polymer surfaces.[19,20] Subinhibitory concentrations of antibiotic also can alter the immunogenicity of the pathogen such that the host can no longer mount the same degree of immune response. *S. aureus* isolates co-incubated with subinhibitory concentrations of oxacillin demonstrated a diminished capacity to stimulate proinflammatory cytokine production (e.g., tumor necrosis factor-α, interleukin-1β [IL-1β], and IL-6) in human monocytes. Given that activation of the complement system and cytokine release are stimulated by peptidoglycan molecules of a certain size or tertiary structure, subinhibitory β-lactam concentrations probably distort the peptidoglycan structure sufficiently that the immune system no longer effectively responds to these immunostimulatory components.[190]

Unless unusual circumstances prevail, the goal of therapy probably will not be to target plasma concentrations below the MIC. However, given the reality of encountering this situation in the clinical setting, practitioners certainly need to be aware of the potential implications for therapeutic response associated with subinhibitory concentrations of antimicrobial agents.

EFFECTS THAT PERSIST AFTER ANTIMICROBIAL EXPOSURE (POST-ANTIBIOTIC EFFECT, POST-ANTIBIOTIC LEUKOCYTE ENHANCEMENT, AND POST–β-LACTAMASE INHIBITOR EFFECT)

Early investigations into antibiotic activity described a delay in the recovery and regrowth of penicillin-exposed staphylococci and streptococci when the drug was removed by enzymatic inactivation or the organism was removed to drug-free media.[18,47,162] In addition, in vivo evaluations of penicillin activity suggested that the effects of penicillin in an immunocompetent animal lasted well beyond the time when blood levels remained above quantifiable concentrations. Despite a half-life of minutes, many hours could elapse after the administration of a dose of penicillin before bacterial growth resumes.[51,104,189] The term *post-antibiotic effect* was coined to describe the suppression of bacterial growth that persists after brief exposure of the organism to an antimicrobial agent.[35] Unlike the subinhibitory effects discussed earlier in the chapter, the PAE occurs as a result of residual antimicrobial activity after initial exposure at inhibitory concentrations, as opposed to the subinhibitory concentrations themselves. The PAEs described to date typically are reversible, and although the mechanisms have not been elucidated fully, probably are caused by either nonlethal damage or persistence of antibiotic at the site of action. In the same vein as the PAEs, the term *post–β-lactamase inhibitor effect* (PLIE) was coined to describe the residual effects of β-lactamase inhibitors after exposure to inhibitory concentrations.[209] Similarly, one encounters the term *post-antibiotic leukocyte enhancement* (PALE), which is used to account for a PAE in vivo that lasts longer than that observed in vitro and is defined as exposure to subinhibitory concentrations of an antibiotic that render the organism more susceptible to the phagocytic and bactericidal action of neutrophils.

The PAE depends on many factors, the most discernible being the drug-microbe combination.[102] Since the initial descriptions with penicillin were reported, similar observations have been noted for a broad range of organisms, and essentially all antibiotic classes demonstrate a PAE against select organisms.[35] Virtually all agents evaluated demonstrate a PAE against susceptible gram-positive cocci. Inhibitors of protein and nucleic acid synthesis produce longer-lasting PAEs in vitro than do cell wall–acting agents, with an average of approximately 1 to 2 hours for β-lactams, 1 to 3 hours for fluoroquinolones, and 3 to 5 hours for protein synthesis inhibitors. For resistant gram-positive cocci, descriptions of a PAE are mixed. Against gram-negative bacilli,

no appreciable PAE is observed for trimethoprim or the β-lactams in vitro, with the exception of the carbapenems, which demonstrate a PAE of approximately 1 to 2 hours. The fluoroquinolones and protein synthesis inhibitors have PAEs of roughly 1 to 3 hours and 3 to 8 hours, respectively. Within this group of organisms, *P. aeruginosa* serves as an exception, and the fluoroquinolones and protein synthesis inhibitors display slightly shorter PAEs, 1 to 2 hours and 2 to 3 hours on average for the respective drug classes. Similar observations have been described for the gram-negative anaerobes, with little or no PAE seen with the β-lactams but a measurable PAE observed for protein synthesis inhibitors.[35]

Given that most drug classes demonstrate a PAE, multiple mechanisms must exist by which this effect arises. For the β-lactams, researchers proposed that the PAE corresponds to the time required for the organism to synthesize new PBPs. The initial high β-lactam concentrations are thought to bind irreversibly to and thus inactivate the PBPs. As such, cell multiplication subsequently is prolonged until a critical number of PBPs are resynthesized and cell division can resume.[210] Within the large class of β-lactam agents, however, further distinctions can be made based on the specific PBP bound and the subsequent morphologic alteration that is induced. Against *E. coli*, the longest-lasting PAEs are observed for agents that induce the formation of spheroplasts and the shortest for agents that induce the formation of filaments. On drug removal, filaments (which may contain a biomass corresponding to more than 20 bacteria) readily separate into individual bacteria, whereas spheroplasts require a longer period to resynthesize a normal cell wall and resume replication.[86] Analogous to the β-lactams, the time required for the resynthesis or recovery of ribosomal proteins is probably responsible for the PAEs observed after the administration of an aminoglycoside. Evaluation of the intracellular events taking place in *E. coli* during aminoglycoside-induced PAEs suggests that both DNA and RNA synthesis resume immediately after drug removal; however, synthesis of structural and functional protein does not resume for nearly 5 hours.[13,102] For the fluoroquinolones, the proposed mechanism behind the PAE is not as consistent with the antimicrobial activity of these agents. A progressive increase in ^{3}H-thymidine incorporation in *S. aureus* during the PAE suggests that DNA synthesis continues to occur, and thus, the PAE may represent the time needed to repair the damage to DNA gyrase, the time required to re-establish the function of DNA gyrase after dissociation of the antibiotic from the enzyme, or the time required to synthesize new DNA gyrase.[77]

In addition to the specific drug-microbe combination, the magnitude and duration of drug exposure also have an impact on the PAE. Cell wall–acting agents (e.g., β-lactams and glycopeptides) demonstrate a concentration-dependent PAE. Increases in the concentration and duration of exposure, (i.e., increasing AUC) prolong the PAE in both gram-positive and gram-negative organisms to a point of maximal effect, typically 2 to 6 hours, although the time may be shorter for some members of this class. In fact, the PAE appears to be related to the log-normalized AUC in a sigmoidal manner.[34,86,121] Similarly, an increasing concentration of protein synthesis inhibitors is associated with progressive prolongation in PAE to a point of maximal effect. However, it can be difficult to establish with the aminoglycosides and fluoroquinolones because complete killing at supratherapeutic concentrations can obscure accurate determination of the PAE.[35,102] Bacteriostatic agents generally demonstrate concentration-independent PAEs such that increasing the duration of antibiotic exposure, but not the concentration, results in an increase in PAE to some maximal effect.[35]

As expected, the magnitude of the PAE also depends on whether antimicrobial agents are administered alone or in combination. Indifferent, additive, and synergistic PAEs all have been described with the use of combination therapy.[65,83,102] However, for some drug-microbe combinations, the magnitude of the PAE may differ with the phenotypic expression of resistance. For *Enterococcus faecalis* isolates that demonstrate only low-level resistance to streptomycin or gentamicin, the effect of a penicillin-aminoglycoside combination on the PAE is markedly synergistic. In contrast, for isolates with high-level resistance to the aminoglycosides, no synergistic PAE is observed.[224] Additionally, physicochemical factors can affect in vitro determination of PAEs, and, although the in vivo relevance is questionable, some are worthy of consideration. In *S. aureus*, the PAEs of penicillin and gentamicin are markedly protracted at the slightly acidic pH 6 as compared with a physiologic pH of 7.4. Given that a relatively acidic pH can occur at the site of active infection, a disease-PAE interaction is possible. A similar pH-dependent effect on PAE is not observed with the fluoroquinolones or macrolides against *S. aureus*, nor is it noted for *E. coli* and *P. aeruginosa* with the β-lactams, fluoroquinolones, and macrolides.[66,82] An increase in PAE in vitro also is observed as temperature drops, a finding that raises the question whether the PAE is truly altered or the generation time is lengthened. Regardless, the temperatures evaluated were much lower than physiologic temperatures and probably have no clinical impact in the presence of infection. Finally, anaerobic conditions are observed to increase the PAE for ciprofloxacin–*E. coli* and gentamicin–*S. aureus* combinations, but not with other combinations.[66]

The attention paid to PAE of late highlights its significance, which lies in the flexibility that it affords to extend the dosing interval before reexposure to drug, essentially re-dosing, is necessary. Researchers suggested that agents with a small PAE require that a dosing interval be selected that will maintain concentrations above the MIC throughout most of the interval. Agents with a more protracted PAE can be given less often and thus at higher doses, thereby supporting the argument for once-daily dosing with drugs such as the aminoglycosides. However, many nuances can be identified between the in vitro conditions under which PAEs are determined and the in vivo conditions of infection such that the ultimate clinical (i.e., therapeutic) implications of these data have yet to be determined. In vitro, attempts are made to remove the drug completely (i.e., abruptly terminate drug exposure to the microbe) after initial exposure when determining the PAE. In contrast, drug concentrations fall in a more controlled, typically first-order fashion in vivo. The impact of this distinction on PAEs in patients remains unknown. Variable growth rates or metabolic states of the organism when growing in vivo similarly may have an impact on the PAE. In vitro, a prolonged PAE is observed when *Enterococcus faecium* is exposed to the combination of gentamicin and penicillin; yet, when the same drug concentrations and the same inoculum size are achieved in the vegetation of a murine aortic valve endocarditis model, no prolongation of PAE can be observed.[91] Similarly, a rat model of *P. aeruginosa* endocarditis failed to demonstrate a PAE in vivo for the combination of imipenem and gentamicin despite a PAE of nearly 5 hours determined in vitro; however, an observable PAE in vitro and in vivo was noted in the same model when ciprofloxacin was evaluated.[90,101]

IMPACT OF INOCULUM SIZE ON THE CONCENTRATION-EFFECT RELATIONSHIP

The antimicrobial effect observed at any given drug concentration may vary with the number of organisms at the site of infection. Accordingly, the size of the inoculum can be a primary determinant of drug efficacy. Early investigations clearly demonstrated that the duration of the infection before treatment is a significant predictor of clinical response.[46] When therapy is delayed, presumably leading to a larger inoculum, the efficacy of

that therapy often is affected adversely. In non-neutropenic rats, larger doses of antibiotic were needed to treat *K. pneumoniae*, whether administered by continuous or intermittent infusion, when the infection was allowed to progress 34 hours before therapy was initiated versus 5 hours.[179] Many potential mechanisms have been proposed to account for this event. Large inocula perhaps generate a higher local density of enzymes that effectively reduce active (i.e., functional) antibiotic concentrations at the site of infection. Large bacterial populations also are statistically more likely to contain resistant organisms that arise by spontaneous mutation and predominate within the population as a result of the selective pressure posed by the antibiotic. One such example has been observed in a murine model of group A streptococcal myositis, in which the activity of penicillin is compromised most severely in the presence of a large inoculum (10^8 to 10^9 CFUs/mL), with relatively little impact on the activity of clindamycin. Given that the isolate did not produce β-lactamase and any residual PAE was irrelevant because both regimens maintained drug concentrations above the MIC for the duration of the dosing interval, this effect of the inoculum was attributed in part to the selection of a cell wall–deficient mutant.[199] Clindamycin, however, is not devoid of susceptibility to the inoculum effect for all organisms; an increase in the size of the inoculum or an increase in the time until therapy resulted in a lower reduction in $\log_{10}$CFUs in a murine *Bacillus fragilis* abscess model.[107] Another proposed mechanism for the effect of the inoculum lies in the finding that dense populations of organisms may grow at a slower rate or be metabolically inactive when compared with their less dense counterparts. An effect arising by this mechanism probably will not affect antimicrobial agents that are bactericidal against both rapidly growing and stationary-phase organisms (e.g., fluoroquinolones). However, for agents that exert their bactericidal effects primarily on rapidly dividing organisms (e.g., β-lactams), activity may be compromised in the presence of an established infection in which the bacterial population is large and as many as 90 percent of the organisms may be slowly dividing and, thus, metabolically inactive. For clinical isolates of group G streptococci, time-kill studies demonstrated rapid complete bacterial killing when the organism was primarily in log-phase growth, regardless of whether 10^4 or 10^7 organisms were involved. In contrast, when the organism was principally in the stationary phase, rapid and complete killing was observed only for the smaller inoculum (10^4 organisms), with no appreciable killing at 10^8 organisms. Furthermore, in patients with a protracted clinical course of infection or recalcitrant infection, therapy failed despite high drug doses and the presence of a susceptible isolate.[125]

Attempting to link multiple pharmacodynamic effects in evaluating the outcome of anti-infective therapy poses an arduous task from both theoretical and practical perspectives, and, hence, a complete discussion is not undertaken in this chapter. Nonetheless, the combination of such effects has received some attention in the literature and merits mention. Specifically, large inocula appear to be capable of modulating the PAE and subinhibitory effects observed with numerous agents. Exposure of *E. coli* to subinhibitory sparfloxacin concentrations produced a pronounced inoculum-dependent subinhibitory effect. At a dose that was 0.3 times the MIC, growth of the organism was delayed by 0.3, 0.9, and 3.3 hours with inocula of 10^8, 10^6, and 10^4 CFUs, respectively, with similar observations noted for other drug-microbe combinations.[34,156]

CONCENTRATION-DEPENDENT COMBINATION EFFECTS (SYNERGY AND ANTAGONISM)

As discussed earlier and elsewhere in this text, antimicrobial combinations are used for many purposes: to prevent or delay the emergence of resistance, to enable dosage reduction and thereby minimize dose-related toxicities, and to treat polymicrobial infections. Combination therapy can be designed with the goal of synergistic or additive activity in mind, or, alternatively, these effects can occur without conscious consideration or forethought. Moreover, the undesirable outcomes of indifference or antagonism similarly can result through the combination of agents. Although a complete review of antagonism and synergy is beyond the scope of this section, we would be remiss not to mention concentration-dependent combination effects. We provide this brief discussion specifically to point out that a simple classification of drug combinations as synergistic, antagonist, and so forth is not always feasible. As discussed elsewhere, disagreement in the classification certainly can arise when different methods are used for evaluation.[21,154]

However, even when restricted to evaluations using the same experimental methods, certain combinations can be classified differently, depending on antibiotic concentration. Synergy is observed with cefoperazone and low imipenem concentrations against MRSA; however, higher concentrations of imipenem antagonize the activity of cefoperazone. Although antagonism with imipenem often is explained away as being β-lactamase–mediated, the concentration-dependent antagonism observed remains unexplained by this mechanism because antagonism was shown for strains that lacked β-lactamase production.[170] The combination of penicillin and clindamycin at subinhibitory concentrations demonstrates synergy against group A beta-hemolytic streptococci. At concentrations ranging from two to four times the MIC, the combination demonstrates antagonism, and at clinically relevant concentrations (≈100 times the MIC), indifference is observed, with the combination exhibiting no advantage over either agent alone.[200] Against isolates of vancomycin-intermediate *S. aureus*, antagonism is observed when methicillin and vancomycin are combined at subinhibitory concentrations. However, when the methicillin concentration exceeds the MIC, synergy is observed with the same combination. Although the mechanism behind this differential activity remains unclear, researchers proposed that the antagonism observed at lower methicillin concentrations results from an increase in the density of non–cross-linked D-alanyl-D-alanine side chains, the target site for vancomycin and a substrate for the PBPs. This increase would decrease the efficacy of methicillin as a PBP inhibitor by substrate competition.[95] For certain strains of methicillin-sensitive *S. aureus*, a combination of rifampin and methicillin below the MIC is synergistic, but above the MBC it is antagonistic. Similarly, a rifampin-vancomycin combination is synergistic at concentrations close to the MBC but indifferent as concentrations rise.[230] Furthermore, for some drug-microbe combinations, it is not the classification per se that is affected by the concentration, but rather the magnitude of the effect observed. Against *E. faecium*, fixed piperacillin and variable teicoplanin concentrations are synergistic. However, the degree of synergy depends on the teicoplanin concentration; comparable synergistic activity occurs at teicoplanin concentrations of 2, 4, or 8 mg/L; reduced synergistic activity occurs at teicoplanin concentrations of 16 and 32 mg/L; and the greatest degree of synergy is observed at a concentration of 64 mg/L.[172]

Thus, the available data support the finding that in many cases, the clinical assignment or "expectation" of synergy, additivity, or antagonism by specific combinations of anti-infective agents cannot be assumed simply by virtue of the drug class or drug-specific mechanisms of action, or both. With drug combinations for which the activity against an infecting pathogen is potentially concentration-dependent, prediction of therapeutic outcome must entail some assessment, be it actual or theoretical (e.g., the use of pharmacokinetic modeling), of the time-dependent drug concentration profile at the site or sites of infection.

PHARMACOGENETIC DETERMINANTS OF EFFECT

Although this chapter is designed to detail the pharmacokinetic and pharmacodynamic determinants of anti-infective drug response, we would be remiss not to introduce the emerging role of pharmacogenetics as a predictor of drug response and a driver of anti-infective drug therapy. Although the application of molecular biology to infectious diseases traditionally has been limited to diagnostics (e.g., polymerase chain reaction–based assays for the detection of viral pathogens and slow-growing microorganisms) and disease monitoring (e.g., viral loads), molecular tools increasingly are finding application with identifying the likelihood of drug response a priori and determining optimal treatment strategies for infectious pathogens. Genotyping strategies are used to identify mutations that confer drug resistance and guide the selection of antiretroviral therapy in management of human immunodeficiency virus infection.[130,216] Similarly, viral genotyping appears to be among the most robust predictors of response to combination therapy in the treatment of hepatitis C virus,[126,182] and it has prompted similar investigations for hepatitis B virus.[84,114] Finally, commercially available molecular-based assays have been developed for the determination of methicillin resistance in *S. aureus*, multidrug resistance in *M. tuberculosis*, and vancomycin resistance in *Enterococcus* in clinical isolates. These kits appear to perform well when compared with conventional phenotype-based methods.[117,146,160] However, the degree of integration for these kits into routine clinical practice remains to be determined.

CONCLUSIONS

Since the mid-1950s, the development of pharmacokinetics has produced a powerful and valuable tool, with applications for both science and clinical medicine. For the clinical scientist, pharmacokinetics can be used to characterize a given drug by providing a profile of its absorption, distribution, metabolism, and excretion in individuals with and without disease, during normal alterations of human physiology (e.g., pregnancy), as well as under conditions of normal altered organ function or body composition (e.g., growth and development, senescence). For the clinical practitioner, the tool of pharmacokinetics can provide a means to individualize drug therapy by characterizing the relationship between drug dose and resultant drug concentrations in plasma or other relevant biologic fluids (e.g., urine, CSF, synovial fluid, pleural fluid, peritoneal fluid). When linked with information regarding the pharmacodynamic behavior of the antibiotic, the susceptibility of the organism, and the status of the host, the application of pharmacokinetics affords the practitioner the ability to exercise some degree of adaptive control over drug therapy by selecting a drug and dosing regimen that have the greatest likelihood of producing both efficacy and safety.
