The patient may experience secondary disease 2 to 10 weeks after the primary lesions manifest. Prominent findings include fever, sore throat, muscle aches, generalized lymphadenopathy, headache, and rash. The palms and soles frequently are involved, in contrast to many other dermatologic conditions. On mucous membranes, the lesions may appear as white mucous patches. Condylomata lata occur around moist areas, such as the anus and vagina. All secondary lesions of the skin and mucous membranes are highly infectious. In their review, Baughn and Musher[10] give a full description of the manifestations of secondary syphilis. Acquired syphilis in early childhood may reveal minimal dermal findings.[1]

Latent Disease

After the clinical signs of secondary disease resolve, the patient enters the stage of latent disease. *Latent syphilis* refers to infection in individuals who have reactive serologic tests for syphilis, but no clinical manifestations. The first year after infection is considered *early latent infection*, and the subsequent period is considered *late latent syphilis*. Early latent syphilis originally was classified as syphilis occurring within 4 years of the acquisition of infection, based on the time when mucocutaneous lesions may recur. More recent classification of early latent syphilis is based on the time period of highest communicability, which is in the first year after infection is acquired. Treponemes still can be present in the blood intermittently, however, and pass across the placenta to the fetus during latent syphilis in a pregnant woman.

If the duration of infection with syphilis cannot be determined, the disease is classified as syphilis of unknown duration; clinical management and treatment should be the same as that for late latent infection. If therapy for syphilis is given first during the latent stage, the patient is unlikely to show regression of nontreponemal antibody determinations. Approximately 60 percent of untreated patients in the late latent stage continue to have an asymptomatic course, whereas 30 to 40 percent develop symptoms of late or tertiary disease. Progression of disease from late latent to late symptomatic syphilis usually is prevented if appropriate antimicrobial therapy is given at this stage. See Gutman[54] for depictions of children with acquired secondary syphilis.

Tertiary Disease

Three to 10 years after the last evidence of secondary disease has occurred, the patient may develop nonprogressive, localized nodules of the dermal elements or supporting structures of the body, called *gummata*. These nodules are granulomatous and can have central necrosis. Because these lesions are relatively quiescent, the term *benign tertiary syphilis* often is used. Spirochetes are extremely sparse or absent. The gummatous reaction is primarily a pronounced immunologic reaction of the host.

Neurosyphilis

During the early stage of syphilis, approximately one third of all patients have involvement of the CNS. If untreated, only half of these patients develop late neurosyphilis. The interval between primary disease and late neurosyphilis usually is more than 5 years. Of the few children recognized to have acquired (versus congenital) late neurosyphilis, several have developed symptomatic disease at a very early age. It is possible that the disease progresses more rapidly in children than in adults.

Late neurosyphilis may be asymptomatic or, if symptomatic, may occur in a variety of ways. Classic presentations include paralytic dementia, tabes dorsalis, amyotrophic lateral sclerosis, meningovascular syphilis, seizures, optic atrophy, and gummatous changes of the cord. Neurosyphilis may resemble virtually any other neurologic disease.

Cardiovascular Syphilis

Approximately 10 to 40 years after having primary syphilis, an untreated patient may develop signs of cardiovascular involvement. Most frequently involved are the great vessels of the heart, where syphilitic aortic and pulmonary arteritis develop. One complication of this development is aortic regurgitation. The inflammatory reaction also may cause stenosis of the coronary ostia, with resulting angina, myocardial insufficiency, and death.

SYPHILIS IN PREGNANCY

Pregnancy has no known effect on the clinical course of syphilis. Untreated syphilis can affect profoundly the outcome of the

pregnancy, however, resulting in spontaneous abortion, stillbirth, nonimmune hydrops fetalis,[8,17] premature delivery, perinatal death, or two characteristic syndromes of congenital disease, early and late congenital syphilis (see later).[53,121] The outcome of untreated fetal infection varies. Intrauterine death occurs in an estimated 25 percent of infections, with abortion usually occurring after the first trimester. Perinatal death may occur in another 25 to 30 percent of untreated infected infants.[94] In a study of the perinatal outcome of congenital syphilis, the fatality rate was 464 per 1000 infected births. Of the fatalities, 27 percent were neonatal deaths, and 73 percent were stillbirths.[117] Currently, most infected infants, if not hydropic at birth, survive the neonatal period, most likely because of early identification and treatment of infected infants and improved neonatal care.

The investigations of Taber and Huber[138] illustrate the importance in pregnant women of recognition of the disease and administration of appropriate therapy. In this study, 22 women with syphilis were undiagnosed during pregnancy and did not receive prenatal therapy. Eleven infants were followed without initial therapy. At delivery, all were asymptomatic clinically, four had a reactive Venereal Disease Research Laboratory (VDRL) test, five had a nonreactive VDRL test, and two were not tested. All these infants were readmitted with obvious disease involving multisystem infection, three with proven spirochetal hepatitis, two with nephrotic syndrome, and three with CNS involvement. This experience emphasizes the importance of recognition of transmission of infection late in gestation, leading to delivery of infants who are well clinically, but whose disease emerges in the weeks after delivery if untreated.[37]

CONGENITAL SYPHILIS

At the onset of congenital syphilis, *T. pallidum* is liberated directly into the circulation of the fetus, resulting in spirochetemia with widespread dissemination. The clinical, laboratory, and radiographic abnormalities of congenital syphilis are a consequence of active infection with *T. pallidum* and the resultant inflammatory response induced in various body organs and tissues. The severity of these manifestations varies and can range from overwhelming involvement of multiple organs and body systems, as is seen in fetal hydrops, to only laboratory or radiographic abnormalities. Most of the infants born to mothers with untreated syphilis seem completely normal at birth and have no clinical or laboratory evidence of infection at birth. These infants may develop manifestations of disease several months to years later if left untreated.[27] The signs and symptoms of congenital syphilis are divided arbitrarily into early manifestations, which appear in the first 2 years of life, and late manifestations, which emerge anytime thereafter, usually near puberty.

Early Congenital Syphilis

The abnormal physical and laboratory findings in early congenital syphilis are varied and unpredictable.[110] Table 156–5 lists the major physical and laboratory findings from 310 reported cases of early congenital syphilis.[17,32,67,74,99,117,138,139] These results undoubtedly are minimal rates for each finding. The onset occurs between birth and approximately 3 months of age, with most cases occurring within the first 5 weeks of life.

SKELETAL SYSTEM

Bone involvement is the most common manifestation of congenital syphilis, occurring in 60 to 80 percent of infants with clinical signs of syphilis. In addition, it may be the only abnormality seen in infants born to mothers with untreated syphilis. Because of their frequency and early appearance, the radiographic changes in the bones, termed *osteochondritis* and *periostitis*, are of diagnostic value.[32] The femur and humerus are involved most often. Radiographically, accumulating calcified matrix is seen at the epiphyseal margin, which may be smooth or serrated. The serrated appearance is known as *Wegner sign* and represents points of calcified cartilage along the nutrient cartilage canal.

A zone of rarefaction at the metaphysis, which represents syphilitic granulation tissue containing a few scattered calcified remnants and a mass of connective tissue containing areas of perivascular infiltration of small round cells, may be seen. Irregular areas of increased density and rarefaction produce the moth-eaten appearance of the radiograph. The demineralization and osseous destruction of the upper medial tibial metaphysis are called *Wimberger sign*. Previously thought to be specific for syphilis, Wimberger sign also may occur in osteomyelitis and hyperparathyroidism. Epiphyseal separation may occur as a result of a fracture of the brittle layer of calcified cartilage. Irregular periosteal thickening also is a common finding. The changes usually are present at birth but may appear in the first few weeks of life. The bony changes are self-limited and usually are healed in the first 6 months, even in the absence of specific therapy. They may be painful lesions, and pain on motion often leads an affected infant to appear to have a limb paralysis, termed *pseudoparalysis of Parrot*.

TABLE 156–5 Findings in 310 Cases of Early Congenital Syphilis

Findings	No. Patients
Hepatomegaly	100
Skeletal abnormalities	91
Birth weight <2500 g	51
Skin lesions	45
Hyperbilirubinemia	40
Pneumonia	51
Splenomegaly	56
Severe anemia, hydrops, edema	50
Snuffles, nasal discharge	27
Painful limbs	22
Pancreatitis	14
Cerebrospinal fluid abnormalities	21
Nephritis	11
Failure to thrive	10
Testicular mass	1
Chorioretinitis	1
Hypoglobulinemia	1

Data from references 17, 32, 67, 74, 99, 117, 138, and 139.

RHINITIS

Rhinitis, coryza, or snuffles are likely to mark the onset of congenital syphilis. Usually, it appears in the first week of life and seldom later than the third month. The snuffles are more severe and persist longer than the common cold. The nasal discharge is white and often bloody, and the snuffles frequently are associated with laryngitis. Secondary bacterial superinfection may result in a purulent appearance. The nasal discharge is teeming with spirochetes and should be examined by darkfield microscopy to confirm its diagnosis.

RASH

The syphilitic rash usually appears 1 to 2 weeks after rhinitis manifests. The typical eruption is maculopapular and consists of small spots that are dark red-copper. If the rash is present at birth, it often is widely disseminated and bullous, and is called *pemphigus syphiliticus*. It is most severe on the hands and feet. The bullous

fluid contains many spirochetes. The rash erupts slowly, taking 1 to 3 weeks, and is followed by desquamation and crusting. As the rash fades, the lesions become coppery or dusky red, and pigmentation may persist. See Gutman[54] for depictions of a variety of cutaneous manifestations of early congenital syphilis.

FISSURES AND MUCOUS PATCHES

Fissures and mucous patches are not seen often but are highly characteristic features of congenital syphilis. The fissures develop around the lips, nares, and anus. They bleed readily and heal with scarring. A cluster of scars radiating around the mouth is called *rhagades* and is a characteristic of late congenital syphilis. Mucous patches may be found on any of the mucous membranes, especially in the mouth and genitalia. Condylomata are raised, moist lesions appearing on areas of the skin where there is moisture or friction. They are highly infectious because they contain many spirochetes.

HEMATOLOGIC FINDINGS

Congenital syphilis is characterized by anemia, thrombocytopenia, hemolytic processes, and leukopenia and leukocytosis.[74] The hemolytic process is Coombs test–negative and often accompanied by cryoglobulinemia, immune complex formation, and macroglobulinemia. The hemolysis, similar to the liver disease, is refractory to therapy and may persist for weeks. Paroxysmal nocturnal hemoglobinuria is a late manifestation of congenital syphilis.

CENTRAL NERVOUS SYSTEM INVOLVEMENT

In the era before the introduction of penicillin therapy, approximately 15 percent of infants with congenital syphilis developed manifestations of meningovascular disease. These findings included meningitis, meningeal irritation, bulging fontanelle, cranial nerve palsies, seizures, and hydrocephalus.[61] In addition, involvement of the pituitary gland in congenital syphilis is a common manifestation, occurring in approximately 40 percent of autopsy cases,[99] and consists of interstitial inflammation and fibrosis with formation of gumma in the anterior lobe. Clinical disease in affected infants is manifested by persistent hypoglycemia and diabetes insipidus.[33,97]

Most infants infected with *T. pallidum* are completely asymptomatic, and involvement of the CNS is inferred from abnormalities of the cerebrospinal fluid (CSF), such as reactivity on a VDRL test, pleocytosis, and elevated protein content. Because of the wide range of normal values for CSF protein, red blood cells, and white blood cells in the neonatal period, defining the proportion of infants with congenital syphilis who have abnormalities of these laboratory values has been difficult. Current consensus identifies an abnormal CSF white blood cell count in infants being evaluated for possible congenital syphilis as greater than 25 cells/mm^3 and protein as greater than 150 mg/dL (>170 mg/dL if infant is premature). A reactive CSF VDRL test is considered to be specific for neurosyphilis in older children and adults. In neonates, the significance of a reactive CSF VDRL test is suspect, however, because maternal non-treponemal IgG antibodies can pass from maternal serum to fetal and neonatal serum and then diffuse into the CSF. Children may fail to have a reactive VDRL test on initial examination and still develop later signs of neurosyphilis.

Using rabbit infectivity testing, which involves the inoculation of CSF into rabbits to determine the presence of the spirochete in the CSF specimen, Michelow and coworkers[88] found that invasion of the CNS with *T. pallidum* occurs in 41 percent of infants who have clinical, laboratory, or radiographic abnormalities of congenital syphilis. None of these infants had clinical signs of neurologic disease. Compared with isolation of spirochetes in CSF by rabbit inoculation, the sensitivity and specificity in CSF of a reactive VDRL test, elevated white blood cell count, and elevated protein were 54 percent and 90 percent, 38 percent and 88 percent, and 56 percent and 78 percent. These investigators also documented CNS infection in three infants who had normal CSF studies. Using current methods, the best indicator of CNS infection in neonates is an abnormal evaluation consisting of an abnormal physical examination, anemia, thrombocytopenia, CSF abnormalities, and abnormal bone radiographs. A normal evaluation renders CNS infection rare.

PNEUMONIA

Syphilitic pneumonia is a common occurrence in congenital syphilis, particularly in developing countries. The classic radiographic appearance is one of complete opacification of both lung fields and is termed *pneumonia alba*. More commonly today, a fluffy, diffuse infiltrate involving all lung areas is seen on the chest radiograph. At autopsy, pneumonia alba consists of a focal obliterative fibrosis with scarring and thickening of alveolar walls with loss of alveolar spaces. Follow-up evaluation of children who have recovered from congenital syphilis has shown that at least 10 percent may have chronic pulmonary disease, particularly if they were premature and required mechanical ventilation.

HEPATOSPLENOMEGALY

Hepatomegaly is the most common clinical sign in congenital syphilis. Its occurrence in the fetus has been documented by ultrasonography, and it may be a marker of inadequate treatment of the fetal infection despite maternal treatment during pregnancy.[58] Hepatosplenomegaly often is caused by extramedullary hematopoiesis. Hepatomegaly may occur in the absence of splenomegaly, but in contrast to congenital cytomegalovirus, the reverse does not. Neonatal syphilitic hepatitis is associated with visible spirochetes on biopsy specimens of liver tissue, jaundice, and cholestasis. Aspartate aminotransferase, alkaline phosphatase, and alanine aminotransferase determinations often are elevated, and direct hyperbilirubinemia is a common finding. The prothrombin time may be delayed. The liver disease often resolves slowly, even after administration of apparently adequate therapy, and may be exacerbated by penicillin therapy before improving.[127]

ECTODERMAL CHANGES

Ectodermal changes in syphilitic infants include suppuration and exfoliation of the nails, loss of hair and eyebrows, choroiditis, and iritis.

OTHER FINDINGS

Other clinical manifestations of congenital syphilis include nonimmune fetal hydrops, possibly intrauterine growth restriction, generalized lymphadenopathy, fever, failure to thrive, nephrotic syndrome, and myocarditis. Involvement of the eyes has been manifested by chorioretinitis, cataract, glaucoma, and chancre of the eyelid. Gastrointestinal presentations include rectal bleeding caused by syphilitic ileitis, necrotizing enterocolitis, malabsorption secondary to fibrosis of the gastrointestinal tract, and fetal bowel dilation seen on antenatal ultrasonography.[112,117] Some children with symptomatic congenital syphilis also may present with sepsis caused by other bacteria, including *Escherichia coli*, group B streptococci, and *Yersinia* spp. Neonates and infants with congenital syphilis may resemble infants with other illnesses peculiar to newborns, including toxoplasmosis, rubella, cytomegalovirus infection, herpes simplex virus infection, "sepsis" of the newborn, blood group incompatibilities, battered child

syndrome, "periostitis" of prematurity, neonatal hepatitis, and osteomyelitis.

Late Congenital Syphilis

Late manifestations or stigmata of congenital syphilis are the result of scarring from the early systemic disease or reactions to persistent inflammation and include involvement of the teeth, bones, eyes, and eighth cranial nerve; gummata in the viscera, skin, or mucous membranes; and neurosyphilis (Table 156–6).[45] Approximately 40 percent of surviving and untreated infected infants, as reported in the early literature, develop late manifestations of infection. Some of these changes can be prevented by treating the mother during pregnancy or the infant before the child reaches 3 months of age. In contrast, treatment of 15 children at 4 months of age or later showed 7 with dental changes.[106] Other stigmata (e.g., keratitis, saber shins) may occur or progress, despite the infants being administered appropriate therapy. Nonspecific sequelae of congenital syphilis have not been described well because follow-up studies of children with congenital syphilis are minimal. It has been the experience of one of the authors (P.J.S.), however, that infants who are diagnosed with congenital syphilis and treated appropriately in the neonatal period generally do well at least through early childhood. There is every reason to be hopeful and optimistic with the families of these children, even if they are symptomatic and have CNS involvement at the time of diagnosis.

DENTITION

Characteristic changes are found in the permanent upper central incisors, which have a notched appearance of the biting edges; x-ray study leads to diagnosis, even while deciduous teeth are in place. These are Hutchinson teeth, which also are small and hypoplastic and widely spaced with abnormal enamelization. If first molars show maldevelopment of the cusps, the finding is called *mulberry* or *moon molars*.

INTERSTITIAL KERATITIS

Interstitial keratitis is the most common late lesion. It may appear at any age between 4 and 30 years or later, but characteristically appears when the patient is close to puberty. A ground-glass appearance may develop in the cornea, accompanied by vascularization of the adjacent sclera. These changes become bilateral and usually lead to blindness. It has been seen in adolescent patients despite their having received previous and appropriate penicillin therapy during infancy. At the time of its occurrence, keratitis is not affected by penicillin therapy, but it may respond transiently to corticosteroid treatment.

TABLE 156–6 Stigmata of Late Congenital Syphilis*

Stigmata	Percent of Total Patients
Frontal boss of Parrott	87
Short maxilla	84
High palatal arch	76
Hutchinson triad	75
Higoumenakis sign	73
Relative protuberance of mandible	65
Saddle nose	63
Interstitial keratitis	39
Rhagades	26
Mulberry molars	9
Saber shin	7
Eighth nerve deafness	4
Hutchinson teeth	3
Scaphoid scapulae	0.7
Clutton joint	0.3

*An analysis of 271 patients.

Adapted from Fiumara, N. J., and Lessell, S.: Manifestations of late congenital syphilis. Arch. Dermatol. 102:78-83, 1970. Copyright 1970, American Medical Association.

CENTRAL NERVOUS SYSTEM

The same manifestations of neurosyphilis seen in acquired syphilis may occur in congenital syphilis. Paresis is seen more frequently and tabes dorsalis less frequently in the congenital form than in the acquired form of the disease. Cranial nerve palsies and optic atrophy are prominent.

EIGHTH CRANIAL NERVE DEAFNESS

Hearing loss usually is sudden and occurs when the child reaches approximately 8 to 10 years of age. It often accompanies interstitial keratitis. The constellation of eighth cranial nerve deafness, interstitial keratitis, and Hutchinson teeth is called the *Hutchinson triad*. The hearing loss usually involves the higher frequencies, and normal conversational tones become affected later. This hearing loss may respond to long-term corticosteroid treatment.

BONE AND JOINT CHANGES

Bone changes include the sclerosing lesions, saber shin and frontal bossing, which are sequelae of periostitis that involved the frontal bone and tibia. Periosteal reaction of the sternoclavicular portion of the clavicle may lead to Higouménakis sign. The gummatous or destructive lesions include saddle-nose deformity, which occurs as a sequela of rhinitis. Perforation of the hard palate is almost pathognomonic of congenital syphilis. Clutton joints are uncommon findings and represent painless arthritis of the knees and, rarely, other joints.

CUTANEOUS LESIONS

Rhagades represent scars resulting from persistent rhinitis during infancy and rarely are seen today.

DIAGNOSIS

The vagaries of the maternal history and signs or lack of signs in the infant at birth (i.e., timing of the mother's initial syphilis infection before or during pregnancy, adequacy and documentation of her treatment, an infant who is infected and symptomatic at birth, an infant who is asymptomatic at birth but may not remain so because infection has occurred, and an infant who is asymptomatic and not infected) demand a "safety first" approach to diagnosis and treatment. Efforts to diagnose infectious syphilis suffer from the lack of a method to culture the organisms on laboratory media. Methods that are used in establishing the diagnosis of syphilis include (1) direct visualization of the organism by darkfield microscopy or fluorescent antibody technique of infected fluids or lesions, (2) demonstration of the organism by special stains on histopathologic examination of tissue,[56,115] (3) animal inoculation (rabbit infectivity test), (4) demonstration of serologic reactions typical of syphilis, and (5) detection of *T. pallidum* DNA in a clinical specimen.[19]

The rabbit infectivity test is still the gold standard for the identification of viable *T. pallidum* in clinical specimens, having a sensitivity of less than 10 organisms.[81,82] It involves intratesticular inoculation of the specimen into a rabbit and awaiting serologic seroconversion and orchitis with subsequent visualization

of motile spirochetes by darkfield microscopy in testicular tissue. The rabbit infectivity test is performed only in research laboratories and may take several months for identification of the organism. *T. pallidum* DNA has been detected by polymerase chain reaction (PCR) in body fluids such as amniotic fluid and infant blood, CSF, and endotracheal aspirate.[52,88] The new genetic information about *T. pallidum* may lead to development of novel diagnostic tools.

In the clinical setting, the diagnosis of syphilis is established by visualization of the spirochete by darkfield microscopy or special staining and serology. Patients with a primary syphilis lesion (chancre) and with active secondary lesions may be diagnosed by darkfield microscopy. Because this diagnosis depends on direct visualization of motile spirochetes, the organisms must be active and viable. Prior use of many antibiotics rapidly destroys the motility of the organisms, as do many topical disinfectants. Serous fluid from the base of the lesion should be collected for darkfield examination. Syphilitic lesions of the mouth may harbor indigenous treponemes, of which the morphologic similarity to pathogenic species can confuse the interpretation of findings.

Direct darkfield examination is particularly helpful in establishing a diagnosis early in the course of the disease, before the development of seroreactivity. If a darkfield microscope is unavailable, a direct fluorescent antibody stain for *T. pallidum* may be made.[17] Exudate is collected in capillary tubes or slides and stained with specific antibody. Amniotic fluid may be examined for the presence of spirochetes using darkfield microscopy or fluorescent antitreponemal staining; the finding of spirochetes may be a marker for more severe fetal disease.[51,146] On a practical basis, however, the diagnosis is established by serologic methods.[78,149]

SEROLOGIC TESTS

The two types of serologic tests for syphilis are the nontreponemal antibody tests and the treponemal antibody tests (Table 156–7). Although the latter tests indicate experience with a treponemal infection in the past, they cross-react with the antigens of other treponemal diseases, such as the antigens causing yaws and pinta. No test is specific for syphilis, and no test is completely sensitive. Efforts to produce a more sensitive and more specific test are continuous. A promising approach is the use of recombinant clones expressing immunogenic proteins of *T. pallidum* to investigate pathogen-specific antigens.[63] Some of these products are being investigated for use as diagnostic material.[122]

TABLE 156–7 Standard Serologic Tests for Syphilis

Type	Test	Percent Reactivity During Primary Stage	Secondary Stage	Tertiary Stage
Non-treponemal				
Extracts of tissue (cardiolipin-lecithin-cholesterol)	VDRL	78	95	71
	RPR	86	98	73
Treponemal				
Treponema pallidum	MHA-TP*	76	100	94
	FTA-ABS	84	100	97

FTA-ABS, fluorescent treponemal antibody absorption; MHA-TP, microhemagglutination assay–Treponema pallidum; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratory.

**MHA-TP has been replaced with* Treponema pallidum *particle agglutination (TP-PA) test.*

Non-treponemal Tests

The original test for syphilis, as described by Wassermann, used syphilitic tissue as complement-fixing antigen to detect the presence of antibody (reagin) that is induced by *T. pallidum*. Extracts of other normal tissue, such as beef heart, had similar properties, and purification and standardization of these materials led to the use as antigen of a preparation containing cardiolipin and lecithin in cholesterol.

Two tests currently using cardiolipin, lecithin, and cholesterol are the VDRL and rapid plasma reagin (RPR) tests. These tests measure mostly IgG, but also IgM antibodies nondiscriminatively. The tests provide similar clinical information and have similar advantages. The RPR titer often is one to two dilutions higher than the titer obtained using the VDRL test, so caution must be exercised when making clinical decisions on the basis of results obtained from these two tests performed on the same patient. Both are inexpensive to perform and show increasing and decreasing antibody titers that often correlate with adequacy of therapy and the clinical status of a patient. A fourfold increase in RPR or VDRL titers indicates active disease, whereas a fourfold decrease suggests adequate therapy. Disadvantages include a high proportion of biologic acute and chronic false-positive reactors and an increasing proportion of false-negative reactions in the later stages of untreated syphilis. The main technical difficulty is a negative reaction owing to the prozone phenomenon, which occurs in 1 to 2 percent of individuals, usually patients with secondary syphilis, and is due to an excess amount of reagin antibody present in the patient's undiluted serum that prevents flocculation. Diluting the serum sample before testing overcomes the inhibition and results in the positive reaction. Because the RPR test generally is more sensitive than is the VDRL test, it is preferred for screening pregnant women. The VDRL test is recommended for use on CSF, however.

The RPR test is used frequently to screen pregnant women for possible infection with *T. pallidum*. Transplacental passage of IgG antibodies to the infant means that mothers with positive RPR tests usually transmit these antibodies to their infants. Taber and Huber[138] reviewed the relationship of maternal to newborn VDRL tests in their study of mothers who were undiagnosed and untreated. Although 12 of 22 mothers had VDRL test results two to four times that of their infants, 6 of these women and their infants had nonreactive serology at the time of delivery. These and other data showed that it was unusual for an infant to have a VDRL test of greater titer than the mother's, even if the infant was incubating congenital syphilis.[136] Nonetheless, the finding of a titer in the infant serum fourfold higher than that seen in the maternal serum when both are obtained at the same time is indicative of active infection in the infant. Even if the infant is asymptomatic, a 10-day course of penicillin therapy should be administered.

Treponemal Tests

The most significant development of the past 3 decades in the serologic study of syphilis was the detection of treponemal antibody by fluorescein-labeled antihuman antibody. These tests are used to confirm the validity of a positive non-treponemal test and to diagnose late stages of syphilis. The tests are sensitive and reliable.

Fluorescent treponemal antibody absorption (FTA-ABS) tests use lyophilized Nichols strain organisms as antigen and measure IgG and IgM antibodies. Antigen is fixed to a slide, and the test serum is applied, allowing reaction of antitreponemal antibody with antigen to occur. The slide is layered with fluorescein isothiocyanate-labeled, antihuman gamma-globulin, and the presence or absence of antibody is determined by fluorescent microscopy.

Test sera are preabsorbed with sorbent to eliminate group-reactive antibody. The test is rendered specific for disease with virulent treponemal species, usually *T. pallidum*. The FTA-ABS test is expensive and time-consuming, however. It is recommended not for general screening but for confirmation of positive non-treponemal tests and for establishing the diagnosis of later stages of syphilis in which the results of non-treponemal tests may be negative.

Microhemagglutination tests, and specifically the *T. pallidum* particle agglutination (TP-PA) test, depend on the passive hemagglutination of erythrocytes or latex particles that have been sensitized with Nichols strain *T. pallidum*. The test has been automated and is easy to perform technically and inexpensively. The TP-PA test has largely replaced the FTA-ABS test as the most efficient specific test for antibody to *T. pallidum*. The TP-PA test is as sensitive as is the FTA-ABS test, except in primary syphilis. The test is positive in 75 to 85 percent of patients with primary syphilis and in 100 percent of patients with secondary syphilis. Similar to the FTA-ABS test, the TP-PA test is unlikely to revert to a nonreactive state after treatment of the patient, unless treatment is given very early.

IgM Tests

In the diagnosis of congenital syphilis, having a means to differentiate between passive transplacental transfer of maternal antibody to the fetus and production by the fetus of endogenous antitreponemal antibody would be most helpful. Because antibodies of the IgM class do not cross the placenta, detection of IgM antibody in the fetal or neonatal serum would indicate antibody production by the fetus because of active fetal infection. No IgM assay currently is commercially available that is sufficiently sensitive and specific to recommend for routine use in the evaluation of infants born to mothers with syphilis. The fluorescent treponemal antibody that measures IgM antitreponemal antibodies, the IgM-FTA-ABS test, has been associated with false-positive and false-negative results. When the test was refined further by use of the IgM fraction of neonatal serum only, it had a sensitivity of 73 percent.[136] The test also is insensitive when the onset of disease is delayed. Occasional false-positive IgM-FTA-ABS tests occur because of the presence of an IgM anti-IgG antibody or rheumatoid factor. For these reasons, the CDC has recommended that the IgM-FTA-ABS test be suspended for diagnostic testing of newborns, and the test is available only as a provisional test.

Efforts to develop a sensitive and specific serologic test for congenital syphilis have led to the identification of antigenic components of *T. pallidum* that are epitopes for the immune response. A 34-kd membrane protein is a dipoprotein[137] and the target of IgM antibody formation in the sera of some congenitally infected infants.[36] The Captia Syphilis M test (Trinity Biotech, Jamestown, NY) is an enzyme-linked immunosorbent assay that uses this treponemal protein; it is commercially available but showed a sensitivity of only 88 percent among infants with clinical and laboratory findings of congenital syphilis.[76,136]

Immunoblotting has been used to characterize the specific neonatal IgM antibody responses to *T. pallidum*. Specific IgM antibodies directed against *T. pallidum* antigens with apparent molecular masses of 72 kd, 47 kd, 45 kd, 42 kd, 37 kd, 17 kd, and 15 kd have been detected in sera of fetuses[58] and infants with clinical findings of congenital syphilis, and in 20 to 40 percent of asymptomatic infants born to mothers with untreated syphilis.[36,79,88,120,122,125] IgM reactivity against the 47-kd antigen, a membrane lipoprotein of the organism, has been the most consistent finding. Similar reactivities also have been seen in CSF of infants with congenital syphilis.[79,124] A more recent study showed that a reactive serum IgM immunoblot identified all 17 infants in whom spirochetes were detected in their CSF by rabbit infectivity testing.[88] Efforts to develop rapid diagnostic tests based on these findings are in progress.[73] In addition, immunoblotting has been used to detect similar IgA reactivities among infants with congenital syphilis.[125]

Polymerase Chain Reaction

PCR has been used on neonatal blood and CSF for establishing the diagnosis of congenital syphilis.[52,88,122] Compared with isolation of the organism by rabbit infectivity testing, the sensitivity and specificity of PCR on CSF was 65 to 71 percent and 97 to 100 percent.[88,122] Among 17 infants who had spirochetes detected in their CSF by rabbit inoculation, blood PCR test was the best predictor of CNS infection with *T. pallidum*.[88] This finding supports further the concept that spirochetes gain access to the CNS by a hematogenous route.

False-Positive Reactions

All of the available serologic tests for syphilis produce occasional reactive results in patients who have no other evidence of syphilitic infection. These reactions usually are called *biologic false-positive* (BFP) reactions and are distinct from positive reactions owing to technical errors. Most BFP reactions occur with non-treponemal tests; approximately 1 percent of normal adults have a BFP reaction by non-treponemal antigen tests. These reactions probably are not more common in pregnant women than in the general population. Reaginic antibody is reactive with at least 200 antigens other than those of *T. pallidum*, and although the specific stimulus for this antibody in syphilis and other diseases is unknown, it may represent antibody to cellular lipoidal antigens of the host that are liberated during various diseases. For clinical purposes, BFP reactions may be classified as acute, in which the reactivity resolves within 6 months, or chronic, in which reactivity is persistent.

ACUTE BIOLOGIC FALSE-POSITIVE REACTIONS

Most BFP reactions are detected by non-treponemal tests and occur in patients with other acute illnesses, especially pneumonia, hepatitis, and viral exanthematous disease, or after receiving vaccinations. The prognosis for the patient's health is not affected by the finding. The titer of antibody usually is low (<1:8), and in most instances the FTS-ABS is nonreactive. Approximately two thirds of patients with BFP reactions have acute reactions, and reactivity subsides within 6 months.

CHRONIC BIOLOGIC FALSE-POSITIVE REACTIONS

Many patients with chronic BFP reactions have or develop systemic disease. Drug addiction, chronic hepatitis, old age, leprosy, and collagen vascular disease, especially systemic lupus erythematosus, are associated highly with chronic BFP reactions. A familial predisposition to this finding may exist. The antibody detected by the VDRL test in chronic BFP reactions predominantly is IgM, whereas it mainly is IgG in syphilis. Patients with chronic BFP reactions and systemic lupus erythematosus commonly also have a reactive FTA-ABS test.[77] The triosephosphate isomerase test may be helpful in the differential diagnosis in these instances. A finding of particular concern is that there seems to be a relative increase in acute and chronic BFP reactions in women who are infected with HIV.

EVALUATION AND DIAGNOSIS OF EARLY CONGENITAL SYPHILIS

The diagnosis of congenital syphilis is suggested by results of serologic tests, physical examination, laboratory tests including

CSF examination, and radiographs of long bones and is established by the observation of spirochetes in body fluids or tissue. Examination of the placenta or umbilical cord using specific fluorescent antitreponemal antibody staining is recommended.[50,107] The decision to evaluate and ultimately to treat an infant for congenital syphilis is based on clinical, serologic, and epidemiologic considerations. The evaluation includes an assessment of the mother for general risk factors for increased rates of syphilis (Table 156–8), followed by an evaluation of the mother's current known serologic status (Table 156–9). If the mother has been treated, the clinician must assess the adequacy of the therapy.

If the mother's serologic assays have been positive, the infant must be assessed for clinically apparent disease. The nontreponemal (RPR) and treponemal (TP-PA) tests measure IgG antibody and do not distinguish disease of the infant from maternally derived antibody. Many infants are born to women who have had syphilis in the past, received therapy, and remained seroreactive. Their infants also are seroreactive. Ensuring that the infant does not have congenital disease in the immediate newborn period may be impossible.

Figure 156–2 and Table 156–10 present an approach to the evaluation of infants born to mothers with reactive serologic tests for syphilis. Testing of all pregnant women with syphilis for co-infection with HIV is recommended strongly, even though infants born to co-infected mothers do not require any different evaluation for syphilis.[20] All infants born to mothers with reactive serologic tests for syphilis should have a serum quantitative nontreponemal test performed and a thorough physical examination that focuses on finding evidence of congenital syphilis. The nontreponemal test that is performed on the infant should be the same as the test done on the mother to be able to compare serologic titers. Although it is an uncommon finding, a serum quantitative non-treponemal titer that is fourfold or greater than the corresponding maternal titer is diagnostic of congenital syphilis; when it has occurred, one of the authors (P.J.S.) has isolated spirochetes from blood or CSF in all infants.

TABLE 156–8 General Maternal Risk Factors Associated with Increased Rates of Early Syphilis in Pregnancy

Infection with HIV
Adolescent or unmarried status
History of sexually transmitted disease
Substance abuse, especially cocaine
Inadequate or absent prenatal care
Prostitution or promiscuity
Localized populations or geographic areas
Treatment of gonorrhea with ciprofloxacin or spectinomycin
Poor communication among medical personnel regarding maternal/infant status

Data from references 22, 34, 116, and 145.

TABLE 156–9 Components of the Epidemiologic Evaluation of an Infant's Mother for Possible Syphilis That Aid in Evaluation and Treatment of Infant

Evaluate mother for prior history of syphilis or major risk factors for syphilis (see Table 156–8)
If mother received treatment for syphilis, evaluate course of therapy for adequacy in the treatment of congenital syphilis (see Table 156–2)
Evaluate current maternal status with a non-treponemal test (e.g., Venereal Disease Research Laboratory, rapid plasma reagin) and, if reactive, a treponemal test (e.g., fluorescent treponemal antibody absorption, *Treponema pallidum* particle agglutination test)
If mother is identified clinically or through contact tracing as having early syphilis during the 3 mo after delivery, re-evaluate the infant and consider therapy at that time
Higher maternal titers to non-treponemal tests are associated with failure of maternal therapy to prevent congenital disease[87]
Unknown duration of maternal syphilis is associated with failure of maternal therapy to prevent congenital disease[87]

The CDC recommends that the infant's serologic test be performed on serum and not umbilical cord blood because false-positive test results have been reported with the use of umbilical cord blood secondary to contamination of the specimen with maternal blood and Wharton jelly. Some clinicians continue to use umbilical cord blood, however, because it is readily available and easily collected; appropriate care should be taken during collection to minimize contamination with maternal blood. In addition, false-negative tests may occur when the maternal titer is low dilution, which argues for maternal screening rather than screening of infant serum.

Infants who have (1) an abnormal physical examination that is consistent with congenital syphilis, (2) a serum quantitative non-treponemal serologic titer that is fourfold or greater than the mother's, or (3) a positive darkfield or fluorescent antibody test of body fluid should have a complete blood cell count and platelet count performed and examination of the CSF for cell count, protein content, and VDRL test. Other tests, such as bone and chest radiographs, liver function tests, cranial ultrasound, ophthalmologic examination, and auditory brain stem response should be performed as clinically indicated. These infants are considered to have *proved or highly probable disease*; spirochetemia with invasion of the CNS occurs in approximately 40 to 50 percent of these infants.[88] Although these infants must receive a full course of penicillin therapy, which treats possible neurosyphilis, it is beneficial for follow-up purposes to establish CNS abnormalities at presentation. Nonetheless, the diagnosis of congenital neurosyphilis is difficult to establish (see section on clinical manifestations). The presence of red blood cells in the CSF as a result of a traumatic lumbar puncture can produce a false-positive serologic reaction. Examination of the CSF for *T. pallidum* DNA by PCR may prove more useful for diagnosing congenital neurosyphilis.[52,88,122]

For infants who have a normal physical examination and a serum quantitative non-treponemal test that is less than fourfold the maternal titer, further evaluation and treatment depend on the maternal treatment history and stage of infection (see Fig. 156–2 and Table 156–10). Whether to perform a complete evaluation (lumbar puncture, long bone radiographs, and complete blood cell and platelet counts) on the infant depends on the maternal treatment history and planned treatment of the infant (see section on treatment). If the mother did not receive any prior treatment for syphilis, or the treatment was inadequate, a complete evaluation must be performed and be normal if a single intramuscular dose of benzathine penicillin G therapy is administered. Although it is preferred to help establish a diagnosis of congenital syphilis, a complete evaluation is unnecessary if a full 10-day course of parenteral penicillin is provided because such therapy would treat for the possibility of congenital infection.[13,90]

The need to perform a lumbar puncture has been questioned because the yield of abnormal findings from examination of the CSF has been very low in some experiences and appreciable in others.[12,42,116] A primary benefit of obtaining CSF studies from infants who are receiving a 10-day parenteral course of aqueous or procaine penicillin therapy is identification of infants for whom follow-up of abnormal CSF results should be done. Likewise, long bone radiographs are abnormal in approximately 65 percent of infants with clinical findings of syphilis but only in a few asymptomatic infants. The finding of osteochondritis or periostitis in an infant born to a mother with reactive serologic tests for syphilis indicates congenital syphilis, and the infant requires

TABLE 156–10 Treatment Guidelines for Congenital Syphilis

Scenario	Maternal Stage/Treatment	Recommended Evaluation	Regimen
Infant with proven or highly probable disease	Any or none	CSF analysis: VDRL, cell count, protein CBC and differential; platelet count. As clinically indicated: long bone radiographs, liver function tests, cranial ultrasound, eye examination, hearing evaluation	Aqueous penicillin G 50,000 U/kg IV q12h (≤1 wk old), q8h (>1 wk old, ≤4 wk old), q6h (>4 wk old) × 10 days *or*
(a) Abnormal physical examination (b) Abnormal evaluation* (c) Serum non-treponemal titer ≥4× maternal titer (d) Visualization of spirochete in clinical specimen			Procaine penicillin G 50,000 U/kg IM × 10 days (≤4 wk old)
Infant with *normal* physical examination and serum non-treponemal titer <4× maternal titer	Any stage of infection *and*	CSF analysis: VDRL, cell count, protein; CBC and differential; platelet count; long bone radiographs	Treatment A: Benzathine penicillin G† 50,000 U/kg IM × 1
	No treatment; *or*	If *all* normal: treatment A	Treatment B: Aqueous penicillin G 50,000 U/kg IV q12h (≤1 wk old), q8h (>1 wk old, ≤4 wk old), q6h (>4 wk old) × 10 days *or*
	Inadequate or undocumented treatment; *or* Erythromycin or non-penicillin treatment; *or* Therapy ≤4 wk before delivery; *or* Adequate therapy >1 mo before delivery, but maternal non-treponemal titers have not decreased fourfold after treatment for early syphilis (primary, secondary, early latent syphilis)	If *any* abnormal or not done‡: treatment B	Procaine penicillin G 50,000 U/kg IM × 10 days (≤4 wk old)
	Adequate therapy >1 mo before delivery, and appropriate for stage of infection; *or* Maternal non-treponemal titer decreased fourfold after treatment for early syphilis; *or* Maternal non-treponemal titers remained stable and low for late syphilis; *and* No evidence of reinfection or relapse	No evaluation	Benzathine penicillin G 50,000 U/kg IM × 1§
	Adequate therapy before pregnancy and stable non-treponemal titers (VDRL ≤1:2, or RPR ≤1:4) throughout pregnancy	No evaluation	No treatment¶
Congenital syphilis in infant >28 days old	Any or none	CSF analysis: VDRL, cell count, protein CBC and differential; platelet count. As clinically indicated: long bone radiographs, liver function tests, cranial ultrasound, eye examination, hearing evaluation	Aqueous penicillin G 50,000 U/kg IV q4-6h × 10 day *and* ? Benzathine penicillin G¶ 50,000 U/kg IM × 1

**CSF examination (VDRL test, cell count, protein), bone radiographs, CBC, platelets, umbilical cord or serum VDRL/RPR (same test as performed on maternal serum).*

†*If the infant's non-treponemal test is nonreactive, no evaluation is required, but the infant should receive treatment A.*

‡*Clinical and serologic follow-up must be certain.*

§*Some experts would not treat but provide close serologic follow-up.*

¶*Benzathine penicillin G 50,000 U/kg IM × 1 if follow-up uncertain.*

¶*Some experts prefer prolonged therapy by administration of a single dose of benzathine penicillin G after the 10-day course of IV aqueous penicillin G.*

CBC, complete blood count; CSF, cerebrospinal fluid; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratory.

Rep. 51(No. RR-6):26-28, 2002; and American Academy of Pediatrics: Syphilis. In Pickering, L. K. (ed.) 2006 Red Book: Report of the Committee on Infectious Diseases. 27th ed. Elk Grove Village, IL, American Academy of Pediatrics, 2006, pp. 631-634.

a full course of penicillin therapy for highly probable disease. Such an infant is likely to have CNS infection, however, even in the absence of clinical signs of neurosyphilis, and close clinical and serologic follow-up would be indicated.[88]

After the newborn period, children with syphilis should have a lumbar puncture performed for evaluation of the CSF to detect asymptomatic neurosyphilis. In addition, birth and maternal records should be reviewed to assess whether such children have acquired or congenital syphilis.[27] Children with acquired syphilis should be evaluated for the possibility of sexual abuse.

TREATMENT

T. pallidum is extremely sensitive to penicillin, as defined by experimental animal work. The minimal inhibitory concentration of penicillin is approximately 0.004 U/mL (or 0.0025 μg/mL). There is no evidence of increasing resistance to penicillin by the spirochetes, but such evidence would come only from the recognition of therapeutic failures. Effective treatment of syphilis must maintain a minimal inhibitory concentration of 0.03 U/mL of penicillin in serum (or CSF) for 7 to 10 days. Therapy is designed to achieve and maintain several times the necessary inhibiting levels and to avoid penicillin-free intervals during therapy. Penicillin remains the drug of first choice because of its established efficacy and minimal toxicity.[20]

ACQUIRED SYPHILIS

Early syphilis (i.e., primary, secondary, and early latent infection) is treated with benzathine penicillin G, 50,000 U/kg up to the adult dose of 2.4 million U intramuscularly in a single dose. Late latent syphilis requires benzathine penicillin G, 150,000 U/kg up to the adult dose of 7.2 million U, administered as 50,000 U/kg up to the adult dose of 2.4 million U at 1-week intervals for 3 weeks. When the duration of infection is unknown, the patient should be treated as for late latent disease.

All patients with syphilis should be tested for HIV infection at diagnosis, and if they have early syphilis, they should be retested 3 to 6 months later. Because neurosyphilis may be asymptomatic and can be defined accurately only by examining the CSF, the CDC recommends performing a lumbar puncture in the following situations: (1) neurologic or ophthalmic signs or symptoms, (2) active tertiary syphilis, (3) treatment failure, and (4) HIV infection with late latent syphilis or syphilis of unknown duration.[20] A lumbar puncture is not recommended routinely for patients with primary or secondary syphilis. Benzathine penicillin does not produce inhibitory CSF levels of penicillin reliably.[134] Shorter acting penicillins must be employed for neurosyphilis. In evaluating a patient for neurosyphilis, a CSF specimen without contamination by peripheral blood is needed.[64]

The recommended therapy for neurosyphilis is aqueous crystalline penicillin G, 18 to 24 million U/day, administered as 3 to 4 million U intravenously every 4 hours or continuous infusion for 10 to 14 days. An alternative regimen consists of procaine penicillin, 2.4 million U intramuscularly once daily, plus probenecid, 500 mg orally four times per day, for 10 to 14 days. Because these regimens are of shorter duration than is the regimen used for late latent syphilis, some experts recommend the additional administration of benzathine penicillin G, 2.4 million U intramuscularly once per week for up to 3 weeks after completion of the 10- to 14-day course. Older children with definite acquired syphilis and a normal neurologic and CSF examination may be treated with benzathine penicillin G, 50,000 U/kg intramuscularly to a maximal dose of 2.4 million U. Children with neurosyphilis should receive aqueous penicillin G, 200,000 to 300,000 U/kg/day intravenously administered as 50,000 U/kg every 4 to 6 hours for 10 days. Similar to the procedure with adults, an additional dose of benzathine penicillin G, 50,000 U/kg intramuscularly, may be given following the 10-day intravenous penicillin treatment.

The evaluation and treatment of early syphilis in HIV-infected individuals are the same as those for individuals not infected with HIV except that they may be at increased risk for developing neurologic complications and have a higher risk of experiencing treatment failure. HIV-infected individuals who have late latent syphilis or syphilis of unknown duration should have their CSF examined for evidence of neurosyphilis before receiving treatment; further management and treatment depend on CSF findings. Close serologic follow-up of HIV-infected individuals is mandatory to detect treatment failure and the need for examination of CSF and re-treatment.

Data to support the use of alternatives to penicillin in the treatment of syphilis are limited. Any history of penicillin allergy should be documented clearly, and, whenever possible, patients should receive skin testing, desensitization, and therapy with penicillin.[20] Doxycycline (100 mg orally twice daily) and tetracycline (500 mg four times daily) have been used for 14 days for treatment of early syphilis and 28 days for late latent infection and syphilis of unknown duration. Close serologic follow-up is mandatory. Neither of these therapies is recommended for children younger than 8 years of age. Ceftriaxone (100 mg/kg/day, maximum of 1 g daily) given either intravenously or intramuscularly for 8 to 10 days may be effective for treating early syphilis, but neither the optimal dose nor duration of treatment has been defined.[59] Preliminary data also suggest that azithromycin as a single dose of 2 g may be effective in adults, but treatment failures have been described, as has emergence of resistance.[20] Because experience with these alternative antibiotics in HIV-infected individuals is limited, they should be used with caution.

Two to 12 hours after receiving treatment for syphilis, a variable proportion of patients develop an acute systemic (Jarisch-Herxheimer) reaction usually consisting of headache, malaise, fever (≥38° C), and resolution within 1 day. The reaction is observed most frequently in the early stages of syphilis, probably represents a reaction to liberated endotoxin,[49] and does not affect the course of recovery. In the later stages of syphilis, fewer than one in four patients develops the reaction. Most reactions in late syphilis clinically are insignificant, but an occasional reaction may produce damage to the CNS or cardiovascular system.

SYPHILIS IN PREGNANCY

Pregnant women with reactive serologic tests for syphilis should be considered infected unless an adequate treatment history is documented, and sequential non-treponemal antibody titers have declined. They should receive the penicillin regimen appropriate for the stage of syphilis.[20,149] For early syphilis, many experts recommend that an additional dose of benzathine penicillin G be provided 1 week after the initial dose. Management and treatment decisions may be guided further by the use of fetal ultrasonography. Evidence of fetal infection may require additional doses of benzathine penicillin G until resolution of fetal abnormalities has been achieved. The Jarisch-Herxheimer reaction may complicate treatment and result in preterm labor and fetal decelerations, although concern for its occurrence should not delay initiation of treatment.[69,93] No alternative to penicillin is available; pregnant women who have a history of penicillin allergy should undergo skin testing, desensitization, and treatment with penicillin.[148] Erythromycin is not recommended; infants have been born with congenital syphilis after maternal treatment with erythromycin. Any therapy other than penicillin is considered to be inadequate fetal therapy.[41,104]

Women who are co-infected with syphilis and HIV should receive treatment regimens corresponding to their stage of syphilis. The follow-up on treated HIV-infected women must be thorough and frequent.[55,92]

Patients who received therapy for gonorrhea with ceftriaxone have a high rate of cure of pre-primary syphilis, but failures have occurred, and efficacy in pregnancy is not well studied.[59] This regimen cannot be assumed to have provided adequate therapy for syphilis in pregnancy.

CONGENITAL SYPHILIS

Infants with Proven or Highly Probable Disease

Infants who have findings on physical examination that are consistent with congenital syphilis—a quantitative non-treponemal serologic titer that is at least fourfold greater than the mother's titer, or spirochetes visualized in body fluids—should be treated with aqueous crystalline penicillin G, 50,000 U/kg/dose intravenously every 12 hours during the first 7 days of life and every 8 hours thereafter for 10 days, or with procaine penicillin G, 50,000 U/kg/dose administered intramuscularly in a single daily dose for 10 days (see Table 156–10).[20] Although the levels of penicillin that are achieved in the CSF after procaine therapy are lower than the levels seen with intravenous penicillin treatment, the clinical significance is unclear.[6] No treatment failures have been reported after procaine penicillin therapy. If more than 1 day of penicillin therapy is missed, the entire course should be restarted.

During a penicillin shortage in the United States, ampicillin was recommended as an alternative agent, although data are insufficient for routine administration. When possible, a full 10-day course of penicillin is preferred even if ampicillin was provided initially for possible sepsis. Data also are lacking for the use of ceftriaxone in these infants. Infants born to mothers co-infected with syphilis and HIV do not require more intense or prolonged treatment for syphilis than is recommended for all infants.

Infants with a Normal Physical Examination and a Serum Quantitative Non-treponemal Serologic Titer That Is the Same or Less than Fourfold the Maternal Titer

Treatment decisions for "asymptomatic" infants are based on the maternal history of syphilis and past treatment. The following situations are associated with a high likelihood that the infant may be infected with *T. pallidum* and should receive treatment: (1) mother was not treated, was inadequately treated, or has no documentation of having received treatment[108]; (2) mother was treated with erythromycin or other non-penicillin regimen; (3) mother received treatment *less than* 4 weeks before delivery[14]; and (4) mother has early syphilis and has a non-treponemal titer that either has not decreased fourfold or has increased fourfold. If the infant's non-treponemal test is reactive, the infant should be evaluated with a complete blood cell count and differential; platelet count; long bone radiographs; and CSF analysis for VDRL test, cell count, and protein content (Fig. 156–3; see Table 156–10).[20] If the entire evaluation is normal and follow-up is certain, the infant may receive benzathine penicillin G, 50,000 U/kg as a single intramuscular dose.

If any part of the evaluation is abnormal or not done, or follow-up is uncertain, treatment should consist of aqueous penicillin G or procaine penicillin G (see earlier) for 10 days. If the infant's non-treponemal serum test is nonreactive, the evaluation may be omitted, but the infant should be treated with a single intramuscular dose of benzathine penicillin for the possibility of incubating syphilis. Some experts prefer that all infants born to mothers with untreated syphilis receive parenteral penicillin therapy for 10 days, even if the evaluation is normal, because many of these infants are likely to be infected with *T. pallidum*, especially if the mother has secondary syphilis at delivery or seroconverted during the pregnancy.[5,20]

More recent studies have re-evaluated the efficacy of treatment regimens for asymptomatic infants who are born to mothers in whom the treatment for possible syphilis was suboptimal.[100,108] Paryani and colleagues[100] randomly assigned 152 infants to receive either one injection of benzathine penicillin or a 10-day course of parenteral procaine penicillin. All study infants were asymptomatic on physical examination and had normal CSF evaluation, normal x-ray studies of long bones, and no visceral abnormalities. The results of both forms of therapy were excellent, with no treatment failures. This study indicates that single-dose therapy may have a high rate of success when an infant has negative studies and is asymptomatic.

Failure of such therapy in three infants has been reported, however, the frequency seems to be low, although it is unknown.[12,151] None of the three infants who developed clinical signs of congenital syphilis several weeks after having received a single intramuscular dose of benzathine penicillin was fully evaluated for congenital syphilis at birth. The concern has been that infected but asymptomatic infants may have CNS infection and fail therapy with benzathine penicillin because benzathine penicillin does not achieve treponemicidal concentrations in CSF.[134] Using rabbit inoculation, Michelow and colleagues[88] showed that invasion of the CNS is an infrequent occurrence among these infants with normal results on clinical, laboratory, and radiographic evaluations.

An infant does not require any evaluation in the following situations: (1) mother was treated during the pregnancy, treatment was appropriate for the stage of infection, and treatment was administered more than 4 weeks before delivery; (2) mother's non-treponemal titers decreased fourfold after administration of appropriate therapy for early syphilis or remained stable and low for late syphilis; and (3) mother has no evidence of re-infection or relapse. The CDC recommends, however, that these infants receive a single dose of benzathine penicillin G, 50,000 U/kg intramuscularly. Infection of the fetus may occur despite administration of appropriate maternal therapy during pregnancy; failure rates of maternal treatment for prevention of fetal infection have been reported to be 2 to 14 percent and are more common with maternal secondary syphilis.[4,31,95,128] Treating the infant at birth may prevent the development of clinical disease if these infants were infected in utero. Some specialists would not treat the infant, however, but provide close serologic follow-up only.

If the mother's treatment was adequate before pregnancy, and the mother's non-treponemal serologic titer remained low and stable during pregnancy and at delivery, no evaluation or treatment is recommended by the CDC. Some specialists would provide a single intramuscular dose of benzathine penicillin, however, if follow-up is uncertain for the remote possibility that the mother was re-infected. These infants are at very low risk of having congenital syphilis; for the most part, these mothers are serofast.

After the neonatal period, all children who are diagnosed with congenital syphilis should be evaluated with a complete blood cell count and differential, platelet count, and examination of the CSF. Other tests, such as auditory brain stem responses, should be performed as clinically indicated. These children and children with late congenital syphilis should be treated with 200,000 to 300,000 U/kg/day of aqueous crystalline penicillin G, given as 50,000 U/kg every 4 to 6 hours for a minimum of 10 to 14 days.

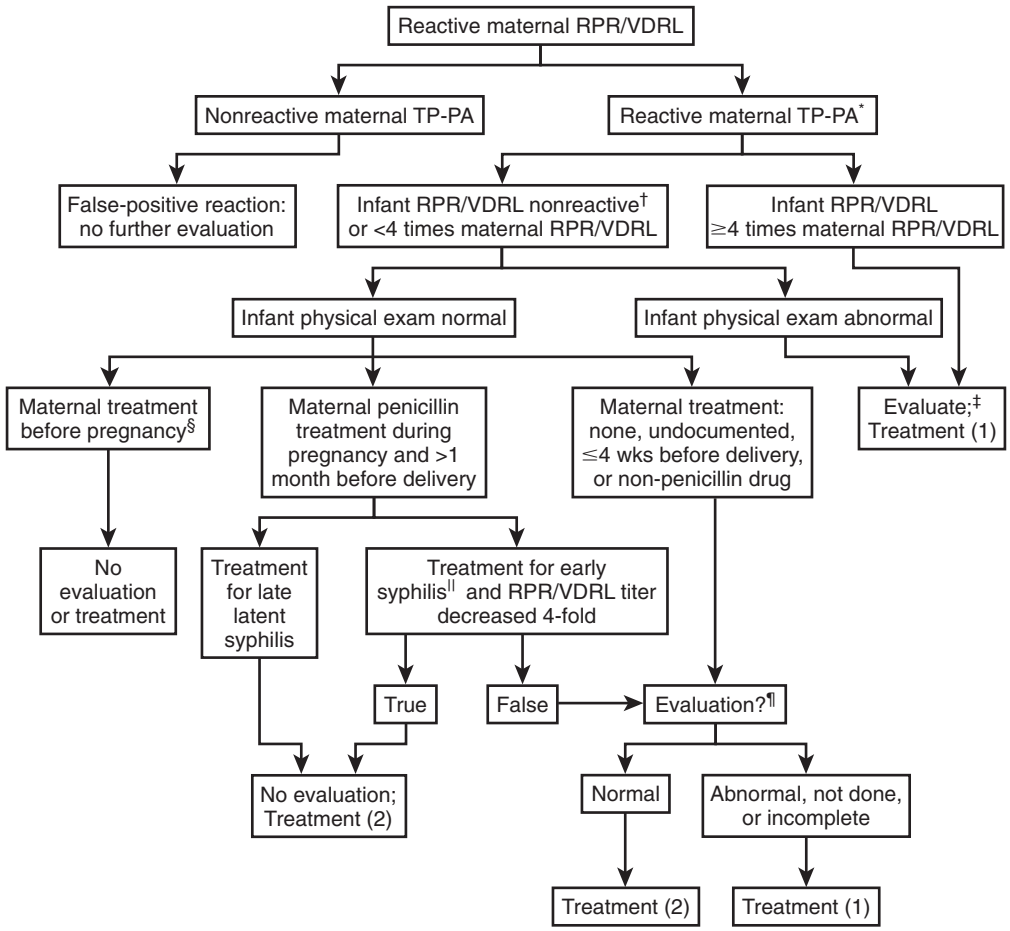

Figure 156–3 Algorithm for evaluation and treatment of infants born to mothers with reactive serologic tests for syphilis. *Test for human immunodeficiency virus (HIV) antibody. Infants of HIV antibody–positive mothers do not require different evaluation or treatment. †Infant's RPR may be nonreactive because of low maternal RPR titer or recent maternal infection. If the mother has untreated or inadequately treated syphilis, and infant's physical examination is normal, treat infant with a single intramuscular injection of benzathine penicillin (50,000 U/kg). No further evaluation is needed. ‡Evaluation consists of complete blood count; platelet count; and cerebrospinal fluid examination for cell count, protein, and quantitative VDRL. Other tests as clinically indicated include long bone x-rays, cranial ultrasound, auditory brain stem response, eye examination, chest x-ray, liver function tests, and urine or meconium toxicology. §Women who maintain a VDRL titer ≤1:2 (RPR ≤1:4) >1 year following successful treatment are considered serofast. ||Early syphilis: primary, secondary, or early latent infection. ¶Complete blood count; platelet count; cerebrospinal fluid examination for cell count, protein, and quantitative VDRL; long bone x-rays. Treatment regimens are as follows: (1) aqueous penicillin G 50,000 U/kg IV q12h (≤1 week old) or q8h (>1 week old), or procaine penicillin G 50,000 U/kg IM single daily dose ×10 days. (2) Benzathine penicillin G 50,000 U/kg IM ×1 dose. RPR/VDRL, rapid plasma reagin/Venereal Disease Research Laboratory; TP-PA, *T. pallidum* particle agglutination.

The Jarisch-Herxheimer reaction may complicate the treatment of congenital syphilis. It rarely is seen in newborns, although it occurs more commonly when syphilis is treated later in infancy. It is manifested usually by fever, but cardiovascular collapse and seizures also have been reported.

FOLLOW-UP EVALUATION

Table 156–11 summarizes recommendations concerning follow-up of infants after they have been treated for congenital syphilis and of seroreactive infants who were not treated because of the presumed adequacy of the management of the mother's serologic status.[60,61,111] Infants born to mothers with syphilis should have serial quantitative non-treponemal tests performed until the test results show nonreactivity.[56,114] Similarly, infants who are seronegative but whose mothers acquired syphilis late in gestation should be followed with serial testing after penicillin therapy is instituted.

Follow-up for infants who received appropriate penicillin therapy for possible syphilis can be incorporated into routine pediatric care at 2, 4, 6, 12, 15, and 24 months. These infants should show a fourfold decrease in non-treponemal serologic titers. In infants with congenital syphilis, non-treponemal serologic tests become nonreactive within 6 to 12 months after they have received appropriate treatment. Uninfected infants usually become seronegative by the time they reach 6 months of age.[26] Infants with persistently low, stable titers of non-treponemal tests beyond 1 year of age may require retreatment.

Untreated infants may benefit from having a non-treponemal test performed at 1 month of age. Untreated infants who are not seronegative by the time they are 6 months old should be re-evaluated clinically and treated. If the non-treponemal titer increases fourfold in any infant during follow-up, full evaluation and treatment are indicated. All infants and children should be evaluated thoroughly for the extent of disease if there is serologic evidence of failure of treatment or of recurrent disease. At a minimum, such evaluation should consist of CSF examination

TABLE 156–11 Recommended Follow-up of Infants Born to Mothers with Syphilis

1. Non-treponemal test (e.g., RPR)
   a. Treated infant: Perform at 2, 4, 6, 12, 15, and 24 months old (or post-therapy) until nonreactive. Non-treponemal test titer should decrease fourfold within 6 mo following treatment and be nonreactive by 6-12 mo. If test remains reactive ≥12 mo after treatment, consider re-evaluation and re-treatment. If non-treponemal test titer increases fourfold, full re-evaluation and re-treatment for proven disease is required
   b. Untreated infant: Perform at 1, 2, 4, 6, 12, 15, and 24 months old (or post-therapy) until nonreactive. Non-treponemal test titer should decrease fourfold within 6 mo following treatment and be nonreactive by 6 mo. If non-treponemal assay is reactive at 6 mo, re-evaluate child (including CSF examination) and treat. If non-treponemal test titer increases fourfold, full evaluation and treatment for proven disease are required
2. Treponemal test (e.g., TP-PA): Perform at 12 mo. If reactive, repeat at 18 and 24 months old*
3. Abnormal CSF examination at diagnosis: Repeat CSF examination (VDRL, cell count, protein content) at 6 months old (or post-therapy). If abnormal and no other explanation found, re-treat infant
4. Monitor yearly for neurologic, hearing, and ophthalmic disorders
5. Monitor developmental status and assess school function

**Approximately 30% of infected children maintain a reactive treponemal test beyond 18 months of age. This finding confirms the diagnosis of congenital syphilis. If child was not previously treated, treatment for proven congenital syphilis is mandatory.*

CSF, cerebrospinal fluid; RPR, rapid plasma reagin; TP-PA, T. pallidum *particle agglutination; VDRL, Venereal Disease Research Laboratory.*

and complete blood cell count and platelet count. Other tests, such as long bone radiographs, liver function tests, hearing evaluation, and ophthalmologic evaluation, can be performed as clinically indicated.

A reactive treponemal test in an infant who is older than 18 months of age and has lost all maternal antibody confirms the diagnosis of congenital syphilis. This finding occurs, however, in only a few infants with congenital syphilis, as documented by isolation of spirochetes by rabbit inoculation of infant blood or CSF. If the child did not receive treatment previously, a full evaluation and treatment are indicated.

Infants with abnormal CSF findings should have a repeat lumbar puncture performed at 6 months after therapy. A reactive CSF VDRL test result or an abnormal protein content or cell count at that time is an indication for re-treatment.

Adults and older children with primary or secondary syphilis should be examined clinically and serologically at least at 6 and 12 months after treatment. Failure of non-treponemal titers to decrease fourfold within 6 months of treatment indicates probable treatment failure. These individuals should be re-evaluated for HIV infection, and consideration should be given to performance of a lumbar puncture for detection of unrecognized neurosyphilis and re-treatment. For latent syphilis, subsequent follow-up with quantitative serology at 6, 12, and 24 months is recommended. Failure of a fourfold decrease in initially elevated non-treponemal serologic titers (≥1:32) within 12 to 24 months of therapy is an indication for examination of CSF and re-treatment. Re-treatment for syphilis also is recommended when clinical signs or symptoms persist or recur, or if there is a sustained fourfold increase in titer of a non-treponemal serologic test. Patients with neurosyphilis require examinations and repeat CSF examinations every 6 months until the cell count is normal. If the cell count is not decreased after 6 months or the CSF is not normal after 2 years, re-treatment should be considered.

In most patients receiving appropriate therapy during the primary or secondary stages, active disease is arrested totally and permanently. Persistent seroreactivity as measured by the FTA-ABS test may be avoided if treatment is given during the pre-primary stage, but seldom thereafter. Nonetheless, progression to tertiary disease seldom, if ever, occurs. Similarly, therapy administered during early or late latent syphilis averts the development of symptomatic tertiary disease. Antimicrobial therapy for symptomatic neurosyphilis, optic neuritis, and cardiovascular syphilis may not be followed by significant clinical improvement, and established damage to vital organs may fail to resolve.

PREVENTION

Methods to control the spread of syphilis have relied extensively on treatment of case contacts. Individuals with active syphilis are interviewed to identify all sexual contacts that may have occurred (1) 3 months plus duration of symptoms for primary syphilis, (2) 6 months plus duration of symptoms for secondary syphilis, and (3) 1 year for early latent syphilis. The contacts are examined, tested serologically, and treated appropriately even if they are seronegative. Advantage is taken of the long incubation period of syphilis by preventing disease in contacts before they themselves can transmit infection.

Adverse outcomes of pregnancy and congenital infection can be prevented effectively by performing routine prenatal serologic screening of and providing penicillin treatment to infected women and their sexual partners.[133,144] All pregnant women should have a non-treponemal serologic test for syphilis at the first prenatal visit. For communities and populations in which the prevalence of syphilis is high or for patients at increased risk of contracting disease, serologic testing should be performed at 28 weeks' gestation and at delivery because some women may acquire syphilis during pregnancy.[2] In the absence of clinical symptoms or proven exposure to an active case and with a negative treponemal test, treatment may be withheld and studies repeated in 4 weeks because this probably represents a BFP result. When epidemiologic, clinical, or serologic evidence of infection is present, or the diagnosis cannot be excluded, treatment should be instituted.

Serologic screening tests should be performed on maternal serum and not on the infant's serum or umbilical cord blood.[112] An infant's serologic titer usually is one to two dilutions less than that of the mother's titer; an infant may have a nonreactive serologic test for syphilis when the maternal titer is of low dilution. Some of these infants, especially infants born to mothers with no prior treatment for syphilis, require treatment for prevention of late-onset disease. They would be missed if only infant screening is performed.

Limitations of current screening practices also exist. A falsely negative non-treponemal test can occur from a prozone phenomenon. Also, a negative maternal non-treponemal test at delivery would not exclude incubating syphilis or even primary syphilis if non-treponemal and treponemal antibodies have not yet reached detectable concentrations.[37,123] Infants born to such mothers may be infected and develop clinical disease in the ensuing 3 to 14 weeks. Repeat screening of mothers who reside in areas with a high prevalence of syphilis or engage in high-risk behaviors may be advisable at the first postpartum visit.

It is a policy statement of the CDC that no infant should leave the hospital without the serologic status of the infant's mother having been documented at least once during pregnancy and preferably again at delivery.[20,83] In this era of early and very early discharge from the hospital after deliveries, fulfilling the policy

goal may require careful planning and advocacy by the clinician.

All syphilis cases must be reported to the local public health department. This practice allows for contact investigation, appropriate follow-up, and identification of core environments and populations in which the greatest transmission of syphilis is occurring in a particular community. Despite great progress in recent years, the prevention, control, and even elimination of endemic syphilis in the United States remains an elusive goal in public health policy and on a global scale in countries where resources may be limited, and the practicalities of serologic screening and treatment in prenatal care settings are challenging.

CHAPTER 157

Nonvenereal Treponematoses

David C. Hilmers ❂ James N. Miller

Pinta, yaws, and endemic syphilis (bejel) are the three chronic granulomatous diseases that constitute the pathogenic nonvenereal treponematoses of humans. These diseases are caused by morphologically and antigenically indistinguishable treponemes found almost exclusively in underdeveloped areas of the tropics and bordering arid regions. Minor genomic differences among species of treponemes have been reported by researchers, but as yet these variations cannot be used to discriminate among the causative agents of these diseases.[5-7,14,42,57,62] The pathogenic treponemes have been given subspecies designations as follows: syphilis, *Treponema pallidum* subsp. *pallidum* (*T. pallidum*); yaws, *T. pallidum* subsp. *pertenue* (*T. pertenue*); and endemic syphilis, *T. pallidum* subsp. *endemicum* (*T. pallidum*). The designation for the causative agent of pinta remains *Treponema carateum* (Table 157–1).

Although apparently neither sexually nor congenitally acquired, agents responsible for the nonvenereal treponematoses are transmitted person-to-person by means of skin or mucous membrane contact. Close contact with children or young adults, traumatized areas of skin, lack of clothing, and poor personal hygiene are important factors in the transmission of these diseases. All three nonvenereal treponematoses are potentially debilitating diseases that have enormous social and economic implications within endemic areas. Although their worldwide prevalence generally has been reduced considerably by means of seroepidemiologic and mass treatment campaigns sponsored by the World Health Organization (WHO) and the United Nations International Children's Emergency Fund (UNICEF) in the 1950s and 1960s, they remain a public health problem in several areas of the world where sporadic outbreaks continue to occur.[47,65]

Since the termination of these mass treatment campaigns, lack of attention to these diseases and diversion of resources to other public health problems, such as human immunodeficiency virus, malaria, and tuberculosis, have led to a resurgence in the nonvenereal treponematoses in some parts of the world. Because of a lack of vigilance and awareness of these diseases, they probably are underreported. Data reported by WHO in 1997 estimated that there were more than 2.5 million cases worldwide.[66] The potential effectiveness of a determined treatment and surveillance program was shown in a region of northern Ecuador where no new cases of yaws were reported from 1993 to 1998.[2] Prior to the inception of this program, there was a prevalence of 16.5 percent clinical cases in the area's population.

The history, development, and global spread of treponemal diseases have been the subject of widespread debate. Because the primary reservoirs for these organisms are humans, their history is intertwined within the economic, cultural, and social frame-

TABLE 157–1 Comparison of the Treponematoses

	Syphilis	Yaws	Endemic Syphilis	Pinta
Organism	*T. pallidum* subsp. *pallidum*	*T. pallidum* subsp. *pertenue*	*T. pallidum* subsp. *endemicum*	*T. carateum*
Distribution	Worldwide	Tropics, Africa, Asia, Pacific	Arid areas of Africa, Arabia	Tropical Central, South America
Peak ages affected	All ages	1-12 yr	<15 yr	15-20 yr
Route of entry	Mucous membranes	Skin	Oral mucosa, fomites	Skin
Incubation period	2-10 wk	3-9 wk	3 wk	2-3 wk
Experimental hosts	Rabbit, primate, guinea pig, hamster	Rabbit, hamster	Rabbit, hamster	Primate only
Sexual transmission	Yes	No	No	No
Congenital transmission	Yes	No	No	No
Skin infection	Yes	Yes	Yes	Yes
Bone involvement	5-10%	20-40%	20-40%	0
Neurologic involvement	Yes	No	Rare	No
Cardiologic involvement	Yes	No	Rare	No

work of humanity. One theory postulates that all treponemal diseases originated from pinta or yaws, first found in Central Africa. This view states that treponemes spread widely from there, and the various disease processes that we know today are a result of mutations caused by the adaptation of the organisms to environmental and development changes in their hosts. The Columbian theory suggests that treponemes began as nonvenereal pathogens in Africa that spread to the Americas via Asia thousands of years ago while mutating into endemic syphilis (bejel) as it crossed Africa and Asia. In North America, it developed into the venereally transmitted form of disease caused by *T. pallidum* that we know today as syphilis. Syphilis was carried to Europe by Columbus and his men on his return voyage from the Americas. Meanwhile, the nonvenereal forms were found in Britain, but not in Continental Europe, in the years before Columbus. Supporters of this theory point to skeletal evidence of syphilis found in the Dominican Republic before the arrival of Columbus on the island and to evidence of nonvenereal treponemal infections, but not syphilis, in Britain during the same period.[18,25,50,68]

On morphologic examination, the treponemes are thin, tightly coiled organisms that do not stain or stain poorly with the usual aniline dyes. They contain 4 to 14 spirals and are actively motile by virtue of periplasmic flagella. The organisms are quite fragile and sensitive to drying, atmospheric oxygen, and temperatures greater than 35° C. The organisms can be stored in either 15 percent glycerol at –70° C or liquid nitrogen and still retain their virulence for long periods.[58] Although limited multiplication of *T. pallidum* subsp. *pallidum* has been achieved in a tissue-culture system,[15] it has not been accomplished as yet with the nonvenereal pathogenic treponemes. No human pathogenic treponemes have been cultured in or on artificial media. Because they measure 10 to 13 μm in length but only 0.15 μm in width, they are below the resolution of light microscopy and must be identified by darkfield microscopy in infected skin or mucous membrane lesions.

Little can be done to distinguish the various species of pathogenic treponemes. Clinical and epidemiologic features of each disease state from which the treponeme is recovered constitute the primary method of differentiation. Although not practical, further differentiation is based on the response of animal models to experimental infection.[26,30,48,53,54] Each of the pathogenic treponemes stimulates cross-reactive antibodies assayed in the serologic diagnosis of the human diseases by non-treponemal and treponemal tests. Various degrees of homologous resistance and cross-immunity exist after infection occurs with any of these spirochetes.[26,27,35,36,53,59] Rabbit models have shown complete immunity against re-infection with homologous pathogens, but only incomplete or nonexistent protection against other subspecies.[58] No specific antigenic differentiation has been found among species to explain these findings. Despite differences in methods of transmission, clinical disease, geographic distribution, and rare reports of resistant cases, all human treponemes remain sensitive to penicillin.[63]

PINTA

Pinta (mal del pinto, carate, enfermedad azul) is a chronic, contagious, nonvenereally transmitted treponemal disease that normally is the mildest of these disorders. Although it affects primarily patients in the first 2 decades of life, it can affect children and adults of all age groups, producing dyschromic skin lesions without pathogenic involvement of deeper organ structures. Pinta is not a fatal disease, but a disfiguring one, which results in social ostracism and an inability to adjust to an urban society.

BIOLOGY AND IMMUNOLOGY

Pinta is caused by *T. carateum*. The organism is characterized primarily by its isolation from patients with clinically apparent pinta and by its lack of pathogenicity in small laboratory animals. Only chimpanzees have been shown to be susceptible to experimental infection.[30,31] Human studies by Medina[36] suggest that *T. carateum* induces significant protection against homologous reinfection and cross-immunity against the treponemes of yaws and syphilis; however, these two subspecies of *T. pallidum* fail to confer cross-protection against *T. carateum*.[36]

EPIDEMIOLOGY

Pinta is found primarily in tropical Central and South America among underprivileged Indians and in the Caribbean. It occurs in major river basins of Mexico, Venezuela, Colombia, Brazil, Peru, and Ecuador. Cases also have been reported in Argentina, Chile, Haiti, Guatemala, Dominican Republic, Honduras, Nicaragua, and Bolivia. Pinta rarely occurs at higher elevations in the mountain regions of these countries. In the early 1920s, approximately 500,000 cases occurred throughout Latin America; however, today, as a result of seroepidemiologic and mass treatment campaigns, few cases are being reported. The possibility of underreporting exists because a 20 percent clinical prevalence was reported in 1982 in a village in Panama.[46] A case of pinta in Austria in a visitor from Cuba was reported in 1999.[67]

The disease is found where poor hygienic and crowded conditions exist. Although endemic areas basically are rural, tribal

tradition allows very close contact among its members to occur. These tropical societies, with their absence of shoes and clothes, continually subject exposed skin to trauma and to contact with infectious lesions. Transmission of *T. carateum* occurs primarily by intimate skin-to-skin contact; a break in the skin is required for invasion of the treponeme. Pinta is not acquired congenitally or by blood transfusion. Transmission of the disease by insect vectors has been proposed but not proven[36]; insects probably initiate disease by producing the necessary breaks in the skin.[12] Pinta is distributed equally between males and females and among all races in endemic areas. It is acquired primarily by individuals aged 15 to 20 years old,[47] frequently spreading to family members because of crowded living conditions.

PATHOGENESIS AND PATHOLOGY

T. carateum penetrates skin through breaks in the epidermis, with resultant damage restricted to the dermal and epidermal tissues. The organisms multiply in these layers, eliciting cellular proliferation and plasma cell, lymphocyte, and Langerhans cell infiltration. The resulting primary lesions (one to three) may appear on any area of exposed skin but usually occur on the legs, the dorsum of the feet, the forearms, or the back of the hands.[47] The lesion enlarges as a result of continual progression and direct extension or by coalescence with adjacent primary lesions; occasionally, a regional lymphadenopathy develops. Secondary lesions, known as *pintids*, may arise years later from treponemal dissemination and exhibit a cellular proliferation and infiltration similar to that of the primary lesion. In contrast to venereal syphilis, blood vessels remain intact and do not show proliferation. The dyschromic or multicolored nature (brown, slate blue, black, or gray) of the primary and secondary lesions is more characteristic of older than of younger lesions, in which pigmentary changes usually are minimal. The variously pigmented older lesions may show hyperkeratosis or parakeratosis. Large numbers of treponemes can be found throughout the dermis and epidermis in the highly contagious primary and secondary lesions.

Late pinta is characterized by pigmentary changes, from dyschromic treponeme-containing lesions to achromic treponeme-free lesions. This depigmentation process occurs at different rates even within the same lesion, which gives rise to different degrees of hypochromia and atrophy around dyschromic and achromic lesions.[47] A concomitant lack of hair follicles and sebaceous glands may occur.[11]

CLINICAL MANIFESTATIONS

Pinta is characterized by a continuing production of early infectious lesions from either direct extension or dissemination and by the concomitant presence of lesions in various stages of dyschromia and achromia. The lesions are not well delineated, often merge, and may be accompanied by regional lymphadenopathy. Primary, secondary, and tertiary stages may or may not occur simultaneously.

The early stage of pinta includes the initial lesions, occasional regional lymphadenopathy, and secondary lesions resulting from dissemination of treponemes. A primary lesion (not always evident) develops after an incubation period of 3 days to 2 months, usually 2 to 3 weeks. The primary lesion begins as one or more small erythematous papules that may appear scaly and indurated. The papules progressively enlarge over 1 to 3 months, often coalescing, becoming pigmented, scalier and more erythematous and developing heaped-up margins. Occasionally, an accompanying regional lymphadenopathy is present. The lesion may disappear in several months or may continue to enlarge for several years, forming larger psoriasiform plaques that coalesce further.

The primary lesions of pinta generally overlap development of the secondary lesions or pintids, which appear months to years after infection occurs. During this stage, dissemination occurs, and almost any area of the skin can be involved. The lesions occur typically on exposed areas of skin and are variously pigmented. The degree of pigmentation is related to the state of development of the lesion, the age of the lesion, the degree of exposure to sun, and the host's natural pigmentation. Pintids begin as small, scaly papules that gradually enlarge and coalesce. Several colors may exist within the same lesion. Initially, pintids usually are red to violaceous; later, they become slate blue, gray, or black as a result of photosensitization. Lesions on the legs typically are yellowish brown or dark brown.

The late stage of pinta is characterized by the development of depigmented lesions. Achromia usually begins several years after the onset of the disease but may appear 3 months after onset. Areas of depigmentation spread slowly, leaving large achromic lesions, reminiscent of vitiligo, as the end result. Early achromia tends to be asymmetric, whereas later depigmented lesions are symmetric. Characteristic of the Cuban form of pinta is the development of hyperkeratosis of the palms and soles. Many chronic dermatologic entities characterized by scaly, psoriasiform lesions or by dyschromia or depigmentation can be confused with pinta in endemic areas. Maculopapulosquamous diseases, including psoriasis, parapsoriasis, and lichen planus, and dyschromic dermatologic diseases such as vitiligo, ochronosis, and argyria must be taken into consideration.

PROGNOSIS

Pinta is not a fatal disease; it produces changes related only to the skin. There is no involvement of the central nervous system, the cardiovascular system, or other internal organs. Untreated, the patient frequently develops large achromic cutaneous blemishes. The major resulting problem is one of social ostracism from the community. Infected individuals are removed from the urban society and find refuge in the rural areas. This isolation separates the patient further from the principal sources of medical therapy.

YAWS

Yaws (frambesia, pian, buba, bouba) is a communicable, nonvenereally transmitted treponematosis of the tropical zones. The disease is characterized by its early acquisition (usually before puberty) and its chronic, relapsing pattern of early benign lesions separated by periods of latency that terminate with late destructive lesions of skin, bones, and cartilaginous tissues. A very prevalent disease in the early part of the 20th century, yaws was estimated to have affected more than 50 million people. Although seroepidemiologic and mass treatment campaigns sponsored by WHO and UNICEF have reduced its overall prevalence dramatically, endemic areas of concern continue to exist.[21,47,61,65]

BIOLOGY AND IMMUNOLOGY

T. pallidum subsp. *pertenue*, the etiologic agent of yaws, is morphologically identical to other pathogenic treponemes. Although not clinically useful, animal models can be used to distinguish between syphilis and yaws. Rabbits and hamsters have been infected experimentally by both diseases, with resultant lymphadenopathy and visible lesions. Characteristic differences in the distribution, form, and number of lesions can be used to

distinguish the identity of the infectious agent. On the basis of human and experimental studies, the organism stimulates a significant degree of homologous resistance to re-infection and superinfection and cross-immunity to *T. pallidum* subsp. *pallidum* and *endemicum*.[26,29,53,58]

EPIDEMIOLOGY

Yaws is a disease of tropical countries found primarily among rural populations. It exists in the warm, moist, endemic areas of rural Africa, Southeast Asia, the Caribbean, South America, the Pacific, and central and southern Africa. As indicated, seroepidemiologic and mass treatment campaigns have resulted in a significant reduction in prevalence of the disease in most of these areas. The failure of many countries to integrate active control measures into the functions of local health services has led, however, to a gradual build-up and extension of reservoirs of yaws, with the emergence of significant numbers of new, active cases since 1974 in Ghana, Togo, Benin, Indonesia, Papua New Guinea, and the Ivory Coast.[65] In a WHO survey in the Central African Republic, Congo, and Gabon, clinical yaws was detected in more than 20 percent of the Pygmy population, and reactive serologic tests were obtained in 80 percent.[65] Health care workers in the periurban settlements of Port Moresby, Papua New Guinea, identified 494 cases between April 2000 and September 2001. A 2001 survey in the Solomon Islands showed that yaws was the sixth leading cause of morbidity, and that the prevalence was 4106 cases per 100,000 population.[56] In Latin American, cases still occur in Brazil, Colombia, Haiti, Venezuela, and Suriname.[13,37]

Poor hygiene, close crowding among children (especially in sleeping areas), and lack of protective clothing facilitate transmission of the disease by direct skin-to-skin contact, whereby *T. pallidum* subsp. *pertenue* enters traumatized exposed areas from an infected lesion. The usual portals of entry are the lower extremities, head, face, and mouth. The presence of treponemal antibodies and isolation of treponemes (most probably *T. pallidum* subsp. *pertenue* from West African monkeys[4,16]) suggest that primates in this area may act as a reservoir for spread of the disease.

Yaws usually is acquired before puberty and is most prevalent among children. Because such a large percentage of the population contracts the disease in infancy, young children represent the primary reservoir. Older children and adults generally are not infectious; therefore, congenital and sexual transmission does not occur. Boys and girls are affected equally.

PATHOGENESIS AND PATHOLOGY

T. pallidum subsp. *pertenue* enters the host through abraded skin, most frequently below the knees. The organisms multiply locally and in the regional lymph nodes. Epithelial hyperplasia and plasma cell, lymphocytic, and macrophage infiltration are elicited. The end result is the formation of a primary lesion and lymphadenopathy containing numerous treponemes. Shortly after their introduction into the host, organisms are carried to skin, bone, and cartilage through the circulation. Disseminated treponemes in these tissues multiply, elicit a chronic inflammatory response similar to that seen in the primary lesion, and produce distant papillomas, lymphadenopathy, hyperkeratosis, and bone involvement that develop uninterruptedly until they are reversed by either immune mechanisms or treatment. In contrast to those associated with venereal syphilis, vascular changes are discrete or do not occur in cutaneous yaws.

Untreated primary and secondary cutaneous lesions generally heal with only minimal scarring, unless they are complicated by secondary bacterial infection. The healing process and maintenance of latency seem to involve humoral and cellular mechanisms of immunity.[52] Relapses may occur during latency and, together with late disease, may be caused by a breakdown in the immune state, the development of antigenic variation by the treponeme, or both.

The late gummatous lesions presumably are caused by a hypersensitivity-induced mechanism similar to that postulated for the syphilitic gumma. Bone changes in late stages of yaws most often involve the long bones and manifest as hypertrophic periostitis, gummatous periostitis, osteitis, and nodular or generalized osteomyelitis.[23] Juxta-articular nodules occur near major joints and are characterized as nonspecific granulomata.[10]

CLINICAL MANIFESTATIONS

Yaws is a chronic, debilitating disease characterized by early infectious lesions; periods of latency and relapse; and late destructive lesions of cutaneous, subcutaneous, cartilaginous, and bony tissue. After an incubation period of 9 to 90 days (usually about 3 weeks), the primary lesion forms at the site of inoculation and is accompanied by regional lymphadenopathy. The lesion typically appears as a raised papule on the lower extremity that enlarges to become a hyperkeratotic papilloma measuring 2 to 5 cm in diameter, referred to as a *mother yaw*. It undergoes shallow ulceration and persists a few months to 3 years, at which time healing occurs with a resultant hypopigmented scar and surrounding dark margins.[10]

Before or weeks to months after healing of the mother yaw, crops of secondary, generalized, nondestructive papular lesions appear together with lymphadenopathy and malaise. These lesions tend to form near areas with mucous membranes, such as the nose and mouth, and may resemble condylomata lata. Some papules fade, whereas others enlarge to become papillomatous lesions referred to as *satellite secondaries* or *daughter yaws*. The multiple papillomas are circular, raised, red-yellow lesions with a granular, lobulated, and verrucous surface. They contain numerous treponemes, usually measure 1 to 3 cm in diameter, and produce a yellow discharge that dries to form a black scab. Hyperkeratotic involvement of the palms and soles occurs commonly. Painful fissuring of the soles may cause the patient to walk on the sides of the feet, producing the characteristic gait of "crab" yaws.[6] Bone pain may be severe, and nondestructive long bone lesions, including periostitis, osteitis, and osteomyelitis, may occur.[10,22]

Untreated secondary lesions may persist for longer than 6 months, at which time, owing to the development of host immune mechanisms, they usually heal without scars or residual defects, unless ulceration caused by secondary bacterial infection occurs. During the dry season, early yaws lesions often are atypical, tending to be macular and fewer in number; papillomas, which are small, scanty, dry, flat, and grayish in appearance and of short duration (about 1 month), are confined mainly to the hidden, protected, moist skin folds.[41,47,60]

Despite healing, some treponemes evade the immune process and persist in the affected tissues (latency). Latency frequently is interrupted by relapses, which tend to occur several times over a 3- to 5-year period. Fewer lesions are produced with each relapse, and they tend to be localized to the periaxillary, perianal, or circumoral area.[47] After cessation of the relapses and usually after a latent period of 3 to 10 years, tertiary lesions occur in 10 percent of patients[47]; the latent state persists in the remaining patients for their lifetime.

The tertiary lesions characteristically are solitary and destructive; they involve skin, subcutaneous tissue, bone, or cartilage, and most commonly occur after the onset of puberty. Painful hyperkeratosis of the palms and soles similar to that seen in early

yaws frequently occurs. Other lesions develop as ulcerating, subcutaneous nodules and may heal spontaneously to form scars or extend widely from their margins. The scarring results in depigmentation and sometimes contractions. Bone deformities of late-stage yaws include chronic hypertrophic periostitis, osteitis, gummatous periostitis, and osteomyelitis, each of which may ulcerate through the skin.[20] Gangosa, or rhinopharyngitis mutilans, the destructive gummatous ulceration of the skin and bones of the central face, and juxta-articular nodules, ganglions of tendon sheaths, and saber tibiae also may occur as manifestations of the late stages of the disease.[23] Gondou, a disfiguring hypertrophic osteitis of the frontal processes of the maxillae, previously often reported among western Africans with yaws, seems to have disappeared.[34] Other diseases that must be differentiated from the skin lesions of yaws include vitamin deficiencies, early stages of leprosy, venereal syphilis, tinea versicolor, molluscum contagiosum, scabies, lichen planus, plantar warts, tungiasis, psoriasis, and cutaneous leishmaniasis. Sickle-cell disease, tuberculosis, and bacterial osteomyelitis may produce clinical manifestations that mimic the bone lesions of yaws.

PROGNOSIS

Yaws is not a benign disease. If left untreated, it can produce destructive, disfiguring lesions of the face, feet, and hands and painful and disabling lesions of the fingers and long bones. Ulcers near joints may result in crippling contractures. Secondary bacterial infection of ulcers and of protruding bone lesions can result in further permanent damage to skin and bone tissues. Fractures generally do not occur.

ENDEMIC SYPHILIS

Endemic syphilis (bejel, njovera, siti, dichuchwa) is a chronic, nonvenereally transmitted disease of prepubescent children. It occurs in the warm, dry, arid regions of the world[47]; lesions are confined to the skin, bone, and cartilage. The disease, known to exist for centuries in Africa, has been recorded in epidemic proportions in areas where conditions among children allow transmission. As with yaws, although seroepidemiologic and mass treatment campaigns have reduced its overall prevalence drastically,[61] endemic areas of concern continue to exist and include the region bordering the southern Sahara Desert, Botswana, and the Arabian Peninsula.[43,47,64]

BIOLOGY AND IMMUNOLOGY

T. pallidum subsp. *endemicum*, the etiologic agent of endemic syphilis, morphologically is identical to the other pathogenic treponemes. *T. pallidum* subsp. *endemicum* exhibits similarity to syphilis and yaws by producing visible lesions and generalized lymphadenopathy in rabbits and hamsters experimentally infected by the intratesticular and intradermal routes.[26,54,58] The degree of induration of lesions, distribution and number of lesions, and the characteristic lymphadenopathy can be used to differentiate among the species. On the basis of experimental studies in inbred hamsters, *T. pallidum* subsp. *endemicum* stimulates a high degree of homologous resistance to re-infection and cross-immunity to *T. pallidum* subsp. *pallidum* and *T. pallidum* subsp. *pertenue*.[54]

EPIDEMIOLOGY

Endemic syphilis continues to persist in the warm, drier desert areas bordering the tropical belt. It is prevalent primarily among the seminomadic rural populations in the Arabian peninsula and along the southern border of the Sahara Desert in Africa known as the Sahel region[43,47]; a significant resurgence occurred in Mali, Mauritania, Niger, and the upper Volta during the 1970s.[47,65] More than 1000 cases were reported in Senegal in 1980.[37] Although scattered endemic foci did exist in central Asia, Australia, Bosnia, and India, they virtually have been eliminated from these areas by mass treatment campaigns.[43,47]

As with pinta and yaws, endemic syphilis propagates under conditions of poor hygiene, crowding, and wearing of little or no clothing. Transmission by oral mucous membranes is favored through contaminated objects, such as drinking vessels and kitchen utensils, and through contact with saliva-contaminated fingers and mouth-to-mouth contact.[9,14,28] Fomites are thought to play a role. Transmission may occur through direct oral lesion–to–skin contact.[47] Occasionally, a previously uninfected nursing mother develops a primary lesion on or near the nipple after the transfer of treponemes from her infected infant.[18,64] Congenital transmission does not seem to occur. The role of insect vectors, such as flies, has been suggested, but it may be caused by creating a portal of entry by breaks in the skin after itching. Endemic syphilis occurs predominantly among children, with onset usually occurring in children younger than 15 years and with equal sex distribution. Spread occurs most commonly within the family, and active disease can be manifest in more than one family member at any given time.

PATHOGENESIS AND PATHOLOGY

T. pallidum subsp. *endemicum* enters the host usually through the oral mucosa. The small number of treponemes introduced into a susceptible host usually precludes the local multiplication and host inflammatory response required to produce a visible primary buccal lesion.[18] When a primary lesion does occur, it appears as a papule or ulcer resulting from a chronic inflammatory response to the proliferating organisms consisting of plasma cell, lymphocytic, and macrophage infiltration. Endothelial cell swelling of small blood vessels also is evident.

The organisms are carried to the regional lymph nodes within a few hours of entry, commonly into the oral mucosa portal entry. They multiply and elicit epithelial hyperplasia and plasma cell, lymphocytic, and macrophage infiltration, with resultant lymphadenopathy. Dissemination occurs through the circulation, and the organisms are carried to the skin, bone, oral mucosa, axillae, and anogenital regions, where they multiply and elicit a chronic inflammatory response characterized by a cellular infiltration, as seen in the lymph nodes. Vascular changes and perivascular cuffing are prominent.

The untreated early lesions heal as a result of mechanisms thought to involve humoral and cellular immune responses by the host,[51] and the disease enters into a state of latency. Maintenance of latency is thought to involve similar mechanisms. The occurrence of infectious relapses during the latent period still is uncertain.

The late lesions of endemic syphilis are strikingly similar to those of late-stage yaws. Late-stage disease and relapses (if they occur) may be caused by a hypersensitivity-induced mechanism similar to that postulated for the syphilitic gumma.[17,18] Juxta-articular nodules may occur and represent a nonspecific granulomatous response occurring near major joints.[10] The rarity of cardiovascular and neurologic manifestations may be due to the slow acquisition of small numbers of organisms over a long time, which results in the immunologic protection of the heart and nervous system.[18,32]

CLINICAL MANIFESTATIONS

Endemic syphilis is a chronic, often debilitating disease characterized by early infectious secondary lesions; variable periods of latency; and late destructive lesions of cutaneous, subcutaneous, and bone tissues. As indicated, primary lesions are rare. They appear usually on the breast or nipple as a papule or shallow ulcer similar to that seen in primary venereal syphilis after an approximate 3-week incubation period[1]; they may persist for years before healing.[28]

Even without the appearance of a primary lesion, generalized infection occurs as a result of early dissemination. The onset begins after an incubation period of 3 to 6 months and is characterized by the presence of highly infectious, relatively painless, ulcerative mucous patches on the oropharyngeal mucosa, including the tongue, lips, palate, tonsils, and larynx, with accompanying regional lymphadenopathy. Involvement of the larynx usually results in hoarseness.[10] Split papules or angular stomatitis occurs at the angles of the mouth. Osteoperiostitis of the long bones of the lower extremities, similar to that seen in yaws, is a common early manifestation causing nocturnal leg pains.[10] Occasionally, axillary and anogenital secondary-type lesions result and consist of condylomata similar to those of yaws or dry papilloma annular patches, with accompanying axillary and inguinal lymphadenopathy. Disseminated papules that are indistinguishable from the papules seen in secondary venereal syphilis may occur. Other forms of cutaneous lesions can occur but are rare.

Untreated secondary lesions may persist for 6 to 9 months, at which time healing occurs because of the development of host immunity. This period of latency varies and, similar to yaws, may last for several years.

Most patients develop tertiary manifestations. Late lesions generally occur during adolescence or adult life and may resemble lesions seen in either late yaws or late-stage venereal syphilis. Gummata may affect any part of the body but commonly occur in the nasopharynx, skin, and bone, resulting in destructive, disfiguring, chronic ulcerations characteristic of gangosa or gangosa-like lesions. Late gummatous lesions can occur during childhood, possibly as a result of superinfection in an already infected host.[19] Bone involvement also is a common finding and results in painful lesions. This condition involves osteitis with gumma formation and, similar to yaws, periostitis affecting most frequently the long bones of the lower extremities. Bilateral synovitis, especially of the knees, occasionally may occur with concomitant juxta-articular nodules.[19] The cardiovascular and neurologic findings common to venereal syphilis rarely occur in endemic syphilis; when clinical manifestations do occur, they usually are atypical and very mild.[8,43]

Endemic syphilis seems to have become "clinically attenuated" in Saudi Arabia.[43] Previously florid, the classic disease seems to have been replaced by a milder form in which the number, severity, and duration of early and late lesions are reduced, and seroreactive latent infection is increased.[43] The most common late manifestation observed in this study was painful osteoperiostitis of the legs affecting mainly the tibia and fibula. Researchers have postulated that attenuation has occurred owing to improvement in hygienic conditions, better nutrition, and medical care,[43] emphasizing the importance of improvements in living conditions and the use of antibiotics in the eradication of the disease.

PROGNOSIS

The main complication of endemic syphilis is the destructive gummatous lesions of the face and bones. Severely disfiguring and disabling, these lesions prevent the patient from working effectively in the community. Many of the bone lesions are extremely painful and incapacitating.

DIAGNOSIS

In the nonvenereal treponematoses, a presumptive diagnosis is based largely on clinical presentation of the disease in an endemic area. Although darkfield examination of early lesions and lymph nodes permits visualization of treponemes, late lesions usually contain few, if any, organisms. Differentiating the treponematoses from one another solely on the basis of serologic testing is impossible because of shared antigens.[17,47] The diagnosis of yaws in nonendemic areas or during periods of latency is difficult to make. The coexistence of yaws and endemic syphilis in certain geographic locations, together with their often identical clinical manifestations, renders darkfield and serologic assays useless for differentiating these diseases in such areas.[47] Similar limitations are applicable in differentiating venereal syphilis from yaws or endemic syphilis in nonendemic areas.[47] Under these circumstances, the diagnosis can be based only on a careful history and epidemiologic data.[47]

In tropical areas, numerous other diseases may be confused with yaws.[25,47] Impetigo and chronic tropical ulcers are found frequently and may respond to penicillin therapy. Ecthyma may produce ulcers that occasionally are similar to the ulcerative papillomas of yaws.

The same serologic testing is used in the diagnosis of venereal and nonvenereal treponematoses. The rapid plasma reagin and Venereal Disease Research Laboratory tests are useful, but may be nonreactive in early lesions. They are nonspecific non-treponemal studies using cardiolipin antigens that produce similar results in the presence of each disease and cannot be used to differentiate between them. Care must be taken in the interpretation of non-treponemal tests in establishing the diagnosis because of the possibility of obtaining false-positive reactions among patients with non-treponemal diseases or conditions.[39] These tests are quantitative, however, and false-positive results usually have a titer of less than 1:4. After treatment has been given, a twofold or greater drop in titers usually signifies a successful outcome.

The treponemal tests, such as the fluorescent treponemal antibody absorption test, the *T. pallidum* immobilization test, and the *T. pallidum* hemagglutination assay, are specific but normally remain positive for life and alone may not be useful in diagnosing active cases. Combining non-treponemal and treponemal tests is useful in establishing the diagnosis where one of these diseases is suspected, whereby a false-positive non-treponemal test is likely when a treponemal test is negative. In pinta, both types of tests may not become reactive until 4 months after the development of the initial lesion, whereas in yaws and endemic syphilis, both tests become reactive within the first few weeks of illness.

Although it may be less practical than serologic testing in remote and resource-poor areas, darkfield examination of fluid obtained from the initial serous exudates from cutaneous or mucous membrane lesions generally reveals the presence of treponemes. As the lesions become more chronic, treponemes become difficult to find. Direct fluorescent antibody testing can detect treponemal species on a slide, but generally is unavailable in the field. Silver impregnation of biopsy material from skin lesions or lymph nodes may reveal the organisms, but care must be taken in differentiating treponemes from tissue artifact.

Newer techniques such as polymerase chain reaction have been used to detect the presence of treponemes. Although polymerase chain reaction is highly sensitive and specific, it cannot differentiate among species as yet and is not practical for field use in resource-poor endemic areas.[44]

TREATMENT AND PREVENTION

The treatment of choice for all treponemes is benzathine penicillin G. Patients older than 10 years of age with clinical disease, in a period of latency or in the incubatory stages, and contacts of cases should receive 1.2 million U of benzathine penicillin G intramuscularly in a single dose; children younger than 10 years of age should receive 600,000 U in a single dose by the same route.[47,65] Isolated cases of resistance have been reported in Papua New Guinea,[3] Ecuador,[2] and Guyana[55]; however, whether these cases represent true resistant strains, other concurrent infections, or problems in storage and administration of the medicine remains unclear. Penicillin continues to be considered effective for treatment and eradication. Oral penicillin was used to treat 17 active cases of yaws in Guyana in 2000 to 2001. All but one patient had complete resolution of the lesions. Although this development is promising because it would eliminate the need for refrigeration and intramuscular injections, more data on the efficacy and compliance with oral penicillin regimens are needed.[55]

Tetracycline is an alternative treatment for penicillin-allergic patients older than 8 years of age and not pregnant. The recommended dosage is 500 mg by mouth four times daily for 15 days (total dose of 30 g)[47]; children aged 8 to 15 years old may be given half the dose.[47] Although the newer tetracyclines have been used and are assumed to be equally effective, no information is available about their use. Studies to determine the efficacy of erythromycin have not been reported, but based on its use in syphilis, erythromycin is presumed to be another alternative for penicillin-allergic patients. The recommended dosage is 8 to 10 mg/kg up to the adult dosage of 250 mg four times daily.[47]

Therapy in yaws renders early lesions noninfectious in a few days, with complete healing achieved in 7 to 10 days. Recurrences after treatment may occur as a result of re-infection.[25] Late lesions heal more slowly after therapy and may require surgery. In endemic syphilis (bejel), infectious lesions disappear rapidly, and relapses usually are prevented after therapy. The clinical response to therapy is remarkably slow in pinta. Primary and early secondary lesions take 4 to 6 months to disappear, whereas late secondary lesions require 6 to 12 months for complete healing to occur.[49] Hyperchromic lesions heal without residua, and hypochromic lesions often result in depigmented areas. Old achromic lesions usually remain intact without repigmentation.

In yaws and non-treponemal bejel, test titers may revert to nonreactive if the patient is treated early in the course of the disease. The longer the patient remains untreated, however, the more slowly conversion to seronegativity occurs, and treatment during the later stages may result in the persistence of high titers.[45] Generally, the serologic response to therapy is absent or slow in pinta; non-treponemal tests may take years to decline after adequate therapy has been given.[38] In each of the treponemal diseases, treponemal tests remain reactive for life after the patient has received adequate therapy.

Improvement of living conditions and the general hygiene of the community, mass treatment of patients and contacts, and seroepidemiologic campaigns contribute significantly to the prevention of yaws. WHO recommendations state that the entire population should be treated when the prevalence exceeds 10 percent. Where prevalences of 5 to 10 percent exist, all cases, close contacts, and all children younger than 15 years are treated. Where a prevalence of less than 5 percent exists, WHO recommends that cases, close contacts, and all members of the household be treated. Where implemented, this strategy has been remarkably effective, such as seen in an eradication program in Ecuador.[2]

FUTURE

It is a tragedy that such easily curable diseases have not been eradicated. Little recent epidemiologic data are available because many governments have stopped collecting prevalence data since the presence of these diseases implies poor health conditions. Researchers expect that genomic or antigenic markers will become available and will simplify establishing the diagnosis and differentiating among species. A renewed commitment to the elimination of these diseases is imperative to prevent the suffering and social ostracism that they bring. Simple measures, such as improved hygiene, education, and better access to health care, can ameliorate greatly the severity of disease. The effective eradication campaigns of the 1950s and 1960s need to be continued, along with awareness and vigilance on the part of health care professionals and health policy makers.

SUBSECTION 7

Anaerobic Bacteria

CHAPTER 158

Clostridial Intoxication and Infection

Gary D. Overturf

Clostridia are obligate anaerobic, endospore-forming bacilli that usually are positive on Gram stain. Of the more than 150 species of *Clostridium*, at least two dozen species are potentially pathogenic in humans, mostly by virtue of their biologically active proteins (toxins). These ubiquitous organisms frequently are found in soil, sewage, decaying tissue, and the intestinal tract of humans and other animals.[10] The genus *Clostridium* has undergone significant revisions in taxonomy since 1994, which has resulted in a proposal for definitions of several clusters based on rRNA gene sequences.[3] Human disease caused by *Clostridium tetani* is discussed in Chapter 160.

BOTULISM

Botulism is an acute descending flaccid paralysis that results when the neurotoxin of *Clostridium botulinum* blocks neuromuscular transmission. Several clinical forms of botulism have been identified and include infant (the most common), "classic" or foodborne, wound, intestinal, and occult and inadvertent. The occult or "unclassified" category was created by the Centers for Disease Control and Prevention (CDC) for adult patients who lack an apparent food, wound, or intestinal source of botulinum toxin[14]

and whose cases hypothetically may have an infant-type pathogenesis.[3] Inadvertent botulism, the form recognized most recently, is an unintended consequence of the treatment of certain movement disorders (such as dystonia) with botulinum toxin A. Recently, the potential use of botulinum toxin as a bioterrorist agent has become an important concern. Infant botulism is discussed in Chapter 159.

EPIDEMIOLOGY AND ETIOLOGY

Seven antigenically distinct types of botulinum toxins are designated by the letters A through G. Disease in humans is caused by toxin types A, B, E, F (rarely), and possibly G.[9,17,21,32,33,38,46,48] Types C and D cause botulism in animals.[21,48] From 1973 to 1996, a median of 24 cases of food-borne botulism, three cases of wound botulism, and 71 cases of infant botulism were reported annually to the CDC.[46] In the United States, approximately 50 percent of the food-borne cases are caused by toxin A and another 25 percent each by toxins E and B. Type A occurs primarily in the western states, whereas type B is seen more commonly in the eastern states. Type E outbreaks occur more frequently in Alaska and the Great Lakes region.

Botulinum toxin is considered the most potent and lethal of all naturally occurring compounds; it consists of a simple dichain composed of a "heavy" 100-kd chain joined by a disulfide bond to a 50-kd "light" chain. The toxin's light chain is a Zn^{2+}-containing endopeptidase that blocks acetylcholine-containing vesicles from fusing with the terminal membrane of the motor neuron, thereby resulting in flaccid paralysis.[33] It is heat-labile; 5 minutes of boiling destroys the toxin, and little remains after 30 minutes of exposure at 80° C. Toxin is produced by *C. botulinum* at all temperatures at which growth occurs (3° C to 48° C). Toxin also is formed at all pH values at which growth occurs (pH 4.8 to 8.5), but the toxin is unstable at pH values higher than 7. Toxin thus is produced only during active growth and released during lysis of the bacterial cells. The presence of organisms in improperly processed acidic food, however, can allow toxin production to occur.[22,48] Type E toxin may be produced quickly in small fragments of fish exposed to air and at lower pH values and cooler temperatures than noted with other toxin types.[21]

Most outbreaks of botulism in the United States are traceable to home-processed foods; however, in recent years the proportion of cases that result from restaurant-associated outbreaks has increased significantly.[46] The most important food vehicles are vegetables, fish, fruits, and condiments. Type E botulism almost always is traceable to fish and fish products, but types A and B also may be involved in outbreaks related to this type of food. Recent outbreaks have been traced to unusual foods, such as potato salad and sautéed onions served by restaurants and commercial frozen pot pies mishandled at home.

Wound botulism results from infection of traumatized tissue by *C. botulinum* type A or B and subsequent production of toxin.[38] In the United States, approximately 80 percent of cases are caused by toxin A and 20 percent by toxin B.[46] Though infrequently reported, wound infection is a disease of pediatric concern: approximately half the cases in the United States that occurred before 1991 involved children and teenagers, most of whom were boys with compound extremity fractures. In recent years, however, most new cases have occurred in users of contaminated injectable black tar heroin.[3,15,46]

PATHOPHYSIOLOGY

Botulinum toxin is absorbed from the proximal part of the intestine or an infected wound into the lymphatics and then distributed hematogenously to peripheral cholinergic nerve synapses, most notably the neuromuscular junction. The toxin does not cross the blood-brain barrier. The nerve endings take up the toxin, which then irreversibly blocks release of acetylcholine and results clinically in flaccid paralysis.[21,22,48] The cranial nerves are affected earliest and often most severely. Death occurs mainly from respiratory muscle paralysis (asphyxia) or its complications, such as cardiac arrhythmia, aspiration, and pneumonia. Recovery occurs by regeneration of terminal motor neurons and the formation of new motor end-plates. The lethal dose of botulinum toxin for humans is not known but can be estimated from primate studies; the dose of crystalline toxin lethal to a 70-kg human would be approximately 0.09 to 0.15 μg intravenously (or intramuscularly), 0.70 to 0.90 μg by inhalation, and 70 μg orally.[43]

CLINICAL MANIFESTATIONS

Because the pathogenesis of botulism involves the systemic absorption of toxin and hematogenous dissemination with subsequent involvement of the cholinergic synapses, virtually all forms of botulism have identical neurologic signs. The signs and symptoms of botulism are summarized in Table 158–1.[6] The onset of illness varies from 12 to 72 hours after the implicated food is ingested, but it has been documented to occur as late as 108 hours after ingestion in some epidemics.[6]

Food-borne illness, or classic botulism, may be preceded by abdominal cramps, nausea, vomiting, or diarrhea. However, the neurologic illness begins as a descending symmetric motor paralysis first affecting muscles supplied by the cranial nerves.[6,21] No sensory disturbance occurs, although vision may be impaired and hearing distorted because of cranial nerve involvement.

TABLE 158–1 Symptoms and Signs of Food-Borne Botulism, Types A and B

Sign or Symptoms	Percentage of Cases
Symptoms	
Dysphagia	96
Dry mouth	93
Double vision	91
Dysarthria	84
Fatigue	77
Arm weakness	73
Constipation	73
Leg weakness	69
Blurred vision	65
Nausea	64
Dyspnea	60
Vomiting	59
Dizziness	51
Sore throat	54
Abdominal cramps	42
Diarrhea	19
Paresthesia	14
Signs	
Alert mental status	90
Arm weakness	75
Ptosis	73
Leg weakness	69
Gaze paralysis	65
Facial palsy	63
Diminished gag reflex	58
Tongue weakness	58
Pupils dilated or fixed	44
Hyporeflexia or areflexia	40
Nystagmus	22
Ataxia	17

Mental processes remain clear, but anxiety and agitation may be present. Fever is absent unless a secondary bacterial infection occurs. The triad of bulbar palsies (including a sluggish or absent pupillary response to light), lucid sensorium, and absent fever always should bring botulism to mind.

Common symptoms include blurred vision, diplopia, dysarthria, and dysphagia. The degree of ocular involvement is quite variable; in severe cases, the pupils may become fixed and dilated. The mucous membranes of the mouth, tongue, and pharynx may be so dry that pain results, which may lead to the mistaken diagnosis of pharyngitis. Dizziness or vertigo may occur. Urinary retention may be seen, occasionally with stress incontinence.

Two thirds of patients have no gastrointestinal symptoms. In those who do, with type A or type B botulism the gastrointestinal manifestations are primarily abdominal pain, cramps, fullness, and diarrhea. However, after an initial period of diarrhea, constipation or obstipation may be noted and, indeed, is more typical of the disease. In contrast to those with the other types, most patients with type E botulism first have gastrointestinal symptoms, including nausea, vomiting, substernal burning or pain, abdominal distention, and decreased bowel sounds. The most common signs encountered in botulism are respiratory impairment; specific muscle weakness or paralysis; eye muscle involvement, including ptosis; dry throat, mouth, or tongue; dilated fixed pupils; and ataxia. Respiratory involvement, even aside from aspiration pneumonia, is a fairly common occurrence. Vital capacity is a more sensitive indicator of respiratory compromise than is measurement of blood gas. Postural hypotension, nystagmus, and somnolence may be noted.

The usual interval between the ingestion of food and the onset of symptoms is 18 to 36 hours, but it may be as short as 2 hours or as long as 8 days. In general, patients with shorter incubation periods are affected more severely and have a poorer prognosis. The shortness of the incubation period and the severity of illness correlate with the amount of toxin ingested. Although the syndrome is similar for each toxin type, type A toxin has been associated with more severe disease and a higher mortality rate than has either type B or type E toxin.[56]

The symptoms of wound botulism are similar to those of food botulism, but some important differences may occur.[38] Fever may or may not be present. Constipation occurs, but nausea and vomiting do not. Unilateral sensory changes in association with the trauma or infection may be noted. The wound itself may have grossly purulent drainage, but sometimes the wound shows no evidence of infection. The incubation period of wound botulism usually is 4 to 14 days.

In the event of intentional food-borne poisoning with botulism toxin, the signs and symptoms probably would resemble those of naturally occurring food-borne botulism.[6,46] If the aerosolized toxin from a bioterrorist attack were to be inhaled, the incubation period might be slightly longer, and gastrointestinal symptoms might not occur.[6,46]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of botulism includes myasthenia gravis, cerebral vascular accidents, Guillain-Barré syndrome (particularly the Miller-Fisher variant), tick paralysis, paralytic shellfish poisoning, chemical intoxication, diphtheritic polyneuritis, psychiatric disease, and the Eaton-Lambert syndrome.[21,48]

Ordinary bacterial food poisoning generally is not a problem in the differential diagnosis because of the absence of cranial nerve involvement. Chemical food poisoning may cause neurologic manifestations, but the signs almost always appear within minutes or at most hours after the consumption of contaminated food. Atropine poisoning has a very rapid onset and is distinctive because of facial flushing and hallucinations. Shellfish and fish poisonings have a rapid onset and often cause characteristic paresthesias, tremors, and other signs. Mushroom poisoning results in severe abdominal pain, violent vomiting, diarrhea, and coma.

Myasthenia gravis usually spares pupillary oculomotor function. An edrophonium (Tensilon) test should be performed. Guillain-Barré syndrome can mimic botulism but usually shows ascending peripheral paralysis and, later, cranial nerve involvement. Muscle cramps, paresthesias, and an elevated protein content in cerebrospinal fluid in the absence of cells help distinguish this disease. Electromyography may be extremely useful in differentiating botulism from atypical cases of Guillain-Barré syndrome.

The problem of identifying a case is complicated by reports of patients with features not characteristic of either botulism or the action of botulinum toxin, such as paresthesias, asymmetric weakness of the extremities, asymmetric ptosis, slightly elevated cerebrospinal fluid protein, and a "positive" response to edrophonium. Some of these symptoms may be a consequence of the high anxiety that prevails in persons who know that they have eaten a food containing botulinum toxin.

SPECIFIC DIAGNOSIS

Confirmation of the diagnosis of botulism depends primarily on detection of botulinum toxin or the organism in the patient or in the implicated food or wound.[21,48] Specimens to be examined for botulinum toxin include serum, gastric contents or vomitus, feces (at least 20 to 50 g when possible), and exudates from wounds and tissues. These specimens, particularly blood specimens, should be obtained as soon as possible and before antitoxin is given. When feasible, at least 15 to 20 mL of blood should be drawn into a large vacuum tube and sent without separation of the serum to the nearest laboratory capable of performing the mouse neutralization test and other tests for toxin. State health departments or the CDC can provide advice regarding specimen collection and handling and laboratories to which samples can be sent (see later).

Specimens should be refrigerated and examined as quickly as possible after collection. Whenever feasible, suspect food should be kept sealed in the original container. Sterile unbreakable containers should be used for other food samples. Specimens to be shipped to laboratories must be placed in leak-proof containers; packed with dry ice in a second leak-proof, insulated container; and marked "Danger, hazardous material." Extreme caution should be used in handling material that may contain botulinum toxin because even minute quantities of toxin acquired by ingestion, inhalation, or absorption through the eye or a break in the skin may cause profound intoxication and death.

Laboratory confirmation of suspected botulism should be attempted, even late in the clinical course. Detection of the organism itself may be achieved by culture or a variety of molecular methodologies.

Toxin is detected in serum or stool specimens in approximately 46 percent of clinically diagnosed cases. When stool specimens also are cultured for *C. botulinum*, confirmatory evidence is obtained in approximately 70 percent of botulism cases.[46,56] Thus, detection of *C. botulinum* toxin or organisms in the stool of a symptomatic person should be considered diagnostic.

TREATMENT

The mainstay of therapy for all forms of botulism is meticulous supportive care, with particular attention paid to the respiratory and nutritional needs of the patient and to anticipation of potential complications for the purpose of preventing them.[21,22] Symptomatic persons known to have ingested toxin-containing

food should be hospitalized, with careful monitoring of respiratory and cardiac function. Measurement of vital capacity has been a useful index of clinical status in adult patients.

In cases of food-borne botulism, if the patient is seen early, emetics and gastric lavage should be used to reduce the amount of unabsorbed toxin; in the absence of ileus, cathartic agents may be helpful. Magnesium-containing cathartic agents should be avoided because they may enhance the action of botulinum toxin. Trivalent antitoxin (types A, B, and E) or bivalent antitoxin (types A and B), both of equine origin, frequently are considered in the management of food-borne botulism in adults, although conclusive evidence of their efficacy is lacking.[21,51] The antitoxin is used to neutralize circulating botulinum toxin molecules that are not yet bound to nerve endings. The dose currently recommended in adults is one vial per patient as a single dose.[46] Hypersensitivity reactions have been reported in approximately 9 percent of persons treated with equine sera, so skin testing should be performed before administration of the antitoxin. Treatment of a single patient with suspected or proven food-borne botulism requires immediate notification of state and federal (CDC) health officials, who also are the antitoxin source, because the food responsible for the index patient's illness still may be available to other persons. The appropriate initial contact is via the state health department. If this agency cannot be reached, the CDC should be contacted immediately (CDC telephone: 404-639-2206, days, or 404-639-2888, nights). Presently, a human-derived botulinum antitoxin is available in the United States exclusively for the treatment of infantile botulism, and is discussed in Chapter 159.

In the event of a potential exposure to contaminated food, the following procedures should be implemented. Locate all persons who ate the suspect food and determine whether anyone has symptoms or signs of botulism.[21] If the patients are seen soon after the suspect meal, the use of gastric lavage, emetics, and cathartics deserves consideration. Antitoxin should be made available. Any samples of the suspect food that may remain should be collected and refrigerated. The health authorities should assist the clinician with these tasks. The fecal and serum specimens needed to establish the diagnosis should be obtained. If neurologic signs are present, one should try to identify defective neuromuscular transmission by electromyelography. If neurologic signs are absent, the patient and family should be informed of the early signs of botulinum intoxication and be instructed to return at the first manifestation of ptosis, diplopia, blurred vision, dysphonia, dysarthria, or dysphagia. Because of the serious side effects of equine botulinum antitoxin, prophylactic administration of it to asymptomatic persons who have ingested food known to contain botulinum toxin generally is not recommended.[3]

When wound botulism is suspected, exploration and débridement of the site must be undertaken, ideally after the administration of antitoxin has begun. Arrangements should be made to obtain material for anaerobic culture in the operating room and antibiotic therapy begun there. High-dose penicillin (250,000 to 400,000 U/kg/day for 10 to 14 days) is the drug of choice. Guanidine, aminopyridine, steroids, and intravenous immunoglobulin have been used to treat a small number of cases of food-borne and wound botulism, but convincing evidence of their efficacy is lacking. Metronidazole has been suggested as an alternative for penicillin, but evidence for its effectiveness is not available.

PROGNOSIS

With an emphasis on mechanical ventilation and intensive supportive care, the mortality rate from botulism has decreased steadily from 60 percent in the 1950s to 5 to 10 percent at the present time. It is lower with type B and type C disease than with type A.[9] The mortality rate is lower in individuals younger than 20 years. An important factor, as noted, is the dose of toxin ingested as reflected by the length of the incubation period. The longer the incubation period, the better the prognosis. If the index case in an outbreak can be detected early, other patients exposed to the same food will have a much better prognosis. Recovery may be prolonged, and some symptoms (e.g., fatigability) may persist for as long as 1 year. Most patients recover entirely.

PREVENTION

Local and state health authorities and the CDC should be notified immediately of all suspected cases of botulism so that appropriate investigations can be undertaken. Although commercial products still are responsible for botulism occasionally, control measures taken by the industry have done a great deal to prevent botulism from this source. Home canners still must be instructed regarding appropriate means for sterilizing containers and food preservation and for adequate cooking of food before serving.[21,48] In canning, a pressure cooker must be used to obtain temperatures well above boiling to destroy the spores of *C. botulinum* types A and B. For certain foods, a temperature of 116° C is recommended. Spores of *C. botulinum* are destroyed at 120° C after 30 minutes. Pressure cookers set at 15 lb will achieve this temperature, but correction for higher altitudes must be made. Home-canned foods should be boiled for 10 minutes before serving. Food containers that appear to bulge may contain gas produced by *C. botulinum* and should not be opened. A pentavalent botulinum toxoid vaccine has been used in military personnel to protect them from a biologic warfare assault. It is given in three subcutaneous doses and leads to detectable antibodies in 83 percent of subjects.[15]

CLOSTRIDIAL INFECTIONS

Clostridia are encountered less commonly in infections than are non–spore-forming anaerobic bacteria, but these spore formers rarely may produce devastating disease. Overall, clostridia are present in 5 to 10 percent of anaerobic or mixed (aerobic and anaerobic) infections.[9,18,21,53] Table 158–2 depicts the relative frequency of clostridial species from clinically significant infections at a single academic hospital.[3]

Clostridium perfringens is the species encountered most commonly. It may be isolated in pure culture but more commonly is part of a mixed flora involving other anaerobes and nonanaerobes as well. Other species that are important clinically or encountered commonly (or both) include *C. novyi*, *C. septicum*, *C. bifermentans*, *C. histolyticum*, and *C. sordellii* (together with *C. perfringens*, these species commonly are referred to as the "gas gangrene group"); *C. tetani* (see Chapter 160); *C. difficile*, a major pathogen in pseudomembranous colitis; and a group of clostridia important in infections other than gas gangrene or myonecrosis (wound infection, abscesses, bacteremia, etc.)—*C. perfringens*, *C. ramosum*, *C. bifermentans*, *C. sphenoides*, *C. sporogenes*, and others.

Clostridia may be involved in a wide variety of infections throughout the body. Certain of these infections have a distinctive clinical picture and are discussed in this chapter. Many other infections, including peritonitis, intra-abdominal infection, wound infection, soft tissue infection, and occasionally, pleuropulmonary infection, central nervous system infection, and urinary tract infection, are not distinctive and will not be discussed specifically here. Emphysematous cholecystitis involving *C. perfringens* has distinctive features, but it is not encountered in the pediatric age group and thus is not discussed. Bacteremia involving *C. perfringens* may or may not have characteristic fea-

TABLE 158–2 *Clostridium* Species Most Frequently Encountered in Clinical Specimens at Indiana University Hospital Anaerobe Laboratory, 1989 through 2001*

Species†	Isolates	
	No.	% of Total
C. perfringens	515	20

**The 2555 isolates do not include 270 isolates that did not belong to a recognized species (total of 2825 isolates), nor do they include C. difficile from fecal specimens.*

†*Six or fewer isolates each of* C. beijernickii, C. botulinum, C. carnis, C. celatum, C. coccides, C. cochlearium, C. ghoni, C. hastiforme, C. histolyticum, C. indolis, C. limosum, C. maelenominatum, C. novyi, C. putrefaciens, C. putrificum, and C. sphenoides.

tures. The distinctive intravascular hemolysis that may occur with *C. perfringens* bacteremia is discussed in connection with female genital tract infections caused by this organism.

EPIDEMIOLOGY

The vast majority of clostridial infections are of endogenous origin. Even those secondary to trauma and contamination of a wound with foreign bodies usually involve *C. perfringens* or other clostridia from the host's flora, chiefly the intestinal tract. *Clostridium* spp. are ubiquitous in nature, with habitats in soil and the intestinal tracts of many animals, including humans and most other mammals. Clostridia even may be isolated from infant intestine as early as the first week of life, and by 6 to 20 months of age, the feces of infants contain approximately the same number of *C. perfrigens* as that of adults.[3]

PATHOPHYSIOLOGY

The principal sites of normal carriage of *C. perfringens* and many other clostridial species in humans are the colon and vagina.[3,21,22] These organisms may gain access to tissues through wounds, by perforation of abdominal viscera, or because of local disease such as tumor. The organism then may grow in tissues if the oxidation-reduction potential is low or host defense mechanisms are impaired, or both. Factors favoring anaerobic growth include the presence of abundant necrotic tissue, a poor blood supply, the presence of foreign bodies, or previous multiplication of other bacteria in the wound leading to a lowered oxidation-reduction potential.

C. perfringens produces at least a dozen different extracellular toxins or other factors that account for its pathogenicity.[21] The most important of the five major lethal toxins is alpha-toxin, a lecithinase and the main toxin responsible for destruction of tissue, hemolysis, and death. Other important factors include collagenase, hyaluronidase, leukocidin, deoxyribonuclease, and fibrinolysin. The enterotoxins produced by some strains of *C. perfringens* and *C. difficile* are important in the pathogenesis of certain gastrointestinal diseases. Gas gangrene, or clostridial myonecrosis, is characterized by profound toxicity, necrosis of muscle, edema, thrombosis of small vessels, gas bubbles in tissues, and minimal infiltration of leukocytes (probably caused by destruction of leukocytes at the site).

CLINICAL MANIFESTATIONS

GAS GANGRENE OR MYONECROSIS

Although other clostridia also are involved in gas gangrene, *C. perfringens* is the causative species in approximately 90 to 95 percent of cases. Gas gangrene usually results from contamination of open wounds with contiguous injured muscle. The tissue destruction in gas gangrene is related to the profound attenuation in blood flow as a result of activation of platelet responses by the alpha-toxin of *C. perfringens*.[10] Clostridial myonecrosis may occur in the absence of a traumatic wound, so-called *spontaneous myonecrosis*, and is caused by bacteremic seeding of muscle with either *C. perfringens* or *C. septicum*. In spontaneous myonecrosis, the source of the organism typically is the bowel, and the usual predisposing factors are mucosal tumors of the bowel or ulcerations produced by cytotoxic chemotherapy.[22] Only a handful of cases of spontaneous myonecrosis in children have been described.[39]

The typical case of clostridial myonecrosis is manifested by the sudden appearance of pain in the region of a wound.[21] The pain increases in severity but remains localized to the infected area. Subsequently, local swelling and edema occur, and a thin hemorrhagic exudate appears. The pulse is very rapid, out of proportion to the mild elevation in temperature. Initially, the skin is tense, white, somewhat colder than normal, and very tender. Bronze discoloration appears and increases with time. The process extends and becomes more severe, and the patient becomes toxemic. The skin becomes dusky or bronzed, and bullae filled with dark-red or purple fluid appear. Crepitus caused by gas may be noted, but the amount of gas produced generally is small. A peculiar sweet smell may be noted in some cases. Occasionally, a fetid odor that probably reflects the presence of a *Clostridium* organism other than *C. perfringens* may be present.[22] Toxic delirium and, later, overwhelming prostration and toxemia may develop. Some patients are alert and apprehensive, whereas others are apathetic. Later in the course of the disease, shock supervenes. At surgery, early changes in muscle consist primarily of edema and pallor, but increased reddening with mottled purple is present. The consistency of the muscle may be pasty or mucoid, and contractility disappears. Eventually, the muscle becomes diffusely gangrenous, dark greenish purple or black, friable, and even liquefied.

SOFT TISSUE INFECTION

C. perfringens and other clostridia also may be involved in less dramatic and less serious infections ranging from minor superficial infections to anaerobic cellulitis and necrotizing fasciitis.[22] The clinical picture in these various infections is no different from that noted with other types of organisms and thus is not discussed further here.

SEPTIC ABORTION AND PUERPERAL SEPSIS

C. perfringens infections of the uterus usually occur after incomplete abortions are induced under nonsterile conditions.[21] Occasionally, this type of infection will develop after spontaneous abortion, prolonged labor, ruptured membranes, or operative interference with pregnancy. Early symptoms include uterine bleeding, suprapubic and back pain, chills, and fever.[21,22] The

incubation period after the precipitating event usually is several days, but it may be less than 24 hours. In addition to vaginal bleeding, a foul-smelling, brown vaginal discharge containing necrotic tissue often is present. The uterus is tender, and the lower abdominal wall may be tense. Nausea, vomiting, and diarrhea may occur. Generalized peritonitis may complicate the picture. The most striking systemic manifestation of the disease, however, is massive intravascular hemolysis with hemoglobinemia, hemoglobinuria, and jaundice. Shock and acute renal failure may complicate the picture. Intrauterine gas formation may be detected.

NEONATAL SEPSIS AND MENINGITIS

A small number of cases of sepsis or meningitis (or both) caused by *Clostridium* spp. have been reported in newborns.[23,25,40,50] Although some of these neonatal cases have been associated with invasive procedures or devitalized tissue, others have not had an obvious source.[25,31,40] In several of these cases, the systemic infection involved both the mother and infant. The typical clinical picture in neonatal infections is one of fulminant septic shock, intravascular hemolysis, respiratory distress, and rapid death. Pneumatocephalus may occur in the presence of meningitis.

PSEUDOMEMBRANOUS COLITIS

Pseudomembranous colitis represents the most severe end of a disease spectrum that the toxins of *C. difficile* can produce. It generally is characterized by profuse watery diarrhea, abdominal cramps, fever, and small (2 to 5 mm) raised, yellowish plaques on the colonic mucosa.[22,26] At the other end of the spectrum are found asymptomatic carriage and mild diarrhea. *C. difficile* diarrhea and colitis almost invariably occur after the administration of antimicrobial drugs, the most common precipitants being ampicillin, clindamycin, cephalosporins and fluroquinolones.[22] However, almost any antibacterial agent can trigger the illness. Sporadic and community-acquired cases not associated with antibiotics have been recognized. This organism is a serious and frequent cause of nosocomially acquired diarrhea, and hospitalized adults and children become colonized with this organism.[28] *C. difficile*–associated disease (CDAD) thus has become a major cause of hospital-acquired morbidity and mortality, with mean rates of 12.1 cases per 10,000 patient-days or 7.4 per 1000 hospital admissions.[5]

CDAD is related to the action of one or both of its toxins, known as A and B. Toxin A is responsible primarily for the enterotoxic activity of *C. difficile*, whereas toxin B is much more potent as a cytotoxin than toxin A is.[30] The spectrum of *C. difficile*–associated diarrhea ranges from a trivial, self-limited disease to a severe illness simulating an intra-abdominal catastrophe. Fever to 104° C, leukocytosis to 25,000 cells/mm^3 and hypoalbuminemia occur in approximately 25 percent of patients. Stools range from 3 or 4 to 20 per day and may be loose, watery, or bloody with mucus; associated abdominal cramping is a relatively common event.[22] Occasionally, pseudomembranous colitis may be caused by *Staphylococcus aureus* or more likely, by clostridia other than *C. difficile* (e.g., *C. perfringens* type C).

Up to half of asymptomatic infants younger than 1 year old harbor *C. difficile*, with rates of carriage declining to adult rates of 2 to 5 percent by the time that the child reaches 2 years of age. As a consequence, it is not recommended that hospital laboratories routinely examine stools for clostridial toxins or report the presence of *C. difficile* or its toxin in young infants. Possibly, receptors for *C. difficile* toxin may be decreased or absent in younger children.[19] Genetic analysis of the pathogenicity locus in *C. difficile* may help distinguish pathogenic from nonpathogenic strains of *C. difficile* in the future.[16] Children's facilities and hospitals have been identified as major reservoirs of *C. difficile*. Important risk factors for the development of CDAD are situations that would decrease the protective effect of the normal intestinal flora (such as antimicrobial therapy, repeated enemas, or intestinal surgery) and thereby allow the bacteria to proliferate and elaborate toxin. Asymptomatic colonization with *C. difficile* may be seen in a proportion of pediatric oncology patients,[11] as well as in children with prolonged hospital stays.

Since the late 1990s, *C. difficile* has emerged as a significant pathogen in North American and some European hospitals.[42] The host and epidemiologic factors associated with *C. difficile* are complex and include the use of antibiotics with borderline activity against *C. difficile*, exposure to gastric acid suppressants, poor host response with low levels of serum immunoglobulins, advanced age, and the severity of disease in the underlying host (reviewed by Owens[42]). The organism responsible for the recently reported outbreaks in North America and Europe, designated BI/NAPI, is distinguishable from the previously predominant J types of strains isolated in the late 1980s and early 1990s.[44,54] The BI/NAPI strains of *C. difficile* produce greater amounts of toxins A and B; carry an additional clostridial toxin, the binary toxin; belong to toxinotype III; have increased sporulation capacity; and are fluoroquinolone-resistant.[27,37] These agents are resistant to alcohol and may have emerged in an era when alcohol hand gels were increasingly being used in place of handwashing as the mainstay of hand hygiene.

Treatment of CDAD in young children is controversial and problematic because of the high rates of carriage in asymptomatic infants.[8a] Treatment may be indicated in those with new-onset diarrhea associated with antibiotics in which toxins A or B are found in the stool, when other viral, parasitic, and bacterial pathogens have been excluded by diagnostic testing.[34a] First-line treatment has relied on orally administered metronidazole administered for 10 days.[4] Recurrence rates after first episodes of CDAD in adults treated with metronidazole have ranged from 12 to 20 percent and, after treatment of a second episode, from 50 to 60 percent.[42] Since recent studies have suggested that metronidazole is ineffective in severe disease, oral vancomycin has been suggested as the preferred agent in severe disease.[57] Severe disease has been defined as greater than 10 stools per day, a white blood count of more than 20,000/mm^3, or severe abdominal pain. For mild disease, 250 mg orally four times a day has been recommended, whereas rancomycin, 125-500 mg four times a day, is recommended for severe disease.[50a]

OTHER ENTERIC INFECTIONS

A mild and self-limited but very common form of food poisoning may be caused by *C. perfringens*, with meat and meat products being the major vehicles for such outbreaks.[21,22] Food poisoning is caused by a heat-labile enterotoxin produced by *C. perfringens* type A. The incubation period after ingestion of the contaminated food varies from 6 to 24 hours but usually is 8 to 12 hours. The major symptoms are crampy abdominal pain and diarrhea. Stools are liquid but do not contain blood or mucus. Nausea may be noted on occasion, but vomiting and fever seldom are present. The illness typically lasts less than 24 hours.

Rarely, *C. perfringens* also may produce a very severe type of enteritis known as *enteritis necroticans*. Although food poisoning is produced by *C. perfringens* type A, necrotizing enteritis involves the beta-toxin of *C. perfringens* type C.[35] Consumption of excessive amounts of rich food by people normally on a low-protein diet who have decreased levels of digestive proteases seems to be an important background factor. Additionally, proteases may be blocked by ingestion of the trypsin inhibitors found in sweet potatoes. In some cases, consumption of contaminated canned

meat is involved. In New Guinea, where this condition is known as "pigbel," enteritis necroticans in children is associated with traditional pig-feasting activities in which large quantities of pork are consumed. The disease is characterized by abdominal cramps, vomiting, shock, diarrhea (sometimes bloody), and acute inflammation of the small intestine with areas of necrosis and gangrene, particularly in the jejunum. A 12-year-old diabetic boy in whom enteritis necroticans developed after the ingestion of pig intestines (chitterlings) has been reported.[43]

MISCELLANEOUS INFECTIONS CAUSED BY CLOSTRIDIA

Fewer than 40 cases of septic arthritis attributable to *Clostridium* spp., including several pediatric patients, have been reported.[29] Anaerobic osteomyelitis caused by *Clostridium* also is a rare finding.[24] Aggressive surgical débridement and prolonged antibiotic therapy are warranted in the treatment of anaerobic musculoskeletal infections.[47]

The clinical spectrum of clostridial bacteremia ranges from an asymptomatic patient with an incidental positive blood culture to fulminant sepsis syndrome.[13] Bacteremia with *C. septicum* is considered a unique syndrome associated with malignancies, particularly leukemia and colon cancer, and it has a devastating clinical course.[36] Infections with this organism also have been linked to children with cyclic neutropenia.[3] In a recent review of 28 pediatric patients with *C. septicum* bacteremia, Caya noted that all of them had underlying cancer or gastrointestinal disease.[12] The overall mortality rate was 72 percent. Five cases of *C. septicum* infection occurring after *Escherichia coli* O157–induced hemolytic-uremic syndrome have been described.[4]

Clostridium sordelli infections have been associated with high fatality rates and most often have occurred after trauma, childbirth, and routine gynecologic procedures. They have been reported after medically induced abortions and intravenous drug injections. In one review of 45 cases, 8 (18%) occurred after normal childbirth, and 5 occurred (11%) after medically-induced abortions, with a 100 percent case-fatality rate in this group.[1] Only four cases occurred in children: a 4-year-old child with arm trauma, a 17-year-old adolescent with omphalitis, a 12-year-old child with ear infection, and an 18-year-old adolescent with a medically induced abortion. Only the 12-year-old child survived; the other three patients died of their infection.

Panophthalmitis involving *C. perfringens* or, occasionally, other clostridia is secondary to penetrating injury, usually with retention of a foreign body.[21] Pain and loss of vision occur within 12 hours after the injury. By 18 hours, evidence of fulminating panophthalmitis is present and consists of chemosis and brawny swelling of the lids, proptosis, hypopyon, increased intraocular tension, gas bubbles in the anterior chamber, and necrosis of the wound margins. Intracranial infections involving *Clostridium*, usually as a result of penetrating trauma with items such as a lawn dart or an arrow, have been described.

Pneumatosis cystoides intestinalis can be produced in animals by *C. perfringens*, and this organism has been recovered from this process in humans.[21,22] Pneumatosis cystoides intestinalis may be found in conjunction with toxic megacolon and neonatal necrotizing enterocolitis and as a complication of ileal bypass for obesity.

SPECIFIC DIAGNOSIS

The diagnosis of gas gangrene must be made on clinical grounds. The presence of a gas-forming infection and recovery of *C. perfringens* from the wound do not establish the diagnosis of gas gangrene. The key to this diagnosis is demonstration of myonecrosis. Clostridial myonecrosis must be differentiated from other gas-forming soft tissue infections, which may or may not involve *C. perfringens*, and from other causes of myonecrosis. The sudden onset, extreme toxemia, and severe pain that are noted in clostridial myonecrosis represent important differential features. Entities such as anaerobic cellulitis and streptococcal myonecrosis have a gradual onset, slight toxemia, and less pain than seen with clostridial myonecrosis. Synergistic nonclostridial anaerobic myonecrosis is a severe infection characterized by discrete areas of blue-gray necrosis of skin, along with extensive involvement of the underlying soft tissue and muscle and foul "dishwater" pus. Anaerobic cellulitis typically has much more gas and does not involve muscle.

In streptococcal myonecrosis, edema of the muscle is present initially, and then the muscle has a hemorrhagic appearance.[21] Specimens for Gram staining and culture should be obtained from the involved muscle rather than from the surface of the wound. Large gram-positive rods will be demonstrated on Gram stain in clostridial myonecrosis; no white blood cells may be demonstrable, or the white blood cells present may be distorted significantly as a result of the toxin of *C. perfringens* acting on them. Anaerobic cellulitis typically shows a mixture of organisms, which may include *C. perfringens*. Streptococcal myonecrosis reveals anaerobic streptococci, sometimes along with group A streptococci, *S. aureus*, and other organisms.[16] In synergistic nonclostridial anaerobic myonecrosis, *Bacteroides* organisms seem to be key pathogens, together with anaerobic cocci and nonanaerobic gram-negative bacilli.[22] Of importance when obtaining material for culture is to place it under anaerobic conditions promptly for transport to the laboratory. Anaerobic blood cultures also should be performed.

Uterine infection by *C. perfringens* varies in severity from secondary invasion of necrotic material into the uterus or a dead fetus to invasion of intact uterine muscle producing myonecrosis and physometra.[21] Although bacteremia is a relatively uncommon finding in gas gangrene, uterine infection with *C. perfringens* frequently is accompanied by sepsis, which leads to the dramatic picture of intravascular hemolysis described earlier. Demonstration of severe hemolytic anemia in association with uterine infection essentially is diagnostic. Anaerobic blood cultures should be performed.

Clostridia, particularly *C. perfringens*, occasionally are isolated from the blood of a patient with a clinically benign course. The usual scenario is that a hospitalized patient has a single fever spike of unclear etiology and blood cultures are performed as part of the evaluation; by the time that the culture becomes positive, no evidence of an infectious process is present. This transient and benign bacteremia probably originates from the colonic flora.[11]

C. perfringens food poisoning usually is seen in the setting of a sizable outbreak.[22] The organism grows to high counts in the responsible food and then sets up an infection in the host, with production of enterotoxin in the colon of patients. Demonstration of large numbers ($>10^5$/g) of *C. perfringens* in the implicated food and demonstration of the same serotype of *C. perfringens* in the stool of affected individuals and in the food are important in documenting the nature of the food poisoning. Enterotoxin also may be found in the stool of affected individuals, and the *C. perfringens* recovered from stool or food can be demonstrated to produce enterotoxin in vitro. Necrotizing enteritis caused by *C. perfringens* may be suspected by virtue of the dramatic clinical picture and confirmed by demonstration of *C. perfringens* type C in the stool or suspect food or demonstration of serum antibody to the beta-toxin of the organism.

C. difficile–associated diarrhea should be suspected in children with diarrhea who have received antibiotics within the previous 2 months or whose diarrhea begins 72 hours after hospitalization.[20] Typically, toxin testing of a single stool specimen will establish the diagnosis, but, occasionally, repeat testing or endoscopy may need to be performed. The finding of exudative plaques

(pseudomembranes) and a hyperemic, friable mucosa by direct endoscopic visualization suggests the diagnosis of pseudomembranous colitis. Although *C. difficile* is isolated conveniently with the use of a selective medium, distinction between toxigenic and nonpathogenic strains cannot be made. Its toxin B (cytotoxin) is identified most easily by tissue culture assay, which remains the gold standard for diagnosis of antibiotic-associated diarrhea.[22] A simple latex particle agglutination test for detection of *C. difficile* is available, although it is considered relatively insensitive and nonspecific and, for that reason, no longer is recommended.[52]

In recent years, commercially available enzyme immunoassay (EIA) kits that detect toxin B or both toxin A and B have become the preferred method of diagnosis.[52] The EIAs in general are easy to perform, relatively inexpensive, and specific. Polymerase chain reaction amplification tests for toxins A and B have been designed but are not available commercially.

Interpreting the significance of finding *C. difficile* or its toxins in very young patients with diarrhea is difficult because infants and toddlers have such a high rate of asymptomatic carriage.[34,55] Quantitation of toxin or organisms has not correlated with the presence or absence of symptoms. Consequently, once the possible presence of other diarrhea-producing pathogens (e.g., rotavirus, *Salmonella*) has been excluded, effort should be made to stop the presumptive precipitating antibacterial agent. If diarrhea with mucus or blood persists, endoscopy should be considered and specific therapy begun.

TREATMENT

The most important aspect of treating clostridial myonecrosis is immediate surgical intervention consisting of radical débridement and drainage and decompression of the fascial compartments.[21,22] The wound should not be closed after this surgery. Of crucial importance is that all bits of necrotic muscle and other tissue be removed. Polyvalent gas gangrene antitoxin was never established firmly as being beneficial in the context of modern therapy, and this product no longer is available in the United States. Hyperbaric oxygen is recommended enthusiastically by some physicians, but no definitive evidence that its use reduces mortality rates has been shown. It does facilitate demarcation of a limb with impaired vascular supply, and it appears to slow down or arrest local spread of the gangrenous infection. Clearly, however, hyperbaric oxygen must not be used as a substitute for any of the important principles of surgical management. Antimicrobial therapy also is important as an adjunct, with high-dose penicillin G (250,000 to 400,000 U/kg/day) being the drug of choice.[21,22] In individuals allergic to penicillin G, clindamycin or metronidazole may be used. In addition, chloramphenicol is routinely active against all clostridia. The combination of penicillin and clindamycin has been used widely on the basis of experimental animal models that have shown enhanced efficacy with such a combination.[49]

Clostridial cellulitis is treated by incision plus drainage and antimicrobial therapy. Radical débridement is not necessary, but it is important to lay the tissues open to effect proper drainage and permit removal of all necrotic tissue.[21,22]

Uterine curettage should be performed for diagnosis and treatment of postabortal or puerperal clostridial infections.[21] Hysterectomy may be required if the myometrium is involved and if the patient's condition is deteriorating. At times, perforation of the uterus may be present without the typical clinical findings. Exchange transfusion has been recommended for sepsis caused by *C. perfringens* when significant intravascular hemolysis is present.

Food poisoning caused by *C. perfringens* is self-limited and requires no therapy. Antitoxin to the beta-toxin produced by *C. perfringens* type C has been of considerable benefit in the treatment of necrotizing enteritis caused by this organism.

In any serious infection caused by *C. perfringens* or other clostridia, the usual supportive measures for shock, dehydration, anemia, and renal insufficiency are implemented as indicated.

Treatment of CDAD involves discontinuation of the offending antibiotic regimen when feasible. Isolates of *C. difficile* are susceptible to metronidazole and vancomycin. Oral or intravenous metronidazole (30 mg/kg/day in four divided doses) is considered the drug of choice. With the recent and rapid increase in the recovery of vancomycin-resistant enterococci, many experts[20,42] and the CDC have suggested that oral vancomycin (40 mg/kg/day in four divided doses) be used to treat *C. difficile*-induced diarrhea only in patients who are critically ill or those who do not respond to metronidazole. Intravenous vancomycin is not effective. Orally administered bacitracin also may be useful, although some experts suggest that it may be less effective than metronidazole or vancomycin. Antimicrobial agents typically are administered for 10 days, but as many as 20 percent of patients may experience a relapse requiring a second course of treatment. The use of cholestyramine or probiotics, such as *Saccharomyces* or *Lactobacillus*, in adult patients with multiple relapses has been advocated by some physicians, but such treatment has not been evaluated in children with disease caused by *C. difficile*.

PROGNOSIS

The mortality rate in patients with gas gangrene varies between 15 and 35 percent and is worse when large muscle groups, such as those of the buttock, thigh, leg, and shoulder, are involved or when areas that are difficult to débride, such as the viscera and pelvis, are involved with disease. Clostridial cellulitis has a much better prognosis, but aggressive therapy still is important to minimize mortality rates. The mortality rate in postabortal clostridial sepsis remains 50 to 85 percent. *C. perfringens* food poisoning has an excellent prognosis, but mortality rates are significant with necrotizing enteritis caused by *C. perfringens* type C.

PREVENTION

Wounds involving areas with large muscle masses are particularly prone to gas gangrene, as are compound fractures, severe crush injuries, and injuries secondary to high-velocity missiles. Extensive laceration or devitalization of muscle tissue, impairment of the main blood supply to a limb or large muscle group, and contamination by dirt and particularly by bowel contents all predispose to the development of clostridial myonecrosis. The most important aspect of prophylaxis by far is early and adequate surgical management.[21,22] All devitalized tissue must be débrided; meticulous hemostasis is very important. Primary closure and tight packing of the wound should be avoided. All aspects of the wound must be drained adequately. If a cast must be applied, it should be bivalved from the outset. Hyperbaric oxygen is not indicated prophylactically. Antimicrobial prophylaxis, however, definitely is indicated. Penicillin is the drug of choice and should be given as early as possible after the injury occurs. Of emphasis is that antimicrobial prophylaxis is strictly adjunctive and far from adequate by itself. Bathing, particularly showering, and application of a compress wet with an iodophor for 15 minutes have been shown to reduce the skin count of *C. perfringens* significantly and minimize the likelihood of postoperative gas gangrene developing. This type of decontamination, of course, also may be useful in the management of traumatic wounds.

Prevention of clostridial uterine infection involves ensuring that all products of conception are removed during abortion and that retained portions of the placenta are removed immediately after the third stage of labor. Prolonged labor should be anticipated when possible and analgesics administered judiciously. During labor, particularly with ruptured membranes, pelvic and

rectal examinations should be kept to a minimum. During delivery, trauma should be minimized and lacerations repaired according to accepted surgical principles.

Proper sanitation in food-preparing facilities and adequate refrigeration are important safeguards against the acquisition of *C. perfringens* food poisoning. In areas where necrotizing enteritis caused by *C. perfringens* type C is found with some frequency (such as in Papua New Guinea), a *C. perfringens* type C toxoid has been given with encouraging results.

Contact isolation for the duration of the illness is recommended for hospitalized children with *C. difficile*–associated diarrhea. Meticulous handwashing, the use of gloves for handling contaminated objects and fomites, environmental cleaning and disinfection, and limiting the use of antimicrobial agents have been advocated widely to control the transmission of *C. difficile* in health care facilities.[27]

CHAPTER 159

Infant Botulism

Stephen S. Arnon

Of the three main forms of human botulism (food-borne, wound, and infant), infant botulism is the most recently recognized (1976) and the most common in the United States and some other countries. Now recognized globally,[55] infant botulism results from a unique pathogenesis. Ingested spores of *Clostridium botulinum* germinate, colonize the infant's colon, and produce botulinum neurotoxin within it. The toxin then is absorbed, binds to peripheral cholinergic synapses, and causes flaccid paralysis. Knowledge of this intestinal pathogenesis resulted in discovery of the novel pathogenic strains *Clostridium baratii* and *Clostridium butyricum*, each of which can produce a botulinum-like neurotoxin and cause the clinical picture of infant botulism. Discovery of these strains enlarged the number of organisms known to cause the "intestinal toxemias of infancy," of which infant botulism is the prototype. Parenthetically, adults and older children rarely may become susceptible to infant-type botulism after broad-spectrum antibiotic treatment, intestinal surgery, or inflammatory bowel disease[6,28,38,62] or in association with a Meckel diverticulum[36,88] or bone marrow transplantation procedures.[93]

HISTORY

Infant botulism is not a new disease; rather, it has been recognized relatively recently and is an "emerging" infectious disease. The first laboratory-proven case of human infant botulism occurred in California in 1931, although it was misdiagnosed at the time.[15] Decades later and well before the etiology of the disease was apparent, the characteristic clinical features of infant botulism had become evident to discerning observers. In 1974, Grover and associates[43] described nine patients from Pennsylvania with a neurologic syndrome of undetermined cause that from today's perspective almost certainly was infant botulism. The same idiopathic syndrome was recognized in southern California and was reported by Ramseyer and colleagues[85] in 1976 to have a characteristic electromyographic pattern. A year later, Clay and associates[29] linked their eight southern California patients to infant botulism.

The first report of frank botulism in infancy was provided by Pickett and colleagues[84] in 1976. Although the source of botulinum neurotoxin for their two patients was undetermined, the possibility of its in vivo production was suggested.[64,84] The diagnosis of botulism in these and other California patients was established by identification of *C. botulinum* toxin and organisms in the infants' feces.[64] Evidence also was obtained that ingested spores of *C. botulinum* had produced the toxin in the infants' intestinal tract.[10,64,112]

In subsequent years, the clinical spectrum of infant botulism was found to include mild outpatient cases and, in some, but not all[23] locations, sudden unexpected death indistinguishable from typical sudden infant death syndrome.[11,72,77,83] In 1985, a *C. baratii* strain that produced a type F–like botulinum neurotoxin was recognized belatedly as the true cause of a case of infant botulism that occurred in New Mexico in 1979,[44,48] and in 1986, a *C. butyricum* strain that produced a type E–like botulinum neurotoxin was recognized as the cause of two cases of infant botulism in Rome, Italy.[16] These latter two novel clostridia were discovered only because they caused human infant botulism; their existence suggests that others like them await discovery.

ETIOLOGIC AGENT

C. botulinum is a gram-positive, spore-forming, obligate anaerobe whose natural habitat worldwide is the soil. Consequently, *C. botulinum* is as ubiquitous as the dust on which it may travel, and, hence, its spores commonly are present on fresh fruits, vegetables, and other agricultural products such as honey. Members of the *C. botulinum* species are so diverse in their biochemical capabilities and nucleic acid profiles that they would not be grouped as a single species except for the similar neurotoxin molecule that each strain produces[47,97]; at present, the *C. botulinum* species is subdivided into four groups (I to IV) based on metabolic characteristics.[97] Almost all cases of infant botulism in the United States have been caused by group I proteolytic type A or type B strains. Unusual strains of *C. baratii* and *C. butyricum* that make botulinum-like toxins E and F also cause infant botulism.[16,34,44,81,102,111] The entire 3.9-megabase (Mb) chromosome and a 16.3-kilobase (kb) plasmid within a *C. botulinum* type A strain were sequenced recently and found to contain 3650 and 19 predicted genes, respectively,[92] thereby launching the era of functional genomic studies of this special bacterium.

In general, each vegetative cell of *C. botulinum* produces just one of seven serologically distinguishable toxins, which arbitrarily have been assigned the letters A to G. Antitoxin raised against one toxin type does not protect against any of the other six types. The different toxin types serve as convenient epidemiologic and clinical markers. Subtypes of several toxin types have been identified by immunologic methods,[56,106] by neutralization studies using monoclonal antibodies,[3,98] and by toxin gene nucleic acid investigations.[47] Each toxin molecule is a simple protein consisting of two polypeptide chains of approximately 100,000 (heavy chain) and 50,000 (light chain) daltons joined by a disulfide bond.

Botulinum toxin is the most poisonous substance known.[39] For this reason and because of the ease with which it may be produced, transported, and disseminated, the Centers for Disease Control and Prevention (CDC) has listed botulinum toxin as one of six "category A" (most dangerous) potential bioweapon agents.[13] By extrapolation from studies involving adult primates, the lethal dose in the bloodstream of humans is approximately 1 ng/kg body weight.[13,39] Its potency for infants may be even higher because of the narrowness of their pharyngeal airway.[109]

The basis of the phenomenal potency of the botulinum (and tetanus) toxins is enzymatic. The light chain of each neurotoxin is a Zn^{2+}-containing protease that hydrolyzes one or more of three intracellular proteins needed for vesicle fusion and release of acetylcholine into the synaptic cleft.[69,78] The specificity of the toxin for peripheral cholinergic neurons results from their expression of a lower-affinity ganglioside cell surface receptor to which the toxin attaches first, which then is followed by attachment to a second, higher-affinity protein receptor that uniquely appears from the interior of the synaptic vesicle when it fuses with the terminal membrane to release acetylcholine.[27,51,79]

PATHOGENESIS

Infant botulism is not the diminutive form of food-borne botulism, and, hence, the disease is not "infantile botulism." Rather, infant botulism results from a unique infectious disease pathway

and was so named to emphasize that fact.[10,64,112] Ingested spores of *C. botulinum* germinate, colonize the infant's colon, and produce botulinum neurotoxin within it.[10,45,66,68,112] The toxin subsequently is absorbed and carried by the bloodstream to peripheral cholinergic synapses, where it binds irreversibly. The light chain then is taken into the cytosol of the neuron, where it blocks the release of acetylcholine by enzymatic cleavage of "fusion complex" proteins.[69,78] Clinically, the most important of the peripheral cholinergic synapses is the neuromuscular junction; the toxin's action results in flaccid paralysis and hypotonia. Preganglionic cholinergic synapses in the autonomic nervous system also may be affected.[60,90]

By use of a mouse model system of intestinal colonization (in which the animals paradoxically remained symptom-free), Sugiyama and colleagues[22,68,103] have demonstrated that the intestinal microflora of adult animals ordinarily prevents colonization of the gut by *C. botulinum*. Administration of 10^6 type A spores failed to colonize the intestine of normal adult mice, whereas after treatment for $2^1/_2$ days with a combination of oral erythromycin and kanamycin, half the mice could be colonized by just 2×10^4 spores. When the antibiotic-treated mice were placed in cages with normal mice, they lost their susceptibility to intestinal colonization after 3 days.[22] (Mice normally exhibit coprophagia.) In addition, adult germ-free mice could be colonized intestinally by just 10 *C. botulinum* type A spores. When the germ-free adult animals were placed in a room with conventional mice (but not in the same cages), in 3 days the formerly germ-free animals became resistant to colonization by 10^5 spores.[68]

In contrast to the experimental work with adult mice, normal infant mice were susceptible to intestinal colonization by *C. botulinum* spores.[103] Like human infants, the normal infant mice were subject to colonization for only a limited period (7 to 13 days of age). Susceptibility of the infant mice peaked between days 8 and 11 in a pattern reminiscent of the peaking of susceptibility seen between 2 and 4 months of age in human infant botulism (Fig. 159–1).[8,103] The infective dose of spores for infant mice was much smaller than that of their antibiotic-treated adult counterparts; the 50 percent infective dose for normal infants was only 700 spores. In one experiment, just 10 spores were needed to colonize an infant mouse.[103] The minimum infective dose of *C. botulinum* spores for human infants is not known, but from exposure to spore-containing honey, it has been estimated to be as low as 10 to 100.[12]

Recognition of the central role of the host's intestinal microflora in determining susceptibility or resistance to colonization by *C. botulinum* has directed attention to factors that may influence the composition of the normal microflora. Diet may be the most important of these factors. When compared with adult-type flora, the infant flora is simpler, with fewer genera and species. The dominant members vary, depending in part on whether the infant is fed only breast milk, only formula milk, or a mixture of the two.[100,101] In addition, the composition of the intestinal flora is changed if solid foods, such as cereals, become part of the infant's diet. The normal human infant microflora contain several bacterial species, mainly *Bifidobacterium* and *Bacteroides*, that in vitro can inhibit the multiplication of *C. botulinum*.[105]

The onset of infant botulism occurs at a significantly younger age in formula-fed infants (7.6 weeks) than in breast-fed infants (13.7 weeks),[9] perhaps reflecting the earlier availability in formula-fed infants of suitable ecologic niches[9,60,100,101] and the formula-fed infants' lack of the immune factors (e.g., secretory IgA, lactoferrin) contained in human milk.[4,5,41] Moreover, introduction of solid foods may "perturb" the intestinal microflora[100] and thereby aid colonization with *C. botulinum*.[4,8,60,99]

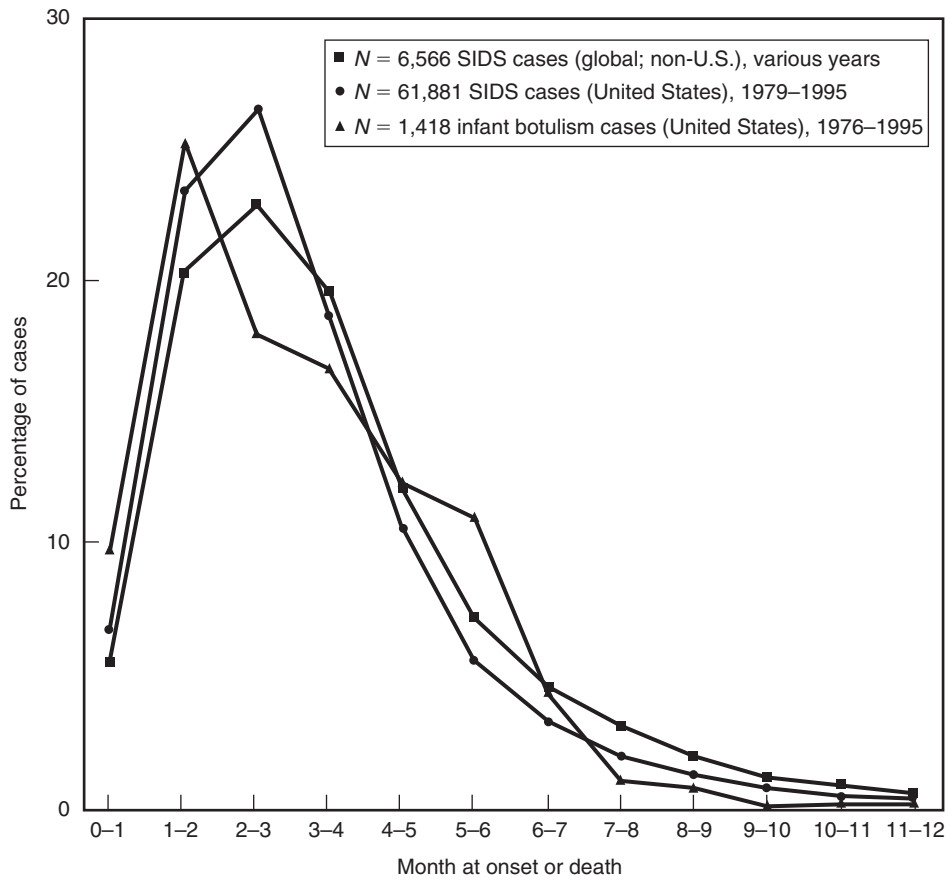

Figure 159–1 Age distribution of infant botulism and sudden infant death syndrome (SIDS).

An additional physiologic risk factor for infant botulism is slower gut motility, as measured by the frequency of defecation before the onset of illness.[91,99] Less than one bowel movement per day is a risk factor for both breast-fed and formula-fed infants, but this factor occurred in just 50 percent of cases.[91] Whether a Meckel diverticulum may predispose to the development of infant botulism caused by *C. botulinum*, as it appears to do for infant botulism caused by *C. butyricum*, is not known.[34,36,88]

EPIDEMIOLOGY

Any discussion of the epidemiology of infant botulism should be prefaced by the caveat that almost all presently available information is derived from study of only part of the clinical spectrum, namely, hospitalized patients. Accordingly, current perspectives may need to be modified as the outpatient and sudden death portions of the clinical spectrum become defined more fully. Furthermore, the perceived incidence remains more a reflection of physician awareness and access to diagnostic testing than the actual occurrence of disease. Almost half (41.6%) of U.S. cases have been reported from California, which has the largest number of births of any state. However, California does not have the highest incidence of infant botulism once adjustment is made for differences in annual births (Table 159–1). Notably, 8 of the 11 states with the highest incidence are located west of the Rocky Mountains, and 6 of the 8 are contiguous. The three eastern states with the highest incidence also are contiguous.

A unique epidemiologic feature of infant botulism is its age distribution, which, perhaps coincidentally, is virtually identical to the age distribution of sudden infant death syndrome (see Fig. 159–1).[8,11,24,99] Almost all U.S. cases (99.8%) of infant botulism reported to date have occurred in children younger than 1 year old. Some 91.2 percent of cases have occurred in the patients' first 6 months of life, 8.6 percent were distributed over the subsequent 6 months, and just 0.2 percent occurred between 53 and 72 weeks of age. The youngest known patient was just 38 hours old at onset (and had illness caused by *C. baratii* type F toxin),[19] whereas the oldest was 72 weeks old at onset. The illness has occurred in all major racial and ethnic groups and in approximately equal proportions in males and females. A national seasonality is not evident.

Infant botulism has been reported from all inhabited continents except Africa. In the United States, with 28 exceptions (1.1% of cases), all hospitalized cases known as of December 2006 were caused by either type A or type B *C. botulinum* toxin. Forty-nine of the 50 states, representing all regions of the country and including Alaska and Hawaii, now have reported infant botulism. Only Rhode Island has not. In general, the distribution of cases by type of toxin has paralleled the distribution of toxin types in U.S. soil,[96] with type B cases predominating from the great plains eastward and type A cases from the Rocky Mountains westward. The 28 exceptional cases resulted from a variety of toxin types. Two cases in Iowa and one each in California, Ohio, Oregon, New Mexico, Texas, and Wisconsin resulted from a type F–like toxin produced by *C. baratii* strains.[19,44,48,81] Fourteen cases were caused by a *C. botulinum* strain that produced mostly type B and some type A toxin (designated type Ba), and four cases resulted from Bf strains. One case caused by both *C. botulinum* type A and type B from today's perspective probably resulted from either a Ba or Ab strain. Two patients with Bf illness lived in California,[18] one lived in New Mexico, and the fourth patient had traveled there from California immediately before onset of the illness. A fifth type Bf case occurred in England.[95] The only *C. baratii* type F case reported outside the United States occurred in Hungary.[111] In Arizona in 2006, a type E case occurred, but neither *C. butyricum* nor *C. botulinum* could be isolated. All three European *C. butyricum* type E infant botulism cases were reported from Italy, and another in Asia was reported from Japan.[16,34-36]

As of December 2006, approximately a sixth (516/2932, 17.6%) of all known global infant botulism cases between 1976 and 2006 had been reported from 24 countries other than the United States.[55] Of these cases, Argentina has reported the largest number (366),[61] followed by Australia (32), Canada (27), Italy (23), and Japan (20). The remaining countries have reported only single-digit case occurrence.[55] The non-U.S. cases occurred in countries in Europe (12), Asia (3), the Middle East (3), North America (2), South America (3), and Australia. The small number of reported cases from most non-U.S. countries most likely reflects limited physician awareness of the disease and limited access to specialized diagnostic testing laboratories, as well as actual variation in disease incidence.[55]

Geographic clustering has been noted. In Pennsylvania, 43 of 53 cases in the period 1977 to 1983 occurred in four suburban counties that form an arc bordering the city of Philadelphia.[58] In Colorado, three type A cases occurred in three separate families in a small town with approximately 300 annual births. Two of the infants had used the same crib sequentially; environmental samples, including the crib, soil, and household dust, yielded *C. botulinum* type A.[50] In California, two type A cases occurred 5 years apart in the children of two families who lived one house apart. In another California family, two successive infants each acquired type A infant botulism, but the third child born in sequence did not. Soil and dust specimens from the house where all three infants lived contained *C. botulinum* type A.

The role of breast-feeding and formula-feeding as factors possibly predisposing to illness remains unsettled. All studies to date have identified an association between being breast-fed and being hospitalized for infant botulism.[5,9,58-60,70,99,108] This finding has resulted in one perspective that holds that breast-feeding predisposes to the development of illness,[58-60,99] whereas the other perspective holds that breast-feeding slows its onset sufficiently to permit hospitalization to occur.[4,5,8,9] However, among hospitalized patients in California, the mean age at onset of botulism in formula-fed infants (7.6 weeks) was significantly younger and about half that of breast-fed infants (13.8 weeks). In addition, in California the patients with fulminant-onset infant botulism who stopped breathing and died at home all were formula-fed.[9] The relative susceptibilities of formula-fed and breast-fed infants to infant botulism and the resultant severity of their disease possibly reflect differences in the availability of suitable ecologic niches in the intestinal flora for *C. botulinum*, differences in the availability of immune factors (such as lactoferrin and secretory IgA) contained in human milk but not in formula milk,[41] or other differences not identified yet.

Probably few, if any, patients with infant botulism acquire *C. botulinum* spores from infant formula, despite isolation in the

**Per 100,000 live births per year.*

United Kingdom of *C. botulinum* type B from powdered infant formula consumed by a patient with type B infant botulism.[21,52] In addition, the possibility that an infant patient may have food-borne botulism needs to be kept in mind because food-borne botulism caused by home-prepared baby food has been recognized.[2]

Honey is the one dietary reservoir of *C. botulinum* spores thus far definitively linked to infant botulism by both laboratory and epidemiologic evidence.* More than 35 instances worldwide are known in which *C. botulinum* spores have been found in the actual honey fed to the affected infant before the onset of illness. In each instance, the toxin type (A or B) of the spores in the honey matched the toxin type of the *C. botulinum* that caused the infant's illness; the probability that such perfect concordance occurred by chance is less than 1 in 10 billion. Occasionally, *C. botulinum* has been isolated from honey in which the spore toxin type in the honey did not match the toxin type of the infant's illness[17,34]; in such instances, the conclusion is that the honey was not the source of the infective spores.

C. botulinum spores have been found in honey from the United States, Argentina, Australia, Canada, China (Taiwan also), Denmark, Finland, Italy, Norway, Spain, Japan, and Central America,† but not in honey from the United Kingdom.[20]

In general, only low concentrations *C. botulinum* spores have been found in honey (≤1 spore/g),[65,74] with the occasional higher concentrations (e.g., 36 to 60 spores/g[74]) thought to result from multiplication of *C. botulinum* in dead bees and bee pupae.[73] Toxin type A, B, C, and F spores all have been found in honey, with some of these toxin types linked to the geographic origin of the honey.[74] For these reasons and because honey is not nutritionally essential, all major pediatric, public health, and honey industry agencies in the United States have joined in the recommendation that honey not be fed to infants. In 2000, several brands of honey sold in the United States began to carry a warning not to feed honey to infants; an equivalent label first appeared on British honey in 1996.

Discussion of the possible role of corn syrup in infant botulism is necessitated by two reports. In 1982, the U.S. Food and Drug Administration (FDA) found *C. botulinum* type B spores in approximately 0.5 percent (5 of 961) of previously unopened retail samples of light and dark corn syrup[54]; the manufacturer then made changes in the production process. In 1989, the federal CDC reported the results of a 2-year epidemiologic study of U.S. cases from all states except California.[80,99] By subgrouping patients by age and using logistic regression modeling techniques, a statistical association was obtained among the triad of exposure to corn syrup, breast-feeding, and age at onset of 2 months or older.[80,99]

In contrast to these reports, a 1988 Canadian survey found no *C. botulinum* spores in 43 samples of corn syrup.[46] A 1991 FDA market survey of 783 syrups (354 of which were light corn syrup and 271 were dark corn syrup) concluded that none contained *C. botulinum* spores.[57] A California study (unpublished) of 103 corn syrups, 72 of which had been fed to infants who subsequently became ill with infant botulism, did not find *C. botulinum* in any sample. Moreover, a 1979 epidemiologic study that simply compared rates of exposure to corn syrup in 41 cases and 107 control infants identified feeding of corn syrup as a significant protective factor against type A infant botulism.[12] The explanation offered for the latter observation was that if a parent chose corn syrup as a sweetener for the infant, the child was unlikely to have been fed honey as a second sweetener. Thus, on the basis of the available evidence, corn syrup appears not to constitute a source of *C. botulinum* spores or a risk factor for the development of infant botulism.

In addition to honey and syrup, hundreds of traditional and nontraditional infant food items, including formula milk, have been examined and found not to contain *C. botulinum*.[63] However, a recent type B infant botulism case in the United Kingdom was traced to *C. botulinum* type B spores in powdered infant formula.[21,52] Also, in instances not associated with illness, *C. botulinum* spores have been found in raw sugar and molasses but not in refined sugar[75] and in herbal (chamomile) tea and other herbal preparations.[55,61]

Potential environmental sources of *C. botulinum* spores have been identified in many locales. The soil in Pennsylvania,[60] soil and cistern water in Australia,[71] vacuum cleaner dust in Finland,[77] and the soil and vacuum cleaner dust in California[8] obtained from case homes were found to contain *C. botulinum*, with the toxin type (A or B) in each instance matching that of the ill infant. However, despite the foregoing, it deserves emphasis that for most cases of infant botulism, no source of *C. botulinum* spores ever is identified, even circumstantially. In these cases, illness probably was acquired by swallowing spores adherent to airborne microscopic (invisible) dust.

CLINICAL MANIFESTATIONS

Like other infectious diseases, infant botulism displays a spectrum of clinical severity.[4,8,11,59,60,83,90,108] To date, almost all recognized patients have been sufficiently hypotonic and weak to need hospitalization. Consequently, the present picture of infant botulism is derived from hospitalized patients. However, outpatient cases that displayed only a few days of lethargy, poor feeding, and some decrease in frequency of bowel movement have been detected by alert physicians familiar with the more "classic" illness. At the opposite end of the clinical spectrum are patients whose "catastrophic manifestation" obscured and delayed establishment of the correct diagnosis[67] and those few cases for which the history and clinical findings were indistinguishable from typical cases of sudden infant death syndrome (crib death),[11,83,108] approximately 1 in 20 of which (in California) appears to result from fulminant infant botulism.[8,11]

The onset of infant botulism ranges from the insidious to the abrupt. At one extreme are patients who were nursing normally 6 hours before becoming so floppy that acute meningitis was the diagnosis at initial evaluation, and at the other extreme are patients who returned to their physicians four times in a week as the signs of illness gradually became apparent. Though rare, illness caused by *C. baratii* type F appears to be characterized by the triad of very young age at onset, rapid onset, and profound paralysis.[19,81] Equally rare, illness caused by *C. butyricum* type E may be manifested as a paradoxically rigid abdomen and associated bowel colonization with *Clostridium difficile*.[34,35]

In the "classic" case of infant botulism, the first sign of illness almost always is constipation (defined as 3 or more days without defecation in a previously regular infant), yet the constipation often is overlooked. A few patients (<5%) will not have a history of constipation. Usually, a mother first notices listlessness, lethargy, and poor feeding, together with breast engorgement if the infant had been nursing. The increasing weakness over the ensuing 1 to 4 days typically brings the baby to medical attention.

Botulism is manifested clinically as a symmetric, descending paralysis. Early in the course, weakness and hypotonia characterize the illness, and the remainder of the physical examination not involving the neuromuscular system is normal. The first signs of illness are found in the cranial nerves; one cannot have infant botulism without having bulbar palsies. The typical patient has an expressionless face, a feeble cry, ptosis (evident when the eyelids must work against gravity), poor head control, and generalized weakness and hypotonia (Fig. 159–2). Eye muscle

TABLE 159-2 Neurologic Signs Helpful in the Diagnosis of Infant Botulism

1. Take the patient to a dark room. Shine a bright light into the eye; note the quickness of pupillary constriction. Remove the light when the constriction is maximal; let the pupil dilate again. Then immediately repeat the light, continuing thus for 1 to 3 minutes. The initially brisk pupillary response may become sluggish and the pupil unable to constrict maximally. (Fatigability with repetitive muscle contraction is the clinical hallmark of botulism.)
2. Shine a bright light onto the fovea and keep it there for 1 to 3 minutes, even if the infant tries to deviate the eyes. Latent ophthalmoplegia may be elicited, purposeful efforts to avoid the light may diminish, or both.
3. Place a clean fifth finger in the infant's mouth while taking care to not obstruct the airway. Note the strength and duration of the reflex sucking. The suck is weak and poorly sustained. The gag reflex strength also may be quickly checked (if the infant has not been fed recently).

paralysis varies, and the pupils often are midposition and initially briskly reactive (Table 159–2). The gag, suck, and swallow reflexes are impaired, as is the corneal reflex if it is tested repetitively. Deep tendon reflexes frequently are normal at initial evaluation and diminish subsequently as the paralysis extends and increases. The "frog's legs" sign often is seen. Patients are afebrile unless a secondary infection (e.g., aspiration pneumonia) is present.

The results of most laboratory and clinical studies are normal. At admission, the child may have evidence of mild dehydration and fat mobilization because of diminished oral intake. Occasionally at admission, the protein concentration in cerebrospinal fluid (CSF) becomes elevated because of the mild dehydration. If infant botulism is suspected soon after the child is admitted, electroencephalography, computed tomography, and magnetic resonance imaging seldom are required, but if performed, these examinations yield nonspecific or normal results. Electromyography may offer rapid bedside confirmation of the clinical diagnosis (see "Differential Diagnosis and Diagnosis").[30,33]

Small amounts (<5 mouse LD_{50}/mL) of botulinum toxin sometimes can be identified in serum specimens if they are collected early in the course of the illness.[16,34,45,61,82,107,110] In one U.S. report, almost one patient in eight had toxin demonstrable in serum.[45] The definitively diagnostic laboratory study is examination of feces for the presence of *C. botulinum* organisms and toxin, which is the only certain way to identify the neurotoxin type (A, B, or other) responsible for the illness. Clinically suspected cases that lack an identified toxin type not are included in official tallies of infant botulism.[25,26,55]

The usual hospital course of untreated infant botulism has certain general features.[4,53,60,90] After the increasing weakness has necessitated admission, the weakness and hypotonia continue to progress and usually become generalized. The deep tendon reflexes, which may be normal at admission, may diminish or disappear temporarily. The nadir of paresis and paralysis in untreated patients usually occurs within 1 to 2 weeks after admission; such patients often remain at their nadir for as long as 1 to 3 weeks before showing signs of improvement. However, once strength and tone begin to return, the improvement continues steadily and gradually over the ensuing weeks in the absence of complications (Table 159–3). In contrast, patients treated with human botulism immune globulin have a mean hospital stay of approximately 2 weeks (see "Treatment").[14]

In the California experience, infant botulism does not have a relapsing or biphasic course, and perceived "relapses" have been

found, in retrospect, to be an indication either of the onset of a complication (see Table 159–3) or of premature discharge. However, the clinical experience elsewhere with regard to relapses has been different.[34,40,86,90] The patient is ready for discharge when gag, suck, and swallow are sufficiently strong both to protect the airway against accidental aspiration and to ensure adequacy of oral intake. Parents also may be taught to feed by gavage at home. In either situation, discharge may occur safely while head lag and constipation still are present.

DIFFERENTIAL DIAGNOSIS AND DIAGNOSIS

When initially brought to medical attention, patients with infant botulism often are so mildly weak and hypotonic that the illness is not considered. Even today, more than 30 years after the disease first was recognized, suspected sepsis remains the most common admission diagnosis for patients with infant botulism. A careful history (constipation commonly is overlooked) and physical examination (especially cranial nerve function) usually can identify patients with infant botulism correctly and render unnecessary most additional testing for the other entities typically suspected (Table 159–4). A review of entities that so closely mimicked infant botulism that botulism immune globulin was administered soon after admission identified spinal muscular atrophy type I, mitochondrial disorders, and a small number of other conditions as the actual diagnoses (Table 159–4).[37]

The diagnosis of infant botulism is established by identification of *C. botulinum* organisms in the feces of an infant with clinical signs consistent with the paralyzing action of botulinum toxin.[25,53,64] Extensive studies have demonstrated that *C. botulinum* is not part of the normal resident flora of infants or adults.[8,45,100,101] If the fecal specimen is obtained sufficiently early in the course of the illness, it also will contain botulinum toxin. Because of the patient's constipation, an enema with sterile, nonbacteriostatic water (not saline) commonly is needed to obtain a fecal specimen for diagnostic examination. The mouse neutralization test remains the most sensitive and specific assay for botulinum toxin.[26] Laboratory diagnosis that identifies the type of toxin responsible for the illness is essential for the case to be registered as infant botulism[55] and is important in determining the prognosis; mean hospital stay is significantly longer in untreated type A cases than in untreated type B cases (see "Treatment").[4,14] Physicians are reminded that in most states, botulism or suspected botulism (all types) is an immediately reportable illness.

At the bedside, electromyography sometimes can be helpful in ambiguous situations in that when a clinically weak muscle is tested, electromyography often discloses a pattern known by the acronym BSAP (brief, small, abundant motor unit potentials).[10,30,33,42,90,94] The edrophonium (Tensilon) test is unnecessary because congenital myasthenia gravis can be excluded by the history and de novo myasthenia does not occur at this age because of the immaturity of an infant's immune system. Likewise, Guillain-Barré syndrome, which is well-documented by finding a consistently elevated protein concentration in CSF, is of negligible occurrence in infancy. In infant botulism the protein concentration in CSF is normal, an occasional exception being that of a specimen collected while the child is mildly dehydrated.

TREATMENT

Specific therapy for infant botulism is now available. In California, a 5-year, randomized, double-blinded, placebo-controlled treatment trial demonstrated the safety and efficacy of human-derived botulinum antitoxin, known formally as human botulism immune globulin intravenous (BIG-IV).[7,14] Use of BIG-IV reduced mean hospital stay per case from approximately 5.5 weeks to approximately 2.5 weeks ($p < 0.001$) and reduced mean hospitalization cost per case by about $90,000 (2004 dollars; $p < 0.001$). In a 6-year, follow-on, open-label study, treatment with BIG-IV within 7 days of hospital admission reduced mean hospital stay to 2.2 weeks. Treatment with BIG-IV should be started as early in the illness as possible to maximally neutralize the toxemia and should not be delayed for laboratory confirmation of the clinical diagnosis. BIG-IV may be obtained from the California Department of Public Health as a public service orphan drug (24-hour telephone: 510-231-7600; website: *www.infantbotulism.org*).

Successful management of infant botulism also depends on meticulous supportive care and the anticipation and avoidance of potentially fatal complications (see Table 159–3). Feeding and breathing generally require the most attention. At admission, patients should receive cardiac, respiratory, and transcutaneous blood gas monitoring (especially carbon dioxide pressure) until it is clear that the paralysis no longer is progressing. An endotracheal tube often is necessary to maintain and protect the airway, even in the absence of a need for mechanical ventilation. Particular care should be taken to avoid transmission of nosocomially acquired *C. difficile* colitis.[35,89]

A third cornerstone of management is forbearance. Antibiotics should be reserved to treat the principal secondary infections (pneumonia, urinary tract infection, otitis media) because their use may result in lysis of intraintestinal *C. botulinum* with libera-

tion of intracellular neurotoxin into the gut lumen and absorption. This potential problem may be avoided by prompt use of BIG-IV because its long (28-day) half-life and substantial antitoxin content enable it to neutralize all absorbed and circulating toxin.

Tracheostomy is not necessary.[1] Improved management of the airway can be accomplished by two simple positioning measures. First, for expansion of the thoracic cage and assistance in diaphragmatic function, patients should be placed in an older-style crib, the rigid bottom mattress of which can be lifted to elevate the entire body to a 30-degree angle. Second, to tip the head back and to maintain normal curvature of neck and airway, a soft cloth should be rolled to the thickness of about three fingers and placed under just the child's neck. This maneuver allows oral secretions to drain away from the trachea and into the true posterior pharynx, where they are swallowed most easily.

Intravenous feeding (hyperalimentation) is discouraged because of its potential for secondary infection and because of the success obtained with nasogastric or nasojejunal tube feeding. Mother's milk is the nutritional fluid of choice. Isolation measures or "enteric precautions" are not required, but meticulous handwashing is. Soiled diapers should be autoclaved because they can be expected to contain botulinum neurotoxin as well as viable spores and vegetative cells of *C. botulinum*. For this reason, staff with open lesions on their hands should not handle the diapers.

In the untreated (placebo) group in the 5-year, randomized clinical trial of BIG-IV, when compared with the untreated type B patients, the untreated type A patients had significantly longer mean hospital stays (6.7 versus 4.2 weeks), mean stays in the intensive care unit (ICU) (6.5 versus 3.1 weeks), and mean time on a ventilator (6.4 versus 2.2 weeks).[14] However, the distributions of the untreated type A and type B patients partially overlapped for all three parameters. Hence, untreated illness caused by type A toxin appears to be generally, but not invariably more severe than that caused by type B toxin. With use of BIG-IV, the mean duration of hospital stay has been reduced to approximately 2.2 weeks for both type A and type B patients, with comparable decreases also in the duration of stay in the ICU and time on a ventilator.[14]

OUTCOME AND PROGNOSIS

Recovery from infant botulism occurs through regeneration of the poisoned terminal unmyelinated nerve endings. The newly synthesized nerve twigs then induce the formation of new motor end-plates that are indistinguishable functionally and morphologically from the original ones.[31,32] In experimental animals and in human infants, completion of this process takes several weeks.[32] Consequently, in the absence of hypoxic cerebral complications, full and complete recovery of strength and tone is the expected outcome of infant botulism. In addition, because botulinum toxin does not cross the blood-brain barrier to any functional degree, the child's intelligence and personality remain intact. Parents often need reassurance on this latter point. Re-infection with the same or a different toxin type of *C. botulinum* has not occurred. In the United States, the case-fatality ratio of hospitalized patients is less than 1 percent, a reflection of, and tribute to, the high quality of intensive care given to these critically ill infants. In other countries, the experience has not been as fortunate.[55]

PREVENTION

At present, the one known way to prevent infant botulism is not to feed honey to infants, and all major pediatric and public health agencies have endorsed this recommendation. Breast-feeding may help moderate the rapidity of onset and the severity of illness. Persuasive evidence that links infant botulism to the ingestion of corn or other syrup is lacking. In the pre–BIG-IV era, the patient with the most protracted illness was hospitalized for 10 months in 1988 at a cost of more than $1,000,000 (2004 dollars). Mean hospital cost for the placebo-treated patients in the 1992 to 1997 randomized clinical trial of BIG-IV was $163,400, which was reduced in the BIG-IV group to $74,800, a net cost-savings of $88,600 (2004 dollars).[14] These economic facts combine with humanitarian considerations to make a compelling case for the prevention and effective treatment of infant botulism.

CHAPTER 160

TETANUS

James D. Cherry ✪ Rick E. Harrison

Tetanus is caused by the anaerobic, spore-forming bacillus *Clostridium tetani*, an organism present in soil and in human and animal feces. The clinical symptoms are not caused by infection but result from a specific toxin, tetanospasmin, that is produced at the site of injury and acts primarily on the spinal cord but also on the brain, motor end-plates, and autonomic nerves. The disease may appear as a local form or as a more generalized syndrome. It is characterized by tonic spasms of skeletal muscles, little or no fever, and occasional spasms of the glottis and larynx. Bilateral trismus is the most common sign. Active immunization is highly protective. Although tetanus is controlled well today in developed countries throughout the world, it remains a major cause of death in developing countries.[26,28,118,129] In 2002, an estimated 213,000 deaths were caused by tetanus worldwide.[129] Neonatal tetanus was the cause of approximately 180,000 deaths, and maternal tetanus was responsible for 15,000 to 30,000 deaths.

HISTORY

The first description of tetanus in recorded medical history probably was written by Hippocrates.[57] A vivid picture of the clinical course of the disease was recorded by Aretaeus the Cappadocian in the second century,[6] but very little of importance was added to this knowledge during the next 18 centuries. Transmissibility of tetanus was demonstrated by Carle and Rattone[23] in 1884. They reported that when the sciatic nerves of rabbits were injected with the contents of a human "pustule," the characteristic disease developed in the animals in 2 to 3 days; inoculation of tissue obtained from their nervous systems into healthy rabbits produced a similar syndrome. The role of soil in the pathogenesis of tetanus was demonstrated by Nicolaier[83] in 1884; although he saw the organism, he was unable to recover it.

The bacterium responsible for the disease was identified first by Rosenbach,[99] who described a bacillus containing a round terminal spore in pus obtained from a human case; tetanus developed when the purulent exudate was injected into animals. *C. tetani* was isolated by Kitasato,[64] who fulfilled Koch's postulates with it in 1889. One year later, von Behring and Kitasato[121] reported the appearance of specific antitoxin in the serum of animals given injections of the tetanus toxin produced by the organism. This finding was followed, in 1926, by the development of toxoid, injections of which produced immunity.

MICROBIOLOGY

The vegetative form of *C. tetani* is a gram-positive, spore-forming, motile, anaerobic bacillus that measures 0.3 to 0.5 μm in width and 2.0 to 2.5 μm in length; in culture, long filament-like cells develop.[12,21,123,126] *C. tetani* is a strict anaerobe that grows best at 33° C to 37° C; it can be cultured in many different routine media used for anaerobic organisms, such as thioglycolate, casein hydrolysate, and cooked meat. Enhanced growth occurs in medium supplemented with reducing substances and maintained at neutral or alkaline pH. With growth, gas with a fetid odor usually is produced.

The first step in the process of spore formation is the development of a bulge at one end of the organism; this bulge contains the spore and is responsible for the characteristic drumstick or tennis racquet appearance. As sporulation progresses, the organism decreases in length and the spores are extruded. They stain poorly by the Gram method. Sporulation occurs in tissues as well as in vitro and is dependent on the composition of the medium and the temperature of the culture. Enhanced sporulation occurs in the presence of oleic acid, phosphates, 1 to 2 percent sodium

chloride, and manganese salts.[12,21,123] In vivo, sporulation is enhanced by lactic acid and other substances toxic to cells. Sporulation is inhibited by high and low temperatures (>41° C and <25° C), glucose, fatty acids, and potassium salts. The metabolic activity of *C. tetani* is limited; carbohydrates and proteins are digested poorly, and the vegetative, nonsporulated forms are killed easily by heat and numerous disinfecting agents. In contrast, the spores are resistant to boiling and phenol, cresol, 1 : 1000 bichloride of mercury, and other disinfectants; however, they are destroyed by heating at 120° C for 15 to 20 minutes. If not exposed to sunlight, the spores may survive in soil for months to years. They also may constitute part of the normal intestinal microflora of some horses, cows, guinea pigs, sheep, dogs, cats, rats, chickens, and humans.

Three nonpathogenic clostridia are present in soil and in human and animal feces: *Clostridium tetanomorphum*, *Clostridium tertium*, and *Clostridium tetanoides*. Diagnostic confusion may occur because they are morphologically similar to the organism responsible for tetanus. *C. tetani* is recovered much more commonly from cultivated than from virgin or uncultivated soil. Rural dwellers and people engaged in agricultural occupations have a higher rate of intestinal, skin, and oral carriage of the organism than city dwellers do. Dust and dirt from houses, streets, and operating rooms, as well as solutions of heroin used by injection drug users (IDUs), have been found to be contaminated with the organism.

EPIDEMIOLOGY

SOURCE OF EXPOSURE

The predominant reservoir of *C. tetani* is the soil; it is also part of the normal flora of the intestinal tract of animals, both herbivores and omnivores.[123] Intestinal spores and bacilli are shed in the feces of animals and contribute to the soil reservoir.

The worldwide morbidity and mortality attributable to tetanus is related inversely to adequate immunization with tetanus toxoid and directly to suboptimal hygiene, childbirth practices, and wound care.[123] Throughout the world, tetanus has a seasonal trend: more cases occur in the summer or in "wet" seasons. Rates of illness are highest in countries that are located near the equator and have fertile soil.

Acute wounds, including relatively minor ones, are the site of most *C. tetani* infections leading to tetanus. In addition, infection may occur after parenteral drug use and surgical procedures. In many cases the source of exposure is unknown. The source of infection in neonatal tetanus is the umbilical cord or stump as a result of unsterile delivery conditions and unhygienic cultural rituals involving the umbilical stump.[58,59,93]

INCIDENCE

The incidence of tetanus in the vaccine era is related inversely to the degree to which effective immunization programs have been implemented in a population.[123] In the early 1980s an estimated 2 million cases of tetanus occurred throughout the world, with 1 million fatal neonatal cases and 122,000 to 300,000 non-neonatal fatal cases.[50,51]

Although neonatal tetanus is of very minor importance in developed areas of the world, it has been a major cause of death in infants in developing countries.[26,27,66,72,110,118,123,129] In 1993, an estimated 515,000 deaths worldwide were caused by neonatal tetanus.[26] These deaths occurred predominantly in Southeast Asia (34.2%); Africa (28.2%); the western Pacific, including China (21.4%); and the eastern Mediterranean region (15.7%). The global mortality rate in 1993 was estimated to be 4.1 per 1000 live births. The very high frequency of neonatal tetanus in these areas probably was related to conditions surrounding the birth of infants.[49] Most babies were born in very unhygienic environments; delivery rarely took place in an adequate hospital. In addition, unclean instruments were used to sever the umbilical cord, rags often contaminated with soil or feces were used as dressings, and mud and manure were applied directly to the umbilical stump. In a study in Senegal that examined risk factors for the development of neonatal tetanus, the major source of *C. tetani* was found to be the hands of the birth attendant, and the mode of contamination of the infant was related to the method that the birth attendant and the mother used to dress the umbilical cord stump.[66] In rural Pakistan, the ritual of bundling (wrapping the baby for prolonged periods in a sheepskin cover after the application of cow dung) is a significant risk factor for the acquisition of neonatal tetanus.[10] In a more recent case-control study of risk factors for neonatal tetanus in Karachi, Pakistan, the following risks were identified: application of substances (mustard oil/ghee/surma) to the umbilical cord, home delivery, and illiterate mothers.[93]

In 2002, deaths worldwide caused by tetanus were estimated at 213,000, with approximately 180,000 occurring in neonates and 15,000 to 30,000 maternal cases.[129] Most maternal cases are the result of unclean delivery or abortion practices.

The reported incidence of tetanus and tetanus-related deaths in the United States from 1947 to 2000 is presented in Figure 160–1, and the reported cases and fatal cases and their incidence are presented by age group for 1998 to 2000 in Figure 160–2.[85] From 1947 through 1976, the incidence of tetanus fell tenfold; since 1976, the continued decrease in incidence has been less than twofold. During the same period, mortality rates fell from 91 percent in 1947 to 44 percent in 1976 to 18 percent in 1998 to 2000.

In the period 1998 to 2000, 36 percent of the cases occurred in patients 60 years or older, 55 percent in patients aged 20 to 59 years, and only 9 percent in those younger than 20 years. During this period, the vaccination status was known in only 50 of the patients (38%). Of this group, eight (16%) had received three or more doses of tetanus toxoid, with the last dose being received less than 10 years before the onset of tetanus. None of these eight patients sought medical care for the injury before the onset of tetanus, and three were younger than 20 years. The outcome of the illness was available for only 18 of the 50 patients with a known immunization history, and one death occurred—in an IDU whose last dose of tetanus toxoid was 11 years before the onset of tetanus.

During the period 1998 to 2000, 60 percent of the cases occurred in males.

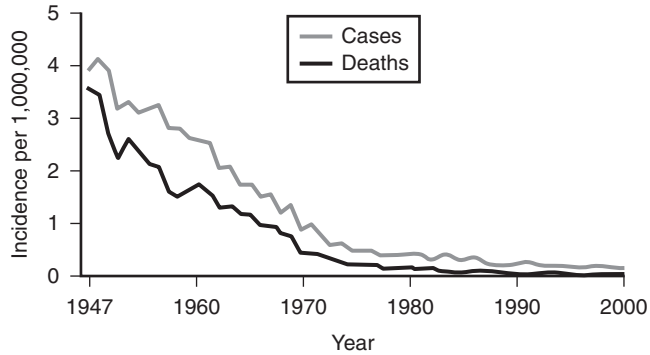

Figure 160–1 Reported incidence of tetanus and tetanus-related deaths in the United States from 1947 to 2000. *(Pascual, F. B., McGinley, E. L., Zanardi, L. R., et al.: Tetanus surveillance: United States, 1998-2000. M. M. W. R. Surveill. Summ. 52[3]:1-8, 2003.)*

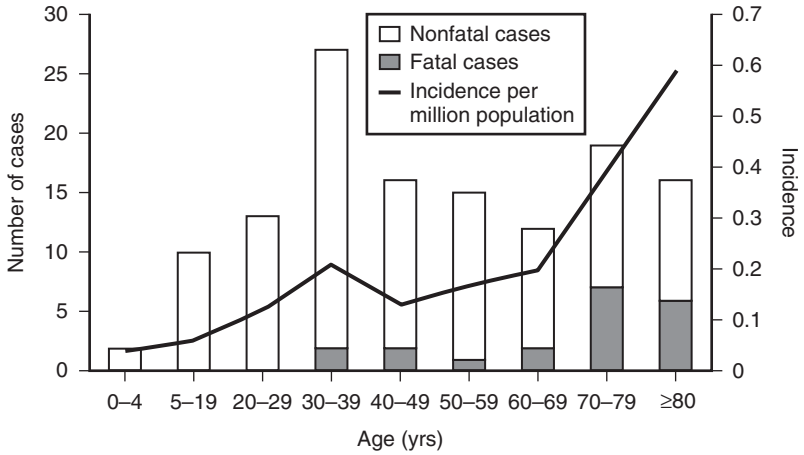

Figure 160–2 Reported tetanus cases and incidence rates by age group in the United States in 1998 to 2000. *(Pascual, F. B., McGinley, E. L., Zanardi, L. R., et al.: Tetanus surveillance: United States, 1998-2000. M. M. W. R. Surveill. Summ. 52[3]:1-8, 2003.)*

PATHOGENESIS

Tetanus is, by strictest definition, not a true infection. Spores introduced at a site of injury remain harmless until they are converted, after being stimulated by a variety of factors, to vegetative forms that multiply but do not produce injury to tissue or provoke an inflammatory response. The clinical syndrome is caused entirely by toxin elaborated in the area where the vegetative cells are growing. *C. tetani* produces two exotoxins: tetanolysin and tetanospasmin.[89] Tetanolysin induces hemolysis but plays no role in the disease. The activity of tetanospasmin is responsible for all of the clinical features of the disease. This toxin has a molecular weight of 150 kd and is activated by proteolytic cleavage into two polypeptides, a heavy (100 kd) and a light (50 kd) chain that are linked by a disulfide bond.[20] One milligram contains 6,400,000 lethal doses for mice; 0.00001 mg may kill a 20-g mouse in 2 hours. With the exception of the toxin produced by *Clostridium botulinum*, tetanospasmin currently is the most potent known poison. Humans are most susceptible to this agent and require only $^1/_{2500}$ and $^1/_{350,000}$ of the dose that is fatal for cats and chickens, respectively.

C. tetani is introduced into an area of injury as the spore, the form usually present in soil and intestinal contents. Disease does not develop until the spores are converted to the toxin-elaborating bacillus, which does not follow the simple inoculation of spores. When these spores are injected with very sharp needles into animals so that tissue is not injured but merely separated, tetanus does not develop. However, the addition of a small quantity of calcium chloride to a suspension of spores before injection leads to development of the typical disease. Such development is not caused by a specific effect of the cation on conversion of the spore to the vegetative form of the organism but is related to the necrosis of tissue produced by it, which leads to a reduction in oxidation-reduction potential and oxygen tension, factors involved in vegetation of the spore; the same effects are produced by the presence of a foreign body, trauma, or a localized suppurative process.

The pathway by which toxin, elaborated at the site at which *C. tetani* is multiplying, reaches the central nervous system (CNS) has been a matter of controversy. Researchers first thought that tetanospasmin was absorbed chiefly by motor nerve endings and then traveled along axis cylinders to the anterior horn cells.[90] Symptoms of the disease were thought to appear only after the toxin had reached the nervous system, with the initial tetanic contractions occurring first in the injured extremity, then in the opposite limb, and finally, as the toxin diffused through the spinal cord, in all the muscles. A small amount of toxin was suggested to be absorbed into the lymph and carried to the bloodstream, from which it was taken up by motor nerve endings in various parts of the body.[76]

Abel and associates[1] postulated that toxin reached the nervous system via the arterial circulation and suggested the following series of events. Some of the toxin diffuses from the local site of injury into adjacent skeletal muscle and acts on neuromuscular organs to produce a state of maintained contraction: local tetanus. Some toxin also enters the lymphatics and bloodstream, from which it is taken up by specifically reactive cells in the spinal cord, medulla, and the motor end-organs of muscle.

Friedemann and colleagues[48] noted that tetanus toxin did not penetrate the blood-brain barrier, and therefore they questioned hematogenous transmission. This finding led researchers to focus attention on transport of tetanospasmin in nerves. Wright and coworkers[130] observed that direct injection of toxin into the vagal, facial, or hypoglossal nerves of rabbits led, within 24 hours, to the development of a syndrome characteristic of involvement of the brain stem, as indicated by the appearance of strabismus, immobility of hairs in the nasal cavity, salivation, bradycardia, and torticollis. Inoculation of the vagus resulted in the successive development of these manifestations; those dependent on innervation from motor nuclei in close proximity to the nerve tended to appear early. This hypothesis is supported by observations indicating that a variety of substances, including India ink and radioactive compounds, migrate along peripheral nerves to the CNS after intraneural injection.[45] This observation, together with the demonstration by numerous investigators that toxin is present in the peripheral nerves closest to the site of inoculation, supports the concept of transport of tetanospasmin in the tissues of the nervous system.

Knowledge of the specific mechanisms involved in the absorption of tetanus toxin and its mechanisms of action on body cells is incomplete. Most of the evidence presently available indicates that some element of the peripheral nerve is involved. Whether transport occurs in the axis cylinder, the perineural space, or the lymphatics remains unsettled. Tetanus toxin is carried to the neurons of the sciatic nerve via the neurofibrillae in axis cylinders at a rate of approximately 3.35 mm/hr.[98]

PATHOPHYSIOLOGY

Tetanospasmin exerts its effects in four areas of the nervous system: (1) the motor end-plates in skeletal muscle, (2) the spinal cord, (3) the brain, and (4) the sympathetic nervous system (in some cases).*

*See references 16, 18, 19, 24, 35, 60, 62, 75, 106, 119, 132.

MOTOR END-PLATES IN SKELETAL MUSCLE

Tetanus toxin has been noted to interfere with neuromuscular transmission. Release of acetylcholine from the nerve terminals in muscle is inhibited. The presence of tetanospasmin in the transverse and terminal sacs of the longitudinal elements of the sarcotubular system of skeletal muscles suggests that it acts by interfering with contraction coupling or with the mechanisms involved in contraction and relaxation. These phenomena probably are involved in the pathogenesis of local tetanus.

SPINAL CORD

The effects of the toxin on the spinal cord are practically identical to those produced by strychnine. It does not act on reflex arcs that include only sensory and motor neurons (two-neuron or monosynaptic reflexes). However, the toxin profoundly alters the activity of the more complex polysynaptic reflexes involving interneurons, thereby leading to the inhibition of antagonists. Hyperpolarization of the membranes of neurons, a mechanism normally operating when direct inhibitory pathways are stimulated, is suppressed. The depolarization associated with excitation is not affected. Whether tetanospasmin blocks inhibitory synapses by preventing release of the inhibitory transmitter substance or by suppressing the action of this substance on the membrane of motor neurons is unknown. Selective blocking of inhibitory synapses in the CNS appears adequate to account for the primary phenomena of tetanus. Unchecked and uncoordinated excitatory impulses multiply and traverse reflex pathways to produce the characteristic tetanic spasms of muscles.

BRAIN

Some investigators have suggested that the action of tetanospasmin on the brain may be responsible for the typical seizures of tetanus.[16] This hypothesis is supported, in part, by the observation that cerebral gangliosides fix the toxin. The antidromic inhibition of evoked cortical activity is decreased. The effects of tetanospasmin on the brain are the same as those on the spinal cord, as well as those that occur after exposure to strychnine.

SYMPATHETIC NERVOUS SYSTEM

Manifestations indicating dysfunction of the sympathetic nervous system have been observed in some patients with tetanus. Signs and symptoms include profuse sweating, peripheral vasoconstriction, labile hypertension, cardiac arrhythmias, tachycardia, increased output of carbon dioxide, elevated urinary concentration of catecholamines, and hypotension late in the course of the disease.

CLINICAL MANIFESTATIONS

Although it may be as short as 1 day or as long as several months, the incubation period of tetanus usually is 3 to 21 days. A direct relationship may exist between the distance of the site of invasion by *C. tetani* from the CNS and the length of the interval between injury and the onset of disease; the greater the distance between the local area and the CNS, the longer, in general, the incubation period. Sustained or separate, repeated tonic spasms of isolated or multiple muscles are the characteristic clinical feature of the disease. Tetanus may appear in two forms: local and generalized.

LOCAL TETANUS

The occurrence of local tetanus most likely is more common than recognized. Although local tetanus is thought to occur infrequently, it probably is so because it may be uncommon as an isolated syndrome or because by the time that diffuse involvement has occurred, the spasms in the muscles in the area of the site of entry of the organism cannot be separated from the generalized spasms. Local manifestations frequently precede development of the generalized disorder. The characteristic abnormality in local tetanus is unyielding, persistent, painful rigidity of the group of muscles that lie in close proximity to the site at which *C. tetani* was introduced. Local tetanus often is present when a dose of antitoxin has been given that is adequate to inactivate circulating toxin but insufficient to neutralize what has accumulated at the site of injury. Symptoms may persist for several weeks or months and finally disappear without leaving any residua.[77,94] Local tetanus may be the only manifestation, usually is mild, and has a fatality rate of approximately 1 percent.

Cephalic tetanus is a variant of local tetanus. It generally occurs after the introduction of *C. tetani* in the course of injuries to the scalp, eye, face, ear, or neck; in conjunction with chronic otitis media; and rarely, after tonsillectomy.[7] Insect bites on the face or head, especially if secondarily infected by pyogenic organisms, also may serve as portals of entry for the organism. The incubation period of this syndrome is short, frequently no more than 1 to 2 days. The principal distinctive clinical features are palsies of cranial nerves III, IV, VII, IX, X, and XII; they may be involved singly or in any combination. Dysfunction may persist for days or many months. In general, the prognosis for survival is poor. However, if death does not intervene, complete recovery without residual neurologic dysfunction is the rule. In some, but not all, instances, generalized tetanus may develop during the course of the cephalic form of the disease.

GENERALIZED TETANUS

Generalized tetanus is the most common manifestation of the disease.[96,124] Despite the general impression that inoculation of the organism is associated most frequently with deep penetrating injury, the portal of entry in approximately 80 percent of cases is an insignificant wound.[90] Burns, injuries induced by blank cartridges, deep punctures, furunculosis, dental extraction, embedded splinters, decubitus ulcers, hypodermic injections, and compound fractures complicated by chronic active osteomyelitis are typical situations in which tetanus may develop because the environment in the tissues is optimal (decrease in oxidation-reduction potential and tension of oxygen) for conversion of spores to the toxin-producing vegetative organisms. Iatrogenic disease has occurred after the use of smallpox vaccine and surgical sutures contaminated with the spores of *C. tetani*. It also has occurred as a postoperative complication in patients exposed to the organisms present in the dust in operating rooms.[92,95,105] Very minor injuries, such as penetration by "clean" sewing needles and bites by chiggers, bees, and scorpions, have been recorded as portals of entry. Tetanus also has occurred after induced abortions, usually performed under poor asepsis.

The initial manifestation in more than 50 percent of cases of generalized tetanus is trismus; it may be unilateral early in the disease but becomes bilateral within a short time. In some cases, it may be absent during the entire course of the illness or appear only after other abnormalities have become evident. In some instances, the only symptoms and signs may be irritability, restlessness, stiffness of the neck, difficulty swallowing, and rigidity of the abdominal or thoracic muscles; these symptoms may be present singly or in various combinations. The diagnostic importance of trismus cannot be overemphasized, despite the fact that

it may be associated with numerous disorders unrelated to tetanus. Among these disorders are postmeasles encephalitis, trichinosis, suppurative and other types of parotitis, tender cervical lymphadenopathy, infected impacted upper molar teeth, and exposure to phenothiazine drugs.

As the activity of tetanospasmin persists, groups of muscles other than the masseters may become involved, including tonic spasms of the jaw, neck, back, and abdomen. Unrelenting trismus leads to the development of a characteristic facial expression, the sardonic smile (risus sardonicus). The abdominal and spinal muscles may become rigid. Intense and sustained contraction of the muscles of the chest and back results in persistent opisthotonos; in young children, this condition may be so severe that the youngster lies on one side with the soles of the feet resting on top of the head.

Generalized seizures, or tetanospasms, are unique in their appearance and peculiar to this disease. Characteristically, a sudden burst of tonic contractions of all groups of muscles occurs and leads to the development of opisthotonos, flexion and abduction of the arms, clenching of the fists on the chest, and extension of the legs. Pain in the spastic muscles usually is severe. Glottal and laryngeal spasm with the chest in the position of full inspiration may develop in some patients. During such an episode, the face becomes florid, the neck veins are distended markedly, and cyanosis develops. All the features of this syndrome are consistent with an intense and sustained Valsalva maneuver; unless the tonic contraction of the glottis and larynx subsides or a tracheostomy is performed, death results. Dysphagia and hydrophobia may develop as isolated phenomena in the absence of a generalized tetanospasm. Dysuria or urinary retention also may occur.

Autonomic nervous system dysfunction commonly occurs in tetanus.[113,122] Manifestations include labile or persistent hypertension or hypotension, persistent sinus tachycardia, tachyarrhythmia or bradycardia alternating with tachycardia, and profuse sweating.

Electroencephalographic studies of patients have indicated involvement of the brain. Of 106 patients studied by Luisto,[70] 76 percent were found to have abnormal electroencephalograms. When patients of the same age and sex who had not had tetanus were compared with 40 individuals who had contracted the disease 7 years earlier, the latter were found to have more muscle fatigue and cramps; difficulty in speech, balance, and memory; and more peripheral paresis, muscular atrophy, decreased or absent tendon reflexes, and impaired mental capacity.[63]

The generalized seizures of tetanus often are triggered by very slight external stimuli, such as a light breeze, talking, a bump on the bed, or slight touching of the patient. The intense work generated by sustained or frequently repeated tetanospasms often leads to increases in body temperature of 1° C to 3° C or more.

The intense suffering of patients with the generalized tonic seizures of tetanus and the total frustration of the physician, who in ancient times had to stand by helplessly, unable to alter the course of the disease, were described best by Aretaeus[6] in the second century BC; no better description has ever appeared:

> An inhuman calamity! An unseemly sight! A spectacle painful even to the beholder, an incurable malady! Owing to the distortion, not to be recognized by the dearest friends; and hence the prayers of the spectators, which formerly would have been reckoned not pious, now becomes good, that the patient may depart from life, or being a deliverance from the pains and unseemly evils attendant on it. But neither can the physician, though present and looking on, furnish any assistance, as regards life, relief from pain or from deformity. For if he should wish to straighten the limbs, he can do so only by cutting and breaking those of a living man. With them, then, who are overpowered by this disease, he can merely sympathize. This is the great misfortune of the physician.

Injection Drug Users

When generalized tetanus develops in IDUs, many of the clinical features differ from those present in people who do not use drugs.[67] Among such features are much higher levels of fever; absence of trismus at onset and throughout the course of the disease or its appearance some time after other manifestations have been present; marked stiffness of the neck and back, which in the absence of trismus may be confused with meningitis (the normal cerebrospinal fluid in patients with tetanus excludes this possibility); and early onset of coma. Prophylaxis is less effective in IDUs than in non-IDUs. The fatality rate approaches 100 percent.

Neonatal Tetanus

Neonatal tetanus usually begins 3 to 14 days after birth and is characterized by poor sucking and excessive crying.[49,124] Manifestations include trismus, difficulty swallowing, other tetanic spasms, and frequently, marked opisthotonos.

A study of the causes of death in patients with neonatal tetanus by Salimpour[101] indicated pulmonary disease to be most common. Bronchopneumonia or hemorrhage in the lungs (or both) was the most frequent finding at autopsy. Among the nonpulmonary disorders responsible for a fatal outcome were hepatitis, omphalitis, cerebral hemorrhage, thrombosis, and rupture of the renal vein. As has been noted not only in infants but also in older children and adults with tetanus, any gross or histologic abnormalities are very uncommon findings. The complications described by Salimpour,[101] especially those involving the lungs, probably are related to aspiration associated with the laryngoglottal spasm characteristic of the disease. Newborns who survived tetanus in rural Kenya often had evidence of brain damage.[8] Indicators of a poor prognosis for neonates include age younger than 10 days when admitted to the hospital, symptoms of less than 5 days' duration, and the presence of risus sardonicus and fever.[73]

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The differential diagnosis depends on the major clinical manifestations of the illness.[123] Cephalic tetanus may be confused with Bell palsy, trigeminal neuritis, and encephalitis, whereas generalized tetanus can be confused with rabies, strychnine poisoning, and phenothiazine reactions. Trismus can result from dental problems, tonsillitis, peritonsillar abscess, temporomandibular joint dysfunction, and parotitis. Tetany caused by hypocalcemia or hyperventilation should be considered as well.

SPECIFIC DIAGNOSIS

The diagnosis of tetanus is established on the basis of the history of an injury, particularly one in which either soil or fecal material has been introduced. In a small number of cases, especially those in which a relatively long incubation period has occurred, the site of entry of the organism may be healed and undetectable. In a review of 130 cases that occurred in the United States between 1998 and 2000, 94 (72%) were related to an acute injury.[85] There were 47 puncture wounds, 31 lacerations, and 8 abrasions. In 34 cases not involving an acute injury, the following associations were noted: abscess, 7 cases; ulcer, 7 cases; gangrene, 2 cases; cellulitis, 1 case; gingivitis, 3 cases; and other infections, 2 cases. In 12 cases, no injury or other source location was identified. One of the 130 patients was a neonate, and 18 of the non–acute injury cases occurred in patients with a history of injection drug use. Laboratory studies are of little help. Peripheral leukocytosis may

or may not be present. The characteristic gram-positive rods, some of which may contain subterminal spores, may be seen occasionally in stained material obtained from the wound that has served as the portal of entry. Anaerobic cultures of exudate or necrotic tissue may grow typical sporulated rods and vegetative forms, but the yield of positive findings tends to be low.[31]

Low or undetectable levels of serum antitoxin at the time of onset of the illness is supportive of the diagnosis, but occasionally, serum antitoxin is present.[123] Rises in antitoxin titer occur uncommonly after infection, so the use of paired sera for retrospective diagnosis generally is not helpful; in addition, this form of serologic diagnosis is not possible when therapy included active immunization. In selected cases, electrophysiologic studies of the masseter muscle may be helpful.[9] A characteristic absence or shortening of the silent period occurs as a result of failure of Renshaw cell inhibition; exaggerated F responses indicating hyperexcitability also may be noted.

TREATMENT

Management of generalized tetanus is directed at the following goals:

1. Neutralization of toxin still present in the blood before it comes in contact with the nervous system. Neutralization is accomplished by the administration of antitoxin as soon as the possibility of the disease is suspected or confirmed.[12] However, no acceptable evidence has shown that toxin can be inactivated by antitoxin once the toxin is fixed to tissues. In fact, the effectiveness of even large doses of antitoxin in reducing the fatality rate has been questioned.
2. Surgical removal of the site of entry of the organism, when possible, to eliminate the "factory" in which tetanospasmin is being produced. Omphalectomy has been performed with good results in children with neonatal tetanus.[37] Hysterectomy has been recommended when the disease has complicated induced and often septic abortions; however, patients in whom the infected uterus is not removed occasionally may survive. When the surgical procedure may be mutilating, as is the case with lesions on the face, it should not be performed.
3. Constant and meticulous nursing care.
4. Close monitoring of fluid, electrolyte, and caloric balance because they frequently are abnormal, especially in patients with high temperature and repeated seizures, as well as in those unable to take food or liquids because of severe trismus, dysphagia, or hydrophobia.

The slightest external stimulus may precipitate potentially lethal seizures in persons with diffuse disease. For this reason, of extreme importance is that all therapeutic and other manipulations be well coordinated and carefully scheduled so that the risk of producing a tetanospasm is reduced to a minimum. All maneuvers are performed best after patients have received optimal sedation and relaxation. A quiet, darkened room in which the light is subdued and the doors padded, removed as far as possible from the mainstream of hospital traffic, is ideal, but at the same time the patient requires constant monitoring and observation in an intensive care environment.

The antitoxin of choice for the treatment of tetanus is human tetanus immune globulin (TIG) at a dose of 3000 to 6000 units intramuscularly; a second dose does not appear to be necessary. When TIG is not available, equine antitoxin (EA) may be used, but it should be avoided if at all possible. The dose of EA is 100,000 units; half is injected intramuscularly after appropriate tests to rule out sensitivity to horse serum have been performed. If EA is well tolerated, the remainder is given slowly intravenously. Patients sensitized to horse serum must be desensitized. An intramuscular injection of 80,000 units of EA produces maximal concentrations of antibody in the blood in 48 to 72 hours; very good levels may be maintained for 7 days.[53,116,117] Intravenous administration of the same dose yields concentrations of 40 or more units of antitoxin per milliliter of serum after 6 hours; it may persist for approximately 48 hours. Essentially no difference in circulating quantities of antitoxin exists 7 days after it is given by either route. Local instillation of antitoxin around the known or suspected wound may be of value if excision cannot be performed; it also has been recommended before surgical removal of the injured area.

Although reports[83] have documented that intrathecal administration of antitetanus serum did not improve the rate of survival in neonatal tetanus, the results of a study by Mongi and colleagues[80] led them to recommend this form of therapy. They found that intrathecal serotherapy may be of great value in the management of tetanus. Their experience indicated that the death rate from this disease in patients given intrathecal therapy was 45 percent; in those who did not receive this agent, it was 82 percent. However, the results of a recent meta-analysis led Abrutyn and Berlin[2] to conclude that intrathecal therapy with either EA or TIG is not of proven benefit and, therefore, should be given only during well-designed, controlled therapeutic trials.

In a controlled trial in Brazil involving 120 adolescents and adults, 58 patients received TIG intrathecally and intramuscularly and 62 received TIG only by the intramuscular route.[79] The patients who received intrathecal and intramuscular treatment had better clinical progression than did those who were treated only by the intramuscular route. Most recently, a meta-analysis that involved 942 patients in 12 trials was reported.[61] In this analysis, the overall relative risk of mortality with intrathecal (antitetanus serum or TIG) versus intramuscular therapy was 0.71 (95% confidence interval, 0.62 to 0.81). Subcategory analyses for both adults and neonates and for high- and low-dose intrathecal therapy also indicated the beneficial effect of intrathecal therapy.

Penicillin kills the vegetative forms of *C. tetani*. Parenteral administration of penicillin G, 100,000 U/kg/day intravenously every 6 hours for 10 days, has been recommended in the past in all cases of tetanus. Observations have suggested that penicillin may act as an agonist to tetanospasmin by inhibiting the release of γ-aminobutyric acid (GABA).[123] Because of this possibility and the results of a controlled study in Indonesia, metronidazole has become the antimicrobial treatment of choice in many centers.[4] The metronidazole dosage is 30 mg/kg/day intravenously every 6 hours after an initial dose of 15 mg/kg. The usual duration of therapy is 7 to 10 days.

The spasticity and seizures of tetanus are caused by exaggerated reflex responses to afferent stimuli as a result of suppression of balancing central inhibition. Several classes of drugs that act at different sites along the reflex pathway are useful for control of these manifestations. Among them are hypnotics and sedatives, which reduce sensory input and generalized excitability; general anesthetics, which produce broad depression of the CNS; centrally acting muscle relaxants or spinal depressants, which lower reflex activity and decrease motor output from the spinal cord; and neuromuscular blocking agents, which inhibit the transmission of excess motor nerve activity to effector muscles.

The ideal drug for the treatment of tetanus must control seizures and decrease spasticity without impairing respiration, voluntary movement, or consciousness. The activity of an agent in inhibiting the convulsions induced by strychnine usually has been a reliable guide for the prediction of effectiveness in the management of tetanus. However, it may not be reliable in all cases. For example, although the phenothiazines act as anticonvulsants in both naturally occurring and experimentally produced tetanus, they fail to control seizures induced by strychnine. Creech and associates[34] point out, "It may be concluded that any type of sedative or hypnotic agent, when properly administered so as to

avoid respiratory depression, has the same effect or lack of effect upon the outcome of tetanus."

Historically, many different drugs have been used in patients with tetanus. Secobarbital sodium (Seconal) and pentobarbital (Nembutal) have been favored for their relatively short half-life.[60,78] Barbiturates, however, may have deleterious effects on both the respiratory and cardiovascular systems. A patient heavily sedated with barbiturates often will have a rise in carbon dioxide pressure and a fall in oxygen pressure, as well as hypotension and a fall in cardiac output. In addition, barbiturates have a lower therapeutic index than the benzodiazepines do.[91] Chlorpromazine (Thorazine) also has been used to control the muscle spasms of tetanus, but it has some drawbacks.[32] Chlorpromazine actually may lower the seizure threshold and should be administered, if at all, only with concomitant anticonvulsant therapy. The acute dystonic reactions occasionally seen with chlorpromazine can confuse the picture markedly in a patient with tetanic spasms and rigidity. Akathisia, the need of the patient to be in constant movement, is another extrapyramidal effect occasionally seen with the phenothiazines and would be undesirable in a patient susceptible to tetanic spasms. Meprobamate historically was used to control the tonic spasms of tetanus.[88] It is relatively ineffective when given orally or intramuscularly (dissolved in propylene glycol).[78]

The barbiturates, phenothiazines, and meprobamate no longer are first-line antispasmodic drugs; benzodiazepines are the preferred drugs for the spasms and rigidity associated with tetanus.[33,84,111,120] They also have the advantage of being potent anticonvulsants, as well as sedative-hypnotic agents. Additionally, they are GABA agonists and perhaps partially overcome the effect of tetanospasmin interfering with the normally inhibitory effect of GABA.[119] Diazepam (Valium) and lorazepam (Ativan) have been the benzodiazepines most frequently used for tetanus. Lorazepam has a somewhat longer half-life and may be preferred for this reason. Very large total daily doses of diazepam (500 mg) or lorazepam (200 mg) may be required.[106] Both drugs are formulated in propylene glycol solution for intravenous administration, and the large doses required may result in significant propylene glycol toxicity, including metabolic acidosis. For this reason, an enteral preparation that is free of propylene glycol should be given enterally if at all possible.[13]

Midazolam (Versed) is a short-acting benzodiazepine that is soluble in water and thus does not include propylene glycol in its parenteral formulation. Because of its short half-life, it should be administered as a continuous infusion, and an initial infusion dose of 0.1 to 0.3 mg/kg/hr may be required. The benzodiazepines all induce tachyphylaxis and will require escalation of the dosage with time. The dosage should be titrated to prevent tetanic spasms and provide adequate sedation instead of being a specified dose. To avoid withdrawal symptoms after long-term use, the benzodiazepines should be tapered over the course of several weeks.

If the benzodiazepines are unable to control the spasms and rigidity associated with tetanus, intrathecal baclofen should be considered. Baclofen is a GABA receptor agonist that directly stimulates the postsynaptic GABA beta receptors on synapses blocked by tetanus toxin, thereby restoring physiologic inhibition of the alpha motor neuron. Numerous centers have described the efficacy of intrathecal baclofen for treating tetanus, although its safety and efficacy have not been established in children younger than 4 years.[14,40,41,103]

When the benzodiazepines and intrathecal baclofen are unable to control the spasms and rigidity associated with tetanus, neuromuscular blockade is indicated. Although succinylcholine has been used in the past,[47] newer agents have supplanted it. Additionally, theoretical reasons provide the basis to avoid the use of succinylcholine. With functional denervation of the motor endplate in neuromuscular junctions directly affected by tetanospasmin, succinylcholine may result in exaggerated release of potassium and hyperkalemia. This condition has been associated with cardiac arrhythmias and death in other denervating conditions. For this reason, nondepolarizing agents should be used. Potential agents include pancuronium, vecuronium, atracurium, cisatracurium, rocuronium, and pipecuronium—the agent of choice in a large tetanus treatment center in Vietnam.[115]

Neuromuscular blocking drugs should be used only by physicians experienced in their use in a critical care environment, typically anesthesiologists or intensivists.[65] Although neuromuscular blockers formerly were used at low doses to preserve diaphragmatic function and spontaneous respiration, current thought is that they should be administered in conjunction with endotracheal intubation and ventilatory support. Remembering that neuromuscular blocking drugs have no effect on cortical function and have no sedative effect is critical. The benzodiazepines are good sedatives and have a significant amnestic effect. They are not, however, analgesics, and if pain is present (such as from previous muscle spasms), morphine sulfate is an effective analgesic. It also may be helpful in treating sympathetic hyperactivity. If sympathetic overactivity remains problematic, a combined alpha- and beta-receptor blocker such as labetalol should be used. The use of a beta blocker such as propranolol alone should be avoided because the unopposed alpha-mediated vasoconstriction could lead to significant hypertension. Clonidine and epidural anesthesia are alternative therapies for increased sympathetic discharge. A combination of epidural bupivacaine and sufentanil has been used by some physicians to treat the sympathetic overactivity.[11]

In a recent large (256 patients) randomized, double-blinded, placebo-controlled trial, infusion of magnesium sulfate in patients with severe tetanus was compared with the administration of placebo.[115] There was no difference in need for ventilation or in survival between the two groups. However, patients randomized to receive magnesium sulfate did have better control of muscle spasms and less cardiovascular instability. Thus, magnesium sulfate infusion may have a role in the management of severe tetanus.

The management approach to a patient with tetanus spasms or rigidity should be one of escalation of therapy based on need. Benzodiazepines should be administered initially, with high doses often being required. If the benzodiazepines are not effective, intrathecal baclofen may be used.[40,41] Infusion of magnesium sulfate to decrease muscle spasms and cardiovascular instability should be considered.[115] If these therapies are inadequate or result in airway compromise or inadequate ventilation, endotracheal intubation should be performed with a nondepolarizing neuromuscular blocking agent. Intubation also should be performed if spasms result in obstruction of the airway. Some physicians have advocated that IDUs with tetanus have an airway established because of the fulminant course of the disease.[88]

Sixty-six percent of 103 children aged 1 to 12 years with severe tetanus studied by Wesley and Pathes[125] required management with total muscle paralysis and intermittent positive-pressure ventilation. The death rate in this group was 14.5 percent.

Very careful attention must be paid to care of the skin, bladder, mouth, and bowel of patients with tetanus. Adequate fluid and electrolyte balance must be maintained. Feeding by gavage in patients unable to eat because of severe trismus, dysphagia, or hydrophobia has been suggested as a means of ensuring optimal caloric intake. Gastric emptying may be impaired, and a transpyloric feeding tube will facilitate adequate nutritional support with a continuous infusion of age-appropriate enteral formula. Transpyloric placement of the feeding tube also may decrease the risk of aspiration.

The use of dantrolene with conservative treatment has been reported to reduce the fatality rate associated with tetanus significantly.[3] The need to block both the sympathetic and the parasympathetic nervous systems to stabilize hemodynamics has

been suggested. Such blockade may be produced by spinal anesthesia.[107] Patients with tetanus treated with metronidazole have been found to have a lower fatality rate, a shorter stay in the hospital, and an improved response to treatment.[4] Intravenous administration of morphine to patients with tetanus has been noted to reduce arterial blood pressure and systemic vascular resistance.[96]

Patients who have survived an episode of tetanus must be immunized actively after recovery because antitoxin usually is not detectable in serum for as long as 3 months after recovery.[116] Recurrent attacks of the disease rarely occur, however.[22]

Studies in mice have shown that adrenocortical steroids are without effect in altering the course of tetanus. The administration of cortisone after a significant delay between the injection of toxin and antitoxin or after clinical manifestations have appeared was found not only to be without benefit but also to decrease the effectiveness of the antitoxin.[30] Other studies also have indicated a lack of therapeutic effect[54,117] but have not demonstrated deleterious effects. Critically evaluated clinical experience has confirmed this finding.[68]

PROGNOSIS

The average fatality rate associated with tetanus ranges from 25 to 70 percent, but mortality rates can be reduced to 10 to 30 percent with modern intensive care.[97,123] The risk of death occurring in patients with tetanus neonatorum is particularly high; it was reported to be 99.5 percent in a group of 5794 infants in 1930.[57] With modern treatment and high-intensity supportive care, the mortality rate associated with neonatal tetanus can be reduced to approximately 25 percent.[123] IDUs are highly susceptible to the development of very severe disease and are likely to die.[63,67]

A variety of other factors play an important role in determining the outcome of tetanus.[55,114] Patients in the second and third decades of life have a higher rate of recovery than do those who are elderly. An inverse relationship exists between the length of the incubation period and risk, as first pointed out by Hippocrates. The risk of death is approximately 58 percent when the interval between injury and the onset of tetanus is 2 to 10 days. When the interval is 11 to 22 days or longer, fatality rates have been 35 to 17 percent, respectively. A relationship also appears to exist between the period elapsing from the time of appearance of the first signs of tetanus and development of the first seizure or maximal intensity of the disease; the shorter this interval, the poorer the prognosis.[31]

The clinical form of tetanus also influences the outcome.[69] Cephalic tetanus and tetanus neonatorum are associated with the highest incidence of death. In contrast, local tetanus, unless complicated by development of the generalized syndrome, has an excellent prognosis. Early administration of prophylactic antitoxin markedly increases the frequency of survival.

CAUSE OF DEATH

Because the clinical course of tetanus may be prolonged and the therapy used is complex and potentially dangerous, the cause of death often is not clear. Animals may die after the injection of toxin without any recognizable signs of the disease appearing.[46] Studies in parabiotic rats have suggested that tetanospasmin exerts a lethal effect on the respiratory center.[104] Involvement of the medulla has been observed in experimental animals and humans, in whom episodes of respiratory failure, often in the absence of seizures, have been described.[65,130] The action of the toxin on brain tissue has been postulated to be the cause of hyperpyrexia, tachycardia, hypotension, bulbar palsy, and cardiac arrest.[81] Myocardial damage also may occur, and both histologic and electrocardiographic abnormalities have been described.[87]

Death may occur during a convulsion, but the specific mechanisms involved are not clear in all cases. Laryngospasm and disturbances in electrolyte balance may play important roles. Pneumonia complicating aspiration, induced by an inability to swallow and oversedation, occurs commonly. It may be directly responsible for death or may contribute to a fatal outcome by increasing the degree of anoxia of the respiratory center.

PREVENTION

As noted in Figure 160–1, tetanus in the United States has decreased dramatically, and this decline can be attributed to routine universal use of tetanus toxoid and improved wound management, including the use of tetanus prophylaxis in emergency departments.

ACTIVE IMMUNIZATION

For complete information regarding tetanus immunization, the reader is referred to the most recent recommendations of the Advisory Committee on Immunization Practices of the U.S. Public Health Service,[25,28,29] the recommendations of the Committee on Infectious Diseases of the American Academy of Pediatrics,[5] and product information from vaccine manufacturers.

In the United States, primary immunization against tetanus is performed in conjunction with immunization against diphtheria and pertussis in the form of diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed (DTaP). The schedule involves an initial series of three doses of vaccine at 2, 4, and 6 months of age; a reinforcing dose at 12 to 18 months of age; and a booster dose at 4 to 6 years of age. After the initial series, additional booster doses of adult-type diphtheria and tetanus toxoids adsorbed (Td) are recommended at 10-year intervals.[37,39] In 2005, two adult-type diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed (Tdap) were approved for use in the United States.[28,29] Initially, these vaccines were approved for only a single dose. For adolescents, the recommendation was for Tdap to replace Td for the routine booster dose. For adults aged 19 to 64 years, the recommendation was that they receive a single dose of Tdap to replace Td for boosting. After additional study is performed, it is anticipated that a boosting schedule of Tdap will be similar to that recommended for Td (every 10 years). The minimal serum level of antitoxin needed for protection is 0.01 IU/mL.[38,71,73,108] After the initial three-dose series, the reinforcing dose, and the booster dose, levels of antitoxin 100- to 1000-fold higher than 0.01 IU/mL are attained, and levels higher than 0.01 IU/mL persist in nearly all vaccinees until the scheduled subsequent dose.

TETANUS PROPHYLAXIS IN WOUND MANAGEMENT

Antimicrobial prophylaxis against tetanus is neither practical nor useful in managing wounds.[15,131] Cleaning of the wound, débridement when indicated, and proper immunization are important factors. The need for tetanus toxoid (active immunization), with or without TIG (passive immunization), depends on both the condition of the wound and the patient's vaccination history (Table 160–1).[17,25,112] Rarely has tetanus occurred in persons with documentation of having received a primary series of toxoid injections.

A thorough attempt must be made to determine whether a patient has completed primary vaccination. Patients with unknown or uncertain previous vaccination histories should be considered to have had no previous tetanus toxoid doses. Persons

TABLE 160–1 Summary Guide to Tetanus Prophylaxis in Routine Wound Management, 1991

History of Adsorbed Tetanus Toxoid (Doses)	Clean, Minor Wounds		All Other Wounds*	
	Td†	TIG	Td†	TIG
Unknown or <3	Yes	No	Yes	Yes
≥3‡	No§	No	No‖	No

**Such as, but not limited to wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.*

†For children younger than 7 years, diphtheria-tetanus-pertussis vaccine (diphtheria-tetanus if pertussis vaccine is contraindicated) is preferred to tetanus toxoid alone. For persons 7 years or older, Td is preferred to tetanus toxoid alone.

‡If only three doses of fluid toxoid have been received, a fourth dose of toxoid, preferably an adsorbed toxoid, should be given.

§Yes, if older than 10 years since the last dose.

‖Yes, if older than 5 years since the last dose (more frequent boosters are not needed and can accentuate side effects).

Td, adult-type diphtheria and tetanus toxoids; TIG, tetanus immune globulin.

From Centers for Disease Control and Prevention: Diphtheria, tetanus and pertussis: Recommendations for vaccine use and other preventive measures; recommendations of the Immunization Practices Advisory Committee (ACIP). M. M. W. R. Recomm. Rep. 40(RR-10):2-28, 1991.

who served in the military since 1941 can be considered to have received at least one dose. Although most people in the military since 1941 may have completed a primary series of tetanus toxoid, such protection cannot be assumed for each individual. Patients who have not completed a primary series may require tetanus toxoid and passive immunization at the time of wound cleaning and débridement (see Table 160–1).

The evidence available indicates that complete primary vaccination with tetanus toxoid provides long-lasting protection for 10 or more years in most recipients. Consequently, after complete primary tetanus vaccination, boosters—even for wound management—need to be given only every 10 years when wounds are minor and uncontaminated. For other wounds, a booster is appropriate if the patient has not received tetanus toxoid within the preceding 5 years.[86] Antitoxin antibodies develop rapidly in persons who have received at least two doses of tetanus toxoid.

Td has been the preferred preparation for active tetanus immunization in the wound management of patients aged 7 years or older. Because a large proportion of adults are susceptible, this plan enhances diphtheria protection. Thus, by taking advantage of acute health care visits, such as for wound management, some patients can be protected who otherwise would remain susceptible. For routine wound management in children younger than 7 years old who are not vaccinated adequately, DTaP should be used instead of single-antigen tetanus toxoid. Td may be used if pertussis vaccine is contraindicated. For patients of all ages who are inadequately vaccinated, completion of primary vaccination at the time of discharge or at follow-up visits should be ensured. Presently, Tdap rather than Td is recommended for wound management in adolescents and adults.[28,29]

If passive immunization is needed, human TIG is the product of choice. It provides protection longer than does antitoxin of animal origin and causes fewer adverse reactions.[74,100,109] The TIG prophylactic dose currently recommended for wounds of average severity is 250 units intramuscularly. When tetanus toxoid and TIG are given concurrently, separate syringes and separate sites should be used. The Advisory Committee on Immunization Practices recommends the use of only adsorbed toxoid in this situation.

NEONATAL TETANUS

Several approaches have been taken to reduce the incidence and fatality rate of neonatal tetanus in developing areas of the world. Among these approaches are (1) educating pregnant women concerning the danger of using contaminated materials for cutting the umbilical cord and covering the stump, (2) training midwives in the application of modern techniques of obstetric asepsis, (3) developing hospitals in which babies are born under strict asepsis, and (4) immunizing all women of child-bearing age or, if such immunization is not possible, all who are pregnant. Studies performed by the World Health Organization (WHO) have demonstrated that such immunization is practical and leads to an appreciable reduction in the incidence of neonatal tetanus.[42-44,110,118,129] Babies born to mothers who have been immunized during pregnancy not only have adequate levels of circulating antibody but also are protected against acquiring the disease. The level of protective antibody in newborns and the magnitude of the transfer rate of passive immunity to tetanus depend directly on the level of tetanus antitoxin in maternal serum. Mothers who had tetanus antitoxin levels of 1.28 IU/mL or greater could transfer protection to almost all the newborns (97-100%), irrespective of the doses of tetanus toxoid administered. Mothers who had received two doses of tetanus toxoid during pregnancy not only conferred good protection but also transferred high antitoxin levels to their newborns.[102]

In 1989, the WHO adopted a resolution to eliminate neonatal tetanus worldwide,[127] and in 1990, the World Summit for Children issued a declaration for global elimination of neonatal tetanus by the end of 1995.[26,128] In 1993, the WHO's goal was defined as elimination of neonatal tetanus as a public health problem by reducing its incidence to less than one case per 1000 live births for all health districts.[52]

From 1989 to 1993, the rate of vaccination coverage with two or more doses of tetanus toxoid administered to pregnant women in areas at risk increased from 27 to 45 percent. To achieve and maintain elimination of neonatal tetanus, 80 percent or more of infants need to be protected at birth through vaccination of their mothers with at least two doses of tetanus toxoid or through clean delivery and cord-care practices.[52] Considerable progress has been made in the reduction of maternal and neonatal tetanus, but the goal to reduce the rate of neonatal tetanus to less than one case per 1000 live births in all geographic areas has not been achieved.[118] In 2003, 57 countries still remained in which neonatal tetanus had not been eliminated in all districts.

CHAPTER 161

ACTINOMYCOSIS

Suzanne Whitworth ✪ Richard F. Jacobs

Human actinomycosis is a clinical illness with typical histologic findings that is caused by a variety of pathogens. It often is polymicrobial, and *Actinobacillus actinomycetemcomitans* frequently is a co-pathogen. It is endogenous worldwide, with sporadic cases reported annually. Occurrence of the disease is unrelated to age, sex, season, or occupation, although it is an uncommon event in the pediatric population. These organisms have the ability to spread locally without regard to fascial planes or other anatomic barriers. Actinomycosis is characterized by localized swelling with suppuration, abscess formation, and draining sinuses. The abscesses have fibrous walls and are filled with pus and characteristic sulfur granules. The three most common types of actinomycosis are oral and cervicofacial, abdominal, and pulmonary. However, involvement of the liver, female reproductive tract, and brain has been described. Definitive diagnosis of the infection rests on isolation of the organism from pus or identification of sulfur granules on histopathologic sections of biopsy material. Adequate treatment generally consists of surgical removal of the lesion, prolonged antibiotic therapy, or both.

MICROBIOLOGY

The clinical entity of actinomycosis is caused by species of the genera *Actinomyces* and *Propionibacterium*. Human actinomycosis most often is caused by *Actinomyces israelii*, although *Actinomyces*

gerensceriae (formerly known as *A. israelii* serovar 2), *Actinomyces naeslundii*, *Actinomyces viscosus*, *Actinomyces odontolyticus*, *Actinomyces meyeri*, *Actinomyces radicidentis*, *Actinomyces neuii*, *Actinomyces radingae*, and *Actinomyces turicensis* also are causes of human illness.[46] *Arcanobacterium pyogenes* (previously in the *Actinomyces* genus) also causes human actinomycosis. *Propionibacterium propionica* is the only species in the *Propionibacterium* genus that is a cause of human actinomycosis. Some authors also include *Bifidobacterium dentium* as an etiologic agent of actinomycosis.[40]

These bacteria are irregular, non–spore-forming, non–acid-fast, nonmotile, gram-positive rods. They grow in most rich culture media and have various oxygen requirements. For example, *A. israelii* requires anaerobic conditions for growth. *A. viscosus*, however, grows in an aerobic environment with carbon dioxide. These species ferment carbohydrates as their source of energy for growth.[16] These organisms now are firmly classified as prokaryotic bacteria, although they originally were thought to be fungi because of the mycelial appearance of the organisms in sulfur granules and because of their branching morphology. However, neither genus contains chitin or glucans, which are characteristic macromolecules of fungi. In addition, they reproduce by bacillary fusion, are sensitive to antibiotics, and are resistant to antifungal agents. These organisms are members of the endogenous flora of mucous membranes. *A. israelii* always is found in the oral cavity when the appropriate anaerobic culture technique is used. It also has been found in the gastrointestinal tract, bronchi, and female genital tract.[45]

A. actinomycetemcomitans is a fastidious, non–spore-forming, nonmotile, facultatively anaerobic gram-negative rod that frequently complicates actinomycosis caused by *A. israelii*. In addition to being associated with actinomycosis, it has been implicated as a pathogen in periodontal disease and is part of the oral flora. Infection by this bacterium often is not resolved by the normal host, possibly because of inefficient phagocytosis and the weak oxidative burst response of neutrophils.[37] In addition, the bacterium has several virulence factors, including induction of apoptosis and tissue destruction.[18] *A. actinomycetemcomitans* is characterized by slow growth in culture and a requirement for incubation in an atmosphere enhanced with carbon dioxide.[29] Other bacterial species concomitantly isolated in human actinomycosis are *Eikenella corrodens*, *Fusobacterium*, *Bacteroides*, *Capnocytophaga*, *Staphylococcus*, *Streptococcus*, and members of the family Enterobacteriaceae.

PATHOGENESIS

The organisms that cause actinomycosis normally are found in the oral flora from infancy to adulthood. Actinomycetes are primary colonizers that can initiate the formation of plaque and set the stage for the development of infectious disease, as well as predispose to the formation of caries.[3,8] These bacteria adhere tenaciously to both the hard and soft tissue surfaces of the oral cavity.[61] Disruption of this mucous membrane probably is the initiating event for oral and cervicofacial disease. The organisms then invade locally and spread without regard to fascial planes. The exact mechanism of this spread is unknown but may be related to the ability of these organisms to suppress part of the host immune system. Organisms of the *Actinomyces* genus have been shown to be chemotactic, to activate lymphocyte blastogenesis, and to stimulate the release of lysosomal enzymes from polymorphonuclear leukocytes and macrophages.[16] In addition, the co-pathogens involved in this infection may reduce local oxygen tension. Dental extractions are associated with mucosal breaks and tissue necrosis and may predispose to oral or cervicofacial actinomycosis.[39] Hematogenous dissemination can occur eventually but is an uncommon development. Gastrointestinal disease probably is associated with disruption of the mucosal barrier, similar to oral and cervicofacial disease.[45] Organisms causing pulmonary actinomycosis probably reach the lungs through aspiration. Thoracic actinomycosis usually is a complication of localized pulmonary parenchymal infection. Actinomycetes produce enzymes and thus spread by extension into the lungs, pleura, and chest wall without regard to tissue planes.[53] Numerous reports in the literature associate actinomycosis with intrauterine devices (IUDs), and some question exists regarding the association of foreign bodies with actinomycosis.[5,13]

PATHOLOGY

Actinomycosis most commonly is manifested as a chronic infection with single or multiple indurated swellings. These lesions eventually soften, become fluctuant, and suppurate. The walls are fibrous and firm and often described as wooden, which frequently results in their confusion with neoplasms. Over the course of time, sinus tracts form and extend through the overlying skin or to adjacent bones or tissues. The overlying skin may have a bluish hue.[45]

Histologically, a typical lesion has a central purulent area containing neutrophils and sulfur granules, surrounded by an outer zone of granulation with collagen fibers and fibroblasts. The sulfur granules are firm, yellowish granules containing the organisms and are virtually diagnostic of actinomycosis, although they can be seen in nocardiosis and botryomycosis. In addition to neutrophils, lymphocytes and plasma cells frequently are seen in the lesions; eosinophils and multinucleated giant cells occasionally are seen.[45]

CLINICAL MANIFESTATIONS

There are three important sites of actinomycotic infection. The order of frequency of occurrence is oral/cervicofacial, abdominal/pelvic, and pulmonary. Actinomycosis resembles several other chronic inflammatory diseases and must be differentiated from mycotic infections, tuberculosis, appendicitis, *Yersinia enterocolitica* pseudoappendicitis, osteomyelitis, amebiasis, hepatic abscess, and other chronic bacterial infections, including nocardiosis.

Because oral and cervicofacial actinomycosis occurs after disruption of the mucous membranes in the mouth or oropharynx, patients who have this type of actinomycosis may have a history of oral surgery, dental procedures, or trauma to the mouth. Clinical findings may include pain, trismus, firm swelling, and fistulas with drainage that contains the characteristic sulfur granules (Figs. 161–1 and 161–2). Patients most commonly have a chronic disease course but may be seen acutely with cellulitis. Infection may spread through the sinus tracts to the cranial bones, which gives rise to meningitis. Bone is not involved early in the disease, but periostitis may develop later. The marked ability of the organisms in this disease to burrow through tissue planes and even bone differentiates actinomycosis from nocardiosis and is an important characteristic of this infection. The cervicofacial type of actinomycosis, or "lumpy jaw," has the best prognosis. With surgical débridement and excision as an adjunct to proper antibiotic therapy, the disease usually is cured. At least two cases of thyroiditis secondary to actinomycosis have been reported in pediatric patients.[19,60]

Because abdominal actinomycosis also is the result of disruption of the mucosa of the gastrointestinal tract, patients may have a history of gastrointestinal surgery, diverticulitis, or appendicitis. The patient also may have a history of trauma to the abdomen. Patients may have chills, fever, night sweats, and weight loss. The course is indolent and similar to that of tuberculous peritonitis. Because appendicitis is the most common predisposing event, on

Figure 161–1 Cervicofacial disease with draining sinus tracts caused by *Actinomyces israelii*.

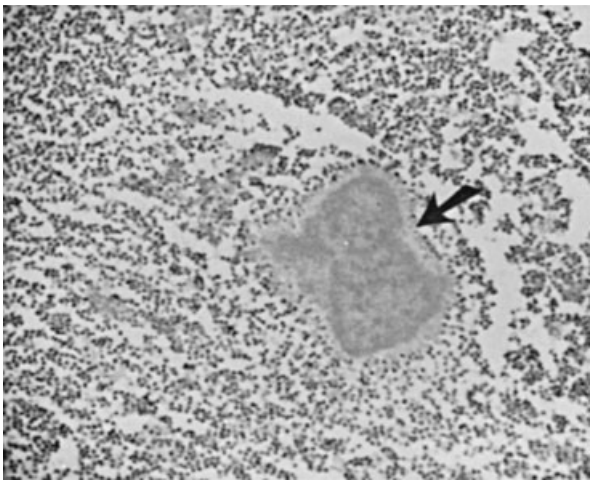

Figure 161–2 Abscess containing an actinomycotic granule surrounded by purulent exudate. The peripheral clubbing (*arrow*) is stained by eosin. (Hematoxylin and eosin; original magnification ×52.)

physical examination patients may have a hard, irregular mass in the ileocecal area that softens and then drains to the outside. Extension from such foci usually is by direct continuity (or, rarely, hematogenously) and involves any tissue or organ, including muscle, liver, spleen, kidney, fallopian tubes, ovaries, uterus, testes, bladder, esophagus, or rectum.[1,2,9,21,26,42] A delayed diagnosis of actinomycosis involving the abdomen or pelvis is typical, and it is frequently confused with malignancy.[22]

Hepatic involvement occurs in approximately 15 percent of cases of abdominal actinomycosis. Involvement of the liver can occur through direct extension from a subdiaphragmatic or subhepatic abscess. It also is a common finding in disseminated actinomycosis.[45] Occult disruption of the gastrointestinal mucosa with spread of organisms through the portal vein may provide a portal of entry for the organisms in cases of primary or isolated hepatic disease. Initial symptoms may include fever, abdominal pain, anorexia, weight loss, nausea, vomiting, shoulder pain, back pain, or diarrhea. The course usually is indolent, with 1 to 6 months of symptoms. On physical examination, the patient commonly has fever, abdominal tenderness, and hepatomegaly. A palpable abdominal mass, jaundice, or draining sinuses may be present. Disseminated intravascular coagulation has been reported to occur.[56] Hepatic actinomycosis has been found in children who have undergone appendectomies.[30] Thrombotic thrombocytopenic purpura has been described in association with hepatic actinomycosis in an adult.[42] Other causes of liver masses included in the differential diagnosis are pyogenic abscess, amebiasis, and malignancy.

Women wearing IUDs are at risk for the development of pelvic actinomycosis. These patients may have a vaginal discharge, pelvic pain, abdominal pain, menorrhagia, fever, a pelvic mass, a history of pelvic inflammatory disease, or a history of prolonged IUD use. The risk is more significant if the IUD has been in place for longer than 2 to 3 years. These devices are thought to cause an inflammatory response in the endometrium with focal necrosis. This anaerobic environment encourages the growth of *A. israelii*. In such patients, removal of the IUD plus treatment with antibiotics is necessary.[13] Pelvic actinomycosis can develop in both men and women; it can appear as a tumor-like mass and be confused with malignancy. A urachus or urachal remnant is also a risk factor.[28]

Establishing the diagnosis of pulmonary actinomycosis depends on having a high index of suspicion because neither the clinical nor the radiographic findings are specific. Patients may have a history of or risk factors for aspiration. Adults with thoracic actinomycosis usually have abnormal local defenses, such as chronic bronchitis, bronchiectasis, or emphysema; however, pediatric patients have been shown to have predisposing factors less often.[23,53] This type of actinomycosis also occurs after the introduction of a colonized foreign body. Patients with oral, cervicofacial, or abdominal actinomycotic infections are at risk for the development of pulmonary infection from direct or hematogenous spread. A history of these preexisting infections should heighten the index of suspicion. Pulmonary actinomycosis may be manifested as an endobronchial infection, a tumor-like lesion, diffuse pneumonia, or a pleural effusion.[7,10,38] The presence of chronic pleural effusion, underlying lung changes, and periosteal rib involvement is indicative of actinomycosis but seldom is reported.[58] The principal symptoms include chest pain, fever, productive cough, and weight loss. Hemoptysis has been reported.[41] The infection frequently dissects along tissue planes and may extend through the chest wall or diaphragm and produce multiple sinuses. These characteristic sinus tracts contain small abscesses and purulent drainage. Empyema necessitans has been reported in one child.[54] The differential diagnosis of pulmonary actinomycosis includes tuberculosis, lung abscess, nocardiosis, fungal infection, and botryomycosis.

Laryngeal actinomycosis rarely has been reported in older teenagers.[32] Colonization of the oropharynx with these organisms may be involved in the development of obstructive tonsillar hypertrophy.[39] Several adult cases of pericardial actinomycosis are reported in the literature.[14] Bacteremia is reported in all age groups, including neonates.[6,20,27] Septic arthritis has been reported.[24] Brain abscess has occurred in a child with complex congenital heart disease.[34] Actinomycetes have been isolated from nearly every organ in the body, including the kidneys, brain, heart, breasts, mastoids, male genitourinary tract, and eyes. Osteomyelitis is reported in children, often involving the mandible, but other bones have been infected as well.[43] *A. pyogenes* has been implicated only rarely as a cause of human infection, but cases of septicemia, endocarditis, meningitis, arthritis, empyema, pneumonia, otitis media, cystitis, mastoiditis, appendicitis, and cutaneous infection have been reported.[12,15]

Actinomycosis does not seem to be associated commonly with human immunodeficiency virus infection, perhaps because these patients frequently are in the health care system and have close monitoring. They may be treated for other infections with intermittent antibiotic therapy that also treats subclinical actinomycosis. Thoracic, esophageal, oral, and anal cases have been reported, however, and all immunocompromised hosts

should be monitored closely for this potential group of pathogens.[1,2,35,55]

*A. actinomycetemcomitan*s is a pathogen in at least 30 percent of actinomycotic infections[29] (see Chapter 137). Failure to recognize this organism and treat it adequately has resulted in clinical relapse and deterioration in patients infected with actinomycosis.[31,61] Severe forms of periodontitis, particularly localized aggressive periodontitis, also are associated with this pathogen, and studies have shown that it is related strongly to children in the 10- to 19-year-old age group.[48] It is characterized by loss of attachment of bone around the permanent incisors and permanent molars, which occurs rapidly. Treatment consists of local débridement and antibiotic therapy, usually metronidazole alone or in combination with amoxicillin. *A. actinomycetemcomitan*s also is an important pathogen in Papillon-Lefèvre syndrome, an autosomal recessive disorder characterized by prepubertal periodontitis and palmar-plantar hyperkeratosis.[44] Additionally, it is one of the HACEK (HACEK includes *Haemophilus aphrophilus*, *Cardiobacterium hominis*, *E. corrodens*, and *Kingella kingae*) organisms that have a propensity for infecting heart valves. The endocarditis caused by this organism usually is insidious, with fever occurring in fewer than 50 percent of cases.[29] This organism also has been reported to cause pericarditis, meningitis, brain abscess, parotitis, synovitis, osteomyelitis, urinary tract infection, pneumonia, and empyema.[29] Cases of endophthalmitis[4,57] and cavernous sinus infection also have been reported.[59]

DIAGNOSIS

To establish a definitive diagnosis of actinomycosis, the clinician must isolate the causative organism from tissue or pus from a normally sterile body site, such as the lungs. Isolation of the organism from the oral cavity or the female genital tract without clinical evidence of disease, therefore, is not diagnostic. Because the organisms that cause actinomycosis are exquisitely sensitive to antibiotics, clinical specimens must be obtained before initiating their use. The specimens should be processed carefully to maintain anaerobic conditions. They should undergo routine Gram stain, which will reveal gram-positive rods that are not acid-fast and appear in diphtheroidal arrangements with or without branching.[16] Gram stain is more sensitive than is culture, particularly if the patient has been given antibiotics. Immunofluorescence is available for confirmation of organisms in biopsy specimens with suggestive Gram stains. Growth on media usually appears within 5 to 7 days but may take 2 to 4 weeks.[45] 16S rDNA sequencing and 16S rDNA–based nested polymerase chain reaction have been used in some research laboratories for precise species identification.[42,49,52]

True microbiologic identification of these organisms occurs uncommonly, and the diagnosis most often rests on the clinical picture, along with identification of the characteristic sulfur granules. The sulfur granules may be found by drawing pus from a lesion, on the bandage covering the lesion, or in surgical specimens (see Fig. 161–2). Pus that is poured down the side of a glass will leave sulfur granules adhering to the sides so that the granules can be identified more easily. On hematoxylin and eosin stain, the granules are eosinophilic or variably surrounded by a radiating fringe of eosinophilic clubs. The formation of granules is a hallmark of actinomycosis and is related to a bacterial secretion that cements elements of *Actinomyces* spp. together. However, the formation of granules related to various nonfilamentous bacteria such as *Staphylococcus aureus* or *Pseudomonas* spp. is called *botryomycosis* or *bacterial pseudomycosis*, and they can look grossly similar to the typical sulfur granules of actinomycosis.[10] Washed, crushed actinomycotic granules or well-mixed pus in the absence of granules is cultured on a rich medium, such as brain-heart infusion blood agar, and incubated anaerobically and aerobically with added carbon dioxide. Plates can be examined at 24 hours and after 5 to 7 days for the characteristic colonies of *Actinomyces* spp.[16] Currently, no skin tests are available for screening purposes, and no useful serologic tests are available for actinomycosis.

Various imaging modalities have been useful in diagnosing and characterizing actinomycosis. Computed tomography has been shown to help differentiate between inflammatory masses and tumors. Additionally, the location, extension, and relationship between the mass and surrounding structures can be defined better. Ultrasonography has been shown in one report to reveal a mass with an ill-defined margin that was hypoechoic with intrinsic hyperechoic spots.[47] Magnetic resonance imaging has been used for diagnosing actinomycotic brain abscess, as well as actinomycosis of the chest, spine, soft tissues, and mandible.[23,34,43]

A. actinomycetemcomitans can be cultured on blood and chocolate agar but grows poorly on MacConkey agar. Cultures require incubation in an enhanced carbon dioxide atmosphere. Growth of the organism in a blood culture may take as long as 9 days in patients with endocarditis, and thus cultures should be held longer. On Gram stain, the organism appears coccoid to coccobacillary. Molecular techniques based on nonamplification nucleic acid probes or on polymerase chain reaction can provide rapid and accurate identification of *A. actinomycetemcomitans*.[25] Because of the frequency of co-infection with this organism in cases of actinomycosis, attempts always should be made to isolate this organism in these patients.

TREATMENT

The mainstays of therapy for actinomycosis remain surgical débridement or removal of the lesion and prolonged antimicrobial therapy. Most experts still recommend drainage of abscesses, fistulotomy, sinus tract excision, and debulking of large masses, although numerous successful outcomes with antimicrobial therapy alone are reported in the literature.[30,45] The option to treat medically and observe for clinical response seems reasonable in a stable, noncritical patient. The antibiotic of choice is penicillin. The recommended total duration of therapy ranges from 6 to 12 months. For patients who are allergic to penicillin, tetracycline or erythromycin is acceptable. Other alternatives are clindamycin, chloramphenicol, and the third-generation cephalosporins. Susceptibility breakpoints for linezolid, imipenem, meropenem, or piperacillin/tazobactam have not been established, but the minimal inhibitory concentrations appear favorable.[17,52] Most isolates are clearly resistant to ciprofloxacin and metronidazole.[17,52] Administration of daily ceftriaxone for 3 weeks followed by prolonged administration of ampicillin was effective treatment in one case.[53] Thoracic actinomycosis has been treated successfully with a total duration of therapy of only 4 months.[50] Failure to respond to adequate treatment has been noted in patients with underlying malignancy. Because the disease is an uncommon occurrence in children and no significant randomized prospective treatment trials have been performed, most authors still recommend 4 to 6 weeks of intravenous therapy followed by oral therapy for a prolonged period. The total duration of therapy is based on clinical and radiographic follow-up. Numerous cases of actinomycosis in various forms that have been treated successfully with a total duration of 3 to 6 months of therapy are reported in the literature. Osteomyelitis may require longer therapy.[43] Certainly in cases for which surgical débridement or incision and drainage have been performed, a shorter duration of therapy would be reasonable provided that close clinical follow-up can be ensured.

A. actinomycetemcomitans is susceptible to the newer cephalosporins, rifampin, trimethoprim-sulfamethoxazole, aminoglyco-

sides, quinolones, tetracycline, azithromycin, and chloramphenicol. It also is susceptible to penicillin and ampicillin in vitro, but test results do not necessarily correlate with clinical outcome. Vancomycin, erythromycin, and clindamycin have very little activity against this organism. Treatment of aggressive periodontal disease consists of local débridement and antibiotic therapy. Metronidazole and amoxicillin appear to be effective in suppressing *A. actinomycetemcomitans* to below the level of detection.[11] Endocarditis caused by this organism has been treated successfully with a combination of ampicillin and gentamicin.[36] Cefotaxime or ceftriaxone also is acceptable.

CHAPTER 162

Other Anaerobic Infections

Steven C. Buckingham

In 1680, Antoni van Leeuwenhoek demonstrated the presence of microorganisms in an environment deprived of oxygen.[59] In hindsight, this observation seems tremendously important, but its significance must have eluded both van Leeuwenhoek and his contemporaries. It was not until 1857 that Louis Pasteur, while studying causes of beer and wine spoilage, proved that bacteria are responsible for the fermentation of sugars and that "fermentation is the consequence of life without air." Pasteur's observations brought down the theory of spontaneous generation and inaugurated the discipline of microbiology.[119]

Anaerobic bacteria constitute a significant portion of the normal flora of humans, beginning in the neonatal period. Moreover, anaerobic bacteria cause infections of many different body sites in children, although their importance as pediatric pathogens historically has been underappreciated. Many anaerobic infections in children never are diagnosed as such because clinicians fail to use appropriate methods for collection or transportation of specimens or because laboratories fail to use appropriate methods for isolation and identification of anaerobes.[38]

BACTERIOLOGY AND TAXONOMY

All bacteria can be divided into groups based on their tolerance of or requirement for free oxygen.[113]

- *Obligate aerobes* require molecular oxygen as a terminal electron acceptor and do not obtain energy through fermentation pathways.
- *Obligate anaerobes* obtain energy via fermentation and use organic compounds as terminal electron acceptors; free oxygen is toxic to these bacteria. These anaerobes may be further subdivided:
  - *Strict obligate anaerobes* cannot survive in an atmosphere containing more than 0.5 percent oxygen.
  - *Moderate obligate anaerobes* can grow in the presence of 2 to 8 percent oxygen (and constitute the majority of clinically important obligate anaerobes).
- *Facultative anaerobes* (e.g., *Staphylococcus aureus*) can grow in either the presence or absence of oxygen; they simply resort to fermentation when oxygen is not available.
- *Microaerophiles* (e.g., *Campylobacter jejuni*) require oxygen as a terminal electron acceptor but can grow only in an atmosphere containing less than 21 percent oxygen.

Why oxygen is toxic to anaerobic bacteria is not entirely clear, but in some species this toxicity is explained, at least partly, by the absence of catalase, superoxide dismutase, or peroxidase.[113]

The scope of this chapter is confined to a discussion of clinically important, obligately anaerobic bacteria that are not discussed principally in Chapters 158 to 161. Some of the most clinically important obligate anaerobes are listed in Table 162–1 and discussed in the following text.

SPORE-FORMING, GRAM-POSITIVE BACILLI

Anaerobic spore-forming, gram-positive bacilli are members of the genus *Clostridium*. These organisms and their invasive and toxin-mediated diseases are discussed in Chapters 158, 159, and 160.

NON–SPORE-FORMING, GRAM-POSITIVE BACILLI

Actinomyces spp. normally colonize the human gastrointestinal tract. Many new species have been described in recent years, and several former *Actinomyces* spp. have been reclassified in other genera.[90] These organisms and their associated diseases are discussed in Chapter 161.

Propionibacterium spp. are part of the normal flora of human skin and mucosal surfaces.[90] *Propionibacterium acnes* is the most clinically important member of the genus; others include *Propionibacterium avidum*, *Propionibacterium granulosum*, and *Propionibacterium propionicum* (formerly *Arachnia propionica*[112]). A former member of the genus, *Propionibacterium innocuum*, has been reclassified as *Propioniferax innocua*.[121] *P. acnes* is the dominant constituent of normal flora in pilosebaceous follicles[95]; is thought to play a role in the pathogenesis of acne vulgaris; and may contribute to pathogenesis of the synovitis, acne, pustulosis, hyperostosis and osteitis (SAPHO) syndrome and, more speculatively,

TABLE 162–1 Anaerobic Bacteria of Clinical Importance

Gram-Positive	
Spore-forming bacilli	*Clostridium* species

Cocci	*Veillonella* species

the pathogenesis of sarcoidosis.[95] *P. granulosum* colonizes oily skin areas, albeit in lower concentrations than *P. acnes* does, whereas *P. avidum* is found only on moist surfaces such as the rectum, axillae, and nares.[87] *P. acnes*, *P. avidum*, and *P. granulosum* can cause infections in patients compromised by recent surgery, trauma, or implanted devices (e.g., prosthetic heart valves and cerebrospinal fluid shunts) but are isolated more commonly in the clinical laboratory as culture contaminants.[38,107] *P. propionicum* has been associated with apical periodontitis[54] and with lacrimal duct infections.[14] *Propionibacterium* spp. uniformly are resistant to metronidazole but susceptible to most other classes of antibiotics.[91,104]

Eubacterium is a genus that previously included numerous gram-positive, obligately anaerobic bacteria of questionable taxonomic position. Many of these species were reassigned recently to newly formed genera, including *Cryptobacterium*, *Mogibacterium*, *Bulleida*, *Collinsella*, *Atopobium*, *Slackia*, *Eggerthella*, *Holdemania*, *Catenibacterium*, and *Actinobaculum*; collectively, they may be termed *Eubacterium*-like genera.[90] *Eubacterium lentum*, the most frequently recovered *Eubacterium*-like organism, has been renamed *Eggerthella lenta*.[77] The *Eubacterium*-like bacteria are normal inhabitants of the mouth and intestines of humans and animals and are associated with periodontal disease in adults.[90] *Eubacterium*-like organisms have been recovered from children with abscesses or peritonitis[35]; rarely, they cause bacteremia in neonates[24] and meningitis in children.[40] In one study, only 1 of 10 *Eubacterium*-like bacterial isolates was susceptible to penicillin, and only 3 of 10 were susceptible to ceftriaxone, but all 10 isolates were susceptible to amoxicillin-clavulanate, clindamycin, meropenem, and metronidazole.[104]

Bifidobacterium spp. are predominantly commensal bacteria residing in the intestinal tracts of humans and animals. These organisms rarely are pathogenic; in fact, *Bifidobacterium longum*, *Bifidobacterium breve*, *Bifidobacterium infantis*, and *Bifidobacterium lactis* Bb12 have been included in putatively health-promoting probiotic mixes, some of which show efficacy in the prevention and treatment of infectious diarrhea and inflammatory bowel disease.[12] The pediatric infections most frequently associated with *Bifidobacterium* spp. are chronic otitis media, abscesses, and peritonitis.[35] *Bifidobacterium* spp. are susceptible to penicillin, cefoxitin, and vancomycin; isolates with resistance to tetracycline, erythromycin, clindamycin, or metronidazole have been reported.[57,86]

Lactobacillus spp. are slender, parallel-sided, gram-positive rods that do not produce catalase. As of this writing, more than 150 named species and subspecies are recognized.[60] Most clinical isolates are microaerophilic, although some are obligately anaerobic. Species-level identification of *Lactobacillus* spp. is quite difficult, and commercial identification methods can give inaccurate results.[90] These organisms normally are found in the mouth, intestinal tract, and vagina of mammals, and they can be recovered from numerous food products.[90] Lactobacilli generally possess low pathogenic potential, and, in fact, some species show promise as health-promoting probiotics. In compromised hosts, however, these organisms can, on rare occasion, cause serious disease, as illustrated by cases of probiotic-associated *Lactobacillus* bacteremia and endocarditis in adults and children.[12] In children, *Lactobacillus* spp. usually are associated with abscesses, aspiration pneumonia, and bacteremia.[35] Essentially all lactobacilli are susceptible to penicillin, chloramphenicol, and imipenem and are resistant to metronidazole; susceptibility to vancomycin, erythromycin, tetracycline, and cefoxitin varies among species.[57]

Mobiluncus spp. are found in the reproductive tract and rectum of primates and are recovered primarily from women with bacterial vaginosis.[90] *Mobiluncus* spp. have not been associated with disease in prepubertal children.

GRAM-POSITIVE COCCI

The taxonomy of the anaerobic gram-positive cocci has been revised extensively in recent years. Many species assigned to the formerly populous, if loosely defined genera *Peptococcus* and *Peptostreptococcus* have been reassigned to extant or newly formed genera, including *Anaerococcus*, *Finegoldia*, *Gallicola*, *Micromonas*, *Peptoniphilus*, and *Slackia*.[90] As of this writing, the only remaining members of the original genera are the type species *Peptococcus niger* and *Peptostreptococcus anaerobius*.[60,92] The genus *Streptococcus* includes numerous microaerophilic species, but only *Streptococcus pleomorphus* is obligately anaerobic (now that two former *Streptococcus* spp. have been reclassified as *Ruminococcus hansenii* and *Atobopium parvulum*).[60,90]

Anaerobic gram-positive cocci are normal inhabitants of the human mouth and upper respiratory tract, gastrointestinal tract, urogenital tract, and skin. They are associated with a variety of infections, including pelvic inflammatory disease, tubo-ovarian abscesses, chronic sinusitis, chronic otitis media, aspiration pneumonia, and peritonitis.[29,90] The obligately anaerobic gram-positive cocci most commonly recovered from clinical specimens are *Finegoldia magna*, *P. anaerobius*, and *Peptoniphilus asaccharolytica*.[90] Microaerophilic streptococci, though not strict anaerobes, are clinically important causes of chronic sinusitis and brain abscesses.[27]

Anaerobic gram-positive cocci usually are susceptible to penicillin, amoxicillin-clavulanate, clindamycin, metronidazole, and carbapenems.[1,78] As is true of their aerobic counterparts, some macrolide-resistant anaerobic gram-positive cocci express inducible resistance to clindamycin.[102]

GRAM-NEGATIVE BACILLI

Bacteroides spp. are the anaerobic bacteria most frequently recovered from clinical specimens. Traditionally, the most clinically important of these bacteria have been collectively classified as the *Bacteroides fragilis* group, which consists of *Bacteroides fragilis*, *Bacteroides distasonis*, *Bacteroides ovatus*, *Bacteroides thetaiotaomicron*, *Bacteroides vulgatus*, and others. Taxonomic revisions based on nucleic acid analysis, however, have thrown matters into confusion. For example, *B. distasonis*, *Bacteroides goldsteinii*, and *Bacteroides merdae* have been reclassified under the genus *Parabacteroides*, and *Bacteroides forsythus* has been reclassified as *Tannerella forsythensis*.[106] In any event, *Bacteroides* spp. and closely related taxa constitute much of the normal human colonic flora and also form part of the normal flora of the female genital tract. These organisms frequently are found in intra-abdominal infections and especially abscesses and occasionally in extra-abdominal infections such as aspiration pneumonia, chronic otitis media, and brain abscess.[65,76] Most *Bacteroides* isolates produce β-lactamases that confer resistance to penicillin and third-generation cephalosporins. Resistance to metronidazole has been reported but is an extremely rare event (Table 162–2).[76,110]

Bacteroides ureolyticus, *Campylobacter gracilis*, *Campylobacter curvus*, *Campylobacter rectus*, and *Sutterella wadsworthensis* are closely related bacteria of the family Campylobacteraceae[76,118] and are normal inhabitants of the oral cavity and intestinal tract. The anaerobic *Campylobacter* spp. are associated with oral and periodontal infections. *Sutterella* spp. are associated predominantly with intra-abdominal infections (perhaps because of their bile resistance), and *B. ureolyticus* has been associated with infections at several body sites.[76] Of the anaerobic gram-negative bacilli, *Suterella* spp. are the ones most frequently resistant to metronidazole (Table 162–2).

Prevotella spp. are pigmented (e.g., *Prevotella corporis*, *Prevotella denticola*, *Prevotella intermedia*, *Prevotella loeschii*, *Prevotella mela-*

TABLE 162–2 Percentages of Clinically Important Anaerobes Susceptible to Anti-anaerobic Drugs in Recent Reports*

Organism	Penicillin G	Amoxicillin-Clavulanate	Cefoxitin	Ceftriaxone	Clindamycin	Meropenem	Metronidazole

†Excluding Clostridium difficile.

ninogenica, and *Prevotella nigrescens*) or nonpigmented (e.g., *Prevotella bivia*, *Prevotella disiens*, *Prevotella oris*, *Prevotella buccae*, and *Prevotella heparinolytica*) saccharolytic bacteria that once were classified under the genus *Bacteroides*. For the most part, these organisms are normal flora of the human oral cavity, and some are normally found in the urogenital and intestinal tracts. *P. bivia* and *P. disiens* are associated particularly with genital tract infections in women.[76] In children, the *Prevotella* spp. most often recovered from clinical specimens are *P. melaninogenica*, *P. intermedia*, *Prevotella oralis*, *P. oris*, and *P. buccae*, and the infections most frequently associated with these organisms are abscesses (especially peritonsillar, retropharyngeal, pilonidal, and dental), aspiration pneumonia, chronic otitis media, and peritonitis.[31] *Prevotella* spp. generally are resistant to penicillin but otherwise are more susceptible to antibiotics than *Bacteroides* spp. are (see Table 162–2).

Porphyromonas spp. are pigmented or nonpigmented gram-negative bacteria that like *Prevotella* spp. were formerly classified as *Bacteroides* spp. Unlike *Prevotella* spp., *Porphyromonas* spp. are asaccharolytic or only weekly saccharolytic. *Porphyromonas* spp. are less likely than *Prevotella* spp. to produce β-lactamase.[76] With regard to their environmental niche and spectrum of disease in children, however, *Porphyromonas* spp. are quite similar to *Prevotella* spp.[31] *Porphyromonas gingivalis* and *Porphyromonas endodontalis* are particularly associated with odontogenic infections.[65]

Fusobacterium spp. are nonmotile anaerobic gram-negative rods that produce butyric acid. The type species, *Fusobacterium nucleatum*, is the one recovered most frequently from clinical specimens.[11] This organism is part of the normal flora of the mouth and upper respiratory, genital, and gastrointestinal tracts and is associated with a range of pediatric infections similar to those of *Prevotella* and *Porphyromonas* spp.[26,76] The virulent pathogen *Fusobacterium necrophorum* is isolated frequently from peritonsillar abscesses and may cause Lemierre disease (postanginal sepsis; see later). *F. nucleatum* and *F. necrophorum* usually are susceptible to penicillin and clindamycin; resistance is more prevalent among the *Fusobacterium mortiferum/Fusobacterium varium* group.[1,76,117] Fusobacteria inherently are resistant to erythromycin, but azithromycin is active against most strains in vitro.[69,76]

Bilophila wadsworthia is the lone species of its genus. This fastidious, bile-resistant resident of the normal bowel flora often is present in intra-abdominal abscesses, including those associated with ruptured appendices.[76] More than 50 percent of isolates produce β-lactamase, but resistance to anti-anaerobic agents is a rare finding.[76,89]

Selenomonas spp. and *Leptotrichia* spp. are normal inhabitants of the oral cavity and are associated with periodontal disease in children and adults. *Leptotrichia* spp. have been isolated in blood cultures from neonates[72] and from adolescent cancer patients with chemotherapy-induced neutropenia.[100] *Leptotrichia* spp. are resistant to aminoglycosides and erythromycin.[66]

The motile bacteria of the genera *Butyrivibrio*, *Succinivibrio*, and *Desulfovibrio* are normal inhabitants of the human intestinal tract that on occasion are associated with intra-abdominal infections in compromised adults. *Desulfovibrio* spp. were isolated from an appendiceal abscess in a 3-year-old girl.[82] *Anaerobiospirillum* spp., which are normal intestinal flora of dogs and cats, rarely cause bacteremia and, possibly, diarrheal illnesses in compromised adults.[88] *Anaerobiospirillum* spp. have been isolated from the feces of several children with gastroenteritis[84,85] and from the blood of a previously healthy 11-month-old girl.[105]

GRAM-NEGATIVE COCCI

The three genera of anaerobic gram-negative cocci, *Acidaminococcus*, *Megasphaera*, and *Veillonella*, are normal fecal flora that rarely cause disease in humans. *Veillonella* spp. also are part of the normal oral flora. In children, *Veillonella* spp. occasionally have been associated with abscesses, aspiration pneumonia, and chronic sinusitis.[36]

With the exception of a single described isolate of β-lactamase–producing *Acidaminococcus fermentans*, strains of *Acidaminococcus* and *Megasphaera* are susceptible to penicillin and to cephalosporins.[67] Although *Veillonella* spp. do not produce β-lactamase, they commonly are resistant to penicillin, perhaps because of alterations in penicillin-binding proteins.[94] *Veillonella* spp. nonetheless remain susceptible to ampicillin, amoxicillin-clavulanate, cefoxitin, and third-generation cephalosporins.[101,104]

EPIDEMIOLOGY

Both aerobic and anaerobic bacteria normally colonize the skin and mucosal surfaces of humans. In the oral cavity, gastrointestinal tract, and female genital tract, anaerobes vastly outnumber aerobes; in the colon, where hundreds of different anaerobic species are found, anaerobes constitute 99.9 percent of all bacteria.[38]

The predominance of anaerobes among the normal microbial flora stands in stark contrast to the rarity of human infections caused by these organisms. However, several types of infections routinely involve anaerobic bacteria, such as odontogenic infections, human and animal bite–associated infections, aspiration pneumonia, peritonitis in the presence of a ruptured viscus,

amnionitis, endometritis, necrotizing infections of soft tissues, and abscesses of the brain, lung, tubo-ovarian tract, and perirectal area. Underlying conditions that predispose patients to anaerobic infections include trauma, foreign bodies, malignancy, recent surgery, shock, colitis, vascular disease, and current or recent infection with aerobic or facultative organisms.[38] Anaerobic infections occur less frequently in children than in adults, probably because children are less likely than are adults to have these types of infections or predisposing conditions.

PATHOGENESIS

Anaerobic infections usually arise either because mucosal surfaces become disrupted, thereby allowing anaerobic bacteria access to normally sterile tissues, or because anaerobes are directly inoculated into such tissues, as occurs with traumatic or bite wounds. Distinguishing characteristics of anaerobic infections include suppuration, abscess formation, tissue destruction, foul odor, and occasionally, formation of gas.

The pathogenesis of anaerobic infections reflects a complex interaction among bacterial virulence factors, host defense mechanisms, and synergy with other organisms. Virulence factors that have been described in various anaerobic bacteria include adherence factors, capsular polysaccharide, lipopolysaccharide, leukotoxins, immunoglobulin proteases, collagenases, trypsin-like proteases, and chemotaxis-inhibiting factors. Moreover, enterotoxin-producing *B. fragilis* isolates have been identified in livestock and humans.[74]

Anaerobic infections typically are polymicrobial and often involve multiple species of both aerobic and anaerobic flora. Experiments in mice demonstrated that although the growth of both aerobes and anaerobes is enhanced in mixed infections, enhancement of the growth of aerobes is by far more pronounced. The factors responsible for aerobic-anaerobic synergism are not fully elucidated. Some have postulated that the bacterial species involved assist one another by providing essential growth factors, interfering with phagocytic uptake and killing, secreting β-lactamase into the extracellular milieu, or altering the oxidation-reduction potential of infected tissue.[21]

CLINICAL INFECTIONS

Serious anaerobic infections are seen more frequently in compromised hosts or in newborn infants than in otherwise healthy children. Outcomes of severe anaerobic infections are tied to patients' underlying disease states and to the promptness with which appropriate antimicrobial therapy is initiated.

BACTEREMIA

Anaerobic bacteremia is a rare occurrence in children; two separate pediatric studies found that only 0.3 percent of processed blood cultures yielded anaerobic bacteria that could be implicated as pathogens.[61,114] When anaerobic bacteremia does occur, it usually arises from a primary focal anaerobic or mixed aerobic-anaerobic infection. Children at risk for developing anaerobic bacteremia are those compromised by conditions such as recent surgery (especially procedures involving the gastrointestinal tract), necrotizing enterocolitis, dental manipulation, malignancy (patients with leukemia are at particularly high risk for severe clostridial sepsis),[51] immunosuppression, neonatal status (especially if premature), asplenia (including sickle-cell disease), and infectious mononucleosis.[41] The etiologic agents vary depending on the entry portal: in the gastrointestinal tract, *Bacteroides* spp. and *Clostridium* spp. predominate; in the head or neck, anaerobic gram-positive cocci and *Fusobacterium* spp. are more likely to be found.[16] Anaerobic bacteremia in patients with lower respiratory tract infections usually is caused by *B. fragilis* group members.[16] *P. acnes* is a well-recognized cause of bacteremia in patients with indwelling vascular devices; however, it is much more likely to be a contaminant than a true pathogen when isolated from previously healthy patients.[61,114]

Anaerobic bacteremia occurs more commonly in neonates than in older children; in one study, anaerobes accounted for 29 of 1290 (2.2%) bacterial isolates from newborns.[93] Factors predisposing to the development of anaerobic bacteremia in neonates include perinatal maternal complications (e.g., premature rupture of membranes), prematurity, and necrotizing enterocolitis.[28] The anaerobes most frequently isolated from neonatal blood cultures are *Bacteroides* spp., *Clostridium* spp., and anaerobic gram-positive cocci.[28] Reported mortality rates among neonates with anaerobic bacteremia range from 4 to 38 percent,[55,61] and mortality rates are higher with *Bacteroides* spp. (34%) than with other anaerobic species (17%).[28]

HEAD AND NECK INFECTION

Anaerobes frequently are involved in odontogenic infections such as periodontitis, periapical and dental abscesses, gingivitis, and Vincent angina. They also are recovered occasionally from suppurative perioral infections such as retropharyngeal and peritonsillar abscesses, cervical lymphadenitis, deep neck abscesses, parotitis, thyroiditis, infected epidermal cysts, and wound infections after head and neck surgery.[38] The anaerobes most commonly recovered from such infections are *Prevotella* spp., *Porphyromonas* spp., *Bacteroides* spp., *Fusobacterium* spp., and gram-positive cocci. In one study of peritonsillar abscesses, anaerobic bacteria were isolated from all 16 children in whom aspiration was performed.[18] A dreaded complication of peritonsillar abscess is Lemierre disease, which is characterized by *F. necrophorum* bacteremia; jugular vein septic thrombophlebitis; metastatic abscesses of the lung, liver, or elsewhere; and a foul-smelling tonsillar pseudomembrane.[75,76]

In patients with chronic otitis media, the bacteria isolated most frequently from middle ear cultures are *S. aureus*, *Pseudomonas aeruginosa*, and anaerobes. Approximately 50 percent of cultures yield anaerobic bacteria when appropriate culture techniques are used. The anaerobic flora most often implicated in these infections are anaerobic gram-positive cocci, pigmented *Prevotella* and *Porphyromonas* spp., *Bacteroides* spp., and *Fusobacterium* spp.[38,49]

Anaerobes also may play a role in the pathogenesis of acute otitis media. In one study, anaerobes (most commonly *Propionibacterium* spp., anaerobic gram-positive cocci, or both) were isolated from the middle ear fluid of 27 percent of children undergoing tympanocentesis for this disease.[45]

Anaerobes are associated only rarely with acute bacterial rhinosinusitis (i.e., symptoms for 10 to 30 days),[109,115] but they frequently are implicated as pathogens in children with chronic sinusitis (i.e., symptoms for >30 days). In one study, sinus aspirate cultures from 37 children with chronic sinusitis yielded an average of 2.7 anaerobes and 0.6 aerobes per patient. The anaerobes associated with chronic sinusitis are similar to those found in chronic otitis media; microaerophilic streptococci also are recovered occasionally.[43]

CENTRAL NERVOUS SYSTEM

Anaerobes can be isolated from most intracranial abscesses that are associated with sinusitis, otitis media, or dental infections. In one study, cultures of brain abscess specimens from 23 children yielded 11 aerobic and 44 anaerobic isolates, and cultures of

subdural empyema fluid from 16 children yielded six aerobic and 35 anaerobic isolates. In both brain abscess and subdural empyema, the anaerobes most frequently recovered are gram-positive cocci, *Fusobacterium* spp. (especially *F. nucleatum*), *Prevotella* spp., and *Bacteroides* spp.[25] These same organisms have been isolated, alone or along with aerobes, from epidural abscesses found in patients (primarily boys aged 10 to 14 years) with frontal sinusitis and Pott puffy tumor.[6,7,64] *B. fragilis* group members are associated particularly with temporal lobe abscesses arising from chronic otitis media.[5]

Anaerobic meningitis, in the absence of an associated brain abscess, occurs rarely in children. The symptoms, signs, and laboratory characteristics of children with anaerobic meningitis are similar to those of children with meningitis caused by more common bacterial pathogens. Unlike most anaerobic infections, meningitis usually is monomicrobial. The anaerobes most frequently recovered from cerebrospinal fluid cultures are *Bacteroides* spp. (especially *B. fragilis*), *Fusobacterium* spp. (especially *F. necrophorum*), and *Clostridium* spp. (especially *Clostridium perfringens*).[40] Meningitis caused by *Bacteroides* spp. generally occurs as a complication of a preceding anaerobic infection of the oropharynx or lower respiratory tract or an underlying gastrointestinal insult (e.g., recent surgery or necrotizing enterocolitis). Meningitis caused by *F. necrophorum* in children usually is associated with an otogenic focus. Most cases of *C. perfringens* meningitis in children occur after cranial trauma or surgery; a third of such infections are fatal despite administration of appropriate antimicrobial therapy.[40] *P. acnes* has been reported to cause 1.6 percent of pediatric cerebrospinal fluid shunt infections.[108] Anaerobic gram-positive cocci, *Veillonella* spp., *Actinomyces* spp., and *Eubacterium*-like organisms very rarely cause meningitis.[40]

INTRA-ABDOMINAL INFECTIONS

Secondary peritonitis occurs when the intestinal wall is disrupted (e.g., by perforation of an inflamed appendix or surgical misadventure), and enteric bacteria consequently gain access to the peritoneal cavity. Over the course of time, the peritoneal infection may evolve and result in the formation of one or more intra-abdominal abscesses.[38] Secondary peritonitis and intra-abdominal abscesses almost always are polymicrobial processes; anaerobes are isolated in 88 percent and aerobes in 86 percent of children with these infections.[15] Dozens of species of anaerobic and aerobic bacteria have been isolated from peritoneal or abscess cultures of children with these infections, but the anaerobes recovered most frequently are *B. fragilis*, other *B. fragilis* group members, anaerobic gram-positive cocci, *B. wadsworthia*, *Fusobacterium* spp., *Lactobacillus* spp., and *Clostridium* spp. The aerobes most frequently isolated in these patients are *Escherichia coli*, viridans streptococci, *P. aeruginosa*, and *Enterococcus* spp.[9,15,80]

Traditionally, *S. aureus* has been recognized as the leading cause of liver abscesses in children. When proper anaerobic culture techniques are used, however, anaerobic isolates outnumber aerobes in liver abscess cultures, with anaerobic gram-positive cocci, *Bacteroides* spp., and *Fusobacterium* spp. being recovered most frequently.[47,46,99] Splenic abscesses are associated with a similar range of anaerobic flora.[47] In a study of retroperitoneal abscess cultures in children, the anaerobes most frequently isolated were gram-positive cocci, *Bacteroides* spp., and *Prevotella* spp; the dominant aerobic isolates were *E. coli* and *S. aureus*.[37] One case of a renal abscess caused by *Peptoniphilus asaccharolyticus* in a child has been reported.[50]

Sexually active adolescent girls are at risk for the development of pelvic inflammatory disease and its complications (e.g., tuboovarian abscess). In addition to being caused by aerobic sexually transmitted organisms (e.g., *Chlamydia trachomatis* and *Neisseria gonorrhoeae*), these infections frequently involve anaerobes such as *Prevotella* spp. (especially *P. bivia* and *P. disiens*), *Porphyromonas* spp., anaerobic gram-positive cocci, *Clostridium* spp. (especially *C. perfringens*), and *B. fragilis* group organisms.[38]

SKIN AND SOFT TISSUE INFECTIONS

Cutaneous abscesses in children can be polymicrobial and involve both aerobic and anaerobic bacteria. Aerobes (particularly *S. aureus*) predominate in infections of the hand, neck, leg, and trunk regions, whereas anaerobes are recovered more frequently in infections of the vulvovaginal, buttock, perirectal, finger, nail bed, and head regions.[19] A similar regional distribution of aerobes and anaerobes also occurs in cases of cellulitis.[33] The anaerobes most likely to be recovered from infections near the perirectal area include, not surprisingly, *B. fragilis* group and *Clostridium* spp.; infections closer to the oropharynx usually involve oral flora such as *Prevotella* spp., *Porphyromonas* spp., *Fusobacterium* spp., and anaerobic gram-positive cocci.[38] Both aerobes and anaerobes are isolated from sundry skin infections such as paronychia, infected burn wounds, gastrostomy or tracheostomy site infections, and secondary infections of scabies lesions.[17,30,34,48]

Bacteria of the normal oral flora of humans and animals figure prominently in infected bite wounds. In children with infected human bite wounds, the anaerobes isolated most frequently are anaerobic gram-positive cocci, *Prevotella* spp., and *Porphyromonas* spp.; the aerobes isolated most frequently are *S. aureus* and *Streptococcus* spp. In infected animal bites, the most common anaerobes are gram-positive cocci, *Veillonella* spp., and *Fusobacterium* spp., whereas the most frequent aerobic or facultative organisms are *S. aureus* and *Pasteurella multocida*.[23]

Anaerobes play prominent roles in complicated skin and soft tissue infections. In a study of pilonidal cysts in children, anaerobes were isolated from all children and aerobic organisms from only 32 percent.[44] Crepitant cellulitis is a superficial infection that is associated with less systemic toxicity but more noticeable crepitus than is clostridial myonecrosis; it may be caused by *C. perfringens* or by combinations of other anaerobes with facultative bacteria. Clostridial myonecrosis ("gas gangrene") is a life-threatening infection of the skeletal muscle that usually is caused by *C. perfringens* and less frequently by *Clostridium novyi* or *Clostridium septicum*; it occurs hours to days after gross contamination of deep traumatic or surgical wounds. Necrotizing fasciitis is another dreaded soft tissue infection that can be rapidly progressive. In one type of necrotizing fasciitis, anaerobes such as *Bacteroides* spp. and anaerobic gram-positive cocci frequently are recovered, often in association with various aerobic enteric flora. This type should be distinguished from necrotizing fasciitis caused by *Streptococcus pyogenes* (or, less frequently, by group B, C, or G streptococci), in which anaerobes generally are not involved.[58]

BONE AND JOINT INFECTIONS

Septic arthritis caused by anaerobic bacteria is a rare occurrence in both children and adults and, unlike most anaerobic infections, generally is not polymicrobial. Most cases result from anaerobic bacteremia with gram-negative rods (especially *Fusobacterium* spp. or the *B. fragilis* group) or anaerobic gram-positive cocci. Cases associated with penetrating trauma, however, often are caused by *Clostridium* spp., and those involving recent surgery or prosthetic joints can involve *P. acnes*. In some cases, the presence of anaerobes is suggested by foul-smelling synovial fluid, gas under pressure within the joint, negative synovial fluid cultures in the clinical picture of septic arthritis, or an anaerobic infection elsewhere in the patient.[39]

Anaerobic osteomyelitis also is quite uncommon in children. When it does occur, it results from direct extension from a contiguous focus rather than via hematogenous seeding. In a series of 26 children with culture-proven anaerobic osteomyelitis,[22] all had preexisting anaerobic infections at adjacent sites or other predisposing conditions for anaerobic infection, including chronic mastoiditis (7 patients), decubitus ulcers (5), periodontal abscesses (3), bites (3), paronychia (2), trauma (1), and perinatal scalp infection (1). Culture results reflected those of the underlying anaerobic infection or the normal flora of the nearest mucous membrane surface. All but 2 patients had polymicrobial infections; in 10 patients, aerobic flora also were recovered. In contrast to acute hematogenous osteomyelitis, these cases had an insidious onset; the mean duration of symptoms before initial evaluation was 21 days (range, 7 to 37 days). Three patients with decubitus ulcers had documented recurrences of their osteomyelitis after receiving successful initial treatment.[22]

PLEUROPULMONARY INFECTIONS

Anaerobic infections of the lower respiratory tract are rare occurrences in healthy children. They are, however, relatively common in children with tracheoesophageal malformations or central nervous system abnormalities that impair cough reflexes. Such children are predisposed toward aspirating not only food, milk, and vomitus but also their oropharyngeal secretions. Thus, aspiration pneumonia usually is a polymicrobial process involving both the aerobic and anaerobic flora of the oral cavity. The risk of pneumonia developing is further elevated in children with poor oral hygiene, gingivitis, or periodontitis. If untreated, aspiration pneumonia can progress with the development of single or multiple lung abscess or pleural empyema, or both. The predominant anaerobes recovered from children with aspiration pneumonia are anaerobic gram-positive cocci, pigmented *Prevotella* and *Porphyromonas* spp., *F. nucleatum*, the *B. fragilis* group, and other *Bacteroides* spp.; the predominant aerobic and facultative bacteria are *P. aeruginosa*, *Streptococcus pneumoniae*, *E. coli*, *Klebsiella pneumoniae*, and *S. aureus*.[43]

Anaerobes occasionally are isolated from pleural fluid cultures of patients with pleural empyema. In a study of 104 children with pleural empyema,[63] anaerobes were isolated from five adolescents, in all cases along with other aerobic or anaerobic oral flora. Predisposing conditions in these patients were pneumonia in four and alcohol intoxication in one. Anaerobes might be responsible for at least some of the roughly half of pleural empyema cases in which routine cultures are negative.[63]

Anaerobes occasionally are isolated from lower respiratory tract specimens of adults with ventilator-associated pneumonia, although their pathogenic significance in this setting continues to be debated.[103] In a study of pathogens causing ventilator-associated pneumonia in children, anaerobic bacteria associated with oral flora were recovered from 9 of 10 sputum culture specimens obtained with protective brush catheters, either alone (3 children) or as part of a mixed infection with aerobic bacteria (6 children).[32]

DIAGNOSIS

The diagnosis of anaerobic infections requires a high index of suspicion. A few anaerobic infections are diagnosed clinically (e.g., tetanus, botulism, and gas gangrene), and for these infections, culture results can be misleading. However, most anaerobic infections must be suspected on the basis of the clinical findings and then diagnosed with microbiologic methods. When anaerobic infections are suspected, specimens for culture must be collected without contamination from the endogenous flora of adjacent mucous membranes. In general, acceptable specimens for anaerobic culture include blood; aspirates of normally sterile body fluids, abscesses, or deep wounds; and surgically obtained specimens. Aspirates and tissue are preferable to swabs. Gram-stained smears of aspirated material should be examined and used to complement culture results.

Specimens submitted for anaerobic culture should be transported rapidly to the laboratory in anaerobic transport devices and promptly inoculated into appropriate media in an oxygen-free environment (e.g., anaerobic jar or glove box). Media that support the cultivation of anaerobes are supplemented with reducing substances (e.g., thioglycolate, dithiothreitol, cysteine, iron shavings, or chopped meat) and antibiotics (to suppress the growth of facultative bacteria).[113,96] Even before being inoculated, such media must be prepared and stored under anaerobic conditions to prevent the generation of superoxide or hydrogen peroxide.[96] Attention given to detail is important. In one hospital, improvements in techniques for recovery of anaerobes (i.e., media and transport conditions) and education of clinicians and microbiologists were associated with dramatic reductions in health care costs and mortality rates in patients with anaerobic infections.[8]

Bacterial isolates that grow anaerobically must be tested for aerotolerance to confirm whether they are obligate or facultative anaerobes. This process necessarily lengthens the time to reporting of culture reports to the clinician; however, the morphologic characteristics of certain anaerobes (e.g., *C. perfringens*, *B. fragilis* group, pigmented *Prevotella*, and *Porphyromonas* spp.) are sufficiently distinctive to allow preliminary reporting of presumptive results before aerotolerance testing is performed at least in experienced laboratories.[113] Definitive identification of anaerobic isolates is performed with biochemical tests, gas-liquid chromatography of fermentation reaction products, direct immunofluorescence, molecular genetic methods, or a combination of these methods.[56,79,81,113,116]

TREATMENT

Appropriate management of anaerobic infections is both surgical and medical. As a rule, abscesses should be drained (and their contents sent for routine and anaerobic culture), and débridement of necrotic tissue is critical to survival with severe infections such as clostridial myonecrosis and necrotizing fasciitis. Hyperbaric oxygen also has been used, in addition to débridement and antibiotics, in some children with clostridial myonecrosis and in others with necrotizing fasciitis, but definitive recommendations regarding its use cannot be made based on this limited experience.[38]

Patients with anaerobic infections should receive appropriate antibiotic therapy promptly. In certain infections (e.g., peritonitis with a perforated viscus, brain abscess related to chronic mastoiditis, gas gangrene), the clinician should assume that anaerobes are present and include anaerobic coverage in the antimicrobial regimen. For many anaerobic infections, there is no particular drug of choice, and many antibiotics (alone or in combination) might be reasonable for a given patient. In selecting antimicrobial therapy, the clinician must consider the aerobic and anaerobic flora that probably are involved (which may be predicted, to some extent, by the anatomic site of the infection) and the toxicity, tolerability, tissue penetration, and cost of available antibiotics.

Aminoglycosides, monobactams (e.g., aztreonam), and older fluoroquinolones are poorly active against anaerobes.[42] Other classes of antimicrobial agents vary in their activity against different groups of anaerobic bacteria (see Table 162–2 and the following sections). The duration of antimicrobial therapy for anaerobic infections generally is similar to that for analogous aerobic infections. Serious anaerobic infections should be treated

with intravenous antimicrobial agents at maximum dosages to optimize penetration into devitalized tissue and abscesses.

PENICILLINS AND PENICILLIN/β-LACTAMASE INHIBITOR COMBINATIONS

Penicillin G and ampicillin are active against most anaerobes that do not produce β-lactamase, including anaerobic gram-positive cocci, *C. perfringens*, and most non–spore-forming gram-positive bacilli (except *Eubacterium*-like bacteria). Anaerobic gram-negative bacilli, however, frequently produce β-lactamases that render penicillins ineffective (and in some cases, even third-generation cephalosporins).[42]

Combinations of penicillins with β-lactamase inhibitors achieve broad-spectrum activity against anaerobic and aerobic bacteria. These agents are particularly well suited for the treatment of intra-abdominal infections, in which β-lactamase–producing gram-negative bacilli are uniformly present. Guidelines for the treatment of complicated intra-abdominal infections in adults endorse (among other options) the use of ampicillin-sulbactam and ticarcillin-clavulanate for infections of mild to moderate severity and piperacillin-tazobactam for severe infections.[111] Unfortunately, no similar guideline exists for children. Furthermore, in the United States, piperacillin-tazobactam is not licensed for use in children, and ampicillin-sulbactam is licensed for use only in children older than 1 year.[2] Amoxicillin-clavulanate is active against most anaerobic and aerobic oropharyngeal flora and, thus, is a suitable oral antibiotic for the treatment of many anaerobic infections arising in the head, neck, and chest.

CEPHALOSPORINS

First-generation cephalosporins have anti-anaerobic activity similar to that of penicillin G, and third-generation cephalosporins are only moderately more active. The most active cephalosporins against anaerobes are the second-generation agents cefoxitin, cefotetan, and cefmetazole; of these, cefoxitin is the most active against *B. fragilis* group members.[42] Because of increasing resistance among these organisms, however, cefoxitin no longer is recommended for empiric treatment of intra-abdominal infections,[111] although it remains useful for perioperative antimicrobial prophylaxis in surgical procedures involving the abdomen.[13]

METRONIDAZOLE

Metronidazole has the best activity of any antibiotic against anaerobic gram-negative bacilli (except *Sutterella* spp.), including *B. fragilis* group members that are commonly resistant to other classes of antibiotics. Its activity against gram-positive anaerobes is less reliable, although most anaerobic gram-positive cocci are susceptible. However, *Propionibacterium* spp. and virtually all aerobic bacteria are inherently resistant to metronidazole. Because most anaerobic infections are polymicrobial, metronidazole generally is not used alone but in combination with other antibiotics active against aerobic bacteria (e.g., with a third-generation cephalosporin for the treatment of intra-abdominal infection).

Metronidazole penetrates well into many tissues, including those of the central nervous system, and can be administered orally. Although it generally is tolerated well, reported serious side effects include seizures and peripheral neuropathy. Moreover, the safety and efficacy of metronidazole in children have not been established.[2]

CLINDAMYCIN

Clindamycin is active against many anaerobes, including gram-positive cocci, gram-positive non–spore-forming bacilli, *C. perfringens*, and most anaerobic gram-negative bacilli (Table 162–2). It also is active against most gram-positive aerobes but not against *Enterococcus* spp. or gram-negative aerobes. Clindamycin resistance has increased among the *B. fragilis* group members[73]; thus, clindamycin is now less reliable than are carbapenems, penicillin/β-lactamase inhibitor combinations, or metronidazole against these organisms. As a result, clindamycin presently is better suited for the treatment of infections involving oropharyngeal anaerobes than for those involving intestinal flora.

Clindamycin achieves comparable serum levels whether administered orally or intravenously and penetrates well into most tissues and fluids, including bones, joints, and abscesses.[53] Clindamycin does not penetrate well into cerebrospinal fluid and, hence, should not be used for the treatment of central nervous system infections.[53] For treatment of polymicrobial infections, clindamycin should be combined with a β-lactam or other antibiotic active against aerobic gram-negative bacilli (e.g., *P. multocida* in animal bite wounds or *Eikenella corrodens* in human bite wounds). Although clindamycin traditionally has been associated particularly with *Clostridium difficile*–induced pseudomembranous colitis, many other antibiotics also can induce this complication.

CARBAPENEMS

The carbapenems are parenterally administered β-lactams with broad coverage against both aerobes and anaerobes, including many cephalosporin-resistant, gram-negative enterics. Because of this broad-spectrum activity, carbapenems are well suited for the treatment of intra-abdominal infections (although *Enterococcus faecium* and methicillin-resistant *S. aureus* are inherently resistant). The commercially available carbapenems approved for use in children are meropenem and imipenem-cilastatin; meropenem is the preferred agent in children because it is less likely to induce seizures. Meropenem is slightly more active than is imipenem against gram-negative bacteria; the converse is true for gram-positive bacteria.[83,97]

QUINOLONES

The quinolones most commonly prescribed in the United States are ciprofloxacin, levofloxacin, gatifloxacin, and moxifloxacin. Of these, only the first is licensed for use in children (and then only for the treatment of complicated urinary tract infections or pyelonephritis or for postexposure treatment of inhalational anthrax),[3] whereas only the last three have significant in vitro activity against anaerobes.[4,62,69] Resistance to quinolones has increased recently among *Bacteroides* spp.[10,68]; thus, these agents should not be used as monotherapy for intra-abdominal infections.[111]

Therapeutic advantages of the quinolones include their wide distribution in tissues and fluids and their good absorption after oral administration.[97] The newer quinolones may provide options for treating anaerobic infections in selected children (e.g., older adolescents). Nonetheless, the role of quinolones in pediatrics remains limited because concern lingers over their potential toxicity, because other agents (e.g., meropenem) with established safety profiles have equal or better activity against anaerobes, and because bacterial resistance to quinolones probably will continue to rise (as a result of their continued widespread use in adults).

CHLORAMPHENICOL

Chloramphenicol possesses very good activity against both gram-positive and gram-negative anaerobes, including *B. fragilis* group members. It penetrates well into tissues and is absorbed well after oral administration.[53] Unfortunately, its use is associated rarely with potentially life-threatening blood dyscrasias, so safer alternatives should be used preferentially.

OTHER ANTIBIOTICS

Macrolides (e.g., erythromycin, azithromycin, and clarithromycin) and tetracyclines are inconsistently active against anaerobic bacteria.[53,69] Vancomycin and daptomycin are active against most gram-positive anaerobes except *Lactobacillus* spp., many strains of which are resistant.[70] Linezolid showed impressively good activity against both gram-positive and gram-negative anaerobes (including *B. fragilis* group members) in a recent study; however, more experience with its clinical use for anaerobic infections is needed.[120] Generally speaking, the role of these antibiotics in the treatment of anaerobic infections is limited.

PREVENTION

Other than tetanus, which can be prevented by immunization, anaerobic infections can be avoided only by preventing the introduction of anaerobes into healthy tissues. Preventive measures include cleaning and débriding wounds properly, removing foreign bodies promptly, maintaining good dental and oral hygiene, avoiding disruption of the intestinal wall during surgery, appropriately prescribing perioperative antibiotic prophylaxis,[13] and following recommendations for the prevention of nosocomial pneumonia.[52]

SECTION XVII

Viral Infections

CHAPTER 163

Classification and Nomenclature of Viruses

Marjorie J. Miller

Viruses originally were differentiated from other microorganisms by their small size and their filterability. Initial efforts to classify viruses were based on disease, pathogenesis, organ tropisms, and epidemiologic characteristics rather than on physicochemical properties of the virus particle. During the 1950s and 1960s, many new viruses were being discovered while evidence of virus structure and composition also was emerging, thereby prompting proposals that viruses be grouped on the basis of shared virion properties. The herpesvirus,[1] myxovirus,[2] and poxvirus[7] groups were among the first taxonomic groups delineated. As more information concerning the physicochemical characteristics of viruses accumulated, the need for a universal system of classification and nomenclature became apparent.

The International Committee on Nomenclature of Viruses (ICNV) was established in 1966 at the International Congress of Microbiology in Moscow, some 20 years after a bacterial taxonomy first was published and 75 years after the discovery of viruses. In 1973, the ICNV became the International Committee on Taxonomy of Viruses (ICTV), which operates under the auspices of the Virology Division of the International Union of Microbiological Societies. The ICTV classifies viruses isolated from vertebrates, invertebrates, plants, fungi, protozoa, bacteria, and mycoplasmas and publishes periodic reports summarizing the most recent developments in viral taxonomy.[4,6,8-10,12,16-18] Interim updates were published in *Intervirology* and more recently in *Archives of Virology*. Additional information on virus taxonomy can be accessed through the Internet at *www.ncbi.nlm.nih.gov* (TaxBrowser drop-down menu) and through a worldwide universal virus database (ICTVdB) being developed through the cooperation of the Australian National University (*http//life.anu.edu.au/viruses/welcome.htm*) in Canberra, the American Type Culture Collection, and the U.S. National Science Foundation (mirror Internet sites are the National Center for Biotechnology Information, Bethesda, MD: *www.ncbi.nlm.nih.gov/ICTVdb*; and the Integrated Approach to Crop Research, Rothamsted, UK: *www.ictvdb.rothamsted.ac.uk/*).

The hierarchic levels of virus taxonomy consist of order, family, subfamily, genus, and species and are based on the structural, physicochemical, biologic, and replicative properties of viruses.[12] Structural characteristics include size, shape, presence or absence of an envelope, and capsid symmetry. Physicochemical characterization is based on type, strandedness, and the number of segments of nucleic acid, as well as the number and size of proteins and their functional activities. Biologic properties include host range, serologic relationships, pathogenicity, and transmission; replicative properties include nucleic acid replication, transcription, and translation.

Virus orders comprise groups of families that share common characteristics (e.g., biochemical composition, viral replication strategy, particle structure, and general genomic organization) distinguishable from those of other orders and families. Virus orders are designated with the suffix *-virales*. Currently, the ICTV has approved two orders, *Mononegavirales*, which comprises the families *Paramyxoviridae*, *Rhabdoviridae*, and *Filoviridae*, and *Nidovirales*, which comprises the families *Coronaviridae* and *Arteriviridae*.

Virus families represent groups of genera that share common characteristics distinct from those of other families. Virus families are designated with the suffix *-viridae*. Most families have unique virion morphology, genome structure, or strategies of replication (Fig. 163–1). Virus subfamilies are designated with the suffix *-virinae* and have been introduced in four families: *Poxviridae* (*Chorodopoxvirinae*), *Herpesviridae* (*Alphaherpesvirinae*, *Betaherpesvirinae*, *Gammaherpesvirinae*), *Parvoviridae* (*Parvovirinae*), and *Paramyxoviridae* (*Paramyxovirinae*, *Pneumovirinae*) (Table 163–1).

Virus genera consist of groups of species that share common characteristics different from those of members of other genera. Common properties within a genus include viral replication strategy, genome size, organization, numbers of segments, sequence homologies, and vector transmission. Virus genera are designated with the suffix *-virus*.

The species taxon is the most fundamental unit in biologic classification, but the viruses have proved to be the most difficult with which to deal, and years elapsed before a definition of virus species was accepted internationally. In 1991, the ICTV accepted the definition of a virus species proposed by van Regenmortel[13]: "A virus species is defined as a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche." Members of a polythetic class have several properties in common, although no single common attribute is present in all members, thereby accommodating the inherent variability of viruses. Common species properties include genome rearrangement, sequence homologies, serologic relationships, vector transmission, host range, pathogenicity, tissue tropism, and geographic distribution.[4,16] Some properties of viruses used in taxonomy are listed in Table 163–2.[12]

The ICTV also has established criteria for formal virus nomenclature[4,16] and recommended abbreviations for virus names.[4,5,16] In formal taxonomic usage, the names of orders, families, subfamilies, genera, and species are printed in italics, and the first letter of the name is capitalized. This form applies when using a species name to refer to a taxonomic category (e.g., in the Materials and Methods section of a paper when describing the particular virus used in the study). Some examples of formal taxonomic terminology are *Poliovirus*, genus *Enterovirus*, family *Picornaviridae* or *Human herpesvirus 1* (herpes simplex virus type 1) and genus *Simplexvirus*, subfamily *Alphaherpesvirinae*, family *Herpesviridae*. Thereafter, vernacular names can be used throughout the publication. In informal vernacular usage when referring to virions or virus particles or if used as an adjective, italics and capital initial letters are not required and the names are written in lowercase Roman script (e.g., "poliovirus cytopathic effect" or "picornaviruses/polioviruses were inoculated into cell

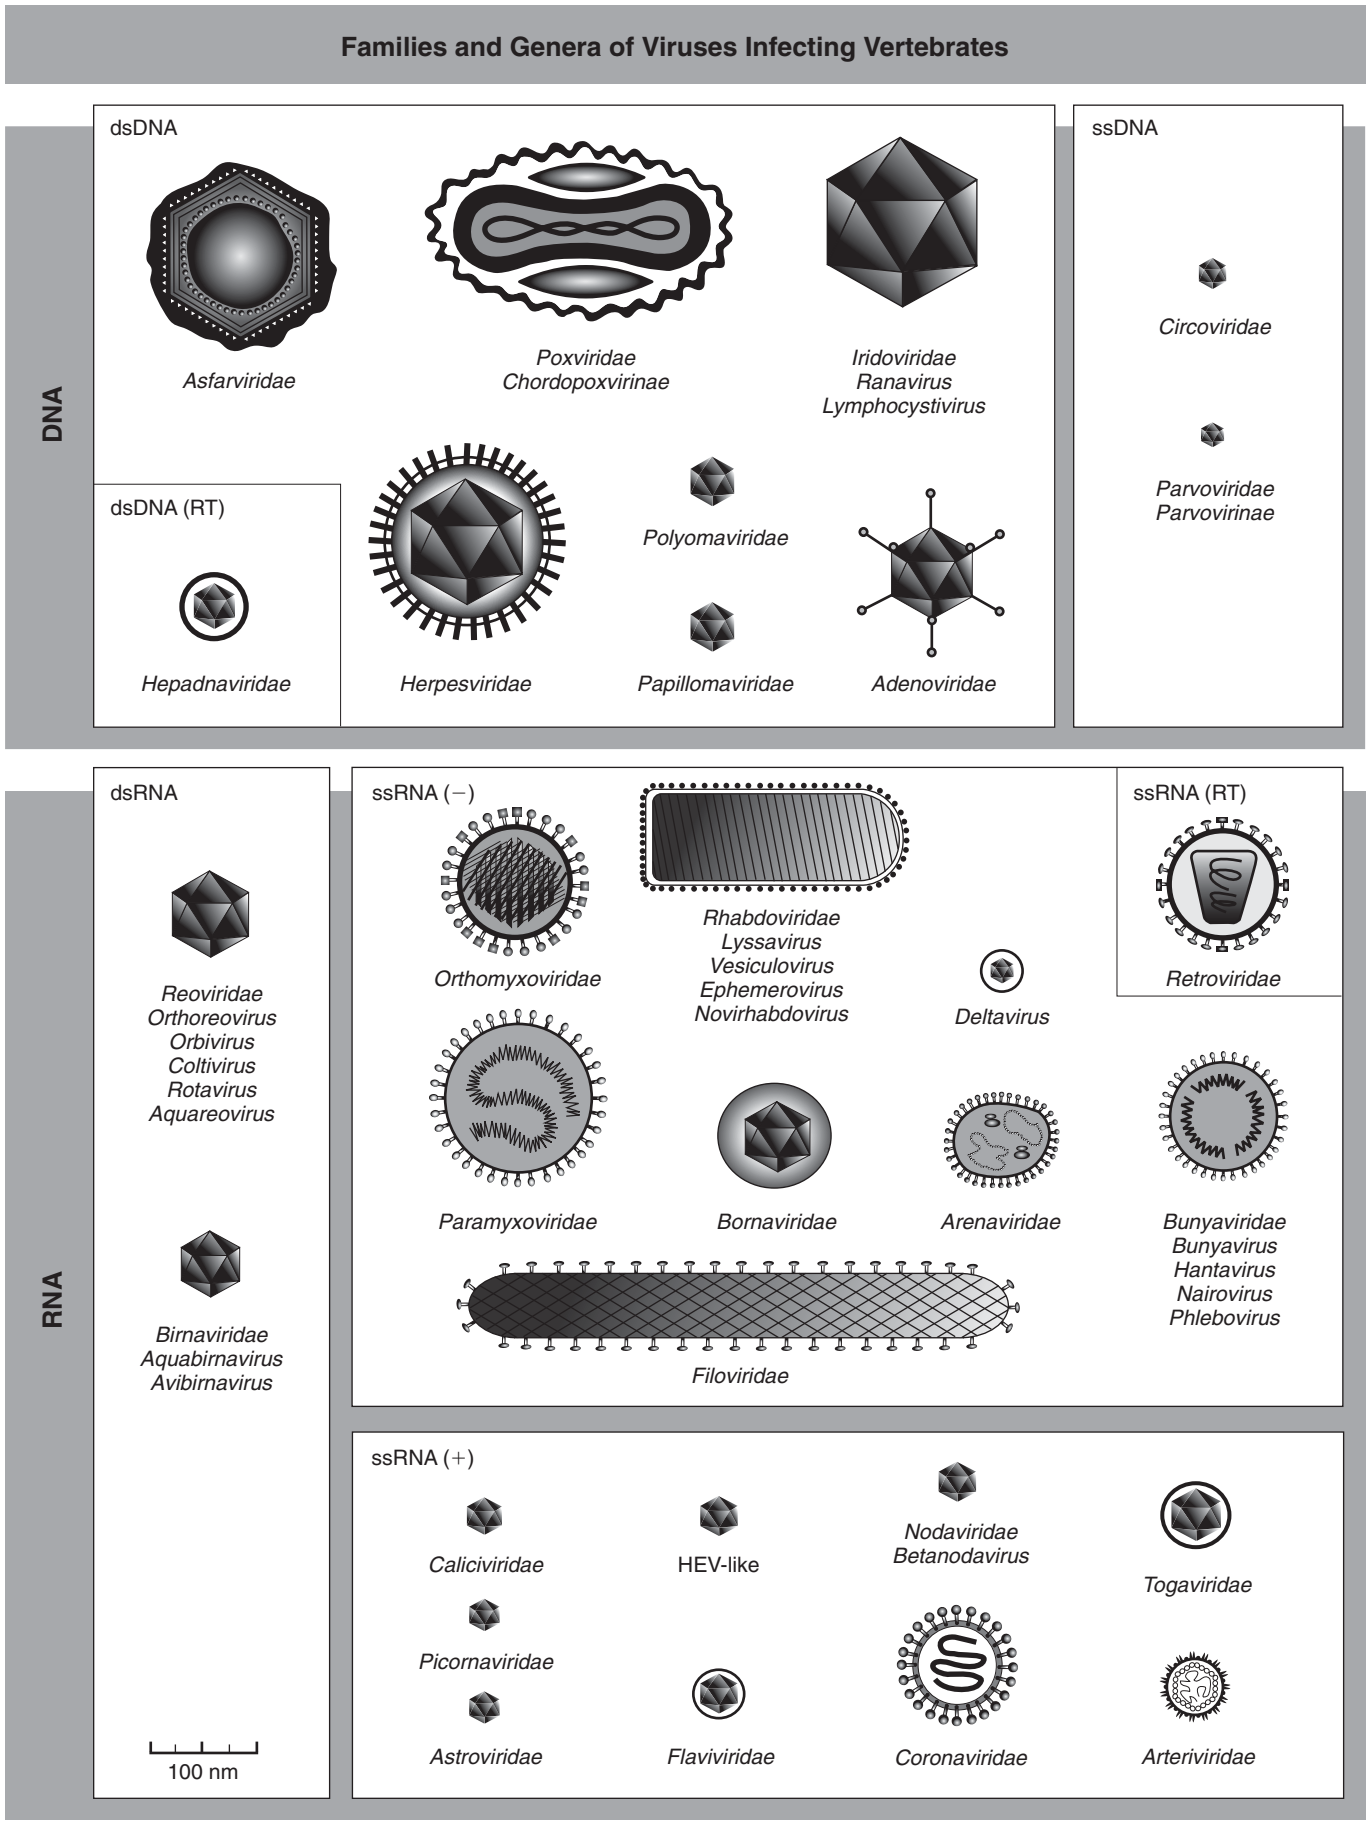

Figure 163–1 Diagram illustrating the shapes and relative sizes of animal viruses of the major families. *(From Van Regenmortel, M. H. V., Fauquet, C. M., Bishop, D. H. L., et al. [eds.]: Virus Taxonomy: Classification and Nomenclature of Viruses. Seventh Report of the International Committee on Taxonomy of Viruses. San Diego, Academic Press, 2000, p. 30.)*

TABLE 163–1 Classification and Nomenclature of Representative Viruses Affecting Humans

Family	Subfamily	Genus	Representative Species Pathogenic for Humans (Abbreviation, Disease, Synonym, or No. of Members)
DNA Viruses			
Poxviridae	*Chordopoxvirinae*	*Orthopoxvirus*	*Vaccinia virus* (VACV) *Variola virus* (VARV)
		Parapoxvirus	*Orf virus* (ORFH, contagious pustular dermatitis) *Pseudocowpox virus* (PCPV, milkers' nodule)
		Molluscipoxvirus	*Molluscum contagiosum virus* (MOCV)
		Yatapoxvirus	*Yaba monkey tumor virus*, *tanapox virus* (YMTV, TANV)
Herpesviridae	*Alphaherpesvirinae*	*Simplexvirus*	*Human herpesvirus 1* (HHV-1, herpes simplex virus type 1) *Human herpesvirus 2* (HHV-2, herpes simplex virus type 2) *Cercopithecine herpesvirus 1* (CeHV-1, monkey B virus)
		Varicellovirus	*Human herpesvirus 3* (HHV-3, varicella-zoster virus)
	Betaherpesvirinae	*Cytomegalovirus*	*Human herpesvirus 5* (HHV-5, cytomegalovirus)
		Roseolovirus	*Human herpesvirus 6* (HHV-6, human B lymphotropic virus) *Human herpesvirus 7* (HHV-7)
	Gammaherpesvirinae	*Lymphocryptovirus*	*Human herpesvirus 4* (HHV-4, Epstein-Barr virus)
		Rhadinovirus	*Human herpesvirus 8* (HHV-8, Kaposi sarcoma–associated herpesvirus)
Adenoviridae		*Mastadenovirus*	*Human adenovirus A* (HAdV-A; 12, 18, 31) *Human adenovirus B* (HAdV-B; 3, 7, 11, 14, 16, 21, 34, 35, 50) *Human adenovirus C* (HAdV-C; 1, 2, 5, 6) *Human adenovirus D* (HAdV-D; 8-10, 13, 15, 17, 19, 20, 22-30, 32, 33, 36-39, 42-49, 51) *Human adenovirus E* (HAdV-E; 4) *Human adenovirus F* (HAdV-F; 40, 41)
Papillomaviridae		*Papillomavirus*	*Human papillomavirus* (HPV, 80)
Polyomaviridae		*Polyomavirus*	*BK polyomavirus* (BKPyV, polyomavirus hominis 1) *JC polyomavirus* (JCPyV, polyomavirus hominis 2)
Parvoviridae	*Parvovirinae*	*Erythrovirus*	*B19 virus* (B19V, human parvovirus, erythema infectiosum or fifth disease)
Hepadnaviridae		*Orthohepadnavirus*	*Hepatitis B virus* (HBV)
RNA Viruses			
Reoviridae		*Orthoreovirus*	*Mammalian orthoreovirus* (MRV, 3)
		Coltivirus	*Colorado tick fever virus* (CTFV)
		Orbivirus	*Changuinola virus* (CGLV; 12); *Great Island virus* (GIV; 36)
		Rotavirus	*Rotavirus A*, *B*, and *C* (RV-A, RV-B, RV-C, numerous serotypes)
Paramyxoviridae	*Paramyxovirinae*	*Respirovirus*	*Human parainfluenza virus 1* and *3* (HPIV-1, HPIV-3)
		Morbillivirus	*Measles virus* (MeV)
		Rubulavirus	*Mumps virus* (MUV), *human parainfluenza virus 2* (HPIV-2) and *4* (HPIV-4a and b)
	Pneumovirinae	*Pneumovirus*	*Human respiratory syncytial virus* (HRSV)
		Metapneumovirus	*Human metapneumovirus* (HMPV)
Rhabdoviridae		*Vesiculovirus*	*Vesicular stomatitis Indiana virus* (VSIV)
		Lyssavirus	*Rabies virus* (RABV)
Filoviridae		Marburg-like virus	*Lake Victoria marburgvirus* (LVMARV)
		Ebola-like virus	*Zaire ebolavirus* (ZEBOV), *Reston ebolavirus* (REBOV)
Orthomyxoviridae		*Influenzavirus A*	*Influenza A virus* (FLUAV)
		Influenzavirus B	*Influenza B virus* (FLUBV)
		Influenzavirus C	*Influenza C virus* (FLUCV)
Bunyaviridae		*Bunyavirus*	*Bunyamwera virus* (BUNV, Bunyamwera serogroup), *California encephalitis virus* (CEV, California serogroup) (mosquito and culicid fly transmitted; ≈47 species, >161 serotypes)
		Hantavirus	*Hantaan virus* (HTNV, Korean hemorrhagic fever or hemorrhagic fever with renal syndrome), *Sin Nombre virus* (SNV, Four Corners hantavirus, hantavirus pulmonary syndrome), and others (rodent associated, ≈22 species)
		Nairovirus	*Crimean-Congo hemorrhagic fever virus* (CCHFV) (tick transmitted, 8 species, >34 strains)
		Phlebovirus	*Sandfly fever Naples virus* (SFNV), *Rift Valley fever virus* (RVFV) (sandfly-borne primarily); *Uukuniemi virus* (UUKV) (phlebotomine, tick, and mosquito transmitted; ≈9 species, 35 strains)
Arenaviridae		*Arenavirus*	*Lymphocytic choriomeningitis virus* (LCMV) *Lassa virus* (LASV) *Junin virus* (JUNV, Argentine hemorrhagic fever virus) *Machupo virus* (MAVC, Bolivian hemorrhagic fever virus)

Continued

TABLE 163–1 Classification and Nomenclature of Representative Viruses Affecting Humans—cont'd

Family	Subfamily	Genus	Representative Species Pathogenic for Humans (Abbreviation, Disease, Synonym, or No. of Members)
Picornaviridae		*Enterovirus*	*Poliovirus* (PV, human poliovirus 1-3)
			Human enterovirus A (HEV-A, 10 serotypes; human Coxsackie A viruses 2, 3, 5, 7, 8, 10, 12, 14, 16; human enterovirus 71)
			Human enterovirus B (HEV-B, 36 serotypes; human Coxsackie B viruses 1-6; human Coxsackie virus A9; human echovirus 1-21 and 24-33; human enterovirus 69)
			Human enterovirus C (HEV-C, 11 serotypes; human Coxsackie viruses A1, A11, A13, A15, A17-A22, A24)
			Human enterovirus D (HEV-D, 2 serotypes; human enteroviruses 68 and 70)
		Parechovirus	*Human parechovirus* (HPeV; human parechovirus 1, formerly echovirus 22; human parechovirus 2, formerly echovirus 23)
		Rhinovirus	*Human rhinovirus A* (HRV-A, 18 serotypes)
			Human rhinovirus B (HRV-B, 13 serotypes) (unassigned serotypes, 82)
		Hepatovirus	*Hepatitis A virus* (HAV, enterovirus 72)
Caliciviridae		*Norovirus*	*Norwalk virus* (NV, 7 strains)
		Sapovirus	*Sapporo virus* (SV, 6 strains)
Astroviridae		*Mamastrovirus*	*Human astrovirus* (HAstV, 8)
Coronaviridae		*Coronavirus*	*Human coronavirus* (HCoV-229E and HCoV-CC43)
Flaviviridae		*Flavivirus*	*St. Louis encephalitis virus* (SLEV), *yellow fever virus* (YFV), *dengue virus* (DENV), and *West Nile virus* (WNV) (group B arboviruses, mosquito-borne, ≈27)
			Kyasanur Forest disease virus (KFDV), *tick-borne encephalitis virus* (TBEV) (tick-borne, ≈15)
			Vector-unassociated viruses (≈17)
		Hepacivirus	*Hepatitis C virus* (HCV, parenterally transmitted non-A, non-B hepatitis)
			Hepatitis G virus (HGV-1)
Togaviridae		*Alphavirus*	*Western*, *eastern*, and *Venezuelan equine encephalitis viruses* (WEEV, EEEV, VEEV); *Ross River* and *Sindbis viruses* (RRV, SINV) (group A arboviruses, mosquito-borne, ≈27)
		Rubivirus	*Rubella virus* (RUBV)
Retroviridae	*Orthoretrovirinae*	*Deltaretrovirus*	*Primate T-cell lymphotropic virus 1* (PTLV-1, human T-lymphotropic virus 1)
			Primate T-cell lymphotrophic virus 2 (PTLV-2, human T-lymphotropic virus 2)
		Lentivirus	*Human immunodeficiency viruses 1* and *2*
Subviral Agents (Satellites, Viroids, and Agents of Spongiform Encephalopathies)			
Prions			Kuru, Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker syndrome (GSS), fatal familial insomnia (FFI)
Unclassified Viruses			
		Delta virus	*Hepatitis delta virus* (HDV)
		Hepatitis E–like viruses	*Hepatitis E virus* (HEV, enterically transmitted non-A, non-B hepatitis)

culture").[4,14,15] Viruses with uncertain taxonomic status are considered "tentative" species, and names are not italicized, although the initial letter is capitalized. Though not part of the formal international code, abbreviations also have been recommended by the ICTV for every virus name to reduce the possibility of duplication when new abbreviations are proposed[4,5,16] (see Table 163–1).

Figure 163–2 is a schematic diagram showing the basic forms and composition of viruses.[3] The type of nucleic acid, capsid symmetry, presence or absence of an envelope, and peplomers (spikes) all are characteristics used in classification. Figure 163–1 is a more detailed diagram not only illustrating the relative shapes and sizes of families and genera of vertebrate viruses but also indicating the type and nature (single-stranded [ss], double-stranded [ds], sense [+/–]) of the nucleic acid, presence of reverse transcriptase (RT), and presence or absence of an envelope.

Figures 163–3 and 163–4 (adapted from Melnick[11]) show classification of DNA and RNA virus families, respectively, by some of the taxonomic characteristics listed in Table 163–2. Representative DNA and RNA viruses affecting humans are listed in Table 163–1, which uses the most recent nomenclature reported by the ICTV (for a complete listing, see Fauquet and colleagues[4]).

TABLE 163–2 Representative Properties Used In Virus Taxonomy

Virion Properties
Morphology
- Size
- Shape
- Presence, absence of envelope and peplomers
- Capsid structure, symmetry

Physical properties
- Molecular mass
- Buoyant density
- Sedimentation coefficient
- pH stability
- Thermal stability
- Solvent, detergent stability

DNA VIRUSES

SUBSECTION 1

Parvoviridae

CHAPTER 164

Human Parvovirus B19

James D. Cherry ❂ Danica J. Schulte

The family *Parvoviridae* includes two subfamilies: *Parvovirinae* and *Densovirinae*.[191,313] The subfamily *Parvovirinae* has three genera: *Erythrovirus*, *Parvovirus*, and *Dependovirus*; the subfamily *Densovirinae* also has three genera: *Densovirus*, *Iteravirus*, and *Centravirus*. Densonucleosis viruses (*Densovirus* spp.) infect insect hosts and have not been found in humans or mammals.[35,353] Currently, human parvovirus B19 is the only accepted member of the genus *Erythrovirus*. Originally, it was classified in the genus *Parvovirus*. Despite this reclassification, the contemporary literature still refers to this *Erythrovirus* as parvovirus B19. This virus is autonomous and does not require the presence of a helper virus.

In 1999, *Erythrovirus* V9, a potential second member of the *Erythrovirus* genus, was found to be clinically significant and result in a spectrum of disease similar to that of B19.[165,343,399] V9 was found in the serum and bone marrow of a 6-year-old boy with transient aplastic anemia[319]; however, routine testing for B19 virus failed to identify the V9 virus.[165] V9 has greater than 11 percent variation from the published B19 genome, with nucleotide discrepancies encompassing the entire genome.[169,171] B19 typically is well conserved, with less than 2 percent sequence variability between isolates.[320] Another B19 variant, A6, has 12 percent variability from B19 DNA, and its clinical relevance is unclear.[118,488]

More recently, two additional parvoviruses have been discovered. One of these, human bocavirus, is presented in Chapter 165. The other virus, PARV4, was found in plasma samples from persons screened for acute human immunodeficiency virus (HIV) infection.[200,273]

Erythema infectiosum is the common clinical manifestation of infection with parvovirus B19. Other clinical findings include arthralgia and arthritis, aplastic crisis in patients with red blood cell defects, chronic anemia in immunocompromised patients, fetal hydrops, neurologic disease, and a variety of other significant illnesses.

HISTORY

The first parvoviruses to be discovered infecting humans were found in stool specimens by electron microscopy.[354] These fecal parvoviruses have been linked with gastrointestinal symptoms, often in outbreaks associated with the consumption of shellfish.[105,441] Their precise pathogenic role remains unclear because these viruses also may be found in the feces of asymptomatic individuals.[354]

In 1974, a second type of parvovirus was found in the serum of asymptomatic blood donors.[90,165] Discovered by chance as an agent responsible for false-positive results in the counterimmunoelectrophoresis tests then in use for detection of hepatitis B surface antigen, they were revealed by electron microscopy to be uniform icosahedral particles with a mean diameter of 23 nm.

Preliminary studies of the physiochemical nature of this agent suggested its probable identity as a member of the family *Parvoviridae*.[90] In the following years, reports concerning this virus named it variously as human parvovirus–like agent, serum parvovirus–like virus,[84] and B19[405] after one of the original isolates. After its chemical properties were elucidated in 1983,[79,424] the virus was referred to as *human parvovirus*—or *human serum parvovirus*—to denote that it is distinct from the fecal viral particles. Today, the virus most commonly is called *human parvovirus B19* or simply *B19 virus*.[10,85,206]

For many years after its discovery, infection with B19 virus appeared to be either asymptomatic or associated with a nonspecific febrile illness.[405] However, in the early 1980s, the central role of B19 virus in the etiology of aplastic crisis in patients with chronic hemolytic anemia was identified.[75,104,204,373,397] Soon thereafter came the appreciation that erythema infectiosum (fifth disease) is the common manifestation of infection with B19 virus.[17] Approximately 20 years ago, the association between B19 virus infection in pregnancy and fetal death was observed, and during the past 18 years, the clinical spectrum of B19 virus infection has broadened considerably.*

Although human parvovirus B19 was not discovered until 1974, its most common clinical disease (erythema infectiosum) was described more than 200 years ago.[44]

Tschamer's report in 1889 was considered by most reviewers to be the first description of erythema infectiosum.[437] However, Boysen[44] noted that the English dermatologist Robert Willan had reported the illness first in 1799 and then more completely in 1840.

After Tschamer's report came a succession of Austrian and German reports of the illness.[44] Tschamer thought that erythema infectiosum was a manifestation of rubella, but a few years later, Escherich[120] suggested that it was a specific disease. Stricker[422] in 1899 gave the name *erythema infectiosum* to the clinical entity.

In 1905, Shaw,[404] after having observed cases of erythema infectiosum in Austria, published the first account in the American literature. Herrick[177] was the first to document in detail an outbreak in the United States; however, cases of erythema infectiosum had been observed previously in St. Louis[494] and in Hamburg, New York.[177] During the past 75 years, numerous outbreaks and epidemics have been described in North America.† Erythema infectiosum frequently is referred to as *fifth disease* and

in the past also was called *ring rubella*, *large-spotted disease*, and *epidemic megaloerythema*.

PROPERTIES OF THE VIRUS

Human parvovirus B19 is a naked icosahedral virus with a mean diameter of 23 nm and a mean buoyant density in cesium chloride of 1.43 g/dL.[90] The capsid is formed from two major structural proteins (VP1 and VP2) discernible by sodium dodecyl sulfate–polyacrylamide gel electrophoresis.[79] VP2 is the major structural protein, with a molecular weight of 58 kd; VP1 has a molecular weight of 84 kd. Ninety-six percent of the capsid is VP2, and 4 percent is VP1. The structure of VP2 has been determined by x-ray crystallography.[165,203] The major nonstructural protein (NS1) has a molecular weight of 77 kd. The genome consists of a single molecule of single-stranded DNA approximately 5.6 kb in length.[96] The DNA in B19 virus occurs as both plus and minus strands in approximately equal numbers.[206] When virions are disrupted with protease, the two complementary strands anneal to form a stable duplex.[424] At each end of the molecule are palindromic sequences forming "hairpin" loops. The hairpin at the 3′ end of the genome serves as a primer for DNA polymerases. The hairpin duplex at the 5′ end of the molecule consists of sequences that are neither complementary to those at the 3′ end, as is found in dependoviruses, nor as highly complementary within this 5′ end as are those at the 3′ end.[64] Folding of the VP1 and VP2 proteins creates alpha-helical loops that appear on the surface of the capsid and are available to the host immune system. The unique region of VP1 is external to the capsid; it contains linear epitopes recognized by neutralizing antibodies and elicits a more efficient immune response than the VP2 region does.[488]

Parvovirus infectivity is relatively heat-stable, tolerant of a wide range of pH, and resistant to ether.[18] Successful replication of parvoviruses can be accomplished only in a dividing cell because of the absolute requirement for the host-cell function or functions found in late S phase.[161] Human parvovirus B19 can be propagated only in human erythropoietic cells from bone marrow and in primary fetal liver culture.[52,353,416,417,429]

The cellular receptor for B19 virus infection is the blood group P antigen, which is a globoside and a neutral glycolipid.[49] The P antigen also requires a cellular co-receptor, $\alpha_5\beta_1$ integrin, for sufficient entry of parvovirus B19 into human cells.[463] P antigen is found on erythroblasts, megakaryoblasts, endothelial cells, and fetal myocytes.[49] People who lack P antigen are resistant to infection with B19 virus, and in vitro studies demonstrate that the erythroid precursors from people lacking P antigen cannot be infected, even in the presence of high concentrations of virus.[7,51,165]

Antigenically, this human erythrovirus is distinct from the parvovirus-like particles found in feces,[355] as well as from the human dependoviruses and autonomous animal parvoviruses.[90] However, the nucleotide sequence and hybridization results reported by Turton and associates[441] suggest that the viruses from gastroenteritis cases in 1977 and 1986 are similar to B19. In contrast to animal parvoviruses, no hemagglutinin has been demonstrated.

The degree to which B19 virus is related to other mammalian parvovirus types has been investigated by DNA-DNA hybridization. Although no relationship is discernible with the human dependoviruses, a distant evolutionary relationship to the genomes of the autonomous parvoviruses of rodents is apparent. Interestingly, this relationship is closer than that between B19 virus and the parvoviruses infecting domestic animals (bovine, feline, and canine parvoviruses).[91] Shackelton and Holmes[402] studied the evolutionary dynamics and phylogenetic history of the *Parvoviridae* and observed a high rate of evolutionary change, 10^{-4} nucleotide substitutions per site per year.

Many recent studies have examined genetic variability in parvovirus B19 isolates.[40,117,136,175,198,214] In general, sequence divergence usually is less than 1 to 2 percent.[169,171,320,434] Hemauer and associates[175] suggested that greater genome variability occurs in isolates from patients with persistent infection than in isolates from patients with acute infection. Erdman and colleagues[117,434] noted that geographically defined genetic lineages of parvovirus B19 existed but that no particular genotype was associated with a specific clinical manifestation.

Parvovirus B19 does not grow in routine tissue cultures. It will grow in erythroid progenitor cells from human bone marrow, fetal liver, erythroid cells from a patient with erythroleukemia, and human umbilical cord and peripheral blood.[165,206,348] It grows only in dividing cells, and, therefore, all the aforementioned tissue culture systems require the addition of erythropoietin. Parvovirus B19 also has been propagated in megakaryoblastoid cell lines.

EPIDEMIOLOGY

Outbreaks of erythema infectiosum have been observed throughout the world, but most reports have come from nontropical regions. The epidemic pattern of erythema infectiosum is surprisingly similar to that of rubella. Community epidemics are most prevalent in the winter and spring, and they usually last for 3 to 6 months. In a review of 30 well-described epidemics,* 26 had their onset in the period from December through May, and 23 of the 30 peaked in March, April, or May. When the North American literature for a 50-year period is examined, a cyclic pattern is evident, with peaks in disease activity occurring approximately every 6 years. The peak periods last for an average of 3 years. A longitudinal study of aplastic crisis in persons with sickle-cell anemia in Jamaica suggested that peaks in incidence occur every 2 to 3 years in this island population.[397]

The case-to-case interval of erythema infectiosum is reported to be between 4 and 14 days.[3,17,106,147,366,453,470] In an epidemic in an elementary school, Greenwald and Bashe[147] noted that the mean case-to-case interval was 8.7 days. Ager and associates[3] in their studies noted clustering of intervals between cases of 7 to 11 days. The data of Wilcox and Evans[470] on multiple cases in households suggest that the case-to-case interval usually is closer to 12 to 14 days. In a volunteer study in which adults were inoculated intranasally, the incubation time until onset of the rash was 17 to 18 days.[14] From this study, the case-to-case interval in the community would be expected to be between 6 and 12 days because shedding of virus occurs between days 5 and 12 of infection. This prediction accords well with intervals in the studies noted earlier, as well as intervals observed in patients with hematologic diseases and aplastic crisis.[300]

In epidemics, the attack rate is high. Lauer and colleagues[248] noted an overall attack rate of 24.3 percent in schoolchildren in grades kindergarten through the eighth grade. Similar attack rates were noted in three other school-related outbreaks.[106,143,147] In the community as a whole, the attack rate is highest in children 5 to 14 years of age,[2,3] but secondary cases occur in preschool children, teachers, and parents. In the home, secondary cases are reported more commonly in mothers than in fathers.[3] In school epidemics, the attack rate is considerably higher in girls than in boys.[3,106,248] Prevalence studies of serum IgG antibody to B19 virus have noted that 40 to 60 percent of adults and 2 to 21 percent of children younger than 11 years are seropositive.[10-12,84] The rate of transmission among household contacts is nearly 50 percent.[445]

*See references 3, 12, 21, 26, 44, 46, 70, 77, 81, 86, 106, 130, 147, 177, 216, 248, 249, 259, 314, 361, 375, 408, 419, 453, 466, 470, 498.

Nosocomial infections do occur; most often, the index case is an unrecognized, chronically infected patient.[2,236,363] During community outbreaks, the risk of acquisition by hospital workers is no greater than that in other community residents.

The role of human leukocyte antigen (HLA) class I and II alleles was investigated by Kerr and associates[217] in northwestern England. Thirty-six patients with symptomatic B19 infection and 900 controls were studied. The frequency of HLA alleles DRB1*01, DRB1*04, and DRB1*07 was significantly higher in patients with B19 infection than in control subjects.

In a cohort study of 169 children with severe anemia in Papua New Guinea, a strong association between severe anemia and B19 infection was observed; however, the authors were unable to show a combined deleterious effect of malaria and B19 infection.[467] They and others demonstrated that 60 percent of the children were infected with B19 before reaching 2 years of age and that greater than 90 percent were infected by 6 years of age.[152,352,388,469]

Although erythema infectiosum long had been postulated to be transmitted by droplet via the respiratory tract,[3] proof of this route was not obtained until a group of volunteers were infected successfully with B19 virus after intranasal inoculation. One week after inoculation, virus was excreted from the respiratory tract for 6 days.[14]

Parvovirus B19 infection also can be transmitted by blood transfusion and clotting factor concentrates.*

One case of transmission of B19 DNA via peripheral blood progenitor cell transplantation that resolved after treatment with intravenous immune globulin (IVIG) has been reported.[19] Hayakawa and colleagues[162] reported a case of parvovirus B19 infection that they thought was transmitted by IVIG. Researchers have described donor-transmitted parvovirus infection in transplant patients.[478]

PATHOGENESIS AND PATHOLOGY

The pathogenesis of erythroviral disease involves two quite separate components. The first is caused by the lytic infection of susceptible dividing cells and the second by interaction with products of the immune response.

As stated earlier, parvoviruses replicate only in dividing cells. Thus, infection of an organ or tissue in which a significant proportion of the cells are dividing may give rise to organ-specific disease. This condition is seen clearly in canine and feline parvovirus infections, in which replication of virus in the crypt cells of the intestine gives rise to a severe and often fatal enteritis.[157,268]

Parvovirus B19 is thought not to infect cells of the gastrointestinal tract; virus could not be detected in the feces of volunteers,[14] nor have viruses of this type been found in stool specimens.

After gaining entry via the respiratory tract, the virus sets up a systemic infection with copious viremia (Fig. 164–1) in which 10^{10} or 10^{11} virus particles per milliliter of blood is not an uncommon finding.[14,368]

Parvovirus infection results in profound reticulocytopenia for some 7 to 10 days, commencing during viremia.[14,488] In vitro studies on cultured bone marrow and peripheral blood have shown that B19 virus inhibits the formation of blast-forming erythroid colonies, thus suggesting that an early erythrocyte precursor cell is susceptible to infection with the virus. B19-associated damage to cells of the erythroid lineage is due to the cytotoxicity mediated by viral proteins, whereas the apoptotic features mediated by caspase 3 are induced by NS1.[74] In addition to profound erythroid hypoplasia, giant pronormoblasts typically

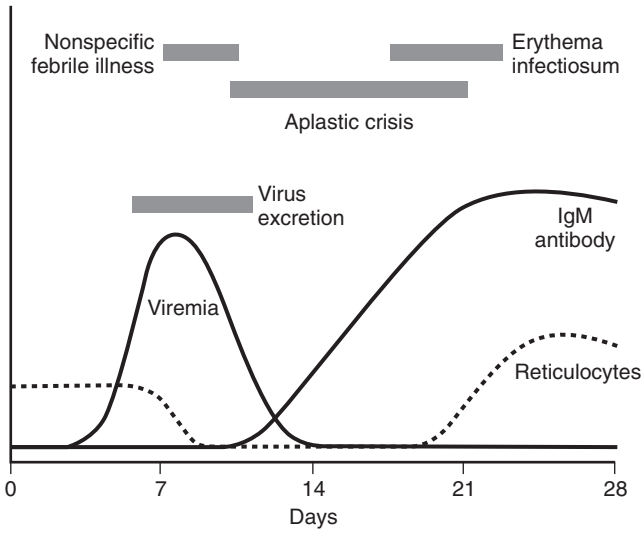

Figure 164–1 Selected virologic, immunologic, hematologic, and clinical events in parvovirus B19 virus infection.

are seen in the bone marrow at the height of transient aplastic crises, and normoblasts have characteristic intranuclear eosinophilic inclusion bodies termed *Lampion* or *Lantern cells*.[56]

Granulocytes and megakaryocytes are unaffected by virus in these in vitro systems. However, during B19 virus infection in a normal host, clinically insignificant lymphopenia and neutropenia occur, as does a drop in platelet number.[14,366] The mechanisms of loss of these cells from peripheral blood remain to be determined. Srivastava and associates[416] noted that B19 virus infection of bone marrow cells in culture results in suppression of megakaryocyte colony formation. In this study, tropism of B19 virus for cells other than erythroid progenitor cells appeared to take place, although viral DNA replication did not occur in the megakaryocyte-enriched fractions. They suggested that the virus might be toxic to cell populations that are nonpermissive of viral DNA replication.

As noted in Figure 164–1, viremia ends at the time of appearance of specific IgM antibody. In addition, researchers have found that the appearance of antibody neutralizes the inhibitory effect of B19 virus on formation of erythrocyte colonies in vitro.[489] The early IgM response is almost entirely VP2-specific. IgG antibody first appears approximately 2 weeks after exposure and later becomes the major antibody subclass; in contrast to the initial IgM response, the IgG response is directed at VP1 rather than VP2. The role of cellular immunity in recovery from infection is unclear. Most patients with persistent infection have T-cell as well as other immune defects, thus suggesting a cellular component in the host response.[40] Surprisingly, few studies of cellular immunity have been performed in patients with parvovirus B19 infection.[133,241,451] von Poblotzki and associates[451] showed that the T cells of persons with parvovirus B19 antibody had HLA class II–restricted responses against B19 structural proteins. Franssila and colleagues[133] demonstrated virus-specific helper T-cell proliferation in recently and remotely infected patients. Their data suggested that B cells that recognize the viral capsid (VP1 and VP2) receive class II–restricted help from $CD4^+$ T lymphocytes. While investigating a parvovirus B19 vaccine, this same group demonstrated that VP1 contains important B-cell epitopes required for protective B-cell immunity, and they concluded that VP2, the major structural protein of B19 virus, appears to provide the major target for B19-specific helper T cells years or decades after initial infection occurs.[131,132] A persistent, activated B19-specific $CD8^+$ T-cell repertoire with maintained effector function occurs in healthy patients who successfully

*See references 19, 102, 165, 283, 302, 365, 415, 473, 480, 491.

clear the B19 virus. Researchers have hypothesized that these activated $CD8^+$ T cells may play a prominent role in controlling acute B19 infection.[192,202,260,330] Additionally, Kerr and colleagues[208,213] reported that circulating cytokine and chemokine levels in acute B19 disease may correlate with clinical disease.

The most common result of infection with B19 virus is erythema infectiosum. Figure 164–1 shows that the symptoms of this disease begin 17 or 18 days after inoculation and that approximately 1 week after inoculation, virus can be detected in either throat swabs or blood. Skin biopsy results have been reported in three studies.[30,148,182] In three skin biopsy specimens from regions of reticulated eruption, Bard and Perry[30] noted either normal skin or very mild inflammatory changes. Hoffman[182] described edema in the epidermis and perivascular infiltration with mononuclear cells; he also noted swelling of the endothelium of superficial vessels and the presence of cleavage spaces between the epidermis and dermis. The histopathology in 10 cases was investigated by Grimmer and Joseph.[148] They reported dilation of blood vessels with lymphocytic and occasional plasma cell perivascular infiltration. However, the clinical manifestations of many of the cases in the epidemic that Grimmer and Joseph[148] studied were quite atypical.

Virus-specific IgM is present at the time of onset of the rash in erythema infectiosum, so although the mechanisms of production of the rash (and arthralgia) of erythema infectiosum remain to be elucidated, postulating an immune-mediated pathogenesis is not unreasonable.[488] The perivascular infiltrations noted by Hoffman[182] would support this suggestion. However, Schwarz and colleagues[395] have found both viral capsid proteins and viral DNA in a skin biopsy specimen of the rash from a patient with erythema infectiosum. They, therefore, suggest that the rash may be a direct effect of the virus rather than being immune complex mediated.

Intrauterine infection results in infection of the fetus and, frequently, abortion.* The main finding in infected fetuses is hydrops fetalis, which results from the anemia caused by infection of the erythrocyte precursor cells. Intranuclear inclusions are seen in nucleated red blood cells, and viral particles are identified in the same cells by electron microscopy.[67] The mechanism responsible for hydrops fetalis stems from the severe anemia, and cardiogenic failure results in generalized ascites, edema, pericardial and pleural effusions, and a thick hydropic placenta.[135] Concomitant myocarditis also occurs, which complicates the clinical picture because the blood group P antigen is expressed on fetal cardiac myocytes.[49,74] The shorter half-life of fetal erythrocytes also exacerbates the disease.[74]

In immunocompromised patients, persistent infection with B19 virus often occurs[241] as a result of failure to produce effective neutralizing antibodies.[74] Patients taking immunosuppressive calcineurin inhibitors may be unable to clear B19 virus because these medications inhibit interleukin-2 (IL-2) production and the patients are unable to mount an effective T_H1 response.[74,295]

CLINICAL MANIFESTATIONS

Infection with human parvovirus B19 results in a spectrum of clinical manifestations; classic cases of erythema infectiosum occupy a central position in this spectrum. Other major manifestations include arthritis and arthralgia, intrauterine infection and hydrops fetalis, transient aplastic crisis in patients with a variety of underlying hemolytic illnesses, and persistent infection with chronic anemia in patients with immunodeficiencies. In addition, subclinical, nonexanthematous infection occurs, especially in children.[14,366]

*See references 8, 10, 63, 67, 97, 141, 165, 221, 371, 379, 393, 472, 487, 488.

Other less common illnesses include myocarditis, vasculitis, glomerulonephritis, and neurologic disease. In addition to the established parvovirus B19 disease associations is an ever-expanding list of categories of illness in which evidence of parvovirus B19 infection has been found. These illnesses are presented in Table 164–1.

TABLE 164–1 Reported Unusual Clinical Findings in Patients with Laboratory Evidence of Parvovirus B19 Virus Infection

- **Persistent Arthritis**
  - Juvenile rheumatoid arthritis[73,223,338]
  - Rheumatoid arthritis[324,418,428]
  - Adult Still disease[261,369]
- **Neurologic Disease**
  - Encephalitis[27,126,170,209,420]
  - Meningitis[64,234,344,419,425]
  - Stroke[149,272]
  - Postinfectious neuralgic amyotropy[29,356]
  - Guillain-Barré syndrome[29,290]
  - Transverse myelitis[29]
  - Facial palsy[274]
  - Carpal tunnel syndrome[29,387]
  - Numbness and tingling of fingers[4,29,492]
  - Myofasciitis[187]
- **Myocarditis**[41,57,98,113,201,237,238,245,309,321,351,384,493]
- **Cutaneous Manifestations**
  - Papular-purpuric gloves and socks syndrome[6,9,23,37,110,155,184,286,346,409,435,446]
  - Vesiculopustular exanthema[317]
  - Erythema multiforme[139]
  - Henoch-Schönlein syndrome[76,449]
  - Petechial and purpuric rashes[1,87,103,186,254,282]
  - Pruritus without rash[267]
- **Hematologic Manifestations**
  - Thrombocytopenic purpura[5,38,127,190,253,486]
  - Pancytopenia[158,235,306]
  - Hemophagocytic syndrome[43,306,440,444,460,490]
  - Neutropenia[279]
  - Diamond-Blackfan syndrome[166,432]
  - Splenic sequestration[270]
- **Other Manifestations**
  - Sepsis[24]
  - Glomerulonephritis[189,195,234,297,468]
  - Nephrotic syndrome[340]
  - Kawasaki disease[183,323]
  - Behçet disease[222]
  - Polyarteritis nodosa[450]
  - Wegener granulomatosis[325]
  - Leukocytoclastic vasculitis[88]
  - Giant-cell arteritis[137]
  - Systemic sclerosis[124,125,343]
  - Systemic vasculitis[95]
  - Systemic lupus erythematosus[99,188,322]
  - Hepatitis[103,246,327,414,484]
  - Raynaud phenomenon[159]
  - Pseudoappendicitis or mesenteric lymphadenitis[298]
  - Necrotizing lymphadenitis[199]
  - Cervical lymphadenopathy[224,439]
  - Parotitis[274]
  - Pneumonia[299,420,459]
  - Pulmonary emboli[20]
  - Acute respiratory distress syndrome[123]
  - Chronic infection without immunosuppression but with chronic hemolytic anemia[215]
    - Persistent arthralgia[214]
    - Chronic fatigue syndrome[196,211,212,214,220,224,276,280]
    - Recurrent paresthesias[121]
    - Fibromyalgia[34]

ERYTHEMA INFECTIOSUM

Although a search of the literature related to outbreaks of erythema infectiosum reveals a conspicuous absence of prodromal symptoms in patients, infected volunteers have had febrile episodes with nonspecific symptoms of headache, chills, myalgia, and malaise accompanying the viremic phase of infection with B19 virus (see Fig. 164–1).[14] These symptoms last for 2 to 3 days and coincide with excretion of virus from the pharynx. This phase is followed by a period of 7 days during which individuals are free of symptoms before onset of the second, or exanthematous, phase of illness. Most likely, the relatively long period between symptoms in this biphasic illness prevented recognition of the link between these nonspecific prodromal symptoms and erythema infectiosum.

The exanthem in classic cases of erythema infectiosum occurs in three stages.* The first stage begins 18 days after the acquisition of infection and is characterized by a fiery red rash on the cheeks (see Fig. 64–6) ("slapped-cheek" appearance). The edges of the involved areas may be raised slightly, and a relatively circumoral pallor is present. At this stage, the appearance may be suggestive of scarlet fever, drug sensitivity or other allergic reactions, or collagen vascular disease. The facial exanthem is aggravated by the transition from outdoors to a warm room.

The second stage of the exanthem occurs 1 to 4 days after the onset of facial involvement and consists of the appearance of an erythematous, maculopapular rash on the trunk and limbs. This rash is discrete initially but spreads to involve large areas. Toward the end of this stage, central clearing of the rash from these areas gives the characteristic lacy or reticular pattern (see Fig. 64–7).

The third stage of the exanthem is highly variable in duration (i.e., lasting from 1 to 3 or more weeks) and is characterized by marked changes in the intensity of the rash, with periodic complete evanescence and recrudescence. These fluctuations are related to environmental factors such as exposure to sunlight and temperature (a hot bath may result in recrudescence in an apparently recovered child).

The rash often is pruritic, especially in adults, and it generally is more prominent on the extensor surfaces; the palms and soles rarely are affected. Slight desquamation has been noted in a small number of patients in most reviews.

Although classic cases of erythema infectiosum are easy to recognize clinically, especially during outbreaks, wide variation in the form of the exanthem can be noted—from a very faint, fleeting rash to a florid exanthem that is confluent over large areas (see Fig. 64–8). In many cases the illness may be indistinguishable from rubella.

The overwhelming majority of cases of erythema infectiosum have no enanthem. Kerr and Marsh[216] and Condon[86] noted a few children with pharyngitis.

Other symptoms and signs occur uncommonly in erythema infectiosum (Table 164–2). In general, complaints are expressed more frequently by adults than by children. Headache is reported in approximately a fifth of childhood cases and about half of afflicted adults. Joint pain and swelling and myalgia are particularly troublesome in adults.

Routine laboratory studies are of little use in erythema infectiosum. The leukocyte count usually is normal, although mild eosinophilia is noted occasionally.[25,44,454,455]

The most common complication of erythema infectiosum is joint involvement; it is relatively rare in children (<10% of cases) but is the norm in adults and occurs in 80 percent or more of cases.† A range of severity from mild arthralgia to frank arthritis is observed. The joints most commonly involved are the knees, ankles, and proximal interphalangeal joints; symptoms generally are bilateral. The joint involvement usually is transient and lasts only a few days. In some individuals, symptoms may persist for some weeks or, rarely, months. When joint involvement occurs after an exanthem, the diagnosis may be inferred, but such is not invariably the case. As with rubella, the frequency of arthralgia and arthritis is higher in women than in men.

TABLE 164–2 Frequency of Symptoms and Signs in Erythema Infectiosum

Sign or Symptom	Percent Occurrence	
	Children	Adults
Rash	100	100
Pruritus	15	50
Headache	20	50
Fever	15	25
Sore throat	15	15
Coryza	10	15
Cough	8	8
Sore eyes	10	10
Anorexia	15	22
Nausea	7	26
Vomiting	4	7
Diarrhea	4	12
Abdominal pain	10	15
Joint pain	10	70
Joint swelling	5	60
Myalgia	4	50

Data from references 3, 106, 147, 454.

OTHER EXANTHEMS

Grimmer and Joseph[148] described cases in which the rashes were morbilliform, hemorrhagic, urticarial, vesicular, and erythema multiforme–like. Their studies were conducted during an epidemic of erythema infectiosum in Berlin, Germany, in which an estimated 50,000 persons were affected. The cases with markedly unusual manifestations quite possibly were not of the same etiology as the typical cases. Other authors also have noted papular, purpuric, petechial, vesicular, urticarial, and morbilliform eruptions.*

García-Tapia and associates[139] described a 5-year-old girl with erythema multiforme bullosum but without other systemic manifestations. Her serum had B19 virus–specific IgM antibody. Additionally, a papular-purpuric or petechial "glove and sock" syndrome has been reported with acute B19 infection.† It is more commonly seen in adults but has been noted in children.

This unique rash is characterized by petechiae and purpura, with painful or pruritic edema of the hands and feet extending proximally with less severity, and it is self-limited.[6,184] A 14-year-old girl with acute parvovirus B19 infection had a petechial-purpuric pruritic rash with edema on her hands and feet, as well as severe leukopenia and mild thrombocytopenia on laboratory evaluation.[286] Henoch-Schönlein syndrome and other vasculitic rashes also have been reported.[1,76,88,103,173,343,355,391,449]

Grimmer and Joseph[148] stated that most of their patients in the Berlin epidemic had dark red spots on the pharynx, gums, soft palate, and uvula. These cases, again, must be regarded with some suspicion because the investigators also noted genital lesions and conjunctivitis in a few patients.

APLASTIC CRISIS

In individuals with chronic hemolytic anemia, the profound reticulocytopenia of human parvovirus B19 infection results in depression of hemoglobin concentrations to critical levels.* With resolution of the infection, reticulocytes reappear in the peripheral blood and hemoglobin concentrations return to the normal steady-state values for these patients. This transient arrest in production of erythrocytes is termed *aplastic crisis* and may occur in any individual whose erythrocytes have a short life span. Examples of such conditions include sickle-cell anemia,[144,397,410,497] hereditary spherocytosis,[119,158,204,333,339,465] thalassemia,[252,254,373] glucose-6-phosphate dehydrogenase deficiency,[142] and pyruvate kinase deficiency.[104] However, there are case reports of aplastic anemia secondary to B19 virus developing in immunocompetent patients without underlying diseases.[265,291,372]

Serjeant and coworkers[398] studied the epidemiology of B19 virus infection over time in 308 children with homozygous sickle-cell disease and in 239 controls with normal hemoglobin. B19 virus infection accounted for all 91 episodes of aplastic crisis that occurred. Twenty-three additional patients with sickle-cell disease had B19 virus infections; of these, 10 had mild hematologic changes and 13 had no changes. By 15 years of age, approximately 40 percent of the sickle-cell group and the control group had IgG antibody to B19 virus, thus indicating equal infection rates in the two groups. No patient or control had two infections caused by B19 virus.

Smith-Whitley and associates[410] studied a cohort of 633 patients with sickle-cell disease (including patients with various sickle-cell disease genotypes—SS-, SC-, Sβ-thalassemia—as well as those receiving chronic transfusions and hydroxyurea) for complications attributable to acute B19 infection. At study entry, 29.8 percent of the cohort had IgG antibody to B19 virus. The secondary attack rate in the group of children who had siblings with sickle-cell disease was 56 percent. Thirty-five percent of the total patient population with B19 infection did not have worsening anemia; however, transient red cell aplasia developed in 50 percent of the children with SC- or Sβ-thalassemia, genotypes characterized by less severe disease. Neutropenia developed in 18 percent of patients and thrombocytopenia in 27 percent. In only one of seven patients receiving chronic transfusions did transient red cell aplasia develop, potentially because of the lower red cell turnover in these patients.

Rao and colleagues[374] found that 70 percent of patients with transient aplastic crisis admitted to their hospitals during a 7-year period had B19 viral infections. No patients had chronic or recurrent infections. In a study of 48 patients with aplastic crises, Mallouh and Qudah[271] found 91 percent to be infected with B19 virus. In addition to the anemia, 21 percent of the patients had leukopenia, 27 percent had neutropenia, and 42 percent had thrombocytopenia. The same investigators noted acute splenic sequestration together with aplastic crisis in three patients with sickle-cell disease and B19 virus infection.[270] Lowenthal and associates[263] noted three young adults with sickle-cell acute chest syndrome associated with B19 virus infection. Yetgin and colleagues[483] reported a case of a 10-year-old child with severe, refractory aplastic anemia ultimately requiring bone marrow transplantation, which resolved the symptoms.

Interestingly, reports of exanthematous illness occurring after aplastic crisis are rare.[205,465] However, patients with aplastic crisis require transfusion with packed cells, and rashes occurring after such treatment possibly would be regarded as transfusion reactions. Joint symptoms occur fairly frequently in patients with conditions such as sickle-cell anemia, so although the symptoms may occur as a result of B19 infection, they may be diagnosed as "painful crises."

As noted earlier, human parvovirus B19 infection does not result in aplastic crisis invariably in a chronic hemolytic anemic patient. Some individuals escape this complication if they have undergone transfusion recently,[13] possibly because of a protective effect of transfused antibody (>60% of donors are immune), the substitution of longer-lived, donated erythrocytes for the patients' own fragile ones, or a combination of these two mechanisms.

In populations in which aplastic crisis does occur, the severity of the episode varies among individuals, perhaps reflecting the variation in erythrocyte life span among these patients.[13]

OTHER HEMATOLOGIC MANIFESTATIONS

In addition to pure red blood cell aplasia, numerous other hematologic manifestations, including thrombocytopenic purpura, pancytopenia, hemophagocytic syndrome, neutropenia, and Diamond-Blackfan syndrome, have been observed in association with B19 virus infection.* Thrombocytopenia has been noted as an isolated event, thus suggesting that idiopathic thrombocytopenic purpura may be associated with aplastic crisis.[5,127,190,253,312,486] Thrombocytopenia is most commonly related to a decrease in megakaryocytes in bone marrow as a result of the inhibitory effect of the virus on granulocyte-megakaryocyte colony-forming-units,[5,367,465] although acquired pure amegakaryocytic thrombocytopenic purpura with resultant absence of bone marrow megakaryocytes secondary to B19 virus also has been described.[38]

Pancytopenia has been observed in association with aplastic crisis, and hemophagocytosis often is demonstrated.† Yufu and coauthors[490] described a 15-year-old girl with hemophagocytic syndrome and lymphadenopathy resembling histiocytic necrotizing lymphadenitis (Kikuchi disease).

McClain and colleagues[279] studied 19 children with immune-mediated neutropenia and found by polymerase chain reaction (PCR) assay of bone marrow specimens that 15 had evidence of B19 virus infection.

ARTHRITIS AND ARTHRALGIA

As noted earlier, acute arthritis and arthralgia occur commonly in patients with erythema infectiosum. In most instances, the joint symptoms subside within a few weeks, but the arthralgia and arthritis persist occasionally. Researchers also have observed that the joint manifestations caused by B19 virus infection can occur without any exanthem or with an exanthem not typical of erythema infectiosum. These findings have led to investigations related to the role of B19 virus in rheumatoid arthritis (RA).‡

Nocton and associates[328] described the clinical characteristics of 22 children seen in their rheumatology clinic with joint complaints and evidence of recent B19 virus infection. Of this group, 16 were girls and 6 were boys. The youngest patient was 2 years old, and the oldest was 19 years of age. Seven of the patients had associated rashes, but none had typical erythema infectiosum. One of these children had a petechial rash on the lower extremities, and another child had a past history of urticaria. Fever, anorexia, malaise, or fatigue occurred in 11 of the patients.

*See references 10, 13, 63, 104, 142, 144, 158, 204, 205, 254, 300, 333, 339, 373, 382, 397, 410, 424, 465, 487, 489, 497.

†See references 43, 158, 168, 207, 235, 247, 306, 312, 437, 444, 460, 490.

‡See references 65, 129, 154, 168, 206, 207, 223, 289, 293, 324, 328, 369, 413, 418, 428.

Of the 22 patients, 20 had arthritis and 2 had only arthralgia. The knee joints were most commonly involved. The following frequency of specific joint involvement was reported: knees, 82 percent; ankles and wrist, 41 percent; elbows, 32 percent; neck, small joints of the hands and feet, and hips, 27 percent; shoulders, 23 percent; and sternoclavicular joints, 9 percent. Ten of the patients had involvement of five or more joints, and in 12 patients the pattern was pauciarticular, with four or fewer joints involved. Two patients had only a single joint involved, and two patients had migratory illness.

The duration of the arthritis or arthralgia was less than 6 weeks in 50 percent of the children and less than 4 months in 64 percent. Of the 11 children with illness lasting longer than 2 months, 6 had manifestations that fulfilled the criteria for the diagnosis of juvenile rheumatoid arthritis (JRA). Selected laboratory results were as follows: the erythrocyte sedimentation rate was greater than 25 mm/hr in 32 percent of the children, antinuclear antibody titers were greater than 1:40 in 7 of 21 of the patients, and 3 of 6 children had a low total hemolytic complement (CH_{50}) value.

The relationship between B19 virus infection and JRA, RA, and adult Still disease has been studied extensively during the past 15 years, but the findings are difficult to interpret.* Clearly, B19 virus can cause illnesses that fulfill the criteria for a diagnosis of JRA[53,328,338,467] and adult Still disease.[207,261] However, three possible scenarios need to be considered: (1) B19 virus causes a similar illness, (2) B19 virus infection triggers the onset of an illness caused by another condition, and (3) B19 virus directly causes JRA, adult Still disease, and RA.

In one study involving patients with refractory RA and refractory polyarticular JRA, researchers found that both groups had a significantly higher frequency of IgG B19 virus antibody as determined by enzyme-linked immunosorbent assay (ELISA) than did aged-matched controls.[289] However, when the data in this study were examined, the prevalence of antibody in the control population clearly was less than expected. In another study, Kishore and colleagues[223] studied IgM antibody to B19 virus by ELISA and found that 28 percent of patients with JRA, 8 percent of controls, and none of the patients with RA had positive values. They interpreted their JRA findings to be either triggering B19 virus infections or perhaps intercurrent infections in patients with established JRA. In a provocative study, Takahashi and coworkers[428] found B19 virus DNA in the synovial tissue of 30 of 39 patients with RA. The data suggested that the virus identified in synovial tissue was active and led to their conclusion that B19 virus is involved in the initiation and perpetuation of RA synovitis. In contrast, Nikkari and associates[324,326] in Finland performed extensive studies and noted that chronic rheumatoid-like arthropathies triggered by B19 virus occasionally occur. However, their data do not support a general role for B19 virus in the etiology or pathogenesis of RA. B19 infection can lead to increased circulation of immune complexes, endothelial injury, inflammation, and exacerbation of underlying vasculitic disease.[56]

Tyndall and colleagues[442] described an adult woman with erosive polyarthritis associated with B19 virus infection, and Samii and coworkers[387] reported two adults with bilateral carpal tunnel syndrome associated with B19 virus infection. Berg and colleagues[34] could find no association with either IgG or IgM antibody to B19 virus and fibromyalgia in a study of 26 adult women and matched controls. Guillaume and coauthors[150] reported a case of chronic arthropathy in the lumbar facet joints after B19 infection.

Other rheumatic and vasculitic syndromes have been noted in association with parvovirus B19 infection; however, the strength of these associations is unclear. These associated syndromes include fibromyalgia,[335] systematic lupus erythematosus,[99,188,400] Kawasaki disease, leukocytoclastic vasculitis, polyarteritis nodosa, Wegener granulomatosis,[107] chronic fatigue syndrome,[211,212,280] systemic sclerosis,[124,341,342] giant-cell arteritis, transient anticardiolipin syndrome and transient antiphospholipid syndrome,[20] hemophagocytic syndrome, Henoch-Schönlein purpura,[76,173,343] uveitis with and without associated systemic disease,[174] myofasciitis,[187] and Raynaud phenomenon.*

INFECTION IN IMMUNOCOMPROMISED PATIENTS

Some immunodeficient patients suffer chronic B19 virus infections.† These patients have persistent anemia caused by continuous lysis of red cell precursors. This problem has been seen most commonly in children with acute lymphocytic leukemia.[62,92,112,122,172,210,231,242,482]

Other immune deficiency states in which chronic B19 virus was documented include Nezelof syndrome, acute myeloid leukemia, chronic myeloid leukemia, Burkitt lymphoma, lymphoblastic lymphoma, myelodysplastic syndrome, astrocytoma, Wilms tumor, HIV infection,[78,316] severe combined immunodeficiency, bone marrow transplantation,[164,218,364,423] other organ transplants,[32,69,108,239,295,347] systemic lupus erythematosus,[426] and patients receiving chemotherapy.[107,122,172,240] The immune deficiency in the aforementioned conditions can be a primary event or a secondary event related to treatment.

Eid and colleagues[109] reviewed 98 transplant recipients in whom acute parvovirus B19 infection developed after transplantation. The median time to B19 disease was 7 weeks after transplantation. Anemia developed in 99 percent, leukopenia in 38 percent, thrombocytopenia in 21 percent, and allograft loss or dysfunction in 10 percent. Three patients died of myocarditis and cardiogenic shock as a result of B19 infection.

Patients with chronic anemia have high persistent concentrations of B19 virus in their serum, although the values (10^8 particles per milliliter) are less than those seen in primary infections (10^{10} to 10^{11} particles per milliliter) in healthy individuals and in patients with hemoglobinopathies.

Viremia and anemia may, if untreated, persist for years. Fatigue and pallor are the most common clinical symptoms, and other findings of B19 virus infection, such as exanthem and arthralgia, occur rarely. Because of immunodeficiency, IgM antibody studies generally are not useful in making the diagnosis. Therefore, the diagnosis of persistent B19 virus infection depends on demonstration of specific B19 antigen or DNA in blood.[56]

In immunocompromised patients, persistent infection with B19 virus often occurs as a result of failure to produce effective neutralizing antibodies.[56,74,235] IVIG preparations have been used successfully for the treatment of B19 virus in immunocompromised patients.‡ Patients taking immunosuppressive agents, especially calcineurin inhibitors, may be unable to clear B19 virus because these medications inhibit IL-2 production and the patients are unable to mount an effective T_H1 response.[74,295] It may be necessary to reduce the dose of immunosuppressive agents in addition to IVIG treatment to successfully eradicate B19 virus.[31,258] LaMonte and associates[244] reported five children (three HIV-infected children and two otherwise normal children) with chronic infections without B19-associated anemia.

INTRAUTERINE INFECTION

Although a large epidemiologic study of an outbreak of erythema infectiosum 40 years ago failed to reveal evidence of teratogenicity, virologic and serologic studies conducted during the past 2 decades indicate that B19 virus crosses the placenta and causes infection in the fetus.* Infection in pregnancy results in fetal hydrops because of the severe anemia and leads to cardiac failure, fetal death, and miscarriage.[74,275,336] To determine the rate and outcome of fetal involvement after infection in pregnant women, a large prospective study was performed in England during a $3^1/_2$-year period from January 1985 to June 1988,[371] and more recently, from 1992 to 1995, a second study was performed.[288] These two studies included 427 pregnant women infected with B19 virus; 367 infants survived, and 129 of them had follow-up examinations at 7 to 10 years of age.[288] The excess rate of fetal loss was 9 percent, and such loss occurred only during the first 20 weeks of gestation. Seven cases of fetal hydrops occurred, and three of these fetuses survived; two of the three received intrauterine transfusions. None of the surviving infants in the two studies had abnormalities attributable to B19 virus infection, and no later effects were found at 7 to 10 years of age. Of the infants exposed in utero after 20 weeks' gestation, more than half were infected, but no clinical effects were identified. In a study by Nyman and colleagues,[337] the frequency of first-trimester fetal loss associated with B19 virus was 3 percent, with 12 percent occurring in the second trimester.

In a study in Connecticut related to a large outbreak of erythema infectiosum in which 39 infected pregnant women were monitored, two miscarriages occurred.[380] The frequency of fetal loss caused by B19 virus infection was estimated to be 5 percent. In another study in Spain, fetal loss occurred in only 1 of 60 women infected with B19 virus during pregnancy.[146] Enders and colleagues[115] studied 1018 pregnant women with acute parvovirus infection. The overall rate of fetal loss was 6.3 percent, with a rate of 11 percent if the B19 infection occurred in the first 20 weeks of gestation. The overall rate of hydrops fetalis was 3.9 percent, and the peak incidence occurred between 17 and 24 weeks' gestation.

Koch and colleagues[229] performed follow-up examinations on 19 infants born to mothers who had serologically confirmed B19 virus infection between the 4th and 38th weeks of gestation. In none of these infants did hydrops develop during pregnancy, and all were normal after birth. One child whose mother had erythema infectiosum at approximately the 20th week of gestation had a persistent asymptomatic infection for at least the first 7 months of life. Donders and coworkers[101] noted a child in whom a sonogram demonstrated fetal hydrops at 30 weeks' gestation. Cordocentesis revealed a hemoglobin concentration of 2.4 g/dL. One week later, a hydropic 1550-g infant was delivered by cesarean section. The baby's bone marrow showed an arrest in erythropoiesis with giant pronormoblasts. The baby received multiple transfusions for the first 4 months of life, and B19 viral DNA was identified in the infant's blood at 19 weeks of age. At 2 years of age, this child was found to be clinically, hematologically, and immunologically normal.

Candotti and colleagues[59] studied plasma samples from 885 pregnant women from Ghana and found that, contrary to the high rate of B19 transmission during primary viremia in pregnancy, pregnant women with B19-specific IgG and low levels of B19 DNA by PCR did not transmit virus to the fetus.

In contrast to the case just noted, Brown and associates[50] reported a baby with a similar exposure and delivery history who had persistent anemia and, despite therapy, was transfusion-dependent at 4 years of age. In addition, Brown and associates reported two other infants who had received intrauterine transfusions for fetal hydrops and had persistent anemia after birth.

At the present time, a large number of babies who were exposed to B19 virus in utero have been studied, with no convincing evidence of specific congenital malformations.[221,301,371,379,380,472] However, van Elsacker-Niele and associates[448] noted B19 virus infection in cells other than those of the erythroid series in two aborted fetuses. Ocular malformation was found in one, and evidence of extensive inflammatory reactions in all fetal and placental tissues was noted in both.

Tiesson and colleagues[433] reported an aborted fetus with a bilateral cleft lip, alveolus, and palate; micrognathia; and webbed joints. In another aborted fetus, ocular abnormalities similar to those seen in congenital rubella were observed.[464] In a newborn with anemia, blueberry muffin rash, and hepatomegaly, parvovirus B19 viral gene sequences were found in the liver and placenta.[406] Gulen and associates[151] described a premature infant born at 29 weeks' gestation with leukoerythroblastosis associated with B19-specific IgM and IgG antibody in both the mother and baby.

Yeh and colleagues[481] described severe, transient dyserythropoietic anemia in puerperal woman with pre-eclampsia and eclampsia with concomitant B19 infection.

NEUROLOGIC ILLNESS

Two children with encephalitis in association with erythema infectiosum were noted in the era before discovery of the causative role of B19 virus in erythema infectiosum.[27,156] In the present era, a number of cases of aseptic meningitis and encephalitis have been reported in association with B19 virus infection in both children and adults.* These cases have been documented by the demonstration of specific B19 virus IgM antibody or the presence of B19 viral DNA in cerebrospinal fluid (CSF). Bilge and colleagues[39] reported a 12-year-old boy with a history of renal transplantation who had recurrent episodes of encephalopathy and focal neurologic defects associated with B19 DNA in blood and bone marrow and on skin biopsy specimens. He was treated successfully with IVIG. Nolan and colleagues[329] reported an HIV-positive patient in whom parvovirus B19 encephalitis developed during immune reconstitution while receiving highly active antiretroviral therapy. Chorea-encephalopathy, with parvovirus B19 DNA in both serum and CSF, developed in a previously healthy 8-year-old girl.[126]

Other neuralgic illnesses associated with B19 virus infection[29] include postinfectious neuralgic amyotrophy,[356] Guillain-Barré syndrome,[290] acute bilateral carpal tunnel syndrome,[264,387] mononeuritis multiplex,[4] stroke,[149,272] and numbness and tingling of the fingers in seven nurses.[492] Five of these nurses had erythema infectiosum, and in the other two the only manifestation of infection was numbness and tingling. All cases in this study were diagnosed by the demonstration of specific B19 virus IgM antibody during an outbreak of erythema infectiosum in Buffalo, New York, in 1987.

MYOCARDITIS

Myocarditis in association with parvovirus B19 infection has been observed in immunocompetent children and adults.† B19-

*See references 29, 39, 64, 126, 160, 168, 170, 206, 209, 233, 329, 344, 419, 420, 425, 462, 479.

†See references 57, 98, 113, 237, 245, 262, 309, 321, 349-351, 357, 384.

associated myocarditis can progress to chronic dilated cardiomyopathy.[237,238,245,262,349,350] In a study of 3345 patients who underwent cardiac biopsy for suspected myocarditis or dilated cardiomyopathy, Pankuweit and colleagues[350] found B19 DNA by PCR in 17.6 percent of patients with dilated cardiomyopathy without significant inflammation, and inflammatory heart disease, ventricular dilation, and reduced ejection fraction were noted in 33.3 percent of patients. Kühl and associates[238] showed that viral persistence in the setting of myocarditis or dilated cardiomyopathy was associated with progressive deterioration of the left ventricular ejection fraction whereas elimination of virus resulted in significant improvement in left ventricular function.

In a study by Wang and colleagues,[458] B19 virus was detected by nested PCR in cardiac tissues in 7 of 42 patients with congenital heart disease and in none of the 38 controls, thus suggesting a correlation between B19 virus and congenital heart disease.

Enders and associates[113] described two children with life-threatening myocarditis. One of these children died, and the second received a cardiac transplant. The illnesses in both these children occurred in the spring (April), and one had joint pain and urticarial lesions on the flexor surfaces of both arms, erythematous macules on the abdomen and upper part of the chest, and purpuric lesions on the back. Both children had B19 viral DNA identified in the heart and B19-specific IgM antibody.

Nigro and colleagues[321] noted three young children, aged 7, 12, and 18 months, with acute lymphocytic myocarditis and parvovirus B19 infection. Two of these children exhibited full cardiac recovery, but chronic persistent myocarditis developed in the other child. Papadogiannakis and coauthors[351] reported a healthy 11-month-old child who had severe respiratory distress and died of sudden cardiac arrest within 3 hours of admission because of parvovirus-associated lymphocytic myocarditis. Zack and associates[493] reported a 5-year-old girl who suddenly collapsed and died of acute myocarditis secondary to parvovirus B19 infection. Significant lymphocytic infiltration of the sinoatrial node and perivascular infiltration around the atrioventricular node probably resulted in conduction disturbances and death. Jonetzko and colleagues[201] reported a case of fatal parvovirus B19–associated myocarditis in a liver transplant recipient.

Parvovirus B19 infection also can mimic acute myocardial infarction[57,237] and isolated diastolic dysfunction in adults.[438]

It is hypothesized that the blood group P antigen on the endothelial cells of coronary vessels is a portal for infection and that such infection results in endothelial dysfunction, impairment of the coronary microcirculation, and inflammation of the myocardium.[29,237,245] The blood group P antigen is not present on the myocytes of children and adults; however, it is present on fetal myocytes.[49,237,245,345]

ACUTE HEPATITIS

Acute hepatitis has been noted as a manifestation of B19 virus infection. Yoto and coworkers[484] described seven children with acute hepatitis in association with B19 virus infection. They carefully studied and ruled out other common causes of acute hepatitis. Sokal and associates[414] reported fulminant hepatitis in four children younger than 5 years in association with parvovirus B19 infection. Their patients had a distinct clinical pattern consisting of low serum bilirubin concentrations and rapid recovery of liver function without transplantation. Nobili and colleagues[327] reported a case of autoimmune hepatitis followed by severe autoimmune hemolytic anemia in a 1-month-old boy with parvovirus B19 infection. Treatment with cyclosporine and prednisone resulted in resolution of his symptoms.

Hsu and associates[185] studied 54 patients with B19 virus infection in addition to hepatitis B virus (HBV) infection and 51 patients with hepatitis C virus (HCV) infection who were not taking immunosuppressive drugs. The study found that the prevalence of parvovirus B19 DNA was high in patients with HBV (85.2%) or HCV (70.6%). Co-infection with B19 and HBV or HCV did not increase the frequency of liver dysfunction in these patients with chronic hepatitis.[185,250] Additionally, in a study by Wong and associates,[475] there was no significant difference in the prevalence of parvovirus B19 DNA in liver biopsy specimens from patients with fulminant hepatitis or hepatitis-associated aplastic anemia and those with HBV or HCV infection. The role of parvovirus B19 in the development of fulminant hepatitis is currently unclear.

OTHER ILLNESSES

One adult patient had chronic red cell aplasia for a 10-year period that was treated with regular blood transfusions.[243] After diagnosis of persistent B19 virus infection, the patient was treated with IVIG, which resulted in an apparent cure. A presumably immunologically normal woman had recurrent episodes of paresthesia over the course of a 4-year period in conjunction with persistent B19 viral DNA in her blood.[121] Evidence of persistent infection in immunologically normal patients has been noted in other studies.[215,311]

Kerr and associates[214] studied 53 patients who had contracted acute B19 virus illnesses. Seven of those studied had B19 viral DNA demonstrated in serum specimens 26 to 65 months after their acute illnesses. All seven were women, and four were asymptomatic. Of the other three, one had chronic hemolytic anemia, one had persistent arthralgia of the knees, and the last had arthralgia and chronic fatigue syndrome.

Multiple case reports have described patients with chronic fatigue syndrome and persistent parvovirus B19 DNA in their serum.[196,211,212,276,280] In 2002, Kerr and colleagues[217] described three patients with chronic fatigue syndrome and chronic B19 virus infection treated with IVIG. Such treatment resulted in the clearance of B19 viremia, improvement of symptoms, and resolution of cytokine dysregulation.

Faden and associates[121] described a nurse with recurrent episodes of paresthesia who had B19 viral DNA demonstrated in her serum for almost a 4-year period. This woman also had persistent serum IgM antibody to B19 virus.

Lymphadenitis associated with parvovirus B19 infection has been described by many authors. Tsuda and coworkers[439] reported five young adults with cervical lymphadenopathy associated with B19 virus infection. All had fever, one had arthralgia, and all had leukopenia. Morinet and colleagues[298] described a 27-year-old man with pseudoappendicitis or acute mesenteric lymphadenitis and serologic evidence of B19 virus infection. A 16-month-old boy had peripheral facial palsy, parotitis, and intraparotid lymphadenitis with evidence of parvovirus B19 IgM antibody and IgG antibody seroconversion.[274] Johnson and associates[199] described an 18-year-old woman with parvovirus B19 resulting in necrotizing lymphadenitis, and Knösel and colleagues[224] reported unilateral cervical lymphadenopathy in a 16-year-old girl. In both cases, parvovirus B19 DNA was detected by PCR on lymph node biopsy specimens.

Parvovirus B19 infection also has been shown to induce proliferative glomerulonephritis, usually endocapillary or mesangioproliferative (or both), with hypocomplementemia and spontaneous recovery.[189,195,297,340,430,431,461] Ieiri and colleagues[189] studied 10 patients with acute glomerulonephritis associated with human parvovirus B19 infection. These authors found that this specific renal disease characterized by endocapillary hypercellularity was associated with hypocomplementemia, leukopenia, positive antinuclear antibody, and a female preponderance (9 of 10 patients). Ohtomo and associates[340] reported a healthy 8-year-

old boy with erythema infectiosum and glomerulonephritis with immune complex deposits associated with B19 virus diagnosed by both monoclonal antibody against human parvovirus B19 antigen and nested PCR on renal biopsy. The association between parvovirus B19 and sepsis also has been reported by multiple authors. These patients exhibited shock, severe respiratory distress, and parvovirus B19 infection.[24,123,299,351,459]

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Because the exanthem of erythema infectiosum is unique, its diagnosis should be easy. During epidemics, no difficulties should arise, but sporadic cases can be a problem. In the differential diagnosis, rubella and scarlet fever are of most concern. Because rubella virus has been recovered from some patients with illness thought to be erythema infectiosum[27] and because an erythema infectiosum–like illness was observed in volunteers who underwent intranasal administration of a rubella virus strain recovered from a patient with erythema infectiosum–like illness,[389] this diagnostic possibility always should be considered. When the risk of development of congenital rubella is a possibility, rubella-specific diagnostic tests should be performed (see Chapter 186).

Erythema infectiosum can be differentiated from scarlet fever by the usual lack of pharyngitis in the former and a positive culture for *Streptococcus pyogenes* in the latter. Other differential diagnostic considerations are other infectious exanthems (see Chapter 64), collagen vascular diseases, drug reactions, and allergic responses to environmental substances.

Although a presumptive diagnosis of B19 virus infection may be made by exclusion of other etiologic possibilities, a definitive diagnosis can be made only by specific serologic tests or identification of B19 antigens or DNA in blood or tissue specimens.

Aplastic crisis in a patient with chronic hemolytic anemia can be diagnosed by finding a hemoglobin concentration that is 2 g/dL or more below the steady-state value for that patient, together with a reticulocyte count either less than 0.2 percent of the steady-state value or elevated above the steady-state value (indicative of hyperplasia of erythrocyte precursors in the recovery phase). Although B19 virus infection is the most common cause of aplastic crisis, moderate to severe degrees of hypoplasia may be associated with systemic bacterial infections (e.g., *Salmonella*, *Streptococcus pneumoniae*) or marrow-suppressive drugs (e.g., chloramphenicol).[284,397]

SPECIFIC DIAGNOSIS

Several tests have been developed and refined that allow a reliable serologic diagnosis of acute and past B19 virus infection to be established and B19 virus in blood and tissues to be demonstrated.* IgM and IgG antibody can be detected by enzyme immunoassay, hemadherence, radioimmunoassay, or immunofluorescence; antigen can be detected by DNA hybridization, PCR, or electron microscopy.

In a normal host, acute or recent infection is determined best by demonstration of specific IgM antibody. In immunocompromised patients with suspected acute or chronic infection, the diagnosis is made by detection of antigen in blood. Similarly, detection of antigen also can be performed early in aplastic crisis and to study aborted fetal tissues. Gallinella and colleagues[138] recommend both specific IgM and B19 DNA PCR to establish a diagnosis of B19 infection.

Past infection and immunity to B19 virus are determined by demonstration of specific serum IgG antibody.

Some caution should be observed in accepting the results of IgM serology and antigen detection in unusual clinical circumstances.[48] The sensitivity and specificity of the various serologic tests vary, and additional false-positive and false-negative results can be expected, depending on the skill of workers in individual laboratories.[55,82,436,445] Antigen-detection systems can be contaminated, and such contamination may not be discernible by conventional controls. When the results of tests on specimens from patients with unusual illnesses are positive, repeating the tests in a different laboratory is worthwhile.

Söderlund and associates[412] reported an IgG avidity assay that is highly sensitive and specific for the identification of recent primary infection with parvovirus B19. Enders and coworkers[114] also recommended VP1 IgG avidity or VP2 epitope–type specificity assays in the presence of low-level IgM or B19 DNA to confirm or refute the diagnosis of B19 infection during pregnancy. Because there is a window of 7 days after initial infection occurs until the development of IgM-specific B19 antibody and because IgM can be negative or low in the presence of overt hydrops fetalis, both serology and B19 DNA PCR are recommended on both maternal and fetal sera (or cord blood).[108]

Beersma and colleagues[33] demonstrated the superiority of B19 VP2 IgM ELISA by showing high correlation with elevated levels of B19 DNA in sera. Persistent infection may be determined by the presence of IgG antibody to NS1.[452]

If parvovirus B19 infection is suspected in pregnancy, ultrasound should be performed to assess for fetal anemia and hydrops (excess of fluid in at least two body compartments of the fetus).[108] The use of middle cerebral artery peak systolic velocity for the detection of fetal anemia may be a useful adjunct to ultrasound scanning.[89,303]

TREATMENT AND PROGNOSIS

No specific treatment of B19 virus infection exists. Symptomatic therapy for erythema infectiosum rarely is necessary, especially in children. Starch baths may be helpful in reducing pruritus. Arthralgia or arthritis may be troublesome and may be treated with analgesics.

Patients with aplastic crisis may require erythrocyte transfusions to raise their peripheral hemoglobin concentration.

The outlook in virtually all cases of erythema infectiosum is excellent. If patients with aplastic crisis receive transfusions with packed erythrocytes when necessary, the prognosis for these patients also is excellent. If B19 virus infection occurs during pregnancy, the pregnancy should be monitored carefully. At delivery, examination of cord blood or blood from the neonate for detection of virus and IgM antibody will reveal whether the virus has crossed the placenta and infected the fetus. When infection has occurred, the child should be examined carefully for any defect and monitored for some years to exclude the possibility of delayed sequelae.

Some researchers have suggested that pregnant women with symptomatic B19 virus infection be observed for fetal aplastic crisis by monitoring maternal serum for elevated levels of alpha-fetoprotein.[61] If levels are found to be elevated, serial ultrasonography can be performed to detect hydrops fetalis. Fetal hydrops can be treated by in utero transfusions.[118,145,383] However, there is a risk of infection and the potential for congenital malformations with cordocentesis and fetal transfusion. Enders and colleagues[115] reported that 84.6 percent of those with severe hydrops fetalis survived to delivery. In 2005, Matsuda and colleagues[277] successfully treated a B19-infected fetus with hydrops at 21 weeks'

*See references 10, 15, 22, 33, 47, 55, 60, 66, 68, 80, 82, 83, 93, 94, 116, 134, 138, 178, 181, 219, 226, 228, 285, 296, 318, 385, 392, 394, 427, 457, 474, 495.

gestation with two injections of B19 IgG–rich immunoglobulin injected into the fetal peritoneal cavity. The fetal ascites and pericardial effusion resolved completely 8 days after the initial injection, and a healthy baby was born at 38 weeks' gestation without evidence of cardiac dysfunction or B19 DNA detected in serum. Therapeutic abortion is not indicated for pregnant women with documented B19 virus infection.

Patients with chronic myocarditis caused by B19 virus have been treated successfully with IVIG.[421] Chronic myocarditis secondary to B19 also has been treated with immunosuppressive agents, including corticosteroids and cyclosporine.[245,309,384] Ito and associates[194] described a patient with baseline refractory autoimmune hemolytic anemia who was taking immunosuppressive medications while infected with B19 virus. The patient had a complicated course; persistent pure red cell aplasia subsequently developed but resolved after treatment with cyclosporine and IVIG.

Immunocompromised patients with chronic B19 virus infection can be treated successfully with IVIG preparations,[40,53,100,168,174,193,206,231,401] as can other patients without demonstrated immune deficiencies who have chronic infections.[121,194,196,305,421] Although the amount of specific B19 virus antibody varies among different IVIG products, all contain significant concentrations.[100] No formal treatment studies have been performed, and several different treatment programs have been used. Even though some cures have been achieved with single-dose IVIG therapy, we favor an initial 4-day course with 500 mg/kg/day. After the patient has received treatment, the viremia should cease and clinical improvement should occur. Some immunocompromised patients have required repeated treatment courses.

PREVENTION

B19 virus is spread by the oral and respiratory routes, and virus shedding during routine infection occurs when patients are not aware of their illness. Because B19 virus infections occur in outbreaks, the virus can be widespread in a community, with many infections going unrecognized.

Patients with erythema infectiosum do not need to be isolated because they have passed their period of infectivity. Although patients with aplastic crisis also usually are past the period of virus shedding, they should be isolated because some will be shedding virus at the time of initial evaluation. All patients with chronic infection should be considered contagious until treated with IVIG and demonstrated to be nonviremic.

Pregnant women are of particular concern during an outbreak.[63,141] The rate of parvovirus seropositivity is approximately 50 percent in women of child-bearing age, so no risk exists in approximately half of those who might become exposed. Determining an IgG antibody titer can allay the fear in those who are antibody-positive. Cartter and associates[63] examined occupational risk factors for B19 virus infection in pregnant women. They found the following rates of infection: school teachers, 16 percent; daycare workers, 9 percent; homemakers, 9 percent; and women working outside the home, 4 percent. In another study, Gillespie and colleagues[141] found the greatest risk for infection occurred in school and daycare personnel. These results suggest that in certain circumstances (in older women and those with past fertility problems), having women in high-risk occupations avoid the workplace during the outbreak period might be reasonable.

Technologic advances have led to the development of experimental recombinant vaccines that show considerable promise for effective prevention.[28,85,118,132,165,488] These vaccines could be useful in selected populations, such as patients with hemoglobinopathies and seronegative women of child-bearing age.

CHAPTER 165

Human Bocaviruses

James D. Cherry

Human bocavirus was described first in 2005 by Allander and associates.[4] Since then, this virus has been associated with a significant number of respiratory illnesses in children throughout the world.*

HISTORY

Allander and coworkers[4] developed a system for molecular virus screening of clinical nasopharyngeal samples. This system was based on host DNA depletion, random polymerase chain reaction (PCR) amplification, large-scale sequencing, and bioinformatics. Using two pools of nasopharyngeal aspirate samples from patients (mainly children) with respiratory illnesses seen in November and December 2003 and March 2004, they found two agents that had an amino acid sequence that significantly matched bovine parvovirus and canine minute virus. These viruses are members of the *Parvoviridae* family, subfamily *Parvovirinae*, genus *Bocavirus*. These investigators proposed the provisional name *human bocavirus* for this new virus. During the ensuing years, this virus has been identified in respiratory samples and at other sites from patients throughout the world.†

PROPERTIES

As noted in Chapter 164, members of the family *Parvoviridae* are small, nonenveloped, single-stranded DNA viruses. The complete genome length of human bocavirus has not been determined, but at least 5299 nucleotides were identified in one of the two reference strains.[4]

The genome is thought to contain three open-reading frames; two of these frames encode the nonstructural proteins NS1 and NP-1, and the other encodes the two capsid proteins VP1 and VP2.[4,36] The function of NS1 in human bocavirus infection is not known. However, in other parvoviruses, NS1 is involved in the binding and hydrolysis of nucleoside triphosphates and has helicase activity. The function of NP-1 is unknown. The virion-associated proteins (VP1, VP2) are more immunogenic than are the nonstructural proteins, and their coding sequences have considerable variability.[36]

The cellular site of human bocavirus replication is not known.[36] The virus has not been propagated in tissue culture, and, as yet, no animal model of infection has been identified.

EPIDEMIOLOGY

Infection with human bocavirus enjoys worldwide prevalence.[36] The virus exists as a single lineage with two genotypes. The virus has been identified in nasopharyngeal samples from children hospitalized with respiratory illnesses in 1.5 to 19 percent of those studied.[2] Infection is seen most frequently in children younger than 2 years old, but infection occurs in older children as well. The prevalence of infection in adults with respiratory illness is low.

In a seroprevalence study in Japan involving sera from 204 subjects younger than 3 months to older than 20 years in which antibody to the VP1 protein was measured, the following positivity rates were found: younger than 3 months, 90.5 percent; 3 to 5 months, 40.0 percent; 6 to 8 months, 5.6 percent; 9 to 11 months, 33.3 percent; 1 year, 42.3 percent; 2 to 3 years, 83.3

percent; 4 to 5 years, 89.5 percent; 6 to 19 years, 100 percent; and older than 20 years, 94.1 percent.[12] Human bocavirus is detected most frequently in nasopharyngeal specimens in children between the ages of 6 and 24 months, and the seroprevalence data from Japan[12] suggest that virtually all children have had an infection during the first 5 years of life.

Infections with human bocavirus occur throughout the year.[3,8,27] In one large study, the peak rate of infection occurred in the spring (March through May) in two successive years in San Diego, California.[6] Human bocavirus was not identified in August and September in this study. In numerous studies, respiratory illness was seen more commonly in boys.[6,8,11,18,21,25,31,32] However, in a study in Korea in which the male-to-female ratio was noted in eight different respiratory viral infections, researchers found that males predominated with all viruses except human bocavirus.[26] The ratio in bocavirus infections was 1:1.4.

Human bocavirus has been identified in stool specimens from children with diarrhea,[1,21,22,40] in the serum of children with respiratory illnesses,[3] and in nasopharyngeal specimens from well children.[15,24]

PATHOGENESIS

The method of transmission of human bocavirus is not known. However, because the virus is present in the nasopharynx in high concentrations, a reasonable conclusion is that its spread is similar to those of other respiratory viruses.[36] This spread could involve contact transmission with droplet nuclei or by aerosol, or both, as well as hand-to-hand and hand-to-surface transmission with self-inoculation.

A unique feature of human bocavirus respiratory infections is the high frequency of mixed infections with other respiratory viruses, leading to concern that bocavirus is a passenger agent and not the cause of the respiratory illness.[2,36] However, in many instances, no co-infecting virus is identified. Investigators also have noted that the severity of illness may correlate with the virus load.[16] Kantola and associates[16] demonstrated the occurrence of IgM antibody responses and titer increases of IgG antibody in children with respiratory illnesses.

In contrast with parvovirus B19 DNA, which was found in lymphoid tissue, bone marrow, and brain of autopsy specimens from persons both infected and not infected with the human immunodeficiency virus (HIV), human bocavirus was not found in any similar specimens.[29]

In one study of 512 outpatients with respiratory illness, 20 (3.9%) were found to have human bocavirus in their nasopharyngeal samples; in this same study, three (1%) controls had human bocavirus–positive nasopharyngeal samples.[15] In another study, 22 (5.3%) of 425 children with respiratory illness had bocavirus-positive nasopharyngeal samples, whereas no positive samples were found in 96 asymptomatic children.[19] In contrast with these two studies, a study in Quebec, Canada, found positive samples in 43 (43%) of 100 asymptomatic children and 31 (13.8%) of 225 symptomatic children.[24]

CLINICAL MANIFESTATIONS

RESPIRATORY ILLNESS

Human bocavirus has been found in nasopharyngeal specimens from children with both upper and lower respiratory tract illnesses. In several investigations, the signs and symptoms of illness in human bocavirus infections have been compared with those occurring in infections with other respiratory viruses.[7,10,13,15,24] In these comparative studies, the number of children by virus category is relatively small, but the overall findings in human bocavirus infections clearly are similar to those of viral infections with respiratory syncytial virus, human metapneumovirus, adenoviruses, influenza viruses, parainfluenza viruses, and rhinoviruses.

Data on routine laboratory studies in human bocavirus infections are sparse. In a U.S. study, the white blood cell count in children was 3000 to 31,000 cells/mm^3 (median, 13,300 cells/mm^3).[6] The median differential cell values were neutrophils, 40 percent; band forms, 10 percent; lymphocytes, 39 percent; and monocytes, 10 percent. The C-reactive protein level in six children ranged from 0.4 to 7.3 mg/dL (median, 0.7 mg/dL). In a German study, the white blood cell count range was 6700/mm^3 to 16,700/mm^3, and the median value was 11,300/mm^3.[42] The C-reactive protein level ranged from less than 0.3 to 114 mg/L, and the median value was 12.5 mg/L (normal value, <0.3 mg/L). In a Japanese study, the white blood cell count range was 4800 cells/mm^3 to 21,980 cells/mm^3 (median, 14,000 cells/mm^3), and the C-reactive protein level ranged from less than 0.20 to 4.48 mg/dL (median, 0.38 mg/dL).[25]

Upper Respiratory Tract Infections

In one study, 86 percent of 49 human bocavirus infections without co-infection with other agents were classified as upper respiratory illnesses.[13] In contrast, only 42 percent of 50 children in this study who had human bocavirus and a co-infecting agent were classified as having an upper respiratory illness. Pharyngitis was observed in 55 percent of the cases in which human bocavirus was the single agent identified. Of the children with human bocavirus infections without co-infections, 18 percent had acute otitis media and 12 percent had sinusitis. In another study, otitis media was reported in 61 percent of all human bocavirus infections.[24]

In a large study, Arnold and associates[7] noted the following findings at the time of presentation: fever, 68 percent; rhinorrhea, 67 percent; cough, 85 percent; conjunctivitis, 7 percent; vomiting, 30 percent; diarrhea, 21 percent; and rash, 7 percent. Of interest was that the cough was paroxysmal in 19 percent of the human bocavirus–infected children, whereas paroxysmal cough was much less common in adenovirus infections (7%) and human metapneumovirus infections (5%).

In one study in Korea, three of 36 (8.3%) children infected with human bocavirus had croup.[10] In a study in Canada, two of 58 (3%) bocavirus-infected children had croup,[8] and in a study in Japan, one of 18 (6%) had laryngotracheitis.[25]

Lower Respiratory Tract Infections

Longtin and colleagues[24] noted that 42 percent of children with human bocavirus infections had pneumonia and that 42 percent had bronchiolitis. In the large study in San Diego, California, involving 82 children with human bocavirus infections, 76 children with adenoviral infections, and 87 children with human metapneumovirus infections, the investigators were able to compare the rates of various clinical findings.[7] In this study, the following rates of events were noted in bocavirus-infected children: hospitalization, 69 percent; need for oxygen administration, 44 percent; admission to intensive care unit, 11 percent; intubation, 4 percent; clinical lower respiratory tract disease, 61 percent; hypoxia, 41percent; increased work of breathing, 59 percent; abnormal lung findings, 51 percent; "atelectasis vs. infiltrate," 11 percent; "infiltrate" or "pneumonia," 9 percent; and bronchiolitis, 46 percent. Comparatively, adenovirus-infected children had less lower respiratory tract disease, less hypoxia, and less increased work of breathing and were more likely to have normal chest radiographic findings than were children with human bocavirus and human metapneumovirus infections.

In a study in Korea, 53 percent of human bocavirus–infected children had rales noted on chest auscultation and 42 percent had wheezing.[10] The clinical diagnoses in this study were bronchiol-

itis (25%), pneumonia (56%), exacerbation of asthma (11%), and croup (8%). In a study in Germany, 32 children with lower respiratory tract disease were studied.[43] The diagnoses were bronchitis (16%), wheezing bronchitis (14%), bronchiolitis (3%), and pneumonia (18%). Ten of the 11 patients in this study with pneumonia had co-infections with other respiratory viruses. In a study in Canada involving 58 bocavirus infections, 40 percent had bronchiolitis and 22 percent had pneumonia.[8] In a study of 18 children in Japan, the lower respiratory tract diagnoses were wheezy bronchitis (33%), pneumonia (33%), bronchiolitis (11%), bronchitis (11%), and asthmatic attack (6%).[25]

GASTROINTESTINAL ILLNESS

Gastroenteritis is not an uncommon finding in human bocavirus infections.* The virus has been identified in nasopharyngeal samples and in stool samples of children with diarrhea. In one study in Hong Kong, diarrhea was noted in 11 percent of 79 patients with respiratory symptoms.[21] In the same study, human bocavirus was identified is fecal samples of 25 children with gastroenteritis. Of these children, 16 percent had blood in the stool, 8 percent had mucus in the stool, 32 percent had vomiting, and 68 percent had fever. The following respiratory findings were noted in these children with gastroenteritis: coryza (56%), acute bronchitis (16%), and pneumonia (12%). Co-pathogens were identified in 56 percent of the children: rotavirus (36%), *Salmonella* spp. (8%), *Campylobacter* spp. (4%), *Staphylococcus aureus* (4%), and *Clostridium difficile* (4%).

In a study of 962 stool samples from children with acute gastroenteritis in Seoul, Korea, a viral agent was found in 44.4 percent of the specimens.[22] The viral agents included rotavirus (25.7%), norovirus (13.7%), adenovirus (3.0%), astrovirus (1.1%), and human bocavirus (0.8%). In another study in Brazil, 2 percent of 705 diarrhea stool samples were PCR positive for human bocavirus.[1]

In studies of respiratory illness associated with human bocavirus infection, diarrhea occurs in 9 to 38 percent.[6,7,13,19,21,33,36]

INFECTIONS IN IMMUNOCOMPROMISED PATIENTS

Koskenvuo and associates[20] described three children with acute lymphoblastic leukemia who had acute febrile episodes in whom human bocavirus was detected in their respiratory secretions. In addition to fever, one of these children had cough, rhinitis, and otitis media, and another child had vomiting and diarrhea. The third child had five consecutive febrile episodes during the course of a 6-month period, and with each of these episodes, human bocavirus was found in nasal swab samples. Smuts and Hardie[39] noted eight children with HIV infections and associated human bocavirus infections but presented no details related to their illnesses.

OTHER CLINICAL FINDINGS

In addition to respiratory and gastrointestinal signs and symptoms, numerous other clinical findings and diagnoses have been observed in children with human bocavirus infections. Arnold and colleagues[6] noted four children with maculopapular erythematous rashes with prominence on the chest and trunk. Two of these children had involvement of the face. Exanthems have been noted in other studies.[11,21,32] In three studies, the rate of exanthema varied between 5 and 9 percent in the children studied. One child had an illness suggestive of roseola infantum, and another child had an illness thought to be Henoch-Schönlein purpura.[21]

In three studies, human bocavirus has been noted in respiratory or fecal samples in children clinically thought to have Kawasaki disease.[7,9,21] Other events noted in temporal association with human bocavirus infection include intussusception,[9,21] aseptic meningitis,[21] and nephritic syndrome.[21]

*See references 1, 2, 6, 7, 13, 19, 21, 22, 33, 36, 38.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The findings in human bocavirus respiratory infections are similar to those in respiratory syncytial virus and human metapneumovirus infections as well as adenoviral, influenza viral, parainfluenza viral, and rhinoviral infections. Similarly, gastroenteritis associated with human bocavirus infection cannot be differentiated from rotavirus infections and illness associated with other viral and bacterial agents.

SPECIFIC DIAGNOSIS

Presently, the only diagnostic method for the demonstration of human bocavirus infection is PCR. Specimens for PCR may be obtained from respiratory secretions, the stool, and blood. Primer sets used target the NP-1 region 4 and the NS1 region of the genome.[4,38]

Because recombinant human bocavirus capsid antigens have been produced and have been used experimentally to detect both IgG and IgM antibodies in the serum of patients with human bocavirus infections or in population studies, commercial serologic tests likely will become available to diagnose human bocavirus infections.[12,16,37]

TREATMENT

No specific antiviral treatment for human bocavirus infections is known. General care should be similar to that employed for other respiratory or gastrointestinal viral infections.

PROGNOSIS

Although the full spectrum of human bocavirus infections and possible sequelae are not known presently, most infections appear to be self-limited.

SUBSECTION 2

Polyomaviridae

CHAPTER 166

Human Polyomaviruses

John A. Vanchiere

The human polyomaviruses, JC virus (JCV) and BK virus (BKV), and the simian virus 40 (SV40), which is also able to infect humans, represent a unique group of viruses that cause disease almost exclusively in immunocompromised patients. Polyomaviruses derive their name from *poly-*, meaning many, and *-oma*, which refers to their ability to induce tumors in laboratory animals. Their colorful history and critical role in the elucidation of fundamental cellular and molecular pathways have immortalized them as research tools. The finding of polyomaviruses associated with several human cancers and their ability to cause central nervous system and urinary tract disease in immune compromised patients have brought them to the foreground of clinical medicine in the past decade. The emergence of polyomavirus disease has highlighted the need to understand the natural history and fundamental host processes that control the persistence of polyomaviruses. The next decade of research undoubtedly will reveal the true nature of these fascinating viruses.

HISTORY

The recognition of progressive multifocal leukoencephalopathy (PML) as a clinical entity in 1958 marked the beginning of our knowledge of the human polyomaviruses.[10] Edward P. Richardson, Jr., a neuropathologist at Massachusetts General Hospital in Boston, and his colleagues described three cases of progressive neurologic disease in patients receiving chemotherapy for leukemia. At autopsy, they found many foci of demyelination, includ-

ing oligodendrocytes with intranuclear inclusions and astrocytes that were enlarged with bizarre nuclear changes.[10] Richardson[108] subsequently reported a larger series of PML cases and proposed a viral etiology associated with immune suppression. In 1965, papovavirus-like particles were observed by electron microscopy of brain tissue from patients with PML, and in 1971, JCV, the etiologic agent of PML, was isolated from primary human fetal glial cell cultures that had been inoculated with a brain extract from a patient with PML.[99,145] In the same year, another human polyomavirus, BKV, was cultivated from the urine of a renal transplant recipient.[44] Each virus was named with the initials of the patient from whom it was isolated.

SV40, the prototype polyomavirus, was isolated in 1960 by Sweet and Hilleman[128] as a contaminant of secondary rhesus monkey kidney cell cultures that were used to produce early poliovirus vaccines. In addition, several early adenovirus vaccines and a respiratory syncytial virus vaccine were contaminated with SV40.[83,90] Interestingly, although rhesus monkey kidney cells showed no cytopathic effect, when supernatants from vaccine cultures were used to inoculate green monkey kidney cells, a pronounced cytopathic effect was observed, thus giving rise to the original name of SV40, vacuolating virus. By that time, millions of doses of both live and killed preparations of poliovirus vaccine containing SV40 had been given to humans in the United States and Europe. Soon after SV40 was identified, researchers demonstrated that SV40-induced tumors in neonatal rodents, prompting great concern about its potential effects in humans.[48] Serologic studies showed that the formaldehyde-inactivated Salk poliovirus vaccine, but not the live-attenuated Sabin poliovirus vaccine, induced high-titer SV40-specific antibody responses.[46] Although the live-attenuated poliovirus vaccine preparations contained higher titers of infectious SV40 virus, they failed to induce virus-specific antibodies in vaccinees, despite prolonged shedding in stool.[88] A 30-year follow-up of infants possibly exposed to SV40 between 1955 and 1962 through inactivated poliovirus vaccine preparations showed no excess risk of cancer, but such epidemiologic studies have significant limitations.[21,125] Since the 1960s, the mechanism of SV40-induced tumorigenesis has been studied intensely, and as a result of SV40-related research, many facets of cell and molecular biology have been elucidated; they include transcriptional regulation, alternative splicing, eukaryotic DNA replication, tumor suppressor proteins, nuclear localization signals, and viral effects on cell cycle control.[25]

VIROLOGY

On the basis of their similar genomic structure and replication strategies, polyomaviruses and papillomaviruses are widely thought to have evolved from a common progenitor virus. Human polyomaviruses are 45 nm in diameter, with a genome approximately 5200 base pairs in length; papillomaviruses are somewhat larger, 55 nm in diameter with a genome approximately 8000 base pairs in length. The genomic organizations of the polyomaviruses and papillomaviruses differ in that polyomaviruses use both DNA strands to encode proteins, whereas papillomaviruses use just one DNA strand. Viruses in both families cause infection in immunocompetent and immunodeficient hosts and also have been associated with malignant neoplasms.

Polyomaviruses are classified in the family *Polyomaviridae*. Sixteen polyomaviruses are known, each with a limited host range in which one or several closely related species are infected.[118] On the basis of genetic comparisons, members of the family *Polyomaviridae* can be subdivided into avian, primate, and rodent subgroups. JCV and BKV infect only humans, and SV40 infects both humans and monkeys. The nucleotide sequence of JCV has 75 percent overall homology with BKV and 69 percent homology with SV40.[25] Molecular detection of two novel human polyomaviruses, KI (for Karolinska Institute) and WU (for Washington University), has been described recently in respiratory secretions from children and adults, but their clinical significance is unclear.[4,45,53,96]

The circular genome of polyomaviruses can be divided into structural, nonstructural, and regulatory regions. The structural (late) region of the viral genome encodes VP1, VP2, and VP3, the capsid proteins that envelop the viral genome. VP1 is the major capsid protein and accounts for more than 70 percent of the virion mass; it participates in host-cell recognition and stimulation of the host immune response. VP2 and VP3 are smaller, less abundant capsid proteins. The nonstructural (early) region of the polyomavirus genome encodes the large T antigen, the best studied of the polyomavirus proteins; this protein initiates viral DNA replication, stimulates cellular entry into S phase, and influences cellular and viral transcription. The small t antigen is produced by alternative splicing of the early viral mRNA and promotes G_1 cell cycle progression; it is not required for viral growth in cultured cells. The large T antigen of SV40 is responsible for the transformation of cells in vivo and in vitro. Large T antigen is a multifunctional protein that contains binding sites for the cellular pRb and p53 proteins. By binding to pRb, the large T antigen allows E2F-mediated progression of the cell cycle, thus providing the right environment for replication of viral DNA. Through its association with p53, a cellular tumor suppressor protein, the large T antigen blocks p53-induced cellular gene expression, thereby leading to genomic instability.[17] The large T antigens of JCV and BKV, similarly, can interact with a variety of cellular proteins, including the p53 and pRb family proteins.[60] The regulatory region of the polyomavirus genome contains both the origin of replication and the viral promoter. The origin is recognized by the large T antigen, in concert with host-cell factors, including cellular DNA polymerase, and viral DNA replication is initiated. Both early and late viral transcription are mediated by cellular RNA polymerase. T-antigen binding to viral DNA autoregulates the production of early mRNA and, by interaction with cellular factors, stimulates late transcription. Polyomaviruses have either an archetypal (single enhancer) or a rearranged (complex) regulatory region that may influence the ability of a particular strain to cause disease by virtue of its effect on efficiency of replication.[17,60]

EPIDEMIOLOGY

Serologic data, screening of environmental samples, and the worldwide distribution of PML cases among immune suppressed individuals suggest that human polyomaviruses are endemic throughout the world[14,41,98] (Fig. 166–1). The prevalence of antibodies against polyomaviruses increases with the patient's age, beginning in early childhood. BKV seroconversion occurs in 50 percent of children by the time they reach the age of 3 to 4 years, and JCV antibodies are acquired by 50 percent of children by the age of 10 to 14 years.[98,120] Population-based seroprevalence data suggest that more than 80 percent of adults have been infected with JCV, BKV, or both viruses.[40,71,98,101,120] BKV seroconversion has been associated with mild upper respiratory tract illnesses in a small number of children, and BK viruria has been reported in a child with acute tonsillitis.[49,50,127] To date, no distinct clinical syndrome has been associated with BKV infection of healthy children. The prevalence of antibodies in humans directed against SV40 has not been well established, primarily because of the variability in methods used by different research laboratories. Several studies have reported seroprevalences of 2 to 11 percent for SV40 with use of a plaque neutralization assay.[19,20,110] However, other studies have suggested that some SV40 reactivity may be due to cross-reactivity with BKV.[22,71,141]

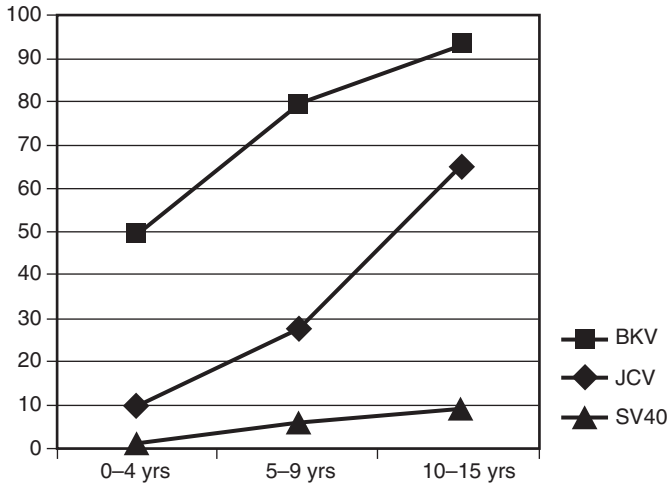

Figure 166–1 Seroprevalence estimates for JC virus (JCV), BK virus (BKV), and simian virus 40 (SV40) in childhood. *(Data from Lednicky, J. A., and Butel, J. S.: Polyomaviruses and human tumors: A brief review of current concepts and interpretations. Front. Biosci.* 4:*D153-D164, 1999.)*

Humans are the only known reservoir for JCV and BKV, whereas SV40 primarily is a simian virus that has crossed species from monkeys to humans. Polyomaviruses persist in the kidney and, to a lesser degree, in B lymphocytes and oligodendrocytes in both humans (JCV and BKV) and monkeys (SV40).[33,36,75,93] The exact mechanism of transmission of JCV and BKV is not known, but studies have shown that fecal excretion of BKV may be a common occurrence in infants, suggesting that fecal-oral transmission could explain the ubiquity of early childhood infection.[136] SV40 was introduced inadvertently into humans as a contaminant of early poliovirus vaccines; however, such direct exposure cannot account for the SV40 seropositivity in children born more recently than 1962, thus suggesting that modern human-to-human spread of the virus occurs. In the pediatric population, one SV40 seroprevalence survey found nearly 6 percent of hospitalized children with antibodies to SV40.[19] Among kidney transplant recipients in the cohort, 40 percent had evidence of SV40 infection, but whether such infection was related to immunosuppressive medications or the underlying kidney disease was not clear.[19] SV40 DNA sequences have been detected in kidney tissue from several pediatric renal transplant recipients.[18]

In immunocompetent individuals, persistence of JCV and BKV in the kidney is asymptomatic, with intermittent shedding in urine of JCV more frequently than of BKV.[2,119] Viral DNA (JCV or BKV) can be found in 30 to 50 percent of kidney samples from immunocompetent adults taken at surgery or autopsy.[24,55,134] The frequency of JCV excretion in urine increases with age, and the prevalence of BKV excretion is approximately 2 to 5 percent in healthy adults.[32,70]

JCV is lymphotropic, and the finding of JCV in plasma and peripheral blood mononuclear cells generally correlates with immune status in that it is noted less frequently in immunocompetent patients and increases in frequency in human immunodeficiency virus (HIV)–infected patients with lower CD4 counts.[31,43,72] A study of SV40 seroprevalence in HIV-infected patients found no difference between patients and age-matched HIV-uninfected controls, implying that SV40 infection may not be related to immune status.[61] Several conditions, including pregnancy and autoimmune disorders, are associated with excretion of BKV or JCV in urine.[86,126,129,130] The immunologic and virologic factors regulating initiation and maintenance of persistence are unknown.

CLINICAL MANIFESTATIONS

CENTRAL NERVOUS SYSTEM MANIFESTATIONS

PML is a clinical syndrome characterized by progressive neurologic impairment in immunocompromised patients. In PML, the host immune system fails to maintain viral latency; JCV replicates in and lyses oligodendroglia and causes destruction of cerebral white matter in a multifocal or patchy distribution. PML is the sentinel acquired immunodeficiency syndrome (AIDS)–defining illness in approximately 5 percent of adults, and its cumulative incidence in HIV-infected adults may be greater than 25 percent.[11,51] PML occurs less frequently in HIV-infected children than in adults. Other immunosuppressed individuals who are at high risk for development of PML include patients receiving chemotherapy, solid organ or hematopoietic stem cell transplant recipients, and those with primary T-cell defects.

Clinical manifestations of PML can include behavior changes; blindness, deafness, and other cranial nerve dysfunctions; motor and cognitive deficits; and lack of coordination as a result of cerebellar involvement.[12] The onset of symptoms usually is insidious, and associated systemic signs such as fever and headache are uncommon manifestations. Progression of symptoms occurs during a period of several weeks to months, and the condition is inevitably fatal. The diagnosis of PML is largely clinical and based on the history, physical examination, and characteristic findings on neuroimaging studies. Computed tomography and magnetic resonance imaging of the brain show focal demyelination and white matter edema with relative sparing of the gray matter[91] (Fig. 166–2). Cerebrospinal fluid analysis usually is normal in patients with PML, likely a result of impairment or depletion (or both) of T lymphocytes.[12] BKV also has been associated with neurologic dysfunction in patients with AIDS, although much less frequently than has JCV.[15,135] In addition, BKV encephalitis has been reported in a patient without known immunodeficiency in association with polyomavirus seroconversion.[142]

RENAL MANIFESTATIONS

Polyomaviruria is a common occurrence in immunocompetent adults and may be so in children as well.[23,63,70,112,137] Hemorrhagic cystitis related to BK viruria has been reported in several immunecompetent children, but no other nonmalignant diseases have been linked to polyomavirus infection in immunocompetent children.[114] Urinary excretion of BKV occurs in approximately 20 to 30 percent of adult and pediatric renal transplant recipients, approximately one third of whom also may have BK viremia.[56-59] Post-transplantation polyomaviruria is due predominantly to reactivation of latent infection, although whether the reactivated virus is of donor or recipient origin remains uncertain. Excretion of BKV usually begins in the first 2 to 3 months after the patient has undergone transplantation. In renal transplant recipients, BK viruria occasionally is associated with ureteral ulceration and stenosis, sometimes requiring surgical intervention to prevent or to relieve obstructive nephropathy. The prognostic significance of polyomavirus reactivation in renal transplant recipients has become a topic of great interest as management of immunosuppression administered to balance allograft rejection and infectious complications has become more sophisticated.

During the past 10 years, BKV has emerged as a significant cause of renal allograft failure. BKV-associated nephropathy (BKVAN) affects 1 to 10 percent of renal transplant recipients, resulting in allograft loss for approximately 50 percent of those affected. Initially, case reports linking polyomavirus infection and allograft failure identified BKV as a possible pathogen.[100,105] In one case series of biopsy-proven interstitial nephritis in adult

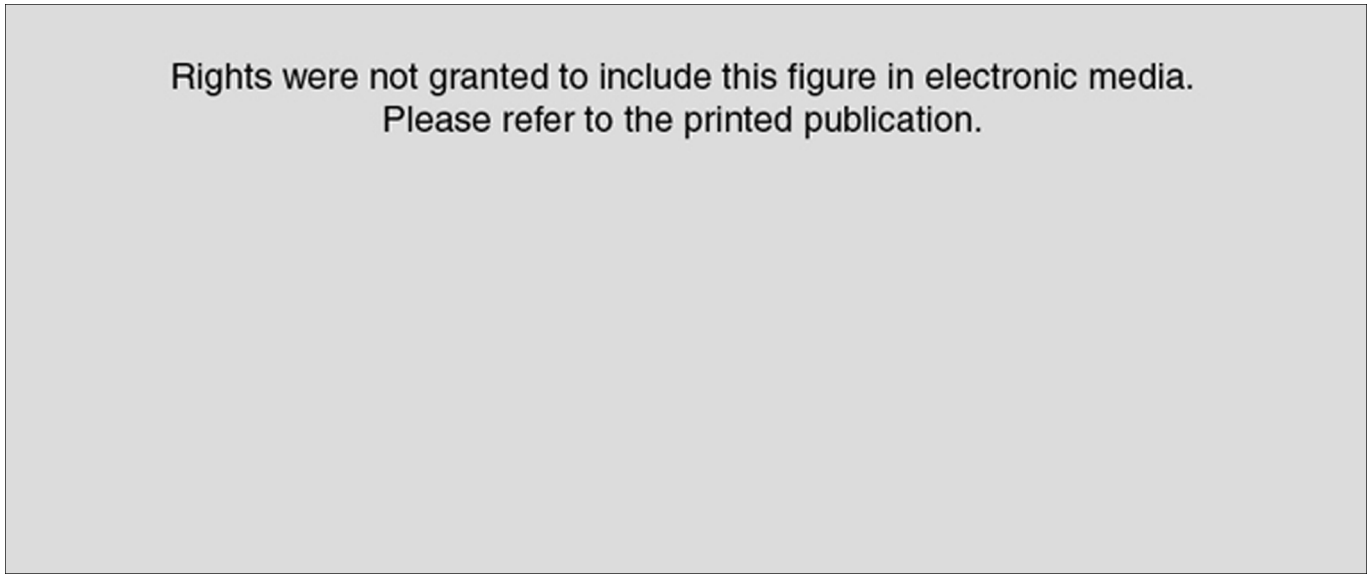

Figure 166–2 **A,** Contrast-enhanced brain computed tomogram of an HIV-infected child with progressive multifocal leukoencephalopathy showing low-density, nonenhancing, right-sided cerebellar white matter lesion without a mass effect. **B,** With T2-weighted magnetic resonance imaging, the lesion produces high signal without a mass effect or edema. **C,** The lesion gives low signal on T1-weighted magnetic resonance imaging and fails to enhance with intravenous administration of contrast material. *(From Morriss, M. C., Rutstein, R. M., Rudy, B., et al.: Progressive multifocal leukoencephalopathy in an HIV-infected child. Neuroradiology 39:142-144, 1997.)*

renal allograft recipients, 19 of 22 patients had increased levels of serum creatinine at 11.5 ± 13.0 months after transplantation.[105] Polyomavirus intranuclear viral inclusions and mononuclear inflammatory infiltrates were common histopathologic findings in allograft biopsies. Antirejection therapy was associated with graft loss in 8 of 12 patients, whereas a reduction in immunosuppression was associated with graft survival and clearance of viruria in three of six patients.[105] A smaller study in Europe had similar findings.[94] Since then, larger studies have begun to reveal the pathogenesis of BKVAN as well as the appropriate diagnostic and therapeutic strategies. Retrospective analyses have found that BKVAN is associated more frequently with the use of tacrolimus and mycophenolate, but BKVAN has been reported in patients receiving other immune suppressive agents.[1,16] Molecular characterization of BKV isolates from patients with BKVAN has not identified particular strains of BKV that are more likely to cause BKVAN.[121] The role of host factors in the pathogenesis of BKVAN is under investigation.

Polyomaviruria, especially that involving BKV, is a common finding after hematopoietic stem cell transplantation, occurring in 50 to 80 percent of patients within 2 to 8 weeks after transplantation (Fig. 166–3).[5,9,118] BK viruria is associated with hemorrhagic cystitis (BKV-HC) in 15 to 25 percent of hematopoietic stem cell transplant recipients.[8,39,78,80,81] BKV-HC is both painful and distressing for hematopoietic stem cell transplant patients, occasionally necessitating frequent erythrocyte transfusions and, rarely, surgical intervention. For the majority of patients with BKV-HC, supportive care, including intravenous hydration and erythrocyte transfusions, is adequate management, as T-cell engraftment eventually controls BKV replication and leads to resolution of symptoms. Adenovirus is an important but less common cause of hemorrhagic cystitis after hematopoietic stem cell transplantation.[3,39,81]

Interstitial nephritis caused by BKV has been described in children with various immune deficiencies, including hyper-IgM immunodeficiency and AIDS.[27,111] Renal dysfunction is a common finding in patients with AIDS, but its etiology has been linked only rarely to polyomaviruses; one study found SV40 in kidney tissue from several patients with AIDS and a collapsing variant of focal segmental glomerulosclerosis, but the pathogenesis of this disease remains uncertain.[84] Several studies of Balkan endemic nephropathy have associated this enigmatic disease in eastern Europe with polyomaviruses, but further study is needed to establish a causal link.[92,124] One pediatric study observed an association between SV40 seropositivity and renal transplantation and detected SV40 sequences in renal biopsy specimens, thus suggesting a possible (but still unproven) role for SV40 in pediatric renal disease.[18,19]

OTHER MANIFESTATIONS

Although some researchers contend that polyomaviruses can be transmitted in respiratory secretions, little evidence indicates that such transmission, if it does occur, is accompanied by clinical disease of the respiratory tract. Several case reports of BKV-associated pulmonary disease have been published, uniformly in the setting of severe immunosuppression and with poor outcomes.[27,115,135] Although interstitial pneumonitis in a patient with severe immune compromise might raise the suspicion of polyomavirus-associated disease, other viral pathogens such as cytomegalovirus and adenovirus should be considered first.

BKV-associated retinal necrosis in an AIDS-infected patient has been described, as have elevated hepatic transaminase levels in association with BK viruria and detection of BKV in normal liver specimens.[15,54,69,97] The clinical significance of these manifestations is unknown.

MALIGNANT NEOPLASMS

The polyomaviruses are named for their ability to induce tumors in laboratory animals. Their association with human tumors was noted first in 1974 when Soriano and colleagues[123] isolated SV40 from a metastatic malignant melanoma in a patient with SV40 neutralizing antibodies. SV40 T antigen and capsid antigen were detected in lung, liver, and muscle metastases of the patient but not in normal tissue.[123] Since that time, polyomaviruses have been

Figure 166–3 Cumulative percentages of bone marrow transplant recipients positive for BK virus (BKV; *n* = 26), herpes simplex virus (HSV; *n* = 22), and cytomegalovirus (CMV; *n* = 14) by the first day of detection. *(From Arthur, R. R., Shah, K. V., Charache, P., et al.: BK and JC virus infections in recipients of bone marrow transplants. J. Infect. Dis.* 158*:563-569, 1988.)*

Vanchiere, M.D., Ph.D.)*

linked to a variety of neoplasms in humans, frequently analogous to the tumor types produced in rodents. SV40 has been detected in association with human cancers much more frequently than have JCV and BKV. SV40 T antigen or DNA has been detected in a significant number of meningiomas, ependymomas, choroid plexus tumors, astrocytomas, pleural mesotheliomas, and osteosarcomas.[7,62] Several studies have reported the presence of SV40 in non-Hodgkin lymphomas.[87,109,140] In the case of pleural mesotheliomas, which also have been associated with exposure to asbestos, the presence of SV40 may be a negative prognostic indicator.[103] A possible synergistic effect of SV40 and asbestos has been observed in vitro and in case-control studies of human patients with mesothelioma, suggesting that the two agents may work in concert as co-carcinogens.[13,26,73] In a study of pediatric patients, JCV DNA was detected in 11 of 23 medulloblastomas, and JCV T antigen expression was detected by immunohistochemistry in four of 16 samples tested.[74] Other investigators have not detected polyomavirus DNA or protein in medulloblastoma tissue.[68,144] JCV also has been detected in colorectal and gastric cancers and in normal tissue samples from the human gastrointestinal tract.[76,106,107] The significance of these findings is unclear at present. A study of bone marrow aspirates and white blood cells from pediatric patients with leukemia failed to find evidence of polyomaviruses.[122] BKV has been detected in both normal and neoplastic prostate tissue, suggesting a potential role for BKV in the pathogenesis of this common cancer of adulthood.[28,29] Further studies, including evaluation of host immunogenetic factors, will be required to establish whether BKV and JCV are commonly oncogenic in humans.

LABORATORY DIAGNOSIS

Although the suspicion of polyomavirus disease is primarily a clinical one, laboratory techniques are important for establishing the diagnosis in the proper clinical circumstances. Serologic tests and viral culture are of little use clinically because these tests are laborious and rarely available. Polyomaviruses in urine could be considered normal flora among immunocompetent patients, much like cytomegalovirus detected in urine after infancy. Histologic study of urinary sediment can reveal "decoy cells," which are uroepithelial cells with characteristic polyomavirus inclusions. The presence of decoy cells is a specific and moderately sensitive marker of polyomavirus-associated nephritis in renal transplant patients.[35,77] Detection of specific polyomavirus DNA from urine samples is of little significance, whereas polymerase chain reaction (PCR) detection from blood samples, especially viremia of greater than 10,000 genomes per milliliter, may correlate with the risk for development of BKVAN.[77,95,104] Immunohistochemical detection of BKV T antigen in renal biopsy material (Fig. 166–4) is the "gold standard" for establishing the diagnosis of BKVAN, although electron microscopic identification of polyomavirus-like particles in renal biopsy material also may be diagnostic.[57,85] The diagnosis of BKV-HC is based on clinical symptoms and the detection of BKV in urine, usually by PCR. Urinary viral loads in patients with BKV-HC and BKVAN can be extremely high, even 10^{12} or 10^{13} genome copies per milliliter.

Detection of JCV DNA in cerebrospinal fluid by PCR is the diagnostic test of choice for suspected PML.[52,72,116,132] In adult patients with AIDS and neurologic symptoms, PCR amplification of JCV DNA from cerebrospinal fluid is 99 percent predictive of PML, whereas brain biopsy has a slightly lower sensitivity.[30] On gross examination, tissue typical of PML has been described as "worm eaten," and microscopic examination reveals multiple foci of demyelination with enlarged oligodendroglia, giant astrocytes, and an intense phagocytic infiltration.[139] Immunohistochemical techniques and other nucleic acid detection methods also can be used to confirm the diagnosis of PML.[64] JC viremia is a general indicator of immune suppression and is a common finding in HIV-infected patients without PML, so its utility in the diagnosis of suspected PML is questionable.[72]

TREATMENT AND PREVENTION

No specific antiviral agents have been studied in randomized trials for the treatment of polyomavirus disease or polyomavirus-

associated tumors. Studies in both adult and pediatric patients have demonstrated that routine monitoring of plasma BK viral loads and preemptive reduction of immune suppression are useful for the prevention of BKVAN without significant risk of allograft rejection, and routine screening for BKV has been recommended by an international expert panel.[16,47,57] However, BKV reactivation may persist and lead to chronic renal dysfunction in some patients.[138] BKVAN should be suspected in any renal transplant recipient with otherwise unexplained allograft dysfunction. For renal transplant recipients with biopsy-proven BKVAN, reduction of immune suppression may be helpful for preservation of allograft function, especially among patients with low-grade disease.[34,42] Whether antiviral agents provide additional benefit beyond that of reducing immune suppression has not been established. Case series have reported variable results with the use of cidofovir and leflunomide in patients with BKVAN.[6,38,65-67] Despite its potential nephrotoxicity, low-dose cidofovir has been suggested by an international consensus group as a potential investigational agent for treatment of BKVAN.[57] Intravenous immune globulin has been used to treat several patients with BKVAN, but no obvious benefit has been observed.[117,143] Both leflunomide and cidofovir have been used to treat hematopoietic stem cell transplant recipients with particularly severe hemorrhagic cystitis caused by BKV, but immune restoration by T-cell engraftment is likely to be the most important factor in resolution of BKV-related cystitis. The role of fluoroquinolone antibiotics, which have some anti-polyomavirus activity, for prevention or treatment of BKV disease in immunocompromised patients is an area of intense interest, and studies of newer, investigational antiviral agents are in progress.[79,82]

Initiation of highly active antiretroviral therapy (HAART) can restore immune function and alleviate the symptoms of PML for patients with AIDS.[37,102,133] Despite administration of HAART, PML may develop in some HIV-infected patients because of incomplete immune reconstitution.[131] Cidofovir has been used successfully in conjunction with HAART in patients with AIDS and PML, but its benefit above that of HAART and in non–AIDS-infected patients with PML has not been determined.[89,113] Given the ubiquity and generally benign nature of polyomavirus infections, as well as the paucity of information about the nature of their transmission and clinical significance, specific efforts to prevent polyomavirus transmission are not indicated at this time.

CHAPTER 167

Human Papillomaviruses

Gail J. Demmler-Harrison

HUMAN PAPILLOMAVIRUSES

The human papillomaviruses (HPVs) are members of the virus family *Papillomaviridae*. They are small viruses containing double-stranded DNA. They replicate in the nucleus of infected cells and have the ability to cause malignant transformation of a variety of cell types. Papillomaviruses are 55 nm in diameter, with a genome approximately 8000 base pairs in length. Papillomaviruses cause infection in immunocompetent and immunodeficient hosts and have been associated with malignancies. They also are responsible for a variety of benign, yet bothersome, cutaneous proliferations, including common skin warts. HPVs also have been associated with serious, even life-threatening illnesses, including genitourinary cancer and respiratory papillomatosis. Our current understanding of the complex role HPVs play in these diverse clinical conditions remains incomplete, and management of these diseases remains an ongoing challenge. Most recently, the licensure of two prophylactic vaccines against HPVs provides hope that the public health impact of these viruses will soon be lessened.

HISTORY

Warts or papillomas have been recognized for centuries to occur at a variety of different body sites, including the skin, genital tract, oral cavity, conjunctiva, and respiratory tract. Their infectious nature has been suspected by clinicians for many decades and has been the product of much folklore. The viral etiology of warts was discovered scientifically, however, in 1907, when human volunteers were inoculated experimentally with a cell-free extract prepared from wart tissue.[41] These early experiments also suggested that warts could be transmitted from person to person. When electron microscopy became available in the 1940s, virus particles were visualized within many of these clinical sites, initially in skin warts and subsequently in genital warts, thereby confirming the viral etiology of these lesions. However, despite the abundance of virus particles seen in some lesions such as skin warts, virologic investigation of the disease processes was hampered by the inability to propagate papillomaviruses in cell culture or laboratory animals. The limited amount of information available from the study of virus particles obtained directly from wart tissue led to speculation, in the 1960s, that HPVs were composed of a single virus type. Scientists further theorized that the specific body site and epithelium involved, rather than the virus type, were responsible for the characteristic morphology and disease process.[195] With the advent of molecular biologic techniques in the 1970s, however, more than 70 different types of HPV were recognized, and researchers quickly recognized that specific clinical diseases were associated with infection with specific HPV types. Most recently, HPV infection of the genital tract has emerged as one of the most prevalent sexually transmitted infections, and the link to some squamous cell carcinomas of the cervix has been strengthened. In addition, at least two mucosal HPV types appear to produce respiratory papillomatosis in pediatric patients. Finally, the role of some cutaneous HPV types in the evolution of squamous cell carcinoma from wart lesions in patients with epidermodysplasia verruciformis (EV) recently has been elucidated. Challenges for the future revolve around developing effective treatment strategies because current measures are palliative, at best, and most lesions recur. New antiviral chemotherapeutic agents are being developed, and immunomodulators such as interferon provide promise for the treatment of serious disease caused by HPVs.

VIROLOGY

The family *Papillomaviridae* contains the HPVs, which are small, nonenveloped viruses with a diameter of about 55 nm. They have a capsid composed of 72 capsomers arranged in icosahedral symmetry and a genome composed of double-stranded circular DNA that is approximately 8 kb in length. The complete nucleotide sequence is available for some HPVs, and partial information is available for all HPV types. The genome is divided into three regions—early, late, and regulatory—and many nucleotide sequences are shared among types. The early region is approximately 4.5 kb in length, contains eight open-reading frames (E1 to E8), and encodes genes that produce the proteins required for viral DNA replication and cellular transformation (Table 167–1). The late region is approximately 2.5 kb in length, contains two open-reading frames (L1 and L2), and codes for major and minor capsid structural proteins. The regulatory or long control region is located between the early and late regions. It is approximately 1 kb in length and contains the origin of replication and many control elements for viral transcription and replication.[178] The virus appears to replicate solely in the nucleus of the cell in association with low-molecular-weight histones. Because the HPV genome codes for only 10 proteins, it does not have a viral pro-

TABLE 167–1 Major Human Papillomavirus Genes

Gene	Protein Products and Function
Early (E) Region	
E1	Viral regulatory protein that initiates viral DNA replication
E2	Viral regulatory protein that controls replication and inhibits or activates early transcription of the viral genome
E3	Unknown
E4	A late viral protein that controls viral maturation; expressed in terminally differentiated keratinocytes
E5	Major transforming protein; causes cellular proliferation
E6	Major transforming oncoprotein; associates with the cellular target, p53, a tumor suppressor protein, and promotes its proteolytic degradation; causes cellular proliferation and perturbation of keratinocyte differentiation
E7	Major transforming protein; associates with the cellular target pRB and inactivates its cell cycle restriction function; causes cellular proliferation and perturbation of keratinocyte differentiation
E8	Unknown; ? regulates viral DNA replication
Late (L) Region	
L1	Major structural viral capsid protein
L2	Minor structural viral capsid protein

tease, DNA polymerase, or other enzymes involved in nucleotide metabolism and, therefore, requires many host-cell enzymes and cellular differentiation factors to complete its viral replicative life cycle.

The life cycle of HPVs is integrated intimately with the life cycle and maturation of epithelial cells. Initial virus infection probably occurs in the basal keratinocyte, with early transcription of the viral genome regulated by the E2 protein. Cellular proliferation and perturbation of keratinocyte differentiation then are induced by the E6 and E7 proteins. The cells are stimulated in the S phase of the cell cycle, and host enzymes for DNA synthesis are used by the virus to complete viral DNA replication. After double-stranded DNA is produced, L1 and L2, the major and minor capsid proteins, and E4, a late-associated structural protein whose gene is located in the early region of the genome, are synthesized. During the final stages of cellular keratinocyte differentiation, the final stages of virus production also occur with the assembly of complete viral particles. However, progeny viruses are not released until dead keratinocytes are sloughed from the epithelial surface.

Papillomaviruses display a high degree of species, tissue, and cellular specificity. HPVs appear to infect only humans, and most animal papillomaviruses also do not infect other species. In addition, they primarily infect the surface squamous epithelium of the skin or mucosa, and specific viral types appear to have a preference for either skin or mucosa, as well as for specific body sites.[76] However, some HPV types recently have been detected in transitional and cuboidal epithelium in the anogenital tract. More than 100 types of HPV have been recognized by DNA homology studies and sequenced,[200] and they fall naturally into two main clinical groups: cutaneous and mucosal (Table 167–2). The cutaneous HPVs contain types from a variety of benign skin warts, as well as more than 15 types recovered from a small group of patients with a rare dermatologic disorder, EV. The mucosal HPVs occur mainly in the genital tract but also infect and produce disease at other mucosal sites such as the respiratory tract, oral cavity, and conjunctiva. The mucosal HPVs also can be subgrouped into low-, high-, and intermediate- or moderate-risk types, depending on the frequency with which they are found in invasive cancers.[19,128,200,227,241]

TABLE 167–2 Human Papillomavirus (HPV) Types and Associated Clinical Conditions

Condition	Usual Location	Morphology	HPV Type
Cutaneous (Skin) Warts			
Common (verruca vulgaris)	Hands, lips, extremities	Multiple, dome shaped	2, 4
Plantar (verruca plantaris)	Bottom of feet	Single, painful	1
Flat (verruca plana)	Arms, face, knees	Multiple	3, 10, 28, 41
Filiform	Face, neck	Multiple, threadlike	2, 4
Mosaic	Feet, hands	Multiple, superficial	7
Butcher's	Hands	Multiple, dome shaped	7
Epidermodysplasia verruciformis	Face, trunk, extremities	Multiple flat warts or reddish-brown plaques	5, 8, 9, 12, 14, 15, 17, 19-25, 36-38, 47, 49
Immunosuppressed patients	Face, trunk, extremities	Dome-shaped or epidermodysplasia verruciformis-like plaques; may be persistent or progressive	1-5, 8, 10, 20, 23, 28, 49
Mucosal (Anogenital) Warts			
Subclinical	Cervix	Asymptomatic	6, 11, 13, 16, 18, 30-35, 39, 40, 42-45, 51-59
Condylomata acuminata	Cervix, vulva, urethra, anus, penis, scrotum	Multiple exophytic, pink, gray	6, 11, 16
Flat condylomata	Cervix	Asymptomatic, flat plaques	6, 11, 16, 18, 31
Giant condylomata acuminata (Buschke-Löwenstein tumors)	Perirectal area	Large, tumor-like	6, 11
Bowenoid papulosis	Penis, vulva, perirectal area	Multiple, large	16
Cervical cancer	Cervix	Asymptomatic; pigmented papillomas; erythematous or white plaques; ulcerations; mass lesion	Strong association: 16, 18, 31, 45 Moderate association: 30, 33, 35, 39, 51, 52, 56, 58, 59, 68 Weak association: 6, 11, 26, 34, 40, 43, 44, 53-55, 57, 62, 66, 74
Vulvar cancer	Vulva	Asymptomatic; pigmented papillomas; erythematous or white plaques; ulcerations; mass lesion	16
Penile cancer	Penis	Painless, ulcerative mass lesion	16
Anal cancer	Perianal area, anal canal	Asymptomatic; pigmented papillomas; erythematous or white plaques; ulcerations; mass lesion	16, 18, 31
Ovarian cancer	Ovaries	Unknown	6?, 16?, 18?
Mucosal (Other) Warts			
Respiratory papillomatosis	Larynx, trachea, bronchi, lungs	Multiple papillomas	6, 11
Nasal and paranasal papillomas	Nose, paranasal sinuses	Single or multiple papillomas	6, 11, 57, 57b
Focal epithelial hyperplasia (Heck disease)	Oral cavity	Discrete, multiple nodules	13, 32
Oral cavity papillomas	Gums, buccal mucosa, soft palate, tonsils	Single or multiple papillomas	6, 11, 16
Conjunctival papillomas	Conjunctivae	Single or multiple papillomas	6, 11, 16
Giant-cell hepatitis	Liver	Unknown	6?

Propagation of HPVs in monolayer cell culture to yield full viral particles has not been possible yet, probably because full epithelial cell differentiation and keratinization of squamous epithelial cells are required for the virus to replicate completely, and such differentiation is not achieved in conventional cell culture. Therefore, other methods have been developed to study the biology of HPVs. For example, research laboratories have propagated a few papillomaviruses successfully by inoculating virion extracts into susceptible tissue and transplanting this tissue into athymic nude mice.[117] Molecular assays of viral transformation with cloned HPV DNA have been used to define the viral genes involved in the induction of cellular proliferation and transformation. Rabbit papillomavirus animal models also have been used to study the function of E5 protein. In addition, the three-dimensional structure of the important viral proteins, such as E2 and potentially E6 and E7, have been determined by x-ray crystallography and multidimensional nuclear magnetic resonance spectroscopy.

Induction of cellular proliferation is the hallmark of infection with the papillomaviruses. Warts, for example, arise when a cell or a small group of cells in the basal cell layer of the epithelium are infected with an HPV type. The viral DNA replicates in an episomal or small circular form and stimulates the cells to proliferate and produce a self-limited tumor, also called a *papilloma*, or *wart*. In a wart, all layers of the normal epithelium are present, except with the addition of hyperplasia of the prickle cell layer, a condition called *acanthosis*. Hyperkeratosis is common in cutaneous warts but usually is absent in mucosal warts. Viral particles are produced in the differentiated, uppermost granular layers of the epithelium, where the viral cytopathic effect (koilocytosis) characteristic of HPVs is displayed. Benign lesions express both early and late genes, but if the lesion progresses to malignancy, expression of the capsid antigens and production of viral particles are inhibited, and only early-region transcripts and proteins are detectable. When invasive cancer occurs, the viral DNA usually is integrated into the cellular genome. Another unique characteristic of the HPVs is the presence of latent or persistent viral genome in apparently normal cells. Such persistence probably accounts for the recurrence of both genital and laryngeal papillomas, even after apparently successful treatment and prolonged disease-free periods.[66,226]

EPIDEMIOLOGY

The papillomaviruses are widespread in nature, and infection with HPVs occurs in people of all ages from all parts of the world. These viruses infect squamous epithelium at several body sites, and individual HPV types display marked specificity for a particular site. Infection appears to be transmitted through fomites, moisture, and minor skin trauma in the case of cutaneous warts; by sexual intercourse in the case of genital warts and condyloma; and during birth through an infected maternal birth canal in patients with juvenile-onset respiratory papillomatosis. In addition, HPV DNA has been detected in aerosolized smoke and vapor during laser and electrocautery treatment of patients with cutaneous and genital warts and laryngeal papillomatosis, and anecdotal reports of possible transmission from patient to surgeon have appeared.[1,65,78,202,203] The incubation period for most infections varies from 3 weeks to as long as 8 months, with an average of approximately 3 months. In respiratory papillomatosis, the incubation period may be 5 years or longer and, with cervical cancer, 10 years or longer. Infection with HPVs may be asymptomatic. Some may produce benign, barely noticeable warts; others may produce recurrent or growing lesions that are life-threatening and resistant to treatment; and a few infections may progress to invasive, even fatal, cancer. The outcome of an infection with HPV is influenced by several factors, including virus type, location of the lesion, immunologic status of the host, environmental and infectious cofactors, and the nature of the epithelium that has been infected.

Cutaneous warts are rare findings in children younger than 5 years old but are relatively common in older children, adolescents, and young adults. In fact, as many as 10 percent of school-aged children may have warts at some site on their bodies at any given time, and as many as 50 percent of individuals may have had cutaneous warts at some time during their life. Certain activities (e.g., use of public swimming pools and tattooing) or certain occupations (e.g., butchers; handlers of meat, poultry, and fish; workers in slaughterhouses) appear to have an increased risk of acquiring cutaneous warts.[54,105,126,197,235] Most warts regress within 2 years, presumably because the host mounts a cell-mediated immune response. Warts may increase in number and size, however, if the individual is immunocompromised, is pregnant, or has the rare familial disorder EV. The genotypes of HPV recovered from skin warts correlate, though not absolutely, with the morphology and body site of the wart. For example, HPV-1 is associated with deep plantar warts, HPV-2 with common skin warts, HPV-3 and HPV-10 with flat skin warts, and HPV-7 with butcher's warts, whereas a large number of different HPV types can be recovered from patients with EV (see Table 173–2).

Infection of the genital tract with HPVs also appears to occur commonly, but its prevalence varies widely according to the population studied and the criteria used to define infection. For example, an estimated 1 to 2 percent of sexually active individuals have external anogenital warts or *condyloma acuminatum*. However, when cytologic methods to detect subclinical disease are used, as many as 10 percent of sexually active women have been shown to have HPV-related disease of the cervix. Even higher prevalence rates have been observed when highly sensitive molecular techniques that detect both asymptomatic infection and disease are used. For instance, one study of young university women found that 46 percent were positive for at least one HPV type when extremely sensitive PCR-based methods were used.[9] Furthermore, studies suggest that as many as 75 percent of women have been infected with HPV at some time during their life.[208,232] In contrast, older women appear to have a lower prevalence of HPV infection than younger women do, even when sensitive molecular methods are used.[147,204] Not all genital infections with HPV may be transmitted sexually, however, because HPV DNA also has been detected on medical instruments and on the underwear of patients with genital HPV disease, thus suggesting that genital tract HPVs may be transmitted in certain circumstances by fomites, similar to cutaneous warts.[64,65]

Infection with HPVs is so common and so easily transmitted that having just one sexual partner often results in infection. Most infections are asymptomatic and rapidly cleared by the immune system within 12 months.[192] The persistence of high-risk HPV types 16 and 18 is associated with cervical cancer, whereas infection with low-risk HPV types 6 or 11 is associated with genital warts and other low-grade abnormalities of the genital tract.[155] The sero-incidence of new HPV 16 infections, as well as the overall seroprevalence of HPV 16 infection in both men and women, is associated with age older than 20 years and number of occasional sexual partners with whom unprotected sex occurred during the antecedent 3 months.[235a] HPV 16 infection also appears to be more common in females than in males. Most epidemiologic studies suggest that HPV infection of the genital tract is a sexually transmitted disease and that age and the number of lifetime sexual partners also are independent risk factors for infection.[16,151] Seropositivity for HPV is exceedingly rare in individuals younger than age 10 years old and peaks in those between 30 and 50 years of age in most populations.[161] Of particular concern is the high and apparently increasing prevalence of cervical HPV infection in adolescents. In fact, recent epidemiologic evidence suggests that infection with HPV is the most common

sexually transmitted disease in adolescent women. For example, in one study of more than 600 adolescents who attended three urban clinics in Colorado, 24 percent of the patients had evidence of HPV infection (15% with clinically apparent genital warts, 36% with subclinical HPV infection detected cytologically, and 49% with subclinical infection detected by the presence of HPV DNA in cervical tissue).[102] In another study of sexually active adolescents, an incidence rate of 29 percent was observed during a 13.3-month study period.[194] Whether this high prevalence of HPV infection represents persistent infection with the same HPV genotype or re-infection with a new genotype remains controversial. For example, one study in Panama showed that the proportion of women with HPV infection increased in accordance with the number of consecutive specimens tested (21 to 82% in a cohort of high-risk subjects sampled monthly for at least six visits) and suggested that persistent HPV infection with periodic viral shedding was the most likely explanation.[155,185] In contrast, other studies have shown that detection of the same HPV DNA genotype on a second examination is unusual and suggested that spontaneous regression or resolution occurred, followed by re-infection with a new type of HPV.[163,194] Male partners also represent an important source of HPV infection in their female sexual partners.[11,12,31]

Epidemiologic observations show a strong link between HPV infection and cervical cancer because they both have characteristics of a sexually transmitted disease. For instance, the number of lifetime sexual partners is a risk factor for both HPV infection and cervical cancer.[31] Furthermore, cervical carcinoma is more likely to develop in women with a history of genital warts than in women with a negative history, and it is significantly more likely to develop in women married to men in whom cancer of the penis develops.[68,84] Associations also have been found between specific genotypes of HPV infection and the presence of invasive cervical cancer. HPV types 16, 18, 31, and 45 are associated strongly with cervical cancer; HPV types 33, 35, 39, 51, 52, 56, 58, 59, and 68 have a moderate association with cervical cancer; and HPV types 6, 11, 26, 42, 43, 44, 53, 54, 55, 62, and 66 rarely have been seen in cancerous lesions of the cervix.[213] In addition, cohort studies have shown that the presence of HPV DNA precedes the development of preinvasive cervical lesions.[187] However, despite strong circumstantial evidence and compelling laboratory documentation of the role that HPV plays in cervical cancer, HPV infection alone appears to be neither sufficient nor necessary for cervical cancer to develop. The disease still may be multifactorial in etiology and involve cofactors such as demography, genetics, socioeconomic status, race and ethnicity, age, nutrition and other dietary factors, pregnancy and parity, hormonal exposure, use of oral contraceptives, smoking, immune status, and the presence of other sexually transmitted infections and diseases.[151,187,213,217] Women infected with human immunodeficiency virus (HIV) have a high prevalence of HPV infection and are infected with a broader range of HPV types and with multiple HPV types compared with HIV-negative women. These HPV types include HPV 16, 18, 31, 33, 51, 52, 53, and 61.[43]

Like cervical cancer in women, the HPVs are associated with squamous intraepithelial lesions and anal canal tumors in men. More than 80 percent of anal cancer specimens have HPV DNA detected in this tissue.[71] Although anal cancer is a rare occurrence in men, certain risk factors, including HIV infection, a homosexual or bisexual lifestyle, and the practice of receptive anal intercourse, have been identified.[68,172] More than 90 percent of HIV-positive homosexual men will have anal HPV infection, and as many as 73 percent will have infection with more than one HPV type at a single time.[172] HPV-16 is the HPV type most frequently detected, but almost all types have been identified in this clinical setting.

Another potential consequence of genital infection with HPV is perinatal transmission of the virus from mother to infant. Genital HPVs, including the high-risk genotypes 16 and 18 and the lower-risk genotypes 6 and 11, may be transmitted from mother to infant, presumably by passage through an infected birth canal, although ascending infection and postnatal acquisition also are possibilities.[33,171] HPV DNA, including HPV 16 DNA, has been detected in human breast milk, suggesting another possible mode of perinatal transmission.[201] HPV DNA has been detected in buccal and genital cells obtained from infants born to mothers infected with HPV-16 and HPV-18, and pregnant women with a high viral load of HPV DNA in cervical cells are more likely to transmit HPV infection to their newborn infants than are mothers with a low viral load.[109] Furthermore, a recent study has demonstrated that HPV DNA may persist for at least 6 months in perinatally infected infants.[33] In fact, infection of the oral mucosa appears to be a common event in healthy adults and children. DNA from HPV-6 and HPV-16 has been detected by polymerase chain reaction (PCR) in 17 and 23 percent of oral mucosa samples from adults and in 24 and 19 percent of oral samples from preschool aged children, respectively.[104] The consequences of infection of the oral mucosa with genital-type and other HPVs range from asymptomatic infection to a variety of oral, respiratory, and ocular lesions. For example, HPV types 6, 11, 16, and 18 have been seen in leukoplakia, lichen planus, oral papillomas, squamous cell carcinoma of the tongue, and verrucous carcinoma of the larynx.[28,55,133] Dysplastic and malignant lesions of the ocular conjunctiva and cornea also have been associated with HPV-16.[144] HPV-6 and HPV-11 have been linked to juvenile- and adult-onset laryngeal papillomatosis.[157] Circumstantial evidence implicating perinatal transmission of HPV as a cause of respiratory papillomatosis includes retrospective analyses that have shown an association between juvenile laryngeal papillomatosis and genital warts in the mother at the time of delivery.[17,47,183] Juvenile laryngeal papillomatosis also appears to be an uncommon finding in children delivered by cesarean section.[212] Also of note, however, is that this disease has a bimodal age distribution. Although the peak incidence of the disease occurs between birth and 5 years of age, almost half the patients with HPV-associated laryngeal papillomatosis are seen for the first time in adulthood.[45]

CLINICAL MANIFESTATIONS

Cutaneous Warts

Common cutaneous skin warts, or verrucae, have variable morphology and may appear at any location on the skin.[36,213] Common skin warts, or verrucae vulgares, usually are well-demarcated, dome-shaped papules with multiple conical projections (papillomatosis) that give the surface of the wart a rough appearance and texture. Common warts generally occur on the hands, especially the dorsum, but they also are seen frequently between the fingers, periungually, and on the palms and soles. They occasionally may be mosaic and spread superficially over the skin, or they may be filiform in morphology and appear as threadlike warts on the face and neck. They most commonly are associated with HPV-2 and HPV-4. Butcher's warts, a form of cutaneous wart seen in meat and poultry handlers who suffer repeated minor trauma to the hands, are associated with HPV-7. Plantar warts, also called *verrucae plantares*, occur most commonly in adolescents and young adults. They generally are single lesions and have a highly thickened corneal layer, or hyperkeratosis, with areas of punctate bleeding. They also are painful because they typically are found on pressure-bearing points on the plantar surface of the foot or the palms of the hand. They usually are associated with HPV-1. Flat warts, or verrucae planae, in contrast, do not have papillomatosis or hyperkeratosis, and they often are multiple. These warts are more common findings in young children and occur

most frequently on the arms, face, and knees. HPV types 3, 10, 28, and 41 have been associated with flat warts.[42,213] Although the clinical appearance of cutaneous warts almost always is diagnostic, the differential diagnosis includes other viral skin disorders, such as molluscum contagiosum, and other infectious diseases, such as actinomycosis, blastomycosis, sporotrichosis, leishmaniasis, chronic vegetating pyoderma, atypical mycobacterial infection (e.g., swimming pool granuloma), and tuberculosis verrucosa cutis (warty tuberculosis). Giant verrucae or warts also must be differentiated from squamous cell carcinoma.

Epidermodysplasia Verruciformis

EV, a rare skin disorder initially manifested in infancy or early childhood, is characterized by the inability to resolve HPV-induced, cutaneous wartlike lesions.[135] Seen worldwide, this disease is familial, and a history of parental consanguinity is noted in approximately 10 percent of reported cases, thus implying a genetic basis for the disease. Although both autosomal recessive and X-linked recessive forms of inheritance have been observed, the precise genetic defect or mode of inheritance remains elusive.[5,53,135,213] Patients with EV also have both nonspecific and HPV-specific defects in cell-mediated immunity, especially T-cell defects, and some patients will have developmental disabilities.[48,83,101,134,136,137] Although the lesions seen with EV are polymorphic, two clinical types of warts are seen primarily in these patients: flat warts and red or reddish-brown macular plaques. Both the flat warts and plaques appear first on the face, trunk, and extremities. They slowly become confluent and then appear to disseminate. Occasionally, the plaques may be achromatic with pigmented borders and resemble pityriasis versicolor.

Malignant transformation develops in 30 to 50 percent of patients with EV and occurs during adulthood, usually decades after the initial manifestation in childhood. Therefore, long-term, careful clinical follow-up of children in whom EV is diagnosed is important. The malignant transformation occurs in multiple foci in the reddish-brown plaque lesions, especially in areas that are exposed frequently to sunlight or other ultraviolet light, such as the forehead. It also is more likely to occur if the patient is infected with the highly oncogenic HPV types 5, 8, or 47. The tumors that result usually are slow growing, yet locally destructive. Histopathologically, they may appear as an in situ or invasive carcinoma.[101] They generally do not metastasize unless exposed to co-carcinogens such as x-irradiation.[169] The skin cancers in patients with EV, though a serious and challenging clinical entity, also provide an excellent example and scientific model to study host factors such as genetic defects, the infecting type of HPV, and environmental factors such as ultraviolet light in the genesis of malignant transformation and the development of cancer.[213]

Patients with EV may be infected with multiple types of HPV, including HPV-3 and HPV-10, that are associated with flat warts in healthy individuals.[135,165,213] The HPV types most commonly associated with lesions in patients with EV, however, are 5, 8, 17, and 20, types not usually seen in the general population. Other HPV types associated with this disorder are 9, 12, 14, 15, 19 to 25, 36 to 38, 47, and 49. The EV-associated HPV types that have a high oncogenic potential are 5, 8, and 47 because they appear in more than 90 percent of skin carcinomas in patients with EV, whereas HPV types 14, 20, 21, and 25 appear to have low oncogenic potential because they usually are detected only in benign skin lesions of patients with EV. It is likely that healthy individuals are infected asymptomatically with many of the HPV types seen in the lesions of patients with EV and that an immunologic defect probably allows the HPV infection to produce a chronic disease process. For example, HPV-8 antibodies have been found in healthy individuals, and HPV-5 DNA and HPV-8 DNA have been detected in refractory warts and skin carcinoma in immunocompromised patients such as renal allograft recipients.[86,130,179,225]

The appearance of EV-like skin lesions also may be seen in individuals who are immunocompromised as a result of HIV infection, as well as in transplant recipients, those receiving cancer chemotherapy, and other immunosuppressed patients.* These lesions may appear as brownish plaques, like typical EV lesions, or they may be morphologically similar to flat or common cutaneous warts. Skin warts in immunocompromised patients may be single or multiple, and they may persist or progress. These patients also have a high risk of developing squamous cell carcinoma, and the risk increases with exposure to sunlight or ultraviolet light, as well as with immunosuppression of long duration.[162,242] A variety of HPV types have been identified in patients who are immunosuppressed. For example, all the main types of HPV (1 to 4, 28) associated with skin warts in the general population have been detected in immunosuppressed patients. In addition, HPV types 5, 8, 10, 20, 23, 28, and 49, which are associated primarily with EV, have been detected, either alone or in combination, in immunosuppressed patients, especially renal transplant recipients.[135]

Infections of the Male and Female Genital Tract

Genital tract infection with the mucosal HPVs probably is the most prevalent sexually transmitted infection caused by a viral pathogen, and because of its link to cervical, penile, and anal cancer, such infection most likely imposes far greater morbidity on the general population than does cutaneous infection with HPVs. Genital tract infection with HPVs may be latent, active yet asymptomatic, manifested as genital warts or condyloma, or associated with various stages of cervical cytologic and histologic abnormalities, including low- and high-grade squamous intraepithelial lesions, carcinoma in situ, and invasive carcinoma. Pregnancy, immunosuppression, and especially HIV infection have been associated with an increased prevalence of HPV infection and disease in both men and women.[69,92]

Asymptomatic or subclinical infection occurs in as many as 10 percent of females older than 15 years, and the rates may be as high as 30 to 80 percent in some sexually active adolescent populations and more than 90 percent in homosexual HIV-positive men.[88] All genital HPVs (types 6, 11, 13, 16, 18, 30 to 35, 39, 40, 42 to 45, and 51 to 59) are involved.[172,213,249] The outcome of infection with a genital HPV is variable and includes resolution of the infection and elimination of viral DNA, viral persistence with no cytologic abnormalities, transient cytologic abnormalities that resolve completely in a few months, cytologic abnormalities that persist, and cytologic abnormalities that progress to in situ or invasive cervical cancer. Although the frequencies of these different outcomes of genital HPV infection are not known precisely, complete resolution of the infection appears to be the most frequent occurrence, whereas invasive cancer is the rarest outcome.[99,154,250] Whether re-infection with the same strain of HPV can occur is unknown. However, viral persistence appears to be likely in older women and HIV-infected individuals with cancer-related HPVs, especially types 16, 18, and 33.[98,154,213,230] Subclinical HPV infections do not cause symptoms and may be detectable only with sensitive molecular techniques that detect HPV DNA. Subclinical HPV infection also may produce subtle flat lesions that can be detected only by acetic acid treatment followed by colposcopy of the cervix.

The most common clinical manifestation of HPV infection of the genital tract is condyloma acuminatum, or genital warts.

*See references 18, 30, 61, 182, 198, 199, 219, 223, 236, 242.

These warts usually are caused by infection with HPV-6 and HPV-11 and occasionally HPV-16. They generally are multiple; exophytic; pink, purplish, or gray; and papular or pedunculated lesions composed of short or long fronds of connective tissue covered by acanthotic squamous epithelium. In females, they involve the vaginal introitus, vulva, perineum, cervix, urethra, and anus. The lesions usually are asymptomatic, but they may cause itching, burning, or pain. During pregnancy, genital warts may increase in number and size and regress after delivery. In males, genital warts occur on the penis, scrotum, perineum, and anus. They generally are asymptomatic but may cause itching, burning, and dyspareunia. Adult and adolescent women and men, as well as children, with external anogenital warts also may have HPV infection at internal cervical-vaginal or intra-anal mucosal sites.[89,100,112,113] In addition to typical papillary warts, flat condylomata may occur, especially in the cervix. These flat warts are difficult to visualize with the naked eye, and their detection may be aided by colposcopy. Flat condylomata usually are caused by HPV types 6, 11, 16, 18, and 31 and may progress to low- and high-grade cervical intraepithelial lesions.[213] Infection with HIV increases the risk for development of HPV infection and HPV-associated genital lesions and neoplasms in adult men and women, and, therefore, patients should be examined carefully for these conditions.[42,172,230,243] Whether HIV infection increases the risk for HPV infection or disease in adolescents and children also is a concern but is unclear at this time.[196,228] In addition, immunosuppression from chemotherapy and transplantation is associated with an increased risk for acquisition of HPV-associated genital infection, disease, and malignant transformation. In a renal transplant recipient, a novel HPV type 74 was discovered recently and subsequently detected in as many as 5 percent of renal transplant recipients.[127] In adolescents, anogenital warts may develop within 1 to 2 months after consensual sexual activity, as well as after sexual assault.[110] Infants and children also may have anogenital warts, which may result from sexual abuse or from perinatal transmission.[52,89,90] The risk of development of genital warts in a sexually abused child is not identified clearly; however, approximately half the cases of genital warts in children reported in the literature appear to be related to sexual abuse. In addition, molecular techniques have shown that anogenital warts in children contain HPV DNA from types 6, 11, or 16, the same types responsible for genital warts in adults, whereas HPV DNA from types 1, 2, and 4, which cause common cutaneous warts, has not been found in anogenital warts in children.[52] Anogenital warts in children are more likely to be acquired by sexual abuse than by perinatal transmission if the child is older than 2 years because this period is outside the plausible incubation period of perinatal transmission of HPV. Rapid progression of anogenital warts has been described in children with recent varicella infection. The differential diagnosis of anogenital warts includes other infectious diseases such as condyloma latum associated with secondary syphilis and molluscum contagiosum, as well as non-infectious disorders such as epithelial papillae, enlarged sebaceous glands or sebaceous cysts, seborrheic keratosis, lentigo, pigmented nevi, skin tags, hemorrhoids, Crohn disease, and carcinoma.

Giant condylomata acuminata may occur on the penis, vulva, or perirectal area. These giant tumor-like lesions also are called *Buschke-Löwenstein tumors* and *condylomatous carcinoma* and were reported first by Buschke in Germany in 1896. The growth of these lesions is indolent and rarely may cause inguinal lymphadenopathy, fistulous tracts, inflammation, fibrosis, and hemorrhage of the surrounding tissues. Histologically, these lesions are benign and appear similar to typical anogenital warts. However, progression to dysplasia and carcinoma has been documented. Buschke-Löwenstein tumors are associated with HPV-6 and HPV-11, in contrast to invasive genital carcinomas, which usually are associated with HPV-16 and HPV-18.[162]

Progression of HPV-induced anogenital condylomatous lesions to dysplasia or invasive carcinoma is well documented but unusual.[119,187,246] Most anogenital carcinomas probably arise from infection with high-risk HPV-16 and HPV-18 because more than 70 percent of human cervical cancers contain DNA from HPV-16 or HPV-18.[119,186] This epidemiologic observation complements in vitro studies that document the transforming properties of these viral types.[213,248] Other risks and cofactors for development of cervical cancer also have been identified, and progression from subclinical infection to carcinoma likely is multifactorial.[213] Invasive cervical cancer appears to evolve in a progressive cascade of cervical epithelial abnormalities that recently have been reclassified. These abnormalities currently are referred to as low-grade and high-grade squamous intraepithelial lesions. The category low-grade squamous intraepithelial lesion includes subclinical HPV infection, condyloma, and what was known formerly as grade 1 cervical intraepithelial neoplasia, or mild dysplasia. In the high-grade squamous intraepithelial lesion category, most or all of the thickness of the cervical epithelium is replaced by abnormal cells or microinvasive carcinoma. This category includes what previously was referred to as grades 2 and 3 cervical intraepithelial neoplasia, or moderate to severe dysplasia, and carcinoma in situ. If not detected and treated, high-grade squamous intraepithelial lesions may evolve into invasive carcinoma, breach the basement membrane, and metastasize to regional lymph nodes and other parts of the body. The HPV types that have a strong association with invasive cervical cancer are 16, 18, 31, and 45, whereas types 33, 35, 39, 51, 52, 56, 58, 59, and 68 are associated only moderately with cervical cancer. The remaining types (6, 11, 26, 43, 44, 53 to 55, 62, and 66) rarely have been associated with cancer. Cervical cancer usually is asymptomatic and detected by cytologic screening. However, patients with advanced invasive cervical cancer may have abnormal menstrual bleeding or pain. The lesions also may be visible by direct visual inspection and appear as pigmented papillomas, erythematous plaques, or leukoplakic lesions or, if further advanced, as ulcerations or large masses. Squamous carcinoma of the penis is a quite rare occurrence, especially in countries that practice routine newborn circumcision. However, when penile cancer does occur, it usually is manifested as a painless, slowly enlarging ulcerative mass.

Bowenoid papulosis is another manifestation of HPV infection of the anogenital tract. It typically occurs in adults younger than 40 years old and is characterized by multiple, large maculopapular lesions that are erythematous and reddish, purplish, or brownish, with a smooth, velvety surface. These lesions may regress spontaneously or persist. Bowenoid papulosis is associated with HPV-16 and histologically appears to be high-grade squamous intraepithelial lesions or squamous cell carcinoma in situ. Bowen disease, on the other hand, is seen in patients older than 40 years of age and causes single, reddish, scaling, or crusting lesions that histologically also appear to be high-grade squamous intraepithelial lesions.[246]

Traditionally, cervical dysplasia and carcinoma have been considered disorders of middle-aged and older women. However, during the past 10 to 20 years, the prevalence of HPV infection and abnormal cervical cytology in young women and adolescents has increased.[88] For example, recent studies suggest 18 to 53 percent prevalence rates for HPV infection in sexually active adolescents, with high-risk HPV-16 and HPV-18 being the most common types detected.[102] The prevalence of cervical low- and high-grade squamous intraepithelial lesions detected by Papanicolaou smear in adolescents also appears to have increased from 3 percent in the 1970s to 18 percent in the 1990s.[196] These alarming observations should alert physicians who care for adolescents and suggest that an epidemic of cervical cancer may occur in the near future.

Recurrent Respiratory Papillomatosis

Recurrent respiratory papillomatosis (RRP) is a rare, histologically benign, yet paradoxically life-threatening, condition caused by HPV-6 and HPV-11.[56,73,96a] Worldwide, it probably is the most common tumor of the larynx in children, with an incidence of 0.1 to 2.8 per 100,000 observed.[228,239] In the United States, the estimated incidence in children is 0.6 to 4.3 per 100,000 and up to 1.8 per 100,000 in adults.[56] The condition is newly diagnosed in an estimated 1500 patients each year.[56,156,239] The disease may be seen in both children and adults. Approximately two thirds of cases of RRP are seen in children, and in this population it also may be called *juvenile-onset recurrent respiratory papillomatosis* (JORRP). Approximately a fourth of the cases in children will be present before they reach 1 year of age, half by 5 years of age, and the remaining by 11 years of age. Adult-onset RRP usually is manifested in patients between 20 and 40 years of age, but occasionally it may be seen in adolescents.[73,213]

Circumstantial evidence suggests that infants and children with JORRP most likely acquire HPV perinatally during passage through an HPV-infected birth canal. For example, 30 to 60 percent of mothers of children with JORRP have a history of genital warts, as compared with less than 5 percent of mothers of children who do not have JORRP.[174,183] Furthermore, children with JORRP rarely are born by cesarean section. In fact, significant risk factors for JORRP include vaginal delivery, being firstborn, and maternal age younger than 20 years.[214] HPV-6 and HPV-11, most commonly associated with JORRP, also are responsible for most of the genital warts seen in women.[63,213] HPV DNA has been detected in the oropharynx of infants born to mothers with genital HPV infection.[213] However, RRP develops in only a small proportion of infants born to mothers with genital warts or subclinical HPV infection. The presence of HPV DNA in human breast milk renders this mode of transmission also a possibility for some infants.[201] The mode of transmission of HPV-6 and HPV-11 in adult-onset RRP is unknown. The most common initial symptom of RRP and JORRP is hoarseness or a change in voice. Infants and toddlers may have a hoarse cry, stridor, airway obstruction, respiratory distress, or difficulty in phonation. They also may have a crouplike illness. The most common site for RRP and JORRP is the true vocal cord of the larynx. Supraglottic and subglottic extension of the lesions also may occur. In addition, the disease may involve the trachea, bronchi, palate, nasopharynx, paranasal sinuses, and lungs. When the lungs are involved, pulmonary nodules, atelectasis, and secondary bacterial pneumonia may occur (Fig. 167–1). The disease also may produce permanent lung damage with bronchiectasis and cavitations (Fig. 167–2). In approximately 2 to 3 percent of patients, progression to invasive squamous papillomatosis and even malignant transformation to squamous cell carcinoma will occur, with invasion of the soft tissues of the neck, esophagus, and lung parenchyma (Fig. 167–3).[220] The incidence increases to 14 percent in patients who received the radiation therapy that commonly was used until 1970 to treat RRP.[81,138,207] Smoking and severe, recurrent disease also appear to increase the risk for development of malignant transformation in adolescents and adults. In addition, sudden and unexpected death may occur from airway obstruction if the lesions obstruct the laryngeal lumen.[221] Clinical courses of RRP and JORRP are highly variable and characterized by common and unpredictable remissions and exacerbations, even despite apparently successful removal of the lesions. Longitudinal studies on the time course of JORRP have shown infection with HPV type 11 and age younger than 3 years at initial diagnosis were associated significantly with a more aggressive tracheal disease requiring surgical débridement procedures more frequently.[184,252]

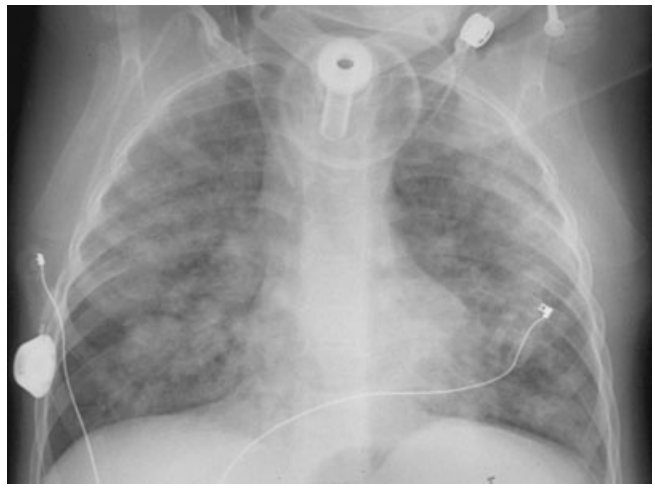

Figure 167–1 Chest radiograph of a 6-year-old girl with severe, recurrent, and progressive respiratory papillomatosis since 1 year of age.

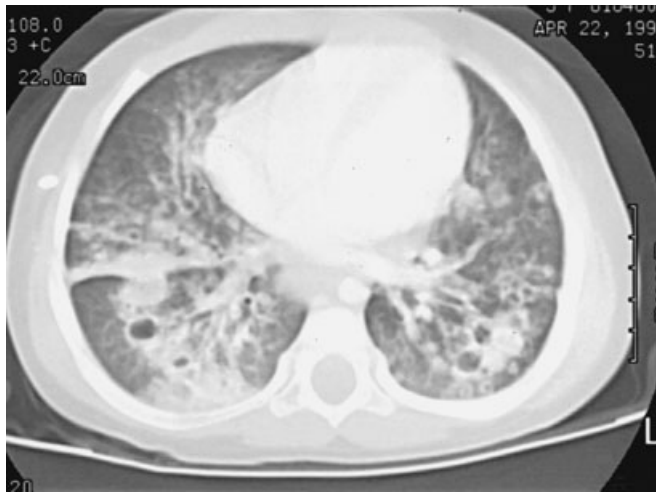

Figure 167–2 Chest computed tomography of a 6-year-old girl with severe, recurrent, and progressive respiratory papillomatosis. The tomograph shows pulmonary nodules, bronchiectasis, and cavitations.

Nasal and Paranasal Papillomas

Nasal papillomas or warts are rare tumors that may develop at any age, including childhood, and may occur as solitary lesions or in combination with papillomas elsewhere in the respiratory tract.[27,191] Histologically, they usually resemble the laryngeal papillomas seen in RRP. They most commonly are caused by HPV-6 and HPV-11, although HPV types 16, 57, and 57b also have been detected in nasal papillomas. Cocaine snorting is one risk factor for the development of nasal papillomas.[210] Papillomas also may involve the paranasal sinuses.[27,191]

Papillomas and Cancers of the Oral Cavity

Papillomas or warts in the oral cavity are heterogeneous etiologically and may be caused by cutaneous HPV types that are associated with warts on the skin, as well as by mucosal HPV types that are associated with genital warts. For example, focal epithelial hyperplasia, also called *Heck disease*, is a rare yet well-defined clinical condition of the oral mucosa that is associated with HPV-

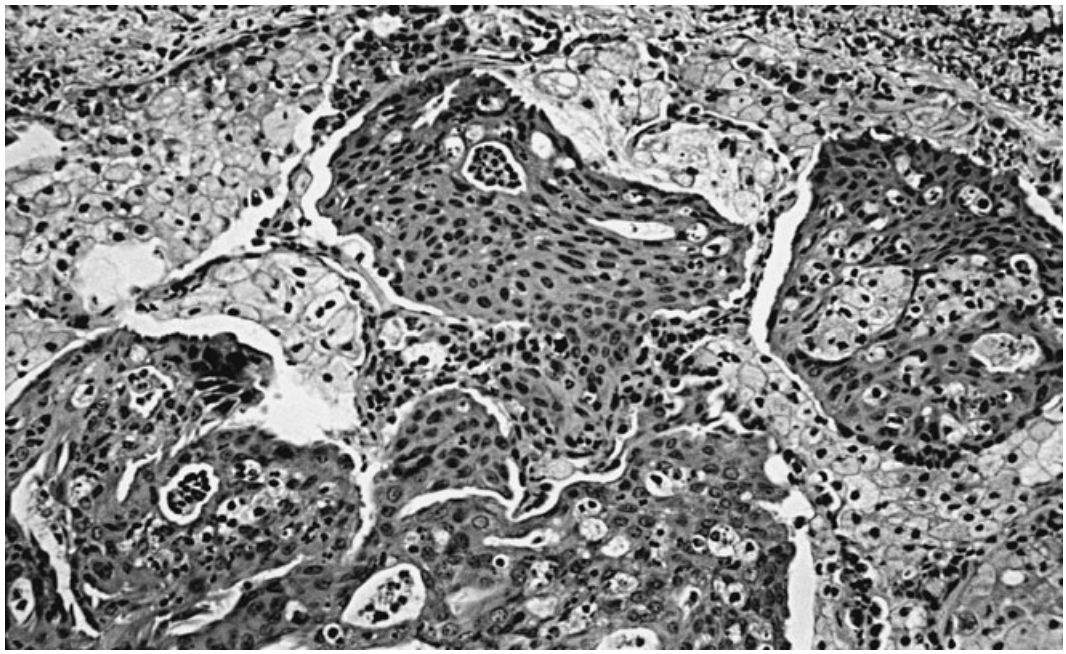

Figure 167–3 Lung biopsy tissue (hematoxylin and eosin stain, 50× original magnification, light microscopy) from a 6-year-old girl with severe, progressive, recurrent respiratory papillomatosis. This tissue demonstrates invasive squamous papillomatosis. The squamous cells are growing along preformed pulmonary structures, but no evidence of malignancy is apparent at this time because of the absence of invasion of lung tissue. *(Courtesy Dr. Claire Langston, Department of Pathology, Baylor College of Medicine and Texas Children's Hospital, Houston.)*

Figure 167–4 Focal epithelial hyperplasia of the oral gingival and mucosa (Heck disease). Patient was a 3-year-old Hispanic boy with a history of orthotopic liver transplantation and mild acute organ rejection, who presented with an extensive eruption of painless, rounded, soft nodules present on the tongue, buccal mucosa and gingivae. (See companion Expert Consult web site for color version.) *(Courtesy Dr. Federico Laham, Department of Pediatrics, Baylor College of Medicine. Photograph taken by Texas Children's Hospital.)*

13 and HPV-32 and infects only the oral cavity (Fig. 167–4).[213,233] It occurs worldwide but is most prevalent in Central and South America, Alaska, and Greenland. Focal epithelial hyperplasia may develop in children or adults and often clusters in families or geographic regions.[167] The lesions are discrete, multiple, elevated nodules readily visible on the oral mucosa. They may persist for years or resolve spontaneously. They do not, however, appear to undergo malignant transformation, nor do they appear to metastasize to other parts of the body. Warts caused by HPV-2, the same type associated with verrucae vulgares, or common cutaneous warts of the skin, may occur on the lips and on the mucosa of the oral cavity.[62] Oral papillomas involving the gums, buccal mucosa, soft palate, and tonsils also may be caused by HPV-6, HPV-11, and HPV-16, which primarily are associated with genital warts, or condylomata acuminata.[158,213] Recently, HPV-16 antibodies and HPV 6 and 16 DNA were found to be associated with squamous cell carcinoma of the head and neck, and HPV-16 DNA was detected in oropharyngeal, tonsillar, and tongue cancers, thus suggesting that HPV may play a role in these cancers.[44,96,150]

Conjunctival Papillomas

Conjunctival papillomas occur in all age groups but are exceedingly rare. They may be asymptomatic initially and then cause a constant foreign body sensation or chronic conjunctivitis. When large, they appear as pink mulberry- or cauliflower-like growths that may cause pain or interfere with lid closure. In most children and some adults, they appear to be caused by HPV-6 and HPV-11, which characteristically infect the genital tract and, therefore, may be transmitted during birth, similar to RRP.[120,145] HPV-16, another HPV that commonly infects the genital tract, also has been associated with conjunctival and lacrimal sac carcinoma in adults.[132,144]

Oral and Gastrointestinal Papillomas and Cancer

Tonsillar and oropharyngeal carcinomas may contain HPV DNA, and patients with head and neck cancers, including cancer of the tongue and oropharynx, may be seropositive for HPV type 16, an oncogenic HPV.[49,150] HPV 6 and 16 DNA also have been detected in papillary squamous cell carcinoma of the oropharynx and tonsillar carcinoma.[44,96] Esophageal infection with HPV may be asymptomatic or produce papillomas that cause dysphagia.[7] HPV DNA has been detected in esophageal brush specimens of

HIV-infected individuals who did not have proliferative mucosal lesions at the time of endoscopy.[237] In addition, HPVs, along with a variety of cofactors, may be involved in the genesis of esophageal carcinoma.[35] Similarly, HPV DNA has been detected in tissue samples from patients with colon cancer, but with unclear implications regarding their role.[213] The association of HPVs with anal warts, anal squamous intraepithelial lesions, and anal cancer, however, appears to be strong. Infection with HPV types 16, 18, and 31 most commonly occurs, but mere infection with these specific HPV types does not appear to be sufficient for the development of cancer. Similar to cervical cancer, cofactors such as other sexually transmitted diseases, chemical carcinogens (e.g., tobacco), and HIV infection and acquired immunodeficiency syndrome (AIDS) also may be involved in the pathogenesis of anal cancer.[73,118,162,172]

Liver Disease

Recent reports also have suggested that HPVs may play a role in liver disease. For example, HPV DNA, especially HPV-6, has been detected by sensitive molecular techniques in the liver of patients with neonatal giant-cell hepatitis, post–infantile giant-cell hepatitis, post–liver transplantation giant-cell hepatitis, and primary hepatocellular carcinoma.[58,173,211] However, the pathogenic role of HPV in these diseases, though an intriguing possibility, remains unproven at this time.

Other Cancers

The potential role of HPVs in the pathogenesis of a variety of unusual cancers has been explored by numerous investigators using different approaches, with conflicting results. Therefore, the role of HPVs in these cancers remains unproven at this time. For example, HPV DNA from types 6, 16, and 18 has been detected in tissue from some but not all patients with ovarian carcinoma.[213,238] HPVs also have been detected in tissue from patients with cancer of the endometrium, urethra, urinary bladder, and prostate, with unclear pathogenic implications.[213]

LABORATORY DIAGNOSIS

The typical appearance of verrucae vulgares on the skin and condylomata acuminata in the anogenital area in otherwise healthy individuals usually is sufficient to establish the clinical diagnosis of these HPV-associated illnesses. However, laboratory confirmation of HPV-associated lesions may be necessary for unusual manifestations in healthy individuals, for immunocompromised patients, and for patients with suspected malignant lesions. Methods commonly and traditionally used in viral diagnosis, such as cell culture, serology, and electron microscopy, have limited clinical utility in detecting HPV infection, whereas a variety of molecular methods, used alone or in combination, have proved to be quite useful in research and clinical settings.[258] Cytologic and histologic approaches also are helpful in diagnosing HPV-associated cancers.

Electron Microscopy

Virions with typical papillomavirus morphology can be detected in abundance in cutaneous warts but are difficult to detect in tissue from patients with RRP, JORRP, genital warts, or histologically diagnosed cancers.

Cell Culture

None of the papillomaviruses has been propagated in cell culture monolayer. Therefore, the routine viral cultures available in most diagnostic virology laboratories will not detect the presence of HPVs. Research laboratories have shown that HPV-1, when inoculated into skin keratinocytes or epithelial cells derived from the respiratory tract, will replicate its DNA transiently in an episomal form over several serial passages. However, viral capsid proteins and intact viral particles are not produced.[39] Other research laboratories have inoculated cervical tissue with extracts of HPV-11 virions obtained from condyloma acuminatum lesions and later transplanted the tissue beneath the renal capsule of athymic nude mice.[117] After several months, viral cytopathic effects have been seen, and viral capsid antigen and complete viral particles were produced. Clearly, these research methods need refinement before routine cultivation of HPVs becomes available to the clinician.

Serology

The inability to cultivate papillomaviruses routinely has hampered significantly the development of serologic tests to detect and study the humoral responses to infection with HPVs. Therefore, routine serologic assays to detect group- and type-specific antibody to HPVs are not available to the clinician. However, research laboratories continue to study the humoral response to HPV by a variety of methods. For example, serologic studies using purified virions of HPV-1 from plantar warts and HPV-11 obtained from mouse xenograft systems have revealed associations between seropositivity and clinical symptoms of infection with these HPV types.[24-27,38,116,180,224,244] Other studies of the serologic response to HPV have used recombinant DNA methods to clone and express late-region L1 and L2 proteins with bacterial fusion proteins.[67,82,103,254,255] Most recently, investigators have used vaccinia virus or baculovirus expression systems to produce virion-like particles composed primarily of viral capsids of HPV types 1, 6, 11, and 16.[32,85,121,159,193,231] However, serologic assays that use intact virions or virion-like particles, although technically the most successful to date, apparently still have problems with sensitivity and specificity.[170] Persistent, high-titer humoral responses are not detected in HPV infections, and in contrast to other sexually transmitted viral infections (e.g., herpes simplex virus, HIV, hepatitis B virus infections), seroconversion does not appear to be a clearly defined marker for primary HPV infection. Cross-reactivity between HPV types also appears to occur and limits the specificity of current assays. In addition to efforts to delineate the virus-specific humoral responses to HPV infection and HPV-associated cancers by measuring antibodies to HPV capsid proteins and HPV transforming proteins, studies evaluating serologic markers as predictors of invasive genital tract disease and ultimate survival also are being conducted.[231]

Colposcopy

Colposcopy is an important procedure to perform in women with abnormal Papanicolaou smears or external anogenital warts. It also may be used to diagnose asymptomatic, flat cervical warts in women whose sexual partners have external anogenital warts or to monitor women who are considered to be at high risk for acquisition of genital HPV infection for other reasons. The urethral meatus, penis, scrotum, and anus of males also may be inspected with a colposcope. Gynecologists, urologists, and family practitioners, as well as pediatricians who are specialists in adolescent medicine, usually perform the procedure. Briefly, the cervix and vulva in females or the urethral meatus, penis, scrotum, and anus in males are visualized under magnification with a colposcope to identify lesions, with special attention paid to their topography, the presence of abnormal whitening, and their vascular architecture. The area then is soaked in dilute acetic acid (3 to 5%) and visualized again for the presence of previously undetected lesions that appear as whitened plaques. Whitening

after application of acetic acid, however, is not specific for HPV infection or disease, and biopsy is required for definitive diagnosis. Colposcopic examination of the cervix not only gives a more accurate assessment of the anatomic extent of suspicious lesions or neoplasia but also allows the colposcopist to direct biopsies of suspicious areas accurately. Tissue biopsy specimens then may be sent for histologic examination and detection of HPV DNA by molecular techniques.

Cytology

Obtaining and staining exfoliated cervical cells via the Papanicolaou method is a routine procedure that detects most HPV infections and has reduced the incidence of invasive squamous cell carcinoma of the cervix dramatically. It should be performed routinely in all sexually active females, including adolescents. Cytologic analysis also has been evaluated as a screening examination of exfoliated urethral cells from males and in the urine of both men and women, but with less success and acceptance than with cervical cell screening.[159] Papanicolaou smear screening, however, is limited by the expertise of the physician who obtains the specimen and the pathologist who performs the cytologic analysis.[153] For example, because most cervical neoplasia arises at the junction of the squamous and columnar epithelium of the cervix (transformation zone), care must be taken to obtain cells from this region. Inter-observer variability also exists among pathologists who read Papanicolaou smears. Furthermore, Papanicolaou smears are not as sensitive as is colposcopy for detecting cervical cancer, and a negative Papanicolaou smear does not eliminate the diagnosis in women at high risk for cervical cancer. Therefore, women with anogenital warts and those who are immunosuppressed should undergo colposcopic examination to detect subclinical cervical lesions and not be evaluated simply with a Papanicolaou smear.

The cytologic abnormality that is specific and characteristic of HPV infection is the presence of koilocytosis (derived from the Greek word *koilos*, which means "hollow" or "cavity") or koilocytotic cells that display fat, swollen, wrinkled, or raisinoid nuclei surrounded by a halo. Other abnormalities, including dyskeratosis, parakeratosis, and hyperkeratosis, may occur but are considered secondary or nonspecific. The prevalence of cytologic abnormalities in women screened by Papanicolaou smears consistently has been estimated at 2 to 3 percent. Most abnormalities, however, resolve spontaneously in 3 to 6 months, but some persist and rarely may progress to cervical squamous cell carcinoma. If the infection progresses to disease, the koilocytosis typically diminishes, and the cells begin to display dysplastic changes and nuclear abnormalities. These abnormalities currently are graded into two categories: (1) low-grade squamous intraepithelial lesions, which include very mild dysplasia and the former grade 1 cervical intraepithelial neoplasia, and (2) high-grade squamous intraepithelial lesions, which include moderate to severe dysplasia and carcinoma in situ and the former grades 2 and 3 cervical intraepithelial neoplasia.[13-15,160]

Histology

HPV infection may occur in histologically normal tissue and be detected only by molecular methods that detect viral DNA. Benign and asymptomatic HPV infection also may cause koilocytosis, the typical histologic feature of HPV infection that has specific nuclear and cytoplasmic characteristics. Condyloma acuminatum lesions display not only koilocytosis but also other histopathologic characteristics of active HPV infection, such as hyperkeratosis, parakeratosis, acanthosis, and lengthening of the rete pegs. Atypical features, including mitotic figures above the basal layer, dysplastic cells, and single-cell keratinization, suggest dysplasia such as bowenoid papulosis. Precancerous and cancerous lesions of the cervix and penis also may be graded as low-grade or high-grade squamous intraepithelial lesions and invasive squamous cell carcinoma.

Histologic examination of tissue for the presence of HPV-associated disease may be augmented in certain circumstances by the detection of shared, genus-specific HPV capsid antigens that may be identified by immunohistochemistry with immunoperoxidase-labeled antibodies raised to bovine papillomavirus capsid antigen. This procedure usually is successful in identifying HPV antigens in low-grade squamous intraepithelial lesions but rarely detects antigen in high-grade squamous intraepithelial lesions because of the biology of HPV expression in these cancerous cells. Similarly, HPV antigens seldom are detected by this method in cutaneous or anogenital warts or other HPV-associated cancers. In addition, the utility of this method for typing the HPV infection currently is limited because unique, type-specific HPV capsid antigens are available only in research laboratories.[253]

Molecular Methods That Detect Human Papillomavirus DNA

HPV DNA may be detected in tissue by several methods, including dot-blot, slot-blot, Southern blot, and in situ hybridization assays and by amplification procedures such as PCR. HPV DNA has been detected by these methods in the majority of HPV-associated neoplasms, as well as in a significant proportion of asymptomatic individuals, including women with normal Papanicolaou smears. The variability of HPV DNA detection among studies is great and appears to be influenced by the population studied, the frequency and type of sampling, and the sensitivity and specificity of the molecular methods used. Because type-specific antisera are not available for HPVs, the diagnosis of type-specific HPV infection or disease requires molecular DNA methods.[20,256]

SOUTHERN BLOT HYBRIDIZATION

Southern blot hybridization is considered the reference standard for detection of HPV DNA in clinical samples. In this assay, nucleic acid is extracted from the sample, which usually is fresh tissue or exfoliated cervical cells, and digested or cleaved into smaller fragments by restriction enzymes. These fragments then are separated by gel electrophoresis and transferred onto special filter paper. Hybridization with radiolabeled probes directed against specific HPV DNA sequences then is performed. Advantages of Southern blot hybridization include good sensitivity (approximately 10^5 DNA copies) and specificity and the ability to distinguish HPV types easily. Disadvantages of this method include the need for special equipment and expertise. It also is technically expensive and time-consuming and requires a large sample of tissue that is destroyed during the DNA isolation procedure.

DOT- AND SLOT-BLOT HYBRIDIZATION

Dot- and slot-blot hybridization apply extracted DNA from a sample directly onto a specific area (dot or slot) of filter paper, with the gel electrophoresis and transfer steps of Southern hybridization being bypassed. The filter paper is incubated with a solution containing a complementary probe, followed by stringency washes to remove any unhybridized probe.[9,253] Detection of successful hybridization is by autoradiography if a ^{32}P-labeled probe is used or by colorimetric reaction if an enzyme-labeled probe is used. Advantages of dot-blot hybridization include commercial availability of some assays, ease of performance, rapid turnaround time, and low cost. Its sensitivity and specificity generally are slightly below those of Southern blot analysis, but the

method is sufficiently sensitive to detect HPV DNA in cytologically normal, as well as abnormal, cervical samples, and its use, in combination with Papanicolaou smear, has been advocated to improve identification of women at high risk for development of cervical cancer.[15,87] Dot-blot hybridization may be performed on tissue samples or cervical swabs collected in special sample transport medium or buffer, and its utility in screening urine for HPV DNA also has been explored.[159] Moreover, typing of HPV DNA may be performed by dot-blot hybridization methods. For example, commercial kits, by using a combination of radiolabeled probe mixtures, delineate as many as seven types of HPV by category group: types 6/11, 16/18, and 31/33/35.[87,152,245] In addition, probes to detect almost all HPV types, both high and low prevalence, have been developed in a variety of research laboratories.[200]

A novel, nonradioactive, chemiluminescent liquid hybridization assay (hybrid capture assay) is commercially available and detects as many as 14 HPV types divided into high-risk (types 16, 18, 31, 33, 35, 45, 51, 52, 56) and low-risk (types 6, 11, 42, 43, 44) groups on the basis of association with cervical cancer.[205] This DNA hybrid capture assay is relatively rapid and simple to perform and provides quantitative data that reflect viral concentration.

IN SITU HYBRIDIZATION

In situ tissue hybridization assays are performed directly on fresh or fixed tissue sections or on cytologic specimens and have the unique advantage of allowing the examiner to correlate histopathologic abnormalities with the location of HPV DNA. They may be performed with radioactive or enzyme-labeled probes. The sensitivity of many in situ hybridization assays is less than that of Southern blot assays, especially if enzyme-labeled probes are used.[34,164,234,253] Commercial reagents and kits are available.

DNA AMPLIFICATION ASSAYS

Classic PCR, as well as PCR amplification with degenerate or consensus primers that are capable of recognizing a portion of one of the late genes from a broad spectrum of papillomaviruses, are used by many laboratories. The popular MY09 (primer for the negative strand)/MY11 (primer for the positive strand) primer system amplifies a 450-base pair target region located in the HPV L1 open-reading frame; this site contains both conserved regions common to most or all papillomaviruses and divergent regions that appear to be unique for each HPV DNA type.[140] Amplification and detection by the MY9/MY11 primers in a PCR assay identifies HPV DNA, which can be confirmed by using "generic" HPV probe mixes. Typing of known HPV types then can be performed with type-specific HPV probes that are labeled oligonucleotides composed of sequences complementary to each viral type. Alternatively, restriction fragment length polymorphism or sequence analysis can be performed on the PCR product to identify new HPV types that are unable to be typed with the available type-specific probes.[21,166,176,177] In addition, commercially available real-time PCR assays have been developed to detect and quantify HPV DNA.[175]

HPV DNA detection by user-developed and commercial enzyme-labeled DNA probes and PCR-based methods can be performed on a variety of specimens, including fresh or fixed tissue, exfoliated urethral and cervical cells, and urine.[96a] Recent studies using real-time PCR assays have shown that self-collected vaginal and urine samples provide highly accurate results with excellent concordance with physician-collected cervical samples.[51,175,247]

By using traditional methods of Papanicolaou smear screening, colposcopy, and biopsy, the prevalence of cytologic, colposcopic, and histologic abnormalities of the cervix in the general population consistently has been estimated at between 2 and 3 percent.[253] However, a wide range of prevalence, between 7 and 82 percent for detection of HPV infection by molecular methods, has been reported; the prevalence varies according to the population studied and the methodology used, but PCR-based methods in high-risk groups have the highest prevalence rates.[9,112,129,185,251,257] The recognition that HPVs, especially high-risk types 16 and 18, are associated with cervical and other cancers suggests that detection of HPV DNA may be used as an adjunct to cytologic screening by Papanicolaou smear and offers the potential opportunity to identify women with cervical neoplasia who have false-negative Papanicolaou smears. On the other hand, the significance of the presence of HPV DNA, even if it is from a high-risk type, in histologically normal tissue is unclear, and the presence of HPV DNA, no matter what type, in histologically abnormal tissue does not influence management at this time. Further studies are necessary to explore and resolve the clinical role of DNA-based diagnostics for screening, diagnosis, and management of HPV infections.[88]

TREATMENT

Most cutaneous and mucosal HPV-associated warts and lesions in healthy individuals will regress spontaneously in 1 to 2 years. Treatment may be desirable if the lesions are large, multiple, or recurrent; if they cause pain or discomfort; or if they are undesirable cosmetically. Treatment is mandatory if the lesions are life-threatening, such as laryngeal papillomas that obstruct the airway, or lead to cervical cancer. A variety of treatment strategies are available, but none produces a universally effective or permanent cure. Rather, current approaches focus on reduction of the clinically apparent lesion, and most require repetitive application. Clinically significant HPV-associated lesions also usually require the additional expertise of a specialist. For example, a dermatologist should be consulted to assist in the management of a patient with severe recalcitrant cutaneous warts, a gynecologist and oncologist for patients with cervical cancer, an ophthalmologist for a patient with conjunctival papillomas, and an otolaryngologist and pulmonologist for children and adults with severe RRP. These specialists are likely to know the currently available treatment regimens most effective for each patient's HPV clinical manifestation. The role of the infectious diseases specialist in the management of HPV-associated disease is evolving and may become more prominent as HPV-specific antiviral chemotherapy becomes available for clinical trial and eventually for routine clinical use in patients. Current standard therapies focus on physical, surgical, or chemical destruction of the clinical manifestation of the HPV infection, such as the wart or papilloma.

Surgical techniques used to treat papillomas include traditional local excision by knife, cryotherapy with liquid nitrogen or dry ice, electrocautery and curettage, and ultrasonication.[8,22,23,106,142,218] Newer ablative surgical techniques that use carbon dioxide laser vaporization and flash-lamp pulsed dye laser therapy allow more precise and complete removal of visible papillomas and are becoming widely used to treat genital and laryngeal papillomas.[64,189,229] Surgical excision by knife remains the initial mainstay of many HPV diseases, however, because it provides tissue for a histopathologic diagnosis, as well as removal or debulking of large lesions. Ablation by cryotherapy with liquid nitrogen, electrocautery, or laser vaporization may be used to remove small, single, or multiple lesions or be performed in combination with surgery for large or difficult lesions.[148] These surgical therapies also may release viral antigens and produce local and systemic immunologic stimulation that may assist in eradicating the lesions. Disadvantages of these physical methods of wart and papilloma removal include pain, scarring, and disfigurement. These methods also are relatively invasive and impractical for

patients with disseminated disease. Furthermore, recurrent treatments usually are necessary. In addition, laser vapors contain HPV DNA and may be a vehicle for spreading the infection in the patient or to the treating physician or surgeon, and, thus, the vapors or smoke plume should be contained.[78] Recurrence of lesions after treatment occurs commonly and most likely is due to the presence of HPV DNA sequences in clinically and histologically normal epithelium adjacent to and beyond the treatment area.[66] The mainstay of treatment for RRP and JORRP is repeated surgical debulking of obstructing papillomata, augmented by immunomodulators and antiviral therapies.[96a] Surgical rates tend to decrease over the course of time in many patients; however, those patients infected with HPV 11 may require more frequent, more extensive, and more prolonged surgical procedures over the could of time.[184,252]

Warts and papillomas also may be disrupted physically and removed by using chemical ablatives applied topically to the lesion. Simple organic acids such as bichloracetic and trichloracetic acid or salicylic acid applied twice daily for several days have shown some success in the localized treatment of skin and genital warts.[74] They are caustic substances that produce a white slough that peels off, and they can be applied weekly until the lesion is destroyed.[74] Antimitotic agents such as the traditional podophyllin or the newer preparation podophyllotoxin can be applied twice daily for several weeks. Antimetabolites such as bleomycin, cantharidin, and 5-fluorouracil also have shown efficacy when administered locally once or twice a week because they inhibit the cellular proliferation induced by HPV infection.[115,181] These topical chemicals usually are easy to apply to skin and genital warts, but they also may cause local pain, redness, swelling, irritation, blisters, and scarring.[115] Moreover, they are not virus-specific, and recurrences occur commonly. They also are impractical for extensive lesions and may be toxic if used in certain circumstances. For example, they may damage the cornea if used to treat conjunctival papillomas, and they should not be used on pregnant women.[148] The systemically administered antitumor agent methotrexate also has been administered to individual patients with disseminated HPV disease, with variable success.

Immunomodulation is another treatment strategy for HPV-associated disease. A systemic immunologic response probably is responsible for the spontaneous regression frequently observed in cutaneous and mucosal warts. Therefore, stimulation of the immune system with immunomodulators also may produce remission in patients with HPV-associated disease. Interferons have antiviral, antiproliferative, and immunomodulating properties. Decades of clinical experience have accrued in treating HPV-associated disease with interferon administered topically, intralesionally, or systemically by subcutaneous injection. Both lymphoblastoid (a) and fibroblast (b) interferon have been used with some success to treat patients with genital warts and respiratory papillomatosis topically, locally, and systemically.[60,70,75,96a,188,209,213,] However, interferon-γ has not been shown to be beneficial. Both recombinant and natural-source interferon-α preparations have been demonstrated in placebo-controlled trials to be effective and are approved by the U.S. Food and Drug Administration for the intralesional treatment of genital warts.[60,70] A 25- to 30-gauge needle is used to inject approximately 0.1 mL (1×10^6 U) at the base of up to five warts at a time for a total dose of 5×10^6 U at each visit. This dose is repeated two to three times weekly for 3 weeks. Maximal effect usually is seen within 4 to 8 weeks. Repeat injections may be given if the warts are persistent or recurrent. Interferon therapy also may be effective if used alone or in combination with laser surgery to treat patients with RRP.[94,97,122,131] Fever, headache, chills, and myalgia frequently occur with local and systemic interferon treatment. Severe and persistent fatigue, nausea, and leukopenia are other fairly common adverse reactions, especially with systemically administered interferon. Systemic natural leukocyte interferon also causes regression of warts and reduction of the virus load in tissues in patients with EV.[4] Cimetidine, an immunomodulator that alters lymphocyte function, has been used in an attempt to treat children with recalcitrant cutaneous warts.[168]

Topical immunotherapy agents provide alternative treatment options for HPV-associated disease in some patients.[79,80,111,149,213] Imiquimod, also known as *imidazoquinoline*, is a first-generation member of a class of immune response modifiers approved for topical treatment of genital and perianal warts.[79,80,111,149] It is a synthetic compound that is a topically active Toll-like receptor (TLR) 7 agonist. It activates innate immune cells to produce interferon-α and other cytokines to enhance antigen presentation and promote antigen-specific T helper type 1 cell-mediated immune responses. Imiquimod is a 5 percent cream that is applied to lesions and appears to be effective in some patients. Resiquimod and other related, second-generation imidazoquinoline analogues also are in clinical development.

Retinoids and retinoic acid, which are analogues of vitamin A, can regulate the growth and differentiation of malignant, premalignant, and even normal cells.[3,190] Clinically, they have a documented effect against squamous cell carcinoma.[124,125] For these reasons, anecdotal reports and small series of patients have emerged in which retinoic acid was used to treat HPV-associated disease, especially RRP. In these reports, retinoids have been used with varying success, primarily as adjuvant agents with surgical therapy, to treat adult patients with severe, refractory RRP.[10,59] The combination of interferon and retinoic acid has been shown to be synergistic against breast cancer cells in vitro and potentially may be useful in refractory cases of RRP.[143]

Unique aspects of HPV infection and disease render designing specific antiviral therapies a challenge. For example, HPV disease usually is focal, the virus is involved intricately in the cell's life cycle, and HPV has great diversity with more than 70 genotypes. The inability to grow HPVs readily in cell culture also hampers our ability to study the antiviral properties and cellular toxicities of candidate compounds. Molecular assays that isolate individual viral functions, therefore, have been used to evaluate the ability of antiviral compounds to inhibit each individual step in the virus life cycle. Furthermore, animal models for HPV-associated disease are lacking. Despite these challenges, the in vitro antiviral activity and clinical efficacy of a variety of compounds have been studied. For example, ribavirin, a nucleoside analogue with a broad antiviral spectrum, has been used in clinical trials for the treatment of laryngeal papillomatosis.[146] Cidofovir, an antiviral compound effective against serious disease caused by cytomegalovirus (CMV), also appears to have activity against HPVs, and possible clinical benefit for certain HPV-associated disease has been shown. For example, repeated intralesional administration of cidofovir directly into the site of papillomata and also submucosally at the sites of resected papillomata is associated with partial or complete regression of lesions, improvement of voice quality and airway status, and decreased need for repeat surgery. Published studies report a wide variety of intralesional doses (2 to 57 mg of a 5 mg/mL cidofovir concentration solution), frequency of injections (every 2 to 8 weeks), and duration of treatment (4 months to 4 years). Rarely, cidofovir has been administered intravenously in patients with refractory, disseminated papillomatosis.[96a] The greatest benefits have most often been documented after the fourth series of injections, and benefit appears to plateau after the eighth series of injections in most patients.[37,40,57,77,93,139,215,216] However, because most published reports are single-center, uncontrolled case series with relatively small numbers of patients, controlled, multicenter trials with larger numbers of patients are necessary to accurately determine the benefits of cidofovir therapy, as well as the optimal dose, frequency, and duration of therapy for RRP and JORRP.

PREVENTION

Prevention of HPV infection and disease involves two potential approaches: behavioral strategies and vaccines. Prevention of genital HPV infection includes the use of barrier methods, such as condoms, to reduce transmission between sexual partners. Hospital infection control policies should address the potential transmissibility of HPV from patients to health care workers during laser vaporization and electrocautery therapy. Care should be taken to wear protective mask and eye wear and to use appropriate and well-functioning suction devices during these procedures.

Two prophylactic, highly immunogenic HPV vaccines, with good safety profiles, are currently licensed and recommended for prevention of HPV infection and HPV-associated disease and malignancies.[6,29,51a,72,95,107,114,141,206,222] Both vaccines contain HPV L1 virus-like particles (VLPs), generated by the expression of the major capsid protein (L1) of HPV in yeast.[123] One vaccine is quadrivalent, contains HPV types 16/18/6/11, and provides protection against the most common HPVs associated with cervical cancer and genital warts. The other vaccine is bivalent, contains HPV types 16/18, and provides protection against the highest-risk HPVs. The L1 proteins self-assemble into pentamer structures that come together to form VLPs, which are antigenically indistinguishable from HPV virions. The VLPs, however, do not contain viral DNA, and, therefore, they are noninfectious. Both vaccines appear highly effective in preventing persistent HPV infection and HPV 16/18-related high-grade intra-epithelial neoplasia (CIN 2/3), and are, therefore, likely to be effective in preventing cervical cancer. In addition, the quadrivalent vaccine is effective in preventing vulvar and vaginal HPV-associated warts and lesions. Both vaccines are recommended for females aged 11 to 12 years and are administered in a series of three injections. They likely are most effective when administered prior to sexual debut and may be given to girls as young as 9 years of age. Because males also appear to play an important role in HPV transmission, as well as suffer from HPV-associated disease, vaccination of preadolescent boys may also be investigated and considered in the near future.

Even though HPV vaccines appear to offer effective protection against HPV infection and HPV-related diseases and malignancies, they cannot completely prevent cervical cancer. Therefore, routine cervical screening should continue, even in vaccinated females, and complement HPV vaccination strategies to minimize the public health impact of HPV-related cancers and genital warts.[2,46,50,91,108,240]

CHAPTER 168

ADENOVIRUSES

James D. Cherry ✪ Tempe K. Chen

Adenoviruses, which are responsible for a varied array of illnesses in children,* are associated most commonly with respiratory illness and gastroenteritis, but cardiac, neurologic, cutaneous, urinary, and lymphatic manifestations also occur frequently. Although many of the clinical manifestations of adenoviral infections are distinctive, the specific viral etiologic agent rarely is recognized by physicians.

Adenoviruses were noted first in explant cultures of human adenoid tissue; this finding, plus the observation of their apparent general affinity for lymphatic tissue, led to the designation of their name.[129,133,153,412]

HISTORY

The first adenoviral strains were not isolated until 1953, when tissue culture techniques became available, although epidemic disease caused by adenoviruses had been observed throughout the first half of that century. Epidemic keratoconjunctivitis first was noted and reported in Austria by several physicians in 1889.[3,157,398,423,447] Major outbreaks of epidemic keratoconjunctivitis were reported in Bombay in 1901, in Madras in 1920 and 1928, in Hawaii in 1941, and on the West Coast of the United States in 1942.[204,222,223,267,515]

Epidemics of illness such as pharyngoconjunctival fever have been observed throughout the 20th century. Béal[20] in 1907 was the first to report the syndrome; in the 1920s, epidemics associated with swimming in public pools and in lakes were noted in Germany and the United States.[16,368] Initial studies by Rowe and colleagues[412] revealed cytopathic changes in explant tissue cultures of human adenoids that had been removed surgically. Fluid from these cultures caused distinctive cytopathologic changes in other tissue cultures, and antiserum prepared in hyperimmunized rabbits neutralized the effect. In 1954, Hilleman and Werner[217] isolated similar cytopathic agents from the throat washings of military recruits with febrile acute respiratory disease. Shortly thereafter, epidemic keratoconjunctivitis and pharyngoconjunctival fever were seen to be illnesses of adenoviral etiology.[98,101-103,244]

Initially, adenoviruses were known by the following names: *adenoid degeneration* (AD) *agent* because of its recovery in human adenoid tissue explants[412]; *respiratory illness patient number 67* (RI-67) *agent*, which was recovered from a military recruit with primary atypical pneumonia during an epidemic of acute respiratory disease[216,217]; *adenoidal-pharyngeal-conjunctival (APC) agent*[233]; and *acute respiratory disease (ARD) agent*.[81] In 1956, early investigators in the field selected the term *adenovirus* for the new group of viruses. The name suggested the characteristic involvement of lymphadenoid tissue, as well as the tissue from which the organism was first isolated.[129]

Because of considerable morbidity and major economic considerations related to adenoviral epidemic respiratory disease in military recruits, the development of vaccines received attention early. Initially, inactivated vaccines were produced, and they achieved some degree of success.[186,215,289] Later, live viral preparations grown in diploid human fibroblast tissue culture became available and proved quite successful in controlling specific adenoviral infections in the military services.[119,120,176,289,407,439,465-468]

In 1975, enteric adenoviruses (adenovirus types 40 and 41) first were reported.[145,425,503] They were demonstrated by electron microscopy and subsequently were shown to be a significant cause of diarrhea in children.[45,77,275,330,389,464,475,478] Particularly important today are adenoviral infections in immunocompromised hosts, particularly transplant recipients.[271]

PROPERTIES OF THE VIRUS

CLASSIFICATION

Adenoviruses that infect humans are placed in the family *Adenoviridae* and the genus *Mastadenovirus*.[141,226,323,427] At present, 51 immunologically distinct adenoviral types have been recovered from humans.* Additional adenoviral types have been isolated from monkeys, cattle, dogs, mice, and chickens.[206,208-210] Mammalian adenoviruses have a common generic antigen that can be identified by complement fixation and enzyme-linked immunosorbent assay (ELISA).[246,378,404,505] Individual serotypes are identified by neutralization.[192,193,265]

Adenoviruses originally were subclassified on the basis of four hemagglutination patterns with rat and rhesus monkey red blood cells.[408] This subclassification is updated in Table 168–1. In 1962, researchers found that adenovirus type 12 could cause tumors in hamsters, and soon thereafter, investigators realized that adenoviruses also could be classified by their oncogenic potential in rodents.[231,470] Grouping by oncogenic potential was similar, with few exceptions, to grouping by hemagglutination properties: organisms in hemagglutination group I had moderate oncogenic potential, group II and group III organisms had low or no potential, and group IV organisms had high oncogenic potential.[168,227,238]

Adenoviruses also have been subclassified (A to F) on the basis of the percentage of guanine plus cytosine in their DNA and other biochemical and biophysical criteria[212,263,385,424,493-495] (Table 168–2). In general, subgroup A organisms are the same as hemagglutination group IV; subgroup B, the same as hemagglutination group I; subgroups C, E, and F, the same as hemagglutination group III; and subgroup D, the same as hemagglutination group II. Restriction enzyme analysis has resulted in genomic typing of specific adenoviral serologic types.[297] In particular, numerous

TABLE 168–1 Separation of Human Adenoviruses into Subgroups by Ability to Agglutinate Rhesus Monkey and Rat Erythrocytes

Subgroup	Characteristic	Type
I	Complete agglutination of monkey erythrocytes	3, 7, 11, 14, 16, 21, 34, 35, 50
II	Complete agglutination of rat erythrocytes	8-10, 13, 15, 17, 19, 20, 22-30, 32, 33, 36-39, 42-49, 51
III	Partial agglutination of rat erythrocytes	1, 2, 4-6, 40, 41
IV	No or little agglutination of monkey or rat erythrocytes	12, 18, 31

Data from references 108, 206, 212, 219, 222, 253, 263, 289, 356, 357, 424, 507.

TABLE 168–2 Grouping of Human Adenoviral Serotypes Based on Biochemical and Biophysical Criteria

Subgroup	Adenovirus Type(s)	Location and Manifestations of Infection
A	12, 18, 31	Gastrointestinal; may cause disease in children
B:1	3, 7, 16, 21, 50	Respiratory, eye, and gastrointestinal symptomatic infections
B:2	11, 14, 34, 35	Urinary and respiratory; symptomatic urinary tract infections (particularly in immunosuppressed patients) and symptomatic respiratory infections
C	1, 2, 5, 6	Respiratory and gastrointestinal; symptomatic respiratory infections and hepatitis in immunosuppressed patients
D	8-10, 13, 15, 17, 19, 20, 22-30, 32, 33, 36-39, 42-49, 51	Eye and gastrointestinal; symptomatic eye infections, gastrointestinal infections in patients infected with human immunodeficiency virus
E	4	Symptomatic eye and respiratory infections
F	40, 41	Symptomatic gastrointestinal infections

Data from references 108, 212, 227, 263, 289, 385, 424, 463, 494.

genotypes of adenovirus type 7 have been identified, and the severity of disease may relate to the genotype.

PHYSICAL PROPERTIES

Adenoviruses are nonenveloped DNA viruses 65 to 80 nm in diameter.[141,168,226,227,238,270,323] The virion consists of a protein capsid composed of 252 capsomeres and a nucleoprotein core that contains the DNA viral genome and two to four internal proteins.[392] The virion is roughly spherical in the form of an icosahedron; each of the 20 sides is an equilateral triangle, with the vertices of each converging in groups of five and resulting in 12 pentagonal vertices.[45,153,226] Each vertex capsomere contacts five other capsomeres and is designated a *penton*. Each penton contains a base plate and a rodlike projection, the fiber. The virion has 240 nonvertex capsomeres that occur in groups of six and are known as *hexons*.[270,357,477] Hexons contain the generic complement-fixing antigen.[153] Each capsomere has a diameter of 8 nm and a central hole that is 2 to 3 nm in diameter.[510] The capsomeres constitute 87 percent of the dry weight of the virion.

The central core of the virion, which accounts for 12 to 14 percent of its dry weight, is composed of linear double-stranded DNA (molecular mass, 23.85×10^6 daltons for adenovirus type 2) and two to four basic proteins.[158,227,510]

Adenoviruses are highly stable in general.[111,153,166,238,291] They are resistant to lipid solvents and retain activity at pH values ranging from 2 to 10.

At 24° C, maximal infectivity is maintained between pH 6 and 9.5. Adenoviruses are stable at room temperature for 2 weeks, at 36° C for 7 days, and at 4° C for at least 70 days. Infectivity is destroyed by heating to 56° C for 30 minutes. Sodium dodecyl sulfate (0.25%) inactivates virus by disruption of the capsid.[270] Adenovirus serotypes 2, 10, 40, and 41 are highly resistant to ultraviolet radiation, and, therefore, they can be used as markers of the quality of water treatment practices.[214]

ANTIGENIC COMPOSITION

The antigenic determinants of adenoviruses are contained on the protein structural subunits (hexons, pentons, and fibers).[477] The hexon antigen (alpha component) carries the generic antigenic component that is common to all mammalian adenoviruses and is measured by complement fixation or ELISA. Another hexon antigen (epsilon component) reacts with neutralizing antibodies lacking hemagglutination-inhibiting activity. The antigen related to viral fiber also induces the production of type-specific neutralizing antibody for some adenoviral types. Minor antigens are related to the pentons. One of them (the cell-detaching factor) causes rounding and clumping of tissue culture cells.

Gerna and associates,[165] using the immunoperoxidase antibody technique, found that the early antigens of all serotypes belonging to one group (see Table 168–1) react strongly with all type-specific immune sera of the same group.

TISSUE CULTURE GROWTH

Although adenoviruses can be grown in a wide variety of cells of human epithelial origin, primary or diploid cultures of human embryonic kidney are preferable for recovery of agents from clinical specimens.[291] Continuous cell lines such as HeLa and HEp-2 also are quite sensitive.[203,238,413] Adenoviruses will grow in monkey kidney tissue culture, but evolution of the cytopathic effect is considerably slower than that occurring in cells of human origin. In addition, the cytopathic effect is more variable in monkey kidney tissue culture, and many isolates will be missed.

Enteric adenoviruses have been detected in human feces by electron microscopy.* These enteric adenoviruses, identified as types 40 and 41, usually do not grow in standard tissue culture systems. Both viral types will grow in Graham 293 cells (a human embryonic kidney cell line transformed by adenovirus type 5); type 40 also will grow in tertiary monkey kidney cells, and some strains of type 41 will grow in HEp-2, Chang conjunctiva cells, and tertiary cynomolgus cells.[458,496] Grabow and associates[178] noted that the PLC/PRG/5 cell line was 100 times more sensitive to a laboratory strain of adenovirus type 41 and 10 times more sensitive to a laboratory strain of adenovirus type 40 than were Graham 293 cells.

Specimens for viral culture may be obtained from the eye, pharynx, blood, lungs, pleural and pericardial fluid, liver, stool, intestinal epithelium, lymph nodes, cerebrospinal fluid (CSF), brain, urine, and renal tissue. For best isolation rates, clinical

*See references 45, 91, 106, 246, 263, 397, 403, 475, 494, 505.

specimens should be inoculated in cell culture within 6 hours of being collected. Tissue culture tubes are incubated best at 37° C, and rolling offers no advantage over stationary incubation.[291] Although the cytopathic effect has considerable variability, the most consistent finding is marked rounding and clumping of cells, often in grapelike clusters.[392,395] A cytopathic effect may be noted as early as 1 to 2 days after inoculation, but it may be delayed as long as 4 weeks. Use of the shell viral technique, in which infected cells in a specimen are centrifuged onto HEp-2 tissue culture cells, yields positive cultures in 1 to 2 days.[131] The cytopathic effect characteristically is followed by detachment of the entire cell sheet from the glass of the tissue culture tube within 2 to 4 days.[183,204,379,410,413]

VIRUS MULTIPLICATION

Initial attachment of adenoviruses to cells is relatively slow, with up to 6 hours being required.[99,167,238] The fiber protein of the virus mediates attachment to the cellular receptor.[428] An important adenovirus receptor is the coxsackievirus and adenovirus receptor (CAR) protein. It is a high-affinity receptor for all adenoviral subgroups except subgroup B. Penetration into the host cell occurs rapidly, either by phagocytosis or by direct entry through the plasma membrane.[238,305] The eclipse period with adenoviruses varies from 11 to 21 hours, depending on the serotype.[167,238] During eclipse, viral DNA uncoating requires approximately 2 hours when determined biochemically.[238] After uncoating, the viral DNA rapidly enters the nucleus of the cell and disassociates from its internal protein.[99,168,305] After the eclipse period, viral DNA accumulates, often doubling the content of the infected cell and becoming part of the typical inclusion bodies of the infected cells.[168]

Characteristic cytopathic changes in tissue culture, as demonstrated by light microscopy of hematoxylin and eosin–stained material or by electron microscopy, appear as early as 8 to 24 hours after infection occurs.[41,43,192] Two types of intranuclear alterations may be seen. In the first, early, small, discrete eosinophilic inclusions are observed. They gradually enlarge, become more prominent, and then form a large crystalline central mass surrounded by a clear zone or halo.[41,174] This type of early cytopathic effect appears to take place in cells that contain only small amounts of infectious virus.[42] The second type of intranuclear alteration, which generally occurs later, consists of large basophilic intranuclear inclusions.[41] Occasionally, giant forms measuring greater than 14 mm across are noted.[41] These mature inclusions may expand the nucleus of the cell so greatly that the cell's DNA content is 10 times larger than that of an uninfected cell. They contain a large amount of viral antigen and infective virus. Cytopathic changes vary considerably with the different adenoviral serotypes.[43,270]

In general, virus remains within the nucleus of intact, infected cells, with less than 1 percent of the total viral content of a culture being free within the extracellular fluid at any one time.[270]

ANIMAL SUSCEPTIBILITY

Human adenoviruses usually do not produce clinical illness in laboratory animals, although infections with several different serotypes have occurred in selected animals.[238] When adenoviral strains were administered intranasally to young, "pathogen-free," colostrum-deprived pigs or 1-month-old cotton rats, pneumonia developed in the animals, and intranuclear inclusions were observed microscopically in their lungs.[238,367] An adenovirus type 5 strain was injected intravenously into a rabbit, and the virus was recovered from the animal's spleen when removed 2 months later. Many adenoviral strains will propagate in a variety of different animal tissue cultures. In addition, in some cultures, marked cytopathic effects are observed, but little infectious virus is produced.

ADENO-ASSOCIATED VIRUSES

Adeno-associated viruses are a group of small, defective, single-stranded, DNA-containing, virus-like particles that replicate in tissue culture only in the presence of adenoviruses.[35,99,153,238,261,440] Four serologic types have been identified; however, only types 2 and 3 have been recovered from humans.[153,270] These agents have been isolated from throat and anal swab specimens of children from whom adenoviral strains also were isolated.[35] Approximately 30 percent of children have complement-fixing antibody to adeno-associated virus types 2 and 3; most of these children have had evidence of adenoviral infection as well.[36] Neutralizing antibody to adeno-associated virus types 2 and 3 is noted in the sera of 60 to 80 percent of children 8 to 14 years of age.[373] The specific relevance of adeno-associated viruses is unknown.

EPIDEMIOLOGY

GENERAL PREVALENCE

Adenoviral infections account for 2 to 5 percent of all respiratory illnesses.[58,78,84,151,152,380] In children, adenoviruses are estimated to be responsible for 2 to 24 percent of respiratory viral illnesses,[47,58,64,66,225,303,313] and they are implicated in 5 to 11 percent of upper respiratory tract infections, 4 to 10 percent of cases of pharyngitis, 3 to 9 percent of cases of croup, 5 to 11 percent of cases of bronchitis, 2 to 10 percent of cases of bronchiolitis, and 4 to 10 percent of cases of pneumonia.[47,64-66,154,341,375] Enteric adenoviral infections are the cause of 5 to 15 percent of acute diarrheal illnesses in children.[77,91,295,330,389,397,475,478] Specific categories of illness caused by adenoviruses vary with respect to viral serotype, patient age, socioeconomic status, and environmental conditions.[61,85,189,202,247,519] Adenoviruses have a predilection for infants and children younger than 5 years who spend portions of their days in closed environments, such as daycare centers, orphanages, and other institutions.[25,28,61,194,304,492] Epidemics of disease caused by adenoviral infection have been associated with swimming pools, daycare centers, resident schools, certain industries, hospitals, physicians' offices, and early basic military training centers in young recruits.* Adenoviruses are recovered commonly from children in tropical countries and in situations characterized by crowding, such as lower socioeconomic settings.[61,66,79,247,519]

AGE INCIDENCE AND PREVALENCE

Although adenoviral infections occur in all age groups, the incidence of infection generally is related inversely to age.[85,270] More than 90 percent of newborn infants have transplacentally acquired complement-fixing adenoviral serum antibody.[348,448] Most infants have neutralizing antibody to one or more of the common adenoviral types, which appears to be protective during the first 6 months of life. When adenoviral infection does occur in a neonate, it often is severe and occasionally fatal.[9,138,525] By the sixth month of life, only 14 percent of infants have demonstrable adenoviral complement-fixing antibody. By the time children reach 1 year of age, complement-fixing adenoviral antibody is observed in 44 to 50 percent of sera tested.[233,351]

*See references 73, 95, 138, 180, 244, 245, 269, 272, 293, 315, 366, 376, 387, 401, 415, 417, 437, 473, 521.

The incidence of adenoviral infection peaks in infants and children between 6 months and 5 years of age.[328,380] By the time that they are 5 years of age, 70 to 80 percent of children have neutralizing antibody to adenovirus types 1 and 2, and 50 percent have antibody to adenovirus type 5.[110,151,233,241,374,380,480]

Adenoviral infections also occur commonly in grade-school and junior high school–aged children, but the incidence diminishes in high school–aged adolescents. Adenoviral infections occur in only 1 to 2 percent of college students, and they are noted infrequently in civilian adults.[132,134,135,182,450] Approximately 1 percent of adults with a respiratory infectious illness will have adenoviral infection; in hospitalized adults, the incidence is approximately 4 percent.[182] The most common adenoviral respiratory infections in children are caused by types 1, 2, 3, and 5.[25,480,490,492] Types 6 and 7 are the next most frequent isolates associated with childhood respiratory infection. Adenovirus types 40 and 41 are the most common causes of diarrhea.[77,274,295]

MILITARY RECRUITS

Epidemic adenoviral disease occurs commonly in military recruits, with virtually all illness developing during the first 8 weeks of basic training.[149,272,312,322,415,417,482,483] The attack rate has varied between 40 and 90 percent.[149,183,312,481] Adenoviruses account for 30 to 70 percent of acute respiratory disease, 67 percent of common cold-like illnesses, 62 to 77 percent of cases of acute febrile pharyngitis and tonsillitis, 67 percent of cases of bronchitis, and 24 percent of cases of pneumonia.[31,150] Some adenoviral infections are associated with minimal or no symptoms.[150,183]

A vaccine against adenovirus serotypes 4 and 7 was developed for use in military basic training centers and effectively prevented outbreaks of adenovirus. Routine vaccination began in 1971, but the sole manufacturer of the vaccine ceased its production in 1995. The first large post–vaccine era outbreak of adenovirus serotypes 3 and 7 occurred in naval recruits in Great Lakes, Illinois, in 1997.[417] A subsequent epidemic of adenovirus 4 occurred in military recruits in Fort Jackson, South Carolina, in 1998.[272]

In a commentary, Gray reported that the U.S. Department of Defense identified a new manufacturer of the adenovirus vaccine (Duramed Pharmaceuticals) in 2001. Results of phase I studies of the vaccine have shown adequate seroconversion and good safety profiles.[180]

GEOGRAPHIC DISTRIBUTION

Adenoviral infections have been noted throughout the world.* Epidemic, endemic, and sporadic infections all occur.

SEASONAL PATTERNS

Sporadic infections with adenoviruses occur throughout the year.† Epidemic adenoviral respiratory disease usually occurs in the winter, spring, and early summer.‡ Seasonal patterns depend on serotypes, population groups, and exposure. Epidemics of disease in military recruits commonly associated with adenovirus types 4 and 7 occur most frequently in the winter and spring.[37,149,150,215] Epidemics of pharyngoconjunctival fever have been noted most commonly in the summer months in school-aged children in association with summer camps or swimming pools.[315,485,510] No seasonal pattern has been identified for adenoviral gastroenteritis.[91,262,403,475]

HOST AND SOCIAL FACTORS

The overall incidence of adenoviral illnesses is higher in males.[85,204] In a study involving 3313 adenovirus isolates, the male-to-female ratio was 1.3 : 1.[85]

Susceptibility to adenoviral infection apparently does not vary by race. More severe disease has been noted in infants of native and Indian populations in New Zealand and Canada.[23,175] However, the relationship of these findings to socioeconomic conditions was not identified initially.

The incidence of adenoviral infection is greatest in lower socioeconomic population groups.[247] Spread of infection has been observed in daycare centers, schools, children's homes, hospitals, clinics, physicians' offices, and certain industrial settings.* Acute, overwhelming illness, including bronchiolitis and pneumonia with severe pulmonary residua, has been reported in neonates, small infants, and occasionally, adults.[9,202,294] Adenoviral infections are a significant problem in immunocompromised hosts; when they occur, they frequently are severe and occasionally are fatal.†

SPREAD OF INFECTION

Adenoviruses frequently are isolated from the conjunctiva, throat, and stool. Despite the ease of isolating the virus, the effectiveness of spread of infection in the general population varies considerably.[66] Adenovirus types 1, 2, 3, 5, and 7 are effective spreaders; however, they are not as highly contagious as varicella, measles, and influenza viruses.[65,66] Close contact appears to be necessary for infection to spread from one person to another.[448] Illness does not spread rapidly in the usual school setting but does spread dramatically in closed environments.[28,65,194,232] Although adenovirus type 4 spreads less effectively in the general population, spread is rapid in non-immune military recruits who live in close contact with each other.[74] In an outbreak of adenovirus type 7 in a children's home, 84 percent of the residents were shown to be infected.

Transmission of virus occurs by droplets reaching the conjunctiva, nose, or throat or, alternatively, by the fecal-oral route. In volunteer studies, adenoviruses have been shown to spread by small-droplet aerosols and, to a lesser degree, by large droplets.[11,86,87] Adenovirus type 4 has been recovered from room air and cough samples of patients with the virus in their throats.[12] A study by Russell and colleagues[415] of 341 military recruits and support personnel at the Marine Corps training center in San Diego, California, demonstrated that more than 79 percent of incoming recruits were susceptible to adenoviral infection in the postvaccine era. They identified incoming recruits with prolonged asymptomatic shedding of adenovirus and the presence of adenoviruses on multiple living quarter surfaces as potential sources of transmission. They also found evidence of extended pharyngeal shedding of adenovirus over the course of several days among recruits who had febrile respiratory illnesses.

In epidemics of pharyngoconjunctival fever, the virus appears to spread from contaminated swimming pool water to the eyes of recipients. Epidemics of keratoconjunctivitis have occurred as a result of contact with contaminated ophthalmic instruments and fingers.[18,101,216,244,245,255,269,334,442] In daycare centers, orphan-

ages, and the military, transmission probably occurs most commonly through small-droplet aerosols in crowded quarters.[387] An alternative in children is the fecal-oral route. Enteric adenoviruses have been identified in fecal specimens for approximately 8 days after the onset of gastroenteritis.[262]

Family members may excrete adenoviruses in their feces intermittently for prolonged periods after initial infection.[47,151] In one study, 20 percent of persons excreted adenoviruses in stool for longer than 3 months. Intrahousehold spread appears to continue as long as susceptible family members are present.[151] Infants born into households in which members are adenoviral fecal excreters often become infected, presumably through the fecal-oral route. In general, 50 percent of susceptible household members will experience infection, although the rate varies inversely with age and also depends on the serotype of adenovirus. Re-infection with specific adenoviral serotypes occurs, but most are asymptomatic or associated with only minimal illness.

Nosocomial spread of both respiratory and enteric adenoviruses is a common occurrence and has been the cause of fatal illnesses in infants and immunocompromised patients.[4,112,144,273,437,525]

PATHOGENESIS AND PATHOLOGY

Adenoviral infections usually are acute and self-limited, and, therefore, opportunities to study the pathogenesis and pathologic process have been infrequent. Study of the pathologic mechanisms has been performed in human volunteers, tissue and organ culture systems, and recent murine model systems and by examination of specimens from persons dying of adenoviral disease.

VIRAL INFECTION

In general, the characteristics of adenoviral infection depend on the host and the serotype of the agent.* In most respiratory illnesses, initial viral infection occurs in the respiratory tract and involves the mucous membranes of the nose, oropharynx, and conjunctiva. Adenoviral agents have been isolated from sputum and oral secretions from 2 days before the onset of clinical illness to up to 8 days after the onset of symptoms. Deeper respiratory involvement of the trachea, pleurae, and lungs may result from initial small-particle aerosol, from progression of local infection, or perhaps as a result of viremia. Gastrointestinal infection in conjunction with respiratory infection also occurs early and probably is the result of swallowed virus. Stool isolates of respiratory viral types frequently are noted concomitantly with respiratory tract infection. However, in contrast to the upper respiratory infection, the virus may persist for a long time in the lower gastrointestinal tract. Infection with enteric adenoviral types is presumed to involve intestinal epithelial cells. In one fatal infection, adenoviral antigen was demonstrated in jejunal cells.[397,504]

In experimental studies with aerosolized adenovirus type 4, recovery of virus from throat specimens occurred on day 5 or 6, progressed to a maximum concentration on day 11 or 12, and was seen uncommonly after day 20. Maximal recovery of adenovirus type 4 from anal specimens occurred on day 13, and shedding continued for longer than 3 weeks. Adenovirus types 26 and 27 inoculated into the conjunctiva resulted in short-term isolation of virus from the eyes on days 3 to 7 and, less frequently, from the throat on day 4.[254] Isolation of virus from the rectum was common beginning at the end of the first week. Maximal fecal shedding occurred during the second and third weeks.

Viremia is a common finding in uncomplicated adenoviral respiratory infections in children. In a study involving 68 children, adenoviral DNA was noted in acute-phase serum samples from 28 (41%) of these children.[1] In the children with primary infection, 72 percent (21 of 29) had adenoviral DNA in their acute-phase serum samples. Other evidence of the presence of adenoviruses in the bloodstream early in disease is the occurrence of maculopapular, morbilliform, or petechial exanthems (or any combination of such rashes), as well as recovery of virus from multiple organs such as the brain, kidney, urinary bladder, lymphoid tissue, and liver and at postmortem examination.* The virus has been cultured from the mononuclear cells of heparinized blood.[8]

RELATIONSHIP BETWEEN ADENOVIRAL INFECTION AND OBESITY

Studies have shown that exposure to human adenovirus serotype 36 is associated with increased adiposity in chickens, mice, and nonhuman primates.[113-115] Paradoxically, reduced serum cholesterol and serum triglycerides are seen in the same animal models. Atkinson and colleagues[13,486] proposed that adenovirus serotype 36 directly affects adipocytes by increasing the number and size of preadipocytes. Vangipuram and associates[487] explored the possible mechanisms by which adenovirus types 36 and 37 increase adiposity in animal models. They performed ex vivo experiments in human adipocytes and a murine preadipocyte cell line (3T3-L1) and in vivo experiments in the rat model, which demonstrated suppression of leptin mRNA expression, decreased leptin secretion, and increased glucose uptake.

PATHOLOGY

Early pathologic changes are observed in the epithelium of the respiratory tract. The severity of adenoviral involvement varies with the different serotypes. In tracheal organ cultures, growth of adenovirus type 7 was characterized by an initial focal cytopathologic effect at 100 hours that quickly progressed to involve the whole epithelium.[89] Frequently, the cilia of inclusion-bearing cells were noted to be intact. In contrast to the findings with adenovirus type 7, a type 12 strain resulted in only a mild cytopathologic effect on the organ culture system.[89]

Microscopic examination of autopsy material from patients dying of adenoviral pneumonia revealed a loss of cilia in the tracheal epithelium, proliferation of other respiratory epithelial cells, and the presence of intranuclear inclusions.[22,30,51,67,156,508,511,513,526] In severe pneumonia, total destruction along with necrotizing bronchitis, bronchiolitis, and pneumonia is observed (Fig. 168–1). Mononuclear cellular infiltration is seen, and hyaline membranes and necrosis are present. Cilia and goblet cells are absent, and muscle fiber bundles and elastic fibers are dispersed. Frequently, epithelial cells have a characteristic appearance with adenoviral infection. These infected cells are enlarged grossly and lose their nuclear membranes; the nuclear material has migrated into the cytoplasm.[388] Blood vessels show edema, separation of filaments in their walls, and occasionally, thrombosis.[526]

On histologic examination, adenoviral inclusions are characterized by small eosinophilic and larger basophilic intranuclear bodies.[22,156,348,444]

Hepatic involvement in adenoviral infection has been reported frequently.[3,12,30,59,156,388,441] In addition to isolation of virus from the liver, focal areas of liver necrosis accompanied by character-

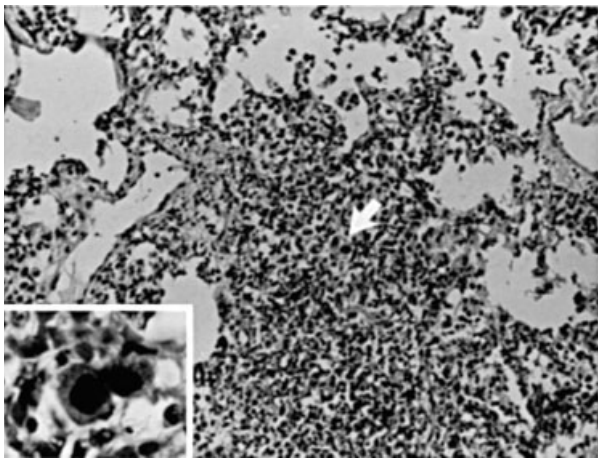

Figure 168–1 The lung of a 17-month-old infant with adenoviral pneumonia. The infant died 10 days after the onset of illness, with no other contributing disease. The adenovirus isolated was not typed. A patchy pneumonia is present, and the *arrow* indicates two cells with nuclear inclusions. *Inset*, Two similar cells with typical adenoviral nuclear inclusions at higher magnification (hematoxylin and eosin staining, ×190; inset, ×770). *(Courtesy of Dr. David D. Porter, Department of Pathology, David Geffen School of Medicine at UCLA.)*

istic hepatic intranuclear inclusions have been demonstrated.[3,59,525] Electron-microscopic examination has revealed adenoviral particles within the intranuclear inclusions.[3,30,388,508,525] Hematogenous spread to the central nervous system (CNS) has been observed.[434] Most patients with adenoviral CNS infection have had an associated pneumonia.[90,433] In CNS disease, the brain is edematous and congested. On microscopic examination, a perivascular accumulation of lymphocytes is noted, along with gigantic nuclear inclusions in the cortical neurons. Viral particles have been observed within these nuclear inclusions by electron microscopy.[76]

In epidemic keratoconjunctivitis caused by adenovirus type 8, the walls of the conjunctival vessels are damaged, and aneurysms are present. The surrounding conjunctival connective tissue is edematous. The virus has been suggested to penetrate the cornea along nerves deep into the epithelial layers in a manner similar to that occurring in herpes simplex virus (HSV) infection.[491]

Adenoviral strains have been isolated from and intranuclear inclusions have been demonstrated in renal tubular epithelium, lymph nodes, muscle, and gastrointestinal epithelium.[27,59,504,522,523,525]

IMMUNOLOGIC EVENTS

The local response in adenoviral infection depends on the site of viral inoculation, the method of transmission, the viral serotype, the concentration of inoculum, and the antibody status of the host. Three days after infection develops, when virus can be recovered from the nasopharynx, marked transudation of proteins from serum into the respiratory tract occurs, along with the production of secretory IgA antibody.[320] Approximately 7 days after the onset of illness, serum-neutralizing, hemagglutination-inhibiting, and complement-fixing antibodies appear.[99,290,390] At the same time, the nasal secretions contain specific IgA and IgG antibody.[29] In general, neutralizing antibody is the most sensitive indicator of adenoviral infection, hemagglutination-inhibiting antibody is less sensitive, and complement-fixing antibody is the least sensitive.[269,389] Antibody titers peak in 2 to 3 weeks; complement-fixing antibody declines in 2 to 3 months but may persist for up to a year.[99,390] Neutralizing antibody persists for a longer period and is measurable in many instances for periods as long as 10 years. Re-infection with the same adenoviral serotype is rare because of type-specific immunity.[26,411]

Although alterations in leukocytes are not common findings, a decrease in the number of lymphocytes has been observed before or at the onset of clinical illness and an increase in neutrophils early in the disease, followed by a decrease later. Neutropenia may develop in severe disseminated illness and is attributed to a direct toxic effect of virus on leukocytes, marrow reserves, or both.[117] The erythrocyte sedimentation rate (ESR) of children has been normal or elevated to 55 mm/hr.[447,448]

Studies by Ginsberg and associates[170-172] in murine adenoviral pneumonia model systems noted that tumor necrosis factor-α, interleukin-1, and interleukin-6 were elaborated during the first 2 to 3 days of infection. However, only tumor necrosis factor-α played an early role in the initial phase of pathogenesis. The second phase of the inflammatory response is caused by the infiltration of cytotoxic T cells. In an extensive study, Kawasaki and colleagues[256] compared numerous clinical and laboratory test results in children with adenoviral infections with those in children with influenza and respiratory syncytial virus (RSV) infections. They found that the children with adenoviral infections had higher white blood cell (WBC) counts with a greater number of neutrophils than did children with influenza or RSV infections (12,322, 7638, and 8460 WBCs/mm,[3] respectively). The children with adenoviral infections also had more atypical lymphocytes and higher C-reactive protein (CRP) and ESR values. The mean serum interleukin-6 concentration was significantly higher in the children with adenoviral infections than it was in those with influenza and RSV infections (131.0, 26.7, and 15.0 pg/mL, respectively).

Mistchenko and coworkers[329] studied cytokines and adenovirus-specific circulating immune complexes in 38 children with adenoviral infections. They placed the patients into three groups based on the severity of their respiratory illnesses: moderate illness, severe illness, and fatal illness. Serum interleukin-1 was not detected in children with moderate illness but was found in 7 of 12 with severe illness and in 13 of the 16 children who died. Tumor necrosis factor-α frequently was present in the sera of fatal cases, it was not present in the sera of moderately ill children, and it was detected in the sera of only 2 of 12 patients with severe but nonfatal illness. Interleukin-8 was noted in all sera, but values were highest in children with fatal illness. Serum immune complexes (containing IgG) were found in 7 of the 16 children who died. Finally, patients with increased concentrations of interleukin-6, interleukin-8, and tumor necrosis factor-α were those with hypoperfusion, febrile peaks, seizures, and a manifestation of septic shock. Five of 10 children with severe or fatal illness had serum autoantibodies specific for smooth muscle.

Matsubara and associates[316] noted the participation of peripheral blood $CD8^+$ T cells and HLA-DR^+, $CD8^+$ T cells in children with adenoviral infection. One child with severe adenoviral type 7 pneumonia had a marked increase in HLA-DR^+ $CD8^+$ T cells, serum levels of interferon-γ, and peripheral blood interferon-γ–producing T cells.

CLINICAL MANIFESTATIONS

Adenoviral infections are exceedingly common events, and the spectrum of disease is quite broad (Table 168–3). As noted in Table 168–3, some specific adenoviral diseases exist; however, the overall majority of infections involve a variety of anatomically associated illnesses. In many instances, similar illnesses are caused by other respiratory viruses, and the clinical spectra of the various adenoviral serotypes frequently overlap. Certain specific adenoviral types do have clinical characteristics that facilitate etiologic diagnosis, however.

TABLE 168–3 Clinical Spectrum of Adenoviral Infections

System/Organ	Illness Category	Epidemic Occurrence	Frequency	Adenoviral Type(s)
Respiratory	Common cold	No	Rare	1, 2, 3, 5, 7
	Nasopharyngitis, pharyngitis, and tonsillitis	Yes	Common	1,* 2,* 3,* 4, 5,* 7,* 7a, 14, 15, (21/H21+35)†
	Acute respiratory disease	Yes (in military recruits)	Very common	2, 3, 4,* 5, 7,* 8, 11, 14, 21
	Acute laryngotracheitis	No	Occasional	1, 2, 3, 5, 6, 7
	Acute bronchiolitis	No	Occasional	3, 7, 21
	Pneumonia (civilian population)	Yes	Common	1, 2, 3,* 4, 5, 7,* 7a, * 8, 11, 21,* (21/H21+35),† 35
	Atypical pneumonia in military recruits	Yes	Common	4,* 7,* 21
	Pertussis-like syndrome	No	Rare	1, 2, 3, 5, 12, 19
	Bronchiolitis obliterans	No	Rare	2, 3, 7, 21
	Unilateral hyperlucent lung	No	Rare	7, 21
Eye	Acute follicular conjunctivitis	Yes	Common	1, 2, 3, 4, 6, 7, 9, 10, 11, 15, 16, 17, 19, 20, 22, 34, 37
	Pharyngoconjunctival fever	Yes	Common	1, 2,* 3,* 4,* 5, 6, 7,* 7a,* 8, 14,* 37
	Epidemic keratoconjunctivitis	Yes	Occasional	2, 3, 4, 5, 7, 8,* 10, 11, 13, 14, 15, 16, 17, 19, 23, 29, 37
Skin	Morbilliform and rubelliform exanthem	Rare	Occasional	3, 4, 7, 7a
	Roseola-like	No	Occasional	1, 2
	Stevens-Johnson syndrome	No	Rare	7
	Petechial exanthem	No	Rare	7
Genitourinary	Acute hemorrhagic cystitis	No	Rare	7, 11, 21,
	Nephritis	No	Rare	3, 4, 7a
	Orchitis	No	Rare	Unknown
	Oculogenital syndrome	Yes	Rare	19, 37
Gastrointestinal	Gastroenteritis	Yes	Common	1, 2, 3,* 5, 7,* 11, 12, 15, 17, 31,* 32, 33, 40,* 41*
	Mesenteric lymphadenitis	No	Rare	1, 2, 3, 5, 7
	Intussusception	No	Rare	1, 2, 3, 5, 6, 7
	Appendicitis	No	Rare	1, 2, 7
	Hepatitis	No	Rare	1, 2, 3, 5,* 7, (11+35/H11+35)†
Heart	Myocarditis	No	Rare	7, 7a, 21
	Pericarditis	No	Rare	7
Neurologic	Encephalitis and meningitis	No	Rare	1, 2, 3, 5, 6, 7, 11, 12, 26, 32
	Transient encephalopathy	No	Rare	3
	Acute flaccid paralysis	Yes	Rare	21
Joint	Arthritis	No	Rare	7
Auditory	Deafness	No	Rare	3
Endocrine	Thyroiditis	No	Rare	Unknown

†Intermediate strain.

RESPIRATORY TRACT

Common Cold

Although adenoviruses frequently receive etiologic consideration in colds, they are, in fact, associated only rarely with this illness.[248] In one report, 3 percent of common colds in children were attributed to adenovirus,[380] and in another study, 6.4 percent of children with coryza had adenoviral isolates.[128] Respiratory tract infections with adenoviruses usually are associated with fever and, frequently, with some degree of pharyngitis; therefore, when strict clinical criteria are applied, they do not qualify as colds.[232,450] Occasionally, adenoviruses, particularly types 1, 2, 3, 5, and 7, have been recovered from patients with typical colds.

Nasopharyngitis, Pharyngitis, and Tonsillitis

Adenoviral pharyngitis is an acute illness characterized by fever, sore throat, extensive exudative tonsillitis, and frequently, cervical adenopathy.[116,128,248,335,440] In two studies involving 74 children with adenoviral pharyngitis, Ruuskanen and associates[416] described the pharyngeal findings. Most commonly, only mild inflammation and redness were observed. When exudates were present, they found them to be thick and membranous, thin and follicular, or thin and spotty; most typical were follicular and spotty exudates. Associated symptoms include malaise, headache, myalgia, chills, and cough. In infants and preschool children, nasal congestion and discharge are noticeable and abdominal pain is a common complaint.[480] Children with adenoviral acute febrile pharyngitis also frequently have laryngotracheitis, bronchitis, or pneumonia.[518] The usual duration of illness varies from 5 to 7 days, although occasionally, symptoms persist well into the second week.[416]

Acute febrile pharyngitis is the most common adenoviral illness in children and is particularly important as an epidemic illness in closed environments.[28,440,448,518] For example, in an epidemic in a children's home, 63 percent of the residents were infected with adenovirus type 7a.[194] Moffet and colleagues[335] noted that adenoviruses were the etiologic agents recovered most commonly from hospitalized preschool children with febrile exudative pharyngitis; 23 percent of the children studied had adenoviral infections. In a university student health service study, 2.4 percent of illnesses with acute febrile pharyngitis were caused by adenoviruses.[346] Adenoviruses account for 37 to 75 percent of cases of nonstreptococcal pharyngitis in military recruits.

In children, 86 percent of cases of febrile pharyngitis are associated with adenovirus types 1, 2, 3, 5, and 7.[194,232,335]

On occasion, adenovirus types 7a, 9, 14, 15, and the intermediate strain 21/H21+35[213,440,448] also have been noted in association with pharyngitis. In military recruits, adenovirus types 4 and 7 are the main etiologic agents.

Acute Respiratory Disease

ARD is an epidemic disease that occurs predominantly in military recruit populations. This illness was studied extensively during World War II by the Commission on Acute Respiratory Diseases, and although individual cases were quite undifferentiated, the epidemiologic aspects of the outbreaks clearly indicated a specific etiologic agent.[81,169,440,452,473,479] The disease is an acute, febrile respiratory illness of short duration with constitutional and localized respiratory symptoms.[139] After an incubation period of 5 to 7 days, fever (mean temperature of 39.5° C), pharyngitis, laryngitis, tracheitis, and a nonproductive cough develop.[34,97,169,374] The initial dry, hacking cough may progress to paroxysms. Malaise, myalgia, chills, headache, dizziness, rhinitis, conjunctivitis, abdominal pain, and local cervical lymphadenopathy are common complaints.[97] The inflammatory process may spread to the bronchi, the bronchioles, and the parenchyma of the lungs. In epidemics, as many as 67 percent of those affected wheeze and have other evidence of small airway obstruction; pneumonia occurs in 10 to 20 percent.[215,294,338] The illness gradually resolves over the course of an 8- to 36-day period.[155] Early in the illness, the total WBC count may be slightly elevated, with a small increase in the percentage of polymorphonuclear leukocytes.

In experimental, aerosol-induced ARD, the incubation period ranged between 6 and 13 days.[87] Typical illness included fever to 39° C, rhinitis, prostration, malaise, myalgia, and headache. Pneumonia occurred occasionally. The virus was recovered from throat culture specimens 5 days after inoculation, from the nose at 6 days, and after 9 days in fecal specimens. Serum-neutralizing antibody responses occurred between the third and fourth weeks. All ill volunteers had leukopenia and an elevated ESR during the illness.

The syndrome occurs most commonly in military recruits early in basic training; illness has been documented in as many as 90 percent of new trainees within the first 8 weeks of arrival at a training site.[215] The usual etiologic agents are adenovirus types 4 and 7. Occasionally, epidemics have been associated with adenovirus types 3, 11, 14, and 21,[153] and sporadic cases have been noted in connection with adenovirus types 2, 5, and 8.[215,374] The peak seasons of illness are winter and spring.[215]

Because of the magnitude of the problem of ARD in military recruits, live attenuated adenoviral vaccines against types 4 and 7 were developed and used in all branches of the U.S. military beginning in the early 1970s.[19,181] These vaccines were used successfully until the early 1990s, when production delays occurred; subsequently, in 1995, the vaccine manufacturer stopped production. Since early 1999, no vaccine has been available, and epidemic disease has returned to military training bases.[272,414,417] Although illness may occur in civilian adults, it is an uncommon event and not epidemic. In volunteer studies, subjects with serum antibody to a particular adenoviral type are protected against disease with that type of adenovirus induced by intranasal inoculation.[26,87]

Epidemic ARD has not been described in children. However, a sporadic comparative illness, usually clinically identified as acute bronchitis, is commonly the result of adenoviral infection.[519] Adenovirus type 7 is the etiologic agent most frequently found in these cases.

Acute Laryngotracheitis

On occasion, adenoviruses have been implicated as a cause of acute laryngotracheitis. In general, the croup caused by adenoviruses is not severe and often is manifested only as a barking, brassy cough. Laryngotracheitis frequently is seen in association with febrile pharyngitis, bronchiolitis, and pneumonia.[475] Epidemics have not been observed. Adenovirus types 1, 2, 3, 5, 6, and 7 have been implicated as etiologic agents.

Acute Bronchiolitis

Adenoviruses account for approximately 5 percent of cases of bronchiolitis in infants.[511] In a recent study of 143 children with adenoviral infections, the admitting diagnosis was bronchiolitis in 24 percent.[402] The bronchiolitis caused by adenoviral infection is sporadic and usually similar to illness associated with other viral agents. Occasionally, adenoviral bronchiolitis occurring early in infancy has been fatal or has resulted in serious residual lung damage and chronic disease.[501] This severe illness has been associated with serotypes 3, 7, and 21.

Pneumonia

YOUNG CHILDREN. Adenoviruses are common isolates in children with pneumonia. The overall frequency of adenoviruses as a cause of nonbacterial pneumonia in children is less than that of RSV and parainfluenza virus type 3, but an alarming number of fatal illnesses have been noted. Severe and fatal illnesses in infants and young children have occurred in association with adenovirus types 1, 2, 3, 4, 5, 7, 7a, 7h, 7i, 8, 19, 21, 35, and the intermediate strain 21/H21+35.* The more severe cases of pneumonia have been linked to types 3, 7, and 21.[435,513] Adenoviral pneumonia has been epidemic and sporadic.[67,74]

Severe pneumonia occurs most commonly in neonates and young children aged 3 to 18 months.† The onset of illness is acute, with persistent cough and fever (>39° C). On physical examination, moderate to severe dyspnea is apparent, as is the associated tachypnea. Inspiratory and expiratory wheezes and rales are heard on auscultation. Other signs and symptoms include lethargy, diarrhea and vomiting, pharyngitis, and occasionally, conjunctivitis. Extrapulmonary complications that occur commonly are meningitis, encephalitis, seizures, splenomegaly, hepatomegaly and hepatitis, myocarditis, nephritis, bleeding tendency, and exanthems.‡ Chest radiographs reveal diffuse infiltrates, which usually are bilateral and may be bronchial, peribronchial, or interstitial.[22,282,402,509] Hyperinflation and lobar collapse occur frequently.[175] Rarely, pleural effusions or mediastinal lymphadenopathy has been described.[282] In surviving infants, symptoms persist for 2 to 4 weeks, and radiographic changes resolve slowly, frequently being present at the 3-week follow-up examination.[67,74,435] Recovery often is gradual, and exacerbations occur commonly.[240,372]

Serious sequelae often result from adenoviral lower respiratory disease, particularly in association with adenovirus types 3, 7, 7a, and 21.[15,23,60,138,175,240,282,435] Such sequelae include bronchiectasis, bronchiolitis obliterans, and unilateral hyperlucent lung.§ An estimated 14 to 60 percent of children with documented adenoviral lower respiratory tract disease have some degree of permanent pulmonary sequelae.[175,282,434,435] In a study of 27 children conducted 10 years after they had documented adenoviral type 7 pneumonia, 12 had radiographic evidence of bronchiectasis or residual pulmonary changes; 16 children had abnormal results on pulmonary function studies.[434]

Macek and associates[309] have suggested that persistent adenoviral infection may be the cause of chronic obstructive airway disease in children. They noted adenoviral antigen in bronchoalveolar lavage specimens from 31 of 34 patients with chronic disease but in no bronchoalveolar specimens from a control group.

On occasion, severe and fatal adenoviral pneumonia has been related to malnutrition, environmental crowding, or a preceding severe viral disease such as measles.[15,22,23,175,277,348,435]

Severe adenoviral pneumonia associated with adenovirus types 3 and 7 also has been reported occasionally in previously healthy adults.[377,387,438] One adult had severe pneumonia caused by adenovirus type 21 that was associated with myalgia, rhabdomyolysis, and myoglobinuria.[514]

ATYPICAL PNEUMONIA IN MILITARY RECRUITS. Approximately 7 to 20 percent of cases of pneumonia in military recruits are associated with adenoviral infection.[54,150,164] Primary atypical adenoviral pneumonia commonly occurs in the winter months and generally is caused by adenovirus types 4, 7, and 21.[150] The illness is associated with fever, cough, sore throat, rhinorrhea, and chest pain. Other common symptoms include nausea, vomiting, myalgia, headache, and diarrhea. On physical examination, rales and pharyngitis are present in almost all cases. Rhinitis and generalized lymphadenopathy are observed in approximately half of those afflicted, and occasionally, conjunctivitis is noted. Chest radiographs reveal a bilaterally mottled appearance, most prominent in the lower lobes; they remain abnormal for 4 to 36 days.[54] Although serum cold agglutinins are observed, titers of 1:32 or higher are detected in only 18 percent of patients.[54,164]

Fatal pneumonia, absolute leukopenia, and disseminated disease have been reported in four previously healthy military trainees. Adenovirus type 7 was the etiologic agent in three of these cases, and the fourth illness was caused by adenovirus type 4.[122,294]

PERTUSSIS-LIKE SYNDROME. A pertussis-like illness has been noted in association with several adenoviruses, including types 1, 2, 3, 5, 12, and 19.[80,82,194,350,363] The illness occurs commonly in children younger than 36 months. The onset of illness is insidious and initially suggestive of a cold. The cough becomes progressively worse and, by 1 to 2 weeks, is paroxysmal. Severe recurrent episodes of paroxysms result in the production of mucus, post-tussive fatigue, and vomiting.[82] Approximately 50 percent of children have a typical whoop, and cyanosis occurs with the paroxysms. Peripheral leukocytosis with WBC counts ranging from 25,000 to 125,000 cells/mm^3 along with lymphocytosis and thrombocytosis is the usual finding.[80,363] The recovery time ranges from 4 to 10 weeks from the onset of illness.[82] Radiologic evidence of bronchiolitis is present in most children; interstitial pneumonia occurs occasionally. In our opinion, most and probably all of these pertussis-like illnesses are indeed *Bordetella pertussis* infections in which adenovirus is a co-infecting agent (see Chapter 140). In young infants, co-infection (adenovirus plus *B. pertussis*) may lead to more severe disease.[24,296,318]

BRONCHIOLITIS OBLITERANS. Bronchiolitis obliterans is a chronic bronchiolitis that initially was described in 1901 by Lange.[283] It has been noted to occur after measles, influenza, and pertussis, as well as after the inhalation of toxic substances.[15,23,511] Adenovirus types 2, 3, 7, and 21 have resulted in a bronchiolitis obliterans–type chronic illness.[15,23,60,332,383,501,511] These adenoviruses cause a severe necrotizing bronchiolitis that heals with fibrosis and predominantly obliterates the small airways.[19] The onset of disease is characterized by an acute febrile illness, cough, and respiratory distress. Disease may wax and wane for several weeks or months and is associated with recurrent episodes of atelectasis, pneumonia, and wheezing. Although some children recover from these episodes, the remainder have chronic pulmonary disease, including irreversible atelectasis, bronchiectasis, or hyperlucent lung syndrome.[23,501,511]

Castro-Rodriguez and colleagues[60] conducted a 5-year follow-up study of 38 children hospitalized with adenoviral pneumonia during an outbreak in Santiago, Chile, in 1998. Bronchiolitis obliterans developed in almost 50 percent of these children. Nosocomial acquisition of adenoviral infection was found to be associated more significantly with the development of bronchiolitis obliterans than community-acquired infection was.

UNILATERAL HYPERLUCENT LUNG. Unilateral hyperlucent lung is a well-defined syndrome characterized by increased translucency of all or part of one lung, along with a reduction in lung size.[92,310] The unilateral hyperlucency is associated with a decrease in the size and number of pulmonary vessels, as observed on pulmonary angiograms, and an absence of peripheral filling at bronchography.[310] Although the disease may have a number of causes, including pneumonia secondary to other viruses, it has been noted to occur after severe necrotizing bronchiolitis and pneumonia caused by adenovirus types 7 and 21.[310,511]

EYE

Acute Follicular Conjunctivitis

Acute follicular conjunctivitis is the most common and benign of the adenoviral infections of the eye. The infection in this disease is confined to the eye, generally is unilateral, and is manifested by follicular lesions on the palpebral conjunctival surface. Symptoms occur after an incubation period of 5 to 7 days and include lacrimation, itching, burning, a foreign body sensation, and conjunctival erythema.[110] Examination shows erythema and lymphoid follicular hyperplasia in the conjunctiva in association with serous drainage and increased lacrimation. Occasionally, adenopathy of the preauricular lymph nodes is seen. Symptoms resolve in 10 days to 3 weeks, with recovery usually complete.[86,110] Adenovirus types 1, 2, 3, 4, 6, 7, 9, 10, 11, 15, 16, 17, 19, 20, 22, 30, 34, and 37 have been isolated from the eyes of afflicted patients.[39,83,110,138,421,427,474]

Pharyngoconjunctival Fever

Pharyngoconjunctival fever is presented in detail in Chapter 12.

Epidemic Keratoconjunctivitis

Epidemic keratoconjunctivitis is caused most commonly by adenovirus type 8, but it also has resulted from infection with adenovirus types 2, 3, 4, 5, 7, 10, 11, 13, 14, 15, 16, 17, 19, 22, 23, 29, and 37.* Currently, adenovirus type 37 is the virus most commonly recovered from patients with epidemic keratoconjunctivitis in the United States and Europe. The most severe disease is associated with adenovirus types 5, 8, and 19.[96]

The illness occurs most commonly in adults, but a few cases have been reported in children.[195,334,459] It has no seasonal pattern. Although transmission of the viral agent from the respiratory tract to the eye occurs in sporadic cases, the usual method of viral

*See references 18, 39, 56, 63, 87, 96, 98, 101, 103, 104, 139, 189, 191, 195, 244, 245, 255, 257, 260, 334, 336, 353, 355, 421, 442, 446, 460, 518.

spread is by contaminated ophthalmic instruments and eye solutions, hand-to-eye contact by medical personnel and others, swimming pools, or hands or fomites in close-contact situations, such as in families and in industry.* The incubation period typically is 5 to 10 days but ranges from as short a period as 2 days to as long as 2 weeks.[98,269] The initial symptom generally is unilateral, acute, follicular conjunctivitis that suggests the presence of a foreign body. Photophobia, lacrimation, discharge, hyperemia, and edema of the conjunctiva are notable. Preauricular adenopathy occurs in as many as 90 percent of patients, and 50 percent of those afflicted have pharyngitis and rhinitis. Spread to the other eye may occur in 2 to 7 days. Seven to 10 days after onset of the disease, the conjunctivitis resolves, and painful, superficial, punctate epithelial opacities appear in the center of the cornea. These lesions frequently extend subepithelially and then heal, with subepithelial infiltrates left behind that may persist for months. In severe cases, hazy vision may continue for several years.[18]

An infantile form of epidemic keratoconjunctivitis has been described that usually affects children younger than 2 years old. This pseudomembranous or membranous conjunctivitis generally is accompanied by high fever, pharyngitis, otitis media, diarrhea, and vomiting. Preauricular lymphadenopathy typically is absent.[459]

Virus can be recovered from the eye for a usual period of approximately 2 weeks but has been detected for 2 to 3 years in patients with chronic papillary conjunctivitis.[96,382] In acute illness, conjunctival scrapings obtained during the first 10 days of infection reveal characteristic inclusion bodies when stained with Giemsa.[205] Virus-specific fluorescent antibody staining is diagnostic in epidemic keratoconjunctivitis.[426] Preparations of corneal and conjunctival epithelia reveal adenoviral particles when examined with the electron microscope.[103]

SKIN

Adenovirus types 1, 2, 3, 4, 7, and 7a, plus several unknown types, have been noted in connection with exanthematous disease.[70] The cutaneous manifestation most commonly associated with adenoviral infection is an erythematous maculopapular rash that appears while the child is febrile. In many instances, children with this illness have been thought to have either measles or rubella.[277] In most adenoviral infections with exanthems, other clinical findings more characteristic of adenoviruses, such as conjunctivitis, rhinitis, pharyngitis, and lymphadenopathy, also are present. In some instances, the exanthem truly is morbilliform with a characteristic confluence, but Koplik spots do not occur.

A widespread erythematous rash often is present early in the course of severe pneumonia in infants.[175] Chany and colleagues[67] noted a measles-like rash in five patients who died of adenovirus type 7a pneumonia. One report describes a child with an adenovirus type 7 infection and illness suggestive of meningococcemia.[418] This patient had fever, vomiting, diarrhea, and a petechial exanthem. Rocholl and associates[402] noted that rash occurred in 10 percent of 143 adenoviral illnesses in children.

On several occasions, illness characterized by fever and defervescence and then the appearance of a maculopapular rash suggesting the diagnosis of roseola infantum has been observed.[148,158,242,243,352] Adenoviral infections also are confused with rubella. However, the respiratory symptoms and the degree of fever associated with adenoviral infection should clarify the diagnosis. With rubella, respiratory complaints and fever are minimal. On occasion, severe disease with Stevens-Johnson syndrome has been noted. Such patients frequently have pneumonia, and the illness is quite similar to that caused by *Mycoplasma pneumoniae*.

Lähdeaho and associates[281] have noted that serum antibodies to the E1b protein–derived peptides of the enteric adenovirus type 40 are associated with dermatitis herpetiformis.

GENITOURINARY TRACT

Acute Hemorrhagic Cystitis

Acute hemorrhagic cystitis is an uncommon manifestation of adenoviral infection in immunocompetent children and is characterized by a sudden onset of dysuria and frequency, with hematuria developing 12 to 24 hours later.[287,288,339,340,342,358] Occasionally, fever, suprapubic pain, and enuresis occur. Antecedent upper respiratory tract infection is noted in some children. Symptoms persist for a few days to 2 weeks, with the usual duration being approximately 5 days. Acute hemorrhagic cystitis has been reported in both the United States and Japan. It occurs primarily in children, most often boys, and usually is associated with adenovirus type 11. Occasionally, adenovirus types 7 and 21 have been implicated. Adenoviral antigen has been identified by immunofluorescence in exfoliated bladder cells. Although no sequelae have been reported, the long-term prognosis is unknown.[339]

Nephritis

Hematuria occasionally has been reported in infants with severe pneumonia and disseminated adenoviral infection. Red blood cells and, at times, red blood cell casts also have been noted in the urine of some children with upper respiratory illnesses caused by adenoviruses and specifically in patients with pharyngoconjunctival fever associated with adenovirus types 3, 4, and 7a.[440,445,480,485] In one instance, a young boy had a maculopapular and petechial exanthem and thrombocytopenia associated with adenovirus type 7 infection. Hematuria also was present.

Orchitis

Orchitis developed in one child who had a 5-day history of pain and fever, erythema, and swelling of the right testicle.[349] The testicular involvement resolved in several days, and the illness was associated with a 16-fold rise in adenoviral complement-fixation antibody titer.

Oculogenital Syndrome

In 1977, Laverty and associates[287] reported a woman who in addition to pharyngoconjunctival fever, had cervicitis and paresthesia of the legs; a type 19 adenovirus was recovered from this woman's cervix. In Perth, Australia, adenovirus type 19 was recovered from the genital tracts of 59 men and women being examined for genital HSV infection in a clinic for sexually transmitted diseases.[236] Several of the patients also had conjunctivitis, and in two, adenovirus type 19 was isolated from conjunctival specimens. Similar oculogenital illnesses have been noted in association with adenoviral types 2, 8, and 37.[62,421,455]

Hemolytic-Uremic Syndrome

Two 2-year-old children with hemolytic-uremic syndrome in association with adenoviral infections have been described.[33]

Hemorrhagic Fever with Renal Syndrome

A 22-year-old woman with an adenovirus type 11 infection and hemorrhagic fever with renal syndrome has been reported.[476]

*See references 18, 56, 63, 96, 98, 101, 147, 244, 269, 315, 334, 336, 459, 500.

GASTROINTESTINAL TRACT

Gastroenteritis

Infantile diarrhea has been associated with epidemic and sporadic adenoviral diseases such as acute upper respiratory tract infection, severe pneumonia, and pharyngoconjunctival fever.[148,282,440,449,504] Outbreaks of diarrhea characterized by acute abdominal pain followed by diarrhea, nausea and vomiting, fever, headache, and pharyngitis have been associated with adenovirus type 3 and 7 infections.[162,448] Other symptoms occurring in patients with diarrhea include conjunctivitis, rhinitis, pharyngotonsillitis, hepatomegaly, and cervical adenitis.[449] In two patients who had diarrhea and upper respiratory illness in association with adenovirus type 15 infection, viral particles were visualized within the nuclei of mucosal cells at autopsy by electron microscopy.[123]

The widespread use of electron microscopy for the study of rotaviral diarrhea led to the finding of previously unrecognized adenoviruses that were fastidious and could not be grown in routine cell cultures.[145,425] These adenoviruses, now identified as types 40 and 41, subsequently were shown to be important causes of gastroenteritis in children.* In enteric adenoviral infection, diarrhea is the most prominent symptom.[474] In children with adenovirus type 40 infection, Uhnoo and colleagues[475] found that the mean duration was 8.6 days, as opposed to 12.2 days in those infected with adenovirus type 41. Most illnesses occur in children younger than 3 years old: the mean age for adenovirus type 40 diarrhea was 15.2 months, whereas it was 28.3 months in type 41 illnesses. Most patients had mild vomiting that lasted approximately 2 days. When compared with illnesses caused by established respiratory adenoviruses, fever occurred less commonly, was less severe, and had a shorter duration in enteric adenoviral infections. Upper respiratory symptoms and signs, such as pharyngitis, coryza, cough, and otitis media, were observed in 21 percent of children with enteric adenoviral infection. Brandt and colleagues[46] noted that dual infections with respiratory viruses (such as RSV and enteric adenoviruses) are common occurrences, so caution should be observed in attributing respiratory symptoms to enteric adenoviruses.

Yolken and Franklin[520] found that enteric adenoviruses were an important cause of nosocomial diarrhea in infants who had previously undergone gastrointestinal surgery for necrotizing enterocolitis.

Mesenteric Lymphadenitis

Adenoviral serotypes 1, 2, 3, 5, and 7 have been recovered from lymph nodes and the appendix in cases of mesenteric lymphadenitis.[27,38,268] Patients with mesenteric lymphadenitis often have abdominal pain and other symptoms similar to those of acute appendicitis. Pharyngitis is a frequently related finding. Mesenteric adenitis often is associated with concurrent or recent adenoviral illness.[83,393] Frequently, the peak incidence of mesenteric lymphadenitis occurs when adenoviral illness is common in the community.

Intussusception

The suggestion that adenoviruses could be an etiologic factor in intussusception arose because these agents frequently can be recovered from throat, stool, and mesenteric lymph node specimens obtained from children who undergo surgery for intussusception.† Most children with intussusception were younger than 2 years old; some had preceding respiratory symptoms.[409,522] Adenovirus serotypes 1, 2, 3, 5, 6, and 7 have been implicated. Typical adenoviral intranuclear inclusions have been demonstrated in cells in stool, intestinal epithelia (ileum), and the appendix by electron microscopy.[359,522,523] Mesenteric lymph nodes often are enlarged at surgery.[523] Increases in antibody titer to adenoviruses have been observed in children after the development of intussusception. Investigators have suggested that bowel wall hypermotility caused by direct viral involvement or by hypertrophy of lymphatic tissue is the lead point for the intussusception.[27,79,161,359,391,409,522,523]

Appendicitis

Adenoviruses have been associated with both acute and chronic appendicitis.[38] Right iliac fossa abdominal pain in conjunction with sore throat is a common finding. The virus has been isolated from the appendix and mesenteric lymph nodes at surgery. During acute infection, lymphoid follicles of the ileum, appendix, and mesenteric lymph nodes are infected with virus. In chronic infection, adenovirus remains in cells; on microscopic examination, slight inflammation is seen in the appendix.

Hepatitis

Hepatitis in association with adenoviral infection has been reported many times in small infants, in children with overwhelming disseminated disease, and in immunocompromised patients.[5,12,30,51,59,265,525] In one study, 27 of 30 persons thought to have sporadic infectious hepatitis were found to be infected with adenovirus type 5.[196] Adenovirus types 1, 2, and 3 were isolated from the stool specimens of 12 children younger than 3 years old in an outbreak of infectious hepatitis on a Native American reservation in Arizona.[198]

In one report, three children with severe, fatal adenovirus type 7 pneumonia had associated findings that simulated Reye syndrome: lethargy, diarrhea, seizures, elevated CSF pressure, myocarditis, hepatitis, and disseminated intravascular coagulation.[280] Edwards and colleagues[127] reported three children with Reye syndrome and adenoviral infection. They suggested that adenoviruses might be an important agent in initiating the syndrome.

HEART

Myocarditis

In children, myocarditis has been noted in association with severe pneumonia and disseminated disease caused by adenovirus types 7, 7a, and 21.[201] Similar cardiac involvement has been seen in military recruits with severe ARD.[67,74,201,440]

The use of polymerase chain reaction (PCR) assays has led to recognition of adenovirus as the cause of many cases of acute myocarditis.[40,48,187,308,314] In an extensive study of myocarditis and dilated cardiomyopathy, Bowles and coworkers[40] analyzed 773 endomyocardial biopsy samples obtained from patients of all ages. In this large group, 624 patients had myocarditis and adenoviral DNA was identified by PCR in 142 (23%) of the endomyocardial biopsy samples. There were 26 neonates, 37 infants, 20 toddlers, 25 older children, 11 adolescents, and 23 adults. The results of this study suggest that adenoviruses are the leading viral cause of myocarditis, with enteroviruses being the second most common association (14%). On histopathologic examination, only 57 (40%) of the enterovirus-positive samples were found to be acute myocarditis.

Dilated Cardiomyopathy

In the study by Bowles and associates,[40] specimens from 149 patients exhibited dilated cardiomyopathy. Of this subgroup, 18

*See references 47, 49, 77, 274, 275, 330, 362, 389, 403, 464, 475, 478.
†See references 27, 32, 79, 161, 230, 359, 387, 409, 522, 523.

(12%) had adenoviral DNA demonstrated by PCR in the endomyocardial biopsy specimen. Of these 18 samples, 2 were from neonates, 2 from infants, 2 from toddlers, 4 from older children, 2 from adolescents, and 6 from adults.

Pericarditis

Pericarditis has been associated with severe adenoviral pneumonia. In a patient with adenovirus type 7 pneumonia, electrocardiographic changes consistent with pericarditis were demonstrated, and the virus was isolated in high titer from pericardial fluid at postmortem examination.[348] In 1995, Mistchenko and coworkers[331] reported a 10-month-old boy with fatal pericarditis caused by adenovirus type 7. In serum and pericardial fluid from this child, interleukin-6, tumor necrosis factor-α, and adenovirus-specific immune complexes were identified.

NERVOUS SYSTEM

Although CNS disease in adenoviral infection is an uncommon finding, a variety of clinical manifestations have been observed. Both meningitis and encephalitis have been noted as the major manifestations of adenoviral infection or in association with severe disease at other body sites.[356,360] Adenovirus types 1, 2, 3, 5, 6, 7, 12, 26, and 32, in isolated instances, have been recovered from both brain and CSF.* Meningoencephalitis often occurs as part of disseminated adenoviral disease in immunocompromised patients, with the most commonly associated serotypes being 2, 3, 5, and 7. Adenovirus serotype 26 DNA was identified in peripheral blood, CSF, urine, and postmortem brain tissue of a 28-year-old woman undergoing radiation therapy for medulloblastoma; progressive neurologic deterioration developed, followed by her eventual death as a result of disseminated adenoviral infection.[118] In two children with respiratory and CNS symptoms, adenoviruses were recovered from spinal fluid.[140] One child was convalescing from herpes zoster and the other from varicella. Adenovirus type 7 was recovered from brain tissue cultures from an elderly patient with chronic schizophrenia.[307] In another instance, adenovirus type 32 was recovered from the brain of a man with lymphosarcoma and subacute encephalitis.[76,406] In an epidemic of adenoviral infection caused by type 7, 25 percent of the hospitalized patients had symptoms referable to the CNS.[433,435] Many of the patients died; those who survived had little residual effect. Too few cases are reported in the literature to predict the prognosis of CNS disease in children accurately. Adenovirus type 2 was isolated from a muscle biopsy specimen from a patient with inclusion body myositis.[327] Ooi and colleagues[364] reported eight children with adenovirus serotype 21–associated acute flaccid paralysis in the setting of an enterovirus 71–mediated hand-foot-and-mouth disease outbreak in Sarawak, Malaysia, in 1997. Of these eight children, four had upper limb monoparesis, two had lower limb monoparesis, and two had paraparesis. Four of the children experienced complete recovery, one was improving at hospital discharge, and three had residual flaccid weakness and wasting. Seven children with initially appearing typical adenoviral infections had transient encephalopathy.[451] All these children were infected with adenovirus type 3. On initial evaluation, five had pneumonia, one had follicular tonsillitis, and one suffered from diarrhea. Three of the children were lethargic, two were stuporous, and two were obtunded. All had elevated serum aspartate aminotransferase values (range, 39 to 401 U/L), and CSF evaluations were within normal limits. The neurologic findings resolved in all patients in about 1 week.

*See references 69, 83, 90, 118, 140, 159, 259, 370, 381, 406, 447, 453, 483.

INFECTION IN IMMUNOCOMPROMISED HOSTS

Adenovirus types 1, 2, 3, 4, 5, 6, 7, 7a, 11, 29, 31, 32, 34, and 35 have been recovered from children and adults who were immunocompromised by immunodeficiency diseases, malignancies, steroid therapy, immunosuppressive therapy, radiation therapy, and transplantation procedures.* Adenoviral infections occur more frequently in pediatric than in adult hematopoietic stem cell and solid organ transplant recipients.[17,220,229] Infection is thought to occur as a result of transmission from the donor, reactivation of latent infection, or newly acquired infection.[276] McLaughlin and colleagues[321] examined the incidence of adenovirus infection in 146 children who underwent liver and intestinal transplants. They found that adenoviral infection occurred in 4.1 percent of liver transplant recipients and 20.8 percent of intestinal transplant recipients.

In a study of eight children with liver and small bowel transplants and six with just small bowel transplants, Pinchoff and coworkers[386] noted that all had evidence of adenoviral infection of the graft. In eight of the children, histologic evidence of infection (adenoviral intranuclear inclusions) developed, and these eight had received intensive corticosteroid therapy, had virus isolated from multiple sites, and had persistent positive viral cultures. For most solid organ transplants, the source of invasive adenoviral disease often is thought to be the transplanted organ.

Kampmann and colleagues[251] conducted a prospective study on 155 pediatric stem cell transplant recipients and identified 17 percent with adenoviremia (26/155). Their study showed that early detection of adenoviremia, withdrawal of immunosuppression, and early antiviral therapy led to resolution of adenoviremia in 81 percent of the patients. de Mezerville and collaborators[109] retrospectively identified 28 solid organ transplant recipients and 27 hematopoietic stem cell transplant recipients with adenovirus infection at the Hospital for Sick Children in Toronto, Canada. Their study found a similar rate of post-transplant adenoviral infection in solid organ transplant recipients (50.9%) and hematopoietic stem cell transplant recipients (49.1%). de Mezerville's group found a much higher mortality rate in the group of hematopoietic stem cell transplant recipients (30% mortality rate versus 0% in the solid organ transplant group).

Control of adenovirus infection is thought to be T-cell–mediated, and patients receiving T-cell–suppressive regimens are thought to be at greater risk for adenovirus disease. Myers and colleagues[347] demonstrated an increased risk for development of adenoviral infection in bone marrow transplant recipients receiving alemtuzumab (Campath 1H), a monoclonal antibody used for T-cell depletion, in comparison to patients receiving antithymocyte globulin (ATG), which was composed of polyclonal antibodies directed toward T cells. Avivi and colleagues[14] demonstrated that the most important risk factors for progression of adenovirus disease included severe lymphocytopenia (absolute lymphocyte count of less than 200/mm^3) and continued immunosuppression. They also found a correlation between lack of cytomegalovirus (CMV) prophylaxis with ganciclovir and risk of progression of adenovirus disease.

Ahmad and coworkers[6] reported a case of severe adenovirus pneumonia developing after infliximab (Remicade) infused was used to treat a 35-year-old man with Crohn disease. Infliximab is a monoclonal antibody directed against tumor necrosis factor-α that is used frequently in the treatment of autoimmune and rheumatologic diseases. Ahmad's group emphasized the fact that

*See references 3, 17, 21, 57, 59, 76, 93, 100, 137, 146, 163, 184, 190, 199, 207, 237, 258, 306, 346, 354, 361, 371, 386, 406, 429-432, 436, 441, 471, 508, 525.

tumor necrosis factor-α antagonists can impair cell-mediated immunity, an essential component of recovery from adenoviral infection in immunocompromised hosts, and, therefore, can predispose patients to the development of viral pneumonia.

Other groups have demonstrated that having low lymphocyte counts at the time of development of adenovirus infection was predictive of adenovirus viremia and that clearance of infection and host survival were dependent on recovery of adenovirus-specific $CD4^+$ T-cell responses.[199,489] Lankester and colleagues[285] showed that isolation of adenovirus from multiple sites was associated with the development of adenovirus disease. Lins' group[299] demonstrated an association between isolation of adenovirus in peripheral blood and progression or dissemination (or both) of adenovirus disease. High levels of adenovirus viremia (i.e., detection of PCR product at 100-fold or greater dilution of template DNA) have been correlated with fatal outcomes in children receiving allogeneic stem cell transplants.[422,488]

Baldwin and colleagues[17] studied the outcome and clinical course of 105 adenoviral infections in 100 patients after they received bone marrow transplants. The incidence was higher in unrelated donor transplants than in matched sibling donor transplants. Diarrhea and fever were the most common initial findings. Six deaths were attributed to the adenoviral infections; five of the six patients had pneumonia, and four had associated graft-versus-host disease. Three additional patients had severe disease.

In a study involving 532 recipients of hematopoietic stem cell transplants, a 12 percent incidence of adenoviral infection was noted.[229] Forty-one patients had infections classified as "invasive," and mortality was 76 percent in this group. Recipients of allogeneic transplants were more likely to have adenoviral infections than autologous stem cell recipients were.

The most common manifestation of adenoviral infection in pediatric patients with bone marrow transplants at St. Jude Children's Research Hospital was hemorrhagic cystitis, followed by gastroenteritis, pneumonitis, and liver failure.[190] Adenovirus-induced acute hemorrhagic cystitis is a complication encountered after hematopoietic stem cell transplantation and, more rarely, after renal transplantation.[221] Gorczynska and colleagues[177] examined the incidence of virus-induced hemorrhagic cystitis in 102 children and adolescents who underwent allogeneic stem cell transplantation. Hemorrhagic cystitis occurred in 25.5 percent of these children, with 3.9 percent of the cases attributed to adenoviruses.

Shirali and coworkers[431] noted that demonstration of the adenoviral genome in endomyocardial biopsy specimens from heart transplant recipients was a predictor of graft loss in children. Scattered reports have found an association between adenoviral infection and viruria and hemorrhagic cystitis in patients with renal transplants.[143,283] A fatal case of subacute meningoencephalitis caused by an adenovirus has been described in a bone marrow transplant recipient.[100]

In many instances, a fulminant, bacterial, sepsis-like picture with high fever, cough, and lethargy is associated with adenoviral infection in compromised patients.[525] Severe pneumonia often is demonstrated, both clinically and radiologically, and hepatic involvement with disseminated intravascular coagulation also is a frequent occurrence. Fatalities are reported, and recovery often is slow.

OTHER MANIFESTATIONS

Arthritis

Arthritis has been noted in association with adenovirus type 7 infection.[369] The illness was characterized by fever, acute respiratory symptoms, erythematous macular rash, aseptic meningitis, and inflammatory arthritis of both knees.

Thyroiditis

In 1964, Swann[454] reported five patients with acute thyroiditis and thyroid enlargement in whom serologic study revealed greater than fourfold rises in titer of adenoviral complement-fixing antibody.

Deafness

Deafness of sudden onset was reported in an adult with a 2-day history of sore throat, low-grade fever, rhinorrhea, and cough. Adenovirus type 3 was isolated from the patient's throat, and a greater than fourfold rise in neutralizing antibody titer to this virus was observed.[239]

Obesity

Based on studies that adenoviruses increase adiposity in animal models, Atkinson and coworkers[13] screened 502 subjects for neutralizing antibodies to adenovirus 36. They detected antibodies to adenovirus 36 in as many as 30 percent of obese study subjects as opposed to 11 percent of nonobese subjects. Similarly, they found paradoxically decreased serum cholesterol and triglycerides in patients with antibodies to adenovirus 36. Additional studies by Whigham and colleagues[502] demonstrated that human adenovirus serotype 37 also is associated with an increase in adipocyte differentiation and reduced serum triglycerides, but increased serum cholesterol.

CONGENITAL AND NEONATAL INFECTIONS

Neonatal and congenital adenoviral infections reflect disseminated infection with the involvement of multiple organs.[2,50,75,138,266,365,447] Major manifestations include hepatosplenomegaly, progressive pneumonia, hepatitis, and thrombocytopenia. Towbin and colleagues[469] reported intrauterine adenoviral myocarditis manifested as non-immune hydrops fetalis. Illnesses frequently appear initially as an early-onset sepsis syndrome. An infant has been reported with a congenital pleural effusion from which type 3 adenovirus was recovered.[325]

A recent study by Couroucli and associates[88] has noted an association between adenoviral infection and bronchopulmonary dysplasia (BPD). They found a significant increase in the frequency of adenovirus genome in tracheal aspirates from patients with BPD versus controls.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of adenoviral infection must be subcategorized on the basis of the major clinical manifestations. In many instances, specific clinical symptoms such as pharyngoconjunctival fever or epidemic keratoconjunctivitis can lead to strong suspicion of the adenoviral etiology. With other, more general respiratory diseases such as pharyngitis, bronchitis, croup, bronchiolitis, and pneumonia, the adenoviral etiology cannot be established on clinical grounds. Fever in adenoviral respiratory infections tends to be higher than that occurring in parainfluenza and RSV infections but similar to that in influenza A and B viral infections.[394] High and prolonged fever occurs as commonly in adenoviral infections as it does in bacterial respiratory infections.

In pharyngitis, adenoviral infection must be differentiated both from other viral diseases, such as those caused by Epstein-Barr virus, parainfluenza and influenza viruses, and enteroviruses,

and from streptococcal disease. In a young child, follicular pharyngitis is more likely to be caused by adenoviral than by streptococcal infection.

Adenoviral pneumonia in young children frequently is not distinguishable on clinical grounds from that caused by bacteria. In older children and adolescents, in particular, adenoviral pneumonia often can be differentiated from bacterial disease by its bilateral nature. Differentiating adenoviral illness from disease caused by *M. pneumoniae* is more difficult; however, cold agglutinin titers generally are higher and more persistently positive in mycoplasmal disease.

Adenoviral eye disease must be differentiated from that caused by viruses of the herpes group, *Chlamydia* spp., and bacteria, including *Neisseria gonorrhoeae*.

Diarrhea caused by enteric adenoviruses can be differentiated from other viral diarrheas by electron microscopy, by identification with ELISA, and by specific culture of the enteric agents in Graham 293 cell culture. Enteric bacterial and parasitic agents also must be considered in the differential diagnosis.

The high, relatively prolonged fever occurring in association with lymphadenopathy, exanthem, and enanthem noted with adenoviral infection often causes confusion with Kawasaki disease.[72,402] Because Kawasaki disease must be treated early with intravenous immunoglobulin, adenoviral infections should be considered early and appropriate studies performed.

SPECIFIC DIAGNOSIS

Adenoviral infection can be diagnosed specifically by isolation of virus in an appropriate tissue culture system or by a direct antigen-detection assay. Most adenoviral types can be recovered from clinical specimens in primary or diploid cultures of human embryonic kidney.[291] The enteric viral types 40 and 41 can be grown in Graham 293 cells.[458,496] The rapidity of detection of adenoviruses by culture is enhanced by centrifugation of specimens in shell vials or plastic-welled plates.[124,131,311]

Direct identification of adenoviruses in respiratory secretions by radioimmunoassay, immunofluorescence techniques, and ELISA now is performed widely.[52,311,324,396,402,416,419,462] However, in general, the sensitivity, when compared with that of virus isolation, is relatively low; on the other hand, the specificity is high (>95%). Rocholl and colleagues[402] demonstrated the impact of rapid diagnosis of adenoviral respiratory disease with an adenoviral direct fluorescent antibody technique by noting discontinuation of empiric antibiotic use in a retrospective analysis of hospitalized patients with respiratory cultures positive for adenovirus. Rapid techniques for the identification of enteric adenoviruses in general have been sensitive and specific.[5,179,205,420,476,512] However, in newborns, false-positive results with a latex agglutination test have been reported.[235] Several techniques using DNA probes have been studied for the rapid identification of both respiratory and enteric adenoviral infection.[55,234,457] PCR assay also is useful for the rapid detection of adenoviral infection.* PCR assay is particularly useful for identifying adenoviral DNA in formalin-fixed, paraffin-embedded tissues and other biopsy and postmortem specimens.[40,187,308,314,431,472]

Several groups have demonstrated the utility of PCR detection of adenoviral DNA in acute respiratory infections in immunocompetent patients.[1,136,402,430,517] Kuypers and colleagues[279] demonstrated significantly increased sensitivity of quantitative real-time PCR assay over fluorescent antibody detection of adenoviruses. They showed that 77.7 percent of respiratory specimens that were negative for adenovirus by fluorescent antibody detection were positive by PCR detection of adenovirus DNA. Xu and Erdman[517] developed a multiplex PCR assay for rapid, type-specific identification of adenovirus serotypes 3, 7, and 21. Lin and colleagues[299] used oligonucleotide microarrays to identify adenovirus serotypes 3, 4, 6, 7, 16, and 21, which resulted in lower detection limits and rapid processing time (1.5 to 4 hours). Aberle and colleagues[1] were able to detect adenoviral DNA with a nested PCR assay in acute-phase sera collected within the first week after the onset of symptoms in 72 percent of immunocompetent children experiencing their first adenoviral infection and in 25 percent of those experiencing recurrent infection.

Other groups have demonstrated the utility of using PCR assays to diagnose and monitor adenoviral infection and disease in immunocompromised hosts.[285,422] Lion's group[300] developed a species-specific, real-time, quantitative PCR assay that allows detection and quantification of all 51 currently known human adenovirus subtypes. They showed that detection of adenovirus DNA in the peripheral blood of allogeneic bone marrow transplant recipients preceded the onset of clinical symptoms of disseminated adenoviral disease by a median of 3 weeks. Two other groups[292,498] have used real-time, quantitative PCR assays to detect adenoviral DNA load to aid in both the diagnosis and management of disseminated adenoviral infections in immunocompromised patients. Ebner and colleagues[125] recently have presented a two-stage PCR algorithm for diagnosis in immunosuppressed patients. It uses real-time quantitative PCR to broadly identify all human adenovirus serotypes without species identification. If it is positive, a species-specific PCR assay is performed with fragment length analysis and then sequencing to determine the specific adenoviral serotype. In a study of 135 pediatric stem cell transplant recipients, they detected adenoviruses in stool specimens in 39 children and the blood of 1 child. The following serotypes were identified: 1, 2, 3, 5, 6, 12, 16, 19, 31, and 49.

At present, most hospitals rely on fluorescent antibody staining, shell vial culture, and viral culture to identify adenovirus infection.

Acute infection also can be diagnosed serologically by the expression of specific serum IgM antibody.[324] Infection can be confirmed serologically by the demonstration of a rise in antibody titer in two sequential serum samples. Antibody response to the adenovirus group antigen can be detected by complement fixation or ELISA. Type-specific antibodies can be determined by neutralization, ELISA, or hemagglutination inhibition.

TREATMENT

During the febrile period of illness, adequate hydration should be maintained and excessive activity discouraged. The fever may be controlled with acetaminophen. In children with eye involvement, careful attention should be paid to the possibility of secondary bacterial infection. If local purulence develops, specimens should be procured for culture and topical antimicrobial therapy started. The use of steroid-containing ophthalmic ointments should be avoided.

A consistent, safe, and effective therapy to treat adenovirus infection has yet to be established. Whereas vidarabine, ribavirin, and cidofovir demonstrate good activity against adenoviruses in vitro, several studies have shown only limited success with the use of vidarabine, ribavirin, ganciclovir, and cidofovir in treating adenovirus disease in humans.[301,343] The potential beneficial effects must be weighed carefully against the adverse side effects of these antiviral agents, including myelosuppression, pancytopenia, and nephrotoxicity. Walls and coworkers[499] conducted a retrospective study of 26 patients undergoing hematopoietic stem cell transplantation. They were unable to demonstrate a direct correlation among adenoviral DNA load, clinical features, and severity of disease. They also identified two children who expe-

*See references 1, 7, 40, 125, 126, 136, 200, 237, 279, 285, 292, 300, 321, 337, 371, 402, 422, 430, 498, 517.

rienced low-level adenoviral viremia after undergoing hematopoietic stem cell transplantation; the children cleared the virus without treatment.

Kurosaki and colleagues[278] demonstrated a possible role for vidarabine in the treatment of adenovirus-induced hemorrhagic cystitis. Vidarabine inhibits the DNA polymerase of double-stranded DNA viruses (including human adenoviruses) and varicella-zoster virus. Vidarabine is metabolized via deamination to 9-β-D-arabinofuranosyl hypoxanthine, and both vidarabine and its metabolite are excreted in the kidney. The studies of Kurosaki and associates demonstrated dose-dependent inhibition of viral replication and adenovirus type 11 activity in vitro. Doses of 10 mg/kg given intravenously once daily for 5 days have been shown to be effective in the treatment of hemorrhagic cystitis.

Ribavirin is a guanosine nucleoside analogue used for the treatment of severe RSV infection in its inhaled form and for the treatment of chronic hepatitis C infection. In a number of instances, immunocompromised patients with disseminated adenoviral infection have been treated with ribavirin administered intravenously, and successful outcomes have been reported.[10,252,298,319,345,516] In one instance, a loading dose of 30 mg/kg/day divided into three doses was followed by maintenance therapy with 15 mg/kg/day.[319] Gavin and Katz[163] reported complete clinical recovery in two of five patients with severe adenovirus disease. A later study by Lankester and associates[284] demonstrated no effect on plasma adenoviral DNA load despite initiation of treatment with ribavirin at the first onset of clinical symptoms in four pediatric patients receiving allogeneic stem cell transplants.

Ganciclovir is another guanosine nucleoside analogue used for the prophylaxis and treatment of CMV infection. Previous studies had demonstrated weak inhibitory activity of ganciclovir in vitro against some adenoviral strains. Bruno and colleagues[53] showed that the use of ganciclovir for prophylaxis of CMV infection in patients undergoing hematopoietic stem cell transplantation had a slight protective effect against the development of adenovirus infection.

The antiviral agent with the most promise to date is cidofovir, a cytosine nucleoside analogue with efficacy against several DNA viruses, including CMV, HSV, polyomaviruses, and adenoviruses. Cidofovir was used successfully in treating a 17-year-old boy who had received a stem cell transplant and had severe adenoviral gastroenteritis.[400] Ljungman and colleagues[302] conducted a study of cidofovir for the Infectious Diseases Working Party for Blood and Marrow Transplantation (EMBT). They demonstrated successful treatment of adenovirus infections in 69 percent of allogeneic hematopoietic stem cell transplant recipients, primarily with a 5-mg/kg dose of cidofovir given intravenously one time per week for the first 3 weeks and every other week after that, along with concomitant use of probenecid and intravenous fluid hydration. Other studies have shown a similar effect with reduced dosing of cidofovir at 1 mg/kg per dose given three times a week.[197,301,343] A case report by Fanourgiakis and colleagues[137] demonstrated successful treatment of severe (grade IV) hemorrhagic cystitis in a 34-year-old man by intravesical instillation of 5 mg/kg of cidofovir in 100 mL saline twice daily. This method avoided the known nephrotoxicity associated with cidofovir. Yusuf and coworkers[524] reported complete resolution of clinical symptoms in 57 of 58 pediatric hematopoietic stem cell transplant recipients treated with cidofovir. Wallot and colleagues[497] had some success using reduced-dose cidofovir, inhaled nitric oxide, and decreased immunosuppression to treat two liver transplant recipients with disseminated adenoviral disease and acute respiratory distress syndrome.

Further studies into possible immunotherapies for the treatment of adenovirus infections also have been investigated. Feuchtinger and associates[142] were able to perform successful and safe adoptive transfer of adenovirus-specific, T-cell immunity in five of six patients with documented adenovirus infection after allogeneic hematopoietic stem cell transplantation. This effect was found to be independent of the T-cell dose. Furthermore, the adenovirus-specific, T-cell expansion was sustainable, and proliferation of the adenovirus-specific T cells was unimpaired by adenovirus viremia, in contrast to the myelosuppressive effects seen with CMV viremia.

Teuchner and colleagues[461] studied *N*-chlorotaurine (NCT), a compound produced by monocytes and granulocytes during the oxidative burst, in a double-blind investigation of adult patients with epidemic keratoconjunctivitis. Among the group of 60 patients, 33 were treated with a 1 percent aqueous solution of NCT and 27 were treated with gentamicin. They analyzed both subjective and objective scores. In the total study group, the NCT-treated subjects were subjectively better than the gentamicin-treated patients at day 8, but there were no objective differences. However, in severe infections, both the subjective and objective scores were better on days 4 and 8 in the NCT-treated patients. They concluded that NCT treatment was well tolerated and that it shortened the duration of illness. A study of the use of 1 percent cidofovir eyedrops with and without 1 percent cyclosporine eyedrops to treat adenovirus-associated keratoconjunctivitis was conducted by Hillenkamp and colleagues.[218] This study demonstrated significant local toxicity in the skin of the eyelids and conjunctiva but a decreased frequency of severe corneal opacities associated with the use of cidofovir.

Human fibroblast–derived interferon, applied topically, was used to treat epidemic adenoviral keratoconjunctivitis in a comparative trial.[405] The duration of illness was reduced in the patients treated with interferon, but many of the control patients received dexamethasone. A child with combined immunodeficiency and severe, diffuse adenovirus type 7a pneumonia improved dramatically after receiving a large dose of high-titer adenovirus type 7a immune serum globulin.[93]

PREVENTION

Serious incapacitating epidemics caused by adenoviruses in military recruits in basic training led to the development of adenoviral vaccines.[9,289] The initial vaccines were formalin-inactivated preparations of monkey kidney tissue culture–grown virus and were administered parenterally.[8,186,215] These vaccines achieved only limited success because of variable degrees of potency in different vaccine lots.[23] An inactivated adenoviral vaccine that contained types 3, 4, and 7 was prepared in monkey tissue culture for trial in children.[484] Three doses of this vaccine resulted in high levels of neutralizing antibody to the three viral types, and this antibody persisted in most infants for at least 1 year. Many of the initial lots of inactivated adenoviral vaccine were found to contain live simian adenoviruses that were capable of producing neoplasms in suckling hamsters. Because of this finding, inactivated vaccine trials were discontinued. Next, a live, attenuated adenovirus type 4 vaccine that was cultivated in human diploid tissue culture was developed and administered orally by enteric-coated capsule to volunteers.[186] Asymptomatic gastrointestinal infection occurred, and a good serum-neutralizing antibody response was elicited.[186,439,443] Most recipients of live oral vaccine excrete virus in stool for several days to a month after being vaccinated. With military use of the vaccine, shedding in stool was not associated with transmission of the virus to non-immune contacts.[338] In other studies of married couples and families with children, virus was transmitted to non-immune contacts.[338,444] Transmission usually occurred without illness.[338]

The administration of live, enteric-coated, type 4 and 7 adenovirus vaccine resulted in a significant decrease in the incidence of ARD in military recruits.[121,176,456] Unfortunately, adenoviral vaccines no longer are available, and the incidence of ARD in

military recruits again is a significant problem.[18,181,272,417] Few attempts have been made to protect children with live adenoviral vaccines. In one study, live enteric-coated adenovirus type 4 vaccine was given to children aged 5 to 11 years. Asymptomatic gastrointestinal infection resulted from administration of the vaccine.

PROGNOSIS

The overall prognosis of adenoviral infection generally is excellent. Secondary bacterial complications, if untreated, can result in prolongation of illness and permanent sequelae in some instances. The prognosis of adenoviral infection in the very young and in immunocompromised patients must be guarded.

SUBSECTION 4

Hepatoviridae

CHAPTER 169

Hepatitis B and D Viruses

Annemarie Broderick ✪ Maureen M. Jonas

HEPATITIS B VIRUS

Hepatitis B virus (HBV) infection occurs throughout the world, although marked geographic differences in rates of both acute and chronic infection exist. An estimated 360 to 400 million individuals (approximately 5% of the world's population) are infected worldwide.[62,105] Fifty-five to 92 million people are expected to die between 45 and 55 years of age as a result of HBV-related chronic liver disease or primary hepatocellular carcinoma (HCC).[56] Most of those with chronic HBV infection acquired the virus through vertical transmission, which can be prevented by active and passive immunization.

BIOLOGY OF THE HEPATITIS B VIRUS

HBV is the prototype of a family of DNA viruses called *hepadnaviruses* (hepatotropic DNA viruses). This group consists of enveloped, coated DNA viruses with similar structure and genome organization. All primarily infect the livers of their respective hosts and can cause acute and chronic infections. HBV is the most studied member of the family, which also includes the woodchuck hepatitis virus (WHV), the ground squirrel hepatitis virus, the duck hepatitis virus (DHV), and hepatitis viruses found in herons, Ross geese, and arctic squirrels.[157] WHV and DHV share approximately 70 percent sequence homology with HBV but do not infect humans.[161] Use of these animal models has facilitated the study of hepadnavirus structure and replication by supplementing information obtained from infected humans and cloning studies.

Three types of particles are found in the sera of HBV-infected people and are shown in Figure 169–1: the Dane particle and two subviral particles, one spherical and the other filament shaped. All three types share a common surface antigen, hepatitis B surface antigen (HBsAg), but only one, the Dane particle, contains viral DNA and is capable of replication. Neither the filament, 20 nm in width and ranging from 50 to 1000 nm in length, nor the sphere, also 20 nm in diameter, contains nucleic acid. The Dane particle, or whole virion, is 42 nm in diameter and contains a core, or nucleocapsid, enclosing the DNA. The outer shell is composed of large amounts of hepatitis B surface proteins in a lipoprotein envelope, which is derived from host cells. Inside this shell is found the nucleocapsid, an icosahedral structure composed of 240 core protein subunits with regular penetrating channels. The nucleocapsid proteins are detected serologically as hepatitis B core antigen (HBcAg). This nucleocapsid is 25 to 27 nm in diameter, and within it are contained the viral genome and polymerase. HBV e antigen (HBeAg) is a soluble antigen produced from the same open-reading frame (ORF) that HBcAg is, but unlike core antigen, HBeAg is secreted into serum, where it is thought to have a role in induction of tolerance to HBV. The viral genome is composed of double-stranded circular DNA that can be relaxed or closed, depending on the stage in the reproduction cycle.[149] This DNA, which is 3.2 kilobase pairs in size, encodes four overlapping ORFs that overlap with other regulatory *cis*-acting sequences such as promoters, enhancers, and polyadenylation and genome packaging signals.

The subviral particles (spheres and filaments) are composed of envelope proteins and host-derived lipid components.[157] These particles are abundant in the serum of infected individuals (10^6 to 10^{14} particles per milliliter), and they are highly immunogenic and stimulate the production of neutralizing antibodies. One hypothesis is that they absorb neutralizing antibodies and thereby shield the intact virion from the host immune response. Subviral particles were used to produce the first effective HBV vaccine.[180]

Figure 169–1 The three forms of HBV surface antigen are whole virions, rods, and proteins. A cutaway view of the whole virion shows the three envelope proteins: major, middle, and large. (*From Mutchnik, M. G.: Acute and chronic hepatitis B.* In *Feldman, M., and Maddrey, W. C. [eds.]: The Liver. Philadelphia, Current Medicine, 1996.*)

MOLECULAR VIROLOGY

The viral genome, as noted previously, contains four ORFs in its circular DNA. The DNA strands are not completely symmetric; the minus strand is shorter, which leads to a region of single-stranded DNA. This gap can be filled by the virus's own polymerase when required. The four genes are *S* for the surface or envelope gene; *P* for the viral polymerase gene; *C* for the core gene, which encodes nucleocapsid protein; and *X* for the X gene. The surface proteins synthesized by HBV are termed the *large*, *middle*, and *major* proteins; they are type II transmembrane proteins that can form multimers. Transcription initiated at the *pre-S1*, *pre-S2*, or *S* epitopes leads to the formation of these three proteins. Although antibodies to S protein alone will provide protection against HBV infection, epitopes of *pre-S1* also can stimulate the production of neutralizing antibody.[106] A group of antigens used for subtyping HBV strains in epidemiologic studies is found in association with S proteins. Analysis of subdeterminants of HBsAg has revealed four major serotypes, *adw*, *adr*, *ayw*, and *ayr*, thus allowing differentiation of HBV infections from different sources. The "a" determinant is found in all isolates. Antibody to hepatitis B surface antigen (anti-HBs) is directed against this determinant and provides protection against all serotypes.

Seven HBV genotypes have been identified by the use of polymerase chain reaction (PCR)–restriction fragment length polymorphism analysis of the complete viral genome.[115] They have been designated A through G, and worldwide distribution varies. Type D occurs more commonly in Mediterranean regions, whereas type F occurs more commonly in Central and Latin America.[129] A study of 187 patients with chronic HBV infection revealed the following marked regional variations in genotype: north Europeans, 63 percent A; south Europeans and Middle Easterners, 96 percent D; Africans, 53 percent A, 27 percent D, 20 percent E; and east Asians, 14 percent A, 43 percent B, and 43 percent C.[116] The clinical differences among HBV genotypes are being elucidated. Infection with genotype C was found in Taiwanese adults to be associated with more severe liver disease and HCC in those older than 50 years, whereas genotype B was associated with HCC in those younger than 50 years.[90] An association of genotype with response to interferon-α (IFN-α) treatment also has been suggested.[91] A recent study from Taiwan analyzed the responses of 58 patients with chronic HBV infection, genotypes B and C, to treatment with IFN-α.[91] The patients with genotype C had higher aminotransferase values at baseline. After a 48-week follow-up period, only 15 percent of those with genotype C were HBeAg- and HBV DNA–negative, as compared with 42 percent of those with genotype B.

HBV polymerase consists of two major domains tethered by an intervening spacer region. Elucidating the structure and biochemistry of hepadnavirus polymerases has proved difficult because they require cellular factors, which are lost during extraction from cells, for enzymatic activity.[138] The ORF that encodes the *P* gene overlaps to a large extent with the core protein ORF; indeed, both proteins are translated from the same mRNA.[28]

The core gene encodes the viral capsid proteins that combine to form the core particles. The core proteins combine first into dimers; 120 dimers unite to form a shell 36 nm in diameter.[41] HBcAg appears to be phosphorylated within cells and becomes dephosphorylated upon export.[175] The main role of core proteins is enclosure of viral DNA, but they also play a role in cytolysis of infected cells when expressed on the cell surface.[111] Mutations in the core gene, the pre-core region, and the promoter for *C* have become clinically important.

Mutations affecting all ORFs of the HBV genome have been described. Most viral genomes carry more than one mutation, and most individuals are infected with more than one variant. Some of the mutations are thought to contribute to viral latency, low-level infection, severity of liver disease, and vaccine escape. The group best studied is the pre-core mutants, which result in lack of HBeAg production, even in the presence of active viral replication, the so-called HBeAg-negative infection. In contrast to the situation in patients with wild-type virus, in whom absence of HBeAg usually signifies absent HBV replication and mild liver disease (see later), in HBeAg-negative infection, HBV DNA levels are high, antibody to HBeAg (anti-HBe) is detected, and liver disease may be severe. Sporadic cases and outbreaks of ful-

minant HBV infection have been attributed to pre-core mutants. Mutations in the *S* or *pre-S* genes, which encode envelope protein, have been reported in patients infected after vaccination and in individuals who receive monoclonal antibody to HBV after undergoing liver transplantation. This variant contains a missense mutation in the *a* determinant of the surface antigen. Subsequently, these mutants were demonstrated in chronic HBV carriers even without these immune pressures. This mutation causes an infection in which HBsAg is undetectable but in which HBeAg and HBV DNA are found, in contrast to the typical serologic pattern (see later).

The role of X protein is not understood completely as yet, but it is required for establishment of infection in vivo, although not for transfection of cells in vitro.[12,37] X protein is involved in transcriptional activation during viral replication[111] and also has been shown to transactivate the promoters of other viruses such as human immunodeficiency virus (HIV) and human T-cell lymphotrophic virus type 1.[152]

VIRAL LIFE CYCLE OVERVIEW

Like retroviruses, hepadnaviruses replicate by means of reverse transcription of an RNA intermediate[177] (i.e., the flow of genetic information is from DNA to RNA to DNA.) As shown in Figure 169–2, after binding of the virus to receptors on the cell surface, virion nucleocapsids are delivered to the cytoplasm, where they translocate to the nucleus. There, the genomic DNA is converted to the cccDNA form (a nuclear pool of viral covalently closed circular DNA that serves as a template for reverse transcription). This form of DNA is transcribed by host RNA polymerase II, and the resulting RNA is translated to originate the *P*, *C*, *S/pre-S*, and *X* gene products. The viral pol initiates encapsidation of viral pregenomic RNA into cytoplasm by binding to the 5′ encapsidation signal, epsilon, on the pregenomic RNA.[122] Through a series of complex host-viral interactions, negative-strand DNA synthesis is initiated and completed, followed by plus-strand synthesis and circularization of the genome. The progeny cores then bud into intracellular membranes and acquire glycoprotein envelopes to form nucleocapsids. Nucleocapsids are exported from the hepatocyte cytoplasm toward the cell membrane, where they become invested with surface proteins bound in the membrane bilayer, thereby resulting in budding of mature virions into the bloodstream.

Although HBV can infect numerous tissues, including the spleen, kidney, peripheral blood mononuclear cells, and pancreas, the virus replicates exclusively in the liver. This is the sole site of replication because the tissue-specific viral promoter and enhancer are found in liver cells. No efficient tissue culture technique supports HBV infection. In the cell culture systems presently available, such as primary duck hepatocytes infected with DHV, immortalized human hepatoma cell lines such as HepG2 and HuH7, and chick LMH, the viral replicative cycle is not cytopathic. The infected hepatocytes are normal morphologically and display growth rates identical to those of uninfected controls.[11,154]

Viral Binding and Cell Entry

Studies of the early phases of the viral life cycle have been conducted primarily with DHV. The binding reaction has two components: one is of low affinity and is nonsaturable, and the second is of high affinity and saturable.[95] At 37° C, cell entry and viral infection occur. After binding, the virus must fuse with the host cell membrane. This phenomenon appears to occur by a pH-independent mechanism. The binding and entry processes are slow, with maximal infection occurring after 16 hours of exposure of the cell to the inoculum.[143] The pre-S proteins appear to be involved primarily in the cell fusion interactions.[95] Monoclonal antibodies to these proteins prevent the development of infection in primary duck hepatocytes.[95] The pre-S proteins also appear to determine the narrow spectrum of the viral host determination (i.e., if the virus entry process is bypassed by transfection into heterologous cells, viral replication of heron HBV is able to proceed normally in duck cells, which usually are not susceptible to this virus).

The cellular receptors for the hepadnaviruses are unknown. The hepatotropism of HBV infection is presumed to be caused by the presence of a specific receptor, although none has been identified.[161] Many proteins, such as apolipoprotein H[23] and endonexin 2 (a phospholipid-binding protein), bind to the HBV envelope glycoproteins, particularly S protein.[76] Receptors for pre-S proteins still have not been identified, and the biologic significance of these findings is yet to be determined. The mecha-

Figure 169–2 The virus enters the cell through a receptor or receptors, and the viral genome is imported into the nucleus, where transcription occurs. Pregenomic RNA encapsidation occurs in the cytoplasm. Reverse transcription leads to negative-strand and then positive-strand synthesis. The nucleocapsid undergoes assembly with hepatitis B surface antigen, followed by budding and secretion in blood endoplasmic reticulum. (*From Loomba, R., and Liang, T. J.: Novel approaches to new therapies for hepatitis B virus infection. Antiviral Ther.* 11:*1-15, 2006.*)

nisms by which viral DNA is delivered to the nucleus after entry also are unclear.

In the nucleus, viral DNA is transformed to cccDNA, a process that entails repair of the single-stranded gap, removal of the 5′-terminal structures, and covalent ligation of the strands.[2] Host mechanisms appear to contribute greatly to this process.[98]

Genomic Replication

The first step in HBV genomic replication is encapsidation of the genomic RNA template.[178] The pregenomic RNA is encapsidated into the core particle.[52] To package this small RNA portion into the capsid, both C protein and *P* gene products are required.[77] Encapsidation of polymerase occurs by binding of the P protein to the RNA that will be packaged.[6] Single-stranded pregenomic RNA is converted to partially duplex virion DNA through reverse transcription and elongations of the plus and minus strands.

Viral Assembly and Release

The 20-nm subviral particles are assembled between the endoplasmic reticulum and the Golgi apparatus.[83] These 20-nm particles contain predominantly S proteins, which are synthesized in the endoplasmic reticulum.[71] In addition, these particles may contain M subunits but generally do not have L proteins.[73] The assembly process is encoded totally in the S domain.[109] Assembled particles are transported through the secretory pathway and traverse the Golgi complex.[92,176] The S protein carries out the entire assembly process without the involvement of other viral proteins.[2] Therefore, subviral particles containing only envelope proteins are released. In vitro studies have shown that overexpression of L proteins gives rise to filamentous viral particles in the endoplasmic reticulum.[38] The overabundance of L, M, and S aggregates apparently is cytopathic to hepatocytes in vitro. Similar cytopathic features have been seen in human infections with HBV, yet the role of envelope protein expression in hepatocyte injury remains to be determined.[2]

Assembly of the Dane particle differs from assembly of the 20-nm particles in that all three proteins, L, M, and S, are present.[73] Studies of HepG2 cell lines transfected with HBV mutants have shown that no virus budding occurs if the envelope proteins are not present (mutations in *S*) and that for formation and release of virions, both L and S proteins are needed.[21] M proteins apparently are not necessary for viral assembly.

Viral Persistence

Nuclear cccDNA appears to be crucial for viral persistence. Hepatocytes that harbor this form of viral genome are the only ones that produce virus.[2] As mentioned earlier, the replicative cycle of HBV is not cytopathic to hepatocytes, and thus infected cells multiply normally. The cytoplasmic mechanism of reverse transcription, which produces the cccDNA and consequently delivers this product to the nucleus, must therefore be passed on to progeny cells. When HBV DNA is integrated into the cell chromosome, viral DNA may be rearranged, although whether this happens before or after integration is unclear. This rearrangement may lead to disruption of viral genes, especially the core and polymerase genes, whereas the coding regions and promoters for the envelope proteins remain intact.[151]

IMMUNOPATHOGENESIS

Individuals infected with HBV show tremendous variation in clinical and immunologic responses. HBV is not directly cytopathic, and the variability in liver damage is due to host immune responses. Although HBV preferentially infects hepatocytes and replicates therein, it can infect other liver cells, such as cholangiocytes, as well as cells in extrahepatic tissue, such as peripheral blood lymphocytes, pancreatic acinar cells, and cornea, spleen, thyroid gland, kidney, adrenal gland, and smooth muscle cells.[127]

Responses to HBV infection and the likelihood of chronic infection developing are dependent on both age at the time of acquisition and immune competence. Ninety percent of infants born to mothers who are HBeAg-positive become chronically infected with HBV as compared with only 5 percent of those infected as adults. The production of antibodies to pre-S and S antigens by B cells, as well as cytotoxic T-lymphocyte (CTL) responses, mediates recovery from acute HBV infection. Individuals who clear HBV have a strong polyclonal human leukocyte antigen (HLA) class I–restricted CTL response to multiple epitopes in the HBV envelope, nucleocapsid, and polymerase regions. This CTL response can be reactivated many years after clearance of all detectable evidence of HBV infection.[116]

Infants infected perinatally are at the highest risk for development of chronic HBV infection. During childhood, those infected as neonates characteristically have high circulating levels of HBV DNA but low disease activity, with very low rates of HBeAg seroconversion, either spontaneously or after treatment with IFN.[116] In children in Taiwan with chronic HBV infection, the HBeAg positivity rate is as high as 100 percent in infancy and 76 percent at 10 to 14 years of age.[31]

Researchers have offered numerous hypotheses why this immune tolerance develops in neonates. One theory proposes that transplacental passage of HBeAg induces $CD4^+$ anergy and, therefore, no CTL responses to HBeAg occur. However, HBeAg-specific T-cell proliferation eventually is detected in those who subsequently seroconvert, thus rendering clonal deletion an unlikely mechanism.[117] Defective interleukin-2 production has been demonstrated in children who have chronic HBV, although whether it is a cause or a consequence of chronic infection is not clear.[70]

The development of chronic infection is either a failure of host immune responses or a testament to the ability of HBV to evade that response. As the virus replicates within hepatocytes, viral antigens appear on the cell surface. Subsequently, CTLs directed against HBcAg infiltrate the liver and cause hepatocyte necrosis.[45] In addition, HBV interferes with the production of cytokines of the T_H1 response, especially IFNs, that would otherwise elicit class II major histocompatibility complex (MHC) antigen expression and enhance viral clearance. For reasons not fully understood, both the HBV-specific CTL response and the $CD4^+$ helper T-cell response are weak in chronic HBV infection. The high HBV viral load may lead to depletion of peripheral T-cell responses.[57] However, HBeAg, produced in large amounts in chronic HBV infection, and HBsAg share T-cell epitopes. HBeAg may enter the thymus and induce immune tolerance to both HBsAg and HBeAg by decreasing the production of HBV-specific CTLs. However, these cells can be reactivated in patients who undergo spontaneous or IFN-induced HBeAg seroconversion.[147] Soluble HBeAg itself may contribute to persistence of HBV inasmuch as some evidence supports the fact that HBeAg favors the production of T_H2 cytokines rather than T_H1 cytokines, which have a greater role in noncytolytic control of HBV.[57] Persistence of HBV infection also may be due to infection of extrahepatic tissue such as the kidney.[57]

Fulminant hepatitis is seen in less than 1 percent of infected individuals and has a high mortality rate. It is characterized by a brisk immune response and viral clearance. Those who survive clear HBV and do not have chronic HBV infection. A higher incidence of fulminant hepatitis occurs in patients infected with HBV mutants that do not produce HBeAg, thus suggesting either an increased rate of replication or lack of immune detection of the mutant HBV.[102]

CARCINOGENESIS

HCC is a recognized sequela of chronic infection with HBV; worldwide, most cases of HCC are linked to HBV infection. In Taiwan, the incidence of HCC in chronically infected individuals is 200 to 812 cases per 100,000 person-years as compared with 10 to 30 cases per 100,000 person-years in the general population. In those with liver cirrhosis secondary to chronic HBV infection, the incidence increases to 1000 to 5000 cases per 100,000 person-years (1% to 5% per year).[35] The lifetime risk for the development of HCC in a chronically infected person is estimated at 40 to 50 percent.[9] The risk of HCC developing after treatment remains unclear; if individuals are still HBsAg-positive after receiving treatment, they remain at risk and need follow-up measurements of alpha-fetoprotein and ultrasound examination. The age at which screening for HCC should commence and the frequency with which it should be performed have not been determined.[118]

In almost 100 percent of woodchucks chronically infected with WHV, HCC develops within 3 years.[100] Detection of integrated HBV sequences in both human HCC and animal models led to numerous hypotheses regarding the mechanisms that result in HCC. Current hypotheses center on integration of viral DNA into the host genome, which may be associated with activation of oncogenes, deactivation of tumor suppressor genes, or other genetic instability. The finding that HCC cells in an infected individual contain HBV DNA in discrete rather than random sites, indicative of clonal expansion of tumor cells, supports this theory. In general terms, the integrated HBV may affect genes locally by replacing or activating genes by insertional mutagenesis, or HBV may affect more distant genes by means of gene products that can be diffused.[144] Integration of HBV occurs at random sites on host hepatocyte chromosomes rather than at one fixed site. HCC tissue itself can contain a variety of chromosomal abnormalities, such as polyploidy, allelic imbalance, and translocations.[140] More than a dozen genes have been implicated in HCC, which not only suggests heterogeneity of genetic etiologic factors but also indicates that an accumulation of genetic mutations is required for HCC to develop.

Although many mutations are found in HCC, they can be clustered into three main pathways.[179] The first is that of tumor suppressor or DNA damage repair genes typified by *p53*. A mutation in *p53* is detected in approximately 30 percent of HCC tumors, although this figure varies in different geographic regions, being more common in China and less so in Europe. The rate of *p53* mutation is increased by exposure to aflatoxin.[140] A second pathway is that of cell cycle control, the *RB1* pathway. An example is the retinoblastoma gene, which is mutated in approximately 15 percent of HCC tumors.[201] The final pathway associated with transformation of a normal hepatocyte to a malignant one is the β-catenin and adenomatosis polyposis coli (*APC*) gene system, which is involved in signal transduction. The E-adherin gene, which produces a protein that forms complexes with β-catenin, frequently is mutated in HCC.[166]

Abnormalities in hepatocyte regulatory genes may be activated by the integration of HBV X protein (HBx). HBx can function as a transcription activator, protease inhibitor, and effector of cell signaling pathways. Two other HBV proteins, middle HBV surface protein and the large HBV protein, share similar properties.[144]

The frequency and significance of integration of viral DNA into the host genome are unresolved issues in childhood HBV infection; some studies have shown early integration, whereas others describe it as a rare event.[7,30,68,160,191,195] Although HCC is detected most often after at least 20 years of chronic HBV infection, cases in children as young as 8 months old have been reported.[66,181,194] Childhood HCC associated with HBV infection have been described in both Asian[32,181] and Western[66,142] populations. Because most cases are reported retrospectively, data regarding incidence are not available. No guidelines have been developed for prospective monitoring of children with chronic HBV infection for the development of HCC, although periodic measurement of serum alpha-fetoprotein levels and hepatic ultrasound are recommended in adults.

The genotype of HBV may be an indirect marker of the risk for development of HCC. Genotype C with TCC at codon 15 of the pre-core region is associated with an increased risk for the development of HCC in a Hong Kong population with cirrhosis.[27] Prevention of HBV infection and eradication of existing infection remain the most effective measures to prevent HCC. The 5-year survival rate in children with HCC is less than 30 percent despite combined modalities of treatment.[197]

EPIDEMIOLOGY

HBV infection occurs throughout the world, although marked geographic differences in rates of both acute and chronic infection exist.

Areas of high, intermediate, and low endemicity, as reflected by the number of carriers, have been identified. Highly endemic areas are those in which more than 8 percent of the population is infected. Examples include Southeast Asia, Africa, the Commonwealth of Independent States, and China. More than 70 percent of the world's population lives in these high-endemicity areas. The Middle East, Central and South America, and parts of Eastern Europe are examples of intermediate-endemicity regions, where infection is found in 2 to 7 percent of the population. The United States, Australia, and Western Europe are areas of low endemicity, with chronic infection rates of less than 2 percent of the total population.[188] In areas of low endemicity, acute infections occur more commonly in adults, and although these infections cause significant morbidity, they are less likely to result in chronic carriage than asymptomatic infections in children are.

In the United States, the prevalence of chronic HBV infection (HBsAg-positive) in the general population, based on the National Health and Nutrition Examination Survey III (NHANES III), is estimated at 0.42 percent. NHANES III was conducted from 1988 to 1994 and revealed that 5.5 percent of the U.S. population had evidence of either past or chronic infection with HBV.[132] Rates among ethnic groups varied, with non-Hispanic blacks having the highest rate at 12.8 percent, as compared with 2.8 percent in non-Hispanic whites and 4.8 percent in Mexican Americans. The strongest predictors of HBV infection were non-Hispanic black ethnicity, increased number of sexual partners, foreign birth, cocaine use, and having less than a high-school education.[132]

HBV may be transmitted vertically, horizontally, parenterally, or sexually. Vertical transmission of HBV occurs in the perinatal setting when an infected mother transmits the infection to her child. Horizontal transmission occurs among children in groups with moderate to high endemicity[51] who were not infected at birth. This form of transmission occurs in households of an infected family member, where other members acquire HBV without sexual or overt contact with contaminated body fluids. In adolescents and adults, infection is transmitted by contaminated blood or other body fluids through percutaneous or mucous membrane routes. Examples are intravenous drug use; occupational exposure to blood; sexual contact, especially in men who have sex with men; and nosocomial infections as a result of sharing contaminated equipment.[126]

In countries where HBV infection is highly endemic, perinatal or vertical transmission occurs very commonly, whereas in regions of low endemicity, sexual transmission occurs more commonly. If a mother is seropositive for both HBeAg and HBsAg,

the risk of transmission of HBV to her child is 85 to 90 percent without immunoprophylaxis.[5] The most common risk factors for acquisition of acute HBV in adults in the United States between 1982 and 1998 were heterosexual exposure to a person with hepatitis or having multiple sexual partners (27%), intravenous drug use (18%), occupational exposure (16%), men who had sex with other men (13%), and household contact (3.6%).[67] Approximately a third of people reported no risk factors during the study period.[67]

Within the United States, the number of reported cases of acute hepatitis B decreased 67 percent between 1990 and 2002 (21,102 to 8064 reported cases).[26] The largest decline (89%) occurred in children and adolescents: from 3.0 in 1990 to 0.3 per 100,000 in 2002.[26] HBV elimination strategies such as screening of pregnant women, universal immunization of infants, and catch-up immunization of older children are credited with the reduced incidence in children. Strategies to eliminate HBV are outlined in Table 169–1. An increase in 1999 through 2002 in incidence among men older than 19 years and women older than 40 years has been noted,[26] thus reinforcing the need for targeting those engaging in high-risk behavior.

The experience from Taiwan, the first country to implement mass vaccination against HBV, is encouraging. Since 1986, all newborns have been vaccinated against HBV. The program has been extended to other children and adults, which has led to a 10-fold decrease in the chronic infection rate.[34] After approximately 10 years, a significant decrease in the incidence of HCC in children was reported.[29] The proportion of infants and children with hepatitis B as a cause of fulminant hepatic failure (FHF) in Taiwan has decreased from 82 percent before mass vaccination to 57 percent, but HBV infection remains a major cause of FHF in infants.[33]

Researchers have estimated that only 45 percent of the expected 20,000 HBsAg-positive women giving birth in the United States between 1993 and 1996 were identified.[167] This low figure may be due to numerous factors: women likely to be infected often do not receive prenatal care,[165] or women may be tested but the information not conveyed to the place of birth or to the pediatrician caring for the child.[5] Attention to this aspect of care is extremely important because the reduction in rate of transmission from mother to child with the use of hepatitis B immunoglobulin (HBIG) and hepatitis B vaccine is 90 percent.[88]

HBsAg can be found in the breast milk of HBV-infected mothers. However, in studies performed in Taiwan and England, breast-feeding by HBsAg-seropositive mothers did not seem to increase the risk for neonatal acquisition of HBV infection significantly.[141] A study of 230 babies in China demonstrated that response rates to HBV vaccination and failure rates of HBV immunoprophylaxis in breast-fed babies were similar to those of bottle-fed babies.[190] Effective immunoprophylaxis should allow safe breast-feeding.

TABLE 169–1 Strategies to Eliminate Transmission of Hepatitis B Virus Infection in the United States

Universal vaccination of infants beginning at birth
Prevention of perinatal HBV infection through
Routine screening of all pregnant women for hepatitis B surface antigen (HBsAg)
Immunoprophylaxis of infants born to HBsAg-positive women and infants born to women with unknown HBsAg status
Routine vaccination of all previously unvaccinated children and adolescents
Vaccination of previously unvaccinated adults at increased risk for infection

E., et al.: A comprehensive immunization strategy to eliminate transmission of hepatitis B infection in the United States: recommendations of the Advisory Committee on Immunization Practices (ACIP) part 1: Immunization of infants, children, and adolescents. M. M. W. R. Recomm. Rep. 54(RR-16):1-31, 2005.

NATURAL HISTORY

ACUTE HEPATITIS B

Acute HBV infection in the United States occurs most commonly in young men older than 19 years and in women older than 40 years,[48,67] but chronic disease does not develop in most people. The clinical and serologic findings in acute hepatitis B are shown in Figure 169–3. Acute hepatitis rarely develops in children infected perinatally, but FHF can develop, particularly in infants born to HBeAg-negative mothers.[33]

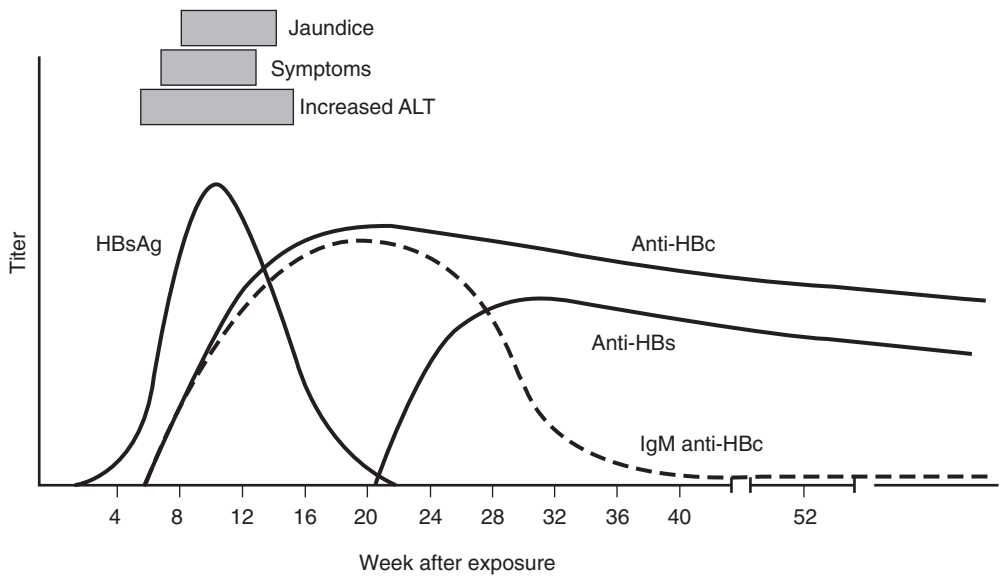

Figure 169–3 Clinical and serologic features of acute infection with hepatitis B virus. Hepatitis B surface antigen (HBsAg) is detectable within 4 weeks and reaches a peak value at 12 weeks. This coincides with the onset of jaundice. Hepatitis B e antigen (HBeAg) becomes detectable at the same time. Anti–hepatitis B core (Anti-HBc) IgM is detected from 6 to 8 weeks and peaks at 20 weeks. It then declines, but anti-HBc IgG persists. Upon resolution of acute infection, the serum contains anti-HBc, IgG type, and anti-HBs.

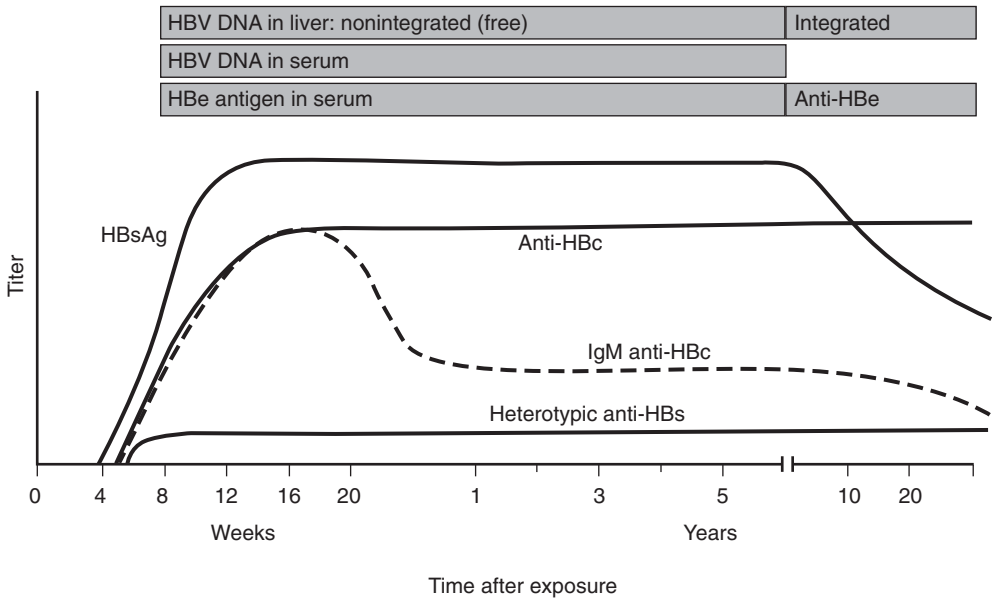

Figure 169–4 Clinical and serologic features of chronic hepatitis B virus (HBV) infection. Hepatitis B surface antigen (HBsAg), hepatitis B e antigen (HBeAg), and anti-hepatitis B core (HBc) are detectable and may persist for years. Seroconversion from HBeAg to HBe antibody is associated with very low levels of HBV DNA in serum. The diagnosis of chronic HBV infection is dependent on finding HBsAg for at least 6 months or the combination of HBsAg and anti-HBc of the IgG class.

CHRONIC HEPATITIS B

The natural history of chronic HBV infection in children has been examined in several populations. The clinical and serologic findings of chronic hepatitis B are shown in Figure 169–4. Most Chinese children, in whom chronic HBV usually is acquired perinatally, remain HBeAg-positive, with very high levels of viral replication, yet only minimal clinical liver disease.[119,120] In contrast, children in the West with chronic HBV infection frequently clear HBeAg and HBV DNA from serum during the first 2 decades of life.[18] In an extended follow-up lasting 14.5 ± 6.1 years of 89 white children in Italy after seroclearance of HBeAg, 4 experienced reactivation, 3 of whom had HBeAg-negative hepatitis.[19] Those who lose HBeAg tend to have higher alanine transaminase (ALT) levels early in life, thus indicating more active liver disease. Some of the children (15.4%) become seronegative for HBsAg as well.[19] Reactivation of viral replication is observed only rarely. Children born to Asian and Afro-Caribbean mothers in the United Kingdom who acquired HBV infection perinatally had a much lower rate (29%) of HBeAg seroconversion than did white children (80%)[20] or Italian children (98%).[19] These differences are ascribed to the older age at acquisition of HBV in the Western children, which is associated with a more efficient immune response. These observations influence the management and counseling of children with chronic HBV infection, as well as the design and interpretation of therapeutic trials.

The risk of acquiring chronic hepatitis B is related to a number of factors such as very young age, other medical conditions, and the presence of other infections. If an infected person has other medical problems, such as end-stage renal disease requiring hemodialysis, or is co-infected with HIV, the risk for development of chronic HBV infection increases. The risk for development of HCC is increased in all HBV chronic carriers, especially those with active viral replication.[9] Four of 99 Italian children had HBeAg-positive cirrhosis at the start of the study, and after 14.5 ± 6.1 years of follow-up, HCC had developed in 2, and 2 had had lost the histopathologic features of cirrhosis.[17,19]

Extrahepatic manifestations of both acute and chronic HBV infection occur more commonly in adults. As many as 25 percent of adults with acute HBV infection have extrahepatic manifestations such as arthralgia and even serum sickness–like reactions. Vasculitides can develop in patients with both acute and chronic HBV infection, and examples include polyarteritis nodosa, renal disease, and mononeuritis.[131] Membranoproliferative glomerulonephritis is an extrahepatic manifestation of chronic HBV infection in some children.[94,173] A case of epididymitis related to acute hepatitis B in a 12-year-old boy has been reported.[182]

HISTOPATHOLOGIC FEATURES

The purposes of obtaining a liver biopsy specimen from patients infected with HBV are to quantify the severity of changes, rule out other causes of liver disease, and allow a comparison of changes after treatment. In patients with typical acute viral hepatitis, obtaining a liver specimen usually is not required or indicated. If performed, the findings are liver cell degeneration and necrosis, with lobular disarray. The acute injury to hepatocytes is manifested as both ballooning and acidophilic degeneration, either of which can resolve or progress to cell death. Inflammatory cell infiltration and liver cell regeneration are also seen.[80]

The histopathologic changes of chronic HBV infection are characterized by portal tract inflammation, interface hepatitis, and fibrosis, which may progress to architectural distortion of lobules and eventually to cirrhosis.[80] Chronic HBV is characterized by "ground-glass cells" (Fig. 169–5A), or hepatocytes containing HBsAg, most easily identified by staining with orcein, Victoria blue, or aldehyde fuchsin. However, these cells also are found in other liver diseases, and the pattern of staining is important. In hepatitis B, ground-glass cells are found either singly or in clusters arranged in a haphazard pattern. "Sanded" liver nuclei are caused by accumulation of HBcAg and generally are identified by electron microscopy[85] or immunoperoxidase techniques (Fig. 169–5B).

Histopathologic staging and grading systems are used to allow standardization and meaningful comparisons in chronic hepatitis. One such system is the Knodell-Ishak score, which evaluates four histopathologic features, each scored with specific criteria.[96] This system has proved reproducible, is now in common use, and also is known as the *modified histologic activity index* (HAI). Other systems are the Batts-Ludwig system[8] and the METAVIR system.[153] Systematic classifications are useful in estimating progression of disease and response to therapy and for comparing

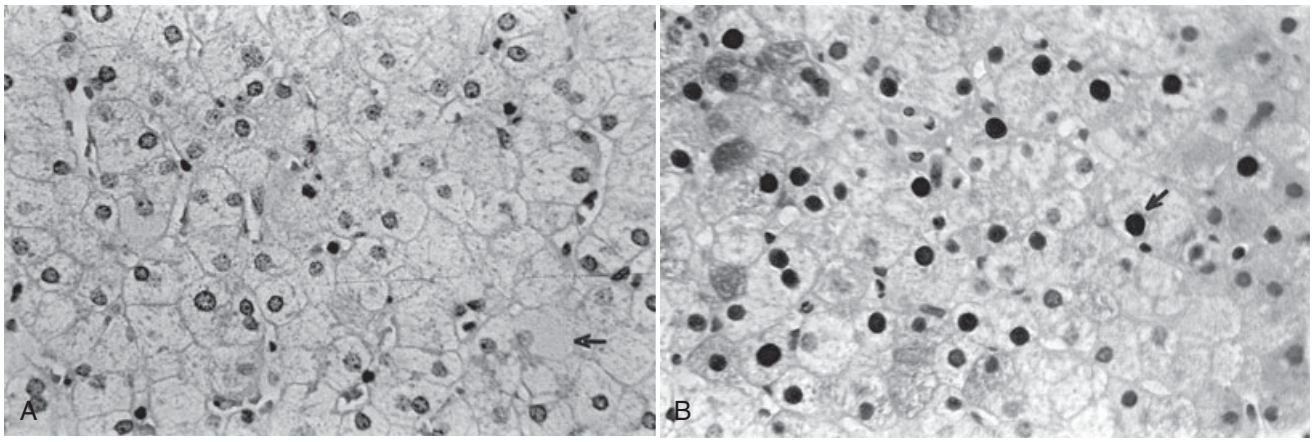

Figure 169–5 **A,** Photomicrograph of a liver biopsy specimen from a child with chronic hepatitis B virus (HBV) infection. Ground-glass hepatocytes (*arrow*) are demonstrated (hematoxylin and eosin stain; original magnification ×20). **B,** Photomicrograph of the liver of a child with chronic HBV infection. The darkly stained nuclei (*arrow*) contain hepatitis B core antigen (HBcAg) (immunoperoxidase stain for HBcAg; original magnification ×20).

outcomes of therapeutic trials. A study from Poland demonstrated that these scores were useful in comparing liver biopsy findings in children before and after they received IFN-α treatment and that inflammatory but not fibrosis scores improved after treatment.[168] However, another study demonstrated interobserver variability in grading and staging of pediatric liver biopsy specimens.[192] Clinicians must be aware of the limitations of liver biopsy reports and that description rather than scoring alone is important.[192]

Serum markers of hepatic fibrosis, such as apolipoprotein A-I, haptoglobin, and α_2-macroglobulin, have been investigated in children. They present many theoretical advantages for noninvasive monitoring of patients, but no single marker has proved useful yet in children with chronic HBV infection.[110]

TREATMENT

Treatment of acute hepatitis B is purely supportive, and most patients recover fully. The role of antiviral therapy in fulminant HBV infection has not been studied systematically. Treatment, when indicated, is directed at those with chronic HBV infection. In this setting, the long-term goals of therapy are eradication of HBV and improvement or regression of liver disease. Other goals of treatment include cessation or decrease in viral replication as indicated by loss of HBeAg and HBV DNA from serum, clearance of HBsAg, normalization of liver histopathology, and normalization of transaminase values.

To date, no agents fulfill all these goals in either adults or children. Children and adults have differences in immune tolerance and rates of progression of liver disease. Therefore, studies of treatment of chronic HBV in adults cannot be extrapolated directly to children. In addition, the timing and choice of therapeutic agents are crucial because of differences in age, maturity, stage in natural history, and co-morbid conditions.

A child being considered for treatment should have serologic evidence of HBV infection, such as HBsAg, for at least 6 months, as well as evidence of active HBV replication: HBeAg, or HBV DNA (in case of HBeAg-negative HBV infection). In addition, children with consistent elevation of ALT to at least twice the upper limit of normal are most likely to benefit from treatment. Liver biopsy should be performed before the start of therapy to provide evidence of chronic hepatitis, to stage the disease, and to rule out other processes. In most studies conducted before the high prevalence of HBeAg-negative infection, seroconversion from HBeAg to anti-HBe in serum was used as the primary outcome variable for response to therapy. Therapeutic trial results must be compared with the "background rate" of spontaneous conversion from HBeAg positivity to anti-HBe, which in children younger than 3 years old is very low (<2% per year) but increases with age such that in children older than 6 years old, yearly clearance rates vary from 14.3 to 35.3 percent.[31] Two medications are approved for the treatment of chronic HBV in children, IFN-α and lamivudine. IFN-α first was reported as a successful treatment of chronic HBV in 1976,[69] and recombinant IFN-α-2b was approved by the U.S. Food and Drug Administration in 1992 for adults and in 1998 for children with chronic HBV. Lamivudine is a nucleoside antiviral agent and was the first oral agent approved for HBV in adults and children. Adefovir dipivoxil was recently approved for children age 12 years and older.[86a] Table 169–2 summarizes published trials to date in children.

INTERFERON

The IFNs are a family of cytokines with immunomodulatory, antiproliferative, and direct antiviral actions. The three types are α, β, and γ. IFN-α has been the primary form used for the treatment of chronic HBV infection. It induces the display of HLA class I molecules on hepatocyte membranes, which in turn promotes lysis by $CD8^+$ CTLs. At the same time it directly inhibits viral protein synthesis.[111] IFN-α is available in several forms, including IFN-α-2a, IFN-α-2b, and lymphoblastoid IFN-α. Only IFN-α-2a and -2b have been licensed in the United States for use in children. Pegylated IFN-α-2a has not been studied or licensed yet for use in children with chronic HBV.

IFN-α treatment led to loss of HBV DNA or HBeAg seroconversion in 20 to 58 percent of European children as compared with 8 to 17 percent of control children.[187] Success rates are not as high for treatment of children in Asian countries, most of whom were infected perinatally; only 3 to 17 percent cleared HBV DNA or underwent HBeAg seroconversion.[104] These differences in treatment responses are thought to be related to age at the time of development of infection. However, in a large multinational, randomized control trial of IFN-α-2b, no differences were found in loss of HBsAg between children born in Asian countries (22%) and those from Europe and North America (26%) if transaminase values were elevated.[171] If only children with elevated transaminases are selected for treatment with IFN-α, children younger than 13 years with intermediate HBV DNA levels are most likely to have a good response, regardless of ethnicity.[171]

TABLE 169–2 Summary of Therapeutic Trials in Children

Author, Year	Treatment Regimens	HBeAg-Negative 6 Months after Therapy	HBV DNA–Negative 6 Months after Therapy
Barbera, 1994[4a]	Group 1 (n = 21): IFN-α-2a, 7.5 MU/m^2 Group 2 (n = 19): IFN-α-2a, 3 MU/m^2 Controls (n = 37): No treatment	Group 1: 5/21 Group 2: 4/19 Controls: 3/37 $p < 0.05$, group 1 vs 3	Group 1: 5/20 Group 2: 4/19 Controls: 7/37 NS
Sokal, 1998[171]	Treatment (n = 72): IFN-α-2b Control (n = 77): No treatment	Treatment: 25/72 Controls: 8/74 $p < 0.05$	Treatment: 27/72 Controls: 8/74 $p < 0.05$
Gurakan, 2000[71a]	Group 1 (n = 15): IFN-α-2b, 5 MU/m^2 Group 2 (n = 15): IFN-α-2b, 10 MU/m^2	Group 1: 5/15 Group 2: 9/15 $p < 0.05$	Group1: 6/15 Group 2: 9/15 $p < 0.05$
Giacchino, 1995[65]	Group 1 (n = 16): Human lymphoblastoid IFN-α preceded by 4 wk of prednisolone, 0.6 mg/kg/day Group 2 (n = 19): IFN-α preceded by placebo	Group 1: 7/16 Group 2: 0/19 NS	Group 1: 10/11 Group 2: 11/19 NS
Jonas, 2002[87]	Treatment (n = 191): Lamivudine daily × 52 wk Controls (n = 95): Placebo daily × 52 wk	Treatment: 50/191 Placebo: 14/95	Treatment: 117/191 Placebo: 15/191 $p < 0.001$
Sokal 2006[172]	Treatment (n = 213): Lamivudine daily × 52 wk, all HBeAg-positive (133 previously treated with lamivudine × 52 wk) Observation (n = 63): Previously treated with lamivudine × 52 wk, all HBeAg-negative	Treatment: 51/213 Control: 48/54 (sustained response 52 wk after end of treatment)	As before
Dikici, 2001[49a]	Group 1 (n = 30): IFN-α-2b and lamivudine Group 2 (n = 27): Same medications but for 12 months	Group 1: 11/30 Group 2: 15/27 NS	Group 1: 29/30 Group 2: 26/29 NS
D'Antiga, 2006[43]	Pilot study (n = 23) Lamivudine, 3 mg/kg daily alone × 8 wk, then lamivudine, 3 mg/kg daily × 48 wk, and IFN-α, 5 MU/m^2 3/wk × 40 wk	5/23 anti-HBe	18/23
Jonas, 2008[86a]	Group 1 (n = 113): adefovir Group 2 (n = 57): placebo	Group 1: 18/113 Group 2: 3/57	Group 1: 12/113 Group 2: 0/57

HBeAg, hepatitis B e antigen; IFN, interferon; NS, not significant.

Higher doses of IFN-α (10 MU/m^2) are not associated with higher clearance rates, although treatment for 6 months seems to improve outcome.[187] In the multinational, randomized, controlled trial referenced previously, children received 6 MU/m^2 of IFN-α-2b three times a week for 6 months.[171] However, the dose of IFN-α-2b had to be reduced because of bone marrow suppression or fever in 23 percent of children. In this study, serum HBeAg and HBV DNA became negative in 26 percent of treated children and 11 percent of controls. In children who responded to therapy, liver histology improved, and serum transaminase values normalized.[170] Prednisone priming (i.e., a course of steroids immediately before the administration of IFN-α) has been proposed to induce an acute exacerbation of hepatitis B, thereby rendering the patient more susceptible to IFN. However, a dual-center, double-blind, randomized trial of lymphoblastoid IFN-α, with or without steroid pretreatment, showed no improvement in the rate of seroconversion of HBeAg to HBeAb over that of IFN-α alone.[65]

Reported studies of IFN-α included only children older than 18 months without hepatitis C and HIV co-infection because such co-infection may alter treatment algorithms. Children with evidence of active immunologic responses to HBV (i.e., low levels of viral replication [HBV DNA] and high ALT values [greater than twice normal]) are more likely to have a response to therapy with IFN-α.[185] Children who acquired disease by vertical transmission are more likely to have established immune tolerance and may be less likely to respond to treatment. Children with very low HBV DNA levels may be in the process of spontaneous seroconversion; therefore, an expectant policy may be prudent.

Ten percent of treated adults and children lose HBsAg as compared with 1 percent of untreated patients.[101,171] Long-term (1.1 to 11.5 years) follow-up of adult responders to IFN-α showed a significantly reduced incidence of HCC in comparison to either treated nonresponders or control patients.[114] The long-term outlook for treated children is not clear. In a Turkish study, neither cirrhosis nor HCC had developed in 23 treatment nonresponders at a mean follow-up of 4.5 years.[97] A second study compared long-term (5.6 ± 3.1 years) outcome in two groups of 37 children, one group treated with IFN-α-2b and a second control group of children matched for age, sex, and baseline ALT level who received no treatment. At the time of follow-up, rates of HBeAg and HBsAg loss were 54.1 percent (20/37) and 8.1 percent (3/37), respectively, in treated children versus 35.1 percent (13/37) and 2.7 percent (1/37), respectively, in untreated children (not significant). Children with ALT levels elevated more than twice normal who were treated had higher rates of HBeAg seroconversion at follow-up than did children with elevated ALT who were not treated.[180] A study from Sweden demonstrated that pretreatment HBV DNA levels were associated with virologic response.[169] Histologic outcomes in children with chronic HBV treated with IFN-α for 20 weeks have been reported in a study of 93 children with an average age of 7.1 years in Poland. Liver biopsy specimens were obtained before treatment and 12 months after the end of the treatment and graded for fibrosis and inflammation with three different scoring systems. Thirty-five children underwent HBeAg/anti-HBe seroconversion, and 58 did not respond. Liver fibrosis did not improve regardless of responder status, but inflammatory activity was decreased after treatment in both responders and nonresponders.[192]

Side effects of IFN-α include a transient influenza-like syndrome (fever, myalgia, headache, arthralgia, and anorexia) that occurs in virtually all patients at the start of therapy. Bone marrow suppression, especially neutropenia, is a common side effect and was seen in 39 percent of children in one series.[84] Changes in personality, irritability, and temper tantrums are reported more frequently in children than in adults.[84,171] These problems resolve once treatment is withdrawn. Epistaxis not associated with

thrombocytopenia or a prolonged prothrombin time, febrile seizures, and marked elevation of transaminases have been reported. The death of a 5-year-old girl with chronic hepatitis B within hours of administration of the first dose of IFN-α-2a, which may have been related to a hypersensitivity reaction, has been reported.[93] Quality of life, as compared with their pretreatment levels, is impaired in children while they are receiving IFN therapy because of medication side effects and fear of injections. However, within 3 months of cessation of treatment, these effects are reversed.[84] Therapy in children seldom is discontinued because of side effects or inability to administer the medication. Two meta-analyses of treatment of chronic HBV in children with IFN-α have been conducted.[185,186] Each report concluded that treatment leads to a higher rate of HBeAg seroconversion than would occur spontaneously. Randomized controlled trials may be analyzed for "number to treat" (i.e., the number of children requiring treatment to have a therapeutic response in one patient). If only children with ALT values twice normal are considered, 2.5 children need to be treated for 1 to clear HBV DNA. However if all infected children are treated, 7.1 children would require therapy to clear HBV DNA from 1 child.[185] Approximately two thirds of children treated with IFN-α show no sustained response to therapy; hence, more effective and better-tolerated treatments are required.

HBV POLYMERASE INHIBITORS

This class of agents includes nucleoside and nucleotide analogues that inhibit HBV polymerase by incorporation into viral DNA, which leads to termination of the chain. They are administered orally and generally are well tolerated.[122]

Lamivudine

Lamivudine (2′,3′-dideoxycytosine), also known as 3′TC, is an oral nucleoside analogue. It is triphosphorylated intracellularly to an active intermediate that is incorporated into the growing DNA chain, thereby terminating the chain and inhibiting viral replication. Two large, randomized, controlled studies of lamivudine as initial treatment of chronic HBV infection in adults showed serologic, biochemical, and histologic evidence of benefit.[49,103]

A number of studies have demonstrated the benefit of lamivudine in children. The first was a double-blind, placebo-controlled, randomized, multicenter study of lamivudine given for 52 weeks to 191 children aged 2 to 17 years at a dose of 3 mg/kg/day (maximum dose, 100 mg) and placebo given to 97 children. All children in the study were HBeAg-positive and had detectable HBV DNA and elevated ALT values. Twenty-three percent (44/191) of those treated with lamivudine cleared HBV DNA and HBeAg as compared with 13 percent (12/97) in the placebo group ($p < 0.05$). Unfortunately, YMDD mutants developed in 19 percent (31/166). Higher response rates were observed in those with higher ALT levels, as had been noted with IFN. In an open-label study of lamivudine in 29 adolescents and young adults with maternally transmitted chronic HBV infection in Taiwan, only those with ALT greater than five times the upper limit of normal demonstrated a better response (undetectable HBV DNA, normal ALT, and HBeAg/anti-HBe seroconversion) than did control patients after 52 weeks of treatment.[134]

The optimum duration of lamivudine therapy was investigated in a multicenter, open-label study of prolonged therapy in children[172] who had participated in the previous 1-year study of lamivudine.[87] Children were enrolled into one of two groups on the basis of their virologic status at week 48 of the original study. Two hundred thirteen children were HBeAg-positive; 134 had received lamivudine and 79 placebo. All the children were offered lamivudine for a further 2 years. At the end of the study, 51 more children had achieved a virologic response; however, YMDD mutant HBV had developed in 100 of 173. The virologic response in those with YMDD mutants was only 5 percent (5/100), as opposed to 49 percent (34/70) in those with wild-type HBV. Sixty-three children who were HBeAg-negative (49 previously treated with lamivudine and 14 with placebo) at the start of the study were observed for 2 more years. At the end of the study period, 48 of 54 (89%) had a durable virologic response.

However, prolonged treatment increases the risk for emergence of mutation in the HBV polymerase gene at the YMDD locus. This mutation arises because of a methionine-to-valine or a methionine-to-isoleucine switch in the C domain of the HBV polymerase.[184] YMDD variants of HBV are associated with reemergence of active hepatitis or decompensation of chronic liver disease. Once lamivudine therapy is stopped, wild-type virus reappears.[60] Based on the observation that both therapeutic response and development of resistant mutants increase in frequency with duration of treatment, the optimal duration of lamivudine therapy has not been defined. In fact, this agent largely has been replaced in adult HBV treatment by newer drugs with more favorable resistance profiles.

Selecting children most likely to benefit from treatment with lamivudine remains a challenge. Children most likely to have a sustained virologic response to lamivudine are those with HBeAg-positive chronic hepatitis and transaminases twice the upper limit of normal. If YMDD mutants emerge, lamivudine should be discontinued and liver enzymes need to be monitored. In patients with advanced liver disease, alternative therapy may need to be provided. No serious side effects of lamivudine were reported in children.[87] Lamivudine is excreted by the kidneys, so the dose should be reduced in patients with renal failure. Because lamivudine is tolerated so well, many patients, including those with advanced liver disease, in whom IFN is contraindicated, can be considered for treatment. Researchers have suggested that the medication should be continued until HBeAg disappears from serum, anti-HBe appears, or if neither occurs, HBV DNA becomes persistently undetectable.

Upon cessation of therapy in adults, 25 percent of treated patients had serum ALT levels elevated up to three times baseline, as compared with 8 percent of placebo-treated patients. This "lamivudine withdrawal flare" may progress to jaundice and incipient liver failure, as noted in 2 of 41 patients in a Dutch study.[78] Therefore, monitoring patients after a course of lamivudine is important.

Combination of Interferon-α and Lamivudine

Preliminary studies of combination therapy with IFN-α and lamivudine have been performed in both children and adults. In adults with HBeAg-positive chronic HBV, pegylated IFN-α-2a, either alone or in combination with lamivudine for 48 weeks, was superior to lamivudine alone.[107]

A pilot study of combined IFN-α and lamivudine in children with perinatally acquired chronic hepatitis B was reported recently from the United Kingdom. It was an open-label, single-treatment arm, single-center study. IFN-α was used, and the children selected were regarded traditionally as poor responders to treatment. Twenty-three children, all infected in the first year of life, HBeAg-positive, and with normal transaminases, were treated with lamivudine alone for 8 weeks, followed by lamivudine plus IFN-α, 5 MU/m^2 three times weekly for 10 months. Five of 23 seroconverted to anti-HBe, and 4 of these 5 became HBsAg-negative and HBsAb-positive. In no child did a YMDD mutant develop, and most (78%) became HBV DNA–negative. A side effect of treatment was a decrease in weight and height increments in comparison to study entry, and the difference remained significant for height 12 months after the end of treatment.[43]

Pegylated IFN-α-2a has not been studied in children with chronic HBV.

Other agents that have been demonstrated to be effective in adults with chronic HBV infection are peginterferon, adefovir, entecavir, telbinidine, and tenofovir. A randomized placebo-controlled trial of adefovir in children with chronic HBV also has been reported.[86a]

Adefovir

Adefovir is a synthetic nucleotide analogue of adenosine monophosphate.[200] It suppresses HBV in both HBeAg-positive and HBeAg-negative adults, and drug resistance is lower and emerges later than with lamivudine. Adefovir dipivoxil has been demonstrated to decrease HBV DNA and transaminase levels with prolonged treatment (144 weeks) in adults with HBeAg-negative chronic hepatitis B without HBsAg seroconversion.[72] When treatment was withdrawn in one subgroup after 48 weeks, the virologic and biochemical benefits were lost, thus suggesting that long-term treatment is required for viral suppression in those with HBeAg-negative chronic hepatitis B. Unlike lamivudine, prolonged administration of adefovir led to infrequent development of resistance (5.9% after 144 weeks). Severe adverse events occurred infrequently, with elevation of serum creatinine being the most serious, and elevated ALT levels also were reported. The most commonly reported events were headache, abdominal pain, and pharyngitis in one study[72] but not noted in another.[200] In a double-blind randomized trial of 480 HBeAg-positive adults in China, suppression of HBV DNA was observed in those receiving adefovir, 10 mg daily for 52 weeks, even if they had wild-type or YMDD mutant infection.[200] Adefovir was recently approved for use in children.[86a]

Entecavir

Entecavir is a cyclopentyl guanosine analogue that inhibits HBV polymerase.[122] Treatment with entecavir for 48 weeks suppresses HBV DNA viral loads in both HBeAg-positive and HBeAg-negative adults at higher rates than occurs with lamivudine.[117] Entecavir is of use in adults with lamivudine-refractory, HBeAg-positive, chronic hepatitis B. A dose of 1 mg led to improvement in histology, reduction in viral load, and normalization of ALT when compared with lamivudine after 48 weeks of treatment.[163]

A number of other nucleotide and nucleoside analogues that are in trials include emtricitabine, which is active against both HIV and HBV and is in phase III trials, and tenofovir, which also is at phase III levels.[122]

HEPATITIS B IN SPECIAL POPULATIONS

HBV AND HIV CO-INFECTION

The prevalence and course of hepatitis B in adults who are co-infected with HIV has been examined in numerous studies. Of 181 HIV-infected adults in Greece, 71.8 percent of the men who have sex with men and 91.7 percent of intravenous drug users had evidence of HBV infection.[50] In a study from Australia conducted between 1985 and 1989, men with HIV infection were more likely to have chronic HBV infection than were HIV-negative men.[13] No evidence has been found of direct interaction between HBV and HIV. Individuals co-infected with HIV and HBV have higher circulating levels of HBV DNA but not worse hepatic necro-inflammation.[39] Spontaneous seroconversion of HBeAg to anti-HBe rarely occurs in this group. Special considerations for treatment and immunization are discussed in the appropriate subsections.

HEPATITIS B IN SOLID ORGAN TRANSPLANT RECIPIENTS

Chronic HBV infection became a relative contraindication to liver transplantation after initial poor results. In the 1970s and 1980s, more than 80 percent of patients became re-infected quickly, and 55 percent died within 60 days of undergoing surgery. In patients who had recurrence of HBV infection after liver transplantation, a characteristic histologic lesion, termed *fibrosing cholestatic hepatitis*, developed and eventually led to loss of the allograft.[10] The demonstration in the 1990s that HBIG is efficacious in decreasing infection of the allograft has allowed successful transplantation. Long-term use of HBIG decreases the risk of recurrence to 30 percent at 12 months and increases patient survival rates to greater than 90 percent 12 months after transplantation.[156] Lamivudine has been added to HBIG after transplantation. In a study from China of 69 patients with chronic HBV infection who received liver transplants and treatment to prevent re-infection, 10 died less than 3 months after receiving their transplants.[196] Of the remaining 59 patients, 8 were not included in follow-up because they did not receive treatment with HBIG and lamivudine, which left 51 patients in the final analysis. The mean follow-up was 14.1 months. Two of the 51 had recurrent disease; 1 died and the other cleared the infection.[196] The allograft re-infection rate is even lower if the patient does not have active HBV replication at the time of transplantation, which is why lamivudine has been added in the pre-transplant period. The cost of HBIG is a major factor, and the duration of therapy appears to be lifelong to maintain a protective HBs titer.

HBV infection is the fourth most common cause of acute liver failure in adults in the United States.[139] Rarely does a child with hepatitis B need a liver transplant for either acute or chronic liver failure.[174] Of 215 children who underwent transplantation between 1986 and 1992 at a major French center, only 4 had HBV-associated disease.[125]

The course of HBV infection in heart, lung, and kidney transplant recipients was examined in a French study. Of 874 heart transplant recipients, 69 were infected with HBV, most through nosocomial infection; chronic HBV infection had little impact on 5-year survival.[124] In a group of 120 lung transplant recipients in Israel, 11 patients who either had chronic hepatitis B or received an organ from an HBcAg-positive donor were treated with lamivudine prophylaxis. The drug was tolerated well, and resistance developed in only one patient, but it responded to a change to adefovir.[164] In a study from Taiwan, overall patient and allograft survival after kidney transplantation were not affected by HBV infection despite increased hepatic morbidity.[82] Of the 113 patients who received a kidney transplant between 1986 and 1998, 20 were HBsAg-positive and 9 were positive for both HBsAg and hepatitis C virus (HCV) antibody. Of the 20 who were infected with HBV alone, FHF developed in four, who died within 2 years of undergoing renal transplantation; cirrhosis developed in 2; and HCC developed in 2 others.[82] Overall, however, 5-year survival was not dissimilar in those infected with HBV and those not infected. Lamivudine and mycophenolate mofetil have been used in combination with some success in renal transplant recipients with chronic hepatitis B.[108]

The child most likely to be treated successfully with today's agents is one who acquired HBV beyond infancy, has evidence of immune responsiveness to HBV, and has mild to moderate inflammatory changes on liver biopsy. The child ideally has no other medical problems, and the child and family can comply with the regimen and monitoring.

Even if the child has some success with treatment but remains HBsAg-positive, the child is still at risk for the development of HCC or reactivation to HBeAg-negative hepatitis. We would suggest yearly follow-up of virologic response and ultrasound. If

the child is HBsAg-negative after treatment and HBV still can be found in the liver, a risk for development of HCC remains but is presumed to be lower than if still HBsAg-positive. Therefore, follow-up should be considered.

IMMUNOPROPHYLAXIS

A comprehensive strategy to prevent HBV infection, both acute hepatitis B and the sequelae of chronic HBV infection, must eliminate transmission that occurs during infancy and childhood, as well as during adolescence and adulthood. Transmission of HBV cannot be prevented by vaccinating only the groups at highest risk for infection. Routine visits for prenatal and well-child care can be used to target hepatitis B prevention (Table 169–3). A comprehensive immunization strategy to prevent transmission of HBV is recommended by the Centers for Disease Control and Prevention (CDC). This strategy has a number of parts as detailed in Table 169–1.

Two types of products are available for prophylaxis against HBV infection. HBIG provides temporary (3 to 6 months) protection by means of passive immunity and is indicated only in certain postexposure settings. Hepatitis B vaccine evokes active immunity against HBV and is recommended for both preexposure and postexposure prophylaxis.

HEPATITIS B IMMUNOGLOBULIN

HBIG is prepared from plasma known to contain a high titer of anti-HBs. The human plasma from which HBIG is prepared is screened for antibodies to HIV, and the process used to prepare HBIG inactivates and eliminates HIV from the final product; no evidence has been found that HIV can be transmitted by HBIG. HBIG is used for the postexposure prophylaxis of newborns of HBV-infected women and for susceptible individuals with sexual, needle-stick, or mucosal exposure. It is administered intramuscularly. The dose for infants with perinatal HBV exposure is 0.5 mL. The dose for adults is 0.06 mL/kg body weight. Efficacy ranges from 70 to 95 percent.[5] HBIG in large doses is used after liver transplantation in HBV-infected patients to prevent infection of the allograft.

HEPATITIS B VACCINE

Hepatitis B vaccines are available as a single-antigen formulation or in combination with other vaccines. The two licensed single-antigen recombinant vaccines are produced by using *Saccharomyces cerevisiae* (common baker's yeast), into which a plasmid containing the gene for HBsAg has been inserted. Purified HBsAg is obtained by lysis of the yeast cells and separation of HBsAg by biochemical and biophysical techniques. Hepatitis B vaccines are packaged to contain 10 to 40 μg of HBsAg protein per milliliter after adsorption to aluminum hydroxide (0.5 mg/mL). The two vaccines available in the United States are Recombivax HB (Merck and Company, Inc, Whitehouse Station, NJ) and Energix-B (GlaxoSmithKline Beecham Biologicals, Rixensart, Belgium). Recombinant HBsAg also is used in the three combination vaccines available in the United States: Comvax (Merck), Pediarix (GlaxoSmithKline Beecham), and Twinrix (GlaxoSmithKline Beecham). Immunogenicity is similar for single-antigen and combined hepatitis B vaccines.

The recommended series of three intramuscular doses of HBV vaccine induces a protective antibody response (anti-HBs) in more than 90 percent of healthy adults and in more than 95 percent of infants, children, and adolescents. HBV vaccine should be administered into the deltoid muscles of adults and children or the anterolateral thigh muscles of neonates and infants; immunogenicity is substantially lower when injections are administered into the buttocks. When HBV vaccine is administered to infants at the same time as other vaccines, separate sites in the anterolateral part of the thigh may be used for the multiple injections.

The vaccination schedule used most often for adults and children has been three intramuscular injections, the second and third administered 1 and 6 months, respectively, after the first. Each of the two available vaccines has been evaluated to determine the age-specific dose at which an optimal antibody response is achieved.

Perinatal transmission of HBV can be prevented effectively if the HBsAg-positive mother is identified and if her infant receives appropriate immunoprophylaxis. Administration of HBIG and the first dose of HBV vaccine within 12 hours of birth prevents the development of 90 percent of perinatal infections.[88] Serologic testing of infants who receive immunoprophylaxis to prevent perinatal infection should be performed to identify the 5 percent of infants who become HBV carriers despite these measures. Testing for anti-HBs and HBsAg in children 12 to 15 months of age determines the success of vaccination and, in the case of failure, identifies HBV carriers or infants who may require treatment or re-vaccination. The following are the current recommendations on timing of immunizations for infants in the United States.[128]

1. **Infants born to HBsAg-negative mothers** should receive the first single-antigen vaccine dose at birth or before hospital discharge. The plan thereafter depends on whether a single-antigen or combination vaccine is used. For single-antigen vaccine, the second dose should be administered at 1 to 2 months of age and the third at 6 to 18 months. If combination vaccines are used, the first dose should be of a single-antigen vaccine at birth or before hospital discharge. The second dose should be at 2 months, the third at 4 months, and a fourth dose at either 6 months or 12 to 15 months, depending on the combination of vaccines used. Testing for serologic response is not necessary and is not recommended.
2. **Infants born to HBsAg-positive mothers** should receive 0.5 mL of HBIG and the first dose of single-antigen HBV vaccine within 12 hours of birth, administered intramuscularly at separate sites. The infant then can complete the immunization series with either single-antigen or combination vaccine. If single-antigen vaccine is used, the infant should receive the second dose at 1 to 2 months and the third when the child is at least 164 days (6 months) of age. If combination vaccine is used, the child should receive single-antigen vaccine and HBIG at birth and then combination vaccine at 2 months, 4 months, and either 6 months or 12 to 15 months, depending on the combination. Premature infants of HBV-infected women should receive vaccine in the same schedule; however, those weighing less than 2000 g at birth have a decreased response to hepatitis B vaccination before they reach 1 month of age. For such infants, the dose given at birth

TABLE 169–3 Prevention of Horizontal Transmission within the Home and School

Home

Coverage of all abrasions with dressings
Full participation by child in normal school life

should not be counted as the start of the vaccine series, and three additional doses of vaccine (for a total of four doses) should be administered beginning when the infant reaches 1 month of age.[128] Testing for serologic response (HBsAg and anti-HBs) should be done when the child is 12 to 15 months of age. If the anti-HBs response is inadequate (<10 mEq/L) and the child is HBsAg-negative, the child should be re-vaccinated. If the child's anti-HBs titers are greater than 10 mU/L and the child is HBsAg-negative, that child is immune and not infected. If the child is HBsAg-positive at 12 to 18 months of age, the child should be considered potentially chronically infected and monitored appropriately.

3. **Infants born to mothers whose HBsAg status is unknown** should receive the first dose of vaccine within 12 hours of birth. Meanwhile, a maternal blood sample should be sent for HBsAg testing. If positive, HBIG should be given as soon as possible (not later than when the infant is 1 week of age). The infant then should complete the routine vaccination schedule. If the baby is preterm and weighs less than 2000 g and the mother's HBsAg is not established within 12 hours of birth, the infant should receive HBIG and single-antigen HBV vaccine and then complete four doses of HBV vaccination in total.

Others Who Should Receive Hepatitis B Vaccine

All non-immunized children and adolescents younger than 19 years should begin HBV vaccination at any health care provider visit. For older children and adolescents aged 11 to 15 years, the routine three-dose schedule may be used, but a two-dose schedule of vaccination with the Recombivax HB vaccine also has been approved. The adult dose (1.0 mL/10 μg) is administered to the adolescent, and the second dose is given 4 to 6 months later. Short-term (2-year) follow-up in groups immunized by either schedule showed similar rates of anti-HBs decline. Of emphasis is that a lower dose of vaccine is used in the three-dose schedule, and if the original dose is not known, the full three-dose schedule should be administered.[25] Immunization also should be offered to high-risk groups until universal childhood immunization has created an immune adult population.

In a three-dose schedule, increasing the interval between administration of the first and second doses of HBV vaccine has little effect on immunogenicity or final antibody titer. The third dose confers optimal protection and acts as a booster dose. Longer intervals between the last two doses (4 to 12 months) result in higher final titers of anti-HBs antibody. Larger vaccine doses, 40 μg, or an increased number of doses is required to induce protective antibody in many hemodialysis patients and other immunocompromised persons (e.g., those who take immunosuppressive drugs or who are infected with HIV). Children with end-stage renal disease respond better than adults do to HBV immunization. Ninety percent of pediatric chronic dialysis patients and 100 percent of children vaccinated before beginning hemodialysis became anti-HBs–positive in one study.[59] An immunocompromised person who previously has shown an adequate anti-HBs antibody titer that then falls to less than 10 mIU/mL should receive a booster dose.

Testing for immunity (anti-HBs titers) is advised only for patients whose subsequent clinical management depends on knowledge of their immune status (e.g., infants born to HBsAg-positive mothers, hemodialysis patients and staff, patients with HIV infection). Post-vaccination testing also should be considered for those at occupational risk who may have exposure from injuries with sharp instruments because knowledge of their antibody response helps determine appropriate postexposure prophylaxis.

When re-vaccinated, 15 to 25 percent of people who do not respond to the primary vaccine series produce an adequate antibody response after one additional dose, and 30 to 50 percent do so after receiving three additional doses.[86] Therefore, re-vaccination should be considered for people who do not respond to the initial series.

The duration of vaccine-induced immunity has been evaluated in long-term follow-up studies of both adults and children. The duration of response from neonatal or later immunization remains unclear, but studies in both Asian and European children vaccinated in infancy demonstrated that immune memory persisted at least 10 years in Italy[199] and 12 years in Hong Kong[198] but started to wane by 15 years after immunization in Taiwanese children.[123] Booster doses were administered to children in the latter study with anti-HBs titers less than 100, and 4 of 128 children demonstrated no response.[123] A previous study from the same group demonstrated excellent response in all subjects to a booster dose at 10 years of age in those who were anti-HBs–seronegative despite receiving neonatal vaccination after being born to HBsAg- and HBeAg-positive mothers.[79] The timing and necessity of a booster dose remain unclear, and hence the booster dose is not recommended on a population basis.[89]

Therapeutic vaccination, that is, immunization of those already infected in an effort to boost their HBV-specific T-cell responses, has shown some modest success in adults. However, a trial of combination immunization (pre-S2/S vaccine) with IFN-α-2b versus IFN-α-2b alone in children with chronic HBV infection did not show any benefit over IFN-α-2b alone.[74]

Vaccine Side Effects and Adverse Reactions

Hepatitis B vaccines have been shown to be safe for both adults and children. Anaphylaxis is the only serious adverse event in children and adolescents, with an observed risk of 1.1 per million vaccine doses administered reported in 2003.[14] Pain at the injection site (3-29%) and a temperature greater than 37.7° C (1-6%) have been the side effects reported most frequently, but they were reported no more frequently in vaccinees than in subjects receiving placebo.[24,180] In the United States, surveillance of adverse reactions has shown a possible association between Guillain-Barré syndrome (GBS) and receipt of the first dose of plasma-derived HBV vaccine in adults (CDC, unpublished data), and hence, plasma-derived HBV vaccine no longer is in use. An expert review did not accept or reject a causal association between hepatitis B vaccination and GBS,[24] and few cases of GBS have been reported in recent years.

Reports of multiple sclerosis (MS) developing after vaccination for HBV led to concern that the vaccine might cause MS in previously healthy subjects. This theory was refuted in a nested control study of two large cohorts of nurses in the United States in which the HBV immunization histories of each of 192 women in whom MS developed were compared with those of 5 healthy controls and 1 woman with breast cancer. No association was found.[4] In a case crossover study using the European MS database, recent vaccination against HBV, tetanus, or influenza did not appear to increase the short-term risk for relapse in MS.[40]

Until 1999, hepatitis B vaccines were prepared with thimerosal, sodium ethylmercuric thiosalicylate, to prevent bacterial and fungal contamination. This preservative has aroused great public concern regarding mercury toxicity and the amount of mercury exposure relative to body weight. No adverse outcomes have been associated clearly with thimerosal use. HBV vaccination in newborns was suspended temporarily in 1999 until thimerosal-free vaccines became available, unless the mother was infected with HBV. Two thimerosal-free HBV vaccines are available now in the United States for use in infants. Hence, parents can be reassured about the lack of exposure to mercury in HBV vaccines.

Contraindications

Only a few clinical situations exist in which hepatitis B vaccine is not recommended: those with a history of anaphylaxis to hepatitis

TABLE 169–4 Recommended Physician Visits for Children with Chronic Hepatitis B Virus Infections

Every 6 months
History taking
Physical examination, including growth
Blood work: AST/ALT, FBC, HBsAg, anti-HBs, HBeAg, anti-HBe
Review of risk factors for transmission
6 months to annual

Alpha-fetoprotein level (optimum frequency not yet clear)

ALT, alanine transaminase; AST, aspartate transaminase; FBC, full blood count; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen.

B vaccine and those with history of hypersensitivity to yeast. Vaccination should be deferred in those with an intercurrent acute infection with or without fever. Pregnancy is not a contraindication to immunization.[128]

RECOMMENDATIONS TO PREVENT HOUSEHOLD TRANSMISSION

When a person is found to have acute or chronic HBV, immunization of household contacts is recommended. Guidance on universal precautions should be provided. As outlined in Table 169–4, parents of infected children and siblings should learn to treat body fluids, especially blood, as potentially infectious. All bloody emissions and blood-soiled items should be handled with gloves, and any blood-stained items either should be cleaned with bleach or should be disposed of carefully. Both the infected person and others in the household should cover skin abrasions with waterproof bandages. Razors and toothbrushes never should be shared. If needle sharps are in use, they should be secured and disposed of according to local guidelines. Schools, workplaces, and health care providers should practice universal precautions for all individuals, regardless of whether their HBV status is known.

FUTURE STRATEGIES AND TARGETS FOR TREATMENT

As new technologies are developed, potential treatments of hepatitis B continue to emerge. They can be classified as (1) disruption of stages of the HBV life cycle other than HBV polymerase, (2) gene therapy, and (3) immunomodulators other than IFN-α.

Disruption of formation of the nucleocapsid by members of the heteroaryldihydropyrimidine class or phenylpropenamides has shown some efficacy in cell and mouse models.[122] Direct manipulation of the HBV gene offers the possibility of viral eradication with technology such as short interfering RNA (siRNA) molecules once technical problems such as how to introduce siRNA into hepatocytes and how to prevent degradation by enzymes have been overcome. However, proof of principle already has been demonstrated in mice. Short hairpin RNA, a form of RNA interference, homologous to HBV RNA was introduced into a cell culture model and into immunocompetent and deficient mice. Substantial reductions were achieved in mouse liver HBV RNA and replicated genome, as well as a 84.5 percent reduction in secreted HBsAg in mouse serum. HBcAg expression also was reduced.[130] siRNA against different regions of the HBV gene has been shown to decrease HBsAg secretion in a human hepatoblastoma cell line.[99] Another group has shown that this effect can persist through multiple cell passages, thus suggesting integration of siRNA into the HBV genome.[148] Other members of the IFN class, γ and λ, as well as cytokines, have shown some efficacy in either cell culture or animal models but have not been tried yet in humans.[122]

Despite advances in treatment, prevention of new infections must remain at the forefront of all therapeutic endeavors. Vertical transmission of HBV to children can be prevented by proper antenatal testing, careful follow-up of results, and availability of immunization programs to infants.

HEPATITIS D

Hepatitis D virus (HDV) is a subviral particle that requires a helper virus, HBV, to cause infection. As a subviral particle, HDV, which also is known as the delta agent or virus, does not encode its own envelope protein and requires HBV to produce its envelope to become an infectious virion. HDV was described first in 1977, when a new antigen was reported in the hepatocytes of patients infected with HBV. Transmission experiments demonstrated that the antigen was indeed a new virus.[149] Infection with HDV and HBV can be contracted at the same time (coinfection), or HDV infection can be contracted as a new infection in a person previously infected with HBV (superinfection). HDV has at least seven clades (or types),[145] which have geographic variation in both incidence and genotype distribution.[162] HDV genotype 1 is found worldwide, but HDV genotypes 2 and 4 are found in the Far East.[112] HDV genotype 1 infection appears to be associated with a more fulminant hepatitis in acute infection and higher rates of cirrhosis and HCC than noted with genotype 2.[193]

VIROLOGY

HDV is a spherical particle with a diameter of 36 nm.[133] When the envelope is degraded, a nucleocapsid containing hepatitis D antigen (HDAg) and the HDV RNA genome is released. The two forms of HDAg are the small s-HDAg, which is 195 amino acids in length and is required for replication, and the larger l-HDAg, which is 214 amino acids long, is required for virion assembly, and inhibits HDV replication.[133] s-HDAg is a nuclear protein that undergoes phosphorylation by protein kinase C, and inhibitors of protein kinase C inhibit HDV replication in cell culture systems.[36] The ratio of the two forms of HDAg found in patients may vary.

The HDV RNA genome is single stranded and circular, with a length of 1679 nucleotides. During viral replication, genomic RNA serves as a template for complementary RNA, which in turn is a template for more genomic RNA. A host-derived RNA polymerase is required.[183] Each copy of the genome and antigenome contains ribozyme activity that cleaves RNA and is required for replication ofHDV.[133] Post-transcriptional modification of the RNA leads to the production of l-HDAg, in addition to the s-HDAg already transcribed.[36,183]

To leave the host cell, HDV RNA and HDAg must be packaged into virions. l-HDAg undergoes isoprenylation of a cysteine residue near its C-terminal to allow assembly of the virion. Inhibition of this isoprenylation step interferes with viral production by preventing interaction with HBsAg.[36] Once this interaction occurs, HBsAg and host-cell membrane lipids enclose HVD RNA, l-HDAg, and s-HDAg to form a virion. Non-infectious HDV particles, which contain only l-HDAg and HBsAg, can be found in serum.[133]

EPIDEMIOLOGY

The epidemiology of HDV parallels that of HBV, for obvious reasons. Modes of transmission of HDV also are similar to those

for HBV and include direct or indirect parenteral exposure to blood or body fluids and sexual and perinatal transmission. Sexual transmission of HDV is less efficient than that of HBV, as evidenced by the relatively low frequency of HDV in homosexual men.[158] Perinatal transmission can occur but is rare because HBV carrier mothers also infected with HDV usually are anti-HBe–positive and thus less infectious. Intrafamilial transmission of HDV has been demonstrated in endemic areas, such as southern Italy, by means of a combined epidemiologic and molecular study, which demonstrated that within family units, the HDV strains were nearly identical.[136] Transmission of HDV infection also has been documented in some residents of institutions for the developmentally disabled.

Geographic differences in HDV endemicity in the world are great, and four levels have been characterized. Highest endemicity (HDV found in more than 20% of asymptomatic HBV carriers, more than 60% of HBV carriers with chronic liver disease) is seen in northern South America and Africa, as well as in Romania.[202] In these populations, HDV superinfection in HBV carriers is a significant cause of chronic liver disease and has resulted in outbreaks of fulminant hepatitis. In these areas, HDV infection is seen commonly in both children and adults, and intrahousehold transmission has been implicated. Parts of the Middle East, Africa, some Pacific Islands, and parts of Asia report intermediate HDV endemicity (10%-20% of asymptomatic HBV carriers, 30%-60% of HBV carriers with chronic liver disease). Infection in these regions occurs predominantly in adults, and outbreaks are uncommon occurrences, but HDV is an important cause of chronic liver disease. Low endemicity (3-9% of asymptomatic HBV carriers, 10-25% of HBV carriers with chronic liver disease) is observed in most developed countries, including the United States, but subpopulations in these countries, such as parenteral drug abusers and prostitutes, have a high infection rate. In areas of low HBV endemicity, transmission of HDV appears to be mainly by the percutaneous route, with higher rates of HDV found in intravenous drug users and hemophiliacs than in other HBV high-risk groups. HDV is considered only a moderately important cause of chronic liver disease in developed countries.[191] Finally, for as yet unexplained reasons, certain subpopulations have a high carriage rate of HBV, but virtually no HDV infection; such groups include Native Americans, Eskimos, and residents of some Asian countries.

Within the blood donor population of the United States, the prevalence of HDV is low; only 1.4 to 8 percent of donors are infected or have evidence of previous infection.[3] Estimates from the CDC for 1990 indicate that among the approximately 250,000 cases of acute HBV infection per annum, HDV infection is acquired simultaneously in 7500. An estimated 70,000 carriers of HDV are found in the United States, where approximately 1000 deaths per year are caused by chronic HDV and 35 by fulminant HDV. In certain regions, the prevalence of HDV infection appears to be decreasing. In Italy, the prevalence of HDV infection in patients who are HBsAg carriers decreased from 23 percent in 1987 to 14 percent in 1992 and to 8.3 percent in 1997.[61,155] Corresponding data for the United States are not available.

IMMUNOPATHOGENESIS

Unlike HBV, HDAg is found only in the liver or serum.[63] The mechanism by which HDV infection leads to hepatic injury has not been elucidated. Despite some evidence that HDV can be directly cytopathic, cytopathic viruses seldom result in chronic infection. In addition, some HDV carriers have no evidence of hepatic cell damage. Both cellular and humoral components of the host immune system are involved in the response to HDV, although the relative contribution of each is controversial. Investigations into the humoral response to HDV demonstrated that HDAg contains epitopes or immunogenic domains to which sera from acutely infected humans and woodchucks react. The predominantly recognized epitopes are not exposed on the virion surface; thus, antibodies that recognize these epitopes cannot neutralize virus particles, which may explain why no association exists between the humoral response and clinical outcome.[133] Autoantibodies, especially liver-kidney microsomal type 3 antibodies and anti–basal cell layer antibody, are found occasionally in people with HDV infection. The significance of these antibodies is unclear, but they may play a role in some of the immunopathogenesis of HDV.

Cellular immune responses to HDV also have been demonstrated. $CD4^+$ and $CD8^+$ lymphocytes have been found in the liver of patients infected with HDV. These cells may either contribute to hepatitis or aid in control of HDV infection.[133] Studies have shown that patients with HDV superinfection of chronic HBV who had peripheral $CD4^+$ cells that reacted to four epitopes on HDAg were seronegative for HDV IgM, thus implying inactive disease.[136] Such $CD4^+$ T-cell clones produce IFN-γ and may be directly cytopathic. Individuals without these specific $CD4^+$ cells had active HDV disease.[137] These epitopes are in highly conserved regions of HDV, which is encouraging for the prospect of vaccine development.

An unusual mechanism of HDAg presentation by hepatocytes has been reported. Processing of HDAg peptide appears to occur outside the cell, where the peptide is cleaved into smaller fragments that bind to the class II MHC molecules of all three HLA types found on hepatocytes and mononuclear cells. This form of antigen presentation could have many possible effects on T-cell responses: amplification of the T-cell response to HDAg, stimulation of CTLs to kill uninfected hepatocytes, or exhaustion of T-cell responses to HDAg, which allows infected cells to escape detection.[133]

The relationship of HBV infection status to the pathogenesis of HDV also is unclear. In patients with active HBV replication (i.e., HBV DNA– and HBeAg-seropositive), HDV viremia is high.[149,150] Conversely, in HBV and HDV carriers without liver disease or with minimal inflammatory hepatic lesions, markers of HBV replication are absent, and HDV viremia is low.[15,150] In co-infected liver transplant recipients, HDV reinfection can occur without evidence of active HBV replication, but necroinflammatory activity does not develop until HBV infection is reactivated.[44]

DIAGNOSIS

Establishing the diagnosis of either acute or chronic HBV infection is a prerequisite for the diagnosis of HDV infection, which is made by detection of antibody to HDV (anti-HDV). HDV antigen can be measured in serum, but usually it is present only transiently during acute infection and in immunosuppressed individuals.[112] Assays for both IgM and IgG anti-HDV are available. HDV RNA can be detected by reverse transcription and real-time PCR, but these tests are not available commercially.[112]

HDV infection may occur at the same time as HBV infection does, a pattern that is termed co-infection. If it occurs and the individual has acute, resolving hepatitis B, the HDV infection also will resolve.[46] In this instance, anti-HDV is found in the IgM form during the acute illness and persists for 2 to 6 weeks. Subsequently, IgG anti-HDV is found in serum, but it also diminishes to undetectable levels when the HBV infection resolves (Fig. 169–6). In HDV superinfection of an individual chronically infected with HBV, both IgM and IgG anti-HDV are detected. Most often, superinfection with HDV leads to chronic HDV infection, which is diagnosed by persistence of both IgM and IgG anti-HDV (Fig. 169–7). Anti-HDV becomes predominantly IgG

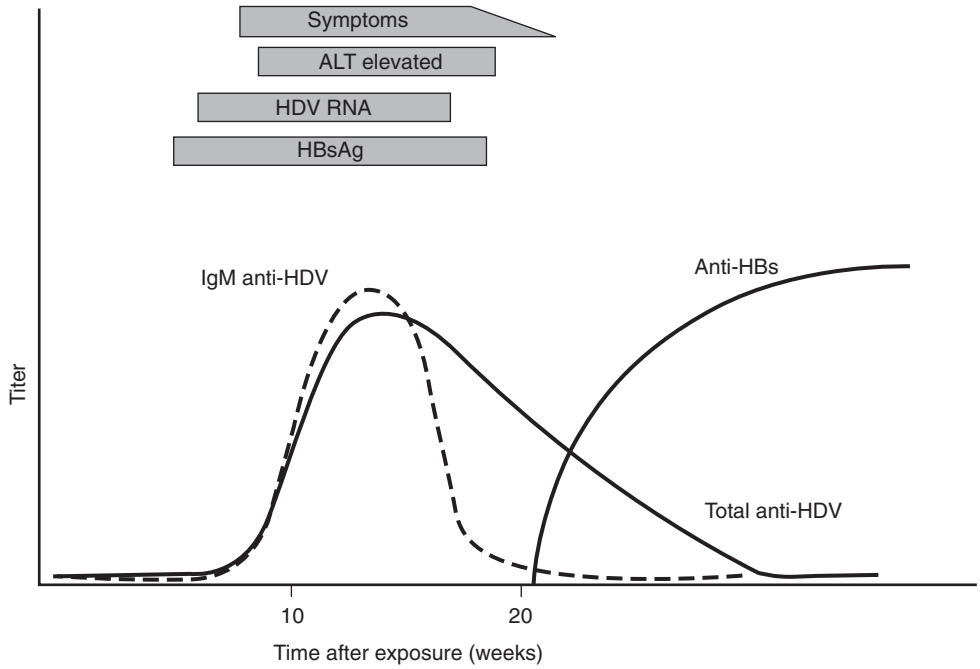

Figure 169–6 Serologic events during hepatitis B virus (HBV) and hepatitis D virus (HDV) co-infection that resolves. After exposure to both viruses, hepatitis B surface antigen (HBsAg) and HDV RNA can be detected shortly before the onset of symptoms. Serum alanine transaminase (ALT) is elevated for the duration of detectable serum HDV RNA and HBsAg. Serum IgM anti-HDV rises when symptoms are present and falls as HDV infection resolves and the anti-HBs titer becomes elevated. When both infections have resolved, anti-HBs is detectable in serum, but total anti-HDV is very low.

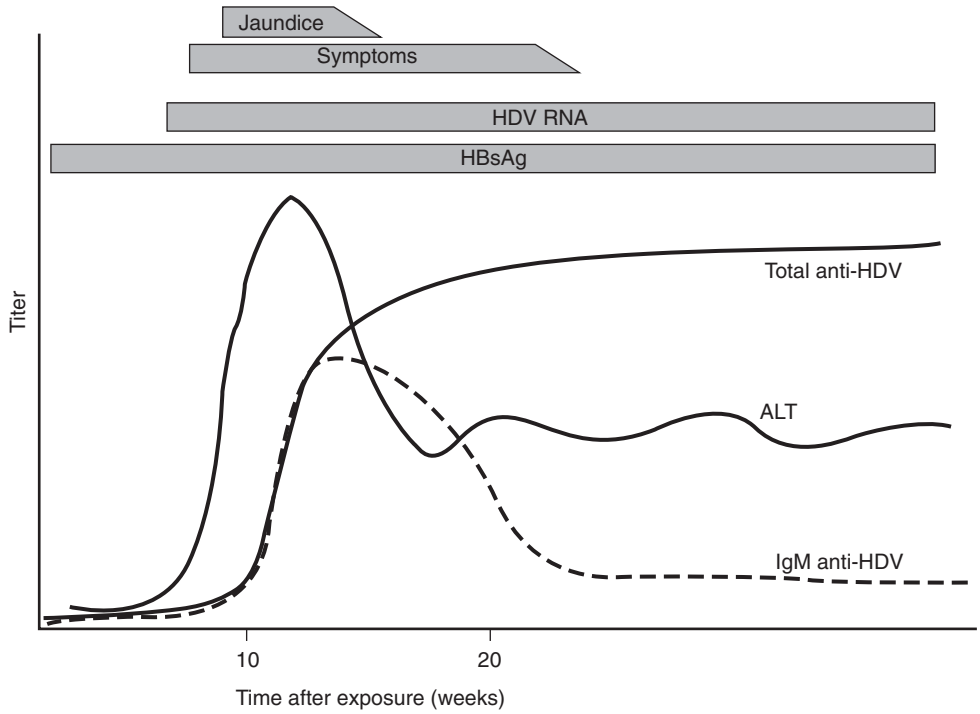

Figure 169–7 Serologic events during hepatitis B virus (HBV) and hepatitis D virus (HDV) superinfection. If an individual already infected with HBV is infected with HDV, there is a marked elevation of alanine transaminase (ALT) coincident with the onset of symptoms and the onset of jaundice. HDV RNA also can be detected at the onset of symptoms. ALT levels fluctuate over the next few months as IgM anti-HDV decreases and total anti-HDV rises. Throughout the course of HDV superinfection, hepatitis B surface antigen (HBsAg) remains detectable.

after approximately 6 weeks and persists if infection does not resolve; titers correlate well with ongoing viral replication.

The histopathologic features of HDV infection are very similar to those of isolated HBV infection (see earlier). HDAg can be identified in nuclei and, to a lesser extent, in the cytoplasm of infected hepatocytes.

CLINICAL FEATURES

In general, co-infection with HDV does not have clinical features that distinguish it from HBV infection alone. Symptoms develop 2 months after exposure, are similar to those of acute HBV infection, and usually resolve by 4 months after exposure. However, two peaks in transaminases often are noted, a pattern that is unusual in HBV infection alone. The infections resolve together.[47] Co-infection with both viruses does not increase the risk for development of chronic HBV infection.[121]

HDV superinfections in individuals with chronic HBV infection have different manifestations. HDV infection becomes persistent in most individuals (Fig. 169–8), and the predominant clinical pattern of chronic HDV infection varies by geographic location. In the United States and Europe, HDV superinfection leads to chronic liver disease in more than 90 percent of cases,

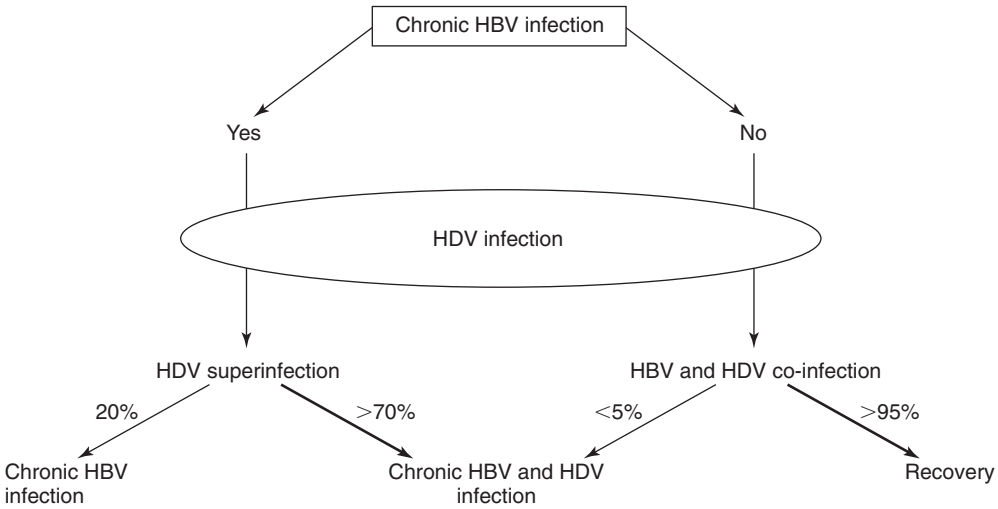

Figure 169–8 Outcomes of hepatitis B virus (HBV) and hepatitis D virus (HDV) superinfection and co-infection. When a person already infected with HBV becomes infected with HDV, there is a greater than 70 percent chance of becoming chronically infected with both HDV and HBV. In contrast, if a person acquires HBV and HDV de novo, there is less than a 5 percent chance of chronic HBV and HDV infection.

whereas in some Pacific Island and African populations, most individuals with chronic HDV are asymptomatic.[150] When chronic liver disease does occur, progression to cirrhosis occurs rapidly; in studies in both adults and children, cirrhosis has been noted to occur in as few as 2 to 10 years. The cirrhosis associated with HDV infection has two patterns: in a minority of patients, especially high-risk drug users, it progresses rapidly to hepatic failure and portal hypertension; in others, more stable cirrhosis occurs, with little inflammatory component and compatibility with prolonged survival.[18] In a small minority of those who are superinfected, a self-limited hepatitis develops, and subsequently both HBV and HDV infections are cleared. HDV infection has been demonstrated to lead to HCC at a younger age and at a higher rate than HBV infection alone does.[150] In a study of 166 patients infected with HBV and HDV from Romania, median survival after the diagnosis of HDV compensated cirrhosis was 58.3 months.[64] A multicenter European study of 200 HBsAg-positive white patients with compensated cirrhosis found that 39 (20%) were anti-HDV–positive. Those with HDV, HBV, and cirrhosis were younger than those with HBV and cirrhosis only; indeed, HDV infection may lead to the development of cirrhosis 15 years earlier.[55] In this study, the addition of HDV infection increased the risk of HCC developing threefold and risk of mortality twofold when compared with those with HBV and cirrhosis.[55] The natural history in those without cirrhosis is difficult to establish. In a study of 13 institutions for people with developmental disabilities in Illinois, 67 of 238 (28%) HBsAg carriers also had anti-HDV antibodies.[75] Long-term (20 years) follow-up information was available on 65 of 66 anti-HDV– and HBsAg-positive individuals and 166 HBsAg-positive persons. Liver-related deaths occurred in 7 of 65 (11%) anti-HDV–positive but only 1 of 166 anti-HDV–negative persons.[1] Hepatitis D infection was associated with both a higher rate of chronic liver disease and a higher liver-related mortality rate.[1]

Children with HDV infection follow a course similar to that of adults. In one European series, the subset of children chronically infected with HBV who also had HDV had more advanced liver disease, and the prevalence of HDV infection increased in parallel with the activity of hepatitis. During the study period, disease progressed more rapidly in children infected with both viruses.[54] Testing for HDV infection is recommended for any child with chronic HBV and unusually severe liver disease or an acute exacerbation of stable liver disease.

HDV infection after liver transplantation can appear without apparent HBV re-infection of either the graft or serum. However, use of PCR assay and buoyant density analysis has demonstrated that low levels of HBV infection in fact do occur in patients with recurrent HDV, and this replication of HBV is sufficient to permit replication of HDV. The HDV virion found in such infections shares the characteristics of typical HDV infection.[16]

TREATMENT

Although several antiviral agents have been studied, the only treatment that has had any beneficial effect on HDV infection is IFN-α. Trials in adults, in both Europe and the United States, have shown that treatment with either 9 million units three times weekly or 5 million units daily of IFN-α results in normalization of serum transaminase levels, decrease or disappearance of HDV RNA from serum, and improvement in hepatic inflammation in about 50 percent of cases.[54] However, most patients relapsed with hepatitis shortly after treatment was discontinued. Maintenance of response after treatment was noted primarily in individuals who became HBsAg-negative.

Pegylated IFN-α-2b as a treatment of chronic HDV has shown promise in two recently reported trials. Pegylated IFN-α-2b was well tolerated and had some efficacy. Fourteen patients were treated with pegylated IFN-α-2b, 1.5 μg/kg weekly for 12 months, and 6 (43%) had a sustained virologic response (undetectable HDV RNA) at 6 months.[22] Combination ribavirin and pegylated IFN-α-2b did not improve the virologic response over pegylated IFN-α-2b alone.[135] No factors predictive of response have been identified. Until the advent of pegylated IFN-α-2b, the prognosis in nonresponders to IFN-α and in those who relapse has been poor. The author of a recent editorial in *Hepatology* recommended continuation of IFN-α or pegylated IFN-α-2b in those with a decline in HDV RNA as long as possible or until HDV RNA and HBsAg disappear.[53]

Currently, no recommendations have been established regarding the use of IFN-α or pegylated IFN-α-2b for the treatment of chronic HDV infection in children. A trial in seven children in Greece treated with IFN-α, 3 million U/m^2 of body surface area three times a week for 1 year, had disappointing results. All remained anti-HDV IgM–positive, and four of seven had persistent HDV RNA in their serum. A significant reduction in serum transaminase values was noted after 1 year of treatment, but no significant improvement occurred in liver histology.[42] A study of eight children from Germany also found no effect of IFN-α on replication of HDV. However, serum transaminase values improved, and children underwent earlier anti-HBe seroconversion than historical controls did.[159] Lamivudine has been shown to have no effect on either HDV viremia or liver disease activity in chronic HDV infection.[146]

Some children and adults require liver transplantation for management of end-stage HDV-associated liver disease. Patients co-infected with HDV and HBV have lower rates of HBV infection of the allograft than do patients with isolated HBV infection. These data were reported in a series of 58 patients with HBV, 25 of whom also had HDV infection and underwent liver transplantation between 1984 and 1996 in Belgium. Fifty-two patients survived longer than 3 months, and median follow-up was 74 months. HDV infection improved survival rates at 5 years, 96 ± 4 percent versus 63 ± 10 percent for those infected with HBV alone.[113] As yet, no explanation has been given for the better outcome of transplantation in individuals who have both HBV and HDV infection. Administration of HBIG is required before and after transplantation, as in patients infected with HBV alone.

IMMUNOPROPHYLAXIS

Passive or active immunization specifically against HDV infection is not available. HDAg itself is highly immunogenic, but antibodies are not neutralizing. Description of a T-cell response to several HDV epitopes in individuals with less severe disease activity has stimulated speculation about possible vaccine development, but studies are preliminary. A DNA-based HDV vaccine successfully induced cellular responses in an animal model and also was successful when used with an HBV vaccine.[81] A trial of vaccine derived from B-cell epitopes of HDAg and HDAg p24 expressed in *Escherichia coli*, yeast, or baculovirus in woodchucks provoked a specific antibody response but did not protect against HDV superinfection.[58]

At the present time, individuals with chronic HBV infection, who are the same people at risk for acquiring HDV, cannot be protected from HDV except by avoidance of high-risk behavior and exposure. However, prevention of HBV infection in susceptible individuals will prevent HDV co-infection and will be the most important mechanism for decreasing the prevalence of HDV infection in a population. The current strategy aimed at decreasing susceptibility to HBV infection by universal immunization of newborns and catch-up immunization of older children and adolescents should reduce the risk for subsequent development of HDV infection substantially during young adulthood. In Italy, the decrease in HDV prevalence in those with chronic HBV infection from 23 percent in 1987 to 8.3 percent in 1997 has led to speculation that chronic HDV may be a "vanishing disease."[61]

SUBSECTION 5

Herpesviridae

CHAPTER 170

Herpes Simplex Viruses 1 and 2

Kathleen M. Gutierrez ✪ Ann M. Arvin

The family of nine human herpesviruses includes herpes simplex virus (HSV) types 1 and 2; cytomegalovirus (CMV); Epstein-Barr virus; varicella-zoster virus (VZV); and human herpesviruses (HHV) 6A, 6B, 7, and 8. This chapter deals with infections caused by HSV-1 and HSV-2 acquired after the neonatal period.

Herpes derives from the word meaning "to creep" in Greek. Initially, this term referred to cutaneous, spreading lesions in general and included the classic description of fever blisters recorded by Hippocrates and Herodotus. In the 1700s, Astrus described genital herpes lesions, and by the 1800s, the term *herpes* usually was restricted to poxvirus and herpesvirus lesions. Cultivation of HSV on rabbit cornea by Gruter (1912) differentiated HSV from VZV. Subsequent work differentiated the antigenic, biologic, and epidemiologic characteristics of HSV-1 and HSV-2.[333]

HSV-1 is the prototype of the alpha-herpesvirus subfamily, which includes HSV-2 and VZV.[235,333] These viruses share the characteristic of neurotropism and establish latency in sensory ganglia; persistence is associated with periodic reactivation and reappearance of infectious virus at mucocutaneous sites. Understanding HSV-1 and HSV-2 infections requires knowing that most infected individuals do not have any clinical manifestations, either at the time of initial acquisition or during episodes of reactivation. The next step is to recognize that when HSV-1 or HSV-2 causes disease, as opposed to HSV infection, the illness may range from minor, such as "fever blisters," to life-threatening, as exemplified by HSV encephalitis. As with all herpesviruses, the immune status of the host is an important determinant of disease severity, as is whether infection is primary or recurrent. Proper management of HSV-1 and HSV-2 infection depends on clinical recognition of the common and atypical syndromes caused by these viruses and knowledge of the laboratory methods that are useful for proving the diagnosis. Attention given to the clinical and laboratory diagnosis of HSV infection is important because oral antiviral treatment is safe and often benefits healthy children and early antiviral therapy reduces the risk of severe or fatal infections developing in immunocompromised patients. When misused, some therapies, such as corticosteroids for ocular HSV infection, may worsen the outcome. HSV-1 infections in children of all ages and HSV-2 infections in adolescents are among the most common treatable viral illnesses encountered in pediatric practice.

THE VIRUSES

HSV-1 and HSV-2 virions consist of an icosahedral protein capsid enclosing a core of double-stranded DNA, surrounded by a protein tegument, and enclosed in a lipid-containing envelope.[235] The genomic DNA of HSV-1 and HSV-2 has substantial sequence homology (approximately 50%), but the viruses also have unique sequences that encode variant proteins, and they differ biologically in their patterns of replication in vitro and in vivo. Tegument proteins are located between the capsid and the viral envelope. The envelope has glycoproteins that are important targets of the humoral and cellular immune responses (gB, gC, gD, and gG). The glycoproteins gE and gI function as immunoglobulin Fc receptors. Other glycoproteins include gH and gL, which form a complex that plays a role in cell entry and spread; gK, which is required for viral exocytosis; and gM, which has a role in capsid envelopment and exocytosis. These glycoproteins are found in both HSV-1 and HSV-2 and exhibit a high degree of amino acid similarity. The glycoprotein G of HSV-2 is larger than its HSV-1 homologue and has unique sites that are recognized by virus-specific host responses. Whereas both forms of HSV can infect either oral or genital sites, HSV-1 usually is a cause of infections of oral mucocutaneous sites (above the waist), and most genital mucocutaneous infections (below the waist) are caused by HSV-2.[92,333] HSV-1 is more likely to recur at oral sites and HSV-2 reactivates more frequently in the genital area, even in persons who were infected initially at both oral and genital sites with HSV-1 or HSV-2.[171]

HSV attaches to and penetrates cells via glycoproteins B and D by using specific cell surface herpes family co-receptors. This process also involves gH. The herpes family co-receptors belong to the tumor necrosis factor family (Hve-A), the immunoglobulin superfamily of receptors (nectins), and the 3-*O*-sulfated heparin sulfates.[235] After the virion enters the cell, an orderly expression of immediate early, or alpha, genes occurs that triggers viral gene transcription and inhibits host cell function; early, or beta, viral genes that encode regulatory proteins and DNA replication enzymes, including thymidine kinase and viral DNA polymerase; and finally, late, or gamma, genes that encode structural proteins. Replication of viral DNA and accumulation of structural proteins allow assembly of the virion capsid in the cell nucleus and envelopment by modified cellular membranes that are incorporated into the virion envelope during final virion envelopment and egress. Infectious virions are released from the infected cell or can spread to adjacent cells via membrane fusion.

Human HSV replicates in tissue culture cells derived from many mammalian species, as well as in embryonated hens' eggs and various laboratory animals, including rodents, rabbits, and primates. Lack of restriction of the host range in infectivity distinguishes HSV-1 and HSV-2 from the other human herpesviruses. HSV-1 and HSV-2 infections progress rapidly in cell culture and cause relatively characteristic focal cytopathologic effects; confirmation that these effects are caused by HSV can be accomplished by staining the infected cells with specific antisera or monoclonal antibodies that differentiate HSV-1 from HSV-2 and from other viral pathogens.

HSV isolates can be analyzed further by using the technique of DNA endonuclease restriction analysis, in which viral DNA is recovered from infected cells, digested enzymatically, and analyzed in gels to determine the pattern of DNA fragments resulting from enzymatic digestion. Epidemiologically unrelated HSV isolates can be differentiated by using multiple restriction enzymes to digest viral DNA, which reveals a unique "viral fingerprint."

Precise differentiation requires genomic sequencing. These methods are useful for molecular epidemiologic studies to confirm the relatedness of viruses recovered from different sites or at different times in the same individual or to document transmission to another individual, such as mother to infant or infant to infant in nurseries; this technique has shown that apparent "outbreaks" of encephalitis were instead random, unrelated case clusters.[47,129,185]

Like other herpesviruses, HSV-1 and HSV-2 have gene products that facilitate the avoidance of immune surveillance during primary infection, latency, and reactivation. These mechanisms include elaboration of virally encoded IgG Fc receptors and complement receptors that bind host immune components; down-regulation of major histocompatibility complex (MHC) class I antigen, which prevents recognition of infected cells by $CD8^+$ T cells; interference with up-regulation of MHC class II molecules by interferon-γ, which inhibits $CD4^+$ T-cell–mediated adaptive immune responses; and inhibition of the lytic activity of natural killer cells.

TRANSMISSION

Infectious HSV-1 and HSV-2 virions are released into the oral or genital secretions of infected but asymptomatic persons who are experiencing primary or recurrent infection. This phenomenon is referred to as *viral shedding* or *excretion* and results in periodic opportunities for the virus to be transferred to susceptible contacts. Though not widely understood, most HSV-1 and HSV-2 transmission is caused by these silent infections, which are common, and transmission occurs with equivalent frequency regardless of whether the individual who is shedding the virus has ever had symptoms of oral or genital herpes.

Although HSV-1 and HSV-2 are highly infectious after inoculation of mucocutaneous sites, they are not transmitted casually from person to person. The enveloped virions are relatively unstable outside mammalian cells, and close interpersonal contact generally is required for transfer of infectious virus particles. In most circumstances, transmission requires direct apposition of infected with uninfected mucous membranes or skin during intimate contact such as kissing or sexual contact. Outbreaks associated with gingivostomatitis have occurred at daycare centers.[262] If the uninfected, exposed skin or mucous membranes are damaged, the risk of transmission appears to be enhanced. Although skin is less susceptible to direct inoculation than the mucous membranes are, transmission via inoculation of skin may be increased by local trauma. For example, affected areas are more susceptible in burned patients[105] and infants with diaper rash, and children with eczema are at risk for contracting serious disseminated HSV infections (Kaposi varicelliform eruption).[331] Transfer of HSV-1 between wrestlers (herpes gladiatorum)[267] and between rugby players (herpes rugbeiorum or "scrum-pox")[269] probably takes place after the abrasion of saliva-contaminated skin. One outbreak at a wrestling camp involved 60 of 175 participants.[33,56] Health care workers may acquire HSV infections of the paronychial region (herpetic whitlow), presumably from direct contact of ungloved hands with oropharyngeal secretions.[112,237] Medical personnel may transfer HSV to their patients and be responsible for subsequent outbreaks of gingivostomatitis. Children may acquire HSV whitlow in the course of primary HSV-1 gingivostomatitis through nail biting or thumb sucking. When herpetic whitlow develops in persons who are not health care workers, HSV-2 is the most common cause and often is associated with primary genital HSV infection.[114] The usual route of transmission to newborns is by exposure during passage through an HSV-infected birth canal. Genital and anal HSV infections are transmitted through direct contact with infected genitalia or from oral-genital or oral-anal contact.

Newly acquired HSV-1 and HSV-2 infections are associated with shedding of very high titers of infectious virus, regardless of whether the individual is symptomatic. In addition, active recurrent HSV-1 or HSV-2 lesions contain substantial titers of virus, which may increase the likelihood of transmission occurring during close contact with a susceptible individual.

The incidence of acquisition is 5 to 15 percent per year in individuals who are HSV-1– and HSV-2–seronegative or HSV-1–seropositive but HSV-2–seronegative and whose sexual partners have recurrent genital herpes.[194,195] In studies of discordant couples, transmission occurred in 10 percent of partners, with higher transmission from men (17%) than from women (4%). In women lacking antibodies to HSV-1 and HSV-2, the rate of transmission was 32 percent; if they had antibodies to type 1, the rate was 9 percent.[194] Studies of patients by HSV-2–specific serology show that many individuals remain uninfected despite having long-term contact with a person who is infected with HSV-2.[167] The extent to which HSV-1 immunity protects against HSV-2 infection is not clear, but the evidence is that symptoms of new HSV-2 infection may be prevented if the exposed individual has HSV-1 immunity, whereas subclinical infection frequently is not blocked.[40,47]

Information about whether HSV-1 or HSV-2 acquired earlier interferes with the acquisition of infection by unrelated HSV-1 or HSV-2 strains is limited, but a few individuals with multiple sexual partners have been found to shed HSV-2 viruses that are genetically distinct. HSV has been isolated from the hands of patients with oral lesions and has been shown to persist for several hours on inanimate objects or in distilled water. Nonetheless, inanimate sources have not been implicated as important reservoirs of HSV persistence and spread.[209,310] HSV transmission from transplanted organs[93] and inseminated donor sperm has been reported.[198]

When HSV-1 and HSV-2 shedding has been evaluated prospectively in seropositive individuals with or without a history of symptoms, the usual frequency of detection of virus in oral or genital secretions is approximately 1 to 2 percent.[12,333] Rates of asymptomatic shedding may be higher after recent reactivation in individuals with symptomatic recurrences. In patients with known genital herpes, silent excretion has been documented as often as 10 percent of the time when they appear to be lesion-free. Twelve percent of women with primary HSV-1 genital infection and 18 percent with primary genital HSV-2 infection subsequently shed virus asymptomatically, especially in the first 3 months after resolution of the primary infection.[156] Two percent of women attending a sexually transmitted disease clinic shed HSV-2 asymptomatically.[165] In partner studies, 70 percent of HSV-2 transmissions were associated with sexual contact during periods of asymptomatic viral shedding.[195]

Polymerase chain reaction (PCR) is considerably more sensitive than is culture for detection of HSV on mucosal surfaces.[319] The use of PCR technology has improved understanding of the extent of HSV viral shedding. PCR detects subclinical shedding of HSV-2 on 20 to 25 percent of days. Factors that influence the magnitude and frequency of shedding include the site of infection, immune status of the patient, and time of acquisition of the virus.[242] Previous studies using viral cultures rarely reported isolation of HSV-2 from the mouth, but recent quantitative PCR studies detected asymptomatic oral HSV-2 reactivation from 40 percent of men with HSV-2 genital herpes. Oral HSV-2 shedding frequently is concurrent with genital HSV-2 shedding.[151]

Investigation of HSV-1 transmission is less extensive, but the high prevalence of asymptomatic HSV-1 infection in the population and its acquisition in early childhood suggest a similar pattern of spread by exposure to virus present in oral secretions from asymptomatic individuals.

EPIDEMIOLOGY

Understanding HSV epidemiology requires distinguishing between the prevalence of infection, which is high, and the frequency of HSV-related disease, which is low. HSV-1 and HSV-2 are infectious for the human host only under usual, natural circumstances. Molecular genetic analysis indicates that the HSV genome has evolved in parallel with the evolution of *Homo sapiens* from primate ancestors. These viruses maintain their persistence in the human population through their capacity to persist and reactivate in the individual host. The prevalence of HSV-1 and HSV-2 is a consequence of efficient transmission to susceptible close contacts and the continuous presence of a large pool of infected persons in the population. Because HSV-1 and HSV-2 are not cleared after primary infection but instead establish latency and reactivate frequently in an infected host, opportunities for viral spread to new susceptible persons are extremely common. HSV-1 and HSV-2 infections are ubiquitous and global in their distribution. Seroepidemiologic studies have shown that HSV infections are found in all human populations, even in the most remote and isolated communities. HSV-1 and HSV-2 have no seasonal pattern because the mechanism of transmission is by intimate contact, which occurs year-round. Individuals who have been infected with HSV-1 or HSV-2 remain a reservoir for infectious virus throughout their lifetimes and, as intermittent shedders, are a source of virus for spread to susceptible contacts. Most transmission is from asymptomatic infection, and most acquisition is asymptomatic. For example, the rate of subclinical shedding of HSV-2 in individuals with no reported history of genital herpes was similar to that in subjects with such a history (3.0% vs. 2.7%).[325] Shedding of HSV-1 in oral secretions is equally prevalent.

When symptoms of a new HSV-1 infection do occur, the source of the infection rarely is identified because the susceptible individual usually has many infected contacts. Furthermore, the first symptomatic episodes of HSV-1 or HSV-2 often represent reactivations of earlier infections.

The average age at acquisition and the prevalence of HSV-1 and HSV-2 infection are influenced by the virus type. Although neonatal HSV infections are acquired from maternal genital infection and most often are caused by HSV-2, HSV-1 acquisition predominates in childhood. Depending on social and economic factors, 40 to 60 percent of young children are seropositive by the time they reach 5 years of age, with somewhat higher rates of acquisition in lower socioeconomic groups. Earlier acquisition of HSV-1 may be influenced particularly by whether the mother, or other major caregivers, has HSV-1 infection. Attendance at child care centers, which brings children together in close contact, may increase the likelihood of acquiring HSV-1 at an earlier age.[169,262] Acquisition of HSV-1 continues with age at an average rate of 1 to 2 percent per year throughout the childhood and adult years; by later ages, 70 to 90 percent of individuals have been infected by HSV-1.[275] Seroepidemiologic studies of higher socioeconomic groups have reported HSV-1 infection in 30 to 46 percent of university students.[111]

The prevalence of HSV-2 is highly variable and depends on the country, region, sex, age, population subgroup, and whether a population is "high risk."[273] Because transmission of HSV-2 is associated with sexual activity, the prevalence of HSV-2 begins to increase with adolescence. Now that serologic methods can be used to differentiate HSV-1 and HSV-2 infection, the seroprevalence of HSV-2 in adults has been shown to range from 20 to 80 percent. The comprehensive investigation of HSV-2 epidemiology in the United States by the National Health and Nutrition Examination Survey (NHANES) documented a 30 percent increase in prevalence from the 1970s to the 1990s, which has resulted in HSV-2 infection in approximately 20 percent of adults.[55,104] An increasing frequency of HSV-2 infection was observed at all ages above 12 years, including teenagers of all ethnicities, and its prevalence rose fivefold in white teenagers. High HSV-2 infection rates are documented in higher as well as lower socioeconomic groups.[40,165,167,297] Rates are consistently higher in women than in men, regardless of other variables, and in individuals with more sexual partners.

Changes in the epidemiology of symptomatic HSV-2 infection have been suggested by rising numbers of medical visits for genital herpes. Approximately 300,000 new cases occur each year in the United States. The extent to which the increase in symptomatic cases of HSV-2 infection reflects a true increase in the prevalence of HSV-2 or a higher likelihood that HSV-2 infection will result in symptoms is not certain; for example, a decrease in the number of young adults with HSV-1 infection acquired in childhood could be associated with loss of cross-reactive HSV immunity and an increased risk for the development of symptomatic genital herpes. A higher risk of contracting genital HSV-2 infection is associated with lower socioeconomic status, early age at first intercourse, increased numbers of sexual partners, female sex, previous marriage, urban living, black race, and incidents of trichomoniasis, bacterial vaginosis, and other sexually transmitted diseases.[104,119,146]

A retrospective analysis of genital HSV cultures obtained from a group of college students over the course of a 9-year period showed that HSV-1 is an increasingly common cause of genital herpes in some populations in the United States. In this particular population, HSV-1 accounted for more than 70 percent of positive genital cultures by the end of the study period, as compared with approximately 30 percent at the beginning.[233]

Symptomatic disease occurs in a minority of individuals after newly acquired infection at an estimated incidence of 10 to 20 percent or less. However, silent infections can give rise to symptoms that appear months or years later as a result of viral reactivation. The epidemiology of HSV-1 or HSV-2 reactivation as a cause of symptomatic illness depends on the prevalence of these infections in the population as a whole, but it also is influenced by host factors that perturb the balance between the virus and the infected individual. For example, HSV-related symptoms may be triggered by exposure to sunlight (ultraviolet), febrile illnesses, immunosuppression from illness or necessary therapies, and other variables. These variables are cofactors that affect the frequency of HSV-related disease within the infected cohort but not the epidemiologic pattern of infection.

PATHOGENESIS AND PATHOLOGY

HSV-1 and HSV-2 exhibit particular tropism for cells of ectodermal origin, including skin and neuronal cells. Initial viral replication is thought to occur at the portal of entry, usually in mucous membranes or skin. In symptomatic cases, the incubation period for primary infection appears to vary from 2 to 20 days. In contrast to varicella, HSV viremia is difficult to detect by culture in a normal host, although it may be found in some immunocompromised patients.[127,285] HSV DNA in plasma and peripheral blood mononuclear cells in HSV-infected neonates has been detected with PCR techniques.[86] If mucocutaneous lesions are induced during primary or recurrent infection, the pathologic cell changes caused by HSV-1 or HSV-2 replication include cytoplasmic enlargement and nuclear alterations; in addition, cell fusion may lead to the formation of multinucleated giant cells. The nuclei of infected cells often have eosinophilic intranuclear inclusions and marginated nuclear chromatin. As the cells manifest injury, a local inflammatory response ensues, intercellular edema develops, and vesicles form in the affected area. The vesicles become visible as they enlarge and usually are surrounded by an erythematous margin. At later stages, the vesicles become pustular and then dry and crust. HSV lesions typically are super-

ficial and do not scar. Vesicles that form on mucous membranes are transient, with rapid sloughing of the superficial layer, and they generally are seen first as shallow ulcers.

HSV-1 and HSV-2 have a characteristic ability to establish latency in neurons of the sensory ganglia by mechanisms that as yet are unidentified. The viruses persist in this latent state for various intervals; reactivation induces viral replication with the production of infectious virus at mucosal or other sites. Evidence related to a possible neural site for latent HSV was presented nearly 80 years ago when Cushing reported the appearance of herpetic vesicles in the trigeminal distribution after rhizotomy of the trigeminal nerve and destruction of the sensory ganglion.[217,333] Persons who have recurrent HSV infections frequently describe tingling sensations, itching, and burning at the site of recurrence beginning several hours before the appearance of clusters of vesicles. Persons who have recurrent genital herpes may experience severe shooting pain in their legs and even urinary retention before and in connection with recurrent genital herpes infections. Occasionally, recurrent HSV skin eruptions may occur in a zosteriform pattern and in a distribution reflecting the sensory innervation of a particular dermatome.

Replication at the portal of entry appears to result in infection of sensory nerve endings, followed by transport of the virus to the dorsal root ganglia along neuronal axons. Latency is established regardless of whether the primary infection is symptomatic, and it appears to be an invariable consequence of HSV infection with either virus type.[26,234,235] HSV-1 and HSV-2 persist in neuronal cells of the sensory ganglia, with substantial numbers of these cells harboring latent virus, as demonstrated by the detection of latency-associated transcripts. The latency-associated transcripts overlap the viral genes *ICPO* and *ICP34.5* in an antisense direction.[73,235,287] The role of these transcripts in the establishment or maintenance of latency remains to be clarified. The presence of latency-associated transcripts appears to be necessary for efficient reactivation of viral production in vivo.[219] Viral particles are not produced in latently infected cells. HSV-1 persists most predominantly in the cranial nerve ganglia, whereas HSV-2 latency occurs in the lumbosacral ganglia. Co-cultivation techniques have been used to recover HSV from the dorsal root ganglia innervating the areas of skin in which persons have experienced recurrent herpes lesions. HSV-1 has been found in trigeminal ganglia, and HSV-2 has been recovered from sacral ganglia.[28] Once latency is established in the sensory ganglia, antiviral drugs cannot eradicate the latent virus from infected neurons. Because the latent virus does not multiply, it is not susceptible to drugs that affect viral DNA synthesis, such as acyclovir. When reactivation is triggered, HSV-1 or HSV-2 is transported back down axons to mucocutaneous sites, where they replicate and release infectious virus into secretions.[26,73,234,235] Individuals with symptomatic recurrent HSV infections almost always have HSV lesions in the identical or a directly adjacent site. Reactivation is not prevented by adaptive immunity, although whether symptoms occur may be influenced by the host response.

The stimulus for reactivation of latent virus may be provided by iatrogenic or naturally occurring episodes of immunosuppression and by endocrine (such as menstruation) or exogenous factors (such as trauma, sun, acupuncture, emotional stress). Ultraviolet irradiation of persons who have a history of recurrent oral herpes reliably induces recurrence either quickly (within 48 hours) or 2 to 7 days later.[276] Skin subject to recurrent HSV infection has been transplanted elsewhere on the body and exchanged with skin taken from the site of graft placement and previously not involved in HSV infections. Subsequent recurrence of HSV infection was found to be localized to the original site, not to the original skin. These studies and others strongly suggest that latent virus does not reside in skin cells.

Primary HSV infection elicits humoral and cellular immunity, which can be detected shortly after the appearance of lesions in individuals in whom symptoms develop. Based on animal models and some human studies, the initial host response is mediated by innate, nonspecific mechanisms, followed by the acquisition of virus-specific adaptive immunity.[157] The nonspecific response consists of mobilization of polymorphonuclear leukocytes and monocytes to the site of infection, release of interferon-α and other cytokines, and activation of macrophages and natural killer cells. The innate response is followed by the production of antiviral antibodies that can be detected 2 to 12 weeks after infection occurs. HSV-specific antibodies mediate neutralization of virus, complement fixation, and cellular or complement cytotoxicity. Induction of specific cellular immunity is detected by measuring T-cell recognition of HSV proteins in proliferation and cytotoxicity assays, production of interleukin-2 and interferon-γ, and a positive delayed hypersensitivity skin test reaction. Failure of virus-specific, cell-mediated immunity to develop, as may occur in newborns and children with genetic immunodeficiencies, immunocompromised children, and other high-risk populations, can be associated with life-threatening dissemination of HSV-1 or HSV-2. If HSV disseminates, these viruses can infect and destroy cells in many organs (e.g., the lungs, liver, adrenals, and brain), with catastrophic effects.

Recently, a small group of immune-seronegative individuals with HSV-specific T-cell responses have been described. None of these individuals had clinical symptoms of oral or genital HSV. All had exposure to HSV-2–positive sexual partners, but HSV was never isolated by culture or PCR from these exposed individuals, even after extensive sampling over a prolonged period.[222] Studies to determine whether genetic immunologic determinants of disease or mutations in HSV entry receptors alter susceptibility to HSV infection are in progress.[294]

Symptomatic HSV-1 and HSV-2 recurrences are less severe than are primary lesions in immunologically intact persons. In persons previously infected with one type of virus (e.g., HSV-1), new infections with the second type (e.g., HSV-2) more often are silent, or the symptoms are less severe than in a host who has never been infected with either virus. When re-infection with unrelated strains has been identified, symptoms also have been mild and, without molecular analysis of viral DNA, would be attributed to reactivation of endogenous virus.[50] The immune response to symptomatic reactivation is not associated with a significant increase in the production of antibody, although fourfold rises and re-emergence of IgA and IgM antiviral antibody may occur. Natural killer cell activity and cytokine production increase, and relative defects in these and HSV-specific T-cell responses may predispose the individual to frequent or severe symptomatic recurrences, but definitive associations have not been established. Patients who have diseases or are being treated with agents that reduce cell-mediated immunity, such as those undergoing antitumor chemotherapy or individuals with acquired immunodeficiency syndrome (AIDS), often have frequent HSV recurrences that are longer in duration and more severe, but dissemination rarely occurs. Nonetheless, no evidence suggests a specific immunodeficiency in otherwise healthy persons who experience symptomatic HSV recurrences.

Viral encephalitis is the most severe consequence of HSV infection in an otherwise healthy host. HSV-1 is the pathogen in almost all these cases, and the pathologic mechanism is thought to be ascending infection along neuronal pathways from the cranial nerve ganglia to the brain.[79] Encephalitis may accompany or develop after primary HSV infection, but it also occurs as a consequence of reactivation of latent virus. When the virus reaches brain parenchymal cells, it replicates efficiently and induces widespread hemorrhagic necrosis and vascular compromise. The neuro-immune response to infection contributes to brain inflammation and subsequent sequelae. Activated glial cells (astrocytes and microglia) respond to HSV infection with the

production of cytokines and chemokines.[188] HSV encephalitis has been associated with an acute-phase elevation in β_2-microglobulin, neopterin, interleukin-6, and interferon-γ in cerebrospinal fluid (CSF).[20,21] During convalescence, increased levels of soluble CD8, β_2-microglobulin, neopterin, and specific anti-HSV IgG have been detected. How these markers relate to the pathogenesis of disease has not been established.

CLINICAL MANIFESTATIONS

Most HSV-1 and HSV-2 infections do not cause symptoms, but when infection is symptomatic, the clinical manifestations usually are self-limited and not severe. If symptoms occur, the disease associated with primary infection tends to be much more extensive than are the minor, localized lesions at mucocutaneous junctions caused by viral reactivation. Nonetheless, prospective studies document that new HSV infections can be as mild as symptomatic recurrences, and as a result, definitive differentiation of primary from recurrent infection is not possible with clinical criteria.

GINGIVOSTOMATITIS

Gingivostomatitis is the most common form of HSV-induced primary illness in children. A history of such symptoms has been reported in as few as 1 percent to as many as 31 percent of seropositive children, the higher percentage being from a study involving the Navajo Indians. It usually is seen in young children between 10 months and 3 years of age. In those younger than 10 months old, residual maternal antibody probably modifies or prevents the appearance of recognizable symptoms in association with primary HSV-1 infection. Although acute gingivostomatitis caused by HSV is a relatively infrequent occurrence, it is sufficiently common that most pediatricians become familiar with the condition and learn to distinguish this infection from herpangina.[214,333]

The illness begins with irritability and fever. Despite these systemic symptoms, HSV is not cultured from blood during this period.[127] More recently, investigators have detected HSV-1 DNA by PCR in whole blood or plasma early in the course of illness in approximately a third of young children with primary HSV-1 gingivostomatitis.[131] The infant usually refuses to eat and may refuse fluids. Thereafter, vesicular lesions appear around and on the lips, along the gingiva, on the anterior of the tongue, and on the anterior (hard) portion of the palate (Figs. 170–1 and 170–2). The vesicles break down rapidly, and when seen, lesions usually appear as 1- to 3-mm shallow gray ulcers on an erythematous base. The gums are erythematous, mildly swollen, and ulcerated. They may appear friable and frequently bleed on contact. The child experiences extreme discomfort, cannot or will not eat, and, if fluids are refused as well, may require hospitalization to ensure that adequate hydration is maintained. The risk of dehydration is compounded by the fever that generally accompanies this syndrome. Vesicles often extend around the lips and chin or down the neck in an immunologically intact child. The child frequently has foul-smelling breath (fetor oris). The lesions bleed easily and may become covered with a black crust. The cervical and submental nodes usually are swollen and tender. The clinical signs continue to evolve for 4 to 5 days, and the process of resolution requires at least an additional week. In an analysis of the natural history of HSV gingivostomatitis in 36 children, oral lesions persisted for an average of 12 days, most children had extraoral lesions, fever lasted for 2 to 6 days, and difficulty taking liquids was noted for 4 to 10 days. The duration of viral shedding was 7 days (range, 2 to 12 days).[5] Herpetic epiglottitis[39] and acute otitis media[60] are unusual complications.

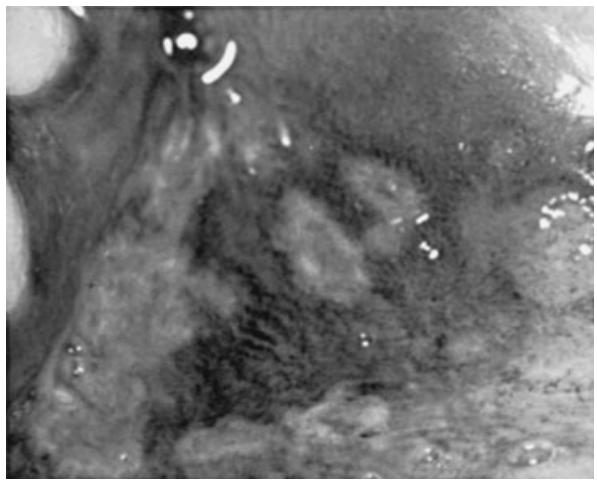

Figure 170–2 Primary HSV gingivostomatitis in a 6-year-old child, demonstrating involvement of the oral mucosa with ulcers.

HSV gingivostomatitis is differentiated from herpangina, a manifestation of enteroviral infection, by the location of ulcers in the anterior and posterior portions of the oropharynx; herpangina generally causes posterior pharyngeal ulcers. In addition, unlike HSV infection, herpangina often has a more acute onset, a shorter duration, and seasonal occurrence.[214] Whereas enterovirus-associated hand, foot, and mouth disease can be manifested as oral ulcers and a vesicular eruption on the distal portions of extremities, the bilateral distribution should differentiate it from HSV gingivostomatitis and concurrent HSV auto-inoculation of a digit. Severe Stevens-Johnson syndrome (erythema multiforme) may mimic HSV infection, but the generalized macular rash accompanied by "bull's-eye" lesions is characteristic of erythema multiforme. Rarely, recurrent HSV infection can be associated with erythema multiforme, as discussed later. Impetigo may be confused with the lesions of HSV infection, and misdiagnosis is re-enforced because colonization of skin by *Staphylococcus aureus* may be identified in bacterial cultures and be considered causative.

Parents and caregivers are familiar with "cold sores" or "fever blisters" but may not know that these lesions are caused by HSV.

Because HSV infection may be thought of as a sexually transmitted disease, the physician is advised to anticipate confusion and anxiety when making the diagnosis of HSV oral infection and to address these concerns by explaining the normal mode of acquisition of oral HSV infection by young children.

In adolescents, primary HSV-1 infection may be seen initially as a posterior, occasionally exudative pharyngitis.[193] The characteristic findings are shallow tonsillar ulcers with a gray exudate. In this setting, HSV infection must be differentiated from streptococcal and Epstein-Barr virus infection and rarely from diphtheria, acute human immunodeficiency virus (HIV) infection, and tularemia-induced pharyngitis. In one study of college students of a higher socioeconomic level, HSV was the most common etiologic agent of acute pharyngitis (24%).[113] A more recent study of 613 college students with upper respiratory complaints documented an incidence of 5.7 percent with positive HSV cultures. Twelve of the 35 students with positive cultures had vesicular lesions on their lips, throat, or gums, and 29 of the 35 had a primary diagnosis of pharyngitis that was indistinguishable from other causes of pharyngitis.[193] In some cases, acute pharyngitis is caused by HSV-2; the symptoms and clinical course appear to be similar, and viral cultures are required to identify the type of infecting virus.

VULVOVAGINITIS

Primary herpetic vulvovaginitis occurs rarely in infants and children. HSV-1 may cause this clinical syndrome, perhaps if inadvertently introduced when the genital area is touched by a caregiver with HSV on the hands. Progression of the infection may be limited to a few lesions, or it may resemble symptomatic primary genital herpes caused by HSV-2. Obtaining material for culture to identify the type of infecting virus is important because HSV-1 infection is less likely to recur and HSV-2 infection may reflect sexual abuse of the child. As is true of other potentially sexually transmitted diseases, genital HSV infection in young children warrants a careful and sensitive appraisal of the circumstances that may have led to the infection. Also useful is knowing that some children infected with HSV-2 in the newborn period have had genital lesions later in childhood.

Pediatricians are likely to encounter genital herpes in their adolescent patients. Reports on the incidence of genital herpes in which data are provided for subgroups of children and adolescents are limited, but a rate of 3 per 100,000 in the 10- to 14-year-old age group and 76 per 100,000 in the 15- to 19-year-old age group was reported in a Minnesota study of a predominantly white, middle-class population of northern European ethnicity.[61] The NHANES study reported the prevalence in 12- to 19-year-old subjects to be 5.6 percent[104]; however, recent NHANES data show a decrease in HSV-2 seroprevalence in this age group.[346] In one report of 379 adolescents aged 14 to 19 years who were treated at a sexually transmitted disease or urban community clinic, 12 percent had HSV-2 antibodies and only 22 percent of these patients had a history of genital herpes. HSV-2 seropositivity correlated with African American race or female gender but not with condom use, the number of sexual partners in the previous 2 months, or a previous history of a sexually transmitted disease, thus indicating that prevalence was related to demographic rather than behavioral variables.[295]

In contrast to earlier concepts, prospective studies have documented that many infections are subclinical and that new genital HSV-2 infections have a wide range of manifestations.[177,195] Variation is common with respect to the extent and severity of lesions; whether the lesions are bilateral or localized; the presence or absence of systemic symptoms such as malaise, myalgia, headache, and fever; dysuria; and regional lymphadenopathy. Symptoms can be mild enough to suggest recurrent infection or may be those of severe, "classic" primary genital herpes. In such cases in adults, local genital symptoms include severe pain (in 95% of men and 99% of women), itching, dysuria (44% of men and 83% of women), vaginal or urethral discharge, and tender inguinal adenopathy (80%). The lesions begin as vesicles or pustules and progress to wet ulcers and then to healing ulcers with or without crusts (Figs. 170–3 to 170–5). Crusting usually occurs only on squamous epithelium. Lesions tend to last for 2 to 3 weeks (mean, 19 days) before complete healing occurs. They may spread in a wavelike fashion from the initial site to the thighs, buttocks, and urethra. Virus shedding generally persists for 1 to 2 weeks or longer. Some primary infections are associated with atypical lesions (e.g., fissures, furuncles, excoriations), and extragenital lesions, typically on the buttocks, may be observed.[34,165]

When evaluating potential primary genital herpes in a sexually active adolescent, the history may reveal recent contact with a partner who is known to have recurrent genital herpes. When exposure can be documented, the incubation period is estimated

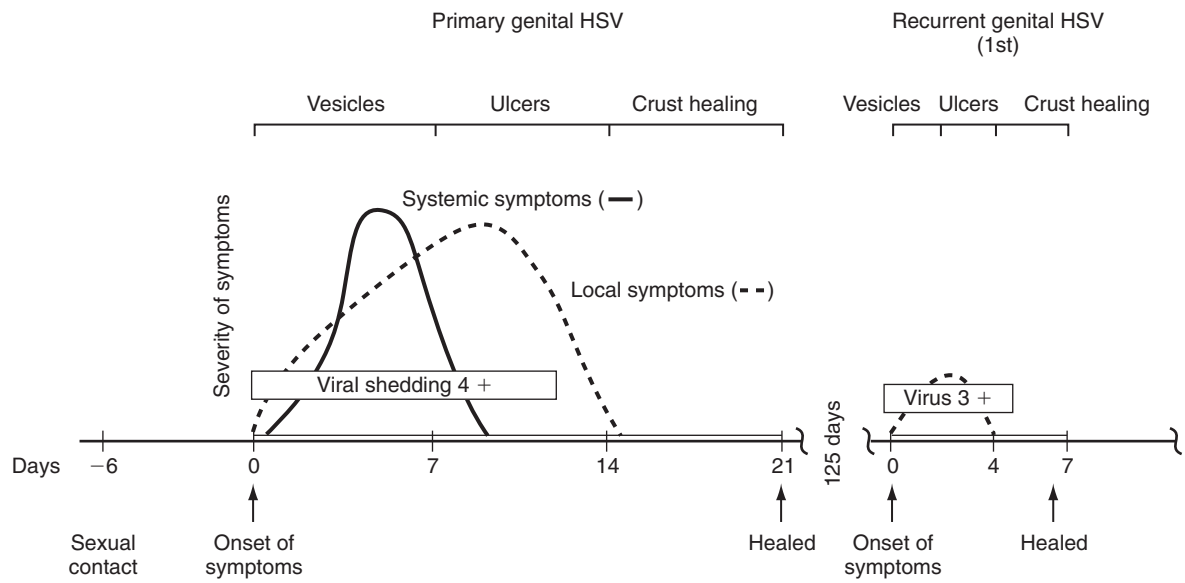

Figure 170–3 Graphic representation of the course of primary and recurrent HSV genital infection. The days illustrated are for average cases.

to be 2 to 14 days. However, most of these episodes will not be associated with a known exposure. In addition, recognizing that as many as two thirds of first-reported episodes of symptomatic genital herpes actually are caused by reactivation is important. In these cases, the exposure may have occurred months or years before the signs of HSV-2 infection appear. In some adult series, 50 to 60 percent of persons without a history of HSV infection can identify symptoms consistent with previous infection after receiving careful instruction about the typical signs, but many have not had any previous episodes.[175] HSV-1 accounts for 5 to 25 percent of primary genital HSV infections in the United States, whereas as many as 50 percent of cases diagnosed in other geographic areas, such as England and Japan, are caused by HSV-1. Indications are that HSV-1 is becoming a more common primary genital isolate in the United States. In recent years, HSV-1 has been isolated from genital cultures more often than HSV-2 has in some populations.[233] Patients with primary HSV-1 genital infection may exhibit lesions elsewhere (25%), typically on the hands and face.[34]

Primary genital HSV-2 infections may be associated with viral meningitis. This complication is manifested as fever, stiff neck, headache, and photophobia with a CSF lymphocytic cellular response and usually a normal glucose level.[134,303] HSV-2 can be isolated from CSF in the early phase of the illness. HSV-2–associated meningitis differs from HSV-1 encephalitis in that it is almost always mild, self-limited, and not associated with neurologic residua.

Other complications of primary HSV genital infection include sacral autonomic nervous dysfunction, which is manifested as poor rectal sphincter tone, constipation, sacral anesthesia, urinary retention, or impotence; extragenital lesions, which occur more commonly in women and occur on the buttocks, groin, thighs, or less commonly, the fingers or conjunctiva, generally in the second week of disease; secondary yeast infections in women; and pharyngitis, which usually is associated with fever, malaise, myalgia, headache, tender anterior cervical adenopathy, and a mildly erythematous to diffusely ulcerative or exudative posterior pharyngitis. Most of these patients have throat cultures positive for HSV. HSV has been associated uncommonly with acute salpingitis[181] and inguinal lymphadenitis.[300]

Of critical importance has been the association of previous HSV infection with an increased incidence of HIV infection.[283] A recent literature review and meta-analysis showed that serologically documented HSV-2 infection is a significant risk factor for the acquisition of HIV. The analysis suggests that the risk of acquiring HIV doubles in persons infected with HSV-2. The possibility that the risk of infection with HIV is enhanced by mucosal ulcers or that the increase in local $CD4^+$ lymphocytes resulting from HSV infection offers a greater number of target cells for HIV attachment and entry has been considered. Conversely, individuals with HIV infection reactivate HSV frequently and also have HIV present in mucosal ulcers.[322] A study from Kenya showed that HSV shedding was associated with significantly higher vaginal and cervical HIV shedding, even after controlling for plasma HIV load and $CD4^+$ count.[25] Although all patients with HSV-2 genital infection appear to be at higher risk for acquiring HIV, those with recent HSV-2 seroconversion appear to be more susceptible.[232,304]

Transmission to the newborn is a complication of primary or recurrent genital herpes in women of child-bearing age. This complication is discussed in the chapter on viral hepatitis of the fetus and newborn.

Genital herpes creates significant psychological difficulties for many patients. Whereas many people cope well with the illness and the likelihood of recurrent disease, a syndrome of profound depression, poor self-esteem, complete abstention from sexual activities, and general withdrawal develops in some. This reaction, or "leper syndrome," must be anticipated and discussed in a sensitive and caring manner. Information about the high prevalence of these infections in the population may be helpful, with emphasis placed on the fact that most infected people do not realize that they are infected and shed the virus intermittently, just like those who have had symptoms. Self-help groups of persons who have genital herpes exist in many parts of the United States and can be contacted through the American Social Health Association, Herpes Resource Center, P.O. Box 13827, Research Triangle Park, NC, 27709, *www.ashastd.org*, and the American Herpes Foundation, *www.herpes-foundation.org*.

OTHER PRIMARY SKIN INFECTIONS

Mucocutaneous junction areas are common sites of HSV infection, and damaged skin often provides a portal of entry for HSV. Vesicular lesions spread throughout the affected skin and usually crust and resolve in approximately 1 week. The illness accompanying eczema herpeticum can be severe (Fig. 170–6) and even fatal, although in most cases it resolves without specific therapy and leaves no sequelae. Increased use of topical calcineurin inhibitors has raised concern regarding possible immune suppression and an increase in cases of eczema herpeticum. One study showed the incidence density of herpesvirus skin infections to be similar in infants who received 1 percent picrolimus cream and those who received the vehicle without active drug.[215] However, of those children characterized as having eczema herpeticum (more extensive skin involvement), all infants were in the group receiving 1 percent picrolimus cream. Further studies are needed to determine the magnitude of risk, if any, of the use of topical calcineurin inhibitors in the development of eczema herpeticum. Current recommendations include discontinuing topical calcineurin inhibitor therapy and beginning appropriate antiviral therapy if eczema herpeticum develops.[215]

Widespread herpetic lesions may occur in skin altered by thermal or chemical burns. In this situation, a secondary fever may occur, usually 1 to several weeks after the initial insult. Careful inspection of the burn site or adjacent normal tissue may reveal vesicles (Fig. 170–7) or nonspecific ulcerative lesions. Without therapy, several of these patients have died of disseminated HSV infection.[105] A similar syndrome occurs rarely in children after they have incurred simple skin abrasions (Fig. 170–8). Herpetic recurrences may follow in these cases, but recurrences are localized to the area of skin that was affected initially. HSV infection can be severe as a secondary infection at the site of common diaper rash.[144]

Herpetic whitlow is a painful, erythematous, swollen lesion that occurs on the terminal phalanx, sometimes associated with a damaged cuticle.[31,112,237] The fingers (69%) and thumb (21%) are involved most frequently.[112] Less commonly, the palm may be the site of inoculation and major involvement.[256] The digit is swollen, and the painful white swelling appears to be filled with

pus but, when opened for drainage, is found to contain little fluid and no purulent material. The white appearance is caused by the presence of necrotic epithelial cells. Occasionally, the whitlow, which may persist for 7 to 10 days, is accompanied initially by a few vesicles that may give a clue to the etiologic agent of the primary infection. Less commonly, the whitlow is associated with fever, lymphadenopathy, and lymphangitis.[251]

Whitlow is seen in four typical situations. Most commonly, infants with primary herpetic gingivostomatitis auto-inoculate their fingers (Fig. 170–9). At times, whitlow is encountered in infants without obvious oral disease, and sometimes it may be caused by adults kissing their children's fingers. In these settings, the viral isolate almost always is HSV-1.[31,112] In sexually active patients, the whitlow more commonly is a manifestation of concurrent genital disease, which should be sought by appropriate history and physical examination.[114] These infections are caused most frequently by HSV-2. In the fourth setting, persons such as dentists, respiratory therapists, nurses, and pediatricians who examine oral cavities or handle secretion-contaminated material without wearing gloves are at risk for acquiring herpetic whitlow (Fig. 170–10).[100] In addition, the same poor medical practice facilitates transfer of HSV to other patients, especially in intensive care settings.[2]

Figure 170–9 Extensive herpetic whitlow in a toddler with oral HSV infection.

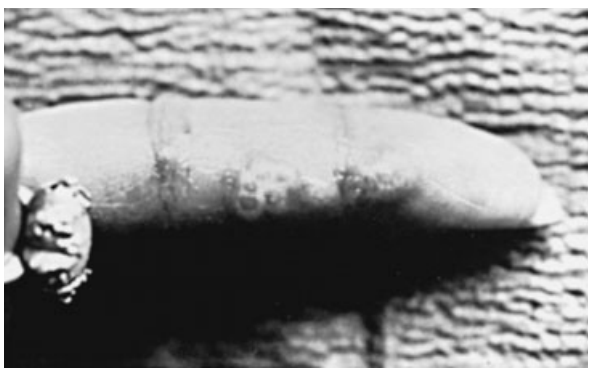

Figure 170–10 Recurrent herpetic whitlow in a pediatrician.

Herpetic whitlow frequently is confused with bacterial felon or paronychia, and such confusion may lead to the incorrect intervention of incision and drainage. This procedure is not indicated and is not beneficial in the management of herpetic whitlow, which should be treated with oral acyclovir. Needle aspiration and culture provide the diagnosis of whitlow, and initiation of antiviral therapy can be based on clinical signs.

In several sports, cutaneous (especially facial) HSV infection is a hazard, particularly in sports with close physical contact such as wrestling (herpes gladiatorum) and rugby (scrum-pox, derived from the line-up of rugby players, the "scrum" or "scrummage").[33,56,267,269,332] Frequently, the initial lesions are diagnosed as impetigo, unless HSV is considered. HSV infection develops in approximately 3 percent of wrestlers in high school, typically on the head and neck but also on the extremities and trunk and in the eyes.[56]

INFECTION OF THE EYE

Ocular herpes may occur as a result of primary infection or reactivation of virus in the trigeminal ganglion. Primary infection may be manifested as blepharitis or follicular conjunctivitis. The symptoms often are accompanied by preauricular lymphadenopathy, corneal injection, watering, discharge, itching, lid swelling, and, in a third of cases, malaise and fever. If restricted to the conjunctivae, the infection (which can be accompanied by vesicular herpetic lesions elsewhere on the face or in the nose or mouth) usually resolves without sequelae or specific features. Herpetic infection of the eye may, however, progress to involve the cornea, with far more serious potential consequences. For this reason, an ophthalmologic consultant always should examine and evaluate these cases.

Corneal involvement by HSV may be manifested initially by minute vesicles at the corneal margin. Progression of the corneal infection (best seen with the use of topical fluorescein dye) is marked by the appearance of branching lesions (a dendritic pattern) or the less diagnostic irregular (ameboid or geographic) ulcer.[32,76] The child complains of severe photophobia accompanied in some cases by blurred vision, chemosis, and lacrimation. Primary eye infection may include stromal involvement, uveitis, and rarely, retinitis.[216] Retinitis is manifested as multiple whitish yellow, punctate retinal lesions. Spontaneous healing, which generally requires 2 to 3 weeks, can be speeded by the application of topical antiviral therapy. Corticosteroids are contraindicated. The risk of visual impairment caused by direct viral damage, immunopathologic reactions, or both is enhanced greatly with recurrences. With each bout of infection, the corneal ulcers become more extensive and can result in scarring and impairment of sight. Herpetic infection of the eye recurs in approximately 32 percent of patients who have primary symptomatic infection and occurs more commonly in younger patients.[342] Recurrences may be manifested as blepharitis, follicular conjunctivitis with or without lid lesions, or ulcers and keratitis, which more often are accompanied by ulcerations deeper into the corneal stroma (diskiform or necrotizing keratitis) with resultant extensive scarring, irregular astigmatism, and even corneal perforation.[342] Children with dendritic ulcers have a better prognosis for good vision than do those with geographic or diskiform keratitis.[32]

Rarely, HSV eye infection may result in acute retinal necrosis. HSV-2 is the most common cause of acute retinal necrosis identified in childhood. Most affected children have a history of congenital or perinatal herpes infection.[174] Many patients have preexisting chorioretinal scars. Reactivation is triggered by periocular trauma or occurs with immunosuppression, such as during treatment with systemic steroids.[306] Symptoms include eye irritation and photophobia.

Very infrequently, an oculoglandular syndrome of conjunctivitis and adenopathy may be caused by HSV infection.[52]

INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

HSV is the most common identifiable cause of serious or life-threatening sporadic encephalitis.[183] It accounts for 2 to 5 percent of all cases of encephalitis in the United States and for as many as 20 percent of all cases with an etiologic diagnosis (60% to 70% of cases of encephalitis have no established cause).[228] With the advent of immunization for measles, mumps, rubella, and varicella, the relative incidence of HSV in cases of encephalitis has increased, although absolute numbers remain stable in children.[162,183,228] The case-fatality rate associated with untreated HSV encephalitis is approximately 70 percent,[340] and survivors generally have severe and permanent neurologic disability. Both HSV-1 and HSV-2 have been implicated in the etiology of central nervous system (CNS) infection by HSV, but typical HSV encephalitis in patients outside the neonatal age range is caused by HSV-1.[72,255,333] Spread of HSV-1 to the CNS seems to proceed via either neurogenic pathways or hematogenous dissemination or perhaps through the cribriform plate from infected nasopharyngeal mucosa during primary infection. Recurrent infection probably results from spread via sensory neurons. HSV-2 meningitis is not associated with brain parenchymal infection; whether the infection is a consequence of hematogenous delivery or spread along neuronal pathways is not known.

Although HSV encephalitis may involve virtually any area of the brain, this infection has a striking tendency to involve the orbital region of the frontal lobes and, with particular frequency, portions of the temporal lobes. Johnson and Mims have suggested that the predilection of HSV to involve regions of the brain governing olfaction suggests that a pathogenetic pathway proceeds from the nasal-respiratory mucosa via the olfactory bulbs and along the subsequent tracts into the brain.[147] Other researchers have suggested that reactivated virus travels from the trigeminal ganglia via fifth nerve fibers to the meninges of the anterior and middle fossae.[79,80] More recent studies in children involving diagnosis by PCR assay and magnetic resonance imaging (MRI) have defined cases with more diffuse cerebral involvement.[257,333]

HSV encephalitis must be differentiated from HSV meningitis, which usually is caused by HSV-2 and is a complication of primary genital infection. In HSV meningitis, symptoms and signs of meningitis, including headache, photophobia, and stiff neck, appear before or shortly after genital lesions are noted. The signs are similar to those of other acute viral meningitides such as enteroviral meningitis. This syndrome may occur in children as well as adults.[89] HSV-2 meningitis may develop less commonly in the absence of genital lesions[259] or rarely in neonates.[258] Seizures and focal CNS findings generally are absent. Examination of CSF reveals lymphocytosis (with 300 to 2600 white blood cells) and may demonstrate low glucose levels. In cases of HSV meningitis, in contrast to HSV encephalitis, virus can be cultured from CSF,[14,72,134] and HSV PCR assay also may be diagnostic.[259] Recovery usually is complete without specific therapy, but with the availability of effective antiviral agents, HSV meningitis should be treated with acyclovir. HSV meningitis may reappear with genital recurrences. Studies using PCR DNA detection analysis have shown that HSV is the major agent responsible for benign recurrent lymphocytic meningitis, also known as *Mollaret meningitis*.[301] These adult patients had three to nine attacks of recurrent lymphocytic meningitis, with 48 to 1600 cells per liter, normal glucose, and protein concentrations of 41 to 240 mg/dL in CSF. PCR analysis detected HSV-2 and, less commonly, HSV-1. Acute viral meningitis caused by reactivation of HSV-1 also has been described in a pre-adolescent child.[67]

HSV encephalitis is a highly lethal disease caused by HSV-1 in 93 to 96 percent of cases.[25,204,333,334,336] It may be a result of primary (30%) or recurrent (70%) infection.[204,333] Although no specific data exist, researchers have suggested that HSV encephalitis is more likely to be associated with primary infection in younger persons because new infections occur more commonly in this age group. One report suggests that primary infection is more likely to be associated with fatal encephalitis. Of 113 cases of biopsy-documented HSV encephalitis, 31 percent occurred in patients younger than 20 years and 6 to 10 percent of patients were between 6 months and 10 years of age.[271,272] Unlike most other common forms of viral meningoencephalitis such as enterovirus or arbovirus infection, HSV encephalitis is not seasonal. It is an acute illness characterized by fever, headache, malaise, irritability, and nonspecific symptoms lasting 1 to 7 days, with progression to the signs and symptoms of CNS involvement in 3 to 7 days and, finally, to coma and death (Table 170–1). A biphasic illness consisting of initial improvement followed by worsening may occur. The signs of HSV encephalitis resemble those of other viral encephalitides, with initial fever and altered behavior.[132] Meningeal signs are uncommon findings. No correlation exists between isolation of HSV from sites extrinsic to the CNS (such as the oropharynx or genital tract) and the diagnosis of HSV encephalitis.[204,335] Thus, the presence of oral or genital lesions is of no help in the establishing or excluding the diagnosis of HSV encephalitis. Nonetheless, if a patient has HSV encephalitis, identical viruses have been isolated from the brain and oral secretions.[337]

The CSF generally reveals pleocytosis, with as many as 2000 white blood cells/mm^3 but usually (80% of the time) more than 50/mm^3. In 90 percent of cases, more than 60 percent of the cells are lymphocytes. Early in the course of infection, neutrophils may predominate. In 75 to 85 percent of cases, red blood cells, reflecting the hemorrhagic necrosis, are seen in the CSF. Between 5 and 25 percent of patients have hypoglycorrhachia, and 80 to 88 percent have elevated protein levels in CSF (median, 80 mg/dL), which rise to striking levels as the disease progresses. Two to 3 percent of patients with early HSV encephalitis have normal CSF.[163,204] Repeat analysis of CSF usually reveals abnormalities consistent with encephalitis. HSV almost never is cultured from lumbar spinal fluid in patients outside the neonatal age range and rarely has been grown from ventricular fluid.[106] Thus, whereas CSF examination is helpful, it is not at all diagnostic of HSV encephalitis. When the CSF of patients with HSV encephalitis

TABLE 170–1 Historical and Clinical Findings in HSV Encephalitis

is compared with that of patients undergoing biopsy for suspected HSV but with another resultant diagnosis, no differentiating characteristics of CSF are found that could allow one to predict HSV infection accurately. HSV DNA can be detected by the use of PCR assay of the CSF of patients who have HSV encephalitis.[7,22,85,172,239,307]

Neurodiagnostic tests have been of limited assistance. Probably one of the most useful is the electroencephalogram (EEG) (Fig. 170–11).[44] A "typical" pattern of unilateral or bilateral (poor prognosis) periodic focal spikes against a background of slow (flattened) activity (paroxysmal lateral epileptiform discharges [PLEDs]) has been associated with HSV encephalitis. These findings are suggestive but not pathognomonic. Other findings include large-amplitude, irregular slow activity, sharp waves, and variable spikes. In 80 to 90 percent of patients, the EEG is not only abnormal but also localizing. In many cases in the pediatric and adult age groups, the EEG may be one of the earliest localizing laboratory tests.[87,120,161] Less commonly, the results of a radionuclide or computed tomography (CT) scan are abnormal and localizing (50-60% of cases).[150,182] CT results may be characteristic late in the illness and consist of low-density, contrast-enhanced lesions in the temporal area, mass effect, edema, and hemorrhage (Fig. 170–12); early in the illness, when establishing the diagnosis is critical, CT results more often are unremarkable.[120,161,200] Indeed, abnormal CT results are a poor prognostic factor.[200] Reports suggest that MRI findings are more likely to be abnormal at initial evaluation for HSV encephalitis because of its high sensitivity to changes in brain water content[264] (Fig. 170–13) and that MRI is more sensitive than is CT for detection of HSV encephalitis.[84,223] Findings include hyperintensity of the temporal areas on T2-weighted images with gadolinium enhancement. However, even MRI imaging may be normal if performed in the early stages of the disease.[3]

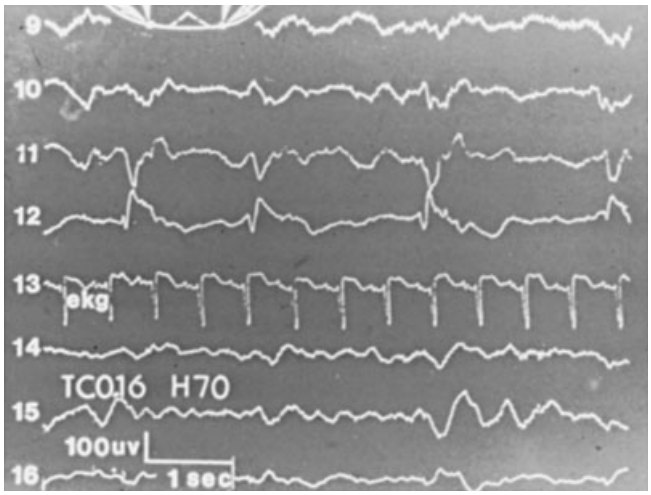

Figure 170–11 Electroencephalogram in a 9-month-old infant with HSV encephalitis. Note the paroxysmal discharges, in lead 12 especially.

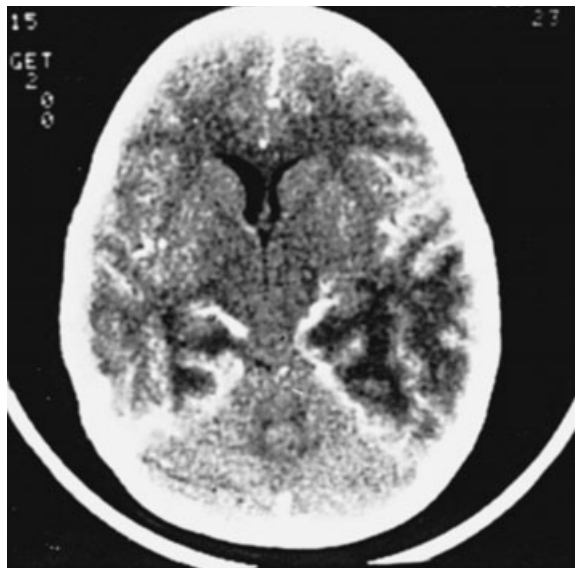

Figure 170–12 Computed tomographic scan 1 week after the onset of HSV encephalitis in a 6-year-old child. Note the bilateral temporal low-density areas with dye enhancement and the greater mass effect on the patient's left side than on the right side.

Focal abnormalities in HSV encephalitis are significantly more likely to be observed on EEG, CT, MRI, or radionuclide brain scan than in other illnesses confused with it. All these findings are biased by the current concept of HSV encephalitis as a focal encephalitis, with very few biopsy data available on the etiology of nonfocal encephalitis. Whether a significant number of cases of HSV encephalitis are milder and nonfocal is unknown because few of them ever come to brain biopsy or even careful retrospective serologic diagnosis. Studies using MRI and PCR technology have identified cases with multifocal brain involvement[182,257]

Clinical and laboratory evaluations of patients with suspected HSV encephalitis are valuable only for increasing the index of suspicion, not for confirming the diagnosis. In one series of 24 children with HSV encephalitis diagnosed by PCR assay and compared with 38 children in whom HSV encephalitis was excluded by PCR, no significant differences were found in clinical manifestations at onset or in CSF cell counts, protein, or glucose.[142] However, more children with HSV encephalitis had localizing findings detected by CT (75% vs. 31%), whereas 36 percent of those without encephalitis had EEG abnormalities as opposed to no EEG abnormalities detected in those with HSV encephalitis. The differential diagnosis of this condition is relatively large (Table 170–2). Especially in the pediatric age range, the ability to discriminate HSV encephalitis from other etiologic agents mimicking it is poor (50% in the national collaborative series in 71 patients younger than 20 years and 42% in a smaller series of 12 patients younger than 12 years).[161] Confirmation of the specific diagnosis of HSV encephalitis remains essential, both to provide optimal aggressive therapy for that condition and, of equal importance, to achieve a diagnosis for the 50 to 60 percent of patients without HSV infection, roughly 16 percent of whom would benefit from other specific therapies.[87,161,200,335] In most cases, the diagnosis can be established by PCR analysis of CSF.[7,22,122,172,239,257,259,312] Large studies show PCR analysis to be 98 percent sensitive and 94 percent specific when compared with brain biopsy.[172] Some of the 6 percent "false-positive" results probably were due to poor handling of the biopsy tissue for culture. PCR analysis may yield positive results by 1 day after the onset of symptoms.[122] However, a negative PCR result obtained soon after the onset of symptoms does not completely exclude the diagnosis of HSV encephalitis. In one small series of patients, repeat testing of CSF 4 to 7 days after an initial negative HSV PCR assay showed positive PCR results.[329] HSV DNA persists in most specimens for a week or more, even after antiviral therapy.[334] PCR primers must be chosen to detect HSV-2, as well as HSV-1, because 4 to 6 percent of HSV encephalitis cases may be caused by HSV-2.[23]

Alcoholic encephalopathy
Leukemia
Cerebral infarction
Adrenal leukodystrophy

If PCR results are negative in a patient who has symptoms and signs of HSV encephalitis, brain biopsy may be contemplated. The risk associated with brain biopsy is low. In the national collaborative study of 432 biopsies, six complications occurred (hemorrhage in three patients and poorly controlled brain edema in three, for a 1.4% complication rate).[336] Roughly 2 to 3 percent of brain biopsies yielded false-negative results, usually because of biopsy of the wrong site.[336] Decision analysis suggests that performing a biopsy is especially critical in a patient with low CSF glucose levels.[253]

Quantitative PCR analysis may have value as a prognostic tool and as a method of assessing the response to antiviral therapy in patients with HSV encephalitis.[90,334] In 16 patients, those with high copy numbers of HSV DNA in CSF tended to have abnormal CT scans, be older, and exhibit more severe sequelae. HSV DNA levels were found to decrease during acyclovir therapy in seven patients; the exception was a patient whose copy numbers increased and who subsequently had a fatal infection.

A less acute form of HSV encephalitis in immunocompromised patients has been reported. Also less commonly, HSV has been implicated in brain stem encephalitis.[97] Relapse occurs in approximately 5 percent of treated patients.[161] Choreoathetosis may be an initial sign of relapse.[326] Reports of a post-herpetic encephalomyelitis caused by a probable autoimmune or demyelinating etiologic factor have appeared[1,158]; moreover, virus-positive recurrence of HSV encephalitis has been described months after patients have undergone apparently successful therapy.[88] These consequences can be differentiated and documented only by PCR analysis or, if necessary, brain biopsy and appropriate tissue histologic examination and culture.

INFECTION OF THE GASTROINTESTINAL TRACT IN NORMAL HOSTS

Whereas infection of visceral organs is well recognized in immunocompromised hosts, case reports of such infection in apparently healthy persons are less common. Nonetheless, HSV esophagitis has been described in these patients, including several children who were 11 months to 17 years of age.[15,29,108,199,213] HSV-1 is the usual pathogen, and the syndrome is associated with primary infection.[108] Initial symptoms include fever, severe odynophagia, retrosternal and subxiphoid pain, and an inability to eat. Skin lesions generally are absent. Esophagoscopy reveals

ulcerations and fibrinous and, at times, hemorrhagic exudate. Distal involvement may be more extensive than the proximal esophageal findings suggest. Double-contrast esophagography may be diagnostic, although endoscopy and biopsy usually are necessary for establishing a definitive diagnosis. Symptoms generally remit in 5 to 7 days after the administration of nonspecific therapy such as antacids, H_2 blockers, and hydration.[15,199]

HSV infection can be manifested as an anorectal infection in males who have sex with males.[117,225] This syndrome occasionally affects women practicing passive anal intercourse. In most series of HSV proctitis, the younger persons are adolescent males involved in passive anal intercourse. Initial symptoms include severe anorectal pain, discharge, tenesmus, hematochezia, and, in particular, fever, difficulty urinating, sacral paresthesias, constipation, and (in 50-70% of patients) ulcers or vesicles in the perianal or distal rectal area.[117] The duration of symptoms is 2 to 3 weeks. Primary HSV infection accounts for proctitis in this group in 25 to 30 percent of cases. Syphilis and infection with *Giardia lamblia*, *Entamoeba histolytica*, *Campylobacter fetus*, *Shigella* spp., other enteric bacteria, and *Neisseria gonorrhoeae* also must be considered in the differential diagnosis of this entity. Appropriate cultures and histologic analysis are crucial for establishing a specific diagnosis.

HSV is a rare cause of hepatitis in an immunocompetent host, but it has been reported in children.[27] In a review of the literature describing 35 patients who had HSV-associated hepatitis, only 14 percent had no underlying condition. The remainder had various immunocompromising conditions such as transplantation, steroid administration, pregnancy, burns, primary immunodeficiency, or cancer. These patients tended to have fulminant hepatic necrosis, extremely elevated serum transaminase levels, disseminated intravascular coagulation, and a mortality rate of 86 percent.[58] In a prospective study of healthy young adults with genital herpes (primary or recurrent), 14 percent had mild elevations in liver enzyme tests.

RECURRENT INFECTIONS

HSV-1 and HSV-2 have the characteristic capacity of herpesviruses to establish latency and undergo episodes of reactivation despite the presence of an apparently adequate immune response. Persistence is facilitated because latent infection of neurons occurs in an immunologically "privileged" site. Reactivation of HSV infection with viral shedding generally causes no lesions. HSV can be recovered from the pharynx and genital sites of asymptomatic persons. It has been found in the tears of persons with a history of recurrent ophthalmic disease, even in the absence of eye lesions or symptoms. All HSV-2–seropositive women from whom samples of vaginal secretions were obtained for more than 100 days had documented asymptomatic viral shedding, and shedding occurred on 1 percent of the days on which cultures were performed.[325]

Patterns of HSV reactivation include asymptomatic reactivation after silent primary infection, asymptomatic reactivation after symptomatic primary infection, and symptomatic recurrence after either silent or symptomatic primary infection. The risk of having symptomatic recurrences may be higher in individuals who have symptomatic primary infections. When reactivation causes disease, the clinical manifestations of recurrent HSV infection depend on the area involved. Most HSV recurrences are milder than the primary illness, although patients may have symptomatic recurrences without having had clinically apparent primary disease. Recurrent infection in a normal host also may be more severe than is the primary infection. This pattern is particularly evident in HSV infection of the eye, in which recurrent illness is associated with deep stromal damage and scarring.[221] This enhanced severity may be related to a greater extent to a more exuberant immune response than to viral damage. HSV encephalitis, which may be a manifestation of viral reactivation, is devastating.[204,333]

The most common manifestation of recurrent HSV infection is herpes labialis ("cold sores," "fever blisters"). Recurrences were observed in 25 to 50 percent of persons who had symptomatic primary HSV-1 oral infection, but in only 24 percent of those who had primary HSV-2 oral infection.[171] The mean rate of recurrence after symptomatic primary HSV-1 infection in adults is approximately 0.1 per month. These recurrences often are associated with a variety of febrile illnesses, local trauma, sun exposure, or menstruation.[24,278,281] Whether acquisition of HSV-1 in childhood is less likely to be associated with recurrent herpes labialis is not known.

Most persons with herpes labialis experience a prodrome (pain, burning, tingling, or itching) at the site that lasts a few hours to several days. Subsequently, an orderly progression ensues from papules (lasting 12 to 36 hours) to vesicles (usually gone by 48 hours) and finally to ulcers and crusting (lasting 2 to 4 days) (Fig. 170–14). The typical lesion is 35 to 80 mm in size. The majority of outbreaks are healed by 5 to 10 days (mean, 200 hours). Most pain occurs during the vesicular stage. Virus is isolated readily from vesicles (80-90% of the time) and less commonly from ulcers and crusts (34% of the time). Maximal virus titers (10^7 to 10^8) in lesions are detected in the first day or two, and virus generally is not isolated after 120 hours.[24,281] Virus also may be detected in the saliva and on the hands of persons with herpes labialis.[310]

Recurrences tend to affect the same location or closely related areas. In general, they occur on the lips, mucocutaneous junction, or other parts of the face. Recurrent lesions found inside the mouths of normal hosts rarely are caused by HSV and more likely are aphthous lesions. When HSV recurrences are within the mouth, they tend to be on tissue adjacent to bone, such as the

Figure 170–14 Recurrent herpes labialis (cold sore) in an adolescent.

gums or palate, and not on the lips or buccal mucosa.[276] A differential diagnosis of the condition also includes pemphigus, lichen planus, ulcers caused by cyclic neutropenia, and ulcers associated with celiac disease, ulcerative colitis, Crohn disease, pernicious anemia, and Behçet syndrome.

Recurrent genital herpes is the second most common manifestation of HSV. Studies have elucidated several factors that increase the risk for recurrent genital disease after symptomatic primary genital infection. Recurrence rates are much higher after primary HSV-2 (90%) than after primary HSV-1 (25-55%) infection.[171,229] The mean rate of recurrence is 0.02 to 0.1 per month after primary genital HSV-1 and 0.3 per month after primary HSV-2 genital infection.[171,229] Recurrences are seen more commonly in men than in women and after a recurrent lesion than after a first attack.[229]

Only 5 to 12 percent of persons with recurrent genital herpes have constitutional symptoms. Local symptoms include pain (average, 4 to 6 days), itching, dysuria (10-30%), adenopathy (20-30%), and lesions (average, 50-60 mm) lasting 4 to 5 days until crusting, with healing taking place by 9 to 11 days (range, 4-29 days) (see Fig. 170–3). Symptoms in females tend to be more severe than those in males. Virus is shed for an average of 3 to 4 days (but in some cases as long as 20 days). Virus generally is shed with titers of 10^2 to 10^4 per lesion. Vesicles are seen in dry areas, but in wet areas, the vesicles rapidly break down into ulcers. Symptoms generally are milder and of shorter duration than those in primary genital disease.[45] New crops of lesions commonly occur during the course of recurrence. The severity of recurrence is quite variable; in some cases, several discrete recurrences blend into a single, prolonged recurrence, and in rare cases, patients have almost continuous recurrences.[123] In one study of patients who were HSV-2–seropositive with no history of genital herpes, 62 percent had recognized herpetic lesions at later evaluation.[325] Recurrences in the previously asymptomatic group were shorter (3 versus 5 days) and less frequent (3.0 per year versus 8.2 per year) when the pattern of recurrence in this cohort was compared with that of subjects with a known history of genital herpes.

With endonuclease restriction analysis, researchers have clear evidence that, whereas most recurrences represent endogenous reactivation of the same latent virus, re-infection with a new homologous virus (i.e., HSV-2 and new HSV-2), as well as heterologous virus (i.e., HSV-2 and then HSV-1 or vice versa), is possible.[50] How common this occurrence is remains to be ascertained and must depend to some degree on the sexual activity and number of partners of the persons studied.[261]

Other cutaneous recurrences may develop at each anatomic site of primary infection. HSV infection may recur on the face or trunk in a typical dermatome distribution, such as that associated with VZV. Indeed, frequent repeated attacks of zosteriform-like lesions on any part of the body in a normal host suggest HSV and not VZV infection.

ERYTHEMA MULTIFORME

Erythema multiforme is thought to be an immune-mediated, "allergic" response to recurrent HSV infection.[103,139,197,212,330] It has been associated with the presence of human leukocyte DQw3 antigen.[149] In several series, approximately 15 to nearly 100 percent of patients who have erythema multiforme, especially those with recurrent erythema multiforme, gave a history of recurrent HSV infection before the skin eruption, which may be macular or urticarial.[139] In one series, 5 of 80 patients who had recurrent oral HSV infection experienced a rash (presumably erythema multiforme) that manifested 8 to 14 days after the onset of a cold sore.[281] Studies in adults and children have documented HSV antigen-antibody immune complexes and HSV DNA (detected by PCR analysis and in situ hybridization) in the skin of patients who had erythema multiforme after having HSV infection.[41,42,212] In a series of 20 children with erythema multiforme (10 who had antecedent herpes), 16 were documented to have HSV DNA at the site of the rash.[330] The mechanism of transport of viral DNA fragments is not clearly understood. Recent studies suggest that $CD34^+$ cells play a role in transport of HSV DNA fragments to lesional skin.[211]

The skin manifestations may last 14 to 21 days, and therapy generally is directed toward the allergic and not the viral component of the illness. Suppression of HSV recurrences prevents the associated episodes of erythema multiforme. Indeed, suppressive treatment of erythema multiforme with acyclovir, even in the absence of recurrent HSV infection, completely suppresses clinical manifestations.[263,299] In one series, the syndrome developed in 12 children at a mean age of 8 years within 4 days after the appearance of herpes labialis lesions, and symptoms lasted for an average of 10 days; 9 children had recurrent erythema multiforme, with an average of 2.6 episodes per year.[330] Detection of HSV by PCR assay of skin biopsy tissue was described in all cases. None of three children given acyclovir suppressive therapy had recurrences during treatment for at least 6 months, but erythema multiforme with recurrent HSV developed in one child when use of the drug was discontinued, thus supporting a causative role of HSV in the syndrome.

HSV INFECTION IN IMMUNOCOMPROMISED HOSTS

As the practice of pediatrics continues to include more patients with severe acquired immunodeficiency states brought about by increasingly intensive therapy for malignancies, expanding application of bone marrow and organ transplantation, and HIV infection, the prevalence of severe HSV infection in immunocompromised hosts is increasing. Table 170–3 lists conditions associated with unusually severe HSV infections. HSV infection in the neonatal period is discussed in another chapter on viral infections of the fetus and newborn. Aside from the several cases of HSV encephalitis in patients with agammaglobulinemia (who also had concomitant infections with enterovirus),[186] common links in these varied groups are either skin abnormalities (eczema, burns) or immunologic defects, primarily in the cell-mediated components of the immune system.[37,105,133,220,288,302] The critical defects have not been defined and may involve one or a combination of inadequate functions (e.g., of $CD4^+$ T cells, $CD8^+$ T cells, natural killer cells, macrophage antigen processing, or other factors).

The incidence of severe HSV infection in children with diseases that predispose them to these complications (see Table 170–3) is defined poorly but, in limited series, was similar to that seen in adults.[107,115,333] Most infections are caused by reactivation, as would be expected given the relative frequency of primary and recurrent infections.

In series of pediatric or adult patients who have received renal, bone marrow, or cardiac transplants, 70 to 90 percent of seropositive persons excreted HSV, usually from the oropharynx and generally at the time of peak immunosuppression (in the first month after transplantation).[205] HSV disease usually occurs within 2 to 3 weeks of solid organ or hematopoietic transplantation in patients who do not receive antiviral prophylaxis.[115] Of 68 children who underwent renal transplantation, a herpesvirus was isolated in 43 percent, with 28 percent of the isolates being HSV.[305] HSV in cardiac transplant cases causes symptomatic illness in 45 to 85 percent of seropositive patients, depending on the intensity of immunosuppression. HSV was the virus most commonly isolated in children who underwent bone marrow transplantation (23%).[327] HSV has been suggested to be one of the etiologic agents of the interstitial pneumonitis that develops

after bone marrow transplantation.[208,227] In children with leukemia, HSV infection occurs more commonly in those with myelocytic leukemia than in those with lymphocytic leukemia, and the risk of infection developing increases with neutropenia and chemotherapy. HSV infection was the most common serious viral infection in children with leukemia. Whereas most infections occurred during periods of remission, on a per-day basis, the risk of infection developing was seven times higher during induction.[343] Of 24 patients who died of infection during remission in the St. Jude's series, 2 (8%) had HSV (1 with disseminated disease, 1 with encephalitis).

In Africa, patients suffering from underlying malnutrition and concomitant measles infection may contract fatal disseminated HSV infection; such events rarely occur in industrialized nations.[30,153,302]

Children with HIV infection and chronic mucocutaneous ulcers (persisting for more than 1 month), bronchitis, pneumonitis, and esophagitis caused by HSV are categorized as having severely symptomatic HIV disease (category C).[57] Chronic HSV mucocutaneous disease or widespread organ involvement was the AIDS-defining condition in 7 of 789 (0.9%) HIV-infected children.[309] In series of children with AIDS, 5 to 29 percent contracted HSV opportunistic infection.[107] Chronic ulcerative HSV lesions often develop in children with HIV infection, although first episodes did not result in disseminated infection.[250] Notably, many of these children also had perianal ulcers from which HSV-1 was isolated. In HIV-infected patients, illnesses caused by HSV usually involved chronic mucocutaneous ulcers or extension to the lungs, bronchi, or esophagus. Dissemination is a rare occurrence.[16] Multiple recurrences of infection are common occurrences as the immunodeficiency worsens. In patients with AIDS, HSV rarely causes a typical[128,314] or more indolent encephalitis. HSV usually does not result in mortality in HIV-infected patients, but it causes significant morbidity.[155] HSV genital ulcer disease increases the risk of acquisition of HIV.[137] Studies show that suppression of clinical and subclinical reactivation of HSV is associated with a decrease in HIV viral load.[254]

Figure 170–15 Chronic, hemorrhagic HSV infection in a girl with leukemia and a bone marrow transplant.

Several major syndromes are attributable to HSV in immunocompromised patients, with some overlap and occasionally progression from one to another. The first and most common manifestation is a local, chronic, often extensive cutaneous or mucocutaneous infection. The second form is infection involving a single organ (e.g., esophagitis or pneumonitis). The most serious illness is characterized by more widespread dissemination involving distant areas of the skin or visceral organs (e.g., the lungs, liver, adrenals) and the CNS. Although data are limited, disseminated disease probably most often represents primary infection except in the most severely immunocompromised patients. More localized syndromes may be a manifestation of either primary infection or recurrent illness.

The typical localized HSV infection begins in the mouth or about the lips, often appearing innocuously as recurrence of ordinary herpes labialis. Over the course of several days, the papules and vesicles progress to bullae, frequently with hemorrhagic fluid. The bullae or vesicles evolve into huge, chronic, bloody, coalescing, ulcerated, oozing lesions eroding into subcutaneous tissue and occasionally destroying underlying structures. The tissue is malodorous, and the lesions are painful (Fig. 170–15). The lip and palate are the sites most commonly affected. Oral lesions account for approximately 60 percent of HSV infections in children undergoing transplantation.[305] A similar syndrome, usually caused by HSV-2 infection, may be seen in the perianal or vaginal area and is one of the characteristic syndromes that occur in males who have sex with HIV-infected males (Fig. 170–16). Untreated, the lesions may lead to death because of local destruction and hemorrhage, or they may regress as the immune status of the host improves or as antiviral chemotherapy is administered. A syndrome of herpetic geometric glossitis has been reported in HIV-infected patients.[121] Affected patients have a tender tongue accompanied by dorsal longitudinal crossed and branching fissures.

Extensive HSV skin infections may occur in patients with burns, eczema, pemphigus, or abrasions, often with conversion of second-degree tissue damage to third-degree damage (see Figs. 170–6 and 170–7). Of 179 children with eczema, herpes skin

infections developed in 10, 7 of whom required hospitalization.[78] Though rare, local infection may progress to dissemination in some cases, possibly as a result of the more severe immunodeficiency occurring with several of these conditions. The widespread necrotizing lesions are known commonly as *Kaposi varicelliform eruption* or *eczema herpeticum* (see Fig. 170–6). The predisposition to severe HSV-1 infection in children with atopic eczema appears to be due to the cutaneous abnormalities because these children have T-cell responses to HSV, as well as high HSV IgG antibody titers.[118] Recent studies have looked at the role of the cathelicidin family of antimicrobial peptides in protecting children with atopic dermatitis against disseminated skin infection with HSV. Variable skin expression of cathelicidin peptide LL-37 may explain why eczema herpeticum develops in some children with atopic dermatitis and others appear to be at lower risk.[138]

Herpes skin lesions must be differentiated from bacterial infections caused by gram-positive or gram-negative organisms, chronic fungal infections (as seen with *Mucor* or *Blastomyces*), other viral infections (vaccinia, varicella), mycobacterial infection, and various non-infectious lesions such as pyoderma gangrenosum, chemotherapy-induced ulcers, or Sweet syndrome. HSV is the agent associated most commonly with oral lesions in immunocompromised patients.[107]

HSV esophagitis rarely has been reported in normal children,[29] but it is a relatively common finding in immunocompromised patients. Pathologic studies have suggested that approximately 25 percent of cases of autopsy-proven esophagitis (1% to 6% of all autopsies) are secondary to HSV infection (14 of 55 cases).[207] Underlying conditions included burns, aplastic anemia, malignancies, transplantation, a variety of other serious medical problems, and postoperative trauma induced by nasogastric tubes.[51,190,207] Twenty to 50 percent of these patients have HSV involvement elsewhere (the lungs, trachea, and less commonly, the skin). The esophagitis may be asymptomatic or associated with dysphagia, odynophagia, epigastric discomfort, and retrosternal pain. Characteristic findings in the esophagus are ulcers with raised granular margins. The ulcers often are covered with fibrinous exudate and, in advanced cases, are confluent, with progression to complete mucosal loss in large segments of the esophagus. Typically, visceral herpes infection is not suspected before the patient's death, but uncommonly, involvement of adjacent gastric tissue can be documented. Diagnostic evaluation should include a barium swallow, which may demonstrate edema, nodules, and ulceration of the esophagus; however, barium studies cannot differentiate HSV from other etiologic agents of esophagitis. Esophagoscopy accompanied by biopsy and viral culture is diagnostic and helps exclude other common causes of this syndrome, including *Candida*, CMV, and possibly other fungi and bacteria or chemotherapy-induced changes.[51,207] Although the oral cavity, esophagus, and rectum are the usual sites of HSV infection in the gastrointestinal tract of immunocompromised patients, HSV-2 colitis has been reported in a young child after combined liver and small bowel transplantation.[83]

HSV pneumonia is an unusual condition, but lung involvement has been described in neonates[35] and immunocompromised hosts. This diagnosis frequently is made post mortem almost exclusively in immunocompromised patients. In one series of 1000 consecutive autopsies,[206] HSV pneumonia was identified in 10 cases. HSV pulmonary infection occurred in 3 percent of children who had undergone renal transplantation.[305] In most adult cases, the process is a result of endogenous viral mucocutaneous reactivation and involvement of lung tissue by contiguous spread, which causes focal pneumonia (60% of the time), or involvement by hematogenous spread from an oral or genital site, which results in diffuse pneumonitis.[227] Although the largest series consisted primarily of adult patients, three of the patients were aged 7 years or younger (with Down syndrome and congestive heart failure, rhabdomyosarcoma, and pneumococcal pneumonia and a seizure disorder).[140] Patients had cough, dyspnea, fever, and hypoxia, and 50 percent had rales. Most had other concomitant pulmonary infections with bacteria, *Candida*, *Aspergillus*, and CMV. HSV pneumonia cannot be diagnosed by the association of upper airway cultures and radiographic abnormalities. It must rest on an aggressive approach involving culture and histopathologic examination of involved lung tissue obtained by either biopsy or bronchoscopy.

HSV meningoencephalitis is not a common occurrence in immunocompromised patients. It may occur as a component of widely disseminated disease, or it may be a localized condition. Several cases have been reported in patients who had agammaglobulinemia in association with concomitant enteroviral infection of the brain.[186] The meningoencephalitis may be fulminant, such as occurs in a normal host. An interesting case that followed an atypical subacute course accompanied by bilateral brain involvement has been reported in an anergic patient who had Hodgkin disease. Although HSV does not appear to have a predilection for CNS infection in immunocompromised hosts, patients with AIDS are an exception and may have ascending myelitis, acute transverse myelitis, and encephalitis.[107,110,128,314]

Hepatitis caused by HSV has been reported most commonly after solid organ or bone marrow transplantation[145,168] and during pregnancy.[154] Signs include fever, abdominal pain, and elevated liver enzyme levels. Hepatitis usually occurs during the first 3 weeks after transplantation, unless prophylactic acyclovir is given. The mortality rate is very high (67% to 100%). In at least one case, orthotopic liver transplantation resulted in survival.[268]

The most severe form of HSV in an immunocompromised host is widely disseminated disease that can involve the liver, adrenals, lungs, spleen, kidney, and often the brain. In a large series from South Africa and Kenya,[30,153,302] measles and severe malnutrition were frequent cofactors (83%) in children aged 2 to 25 months who had widely disseminated HSV infection. These illnesses represented fatal primary infections. Similar syndromes have been described; they and other underlying conditions are listed in Table 170–3. Dissemination has been reported coincident with pertussis, *Haemophilus influenzae* meningitis,[143] and other bacterial infections.[30] Disseminated HSV infection occurred in 10 percent and 25 percent of children who had HSV infection and underwent bone marrow and renal transplantation, respectively.[205,327]

The clinical manifestation of disseminated HSV usually is one of initial fever and skin or mucocutaneous involvement in 80 percent of cases, but instead of healing as expected, the infection disseminates. The cutaneous dissemination may involve a widespread vesicular eruption that looks much like varicella, or it may involve more local, large hemorrhagic vesicles and bullae. Involvement of the major target organs, as noted previously, gives rise to syndromes of hepatitis, pneumonia, shock, bleeding, disseminated intravascular coagulopathy, seizures, coma, renal failure, hypothermia, and death in days to weeks. Laboratory examination may reveal leukopenia, thrombocytopenia, elevated liver function test values, hyponatremia, azotemia, pneumonitis, hypoglycemia, CSF pleocytosis, abnormal EEG results, and electrocardiographic abnormalities. Death occurs commonly in this syndrome (90%), even after the institution of antiviral chemotherapy. Because the liver frequently is involved and biopsy may be precluded by the tenuous condition of the patient, HSV infection should be considered in all high-risk groups (see Table 170–3) with fulminant hepatitis.

Neonatal HSV infection is discussed in another chapter devoted to viral infections of the fetus and newborn.

DIAGNOSIS

Clinical findings may suggest a probable diagnosis of HSV infection, but obtaining a definitive laboratory diagnosis is necessary or useful in many circumstances.[13] Accurate laboratory diagnosis requires giving attention to obtaining the correct specimens necessary for identifying the etiology of the clinical syndrome. Appropriate interpretation of the laboratory results is the second critical factor. Evaluation of mucocutaneous lesions in high-risk patients guides the use of antiviral therapy if the lesion is herpetic. However, because HSV often is shed in immunosuppressed and otherwise healthy individuals, finding HSV in oropharyngeal secretions does not mean that the clinical condition is caused by HSV. In general, the virus must be isolated from the relevant tissue for confirmation of the diagnosis. The test selected also is important (e.g., HSV is rarely found in spinal fluid cultures of patients outside the neonatal age group with HSV encephalitis), and detection of viral DNA by PCR assay or, if necessary, by brain biopsy is required to prove the diagnosis and exclude other treatable causes. Laboratory diagnosis also is valuable when HSV infections are not life-threatening. For example, establishing that a genital lesion is caused by HSV-1 or HSV-2 facilitates making decisions about antiviral therapy and allows initiation of appropriate counseling regarding the risk of recurrences and measures that may reduce transmission of HSV to contacts.

VIRAL CULTURE

The gold standard of HSV diagnosis remains recovery of infectious virus in tissue culture. HSV grows rapidly (mean, 2 to 3 days; high-titer samples, 12 to 24 hours; low-titer samples, 5 to 7 days) and produces a typical cytopathic effect (Fig. 170–17). Human diploid cells (WI-38 or human embryonic lung cells) and primate cells (Vero) are used by most diagnostic laboratories. A tentative diagnosis can be made in 95 percent of cases by the cell types infected and the typical cytopathogenic effect. High-titer specimens of VZV or CMV occasionally cause confusion. Sensitivity can be improved by centrifugation of specimens directly onto cell monolayers; a more rapid result can be obtained by using shell vial cultures combined with antigen-detection methods.[99,141,308]

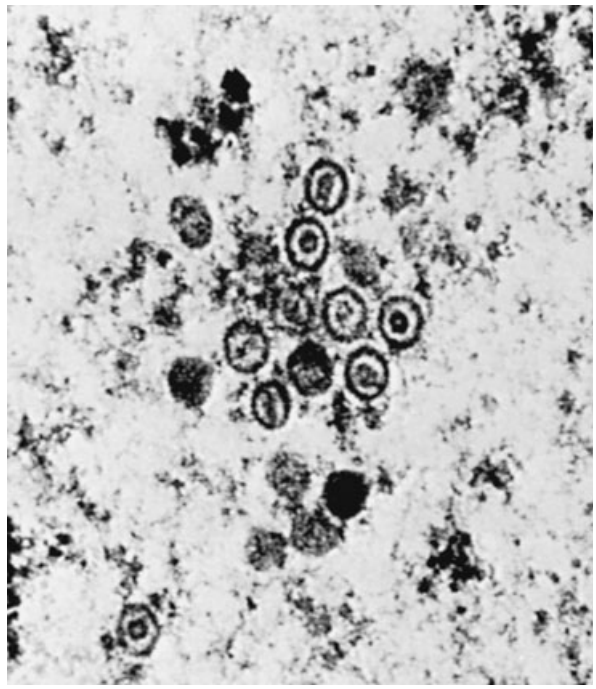

Figure 170–17 Electron-microscopic demonstration of HSV particles in a brain biopsy specimen from a 9-month-old infant with HSV encephalitis.

Definitive identification of the infecting virus is accomplished by using HSV-1– and HSV-2–specific antisera or monoclonal antibodies or by endonuclease restriction patterns. HSV-1 and HSV-2 also have biologic differences (replication in chicken embryo cells, effects on baby mice, allantoic membrane pock morphology, and sensitivity to various chemicals). Co-cultivation of ganglia tissue along with permissive cells remains the standard technique for detecting latent virus, but this technique has little application in clinical medicine.[26,28]

DIRECT DETECTION OF HSV-INFECTED CELLS

Direct detection methods allow a diagnosis of HSV infection to be established rapidly when mucocutaneous lesions are present or when tissue sections from infected organs are examined.[13,77,201,202,260] Direct immunofluorescence or immunoperoxidase staining of cells taken from mucocutaneous lesions is the procedure used most commonly. Specimens are obtained by exposing the base of the lesion, scraping to remove cells, and transferring the cells to a glass slide. The use of fluorescein-conjugated monoclonal antibodies to HSV to stain lesion scrapings yields sensitivities, when compared with viral culture isolation, in the range of 78 to 88 percent with few false-positive reactions.[210] Nonetheless, a sample for viral culture should be obtained when the lesion scraping is performed so that the direct

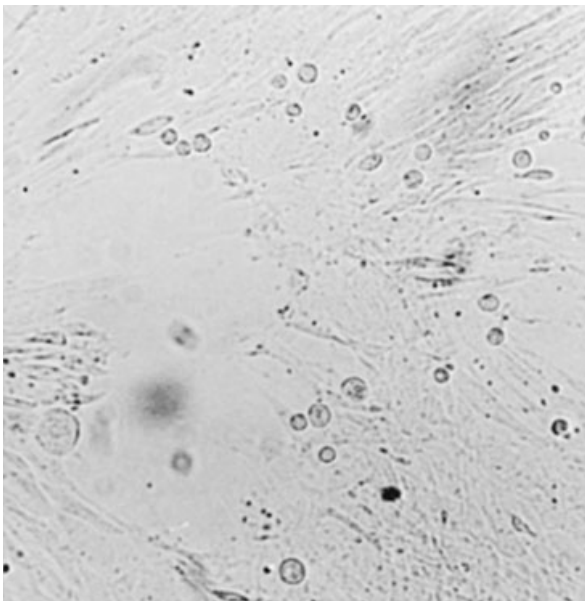

Figure 170–18 Culture of HSV on human fibroblasts demonstrating disruption of the cell monolayer and rounding and enlargement of cells to show the cytopathogenic effect.

detection result can be confirmed. Direct detection methods should not be used to test secretion specimens for asymptomatic shedding, cells from the CSF of patients with suspected encephalitis, or cells from oropharyngeal or tracheal aspirate or bronchoalveolar lavage samples. HSV antigens can be detected directly in clinical specimens by enzyme-linked immunosorbent assays (ELISAs), immunoperoxidase assays, hemagglutination assays, or avidin-biotin enzyme conjugate assays.[6,43,66,210,260] Sensitivities range from 70 to 95 percent, with specificities of 65 to 95 percent, when compared with viral culture. None of these methods is reliable for detecting asymptomatic HSV shedding.[313] Except for sporadic reports, antigen-detection tests for HSV in CSF have been unsuccessful and should not be used.[159]

Nonspecific methods such as Papanicolaou (Pap) staining or the Tzanck test have been used in the past to suggest possible HSV infection. Even though these methods may show cytologic changes in specimens obtained from suspected HSV lesions, the diagnosis of HSV should not rely on these methods in current practice because rapid, specific methods are available. Although cytologic examination of HSV lesions reveals typical giant cells and, less commonly, Cowdry type A intranuclear inclusions, these changes also are seen with CMV and VZV. Some series report finding cytologic changes in 80 percent of culture-positive specimens if the examiner is experienced, but other series find such changes in only 40 percent. Electron microscopy of vesicular fluid or tissue preparations may reveal the characteristic virus of the herpes family (Fig. 170–18). However, the microscopist cannot differentiate HSV from other herpesviruses, and this diagnostic approach rarely is available as a rapid method. Because selection of antiviral drugs for herpesviruses requires specific identification of the infecting virus (e.g., HSV must be differentiated from CMV in the brain, lungs, or liver because therapy differs), nonspecific methods have limited clinical value.

POLYMERASE CHAIN REACTION ASSAYS

PCR assays involve repeated amplification of targeted regions of HSV DNA by the design of primers that will anneal to denatured DNA and produce millions of copies of the DNA sequence.[22,239] The sensitivity of PCR methods can permit detection of fewer than 10 copies of the viral genome in a sample. PCR has been applied successfully to the diagnosis of HSV infection.[7,22,136,191,239,248] PCR clearly is more sensitive than is virus culture for detection of HSV DNA. In one study of mucosal specimens, the ratio of PCR positivity to virus culture ranged from 3.8:1 in the winter to 8.8:1 in the summer.[319] The decrease in isolation of virus by culture in the summer reflects poor viability of virus at warmer temperatures. The extreme sensitivity of PCR renders it prone to false-positive results in the event of poor technique or specimen contamination.

In clinical laboratories that have proper experience with PCR and when appropriate controls are used in the assay, PCR assay is the method of choice for detection of low copy numbers of HSV DNA and for detection of HSV DNA in CSF for the diagnosis of HSV encephalitis.[22,239,307] Sequential testing by PCR assay has rendered the use of brain biopsy unnecessary in most situations.[172] Studies consistently have demonstrated that HSV PCR has value for testing the CSF of patients with suspected herpes encephalitis.[122,152,224,239,259,271] HSV DNA was detected by PCR in the CSF of 53 (98%) of 54 patients with biopsy-proven herpes simplex encephalitis and was detected in all 18 CSF specimens obtained before brain biopsy was performed on patients with proven herpes encephalitis.[172] However, clinicians must recognize that PCR may be negative early in the course of HSV encephalitis.[329] A negative PCR result does not exclude the diagnosis of HSV because specimens obtained early in the clinical course of some infections may be negative and clinical specimens often contain inhibitors of PCR.[53,130,231] PCR also has been used to demonstrate prolonged presence of HSV DNA in genital lesions.[65] The sensitivity of the PCR method is adequate for detecting asymptomatic shedding of HSV, although a positive PCR result does not indicate the presence of infectious virus necessarily.[64,130] HSV PCR also has utility when the clinical diagnosis is difficult to make, as illustrated by detection of HSV in vitreous fluid and in unusual mucocutaneous lesions in patients with AIDS.[74,178] Primers for both HSV-1 and HSV-2 can be included in the PCR reaction to allow simultaneous detection and typing of the infecting virus.[307]

DNA hybridization with radiolabeled or biotinylated probes also can be used to detect HSV directly in pathologic specimens.[95,103] This technique may detect virus or incomplete viral DNA or RNA in latency or in sites with low levels of productive infection.

SEROLOGIC DIAGNOSIS

In contrast to methods that detect the virus (viral culture), viral DNA (PCR assay), or proteins (direct antigen detection), serologic methods historically have had limited value for the clinical diagnosis of HSV infection. With standard methods, demonstration of the presence of IgG antibodies to HSV in serum means that the individual has acquired HSV-1 or HSV-2, or both, at some time in the recent (2 to 4 weeks) or distant (many years) past. Because these viruses cause persistent infection, the presence of HSV antibodies signifies only that the individual has latent HSV-1 or HSV-2 (or both) in sensory ganglia and that the virus can be expected to reactivate and be shed in secretions intermittently. Many serologic methods can be used to assess HSV IgG immune status to document whether an individual is infected with HSV, and most are sensitive. HSV serologic testing generally has been performed by using commercial ELISA or latex agglutination procedures that use crude infected cell–protein mixtures and detect predominantly type-common antibodies.[109,318] Practitioners must understand that the extensive cross-reactivity between HSV-1 and HSV-2 antibodies renders differentiating past HSV-1 from past HSV-2 infection impossi-

ble with any of these methods.[17,18,109,297] Serologic reports that list HSV-1 and HSV-2 antibody titers separately are misleading, but they frequently are provided without the necessary explanation about the lack of sensitivity for identifying the patient's infection status.

Research laboratories use Western blot (immunoblot) analysis to demonstrate reactivity with type-specific viral proteins. For example, the fact that the gG of HSV-1 (gG_1) differs significantly from the HSV-2 homologue (gG_2) permits detection of type-specific IgG and IgM antibodies.[17,135,297] Recently, commercial laboratories have begun to use validated serologic methods that circumvent the problem of cross-reactivity between HSV-1 and HSV-2 antibodies.[318] These specialized serologic methods can be used to show whether the individual is infected with HSV-1, HSV-2, or both, but not when the infection was acquired. If paired sera are available, showing seroconversion to HSV-2 even when the patient has HSV-1 infection may be possible.[17,40,96,146,165] The newer commercial type-specific HSV tests have performed well when compared with Western Blot testing. When one of these methods was evaluated in patients with HSV-2 infection proved by viral culture and Western blot analysis, its sensitivity for detection of HSV-2 antibody was 96 percent and its specificity was 98 percent.[19] Although HSV type-specific serologic tests have become available through commercial diagnostic laboratories, practitioners must confirm that the laboratory is using such a method and not the "standard" ELISA or other tests that are commonly—and misleadingly—reported as though HSV-1 and HSV-2 antibodies have been identified accurately. The Centers for Disease Control and Prevention's Sexually Transmitted Diseases Treatment Guidelines list the type-specific glycoprotein-based assays that are validated by the U.S. Food and Drug Administration.[344] The sensitivities of these tests range from 80 to 98 percent, and specificities generally are greater than 95 percent. False-negative results are more likely to be seen early in the course of infection, and false-positive results may occur in patients with a low likelihood of having HSV infection.

If the patient is seronegative at the onset of symptoms or at initial evaluation, primary HSV infection can be documented by using any of the standard ELISA methods to show seroconversion with paired sera.[160] However, again, the serotype of HSV responsible for the seroconversion cannot be determined with most commercial serologic tests. Serologic tests also are not useful for evaluating possible recurrent HSV because recurrences often are not accompanied by a significant rise in antibody titer. Determining HSV IgG antibody titers in paired sera is not helpful because titers may vary more than fourfold in the absence of viral reactivation. Testing for IgM antibodies does not improve the serologic diagnosis; HSV IgM assays cannot be used to distinguish primary from recurrent infection because reactivation also can induce the production of IgM antibody. In addition, HSV IgM antibody assays are difficult to standardize, and false-positive results occur commonly, even when effort is made to fractionate serum IgG and IgM before testing.

Local production of HSV IgG in CSF samples can be used to document HSV encephalitis in some patients, but a 2- to 4-week interval is required to demonstrate this change,[204] and it cannot be used to guide antiviral therapy.[22,159,272,312] Testing CSF for HSV IgM antibodies has no demonstrated diagnostic value.

GENETIC ANALYSIS FOR MOLECULAR EPIDEMIOLOGY

HSV DNA from epidemiologically unrelated isolates has a specific cleavage pattern, or "fingerprint," when digested by endonuclease restriction enzymes and subjected to electrophoresis in a gel (Fig. 170–19).[49] These methods can be used to type the virus and demonstrate relatedness or differences among isolates obtained from different sites in the same person during one illness or from the same site over the course of time for the purpose of evaluating apparent "outbreaks" or nosocomial transmission.[49,50,129,185,337] This method has improved the understanding of HSV-1 and HSV-2 epidemiology, investigation of the possibility of exogenous re-infection versus recurrence, and the possibility that individuals may harbor more than one latent virus "strain." To be sure of identity, several restriction enzymes must be used to test each isolate. Thus, this method is valuable for epidemiologic purposes, but it is time-consuming and requires special expertise beyond that of most viral diagnostic laboratories. HSV genotyping by PCR and sequencing is done as a research method.

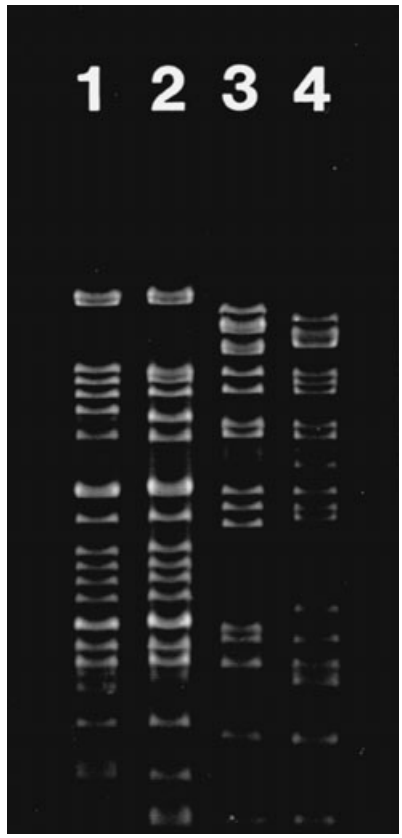

Figure 170–19 Electrophoretic separation of the DNA fragments of four HSV isolates by size, produced by restriction endonuclease enzyme digestion using the BamHI enzyme. Lanes 1 and 2 are two different HSV-2 clinical isolates, whereas lanes 3 and 4 are two different HSV-1 clinical isolates. DRUG SUSCEPTIBILITY TESTING

Though not in general use, antiviral drug susceptibility testing of HSV isolates is becoming available in many centers. Methods for antiviral susceptibility testing include plaque reduction assay, viral cytopathic reduction assays, dye uptake methods, and DNA hybridization.[226] With the availability of specific antiviral therapy and evolving mechanisms of viral drug resistance, the clinician must rely increasingly on sensitivity tests that resemble the in vitro minimal inhibitory concentration tests used for bacteria. Evolving clinical data are providing meaningful values for "sensitive and resistant" virus, although the specific numbers vary by assay. In general, a median infectious dose (ID_{50}) of greater than 3 μg/mL for acyclovir and greater than 100 μg/mL for foscarnet

denotes a resistant isolate,[63,245] although the ID_{50} value may vary depending on the specific method used. Simpler and more rapid screening tests are being developed.[75,247] In addition, detection of HSV enzyme characteristics, such as thymidine kinase–negative HSV isolates, which therefore are resistant to acyclovir, can be useful. In an immunocompromised patient, in particular, failure to respond to antiviral therapy should alert the clinician to the need for viral susceptibility testing.

PROGNOSIS, COMPLICATIONS, AND SEQUELAE

Most HSV infections occurring beyond the fetal and neonatal periods cause minor morbidity but very rarely are life-threatening. The introduction of antiviral drugs that inhibit HSV replication has changed the management and outcome of these infections during the past 20 years. Even before these drugs were available, eczema herpeticum resolved without sequelae in most cases. Despite administration of antiviral therapy, HSV encephalitis can be fatal or be associated with serious consequences ranging from moderate to extensive and permanent neurologic disability. The case-fatality rate for untreated encephalitis may be as high as 75 percent,[340] and progressive neurologic damage may occur.[88,126,159] In a series of PCR-diagnosed cases, a Glasgow Coma Scale score lower than 11 was associated with a poor outcome, and the youngest cohort, those younger than 3 years, had higher morbidity and mortality rates.[142] Genital herpes causes significant physical and psychological morbidity. In immunocompromised patients, disseminated HSV infection can result in fatal or serious illness. HSV is one of the most common infectious causes of blindness in developed countries.

TREATMENT

HSV-1 and HSV-2 infections are treated with acyclovir or related drugs. Acyclovir is a nucleoside analogue that is a competitive inhibitor of HSV DNA polymerase, and it terminates DNA chain elongation. Acyclovir is an inactive agent; inhibition of viral DNA synthesis by blocking viral DNA polymerase and DNA chain elongation requires phosphorylation of acyclovir. HSV-1 and HSV-2 viral thymidine kinases are much more active than are mammalian cell kinases, and acyclovir becomes a specific antiviral agent in the presence of viral thymidine kinase.

Because the oral bioavailability of acyclovir is only approximately 20 percent, efficacy with oral administration requires high and frequent dosing. Concentrations of acyclovir achieved in CSF are approximately 50 percent of plasma levels. Acyclovir is excreted by glomerular filtration, so doses must be reduced in patients with impaired renal function. Acyclovir has been an exceptionally safe drug in clinical practice, but adverse reactions, including rash, nausea, vomiting, diarrhea, abdominal pain, headache, and neutropenia, can occur. Neurotoxicity may occur with an overdose, usually when the dose is not adjusted for poor renal clearance. Acyclovir also can cause acute renal insufficiency by precipitation in the renal tubules in dehydrated patients with high plasma concentrations or by rapid infusion of the drug. Valacyclovir, the L-valine ester of acyclovir, is converted to acyclovir[311] and has much higher bioavailability after oral administration, with plasma concentrations similar to those obtained after intravenous administration of acyclovir. Famciclovir is an oral prodrug of penciclovir[82]; it also is well absorbed orally and is metabolized to the active form on absorption. The major advantage of these agents is that less frequent dosing is required than with acyclovir. HSV-1 and HSV-2 seldom are resistant to acyclovir or related drugs, but resistance can occur in immunocompromised patients who receive prolonged antiviral therapy. However, these doses have not been tested in young children. HSV isolates resistant to acyclovir usually have mutations in viral thymidine kinase. Foscarnet or, in some cases, cidofovir is an alternative for the treatment of acyclovir-resistant HSV.[38] Resistance to foscarnet and, more recently, cidofovir has been reported.[345]

ORAL HSV INFECTION

Although published experience is limited, administration of oral acyclovir to children with gingivostomatitis is appropriate and can be expected to modify the duration of symptoms if it is initiated early in the clinical course. Several small placebo-controlled trials of primary herpes gingivostomatitis in young children have been reported.[4,9] In one study, the pain and hypersalivation resolved more quickly in acyclovir-treated patients.[94] In a larger study, symptoms resolved more rapidly with a 10-day course of oral acyclovir (600 mg/m^2 four times a day); differences were observed in drooling (4 vs. 8 days with placebo), gum swelling (5 vs. 7 days), speed of healing of intraoral lesions (6 vs. 8 days), appearance of new lesions (57% vs. 94%), and viral shedding in saliva (4 vs. 10 days). Therapy had no effect on the subsequent development of cold sores.[9] A comparison of oral acyclovir suspension, 15 mg/kg five times a day for 7 days, and placebo started within 72 hours documented that drug recipients had a shorter duration of oral lesions (median of 4 vs. 10 days [difference, 6 days; 95% confidence interval (CI), 4.0 to 8.0]) and earlier resolution of other symptoms, including fever (1 vs. 3 days [difference, 2 days; CI, 0.8 to 3.2]), extraoral lesions (0 vs. 5.5 days [difference, 5.5 days; CI, 1.3 to 4.7]), difficulty eating (4 vs. 7 days [difference, 3 days; CI, 1.31 to 4.69]), and difficulty drinking (3 vs. 6 days [difference, 3 days; CI, 1.1 to 4.9]).[4] Treatment also decreased the period of viral shedding (1 vs. 5 days [difference, 4 days; CI, 2.9 to 5.1]). Symptomatic therapy includes antipyretics and oral hydration. The use of oral anesthetics is not recommended and has resulted in self-injury as a result of children chewing on anesthetized oral mucosa or lips.

Although the duration of symptoms is shorter with recurrences, children with frequent or severe recurrences may benefit from treatment with oral acyclovir as soon as new lesions appear. Topical acyclovir has been licensed for the treatment of recurrent oral herpes labialis based on experience in adults. However, its benefits on clinical symptoms are minimal. If treatment in children is indicated, oral acyclovir is the best option. Studies in adult patients with herpes labialis show that patient-initiated, high-dose, short-duration treatment with valacyclovir or famciclovir initiated at the onset of symptoms significantly reduces the time to healing and hastens resolution of pain and tenderness when compared with placebo.[277,280]

Several studies have produced conflicting results regarding the use of topical acyclovir for the treatment of oral herpes recurrences. Topical acyclovir can decrease the duration of HSV shedding from 2 to 3 days with placebo treatment to 1 to 2 days,[282] and the effect on symptoms is either none or subtle (1 less day with vesicles and a 2- to 3-day acceleration of healing). Although no controlled studies have been conducted, acyclovir therapy should be used for the treatment of rare cases of HSV esophagitis in normal hosts.[108]

HSV KERATITIS

Children with HSV keratitis should be referred for immediate evaluation by an ophthalmologist who is familiar with this illness and its progressive, sight-threatening forms and with optimal antiviral therapy. The use of cycloplegic and anti-inflammatory agents, which may be necessary, requires specialized experience. Topical preparations have been shown to have a beneficial effect on HSV keratitis and probably other superficial ocular HSV

infections such as conjunctivitis and blepharitis.[184] These preparations include idoxuridine (Stoxil), vidarabine (Vira-A), trifluridine (Viroptic), and acyclovir. Orally administered acyclovir also has been used to treat dendritic keratitis, with effects that were similar to those achieved with topical acyclovir in the treatment of dendritic corneal ulceration. Several series suggest that oral acyclovir is therapeutic in patients who have stromal keratitis or kerato-uveitis.[179,265] When given in conjunction with topical antiviral therapy, the response to oral acyclovir was good, even in those who had failed topical therapy.[266] Oral therapy also is useful for prophylaxis against viral reactivation in those with stromal keratitis.[341]

HSV ENCEPHALITIS

Intravenous acyclovir is the drug of choice for HSV encephalitis.[334] For children 3 months to 12 years of age, 20 mg/kg/dose every 8 hours is recommended. For children older than 12 years of age and for adults, 10 mg/kg/dose every 8 hours is recommended. The recommended duration of therapy ranges from 14 to 21 days or longer. Two well-controlled clinical studies in Sweden and the United States that compared vidarabine with acyclovir (30 mg/kg/day in three divided doses for 10 to 12 days) provided evidence that acyclovir is significantly more effective than vidarabine in treating HSV encephalitis.[272,335] In the Swedish study, the early mortality rate was 19 percent in the acyclovir-treated group and 50 percent in the vidarabine-treated group.[272] The National Institutes of Health collaborative study[335] generated similar data. As was observed in the earlier vidarabine studies,[340] younger age and less severe neurologic signs at initiation of therapy markedly influence the outcome of HSV encephalitis treated with acyclovir. Lethargic patients have a 15 percent mortality rate, whereas comatose patients have a 40 percent mortality rate. The use of long-term therapy remains controversial.[126,159,333]

In addition to antiviral therapy, intensive care is required for optimizing the outcome of these patients. Fluid management for the prevention of overhydration is critical. Frequently, direct measurement of intracranial pressure is necessary for effective monitoring of increased pressure and treatment with diuretic agents. The use of steroids is common but remains controversial and unstudied; viral replication does not appear to be more extensive as a consequence of steroid therapy. Anticonvulsant therapy for management of the often severe and prolonged seizures, as well as ventilatory support, usually is necessary at some time during the illness.

GENITAL HSV INFECTION

Recommended antiviral therapies for genital herpes simplex infection include acyclovir, famciclovir, and valacyclovir (see Table 170–4), but acyclovir remains the best studied drug in children.[82,344] Although topical acyclovir was the first antiviral therapy used to treat genital herpes, it has been replaced by the oral agent. Some benefit was observed with the topical drug, but it is difficult to use, and its effectiveness is limited when compared with oral acyclovir; treatment decreased the mean duration of viral shedding (4.1 vs. 7.0 days with placebo) and time to crusting of lesions (7.1 vs. 10.5 days).[70] In the treatment of recurrent genital disease, topical acyclovir generally tended to have a minor effect on the duration of viral shedding (from 1-2 days in treated patients vs. 2-3 days in placebo recipients), with little or no effect on symptoms.[189,230] These results were not improved markedly with the immediate use of topical ointment. Early studies in which intravenous acyclovir was given to patients with primary genital HSV infection also were performed.[68,196] When used in a placebo-controlled, double-blind study at a dose of 5 mg/kg every 8 hours for 5 days, acyclovir decreased the duration of viral shedding (2 vs. 8-13 days in placebo-treated patients), shortened the duration of local and systemic symptoms by 2 to 5 days, and decreased the time to healing by 7 to 12 days. Complications such as extragenital lesions or urinary retention were reduced significantly.[218]

TABLE 170–4 Recommended Treatment Regimens for Adults and Adolescents with Genital HSV Infection

First Clinical Episode
Acyclovir, 400 mg orally three times a day for 7 to 10 days
or
Acyclovir, 200 mg orally 5 times a day for 7 to 10 days
or
Famciclovir, 250 mg orally three times a day for 7 to 10 days
or
Valacyclovir, 1 g orally twice a day for 7-10 days
Suppressive Therapy
Acyclovir, 400 mg orally twice a day
or
Famciclovir, 250 mg orally twice a day
or
Valacyclovir, 500 mg orally once a day
or
Valacyclovir, 1 g orally once a day
Episodic Therapy*
Acyclovir, 400 mg orally three times a day for 5 days
or
Famciclovir, 125 mg orally twice daily for 5 days
or
Valacyclovir, 500 mg orally twice a day for 3 days

**Additional dosing recommendations can be found in the guidelines referenced.*
From Centers for Disease Control and Prevention: Sexually Transmitted Disease Treatment Guidelines 2006. M. M. W. R. Recomm. Rep. 55(RR-11);1-94, 2006.

Oral acyclovir has therapeutic effects on both primary and recurrent HSV infection in adults and should be given to adolescents with these infections. The major effect of intravenous acyclovir therapy on the first episode of genital HSV infection is seen in those who have true primary disease, as opposed to those who have HSV-1 immunity and are experiencing new HSV-2 infection.[218] The intravenous route of administration has been replaced by oral therapy with acyclovir and related agents. In either case, optimal benefit requires early intervention. In a double-blind, placebo-controlled study of patients with primary genital infection, acyclovir at a dose of 200 mg five times per day for 5 to 10 days significantly reduced viral shedding (1-6 days vs. 13-15 days with placebo), lesion formation after 48 hours (0-4% vs. 43-44%), the duration of lesions (10-12 vs. 16-21 days), and the duration and severity of symptoms.[48] In similar studies of adult patients with recurrent genital HSV infection, acyclovir (200 mg five times per day for 5 days) decreased the duration of virus shedding (1-2 vs. 2-4 days), time to healing (5-6 vs. 6-7 days), and development of new lesions (2-10% vs. 19-25%), especially when administered early in the recurrence.[209a]

In these short-term studies in which patients were cautioned regarding hydration, no significant side effects were observed. Furthermore, no cytogenetic effects were noted.[62] Studies of virus from either placebo or acyclovir recipients showed that 4 to 15 percent of viruses isolated after therapy were more resistant to acyclovir, regardless of therapy.[63] Neither oral nor intravenous acyclovir reduces the rate of recurrence when used to treat either primary or recurrent genital infection. Oral acyclovir is the drug of choice for patients who have primary genital HSV infection, HSV proctitis,[236] and frequent recurrent disease. Intravenous acyclovir should be reserved for patients who have severe local or systemic symptoms or complications such as urinary retention or aseptic meningitis syndrome.[218]

In adults, valacyclovir administered two times a day was as effective as acyclovir administered five times a day in the treatment of first-episode genital herpes.[101] When compared with placebo, valacyclovir is as effective as acyclovir in suppressing HSV viral replication as measured by culture and HSV PCR.[125] Similarly, famciclovir is efficacious in the treatment of first-episode and recurrent genital HSV infection.[10,241]

Symptomatic therapy for HSV lesions should be directed toward reduction of local discomfort, promotion of healing, and prevention of auto-inoculation and superinfection. Nonspecific creams and ointments probably delay healing and increase risk for the development of maceration and infection. Keeping lesions clean and dry probably is the most important local measure. Urinating sometimes is painful and can be made less so if done in a bathtub or sitz bath. Some experts advise Burow solution sitz baths or short compress treatments. Prolonged soaking delays healing.

MUCOCUTANEOUS HSV INFECTION IN IMMUNOCOMPROMISED HOSTS

Acyclovir and related drugs given orally or intravenously are the agents of choice for serious mucocutaneous HSV-1 or HSV-2 infection in high-risk hosts. Early initiation of treatment provides the best outcome. Given the limited oral bioavailability of acyclovir, higher plasma concentrations can be achieved with valacyclovir or famciclovir, but clinical experience with these drugs is limited in children. If the infection is considered potentially life-threatening, intravenous acyclovir is the treatment of choice. Therapeutic responses to HSV infection in immunocompromised hosts have been difficult to study because of the variable nature of the disease. The experience with vidarabine demonstrated the benefits of antiviral therapy initially. In a randomized, controlled, crossover study of mucocutaneous HSV infection, vidarabine (10 mg/kg/day intravenously in a 12-hour infusion) was shown to decrease pain and induce defervescence in patients older than 40 years. In none of the 85 patients in this study did visceral dissemination of HSV develop. However, these observations are of historical interest now because the drug is not available and has been replaced by acyclovir. Acyclovir ointment appears to have some minor effects on pain, viral shedding, and time to complete healing of lesions in immunocompromised persons with mild, non–life-threatening mucocutaneous HSV infection,[338] but oral acyclovir is more effective for mild illness.

Patients with more severe illness should receive care in a hospital setting with the intravenous preparation. Intravenous acyclovir has been analyzed extensively in immunocompromised patients with mucocutaneous HSV infection.[107,333] When used early, acyclovir arrests the progression of infection. In several double-blind, placebo-controlled studies, acyclovir has been shown to be highly effective. It decreased the time to cessation of new lesions (1 vs. 3 days with placebo), time to lesion crusting (3-7 vs. 9-14 days), time to lesion healing (12-14 vs. 18-28 days), cessation of pain (4-10 vs. 7-16 days), and termination of viral shedding (3 vs. 14-17 days).[317] Acyclovir administered intravenously is the most effective agent and the drug of choice for treating HSV in an immunocompromised host. The dosage is 250 mg/m^2 or 5 to 10 mg/kg/dose every 8 hours infused over a 1-hour period. In patients with severe disease, the dose may be doubled. The major toxic effect has been renal, with reversible obstructive nephropathy and transient rises in serum creatinine levels (5-10% of patients). Adequate hydration usually prevents this problem. Dosage guidelines have been established in patients who have impaired renal function (Table 170–5). One to 5 percent of patients may experience nausea and vomiting. Less commonly (1%), reversible neurologic symptoms (lethargy, agitation, tremor, disorientation, coma, transient hemiparesthesia) and laboratory abnormalities (abnormal EEG, increased CSF myelin basic protein) have developed in bone marrow transplant recipients. These patients usually had received interferon and CNS chemoprophylaxis for leukemia.[316] Other less serious problems include phlebitis (14%) and hives (5%).

TABLE 170–5 Guidelines for Use of Acyclovir in Patients with Renal Impairment*

Creatinine Clearance (mL/min/1.7 m^2)	Dose (mg/kg)	Dosing Interval (hr)
50	5	8
25-50	5	12
10-25	5	24
0-10	2.5	24

**A dose (5 mg/kg) should be administered after each dialysis session in patients undergoing hemodialysis.*

Several studies have focused on the use of oral acyclovir in this patient population.[292] The 50 percent virus-inhibiting concentration (IC_{50}) of acyclovir generally is 0.1 to 0.5 μg/mL for HSV-1 and 0.5 to 2 μg/mL for HSV-2. Many studies use molar concentrations; in the case of acyclovir, the dose in micromoles divided by 4 equals the dose in micrograms per milliliter. Whereas peak serum levels with intravenous acyclovir vary from 8 to 15 μg/mL, the levels achieved with oral therapy are considerably lower (1-2 μg/mL). In preliminary studies of relatively small populations of immunocompromised adults, oral acyclovir at doses of 200 mg five times per day effectively promoted the healing of lesions and inhibited viral shedding.[292] Pediatric studies have used oral doses of 600 mg/m^2 given four times per day.[296] The relative efficacies of oral and intravenous acyclovir have not been compared in this setting. The choice of route of administration requires clinical judgment about the degree of immunosuppression, assessment for evidence of dissemination, and frequent re-evaluation if oral drug is given.

Preliminary pharmacokinetic information regarding valacyclovir in immunocompromised children is available.[203] Valacyclovir was administered to 28 immunocompromised children aged 5 to 12 years in an open-label, randomized, dose-ranging study. Doses of valacyclovir administered were 250 or 500 mg twice a day or 500 mg three times a day. Pharmacokinetic evaluation has estimated that the bioavailability of oral valacyclovir is twofold to fourfold greater than that of oral acyclovir. The information provided in this study provides preliminary guidance for dosing of oral valacyclovir in children; however, more studies are needed to determine efficacy and safety in children.

To date, all studies of acyclovir in immunosuppressed patients have documented the propensity of recurrent lesions to reappear when therapy is withdrawn. Whether acyclovir reduces the humoral and cellular immune responses to HSV is not certain[315]; more likely, these patients remain subject to HSV recurrence because adaptive immunity is reconstituted as a consequence of the underlying disease.

Neonatal herpes simplex infection is discussed in the chapter on viral infections of the fetus and newborn.

ACYCLOVIR-RESISTANT HSV INFECTION

Despite its widespread use, acyclovir remains an effective antiviral compound. In immunocompetent hosts, acyclovir resistance has been a rare problem, even with prolonged courses of suppressive therapy. Mutant, thymidine kinase–negative virus strains have been recovered in 3 to 10 percent of patients treated with acyclovir, but acyclovir-resistant virus also can be recovered in placebo-treated patients, thus indicating that subpopulations of

HSV are present in the lesions.[63] Thymidine kinase–negative HSV recurrences in immunocompromised patients have been documented well, with demonstration of the ability of these viruses to establish latency and recur. These viral mutants are less virulent in animal models. Patients who were culture-positive for such mutants often have thymidine kinase–positive HSV isolates recovered from lesions during their next recurrence.[270]

Acyclovir-resistant virus occasionally has been shed by immunocompetent patients before, during, or after receiving therapy, yet it usually has not been associated with treatment failure.[124,164,180,293] In pretreatment patients, 3.6 percent of isolates (31 of 870) were resistant to acyclovir (not inhibited by 3 μg/mL). A similar percentage (3.1%) of resistant isolates was recovered from 663 immunocompetent patients after administration of acyclovir therapy.[63] An immunocompetent patient was reported who had an acyclovir-resistant virus containing an altered thymidine kinase that caused multiple recurrences of genital herpes unresponsive to acyclovir therapy.[164] In another immunocompetent patient receiving prophylactic acyclovir for recurrent genital herpes and long-term prednisone therapy for chronic urticaria, recurrent genital lesions with acyclovir- and penciclovir-resistant HSV-2 developed.[166] To date, these occurrences remain rare findings in the immunocompetent patient population.

Drug resistance occasionally is a problem in the acyclovir-treated immunocompromised population. Cases of acyclovir-resistant virus causing local invasive disease and, less commonly, dissemination and acyclovir-unresponsive meningoencephalitis have been reported.[107,110,187,244] Recurrences with acyclovir-resistant HSV-1 may be encountered, as described in a child with Wiskott-Aldrich syndrome.[249] Of the three mechanisms of altered sensitivity of HSV to acyclovir (absent thymidine kinase [TK^-], altered thymidine kinase [TK^A], and altered viral DNA polymerase), the TK^- type is encountered in the vast majority of cases.[63,107,110] These viruses cannot phosphorylate acyclovir and convert it to the active triphosphate. Among bone marrow transplant recipients receiving multiple courses of acyclovir, acyclovir-resistant virus was recovered from 2 percent of patients during initial therapy and from 9 percent after treatment of a second recurrence. In a tertiary care center, acyclovir-resistant, clinically significant virus was recovered from 5 percent of immunocompromised patients (usually after receiving acyclovir), but not from any immunocompetent hosts.[98] Illness caused by acyclovir-resistant viruses was more severe in pediatric patients and occurred more commonly in very immunocompromised patients such as those with AIDS or those who had undergone bone marrow transplantation.[98] Among bone marrow transplant recipients and patients with AIDS who were tested after receiving acyclovir therapy, 18 percent (105 of 582) had isolates that were acyclovir-resistant.[63] In vitro viral susceptibility of HSV has been highly associated with clinical response to acyclovir in HIV-infected patients.[245]

Acyclovir-resistant isolates are resistant to penciclovir and ganciclovir, which also require phosphorylation. Foscarnet has been used and is associated with successful clinical response and cessation of viral shedding. The most common side effects of foscarnet are nephrotoxicity (azotemia), alterations in serum calcium and phosphorus, and neutropenia, observed in 10 to 25 percent of patients.[148,244] In an immunocompromised patient who has HSV infection unresponsive to acyclovir, foscarnet therapy is indicated. Viral susceptibility testing may aid in clinical management.[246]

More recently, in patients receiving chronic or multiple courses of foscarnet, foscarnet-resistant HSV isolates (IC_{50} > 100 μg/mL) have been recovered from lesions failing to respond to foscarnet.[245,246] Of note, these lesions often responded to acyclovir, alone or in combination with foscarnet.[246] Perhaps the mutation in DNA polymerase responsible for foscarnet resistance was in an area not related to acyclovir activity. Other experimental strategies used to treat acyclovir-resistant viruses have included high-dose, continuous-infusion acyclovir (1.5 to 2.0 mg/kg/hr) or intravenous cidofovir,[46,97a,173,274] although recent cases of cidofovir-resistant isolates have been reported.[345] In the case of acyclovir- and foscarnet-resistant viruses, topical 3-hydroxy-2-phosphonomethoxypropyl cytosine (HPMPC or cidofovir) or a combination of topical trifluorothymidine and interferon-α[36,243,249] has been used successfully in patients with chronic mucocutaneous lesions.

PREVENTION

INFECTION CONTROL

Because HSV infection is ubiquitous in the human population and intermittent asymptomatic shedding is extremely common, preventing transmission of HSV is difficult. HSV is sensitive to heat and lipid solvents, so the use of antiseptics, soap and hot water, or chlorine decreases the risk of transfer of virus in settings such as the home, spas, pools, wrestling meets, and hospitals. In addition, appropriate use of gloves by all healthcare personnel who come in contact with potentially infected body secretions or rashes should decrease the acquisition and nosocomial spread of HSV. These recommendations are part of universal body substance precaution policies. Condoms may diminish the passage of infectious HSV-2 and should be recommended routinely.[321] The use of cesarean section for preventing neonatal HSV is discussed in the chapter on viral infections of the fetus and newborn.

Health care providers should wear gloves and wash carefully before and after contact with respiratory or genital tract secretions. Parents and caretakers of infants with eczema or severe diaper rash should be especially careful to avoid making direct or indirect contact of this altered skin with an active HSV lesion. Burn patients should be protected against exposure to or direct contact with personnel or visitors who have active HSV lesions. Immunosuppressed patients with evidence of HSV infection usually are experiencing reactivation of latent virus. Primary HSV infections in immunosuppressed persons, as in neonates, may be especially severe, and protecting these susceptible patients against exposure to HSV lesions is important. Wrestlers and rugby players who have exposed skin lesions caused by HSV should be excluded from competition.

IMMUNOPROPHYLAXIS

The development of vaccines is a long-term objective that has significant potential to ameliorate the disease burden associated with HSV-1 and HSV-2.[11] However, attempts to create effective HSV vaccines have met with limited success to date.[194,238,284] In one early report, a vaccine containing the recombinant glycoprotein D of HSV-2 (gD_2) was used in patients who had established recurrent genital HSV infections, and vaccine recipients had a third fewer genital herpes recurrences than those experienced by placebo recipients during the study year.[289] However, experience with the use of recombinant vaccines to prevent primary HSV infection has yielded mixed results. Recombinant HSV-2 gD_2 and gB_2 have been demonstrated to induce high humoral and cell-mediated immune responses in seronegative and seropositive recipients.[176] Some vaccines may protect some women who have no HSV immunity at baseline.[284] An HSV-2 glycoprotein D_2 subunit vaccine with alum and monophosphoryl lipid (MPL) adjuvant was approximately 73 percent effective in preventing symptomatic genital HSV-2 disease (although it was less effective in preventing infection) in women who were seronegative for both HSV-1 and HSV-2.[286] An HSV-2 gD_2 and gB_2 subunit vaccine with M59 used as an adjuvant was ineffective in prevent-

ing disease in seronegative partners of HSV-2–infected persons or in other individuals at high risk of acquiring HSV-2 infection.[69] Although efficacy was poor overall, it appeared to be better in women than in men. The results of these vaccine studies suggest that the choice of adjuvant may be critical in inducing protective immune response to HSV antigen. These studies also illustrate that high levels of neutralizing antibody do not guarantee protection against infection. Other vaccine types in early stages of development include disabled infectious single-cycle (DISC) virus vaccines, live genetically attenuated vaccines, and naked DNA.[284,339]

No adequate controlled trials of high-dose intravenous immune globulin as an intervention to suppress frequently recurring genital herpes have been reported, and this method is not likely to be effective because these patients have high titers of HSV-specific antibodies.[192]

CHEMOPROPHYLAXIS

Intramuscular human interferon-α administered before and after surgery on the trigeminal nerve root significantly decreased the incidence of HSV shedding and clinical reactivation.[217] In similar studies, interferon had no significant effect on HSV shedding or reactivation in renal transplant patients.[59]

Intravenous acyclovir has been shown to prevent reactivation of HSV almost completely in immunosuppressed patients receiving a bone marrow transplant or antileukemic chemotherapy.[252] In patients with bone marrow transplants, intravenous therapy is begun at the onset of immunosuppression and continued through the immediate transplant period, and then therapy is switched to oral acyclovir for several months.[115] Oral acyclovir administered chronically markedly suppressed recurrence in immunodeficient patients.[298] The use of prophylactic acyclovir is indicated in HSV-seropositive, immunosuppressed pediatric patients.

Oral acyclovir (200 mg two to five times per day) administered chronically can prevent reactivation of genital HSV nearly completely in patients with frequent recurrences. Recurrences decreased by 50 to 70 percent, and the time to recurrence changed from 14 to 25 days in patients receiving placebo and from 100 to 125 days in those receiving acyclovir.[91,293] Breakthrough recurrences tended to be mild and to have less viral shedding and rarely were caused by acyclovir-resistant virus. When acyclovir was discontinued (after 12 to 15 weeks of administration), HSV recurrences reverted to the pretreatment frequency. Higher doses of acyclovir suppressed recurrences in patients experiencing a "breakthrough" with more conventional doses. In patients receiving therapy for 5 years, the number of recurrences declined from the first year (1.7) to the fifth year (0.8).[116] Twenty to 25 percent of patients are recurrence-free for 4 to 5 years.[116] After prophylactic therapy ended, suppressive therapy no longer was warranted in some patients because of longer periods between recurrences.[102,290] Patients who had resistant virus exhibited reisolation of acyclovir-sensitive virus. Thus, acyclovir suppressed recurrences without eliminating latent virus. A study has reported that acyclovir does not seem to change the rate of asymptomatic viral shedding.[291] A more recent study has demonstrated that acyclovir (400 mg twice a day) resulted in a 95 percent reduction in subclinical viral shedding when compared with placebo in women with genital herpes.[324] Side effects of chronic acyclovir therapy include an increase in mean corpuscular volume and hemoglobin concentration without anemia or megaloblastic changes, neutropenia and asthenia, and mild gastrointestinal upset.[293] Valacyclovir and famciclovir also can be used to suppress frequently recurring genital herpes effectively, and they suppress both symptomatic and asymptomatic HSV shedding.[81,125,240,323] Both drugs are more expensive than is acyclovir. The decision of whether to use episodic or suppressive therapy for individuals with recurrent genital HSV infection depends on the frequency of recurrences. Those with a recent primary infection and frequent recurrences may prefer long-term suppressive therapy. If episodic therapy is used, it should be initiated as soon as symptoms begin. Oral herpetic recurrences were prevented in skiers given a brief course of acyclovir during their ski trip.[279]

Chronic antiviral suppressive therapy with valacyclovir reduced genital HSV transmission in heterosexual HSV-2–discordant couples in one study.[71] Once-daily suppressive therapy with valacyclovir or placebo was given to the HSV-2–seropositive partner. Acquisition of HSV-2 occurred in 4 of 743 susceptible partners given valacyclovir and 16 of 741 susceptible partners given placebo (hazard ratio, 0.52). HSV was identified in genital secretions 2.9 percent of days in source partners receiving valacyclovir and 10.8 percent of days in placebo recipients. Use of condoms and abstinence during symptomatic outbreaks still are recommended. Use of HSV type-specific serologic testing to identify HSV-seropositive individuals and disclosure of HSV status, in combination with condom use, risk reduction counseling, and long-term suppressive antiviral therapy, have the potential to control the spread of HSV-2 infection.[119,320] The potential utility of antiviral therapy against herpes simplex is currently being evaluated as a strategy for prevention of HIV infection.[54]

The role of antiviral therapy during pregnancy to prevent neonatal HSV infection is still undergoing evaluation for safety and efficacy. In one randomized, blinded trial, women with recurrent genital HSV received either acyclovir, 400 mg three times a day, or placebo from 36 weeks' gestation until delivery. Genital lesions were present at delivery in 14 percent of women receiving placebo and 5 percent of women taking acyclovir ($p = 0.08$). A significant decrease in HSV culture and PCR positivity was noted in the acyclovir group near the time of delivery. No significant difference in delivery by cesarean section was found between the groups. Suppressive acyclovir treatment decreased but did not eliminate genital lesions or HSV viral detection at delivery.[328] Another randomized, placebo-controlled study evaluated the effect of daily valacyclovir suppression initiated at 36 weeks' gestation. Women receiving valacyclovir had fewer recurrences of genital HSV; however, valacyclovir suppression did not decrease the number of women who had viral shedding or lesions near delivery. A limited sample size may have contributed to failure to observe a significant difference in groups treated with drug versus placebo.[8]

Experience with acyclovir prophylaxis for reactivation of HSV in children is limited. Prophylactic oral acyclovir (30 to 60 mg/kg/day in three to five doses for 1 week) has been shown to decrease seroconversion effectively and to eradicate symptomatic cases of HSV gingivostomatitis in a nursery setting in which outbreaks of primary HSV infection were occurring.[170,223] Suppression has been effective in infants with frequent recurrences of HSV-2 after neonatal HSV-2 infection and has been safe, although prolonged use has been associated with significant neutropenia. To date, up to 10 years of suppressive therapy in adults has not resulted in serious side effects[102,116,290] or an increase in the problem of drug-resistant HSV in a healthy host.

CHAPTER 171

Cytomegalovirus

Gail J. Demmler-Harrison

Cytomegalovirus (CMV) is a ubiquitous agent that commonly infects persons of all ages from all parts of the world and from all socioeconomic and cultural backgrounds. Although most CMV infections are asymptomatic, certain patient groups are at risk for acquiring serious, even life-threatening illness. Discerning which role CMV is playing in a particular patient requires a thorough understanding of the epidemiology, virology, and pathophysiology of the virus and can be difficult, even for the most experienced clinicians.

HISTORY

The recorded history of CMV probably began when Ribbert[273] described in 1881 and then reported in 1904 "protozoan-like

cells" in the organs of an infant who died of presumed congenital syphilis. In 1921, Goodpasture and Talbot[138] hypothesized that these swollen cells, or "cytomegalia," were host cells that had been injured by a virus. During the first half of the 20th century, CMV was recognizable only by the pathologic changes that it produced in infected cells, and because these cells frequently were seen in the salivary glands of animals and humans, CMV originally was called the salivary gland virus.

In 1956, human CMV was isolated in tissue culture by independent investigators, Rowe and colleagues,[282] Smith,[305] and Weller and colleagues.[355] Because several human and animal viruses subsequently were found to replicate in salivary glands, the descriptive name *cytomegalovirus* was proposed by Weller in 1960. The ability to cultivate CMV in tissue culture led to the development of serologic techniques, which in the 1960s and 1970s resulted in many important clinical and epidemiologic observations. For example, CMV was found to infect people of all ages throughout the world. By 1962, CMV was established as a significant pathogen of the fetus and newborn that was capable of producing a spectrum of clinical manifestations and neurologic sequelae.[354] In 1966, Kaariainen and colleagues[173] presented evidence supporting CMV as a cause of post-transfusion mononucleosis syndrome.

The molecular biology of the virus was explored during the 1970s and 1980s and continues to be studied by many investigators. In addition, during the 1970s and 1980s, CMV emerged as a major cause of morbidity and mortality in immunosuppressed patients, especially those who underwent organ or marrow transplantation or who had acquired immunodeficiency syndrome (AIDS). In 1976, the first clinical trial of the live attenuated CMV vaccine Towne 125 was reported; since then, more than 500 renal allograft recipients as well as healthy young men and women have received the vaccine under investigational protocols.[122,251] In addition, research on a subunit vaccine based on glycoproteins of the virus began in the 1980s; and in the 1990s and the early part of the 21st century, recombinant vaccines were developed and tested in human volunteers. However, after decades of research, a successful CMV vaccine remains elusive. In 1999, the Institute of Medicine of the National Academy of Sciences assigned a high priority for a vaccine to prevent CMV infection, an action that was quickly endorsed in 2000 by the National Vaccine Advisory Committee, based on the lifetime costs to society and the human suffering associated with CMV disease in newborns and immune compromised individuals.[18,180] Furthermore, a resurgence of awareness of CMV from public health officials and the lay community began in 2004, providing hope that prevention and treatment of CMV disease may become a priority for research, education, and public health policy.[58] Attempts by clinicians to treat CMV disease began in the late 1960s and early 1970s,[114] and now CMV infection has become a treatable disease; several specific and effective antiviral agents, including ganciclovir (licensed in 1989), foscarnet (licensed in 1991), and cidofovir (licensed in 1996), are available to clinicians to treat seriously ill patients.

VIROLOGY

CMV is a member of the *Herpesviridae* family of DNA viruses. This family contains many important human pathogens and is subdivided into three subfamilies: (1) *Alphaherpesvirinae*, fast-growing, cytolytic viruses that are latent in neurons and include herpes simplex virus (HSV) types 1 and 2 and varicella-zoster virus (VZV); (2) *Betaherpesvirinae*, slow-growing, cytomegalic viruses that contain the CMVs; and (3) *Gammaherpesvirinae*, herpesviruses that preferentially grow in lymphocytes and sometimes transform them into malignant states; this subfamily includes Epstein-Barr virus and human herpesviruses 6, 7, and 8.

CMV is the largest member of *Herpesviridae*. The genome is double-stranded DNA 240 kb in size (150×10^6 d; guanine + cytosine [G + C] content, 58%), and it has a unique long sequence and a unique short sequence, both of which are bounded by repetitive sequences that are inverted relative to each other. The genome, therefore, can assume four isomeric forms. The viral particle has a 110-nm icosahedral capsid composed of 162 capsomeres. The entire virion is enclosed by a lipid envelope, which yields a final diameter of approximately 200 nm.[324]

Replication of CMV is slow compared with that of HSV. Whereas it takes herpes simplex only 4 to 8 hours to produce infectious progeny virus, CMV requires at least 24 hours. The CMV genome is transcribed slowly in a regulated sequence; on the basis of the appearance of different classes of CMV-specific proteins, the replicative cycle can be divided into three periods: immediate-early, early, and late. The immediate-early period is defined as the first 4 hours after infection occurs. During this period, specific segments of the DNA genome undergo restricted transcription, and certain regulatory proteins are produced that allow the virus to take control of host-cell macromolecular synthesis. The early period of replication begins after the immediate-early phase and persists for almost 20 hours. This period is characterized by replication of viral DNA, synthesis of infected cell proteins, and production of progeny virus. The late period usually is considered to occur 24 hours after infection develops. During this period, the structural components of the virus are produced, and infectious virus is released from the cell. Monoclonal antibodies against the various immediate-early, early, and late proteins produced by CMV have been used as rapid viral diagnostic tools.

CMV has no distinct serotypes. However, strain relatedness or differences can be determined by molecular analysis of viral DNA. Restriction enzyme analysis of DNA extracted from CMV isolates that are linked epidemiologically (e.g., serial isolates from the same person, mother-infant pairs, or family members experiencing temporally related CMV infections) shows identical or similar DNA fragment mapping patterns. This technique or modifications of this technique have been applied to the epidemiology of CMV in a variety of patients, such as transplant recipients, congenitally infected infants, and patients whose CMV was transmitted from person to person in hospitals, daycare centers, and residences. More recent studies have used polymerase chain reaction (PCR) methodology to determine whether CMV genotypes exist by showing differences in the a sequence, major immediate-early, glycoprotein B (gB or UL55), and UL144 regions of the viral genome.[27] Four gB genotypes have been characterized, and although all genotypes cause congenital and acquired infections, studies suggest that adverse outcomes after CMV infection may be linked to infection with a specific gB genotype. Infection with the CMV gB3 genotype appears to be associated more commonly with fatal infections in bone marrow transplant recipients and hearing loss in congenitally infected newborns, and CMV gB2 and gB4 genotypes appear to be more often fatal in patients with AIDS.[27,128,262,370]

EPIDEMIOLOGY

Seroepidemiologic studies have shown that infection with CMV occurs commonly and usually is inapparent.[377] However, the burden of CMV infection and severe disease may be increasing in certain high-risk groups, such as premature and newborn infants, and older children and adults with immune deficiencies as well as transplant recipients.[296,331] The incidence of CMV infection does not appear to be seasonal. However, the prevalence of CMV IgG antibody is influenced by many factors, including the age, geographic location, cultural and socioeconomic status, race or ethnicity, and child-rearing practices of the

group. For example, in developed countries such as the United Kingdom and the United States, the prevalence of CMV antibody is 40 to 60 percent in adult populations of middle-upper socioeconomic status and more than 80 percent in lower socioeconomic status groups.[144,318,376] CMV seroprevalence in the United States also may differ by race and ethnicity, with reports of 51 percent of non-Hispanic white individuals being CMV seropositive compared with 76 percent of non-Hispanic black individuals and 82 percent of Hispanic or Mexican Americans.[79,99,321] In contrast, in developing countries, 80 percent of children acquire CMV by the time they reach 3 years of age, and almost all persons have been infected by adulthood.[12,19,350] Studies on the age-related prevalence of infection with CMV in the United States suggest three periods of increased incidence of acquisition: early childhood, adolescence, and the child-bearing years.[12,356,375]

INFANTS AND CHILDREN

Approximately 1 percent of all newborns are born congenitally infected with CMV; ranges of 0.18 to 2.5 percent are reported.[31,63,284] Maternal CMV infection that is either primary or recurrent during pregnancy can result in an infant who is infected congenitally with CMV. However, the rate of intrauterine infection with recurrent infection in the mother is less than 1 percent, whereas transmission to the fetus occurs in 32 to 50 percent of mothers who are infected primarily with CMV during pregnancy.[179,318] Although most newborns congenitally infected with CMV are asymptomatic, symptoms and sequelae are much more likely to occur in infants congenitally infected as a result of the mother's primary infection during pregnancy than in infants congenitally infected from a recurrent maternal infection.

CMV also can be transmitted perinatally from a mother to her infant. The virus can be shed in the CMV-seropositive mother's cervicovaginal secretions, urine, saliva, and breast milk. The most common and most efficient routes of perinatal transmission are ingestion or aspiration of cervicovaginal secretions at the time of delivery or ingestion of fresh breast milk after delivery. CMV-seropositive mothers, especially mothers with high levels of CMV IgG antibody, frequently shed CMV in their breast milk, and as many as 53 percent of children who are breastfed with milk that contains infectious virus or CMV DNA can become infected with CMV.[107,169,237,347] These infections usually are benign in normal term infants but may be extremely serious in preterm, very low-birth-weight neonates.[208,346] In addition, as many as 57 percent of babies whose mothers shed CMV at or around the time of delivery become infected with CMV.[272]

Children not congenitally or perinatally infected with CMV may be infected during the toddler or preschool years. The acquisition of CMV by children between 1 and 3 years of age is influenced by home exposure to the virus, by the socioeconomic status or country of origin of the family, and by group daycare exposure. Weller and Hanshaw[354] suggested that the child-rearing practices in Sweden, where group daycare was common practice, accounted for the relatively high prevalence of CMV infection in Swedish children compared with children in the United States and Great Britain, where daycare centers were not common at that time.

Pass and colleagues[241] first reported the prevalence of CMV in daycare centers in the United States in 1982. They found that 51 percent of children who attended a daycare center in Alabama excreted CMV in their saliva or urine. In this study, the prevalence of CMV excretion varied with age; 83 percent of children aged 13 to 24 months shed virus as opposed to only 9 percent of children younger than 1 year old. Pass and colleagues concluded that the high prevalence of CMV infection probably was due to horizontal spread between the children in daycare. Subsequent studies have confirmed a high prevalence of CMV excretion in children in daycare centers across the United States. Overall prevalence rates of 22 to 57 percent have been observed, with the highest prevalence of active CMV infection (29-78%) found in children 1 to 3 years of age.[1,170,223,241,243,244] Children who attend daycare centers also shed high titers of virus (up to 10^5 median tissue culture infective dose per milliliter), with a mean duration of viral shedding of 13 months in urine and 7 months in saliva.[223] This prolonged, generally asymptomatic shedding of large quantities of virus, coupled with mobility and the less than hygienic daily habits notorious in toddlers, no doubt facilitates the transmission of CMV in daycare centers.

Several studies support the idea that the high prevalence of CMV infection in young children who attend daycare centers is due to horizontal transmission; these studies used molecular fingerprinting techniques to show that infected children in contact with each other shed strains of CMV with similar or identical restriction enzyme banding patterns and that predominant strains of CMV appeared to circulate during a given period in a given daycare center.[1,2,162] Re-infection with a genetically different strain of CMV also has been observed and may be important in child-to-child transmission of CMV in the daycare center environment.[5] The importance of horizontal spread of CMV has been shown in special care centers for mentally retarded children as well.[299] CMV also has been isolated from plastic toys and from the hands of daycare center workers.[112,162,241]

CMV-infected children may transmit the virus to the daycare center workers who care for them.[2,4] In addition, children who attend daycare centers may transmit CMV to their CMV-seronegative parents. In one study of parents of children who attended one of three daycare centers in Alabama, 14 of 67 parents (21%) whose children attended daycare seroconverted, compared with none of 31 parents whose children were cared for at home.[245] Excretion of CMV by the child clearly was a key risk factor for parental seroconversion because none of the seroconversions occurred in parents whose children attended the daycare center but did not shed CMV. Moreover, this study revealed a strong trend toward a greater risk of acquiring CMV infection (seroconversion rate, 45%) in the parents of children 18 months or younger. Additional evidence implicating young children who attend daycare centers as a source of CMV infection for their parents was provided by a study in Virginia daycare centers, in which the parents of children in daycare shed CMV strains identical to the strains shed by their children.[3] Furthermore, CMV strains from daycare settings, when transmitted from toddlers to their pregnant mothers, may be the source of congenital infection.[224]

Whereas early childhood probably is the most rapid period of acquisition of CMV, annual seroconversion rates of only 3 to 6.2 percent have been observed in older children aged 3 to 10 years in the United States and other countries, thus reflecting an age-related plateau in the acquisition of CMV. One identified risk factor for the acquisition of CMV infection in a school-aged child has been recent or active CMV infection in a family member.[79,87,99,321,322,375]

ADOLESCENTS

In support of these early findings, a seroepidemiologic study of CMV infection in sexually active adolescent girls found a strong association between indicators of sexual activity and serologic evidence of CMV infection and concluded that sexual activity is an important risk factor for the acquisition of CMV infection in adolescent girls.[67,309] Early cross-sectional epidemiologic studies of CMV implied that a gradual increase in CMV antibody prevalence occurs during the teenage years, and this period of rapid acquisition was attributed to the intimate physical contact that commonly occurs during the teenage years.[12,279] However, these

studies were conducted primarily in lower socioeconomic groups. In a seroepidemiologic study of several groups in Houston, Texas, on the acquisition of CMV infection in late childhood and adolescence, the prevalence of antibody increased with age in subjects of nonwhite races, as it did according to previous studies, but the prevalence of antibody in subjects of white race did not increase with age.[356]

Vertical transmission of CMV acquired during the teenage years may result in congenital infection with CMV in infants born to teenage mothers. In 1984, Kumar and colleagues[189] studied primary CMV infection in more than 3000 pregnant adolescents in Ohio. They found that 57 percent were CMV seropositive, that 1 percent of susceptible pregnant adolescents acquired CMV, and that the risk of intrauterine transmission was 50 percent if primary CMV infection occurred during pregnancy. Information provided by the National Congenital Cytomegalovirus Disease Registry and the National Center for Health Statistics suggests that adolescents who are pregnant actually may be at higher risk than are older mothers for giving birth to an infant with congenital CMV disease because 34 percent of mothers who give birth to a baby with congenital CMV disease are younger than 20 years; however, this age group represents only 16 percent of the mothers giving birth in the United States.[88,163]

INTRAFAMILIAL TRANSMISSION

CMV also can be transmitted within the family setting. Evidence for intrafamilial transmission of CMV has been provided in the form of case reports, seroepidemiologic studies, and accounts in which molecular analysis of CMV strains was used to trace the transmission of CMV in family members or extended family members with temporally related CMV infections. In most studies, the index case was a child; when a CMV-infected child entered a household, attack rates were 47 to 53 percent.[332,337]

Three patterns of intrafamilial transmission have been observed: transmission between siblings, transmission between parents, and transmission between children and parents. Additional support for the intrafamilial transmission of CMV has been provided by published studies in which molecular analysis was performed on CMV isolates from family members or extended family members who experienced temporally related CMV infections. In each of these studies, restriction enzyme analysis of viral DNA from CMV isolates in family members showed that the strain of CMV was the same within each family.[105,246,316] New molecular techniques based on PCR amplification of a hypervariable region of the CMV genome also have corroborated the observation that genetically similar strains of CMV can be transmitted between family members over the course of time.[310]

SEXUAL TRANSMISSION

CMV also appears to be transmitted by heterosexual and homosexual contact. The evidence to support sexual transmission is anecdotal, virologic, serologic, and molecular and, taken together, suggests that sexual transmission of CMV is important in certain groups. However, because the virus is shed in saliva, cervicovaginal secretions, and semen, which form of intimate contact results in transmission between sex partners is unclear.[91,195,272]

Several observations support the idea that CMV can be transmitted sexually. For example, CMV antibody prevalence increases with age; CMV antibody is more prevalent in sexually active women than in celibate women; CMV antibody is associated with indices of sexual activity, such as recent infection with *Chlamydia trachomatis* or *Neisseria gonorrhoeae;* and a strikingly high annual incidence (37%) of primary CMV infection has been observed in young women with a recent first sexual experience.[68,78,86,126,171,309,322,362] In addition, in a longitudinal study of the site-specific shedding of CMV in human immunodeficiency virus (HIV)–seropositive homosexual and bisexual men, CMV was cultured from semen more frequently than from other body sites or fluids.[275] Moreover, molecular analysis of viral DNA has shown strains of CMV isolated from sex partners to be identical in most cases analyzed.[91,152]

Infection of the genital tract can recur by reactivation of an endogenous strain or by re-infection with an exogenous or different strain of CMV.[309] The consequences of such re-infections are unknown but may have important implications for transmission, especially if a CMV vaccine is used to control congenital CMV disease in the future. Sexual debut and recent sexual activity significantly influence CMV seroprevalence among women of child-bearing age. In addition, engaging in sexual activity within 2 years of delivery of an infant adds increased risk of delivering a congenitally infected baby. Because sexual activity appears to influence CMV seroprevalence and congenital CMV infection rates, strategies to reduce sexual transmission of CMV may be important.[126,322]

NOSOCOMIAL TRANSMISSION

CMV can be transmitted in the hospital setting by transfusion of blood products, by bone marrow and organ transplantation, and, rarely, by person-to-person transmission. Despite numerous studies that have used serologic, virologic, and molecular epidemiologic techniques, transmission of CMV from a CMV-infected patient to a health care worker has not been documented.[6,23,28,47,93,106,160] Therefore, even though health care workers are exposed to CMV-infected patients, their risk of acquiring CMV appears to be no greater than that of the general population. In addition, unlike homes and daycare centers, hospitals routinely perform rigorous infection control procedures, including universal precautions, which probably accounts for the relatively low risk of acquiring CMV as well as other infections in the hospital setting. However, infant-to-infant transmission has been shown to occur, albeit infrequently, in crowded hospital units with a high prevalence of CMV excretion in patients.[93,312] CMV also can survive on plastic surfaces and has been cultured from inanimate objects in contact with CMV-infected patients in the hospital setting.[93,312]

Blood products are a well-established source of CMV infection, and donor-to-recipient transmission of CMV has been documented by restriction enzyme analysis of viral DNA.[336] Post-transfusion CMV mononucleosis can be seen in adults who receive large volumes of fresh whole blood.[173] In addition, 15 to 17 percent of CMV-seronegative neonates who receive blood products from CMV-seropositive donors acquire CMV.[372] Post-transfusion CMV infection in newborns, especially premature infants, can cause a syndrome of shock, lymphocytosis, and pneumonitis; CMV infection also appears to hasten the progression to bronchopulmonary dysplasia in these patients.[288,372]

CMV apparently is transmitted in the residual leukocytes found in whole blood, packed red blood cells, and platelet fractions as well as by pure leukocyte transfusions. The risk for development of post-transfusion CMV infection is approximately 3 percent per unit transfused, and the risk of symptomatic infection is much higher in CMV-seronegative recipients than in CMV-seropositive recipients.

IMMUNOSUPPRESSED PATIENTS

Primary and reactivation infections as well as re-infection with CMV occur commonly in organ and marrow transplant recipi-

ents. The health care burden of severe CMV disease appears to be increasing in this special patient group.[296] Active infection with CMV occurs in almost all organ and marrow transplant recipients and usually is manifested clinically and virologically 30 to 90 days after transplantation. Rarely, CMV retinitis can occur years after a patient has undergone transplantation and generally is associated with chronic CMV viremia.[119] CMV can be transmitted to the recipient by the transplanted organ, by transfused blood products, and, theoretically, also by intimate contact with persons actively infected with CMV.

Infections with CMV are primary when they occur in CMV-seronegative recipients who receive transplants or blood products from CMV-seropositive donors. Recipients who are CMV seropositive before undergoing transplantation can experience reactivation of their own endogenous strain of CMV. In addition, CMV-seropositive transplant recipients may be superinfected by strains of CMV present in the donor organ.[71] In fact, in one study of renal transplant recipients in the United Kingdom, proven superinfection with the donor's strain of CMV occurred more frequently than did proven reactivation of the recipient's strain of virus.[148] Although reactivation, re-infection, and primary CMV infection all can produce symptoms in immunosuppressed transplant recipients, primary CMV infections are much more likely to be severe and even fatal.[256]

The type of transplant also appears to influence the type of CMV disease expressed. For example, the most severe and lethal form of CMV interstitial pneumonitis is seen in bone marrow transplant recipients, especially those experiencing a graft-versus-host reaction. CMV pneumonia also is a common occurrence after heart, lung, or renal transplantation, and severe CMV hepatitis is a special problem after liver transplantation.

The iatrogenic immunosuppression essential for graft maintenance probably is responsible for the common occurrence of reactivation infection after transplantation, as well as the increased incidence of severe and symptomatic infection seen after primary CMV infection in transplant recipients. Cytotoxic drugs such as cyclophosphamide and azathioprine, in addition to corticosteroids, have been associated with reactivation of latent CMV infection, and the addition of antilymphocyte globulin to an immunosuppressive regimen can increase the morbidity of CMV infections.[247] The use of cyclosporine as the primary immunosuppressive agent, even in conjunction with corticosteroids, does not appear to reduce the risk of acquiring CMV infection compared with a regimen of azathioprine and corticosteroids; however, it may decrease the incidence of severe, symptomatic CMV disease in some transplant recipients.[104] The use of OKT3 to treat rejection in certain transplant patients increases the risk for dissemination in those with primary CMV infection.[302]

The frequency and morbidity of CMV infection in patients with malignant neoplasms are not as high as in patients who have undergone marrow and organ transplantation; however, the use of chemotherapy, especially for leukemia, is associated with significant CMV disease, particularly pneumonitis and persistent fever with viral dissemination. CMV-seropositive patients receiving immunosuppressive therapy for connective tissue disease also can have significant reactivation infection with CMV.[100]

The progressive and profound immunosuppression in adults and children with AIDS also is associated with CMV infection and disease. Although the source of CMV infection in adults with AIDS most likely is heterosexual or homosexual contact, sources of CMV infection in young children with AIDS have not been determined. One can hypothesize, however, that many of these infections are acquired from the mother, either congenitally or perinatally. Infants infected perinatally with HIV who also acquire CMV congenitally appear to be at significant risk for experiencing rapid progression of disease in the first 18 months of life, as well as debilitating neurologic disease.[101,188,295] Patients with AIDS also may be infected with multiple strains of CMV.[103,313]

PATHOLOGY, PATHOGENESIS, AND IMMUNITY

CMV infection causes characteristic type A Cowdry intranuclear inclusions and massive enlargement of the affected cells (Fig. 171–1). It is this property of "cytomegaly" from which CMV acquired its name. The cytomegalic cells (25-40 μm in diameter) are two to four times larger than normal cells, and the nucleus usually is more than 10 μm in diameter. The intranuclear inclusion also is large (up to 10 μm in diameter) and is surrounded by an intranuclear halo and then the nuclear membrane, which gives a characteristic "owl's eye" appearance. Basophilic, granular, intracytoplasmic inclusions (2-4 μm in diameter) also may be present in cells that have intranuclear inclusions. These large cells represent productive virus infection, and both the nuclear and cytoplasmic inclusions contain viral nucleocapsids and express virus-specific antigens.[157] These cytomegalic cells frequently are associated with epithelial cells, and their presence generally indicates a productive and symptomatic infection with CMV. Cells also may be infected latently with CMV. These cells may express virus-specific antigen and contain viral nucleic acid without producing typical cytomegaly or a cytopathic effect. The significance of these cells must be considered carefully within the clinical context of the patient.

With severe, disseminated CMV disease, involvement can be seen in virtually all organ systems. The salivary glands frequently are infected in both symptomatic and asymptomatic infections, and the ductal epithelium usually is the site of pathologic involvement. The kidneys also are infected frequently in both symptomatic and asymptomatic CMV infection. In the kidneys, cytomegalic cells are most pronounced in the proximal tubules and interstitial cellular infiltrates, and even immune complex deposits can be seen in the glomeruli.

CMV infection often causes prolonged viruria, but it rarely results in significant renal dysfunction. In the lungs, cytomegalic cells are seen in alveolar and bronchial epithelium and are associated with mononuclear cell inflammation. Pulmonary alveolar macrophages also may express viral antigen and contain CMV DNA. The brain parenchyma can be involved, and a variety of pathologic processes can be observed and include sensorineural hearing loss. Other organs that can be infected or diseased with CMV include the liver, pancreas, adrenals, eyes, lymph nodes,

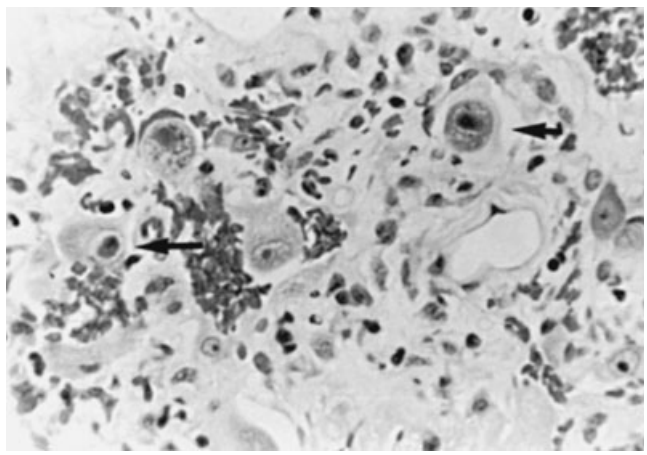

Figure 171–1 Typical cytomegalic inclusion cells seen in lung tissue obtained by open lung biopsy from a bone marrow transplant recipient with fatal cytomegalovirus pneumonitis (×640). *(Courtesy of Dr. Milton J. Finegold, Department of Pathology, Texas Children's Hospital, Houston.)*

heart, skin, bone, male and female genital tracts, esophagus, stomach, intestine, and placenta.

Infections with CMV can be latent and nonproductive, productive yet asymptomatic, or productive and symptomatic. Therefore, determination of whether a patient is "sick with CMV" or "sick from CMV" sometimes is difficult. Viral strain differences have not been shown to date to influence pathogenicity. However, immune responses, including maturity of the immune response, appear to be a major factor in virulence of the infection because CMV disease occurs more frequently in fetuses, premature neonates, transplant recipients, and patients with AIDS than in older healthy infants, children, and adults with acquired CMV infection.

The cell-mediated immune response, both specific and nonspecific, is thought to be important in host defense against CMV. The nonspecific immune mechanisms of natural killer cells and interferon production occur soon after the development of CMV infection, when early antigens are being produced and before infectious virus is released from the cell. The generation of cytotoxic T cells against CMV early antigens probably is the most important specific host immune response to CMV, and patients who are defective in this T-cell response are at high risk for acquiring serious CMV disease.[145]

Clinical and laboratory evidence also supports the concept of CMV as an immunosuppressive agent. The proliferative response of T cells to stimulation with mitogens and CMV antigen is suppressed in patients with CMV mononucleosis, and immunosuppressed patients with active CMV disease frequently have other opportunistic infections.[274] In addition, CMV pneumonitis in bone marrow transplant recipients has been hypothesized to result from host cell–mediated events produced in response to chronic viral replication.[378] Homology between certain CMV proteins and class I and class II major histocompatibility complex products has been observed. This "molecular mimicry" implies that the severe tissue destruction seen in CMV pneumonitis may be partly an autoimmune phenomenon in these patients.

Humoral immunity, on the other hand, does not appear to be a key factor in the host's defense against CMV infection. For example, the fetus can be infected by intrauterine transmission as a result of reactivation of CMV infection in a woman who is CMV seropositive before pregnancy, and infants frequently are infected perinatally from infected cervicovaginal secretions or breast milk in the presence of passive maternal antibody.[318] In addition, CMV-seropositive transplant recipients can be reinfected with a new strain of CMV from the donor organ, and viruria and viremia occur in transplant recipients despite high titers of neutralizing antibody against the specific strain of CMV.[71,72] The presence of CMV antibody, therefore, should be considered a marker of previous or current infection with the virus rather than a measure of immunity per se.

Although humoral immunity does not appear to prevent infection with CMV, it does appear to lessen the severity of associated symptoms. Infants congenitally infected with CMV as a result of reactivation of infection in their mother almost always are asymptomatic, whereas perinatally infected infants rarely have significant symptoms. Primary infections in transplant recipients are more likely to be symptomatic than is re-infection or reactivation. One hypothesis regarding how CMV eludes host humoral defenses is that the virus binds to the host protein β_2-microglobulin and masks the antigenic determinants that are important for neutralization by antibody.[211]

CLINICAL MANIFESTATIONS

FETAL AND CONGENITAL INFECTIONS

The fetus with in utero CMV infection may show ultrasonographic abnormalities, including signs of abnormal somatic or head growth, enlarged liver or spleen, echogenic bowel patterns, and hepatic calcifications, as well as biologic findings such as fetal thrombocytopenia and lymphopenia and elevated liver enzymes and elevated CMV-specific IgM antibody levels. In addition, cerebral fetal sonography may show enlarged ventricles in the fetal brain, intracranial calcifications, or microcephaly or mimic a Dandy-Walker malformation in severe cases.[21,150,203] Annually, 30,000 to 40,000 babies are born with congenital CMV infection. Of these babies, as many as 10 percent have severe, classic "cytomegalic inclusion disease" characterized by intrauterine growth retardation, jaundice, hepatosplenomegaly, thrombocytopenia with petechiae and purpura, pneumonia, and severe central nervous system (CNS) damage with microcephaly, intracerebral calcifications, chorioretinitis, and sensorineural hearing loss. Another 5 percent have atypical involvement, such as ventriculomegaly, periventricular leukomalacia, periventricular cystic malformations with or without calcifications, strabismus, optic atrophy, long bone osteitis characterized by fine vertical metaphyseal striations, isolated and transient thrombocytopenia and petechiae, cutaneous vasculitis, hemolytic anemia, ascites, chronic hepatitis, and intrahepatic cholestatic disease.[13,76,121,168] As many as 90 percent of these infants who are symptomatic at birth later have neurologic sequelae, vision loss, or progressive deafness. However, the range of severity of these sequelae appears to be broad, and severity may be predicted by head circumference and computed tomographic findings at birth.[43,231] In addition, CMV viremia and DNA in congenitally infected newborns is associated with symptomatic disease and hearing loss at birth, suggesting that the level of virus contributes to disease severity.[44,46]

The differential diagnosis of symptomatic congenital CMV disease includes congenital toxoplasmosis, congenital HSV infection, congenital syphilis, congenital rubella syndrome, congenital infection with lymphocytic choriomeningitis virus, and congenital HIV infection. In addition, non-infectious causes, such as genetic disorders, metabolic disease, and maternal exposure to drugs and toxins, should be considered.

Most infants who are infected congenitally with CMV are asymptomatic at birth. However, 10 to 17 percent of these infants later may have unilateral or bilateral deafness or differences in higher level auditory function.[80,318,361] Progressive or late-onset hearing loss also may occur in these infants, thus rendering it likely that universal newborn hearing screening programs will miss rather than detect many of these children.[124,232] Small retinal lesions may occur as well.[76] Earlier studies suggested that developmental problems may occur in asymptomatically infected children, but more recent studies suggest that cognitive outcome appears to be normal compared with uninfected children.[177]

Very low-birth-weight infants who are infected congenitally with CMV may experience pulmonary and systemic deterioration temporally associated with steroid therapy.[339]

PERINATAL INFECTIONS

Perinatally acquired infections in healthy infants usually are manifested when the child is between 4 and 16 weeks of age, but most such infections are asymptomatic. However, as many as one third of infants exposed to CMV perinatally may have signs and symptoms of disease associated with CMV infection, most often self-limited lymphadenopathy, hepatosplenomegaly, hepatitis, or pneumonitis.[191] Perinatally acquired infection with CMV also can cause a viral, sepsis-like syndrome or severe, protracted pneumonitis that has been associated with the development of bronchopulmonary dysplasia in premature infants.[208,288] A limited number of studies suggests that these infections, however, do not appear to cause neurodevelopmental sequelae or deafness.[192] The differential diagnosis includes other perinatally acquired infections, such as *Chlamydia* pneumonitis, hepatitis B virus infection, and

infection with HIV, as well as postnatally acquired infections with enteroviruses, adenovirus, and a variety of bacterial pathogens.

MONONUCLEOSIS SYNDROME

CMV-induced mononucleosis occurs as a primary infection in both immunocompetent and immunosuppressed persons and, occasionally, as a reactivation infection in immunosuppressed patients. It can result from person-to-person transmission of the virus as well as from transmission by blood products or by organ or marrow transplantation. Although originally described in adults and most often occurring in patients between 20 and 40 years of age, it also can be seen in adolescents, children, and even infants.[206,240] Typical CMV-induced mononucleosis is characterized by fever and strikingly severe malaise of approximately 1 to 4 weeks' duration, peripheral lymphocytosis with atypical lymphocytes, and mildly elevated liver enzymes. In some patients, headache, myalgias, and abdominal pain with diarrhea are prominent symptoms. In premature infants with transfusion-acquired CMV mononucleosis, prominent manifestations include shock, hepatosplenomegaly, pneumonitis, thrombocytopenia, and renal failure.[312] In contrast to Epstein-Barr virus–induced mononucleosis, CMV-induced mononucleosis rarely causes pharyngitis, tonsillitis, or significant splenomegaly, and it does not result in production of heterophil antibodies.[77,161] However, like Epstein-Barr virus–induced mononucleosis, it can be associated with morbilliform rash after administration of ampicillin, elevated erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and production of other antibodies such as rheumatoid factor, cold agglutinins, and antinuclear antibodies. Complications rarely occur but include interstitial pneumonitis, myocarditis, pericarditis, hemolytic anemia, thrombocytopenia with or without petechiae or purpura, hemophagocytic syndrome, arthralgias and arthritis, maculopapular rashes, adrenal insufficiency, splenic infarction, ulcerative colitis and proctitis, Guillain-Barré syndrome, and meningoencephalitis.[66,77,83,118,161,186,187,200] Severe, icteric hepatitis as well as granulomatous hepatitis also can occur, but hepatic necrosis and liver failure caused by CMV have not been documented convincingly in normal hosts.[41,77,161,187,269]

The differential diagnosis of CMV-induced mononucleosis includes mononucleosis induced by other viruses such as Epstein-Barr virus, hepatitis A or B virus, and HIV. In addition, acquired toxoplasmosis can produce a mononucleosis syndrome in healthy persons.

INTERSTITIAL PNEUMONITIS

CMV is a major cause of interstitial pneumonia in both adults and children who are immunosuppressed because of congenital immunodeficiency, AIDS, organ or marrow transplantation, or malignant disease. In recipients of bone marrow transplants, CMV accounts for 17 to 70 percent of cases of interstitial pneumonitis in adult patients but only 10 percent of cases in patients younger than 21 years.[353] Pneumonia also can occur in apparently immunocompetent young infants with perinatally acquired CMV infection and in healthy adults with CMV-induced mononucleosis.[181,191,317,357] Whereas the pneumonia in immunocompetent hosts almost always is benign and self-limited, CMV pneumonia in immunosuppressed patients is a serious, often fatal illness, especially in bone marrow transplant recipients, who have a mortality rate of up to 90 percent. It also can be particularly troublesome after pediatric heart and lung transplantation.[230] CMV pneumonitis usually occurs 1 to 3 months after the patient has undergone transplantation and begins with symptoms of fever and a dry, nonproductive cough. It then can progress during the course of 1 to 2 weeks to dyspnea, retractions, wheezing, and hypoxia, which require ventilatory support. It may occur as the only disease manifestation or be part of a disseminated CMV infection. The radiographic appearance of CMV pneumonia usually is diffuse, interstitial infiltrates, but peribronchial infiltrates with hyperinflation and nodular pulmonary infiltrates also have been described (Fig. 171–2).[181,334] Co-infection with other pathogens, especially gram-negative enteric bacteria and fungal pathogens in transplant recipients and in patients with *Pneumocystis carinii* infection and AIDS, can occur.[349]

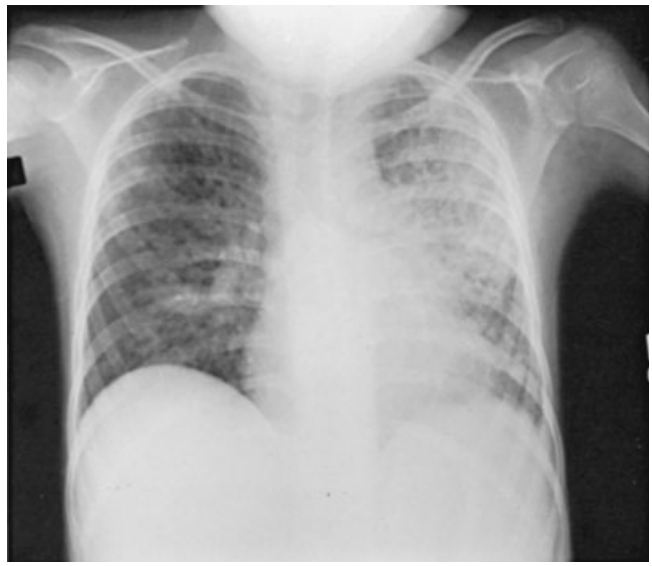

Figure 171–2 Chest radiograph of a bone marrow transplant recipient with rapidly fatal cytomegalovirus pneumonitis. An open lung biopsy specimen showed numerous cytomegalic inclusion cells, exhibited cytomegalovirus early antigens by immunoperoxidase staining, and grew cytomegalovirus after inoculation into tissue culture.

Congenitally infected infants also may be born with CMV pneumonitis, which often is sufficiently severe to require ventilatory support and usually is part of a multisystem CMV disease process. Very low-birth-weight infants who are infected congenitally with CMV may experience CMV pneumonitis in temporal association with steroid therapy.[339]

The differential diagnosis of CMV pneumonitis in immunocompromised patients, including neonates, is extensive. It includes infection with other viruses, such as HSV, VZV, measles virus, respiratory syncytial virus, influenza A and B viruses, parainfluenza viruses, and adenoviruses; bacterial pneumonia caused by a variety of gram-positive and gram-negative organisms; infection with protozoa, such as *P. carinii* and *Toxoplasma gondii; Chlamydia* and *Mycoplasma;* and fungal pneumonia, caused especially by *Candida* and *Aspergillus.* Non-infectious causes of pneumonitis, such as pulmonary hemorrhage, aspiration pneumonia, rejection, and pulmonary damage from chemotherapeutic agents, also should be considered.

RETINITIS AND OTHER EYE ABNORMALITIES

Chorioretinitis as well as optic atrophy, cortical blindness, and strabismus occurs in 17 to 41 percent of newborns with symptomatic congenital CMV infection and rarely in children born with asymptomatic congenital CMV infection.[42,76,284] Although most retinal lesions in congenitally infected infants appear to be inactive at birth, some observations suggest that progression of preexisting lesions and late-onset new lesions resulting in vision

loss may occur rarely in both symptomatic and asymptomatic congenitally infected infants.[42] Retinitis does not seem to be a prominent part of perinatally acquired infection.[192] CMV retinitis once was a rare manifestation of CMV disease in solid organ transplant recipients undergoing chronic immunosuppression for more than a year and in patients receiving chemotherapy for malignant disease.[119] In the 1980s, CMV retinitis emerged as a frequent manifestation of CMV disease in patients with severe immunosuppression, especially bone marrow transplant recipients and patients with AIDS. It probably is a result of hematogenous spread of the virus to the retina, with continued local viral replication. Despite the common occurrence of CMV retinitis in adults with AIDS, however, it rarely has been reported in children with AIDS.[201]

CMV produces characteristic white, perivascular infiltrates and hemorrhage, with a necrotic, rapidly progressive retinitis. It descriptively has been called *cottage cheese retinitis* and *ketchup* or *brushfire retinitis*.[40] Early, peripheral retinitis can be asymptomatic, or the complaints may be minimal and nonspecific; it is especially difficult to ascertain in infants and young children. It does not cause eye pain, photophobia, or conjunctivitis. Once the retinitis has progressed, it can cause blurred vision, decreased visual acuity, visual field defects, and blindness. Young children and infants who have suffered visual loss as a result of CMV retinitis may exhibit strabismus or failure to fix and follow objects within their visual field. CMV retinitis also can progress rapidly to total blindness if the macula is involved. Immunosuppressed children with CMV disease should receive regular expert ophthalmologic examinations to monitor for the development of sight-threatening retinitis. Establishing the diagnosis early may allow prompt institution of antiviral therapy, which may be sight saving.[201]

The ophthalmoscopic appearance of CMV retinitis usually is characteristic. However, in patients in whom the appearance of the retina is not typical or in whom the retinitis has progressed despite specific antiviral treatment, other causes of retinal lesions that should be considered include cotton-wool spots associated with hypertension, diabetes, connective tissue disease, anemia and leukemia, ocular toxoplasmosis, and candidal infection of the retina as well as syphilis, HSV infection, lymphocytic choriomeningitis virus infection, and VZV infection. Detection of the virus by culture or its DNA by a PCR-based method in vitreous fluid may help establish the diagnosis in difficult or atypical patients.[116] CMV antibodies also have been detected in the tears of patients with active ocular infections, including retinitis.[283]

CMV also has been associated in some studies with other unusual eye abnormalities. In coincidentally congenitally infected infants, microphthalmos, anophthalmia, optic nerve hypoplasia and coloboma, optic nerve atrophy, Peter anomaly, and irregular retinal pigment have been observed.[129] However, the role that CMV is playing in these anomalies is unclear and unsubstantiated by prospective studies.[76] CMV also does not appear to cause congenital cataracts.[301] CMV also has been isolated from tears and has been associated with conjunctivitis in patients with CMV mononucleosis and AIDS as well as with corneal epithelial keratitis and disk neovascularization.[198]

HEPATITIS

CMV hepatitis in bone marrow, heart, and lung transplant recipients, in patients with cancer or AIDS, and even in healthy persons experiencing a primary CMV infection usually is manifested as mild hepatomegaly and mildly elevated serum hepatic enzyme levels. It commonly occurs in conjunction with fever, thrombocytopenia, and lymphopenia or lymphocytosis. Jaundice and hyperbilirubinemia usually do not occur, severe hepatitis or cirrhosis is exceedingly rare, and hepatic necrosis and liver failure caused by CMV hepatitis have not been documented convincingly in these patients. CMV infection also has been associated with granulomatous hepatitis.[41,269] In addition, CMV hepatitis is a unique and prominent problem in children who have undergone liver transplantation.[49] Most CMV hepatitis occurs 1 to 2 months after the patient has undergone transplantation, but it may be noted as early as 2 weeks or as long as 4 months afterward.[51] It is more common and more severe after a primary CMV infection and is associated with liver transplantation from a CMV-seropositive donor and the use of OKT3 antibodies for severe rejection.[303] CMV hepatitis in liver transplant recipients is characterized by prolonged fever, leukopenia, thrombocytopenia, elevated liver enzymes, hyperbilirubinemia, and liver failure. Distinguishing between CMV hepatitis and acute rejection often is difficult, even with a liver biopsy, and the two commonly coexist. CMV infection also has been associated with ascending cholangitis, chronic rejection, and the vanishing bile duct syndrome in liver transplant recipients.[51,233]

Infants with congenital CMV disease also may have hepatitis. The liver usually is smooth and nontender and commonly extends 3 to 5 cm below the right costal margin. Ascites may be present prenatally and may persist postnatally for 1 to 2 weeks. The hepatomegaly usually resolves by the time the infant is 3 months of age, and persistence beyond 1 year is highly unusual. Mild hepatitis generally is present, and transaminase levels in neonatal hepatitis caused by CMV rarely exceed 500 IU. Hyperbilirubinemia is present at birth in approximately a third of newborns with congenital CMV and may be striking, with conjugated (direct) bilirubin levels up to 30 mg/dL.[163] The abnormal results of liver function tests gradually resolve during the course of the first few weeks of life, and chronic hepatitis as a result of congenital infection with CMV is an unusual occurrence. Congenital CMV disease also has been associated with intrahepatic and extrahepatic biliary atresia in some studies, but the direct role of CMV in neonatal cholestatic disease is unclear.[13,121,168]

The differential diagnosis of CMV hepatitis includes other causes of viral hepatitis, such as hepatitis A virus, hepatitis B virus, hepatitis C virus, Epstein-Barr virus, HSV, enterovirus, and adenovirus as well as toxoplasmosis; other infections, such as bacterial ascending cholangitis; and non-infectious causes, such as ischemic injury, vascular thrombosis, hemolysis, rejection, and hepatitis induced by drugs or toxins. In newborns with a significant and persistent direct hyperbilirubinemia, the diagnosis of biliary atresia should be considered as well.

GASTROINTESTINAL DISEASE

Serious gastrointestinal disease causing esophagitis, gastritis, gastric outlet obstruction, gastroenteritis, pyloric and small bowel obstruction, duodenitis, colitis, proctitis, pancreatitis, hemorrhage, and acalculous cholecystitis has been associated with CMV infection in immunocompromised persons, especially patients with AIDS or neoplastic disorders and those who have undergone bone marrow, kidney, intestinal, or liver transplantation.* Rarely, self-limited CMV gastroenteritis, colitis, and proctitis have been associated with CMV mononucleosis syndrome in apparently normal individuals.[77,161,259,260] Characteristic signs and symptoms in infants and children include nausea, vomiting, dysphagia, epigastric pain and tenderness, delayed gastric emptying, watery guaiac-positive stools or gastrointestinal hemorrhage, and disaccharide and monosaccharide intolerance. Severe disease may cause dehydration and failure to thrive. Endoscopy with biopsy is required to establish a definitive diagnosis and usually shows linear, localized, or punctate ulcers. Hemorrhagic lesions or diffuse erosion can occur in severe disease. Characteristic cyto-

*See references 11, 94-96, 204, 219, 236, 249, 258, 267, 342.

megalic inclusion cells can be seen in the gastrointestinal endothelium, epithelium, and glandular tissue; CMV may be cultured from stool or biopsy specimens; or CMV DNA may be detected by PCR-based methods.[137] In addition, these patients often are viremic and occasionally have evidence of disseminated CMV infection with involvement of the lungs and retina.

The differential diagnosis of CMV colitis includes infection with other viruses, especially HSV and adenovirus, and infection with bacteria, particularly *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia*, as well as *Clostridium difficile* and *Mycobacterium avium-intracellulare*. Parasitic infection with *Cryptosporidium*, *Giardia*, and amebae also should be excluded. The differential diagnosis of CMV esophagitis and gastritis includes HSV infection, *Candida* esophagitis, reflux esophagitis, and peptic ulcer disease.

MENINGOENCEPHALITIS AND OTHER NEUROLOGIC DISORDERS

CNS involvement is well described and occurs relatively frequently in infants with symptomatic congenital CMV infection. Although the severity of damage to the CNS during congenital infection varies greatly, postmortem examination of severely affected infants has demonstrated necrotizing encephalitis, especially in the deep periventricular structures, and scattered areas of necrosis and inclusion-bearing cells. Although direct viral infection of neural structures probably plays a major role in CNS disease in congenital CMV infection, infectious vasculitis also may occur. In addition, because congenital CMV disease can be associated with marked thrombocytopenia, intracranial hemorrhage can contribute to CMV-related CNS injury.[26,57,153,345] Clinical manifestations of this disease process include microcephaly, cerebral palsy, intracerebral calcifications, seizures, hemiparesis, developmental delay, ventriculomegaly, paraventricular cysts, intraventricular strands, periventricular leukomalacia, lissencephaly-pachygyria, porencephaly, multifocal deep white matter lesions, meningoencephalitis, and sensorineural deafness (Fig. 171–3).[193,330,341] Remarkably, despite the well-documented neuropathologic process in congenital disease, isolation of CMV from the cerebrospinal fluid (CSF) of a congenitally infected child is an extremely unusual finding.[167] CMV DNA has been detected in the CSF of congenitally infected infants, and its presence at birth appeared to identify infants at risk for a poor neurodevelopmental outcome.[20]

The differential diagnosis of symptomatic congenital CMV infection with neurologic disease includes congenital toxoplasmosis, congenital HSV infection, congenital rubella syndrome, congenital infection with lymphocytic choriomeningitis virus, brain tumors such as craniopharyngioma, and calcified hematoma. In addition, congenital CMV disease involving the CNS also may be mimicked by genetic disorders such as tuberous sclerosis, Sturge-Weber syndrome, and Aicardi syndrome; metabolic conditions such as hyperthyroidism; α_1-antitrypsin deficiency; galactosemia; peroxisome disorders such as Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease; urea cycle deficiencies; organic acidemias; and liposomal storage disorders.[25] Maternal exposure to drugs and toxins, especially isotretinoin, cocaine, and alcohol, also is included in the differential diagnosis. The presence or absence of intracerebral calcification as well as the pattern of calcifications when they are present may be helpful in distinguishing among these disorders. In addition, the appropriate microbiologic studies, chromosome analysis, metabolic studies, and drug screens should be performed.

In postnatal life, CMV meningoencephalitis appears to be rare yet well documented.[24] It may occur as a complication of CMV mononucleosis, as an isolated manifestation of primary CMV infection in a normal host, or as a primary or recurrent infection in an immunocompromised patient.[260] Symptoms include headache, photophobia, nuchal rigidity, memory deficits, and inability to concentrate. CSF findings include mild mononuclear pleocytosis and slightly elevated protein. Although the virus is isolated from the CSF and brain parenchyma exceedingly rarely, neuropathologic findings of intranuclear inclusions and microglial nodules are characteristic.

CMV encephalitis may complicate adult immunocompromised transplant recipients, and recognition of CMV encephalitis in patients with AIDS is growing.[30] As many as 50 percent of patients with AIDS may have evidence of CMV infection of the CNS at postmortem examination.[226] CMV has been reported to cause a subacute, occasionally progressive encephalitis in patients with AIDS and has been implicated as a cofactor in the pathogenesis of the AIDS dementia complex seen in both adults and children.[82,156,220,306,360] In this disease, CMV may be isolated from CSF, or CMV DNA may be detected in the fluid or brain by PCR-based methods.[140] In children, this syndrome is characterized by weakness, confusion, and loss of developmental milestones.

The differential diagnosis of CMV encephalitis and meningoencephalitis in a normal host includes primarily other neurotropic viruses, such as HSV, Epstein-Barr virus, VZV, enterovirus,

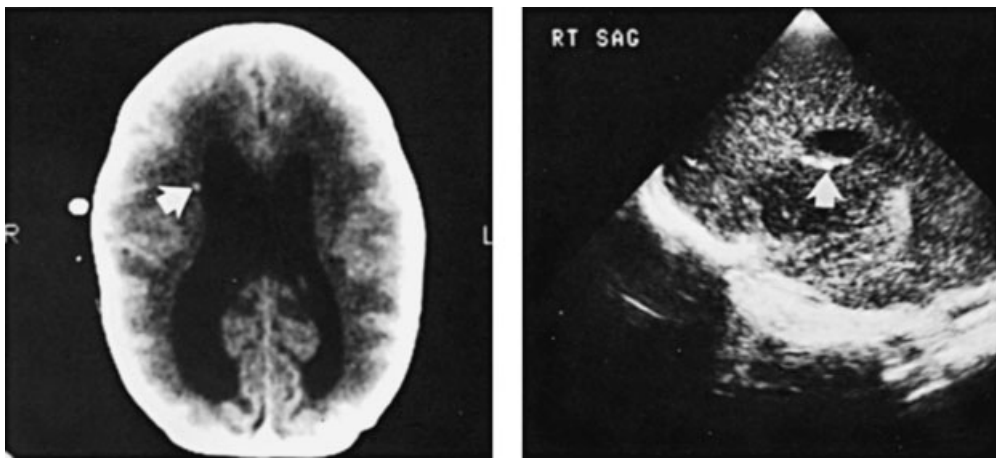

Figure 171–3 Computed tomographic scan *(left)* and ultrasound examination *(right)* of the head of an infant with congenital cytomegalovirus disease. Both tests showed moderate asymmetric enlargement of the lateral ventricles with punctate periventricular calcifications.

and arboviruses. Neurosyphilis and tuberculous meningitis also should be considered. In immunocompromised patients, especially those with AIDS, the following should be added to the differential diagnosis of CNS infection: progressive multifocal leukoencephalopathy caused by papovavirus; HIV encephalitis; fungal CNS infection caused by *Cryptococcus neoformans*, *Candida* spp., *Aspergillus*, or *Histoplasma*; protozoal infections with *T. gondii* and, rarely, *P. carinii* and *Strongyloides stercoralis;* bacterial infections with *M. avium-intracellulare* and *Nocardia asteroides;* non-infectious diseases such as primary cerebral lymphoma and lymphomatoid granulomatosis; and vascular complications such as hemorrhage and infarction.[14] In immunosuppressed patients, more than one of these conditions can coexist in the CNS.

CMV also can invade the peripheral nervous system and cause a painful peripheral neuropathy in patients with AIDS.[130,278,344] Ascending paralysis caused by myelitis, with or without vasculitis or necrosis, also can occur and may appear similar to Guillain-Barré syndrome.[344] In addition, CMV polyradiculopathy has been described in adult patients with AIDS and may occur in older children. This disease usually begins with leg pain and sacral paresthesias and may progress to weakness and flaccid paralysis. The CSF characteristically has a polymorphonuclear pleocytosis and moderately elevated protein.[182] The association of CMV infection with infantile spasms, Guillain-Barré syndrome, Charcot-Marie-Tooth disease, Huntington disease, Alzheimer disease, myasthenia gravis, and neuropsychiatric diseases (e.g., schizophrenia) has been reported, but a definite causal relationship between CMV and these diseases remains to be proved.[24]

DEAFNESS AND OTHER EAR DISORDERS

Hearing loss is present at birth in approximately 25 to 50 percent of infants with symptomatic congenital CMV infection and in approximately 15 percent of infants with asymptomatic congenital CMV infection.[163] Given that congenital CMV infection affects 30,000 to 40,000 infants annually in the United States, this congenital infection probably is the most common cause of nonhereditary sensorineural deafness. Investigators have estimated that congenital CMV infection may account for as many as 40 percent of cases of congenital hearing loss.[32,97,147] Progression or fluctuation of the hearing loss occurs in at least two thirds of these children through the preschool years, and continued progression may occur through the school-age and adolescent years.[125,361] Although CMV has been detected in the endolabyrinth of infants who died of congenital CMV disease, whether this progressive deafness is caused by continued viral replication in the inner ear, re-infection with a new strain of virus, or a complex cascade of immunopathologic events remains unclear.[85] Mondini dysplasia of the temporal bones has been seen in infants with congenital CMV infection, but the importance of this observation relative to the pathogenesis of the progressive hearing loss commonly seen in congenitally infected infants is unknown at this time.[36] Some studies suggest that higher levels of CMV in urine and blood are present in newborns who develop hearing loss from congenital CMV infection,[17,194,277,348] whereas other studies speculate that genetic mutations or inflammatory genes may play a role in CMV-associated hearing loss.[232,234,281,294]

CMV has been isolated from the middle ear effusions of healthy and immunocompromised children with otitis media.[70,109] In addition, CMV infection, defined serologically, has been associated with sudden-onset deafness, acute labyrinthitis, and Meniere syndrome.[326,363] Older children who were born with asymptomatic congenital CMV infection also may exhibit differences in higher auditory function, even though they do not have sensorineural or conductive hearing loss.[80]

MYOCARDITIS AND OTHER CARDIOVASCULAR DISORDERS

Myocarditis has been described as a rare complication of severe congenital CMV disease and CMV mononucleosis in presumably healthy adults and children.[335,351,364] CMV myocarditis also has been seen in renal and heart transplant recipients, usually as part of a disseminated CMV infection and associated with graft rejection treated with high-dose immunosuppressive therapy.[136,257,297] Patients can have heart failure, cardiomegaly, electrocardiographic abnormalities, and poor left ventricular function on echocardiography; cytomegalic inclusion cells and the presence of CMV DNA can be documented by myocardial biopsy.

The association of CMV infection with other cardiac disorders such as congenital heart block, structural cardiac anomalies, and pericarditis is anecdotal, and a cause-and-effect relationship is not well documented.[176] CMV coronary endotheliitis with superimposed thrombosis and myocardial infarction has been described in adult heart transplant recipients and was reported in an infant who died of disseminated CMV disease with an apical ventricular aneurysm.[218,286] CMV infection also has been postulated to play a role in the pathogenesis of atherosclerosis and coronary artery disease in both normal persons and heart transplant recipients.[142,210,213]

ENDOCRINE SYSTEM

Histopathologic evidence of involvement of the organs of the endocrine system is described well in both congenital and postnatally acquired disseminated CMV infections.[157] Endocrine disorders such as Graves disease and diabetes insipidus have been associated with congenital CMV infection, but these reports may represent coincidental findings.[214,285] Longitudinal studies are required to determine whether the autoimmune endocrinopathies in children with congenital rubella parallel the findings in children with congenital CMV infection. CMV infection also has been associated with autoimmune type 1 diabetes, although a specific cause-and-effect relationship has not been established.[239] In addition, immunosuppressed patients, especially persons with AIDS, may manifest clinical endocrinopathies caused by CMV infection, such as adrenal insufficiency and adrenal necrosis.[143] CMV inclusions also have been found in the pituitary gland of patients with AIDS, all of whom showed evidence of CMV encephalitis or disseminated infection elsewhere in the body.[117] Moreover, involvement of the thyroid and parathyroid glands with CMV has been reported in adults with AIDS.[127]

GENITOURINARY SYSTEM

Disease of the male and female genitourinary system as a result of CMV has been reported. Patients with AIDS may have symptomatic epididymitis and cystitis caused by CMV.[38,261,328] Lower urinary tract infections and hemorrhagic cystitis caused by CMV have been diagnosed in patients after they have undergone stem cell and solid organ transplantation.[238] CMV also commonly yet asymptomatically infects the cervicovaginal secretions and semen of both healthy and immunosuppressed adults.[171,195]

SKIN

Cutaneous manifestations of CMV infection are described well and can occur with both congenital and acquired CMV infection.[200] Infants with symptomatic congenital infection may have nonpalpable petechiae, purpura, or bruises, usually as a result of thrombocytopenia. Violaceous or dark, magenta infiltrative papules or nodules, called *blueberry muffin lesions*, also may occur,

but these lesions are more characteristic of congenital rubella syndrome. The skin lesions associated with acquired CMV infection usually are localized cutaneous ulcers or a widespread, exanthematous, maculopapular eruption, although vesiculobullous lesions also have been described.[248] CMV mononucleosis syndrome in adults and children may be accompanied by a maculopapular, rubelliform rash that may be pruritic. In addition, ampicillin-associated rashes may occur with CMV mononucleosis. CMV also may cause a cutaneous, leukoblastic vasculitis.[287] Well-demarcated, ulcerated lesions that show histopathologic evidence of CMV infection may be seen in immunocompromised patients who have undergone transplantation or in those who suffer from AIDS. Finally, CMV may play a role in the neoplastic process in Kaposi sarcoma, but definitive proof of a causal relationship remains to be shown.

UNUSUAL ASSOCIATIONS

CMV infection, either congenital or acquired, has been detected in association with a wide variety of conditions, including defects in tooth structure and the formation of enamel, portal vein thrombosis associated with protein S and protein C deficiency, unexplained fevers in burn patients, bacterial sepsis in burn patients, congenital eventration of the diaphragm, inguinal hernia, and fatal *Staphylococcus epidermidis* infection in very low-birth-weight infants.[16,37,174,190,205,319] However, given the common occurrence of CMV infection, these associations may be coincidental rather than part of a cause-and-effect relationship.

LABORATORY DIAGNOSIS

DETECTION OF THE INFECTIOUS AGENT

CMV can be isolated in tissue culture with fibroblast cell lines such as human foreskin fibroblasts and human embryonic lung fibroblasts.[293] Specimens that contain a high titer of virus, such as those from congenitally infected infants, may show growth in 24 hours. Some specimens, such as those from persons with acquired asymptomatic infection, may require as long as 6 weeks for detectable growth, but most cultures grow in 1 to 2 weeks. CMV has been isolated from a variety of specimens, including urine, saliva, nasopharyngeal and sinus washings, conjunctiva, tears, middle ear fluid, breast milk, semen, cervicovaginal secretions, stool, CSF, white blood cells, amniotic fluid, bronchial lavage samples, and biopsy or autopsy specimens. All samples for isolation of virues (except blood, which should be at room temperature) should be held at 4° C (on wet ice or in a refrigerator) until processed in the virology laboratory. Specimens for isolation of virus should be inoculated within hours of collection for an optimal isolation rate. Although isolation of CMV proves that a productive infection is present, it does not confirm an etiologic relationship with the disease process and requires careful interpretation within the patient's clinical context.

An adaptation of tissue culture is a low-speed centrifugation enhancement, monoclonal antibody culture technique, also called *shell vial assay*. In this test, inoculated tissue culture cells in small vials are stained with a fluorescein-conjugated monoclonal antibody to either an early or a late CMV antigen (or both). Cells infected with CMV exhibit nuclear and membrane fluorescence 18 to 72 hours after inoculation. This rapid viral diagnostic technique is especially reliable with urine and bronchoalveolar lavage specimens and has been applied with variable results to blood and tissue specimens.[135] However, maximal sensitivity and specificity are obtained when shell vials are used as an adjunct to and not in place of routine tissue culture. CMV-infected cells also can be detected by direct immunofluorescence assay on exfoliated cells in bronchoalveolar lavage specimens or in frozen tissue specimens.[151] These procedures, however, require a laboratory experienced in direct immunofluorescence assay technique.

Traditional DNA-DNA hybridization methods and, more recently, traditional and real-time PCR-based methods are available in many laboratories for detection of CMV DNA. These very sensitive tests may be used to detect and to quantify CMV DNA in a variety of samples and are useful for diagnosis or prediction of CMV disease and for monitoring, as well as for monitoring response to antiviral treatment.[54,62,84,90,134,306,309,315]

Detection of CMV DNA in the CSF of patients with AIDS seems to be a reliable diagnostic method for detection of CMV infection of the CNS, and detection of CMV DNA in the CSF of newborns with congenital CMV disease correlates with poor neurodevelopmental outcome.[20,75,140,366] Similarly, detection of CMV DNA by PCR in vitreous fluid provides persuasive evidence that a patient's retinitis is CMV related.[104] CMV DNA also may be detected in the white blood cells of patients with CMV infection, and detection of CMV DNA in the plasma or serum of selected groups of patients, such as newborns and immunocompromised patients, appears to correlate with severity of disease and viral dissemination.[225,300,314,315] Detection of CMV DNA in amniotic fluid can provide prenatal diagnosis of congenital CMV infection and disease.[203] PCR assays also have detected CMV DNA in dried blood spots or Guthrie cards collected as part of newborn screening programs and used to diagnose congenital CMV infection and disease.[32,33,348]

Another use for PCR-based diagnosis of CMV infection is the very early diagnosis of CMV infection in high-risk patients, such as transplant recipients, before the development of potentially fatal CMV disease, such as pneumonitis. This approach may allow preemptive antiviral therapy to be initiated when CMV infection appears active but before overt disease is detected.[53,367] The role of CMV DNA detection by PCR assay in monitoring a patient's response to antiviral therapy, however, appears to be limited because CMV DNA persists for long periods after the resolution of CMV-related clinical symptoms in many patients.[131]

CMV pp65 antigen also may be detected in the white blood cells of patients with CMV infection and disease, and this CMV antigenemia test is used by many clinical laboratories as a rapid screen for CMV viremia, providing results the same day. It is relatively easy to perform, and the degree of antigenemia may be quantitated to monitor response to antiviral therapy.[131]

Exfoliated cells in urine or bronchoalveolar lavage specimens or cells in tissue obtained by biopsy can be examined for histologic evidence of CMV infection. Cells that are infected productively with CMV are enlarged, have type A Cowdry intranuclear inclusions, and occasionally have perinuclear inclusions. The appearance of these cells is characteristic and has been likened to owl's eyes. Immunohistochemical staining can be used to augment the detection of these typical cells. The presence of these cells correlates with the presence of active CMV disease and may be useful clinically.

SEROLOGY

Standard serologic techniques also can be applied to the diagnosis of CMV infections. CMV IgG antibody can be determined in serum by several different methods, including complement fixation, hemagglutination inhibition, indirect fluorescent antibody assay, anticomplement immunofluorescence assay, enzyme-linked immunosorbent assay (ELISA), and latex agglutination and neutralization tests. ELISA and the indirect fluorescent antibody assay are used most commonly in clinical virology laboratories. The presence of CMV IgG antibody in a single serum specimen implies that the patient at some time has been infected

with CMV. On the other hand, a negative IgG antibody determination is good evidence against current or past CMV infection because CMV antibody usually is present at the time of infection and persists for life. Severely immunocompromised patients, especially bone marrow transplant recipients, however, can lose their ability to make IgG antibody and become CMV seronegative, even though they are infected actively with CMV. This occurrence has a poor prognosis and usually is a terminal event. Primary infection with CMV is documented best by clear seroconversion from negative to positive CMV IgG antibody. A fourfold rise in CMV IgG antibody titer is not diagnostic of a primary infection because reactivation infection also can cause titers to fluctuate. In addition, the height of the titer or ELISA index in a single serum specimen is not diagnostic.

CMV IgM antibody can be determined in serum by radioimmunoassay, indirect fluorescent antibody assay, or ELISA. Both the indirect fluorescent antibody assay and ELISA are used commonly in clinical laboratories, although some indirect fluorescent antibody assays have a considerable false-positive rate. Accurate interpretation of CMV IgM antibody results requires knowledge of the methods used and careful consideration of the clinical context to exclude diseases that produce cross-reacting antibody or polyclonal responses. Test methods also should remove rheumatoid factor from the test serum, a common cause of false-positive IgM reactions. If the test is performed properly, the presence of CMV IgM antibody implies a current or recent primary CMV infection. In healthy adults, CMV IgM antibody usually persists for 6 weeks and may be present for as long as 3 to 12 months, rarely even longer, after the primary infection.[92] Western blot assays using viral structural proteins separated from purified viral particles or from recombinant viral proteins appear to be sensitive and specific for detection of CMV IgM. Currently, these tests are available only in research or reference laboratories.[197] The CMV IgG avidity index, another research test, also may be used to time a suspected primary infection with CMV.[196,270] A low avidity index (30%) suggests a recent primary infection, usually within 3 months, whereas a high avidity index (above 60%) suggests a past or recurrent CMV infection.[141] In immunocompromised adults experiencing clinically significant reactivation infection with CMV, CMV IgM antibody may be detected for prolonged periods.[227] The sensitivity and specificity of CMV IgM antibody determination in diagnosis of acquired, primary CMV infection or clinically significant reactivation infection in infants and children have not been studied systematically, although clinicians frequently use this test for this purpose.

LABORATORY DIAGNOSIS OF SPECIFIC CLINICAL SYNDROMES

Congenital Infection

Viral culture is the diagnostic test of choice in considering congenital infection with CMV.[88] The diagnosis is established by isolation of the virus from urine or saliva in the infant's first 1 to 2 weeks of life. Urine cultures obtained after 3 weeks of life must be interpreted cautiously because perinatally acquired and transfusion-acquired infections with CMV may be manifested as early as 3 weeks of age.[288] Detection of nuclear inclusion-bearing renal epithelial cells in urinary sediment collected in the first 2 weeks of life also implies the presence of congenital infection. This technique is insensitive, however, compared with tissue culture and is important only historically. Detection of CMV DNA in the urine, saliva, serum, or CSF of newborns by DNA hybridization or DNA PCR amplification techniques also correlates with congenital infection and disease.[20,52,90,225] Detection of CMV DNA in dried blood spots or Guthrie cards collected for newborn metabolic screens also has been used for the retrospective diagnosis of congenital CMV infection and disease. However, this method does not detect all congenitally infected newborns, especially those newborns with silent or asymptomatic infection, because the level of CMV in blood is lower in asymptomatic congenital CMV infection.[33-35,308,341,368,369] Newborns with high CMV DNA levels by quantitative PCR methods appear to be at highest risk for hearing loss and, therefore, are potential candidates for CMV antiviral therapy.[194,348]

The diagnosis of fetal intrauterine CMV disease in single, twin, and multiple births also may be established by isolating the virus from amniotic fluid or detection of CMV DNA by PCR amplification in amniotic fluid obtained at least 2 weeks after the suspected time of maternal primary infection.[196,373] Fetal condition also can be determined by serial fetal ultrasound examinations.[98,159,270] Fetal blood samples that show the presence of CMV IgM antibody, thrombocytopenia, or leukopenia or elevated liver function test results also provide supportive evidence of CMV-associated fetal disease and may predict severe disease. Prenatal screening of pregnant women and prenatal diagnosis of congenital CMV infection should be accompanied by prenatal counseling by personnel knowledgeable about all the possible outcomes that can occur and all the options that are available to the parents and physician.[110,270]

Standard serologic tests also can be applied to diagnose congenital infection with CMV, but this approach is cumbersome and retrospective. The absence of CMV IgG antibody in cord blood rules out congenital infection, whereas its presence may imply passive transfer from the mother or indicate a congenital infection. Serial serologic specimens also can be obtained when the infant is 1, 3, and 6 months of age. If CMV IgG antibody levels disappear during the infant's first months of life, congenital infection is ruled out. However, if CMV IgG antibody persists, the infant either was infected congenitally or acquired CMV infection perinatally or postnatally. The presence of CMV IgM antibody in cord or infant blood collected in the first 3 weeks of the infant's life suggests the diagnosis of congenital CMV infection.[146,320] However, CMV IgM antibody may be insensitive (22%) compared with urine CMV culture for the diagnosis of congenital infection, according to one study.[225]

Perinatal and Postnatal Infection

The diagnosis of perinatal infection with CMV is difficult to establish but is documented best by a negative CMV viral culture and CMV IgM antibody level at birth, a positive viral culture and CMV IgM antibody at 8 to 16 weeks of age, and persistence of CMV IgG antibody. Postnatal primary CMV infection is diagnosed by CMV IgG seroconversion, the presence of CMV IgM antibody, and viral shedding in saliva, urine, and other body fluids.

Cytomegalovirus Syndromes in Immunocompromised Hosts

In immunocompromised patients, determination of whether serologic or virologic evidence of active CMV infection correlates with disease is difficult because CMV commonly is shed from saliva, urine, and respiratory tract secretions in these patients without clear evidence of a disease process. Therefore, detection of a productive virus infection in the organ system suspected to be involved usually is necessary to establish the diagnosis of CMV disease in an immunocompromised patient. For example, interstitial pneumonitis caused by CMV is documented best by an open lung biopsy specimen that shows characteristic CMV histopathologic features and positive viral culture. Detection of CMV in bronchoalveolar lavage specimens also correlates with lung biopsy results.[134] Similarly, the diagnosis of CMV hepatitis or colitis is documented best by the presence of cytomegalic inclusion cells, isolation of CMV, or detection of CMV by DNA

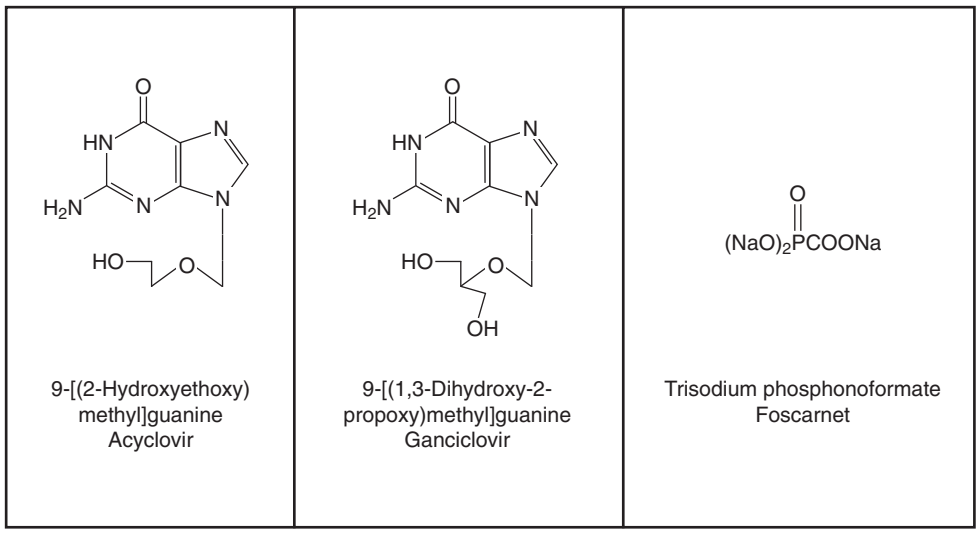

Figure 171–4 Structures of acyclovir, ganciclovir, and foscarnet.

PCR or immunohistochemical stains from biopsy specimens. In addition, viremia often precedes or accompanies serious disease, such as CMV pneumonitis in bone marrow transplant recipients or CMV retinitis or colitis in patients with AIDS.[315,343]

Prospective monitoring of high-risk adult patients by serial CMV cultures of urine or blood or bronchial lavage samples, serial blood samples to test for evidence of CMV antigenemia or DNAemia, and collection of serum to detect seroconversion by serologic testing usually are indicated because they may allow early administration of preemptive therapy with a CMV-specific antiviral agent, such as ganciclovir, when CMV infection is active but before overt disease develops.[292,334]

TREATMENT

Antiviral agents with activity against CMV include derivatives of acyclovir, such as ganciclovir and valganciclovir, as well as foscarnet and cidofovir (Fig. 171–4).[10,56,58,175,199,276,327] Acyclovir and valacyclovir also may have limited activity against CMV under certain conditions. In addition, biologics such as immune globulin and CMV hyperimmune globulin may benefit selected patients, and novel approaches such as antisense and non-nucleosis inhibitors and cell-based adoptive immunotherapy also are being investigated.[15,39] Treatment is beneficial for adult and pediatric immunocompromised hosts as well as for newborns with serious CMV disease but currently is not indicated routinely for normal hosts with asymptomatic or mildly symptomatic CMV infection.[183-186,235] However, normal hosts with severe CMV disease may benefit from antiviral therapy.[260]

Treatment of CMV-associated disease, such as retinitis, pneumonitis, hepatitis, colitis, esophagitis, or encephalitis, in immunocompromised hosts usually involves a 2- to 3-week period of induction therapy with an intravenous antiviral medication, usually ganciclovir.* In special circumstances, such as suspected drug resistance, foscarnet or cidofovir may be indicated.[111,329] The induction period should be accompanied by clinical improvement and a virologic response. If the host is expected to remain severely immunocompromised after receiving successful induction therapy, maintenance therapy at a reduced dosage schedule, three to five times a week, administered intravenously or orally, is indicated through the expected period of immune suppression. In patients with AIDS, oral or intravenous maintenance therapy usually is continued indefinitely.[102] In adult patients with AIDS who have refractory CMV retinitis, treatment with a ganciclovir implant may augment systemic therapy, but published experience evaluating this approach in children is limited.[60,338] One study showed that valganciclovir, an orally bioavailable prodrug of ganciclovir, appears to be as effective as is intravenous ganciclovir for induction therapy for CMV retinitis.[207] If, despite administration of antiviral therapy, CMV disease persists or progresses or if a virologic response does not occur, drug resistance should be considered. Resistance to ganciclovir has been documented most commonly in patients with AIDS, but it also can occur in patients with malignant neoplasms and in transplant recipients.[73,164] Most ganciclovir-resistant CMV strains have a mutation in the UL97 phosphotransferase gene, but specific mutations in the UL54 DNA polymerase gene also may occur alone or in combination with UL97 mutations.[64] Most ganciclovir-resistant CMV strains are susceptible to foscarnet but may exhibit cross-resistance to cidofovir, and strains simultaneously resistant to ganciclovir, cidofovir, and foscarnet also rarely may occur.[74,329]

The administration of ganciclovir along with intravenous immune globulin or CMV hyperimmune globulin to bone marrow transplant recipients with CMV pneumonitis has been shown to increase survival over that of historical controls who were treated with a variety of other antiviral regimens, including ganciclovir alone, immune globulin alone, acyclovir, vidarabine, and interferon. However, differences in the method used to diagnose CMV pneumonitis, duration of illness, and treatment regimens between study subjects and historical controls obscure interpretation of these studies.[108,264] Nonetheless, CMV-associated interstitial pneumonitis in bone marrow transplant recipients may be an immunopathologic process, and combination therapy may prevent active virus replication (ganciclovir, foscarnet, cidofovir) while blunting the immune response to viral antigens already expressed on CMV-infected cells (immune globulin).[298] In contrast, a small pilot study showed that the addition of CMV hyperimmune globulin did not appear to enhance the efficacy of ganciclovir treatment in patients with AIDS-associated CMV retinitis.[166]

Standard immune globulin or CMV hyperimmune globulin should not be used alone for the treatment of established CMV infections in immunocompromised patients.[212] The combination of high-dose corticosteroids with ganciclovir does not appear to improve survival in bone marrow transplant recipients with biopsy-proven CMV pneumonitis.[265] On the other hand, a

*See references 55, 81, 94, 115, 123, 149, 165, 178, 202, 204, 209, 311, 352.

regimen combining ganciclovir with hematopoietic growth factor may allow ganciclovir to be continued in selected patients with mild marrow toxicity.

Treatment of infants with symptomatic congenital CMV infection was reported first in 1969 and 1971,[114] and more recent reports suggest that antiviral agents, such as ganciclovir, may benefit selected infants.[217,290] Anecdotal reports have shown clinical and virologic improvement in congenitally infected newborns treated with ganciclovir.[158,228,268,333,339] A multicenter phase I/II study of the pharmacokinetics, antiviral effects, and safety of intravenous ganciclovir was conducted in 47 newborns with symptomatic congenital CMV disease and neurologic involvement.[337,358,379] In this study, a 6-mg/kg dose of ganciclovir administered by a 1-hour infusion every 12 hours for a period of 6 weeks produced a significant reduction in the quantity of urinary virus excretion; however, viral shedding recurred when ganciclovir treatment was discontinued. Neutropenia, thrombocytopenia, and elevated liver enzymes also were observed. Limited clinical follow-up in 30 of the original 47 infants showed that hearing loss improved or stabilized in 16 percent of the treated infants. Subsequently, a phase III, multicenter, randomized clinical trial enrolled 100 infants and was completed in 1999.[183] In this study, ganciclovir treatment in the newborn period appeared to have an impact on hearing loss by slightly improving hearing, maintaining normal hearing, or preventing hearing deterioration, as measured when the infants reached 6 and 12 months of age. Because only 44 percent of the enrolled infants were assessed in follow-up, a long-term follow-up study of these infants is ongoing to determine whether the beneficial effect lasts through childhood and adolescence. In addition to an effect on hearing loss, treatment provided more rapid resolution of hepatitis, when present, and improved short-term growth in weight and head circumference and developmental milestones. Currently, the decision to administer antiviral therapy to a newborn with congenital CMV disease remains at the discretion of the clinician.[359] Short-term antiviral therapy is likely to benefit infants who have multisystem disease with viremia, pneumonia, severe or persistent thrombocytopenia or hepatitis, or active sight-threatening retinitis. In these clinical circumstances, a reduction in viral load should improve the infant's clinical condition and resolve end-organ disease. However, the sustained effect of short-term treatment on long-term sequelae, such as hearing loss and neurodevelopmental disabilities, is not clear at this time. A longer duration of therapy, perhaps with an oral antiviral agent such as valganciclovir, possibly will improve or prevent the development of long-term sequelae in these infants.[359] Anecdotal reports and phase I pharmacokinetic and pharmacodynamic studies have demonstrated that valganciclovir oral solution provides plasma concentrations and antiviral effects similar to those levels achievable with use of intravenously administered ganciclovir.[184,222] Clinical trials evaluating the long-term benefits of prolonged treatment with oral valganciclovir in congenitally infected infants are under way. In addition to specific antiviral therapy, management of congenitally infected infants includes supportive care and control of seizures. If thrombocytopenia is severe and persistent, platelet transfusions and immune globulin also may be of benefit. Long-term management includes careful attention to nutrition to ensure adequate growth, serial hearing tests to detect progressive or late-onset hearing loss, developmental assessments to evaluate for cognitive and motor disabilities, and ophthalmologic follow-up of abnormalities present in the newborn period.[359,361]

PREVENTION

Prevention of CMV disease is important because it causes significant morbidity and mortality in a variety of patients. In immunocompromised hosts, it also is associated with the development of other complications, such as opportunistic co-infections and graft rejection in transplant recipients, and it increases resource use in transplant programs. In premature newborns, potentially fatal viral sepsis syndromes can occur. Furthermore, congenital infection is a leading cause of deafness and developmental disabilities in children. Approaches to the prevention of CMV disease include the use of CMV-seronegative blood products, selection of CMV-seronegative donors for transplant recipients, passive immunoprophylaxis with immune globulin, prophylactic or preemptive use of antiviral agents, active immunization with a CMV vaccine, and behavioral strategies to reduce exposures to CMV-infected secretions.

BLOOD PRODUCT, HUMAN MILK, AND TRANSPLANT DONOR SELECTION

Transplant recipients who are CMV seronegative and receive solid organ or bone marrow transplants from CMV-seropositive donors are at significant risk for acquiring symptomatic primary CMV infection. Therefore, whenever possible, CMV-seronegative recipients should receive transplants from CMV-seronegative donors, and all blood product transfusions should be from CMV-seronegative donors.

Infection with CMV in seriously ill CMV-seronegative neonates can be prevented by use of blood products from CMV-seronegative donors or by use of frozen deglycerolized red blood cells.[48,372] Saline-washed red blood cells also reduce but do not always prevent the acquisition of CMV infection in neonates, even though as many as 90 percent of the leukocytes can be removed by this method.[89] An alternative method of preparing leukocyte-depleted blood, filtration through a cotton-wool filter, appears to prevent post-transfusion acquisition of CMV infection in neonates.[133] Many institutions now provide CMV-seronegative or leukocyte-depleted blood products routinely to all neonates or to all low-birth-weight neonates, regardless of the CMV serostatus of the mother. Ingestion of CMV-positive breast milk by premature infants has been associated with illness, and donor selection or pretreatment of human milk administered to extremely premature infants may reduce the risk of acquisition of CMV-associated disease in these infants, although clinical trials to prove this hypothesis have not been published yet.[169,208,237,346,347]

PASSIVE IMMUNOPROPHYLAXIS

Although immune globulin or CMV hyperimmune globulin should not be used alone for the treatment of established CMV disease in immunocompromised patients, these preparations may be used to prevent the acquisition of serious CMV disease in selected immunocompromised patients. Passive immunization remains controversial, however, partly because studies have used different dosages (100 to 200 mg/kg) administered at varying intervals (1 week before transplantation and every 1 to 3 weeks after transplantation) for varying times (60 to 120 days). CMV immune globulin has been shown to decrease the incidence of symptomatic CMV disease from 60 to 21 percent in CMV-seronegative renal transplant recipients who received a kidney from a CMV-seropositive donor.[307] CMV immunoprophylaxis also has decreased the incidence of CMV pneumonitis in CMV-seronegative bone marrow transplant recipients who did not receive granulocyte transfusions.[45,215,263,365] The use of CMV hyperimmune globulin in pregnant women with primary CMV infections to prevent or to ameliorate CMV infection in the fetus has been reported, but definitive recommendations await results of randomized clinical trials.[221,229]

PROPHYLAXIS AND EARLY PREEMPTIVE THERAPY WITH ANTIVIRAL AGENTS

The prophylactic use of antiviral agents in transplant recipients has been evaluated and in some studies appears to reduce the incidence of serious CMV disease. However, this approach remains controversial because no regimen has been shown to completely prevent the acquisition of CMV infection or disease.[249] For example, acyclovir is used by some clinicians as prophylaxis for CMV disease in organ transplant recipients, despite evidence that acyclovir is inactive against most strains of CMV and CMV disease occurs despite such prophylaxis.[303] In one study, intravenous administration of acyclovir, 500 mg/m^2 of body surface area per dose every 8 hours for 5 days before and 30 days after transplantation, to CMV-seropositive bone marrow transplant recipients appeared to reduce the incidence of CMV disease.[216] High-dose oral acyclovir administered 1 day before and for 12 weeks after transplantation also has been shown to reduce the incidence of CMV disease and infection in renal transplant recipients.[29]

The prophylactic administration of human leukocyte interferon-α has been shown to reduce the incidence of severe CMV disease in renal transplant recipients, but it has no apparent benefit in bone marrow transplant recipients, and it is not used routinely in any patient population.[69,155,266] Many clinicians currently favor the prophylactic use of ganciclovir in transplant recipients at high risk for acquiring serious CMV disease. Prophylaxis treatment regimens vary, however, and it is difficult to make recommendations about which regimen is best. Most solid organ transplant recipients appear to benefit from intravenous ganciclovir, 5 to 10 mg/kg/day administered once or twice daily for 2 to 6 weeks after transplantation, usually followed by continuing antiviral prophylaxis with a reduced dose of ganciclovir.[22,340] Prophylactic ganciclovir does not appear, however, to benefit adult lung transplant recipients in most published studies. Similarly, administration of a short 2-week course of ganciclovir near the time of transplantation, without continuing antiviral prophylaxis, does not appear to reduce significantly the incidence of CMV disease in most solid organ transplant recipients studied.[22,340] The impact of intravenous immune globulin or CMV hyperimmune globulin, when it is given with a prophylactic antiviral agent, on the incidence of CMV disease in solid organ recipients is unclear. However, many clinicians administer it concomitantly with an antiviral agent in attempting to prevent CMV disease in certain high-risk transplant recipients. In bone marrow transplant recipients, the administration of ganciclovir prophylaxis after marrow engraftment reduced CMV disease but did not seem to reduce the overall mortality rate significantly. In addition, ganciclovir-treated bone marrow transplant recipients experienced prolonged neutropenia.[139]

The strategy of preemptive antiviral therapy has certain advantages over strategies that either treat only patients with overt clinical disease or administer prophylactic antiviral agents to many patients at risk, only a few of whom appear to benefit.[132] In addition, preemptive or very early antiviral treatment strategies include viral surveillance of blood, urine, and respiratory samples. Viral surveillance of these samples can be by standard viral culture, viral antigen detection, viral nucleic acid detection by qualitative or quantitative PCR assay, or a combination of these tests. Detection of CMV viremia and culture-positive bronchoalveolar lavage samples have correlated with the development of serious CMV disease in transplant recipients.[53] At least two studies of bone marrow transplant recipients now have documented the efficacy of early intervention with intravenous ganciclovir therapy at the time that positive CMV surveillance cultures were obtained but before clinical disease developed.[139,292] This strategy also appears to be efficacious in solid organ transplant recipients.[303] Another approach to preemptive therapy that does not entail viral surveillance techniques is to administer an antiviral agent, such as ganciclovir, during times of rejection, when CMV reactivation is likely to occur. This approach has been modestly successful in high-risk renal transplant recipients.[154] Simultaneous virologic and immunologic follow-up is the best approach for monitoring CMV infection in transplant recipients. Lack of immune reconstitution or presence of graft rejection or graft-versus-host disease usually heralds repeated episodes of recurrent or persistent CMV infection or disease, requiring multiple or prolonged courses of antiviral therapy.[132] Antiviral resistance to single or multiple agents may occur in these high-risk patients and has been increasingly recognized as a significant problem.[64]

ACTIVE IMMUNIZATION

Prevention of acquisition of CMV disease through active immunization should be a priority for the 21st century.[289,325] Pregnant women and their fetuses as well as transplant recipients would benefit greatly if a safe, effective CMV vaccine became widely available.[18,289,291] The ideal CMV vaccine should be safe, effective, immunogenic, and cost-effective. It should prevent the development of primary CMV infection without causing chronic persistent infection. The vaccine also should not be capable of infecting the fetus, and it should not be oncogenic.

In 1975, Plotkin and associates[253] characterized and reported a candidate CMV vaccine strain, Towne 125, that was isolated originally from the urine of a congenitally infected infant named Towne. Since then, more than 500 subjects, including renal transplant recipients and healthy adult male and female volunteers, have received the investigational Towne 125 vaccine.[61,122,172,251-253,255,323] Studies of these subjects showed that Towne 125 is attenuated and relatively safe and that it induces humoral and cellular immunity in both healthy and immunosuppressed subjects.

The vaccine also appeared to be protective in a randomized, placebo-controlled study of 91 immunosuppressed renal transplant recipients.[252] In this study, 30 CMV-seronegative vaccine recipients received a kidney from a CMV-seropositive donor, and the incidence of severe CMV disease was significantly lower in the vaccine group than in the placebo group. However, the CMV infection rate did not differ significantly between the groups, and members of both groups experienced mild to moderate CMV disease. Subsequent studies have confirmed that CMV-seronegative renal transplant recipients who receive a live attenuated CMV vaccine are more resistant to serious CMV disease.[254] Whether a CMV vaccine given to CMV-seronegative women of child-bearing age before pregnancy will protect the fetus from intrauterine infection or disease is not known, but studies that may answer this question are in progress.

Another vaccine strategy investigated was the development of mutant hybrid strains of CMV that combine the safety of the Towne strain with Toledo, another CMV strain, to produce enhanced immunogenicity and possibly, however, also enhanced virulence.[8,250] Other investigators have evaluated subunit vaccines for CMV that contain purified glycoprotein B (gB) complexed with a powerful adjuvant.[50,113,242] Most recently, the cellular immune system has been targeted by "DNA vaccines" that encode gB and appear to induce protective cellular immunity against CMV. Finally, adoptive immunotherapy with sensitized T cells is available to patients enrolled in clinical trials.

BEHAVIORAL STRATEGIES TO PREVENT PRIMARY CYTOMEGALOVIRUS INFECTION

With the current complexities associated with the development of a CMV vaccine and the challenges of administering effective

antiviral therapy, an alternative practical option for prevention of CMV infection during pregnancy and other high-risk times of life is education to increase public awareness about CMV and its modes of transmission.[65,167a,271,280,374] Educational materials are available from clinicians and from the Web sites www.cdc.gov/cmv and www.bcm.edu/pedi/infect/cmv and provide factual information and guidelines for reducing the risk of CMV transmission to pregnant women, women of child-bearing age, and other susceptible individuals. Reliable, relatively inexpensive serologic evaluation is available, so all women contemplating pregnancy should know their CMV serologic status. In addition, because epidemiologic studies have shown a major source of CMV infection to be close contact with young children, women who are CMV seronegative should be aware that a high percentage of young children are infected actively with CMV and that while pregnant, they should exercise good hygienic practices when in close contact with young children, especially those who attend daycare centers or are known to have an active CMV infection.[59,243] In fact, some studies have shown that the incidence of child-to-parent transmission of CMV may be reduced by interventions that identify susceptible pregnant women and educate them about increasing protective behaviors, such as handwashing after diaper changes and wiping tears and nasopharyngeal mucus, and decreasing risky behavior for acquiring CMV, such as kissing on the mouth and sharing eating utensils.[7,9,120] In addition, CMV can be transmitted from husband to wife, and if the spouse or partner experiences a CMV mononucleosis syndrome, a CMV-seronegative woman may wish to consider avoiding pregnancy for an individualized period.[91]

CHAPTER 172

Epstein-Barr Virus

Charles T. Leach ❂ Ciro V. Sumaya

Epstein-Barr virus (EBV) is an extremely common herpesvirus that is the etiologic agent of classic infectious mononucleosis (IM). Evidence that the virus also plays a principal role in the development of certain lymphoproliferative diseases and epithelial malignancies continues to mount. Its ability to remain in a dormant (latent) state after infection allows reactivation and recurrence of disease, especially under immunosuppressive conditions. Unfortunately, antiviral agents have little effect on EBV-associated diseases, but progress is being made toward improved treatment for EBV-associated malignancies. Eventually, vaccination may provide protection for those persons at highest risk for development of severe disease manifestations.

This chapter reviews progress in understanding the immunobiology of EBV and its disease associations. Enhanced understanding of EBV is leading to newer diagnostic methods and improved management of EBV-associated diseases.

HISTORY

One can identify four distinct periods of history related to IM and its etiologic agent EBV[124,445]: (1) early descriptions of IM, (2) identification of the heterophile antibody test associated with IM, (3) discovery of EBV in Burkitt lymphoma (BL) cells, and (4) the association of acute EBV infection with heterophile-positive IM.

Credit for the original description of a disease consistent with what is now called *infectious mononucleosis* commonly is given to a German physician named Pfeiffer,[394] who, in 1889, described relatively mild illness characterized by fever and lymphadenopathy; later, his report was translated into English.[327] The illness came to be known as *Drüsenfieber*, or *glandular fever*. Although some cases of glandular fever were typical of what is now recognized as IM, certain characteristics of this illness, including its predominance in children and familial clustering, did not fit. In England, glandular fever and IM have become synonymous, yet many experts consider glandular fever to be a different illness.

In the early 1900s, numerous case descriptions of illnesses epidemiologically and clinically compatible with IM appeared.[55,183,233] However, because the illness now recognized as IM had not yet been described and these illnesses were suggestive of leukemia, most of them were reported erroneously as acute leukemia with spontaneous cure. Although the term *infectious mononucleosis* was used first in one of these case reports,[233] the illness was not distinguished from leukemia until Sprunt and Evans published their landmark paper in 1920.[466] These authors described a series of patients with clinical syndromes consistent with typical IM, including classic hematologic findings. A subsequent report by Downey and McKinlay provided a more detailed description of the hematologic manifestations.[107]

Although most cases of IM could be identified by hematologic and clinical findings, not until a specific serologic test was identified in 1932 could classic IM be better defined. In the course of investigating heterophile antibodies in serum from patients with rheumatic fever and other diseases, Paul and Bunnell[386] noted high titers of heterophile antibodies in serum from a control patient. Further investigation revealed that the control patient was a medical student with IM. Evaluation of sera from three other patients confirmed the presence of high titers of heterophile antibodies during acute IM.

In 1958, Dennis Burkitt, an English surgeon, described 38 cases of "round-cell sarcoma" developing in children and adolescents living in one region of Uganda, Africa.[53] Eventually, the tumors were determined to represent lymphomas, not sarcomas. Although a new mosquito-borne infectious disease was suspected as the culprit initially, Epstein and colleagues[115] eventually were able to cultivate and evaluate tumor cells by electron microscopy; they noted particles with ultrastructural characteristics similar to those of herpes simplex virus (HSV), which had been described a few years earlier. Further work established this virus as the fourth human herpesvirus (after herpes simplex 1, herpes simplex 2, and cytomegalovirus [CMV]).

The association between this new herpesvirus and IM was noted serendipitously in 1968 when an IM-like illness developed in a technician working in the laboratory of the Henles.[197] Stored, pre-illness serum from this technician contained neither heterophile nor EBV antibodies, but both heterophile and EBV antibodies appeared 6 days after the onset of symptoms. In addition, virus was cultivated from the technician's peripheral blood cells. Subsequent testing of serial specimens from other patients with

IM also demonstrated seroconversion to EBV in all cases. This work, as well as studies from Yale University,[123,365] among others, firmly established EBV as the cause of IM. Investigators subsequently showed that EBV has the capacity to transform ("immortalize") human B-lymphocytes in vitro, which allows the derivation of EBV-transformed B-lymphoblastoid cell lines capable of being propagated indefinitely in tissue culture.[199,397]

VIROLOGY

EBV is in the family *Herpesviridae*, subfamily *Gammaherpesvirinae*, genus *Lymphocryptovirus*.[96] Its closest relative, human herpesvirus 8 (also known as *Kaposi sarcoma associated herpesvirus*) is also a gammaherpesvirus. Although its taxonomic name *(human herpesvirus type 4)* is used by most bibliographic search services, most scientists and physicians use its historic name.

STRUCTURE AND GENOME

The structure of the EBV is typical for a member of the herpesvirus family: It displays an inner core of DNA surrounded by a nucleocapsid, tegument, and an envelope.[116] Within the inner core, which measures approximately 45 nm, exist approximately 184 kilobase pairs (kbp) of double-stranded DNA coding for nearly 100 proteins. The surrounding nucleocapsid displays icosahedral symmetry (162 capsomeres) and measures approximately 100 to 110 nm in diameter. Outside the capsid lies the tegument, which consists of loosely packed, amorphous proteinaceous material, and the tegument in turn is surrounded by the viral envelope containing glycoprotein spikes. The complete virion measures approximately 150 to 220 nm.

The entire EBV genome has been sequenced.[28] The structure of EBV is characteristic of all the herpesviruses, with short and long sections of "unique" sequences (U_s and U_L, respectively) separated by a major internal repeat region (IR_1) generally consisting of 6 to 12 direct repeats of a 3 kbp sequence. The virus also has numerous other regions of repeated nucleotide sequences, including direct repeat of a 0.5 kbp sequence at its termini.

MOLECULAR BIOLOGY

Much of the early information regarding the molecular biology of EBV comes from laboratory strains derived from BL tumor cell lines (e.g., HR-1)[208] and marmoset lymphoid cell lines transformed by viral strains infecting human beings (e.g., B95-8).[346]

REPLICATION

EBV infection of cells is initiated by attachment of EBV glycoprotein gp350 to a cell-surface receptor (CR2, CD21) found primarily on B-lymphocytes and nasopharyngeal epithelial cells[459,543] and less commonly on other cells.[254,336,538] This receptor is the same as the surface moiety that functions as the receptor for the third component of serum complement (the C3d receptor).[133] Penetration of the cell requires a complex consisting of viral glycoproteins gH, gL, and gp42 (for B-cell infection), whereas only gH and gL are necessary for infection of epithelial cells[515]; gp42 binds with human leukocyte antigen (HLA) class protein found in B cells but not present in epithelial cells. After entering the B lymphocyte, the virus is transported through the cytoplasm and is stripped of its envelope in endocytic vesicles.[362] Subsequently, the viral genome circularizes and is maintained in the cell nucleus as a multicopy plasmid (or episome).[318] The initial and predominantly replicative (lytic) EBV infection probably occurs in epithelial cells of the oropharynx and adjacent structures,[457,532] with virus then transmitted to circulating B cells passing through these lymphoepithelial tissues. Although lytic genes may be found in EBV-associated tumors (e.g., post-transplant lymphoproliferative disease [PTLD]),[349] the overall proportion of replicating cells is far surpassed by latently infected B cells. In contrast, after infection of epithelial cells occurs, active replication occurs and leads to lysis and death of the cell. Alternating replication of viral glycoproteins in B cells and epithelial cells appears to modify the viral tropism, allowing virus from replicating B cells to infect epithelial cells more efficiently, and vice versa.[45] Recent data also suggest that monocytes may play an important role as a reservoir for EBV and could provide an important link for the transfer of virus from B cells to the oral epithelium.[504] Proteins synthesized during viral replication are important for viral gene regulation, replication of the genome, production of mature particles, and modulation of the immune system.

LATENCY

Latently infected B cells are the primary reservoir of EBV in the body. In a typical healthy EBV-seropositive adult, from 1 to 50 per million B cells are infected with EBV, and this condition remains relatively constant over many years.[25] Although more than 80 gene products may be expressed during active viral replication, only a limited number are expressed during viral latency. This is one method by which the virus limits cytotoxic T-cell recognition of EBV-infected cells. The EBV gene products that may be expressed during latency include six nuclear proteins (EBV nuclear antigens [EBNAs] 1, 2, 3A, 3B, 3C, and a leader protein [EBNA-LP]); three membrane proteins (latent membrane proteins [LMPs] 1, 2A, and 2B); two small, nonpolyadenylated (noncoding) RNA molecules (EBV-encoded RNAs [EBERs] 1 and 2); and the Bam H1A rightward transcripts (BARTs).

Based on in vitro genetic and somatic cell hybrid experiments, three different patterns of latent gene expression can exist in EBV-infected cells from patients with EBV-associated disease.[282,417,483,496,539,545] Type I latency, exemplified by cells derived from BL, exhibits a limited repertoire of genes consisting of EBNA-1, EBERs, and BARTs. Type II latency typically is observed in cells derived from Hodgkin disease (HD) and nasopharyngeal carcinoma (NPC). Besides EBNA-1, EBERs, and BARTs, these cells also express latent membrane proteins (LMP-1, LMP-2A, LMP-2B). Lymphoblastoid cell lines, as well as tissues from patients with IM, PTLD, and acquired immunodeficiency syndrome (AIDS)-associated lymphomas, display the broadest pattern of latent gene expression (Type III), wherein all genes associated with latency are expressed.[282,441,494,542] A "Type 0" latency also may exist within circulating EBV-infected memory B cells from healthy persons, wherein only EBERs and BARTs are expressed.[417] Although these latency expression pattern categories may be useful for histopathologic characterization, it is important to note that significant heterogeneity among histopathologically similar tumors can occur.

A brief description of latency-associated EBV genes follows:

EBNA. EBNA-1 is required for replication and maintenance of EBV episomal DNA in latently infected cells.[282] It also interacts with various viral promoters in regulating transcription of the EBNAs (including itself), as well as LMP-1. As mentioned previously, amino acid repeat structures in the EBNA-1 protein protect it from proteosomal degradation, thereby stabilizing protein levels and possibly preventing presentation by MHC Class I molecules.[307] A role for EBNA-1 in B-cell transformation and oncogenesis remains somewhat debatable.[483] EBNA-2 clearly is a viral oncogene that is essential for cellular transformation. It

transcriptionally activates several viral genes (e.g., LMP-1, -2A) and cellular genes (e.g., CD21 and CD23) via its interaction with the DNA-binding protein RBP-Jκ (Jκ recombination-binding protein).[195] All three EBNA-3 proteins (A, B, and C) are transcriptional regulators of key cellular and viral promoters, but only 3A and 3C have proven to be indispensable for in vitro B-cell transformation.[501] Like EBNA-2, the primary regulatory functions of EBNA-3 proteins occur via interactions with RBPJκ.[421] Moreover, EBNA-3C is able to overcome the arrest of the retinoblastoma (Rb) gene cell cycle and increases expression of LMP-1.[316] The exact mechanistic contribution of EBNA-LP (also called EBNA-5) to B-cell immortalization is not well understood. Although EBNA-LP is not required for transformation of B cells, the absence of EBNA-LP drastically reduces the efficiency of transformation.[331] EBNA-LP possibly contributes to immortalization by enhancing EBNA-2-mediated transcriptional activation of the LMP-1 gene.[391] Also, previous studies have demonstrated that EBNA-LP cooperates with EBNA-2 in driving cells into the G1 cell cycle phase by binding and inactivating the tumor suppressors Rb and p53.[485]

Latent Membrane Proteins. Like EBNA-2, LMP-1 (a viral oncogene) is essential for EBV transformation of B cells and appears to be the main transforming protein of EBV. LMP-1 displays pleiotropic effects when expressed in EBV-infected cells. Most prominently, LMP-1 mimics the CD40 B-cell receptor, which plays a key role in the activation and differentiation of B cells.[271] The protein also induces expression of anti-apoptosis genes (e.g., BCL-2 and A20), as well as activation and adhesion of B cells.[545] LMP-2 consists of two transmembrane proteins: LMP-2A contains two intracytoplasmic domains (at the amino and carboxy termini) and 12 integral membrane domains; LMP-2B differs by the lack of the amino terminal cytoplasmic domain. LMP-2 generally is recognized as a modifier of normal B-cell development, promoting maintenance of viral latency.[545] LMP-2A mimics the B-cell receptor and alters normal B-cell signal transduction by inducing a range of genes involved in cell cycle induction, inhibition of apoptosis, and suppression of cell-mediated immunity. Functions of LMP-2B are less well described, but a recent report indicates a key role in regulating LMP-2A activity.[432]

EBERs. These two small nonpolyadenylated (non-coding) RNAs are the most abundant viral transcripts found in latently infected EBV cells (approximately 10^7 copies per cell) and, indeed, serve as important diagnostic tools through the use of in situ hybridization (see "Diagnosis—EBV Nucleic Acid" later). Recent studies indicate that EBERs may play important roles in viral persistence and oncogenesis for some tumors. For example, EBERs bind to double-stranded, RNA-activated protein kinase (PKR), which serves to inhibit interferon-inducible apoptosis.[360] Moreover, EBERs play a key role in the maintenance of malignant phenotypes of BL cells.[487]

BARTs. These consist of a family of differentially spliced RNAs, first identified in NPC and later found in other EBV-associated malignancies.[460] Although noted abundantly in all forms of latency, protein products of their open reading frames have not been clearly identified.

TRANSFORMATION

In vitro, resting human B cells infected with EBV develop into lymphoblastoid cell lines. These cells are described as immortalized or transformed because instead of following one of two normal pathways (differentiation or apoptosis [programmed cell death]), they proliferate continuously. Current evidence suggests that EBV proteins coded by six latency-associated genes (described previously) are important for this cell transformation process: EBNA-2 and LMP-1 are absolutely essential; EBNA-1, EBNA 3A, EBNA-3C, and EBNA-LP also play critical roles.[417] The remaining latency-associated viral gene products, although not essential for transformation, are involved in the initiation and maintenance of cell transformation.

EBV generally transforms relatively mature B lymphocytes, secreting a complete immunoglobulin product (heavy chain plus light chain).[49,370] EBV also is capable of infecting and transforming B cells in earlier stages of development (e.g., pre-B cells [producing only μ chains] and lymphoid precursors lacking immunoglobulin gene rearrangement)[143,144,261]; mature plasma cells cannot be infected by EBV. Tumor cells and cell lines from BLs are B cells that generally express small amounts of immunoglobulin, which may be detected as surface immunoglobulin molecules, cytoplasmic/secreted molecules, or both. The major heavy-chain isotype expressed by Burkitt tumors appears to be μ chain (IgM), although other isotypes can be observed.[370] Similarly, the EBV-infected cells observed in the blood of persons with mononucleosis and the tumor cells found in immunodeficient hosts with EBV-associated lymphoproliferative diseases and lymphoma are B lymphocytes; these EBV-infected cell populations may include cells producing any of the major classes of human immunoglobulin (IgG, IgA, or IgM).[49,370,423,424] EBV-related malignant lymphoproliferations in immunosuppressed patients may be polyclonal, oligoclonal, or monoclonal; the lymphoproliferations probably are polyclonal at first but eventually progress to monoclonality.[100] BLs, on the other hand, always appear to be monoclonal at initial evaluation.[34,370]

EBV GENOTYPES

Two genotypes of EBV (EBV-1 and EBV-2) were identified in the 1980s on the basis of marked genomic differences in EBNA LP, 2, 3A, 3B, and 3C genes.[433,439] Using this methodology, seroepidemiologic and virologic studies suggested geographic differences in the prevalence of these two genotypes, with both types found widely in central Africa and elsewhere, but type 1 predominating in Western countries. Most EBV-infected persons appear to harbor one genotype, yet immunocompromised persons may be co-infected with both type 1 and type 2 genotypes. Recently, more detailed genetic analyses have been conducted, revealing more subtle differences in the genome and the presence of multiple EBV "strains" in healthy patients.[456,499,514] Multiple strains probably are acquired at the time that the initial EBV infection occurs,[499] yet it is possible that superinfections with other EBV strains occur following primary infection with one strain. No substantial evidence supports the view that any one genotype (or strain) is responsible for specific lymphoproliferative diseases.[404]

IMMUNOPATHOGENESIS

INFECTIOUS MONONUCLEOSIS

EBV elicits a wide range of immunologic responses in humans, partly because of its propensity to infect B lymphocytes. In a normal host, the immunologic effects probably are responsible for most EBV-associated disease manifestations. Both cellular and humoral immunity develop in response to EBV infection. Detection of humoral antibodies directed against viral capsid and nuclear proteins is important for establishing the diagnosis of acute infection. However, the responsibility for effective control of EBV infection lies primarily with the cellular immune elements. Two to 7 weeks after exposure, up to 20 percent of circulating B lymphocytes become infected during primary EBV infection, although 1 percent is typical.[422] A brisk cellular immune

response ensues. In the acute stage, proliferating EBV-infected B cells are controlled principally by natural killer (NK) T cells, helper ($CD4^+$) T cells, and cytotoxic-suppressor ($CD8^+$) T cells.[416] In some rare EBV syndromes, these T cells can themselves become infected and directly cause disease.[242,274] In adults the proliferation of $CD8^+$ T cells causes a temporary inversion of the normal $CD4^+/CD8^+$ T-cell ratio; however, $CD8^+$ T-lymphocyte expansion is less marked in children.[518] After this T-cell response, the number of EBV-infected B cells falls dramatically during the next 4 to 6 weeks to concentrations of approximately 1 per million circulating B cells.[425] During convalescence, HLA-restricted cytotoxic T lymphocytes keep EBV in check, primarily by targeting the latently expressed EBNA-3 protein.[489]

During the acute stages of IM, despite a brisk immune system response to EBV, widespread and extensive impairment in general cell-mediated and humoral immunity also exists. For example, low or absent delayed-type hypersensitivity reactions develop in response to tuberculin and other antigens.[180,330] In addition, T cells from patients with IM display unusually weak proliferative responses when exposed to recall antigens (e.g., *Candida albicans*, tetanus toxoid).[350,493] Although EBV-specific cytotoxic and suppressor T cells appear during acute infection, the T-cell response is primarily nonspecific and HLA unrestricted.[275,276,383,412] Furthermore, a polyclonal humoral response occurs during acute infection with EBV.[431] Each B cell committed to one isotype continues to produce that isotype after transformation of EBV, thereby leading to secretion of all classes of immunoglobulins, though primarily IgM.[482,533]

Once primary infection occurs, EBV, like other herpesviruses, is able to persist in a latent state in a human host throughout that person's lifetime. This ability indicates that EBV exerts some influence on the immune response to prevent its complete eradication. With its large genome, this process of immune system evasion is carried out primarily through the coding of functional homologues of many cellular factors that are involved in cell cycle regulation, signal transduction, and inhibition of programmed cell death (apoptosis). For example, the EBNA-1 protein contains a spacer region consisting of multiple Gly-Ala repeats that inhibit protein processing and MHC class I recognition of cells expressing EBNA-1.[308] Another viral protein (BARF1) blocks the receptor for colony-stimulating factor type 1, which normally stimulates secretion of antiviral factors such as IFN-α through interaction with monocytes.[79] In addition, one crucial EBV protein, LMP-1, up-regulates certain anti-apoptosis factors, allowing for prolonged survival of cells.[544]

EPSTEIN-BARR VIRUS–ASSOCIATED TUMORS

In normal hosts, cellular immune responses are adequate for control and sequestration of EBV-infected cells. However, cellular immune deficiency may allow uncontrolled proliferation of EBV-infected B cells to occur during primary or reactivated (recrudescent) EBV infection. Such an excessive EBV-associated production of B cells may be histologically pleomorphic (such as B cell lymphoproliferative diseases) or relatively uniform (monomorphic, such as B cell lymphomas). In organ transplant recipients, no consistent chromosomal translocations are associated with the lymphomas. Many of these lesions regress once immunosuppressive therapy initiated after transplantation is withdrawn.[542] In rare, severe cases, B cells harboring EBV DNA and expressing EBNA may become disseminated throughout the body as plasmacytoid cells visible on peripheral blood smears and as B-lymphoid cells potentially invading all organs of the body. Life-threatening EBV infections also may be correlated with an overly strong virus-induced T-cell proliferation that might cause autoaggressive activity, producing hypogammaglobulinemia or other major organ dysfunctions.[33]

The pathogenesis of EBV-associated malignant disorders in some settings may be multifactorial and involve a mixture of virologic, genetic, and environmental factors. NPC, which occurs predominantly in a specific geographic locale, has been linked etiologically with EBV.[201,209] The identification of epithelial cells as potential targets for EBV infection, thereby allowing a lytic (productive) infection, has strengthened this relationship.[457] Further studies have revealed that NPC is a monoclonal proliferation that develops subsequent to EBV infection, with EBV gene products required for tumor growth.[384] However, NPC also clearly has a genetic association, inasmuch as strong linkage to a specific HLA type exists.[310] Furthermore, early EBV gene expression can affect profoundly the growth of infected cells, with full malignant potential reached when mutations occur on chromosomes 3 or 9 (presumably affecting tumor suppressor genes).[223,224] These mutations possibly result from adverse environmental conditions (e.g., exposure to chemical carcinogens such as the volatile nitrosamines and polycyclic hydrocarbons in salted fish).[247]

The EBV genome and expression of EBNA-1 are present in more than 95 percent of BL cells derived from African patients with BL (endemic BL), with the genome existing as circular episomes. In contrast, only 15 to 30 percent of cases of nonendemic (or "sporadic") BL occurring in Europe and the United States contain EBV DNA.[227,553] On the other hand, EBV is present in more than 95 percent of primary lymphomas of the central nervous system (CNS) in patients with AIDS.[324] BL cells, but not the lymphoid cells found in IM, exhibit characteristic chromosomal alterations associated with enhanced malignant potential. Approximately 90 percent of BL tumors exhibit a reciprocal translocation involving the long arms of chromosomes 8 and 14, t(8;14); most of the remainder have t(8;2) and t(8;22).[278,434] These translocations place the c-*myc* oncogene under the control of an immunoglobulin promoter,[93,492] which results in transcriptional deregulation and overexpression of the c-*myc* oncogene.[88,297] Malaria is well known to cause chronic B cell stimulation, providing enhanced opportunities for c-*myc* translocations within germinal centers of lymphatic tissue. Healthy children living in areas with holoendemic malaria may have high viral loads of EBV in peripheral blood, with acute malaria further augmenting the viral load[541] and anti-malaria treatment subsequently reducing the EBV load in the peripheral blood.[106] Therefore, the evolution of endemic BL appears to be a multistep process involving EBV infection, malaria-induced B cell proliferation, c-*myc* gene rearrangement and activation, and probably other elements.[97,98,277,369,451]

PTLD may develop in organ and bone marrow transplant recipients during the intense immunosuppression that occurs after placement of the graft. PTLDs span a spectrum of lymphoproliferation from polyclonal disease to monoclonal, monomorphic disease that often is difficult to distinguish from typical malignant lymphomas developing in patients with intact immune systems. No proof exists that an orderly progression leading to malignant lymphoma occurs; however, one model for the pathogenesis of PTLD proposes that defective immune surveillance after transplantation allows polyclonal proliferation of EBV-infected cells displaying a type III latency pattern (similar to that observed in IM).[80] Subsequently, genetic mutations at various loci (e.g., c-*myc*, p53) may allow progression to full malignant lymphoma to occur.[99]

HISTOPATHOLOGY

INFECTIOUS MONONUCLEOSIS[90,162,500]

Because IM typically is benign and the diagnosis is based primarily on clinical and serologic findings, histopathologic examination

of tissues seldom is required. However, histopathologic information is available on some tissues (e.g., lymph nodes, tonsils, spleen) from unusual cases and from patients requiring surgery. For patients in whom lymphoproliferative disease and other serious manifestations of EBV infection develop, a larger amount of information is available from a broader range of tissues.

Lymph nodes are enlarged diffusely during acute IM. Histologically, active lymphoid follicles are noted, with lymphoid proliferation extending to the sinuses, blood vessels, trabecula, and capsule. The capsule remains intact despite substantial hyperplasia. The lymphoid response consists primarily of T and B immunoblasts, typically with a pleomorphic pattern and frequent mitoses indicative of rapid cell turnover. Other cells identifiable in lymph node tissues include a substantial number of small lymphocytes, large atypical lymphocytes, plasma cells, histiocytes, and eosinophils. Micronecrosis may be present, although it is less extensive than is that observed with herpes lymphadenitis. Tonsillar tissue also contains an active lymphoproliferative response, but with more prominent follicles and extensive necrosis.

The spleen is enlarged two to three times its normal weight during acute IM, primarily as a result of hyperplasia of the red pulp. Like lymph nodes, the cellularity is principally from immunoblasts with substantial pleomorphism. Hemorrhage, primarily subcapsular in location, is identified commonly. The liver typically shows minimal disease, with infiltration by lymphocytes and monocytes occurring principally in the portal areas and possibly minor degenerative changes taking place in hepatocytes. Bone marrow may appear relatively normal during IM, but some series have reported hypercellularity and small granulomata. From the relatively few cases of CNS disease associated with EBV infection, histopathology reveals lymphocytic infiltration of the meninges.[9] Less common findings include demyelination, degeneration, focal hemorrhage, congestion, and edema.

EPSTEIN-BARR VIRUS–ASSOCIATED MALIGNANCIES

The most common form of non-Hodgkin lymphoma (NHL) is BL, which consists of sheets of small noncleaved cells that are histologically uniform. Most arise from a single infected cell (monoclonality). The majority of CNS NHL tumors display large-cell morphology, with virtually all containing monoclonal EBV DNA. In PTLD, a wide range of histologic findings may be noted. At one extreme, one finds benign lymphoid hyperplasia with normal tissue architecture and a pleomorphic response arising from numerous infected cells (polyclonality). At the other end is observed frank malignant lymphoma.[86]

HD is somewhat unique among cancers, as less than 1 percent of cells within the tumor are actually neoplastic.[268] HD tissues are characterized by the presence of diffuse inflammatory cell infiltrates admixed with a low level of neoplastic cells: classic Reed-Sternberg cells and mononuclear Hodgkin cells (referred to collectively as *H-RS cells*). Reed-Sternberg cells are large (15-45 μm), multinucleated cells demonstrated to derive from germinal center–derived B cells.[282] These cells exhibit strongly stained nucleoli surrounded by a characteristic clear area resembling a halo. The World Health Organization (WHO) classification system for HD recently has been revised,[238] and two main subgroups now are defined: nodular lymphocytic-predominant HD and classic HD. Within classic HD are four distinctive histologic categories, based on the predominant cell type and characteristics of the background cellularity: (1) lymphocyte-rich, (2) nodular sclerosis, (3) mixed cellularity, and (4) lymphocyte depleted. In Western countries, EBV can be identified in approximately 40 percent of HD tissue specimens; mixed cellularity and lymphocyte-depleted types are associated most strongly with EBV. Children most commonly develop the nodular sclerosing variety.

Of the three histopathologic categories of epithelial tumors in the nasopharynx, the most common form in children is the undifferentiated variety, which is associated most strongly with EBV.[24] Examination of these tumors reveals undifferentiated squamous cells, with substantial infiltration by lymphocytes. Malignant cells consistently contain multiple copies of monoclonal EBV DNA within episomes, and several EBV proteins are expressed.

OTHER EPSTEIN-BARR VIRUS–ASSOCIATED DISEASES

The tissues involved in hemophagocytic lymphohistiocytosis (HLH) typically include the bone marrow, spleen, liver, and lymph nodes, but the skin or brain may be affected as well.[134] In the bone marrow, hypocellularity often is noted. Activated macrophages (or "histiocytes") appearing "stuffed" are observed engulfing all bone marrow cellular elements or their precursors or fragments, including erythrocytes, leukocytes, and platelets.[134,420,529]

Tissues affected by oral hairy leukoplakia (predominantly in adult patients with AIDS)[114] reveal keratin or parakeratin projections, mild hyperparakeratosis and acanthosis, ballooning and hyperplasia of the prickle-cell layer, and only a sparse inflammatory cell infiltrate in the subepithelial connective tissue.[166] The principal histologic findings in pulmonary tissue from children infected with human immunodeficiency virus (HIV) and having lymphocytic interstitial pneumonitis are lymphoid nodules and diffuse infiltration of the alveolar septa and peribronchiolar regions by lymphocytic cells, including lymphocytes, plasma cells, plasmacytoid lymphocytes, and immunoblasts.[17] Some lymphoid nodules may be observed as well. The infiltrating lymphocytes consist of B cells and T cells.[256] Necrosis is not observed, and blood vessels are not affected.

EPIDEMIOLOGY

SEROPREVALENCE

Epidemiologic studies of EBV were stimulated by development of reagents for detection of specific anti-EBV antibodies in serum in the mid-1960s. Specifically, tests detecting antibodies to VCA (long-lasting, early in infection) and EA (short duration, early in infection) were used. Henle and Henle,[196] using an immunofluorescence method, first noted a high prevalence of EBV VCA antibodies (100%) in patients with BL, but they also discovered a relatively high prevalence (85%) in normal adults. Subsequent studies in American[152,198,399,473] and British[393] populations have established that 80 to 95 percent of adults have serologic evidence of past EBV infection, with most infections occurring during infancy and childhood.

The age at initial (primary) infection varies markedly in different cultural and socioeconomic settings, a fact that has great pertinence to manifestations of disease associated with primary infection. In developing countries, EBV infection generally occurs at an early age, with 80 to 100 percent of children becoming infected by the time they reach 3 to 6 years of age. In these settings, most children with primary EBV infection have clinically silent or mild disease.[38,135,476] In privileged communities and in industrialized countries, primary infection with EBV commonly occurs later in life. In these settings and for reasons that are unclear, primary infection in older age groups, for example, individuals between 10 and 30 years of age, is more likely to induce clinical symptoms, most often a mononucleosis syndrome. An IM case rate of 50 to 75 percent associated with primary EBV infection was documented in U.S. college students.[366] An unexpectedly high rate of IM also has been noted with eventual

development of primary EBV infection in siblings of a pediatric case of IM.[480]

INCIDENCE

The incidence of IM from population-based studies ranges between 50 and 100 cases per 100,000 population.[123,192,194] These studies indicate that the highest incidence rates for IM occur in the age group 15 to 19 years. Although two reports have described a modest seasonal change for IM,[173,192] most studies have indicated no seasonal predilection. IM consistently has developed at a higher rate in persons of white race than in other ethnic groups.[192] In one study, IM developed in males at a rate slightly higher than that in females.[194]

VIRAL SHEDDING

The initial indication that EBV was shed in oropharyngeal secretions came from Chang and Golden[64] in 1971 when they identified a "leukocyte transforming agent" in throat washings from four of eight adults with IM. Although EBV was suspected, specific laboratory tests could not confirm it. Other investigators using more specific identification methods clearly established EBV as the leukocyte transforming agent.[154,319,347] Subsequent studies in healthy populations have indicated the following:* (1) most children and adults with acute IM shed EBV in their oropharynx, (2) between 6 and 20 percent of the general population are shedding EBV in the oropharynx at any given point of time, (3) oropharyngeal shedding may be intermittent or continuous, and (4) high concentrations of EBV in oropharyngeal secretions are associated with high concentrations of EBV in B-lymphocytes in the peripheral blood but not with concentrations of EBV-specific serum antibodies.

In addition to the oropharynx, EBV DNA may be found in the urine of persons during and for several months after an episode of IM.[288] Shedding of EBV also has been reported in the uterine cervix,[458,495] the male reproductive tract,[235,495] and breast milk.[257]

TRANSMISSION

Common Modes of Transmission

Reports in the first half of the twentieth century, before widespread acceptance and use of the heterophile antibody test, suggested the occurrence of epidemics of IM.[182,371,498] However, researchers generally thought that the criteria used in most of those reports for establishing the diagnosis of IM were inadequate to convince one that the outbreaks were indeed associated with EBV.[212] Although some success was reported for transmission of human EBV infections to certain primate species,[250] attempts to experimentally infect humans with EBV collected from the oropharyngeal secretions, blood, urine, and feces of patients with IM generally failed.[120,121,364,463] These experiments, conducted prior to development of specific EBV antibody tests, presumably were unsuccessful because most experimental subjects were immune as a result of having had a previous EBV infection.

Intimate sharing of oral secretions is thought to play a major role in the transmission of EBV.[122,212] The fact that EBV infection is extremely common worldwide, especially in underdeveloped regions, suggests that the virus is spread relatively efficiently in the general population. Surprisingly, outbreaks of EBV infection are uncommon events. However, transmission of EBV, even among close contacts of a person with acute EBV infection, may occur slowly. Studies of families of index cases of IM have indicated that EBV is not transmitted efficiently.[66,138,194] Furthermore, Chang[67] reported a lack of EBV transmission from a man with IM to his EBV-seronegative wife, even after 16 months of follow-up. In addition, data from another family study indicated that after the index IM episode, EBV antibodies (seroconversion) developed in only 35 percent of the non-immune sibling contacts after an average observation period of 5.6 contact months.[480] Nonetheless, this same study also noted that the eventual seroconversion event in siblings was more likely to be associated with an IM episode than would be expected in the general population.[480] The complexity of EBV transmission and induction of IM is suggested further by the finding of multiple strains and variability of strains in distinct body compartments of individuals with primary EBV infections.[456]

Evidence has shown that EBV replicates in oropharyngeal epithelial cells,[457] with subsequent infection of B cells possibly occurring as a result of contact with these epithelial cells.[4] Further studies indicate that latent and productive EBV infection occurs in lymphoid cells on the surface of the tonsillar epithelium and within the crypt, but not in epithelial cells.[10] Thus, transmission of EBV from person to person may be due to transfer of virus from persistently infected EBV lymphoid cells; EBV-infected epithelial cells may not be required for this phenomenon.[368] The incubation period for typical EBV-associated IM is imprecise but is estimated at 30 to 50 days.[138,212]

Transmission via Blood Products or Transplanted Organs

Transmission of EBV via blood transfusion has been reported,[2,153,200,212,342,491] but it occurs much less commonly than does transmission of CMV. High levels of immunity, transfer of neutralizing antibodies during transfusion, and limited survival of B cells may account for the rarity of this occurrence.[203] In transplant recipients, EBV-positive donor organs may transmit EBV to the recipient.[62,189]

Intrauterine and Perinatal Transmission

Because most females reaching child-bearing age already have been infected with EBV, primary infections during pregnancy occur infrequently.[137,229,294] Therefore, the risk of fetal transmission is difficult to study. One prospective study of primary infections occurring during pregnancy (silent or symptomatic) indicated no adverse fetal outcomes and, when studied, no viral transmission to the fetus.[136] Moreover, Chang and colleagues[65,69] could find only one EBV-infected specimen among 2696 samples of cord blood lymphocytes. On the other hand, case reports suggest that rare instances of intrauterine transmission may occur.[50,159,253] The significance of one report noting EBV DNA in breast milk of approximately 50 percent of healthy women is unclear.[257]

Sexual Transmission

Detection of EBV in genital ulcers,[401] the uterine cervix,[458] and the male reproductive tract[235] raises the possibility of venereal transmission. Additional epidemiologic findings suggest that EBV transmission and onset of IM can be correlated with sexual intercourse or closely associated behaviors.[87]

NONMALIGNANT CLINICAL SYNDROMES ASSOCIATED WITH EBV INFECTION

SILENT, NONSPECIFIC INFECTIONS

Similar to other lymphotropic human herpesviruses, primary EBV infection in children typically is silent but may result in mild clinical symptoms. Nonspecific clinical symptoms may include prolonged low-grade fever with or without lymphadenopathy, cough, rhinorrhea, and pharyngitis.

INFECTIOUS MONONUCLEOSIS

The signs and symptoms of classic IM[70,110,132,213,478] develop in most adolescents and adults, as well as some young children, when they experience a primary (initial) EBV infection. Factors determining an asymptomatic versus symptomatic response to EBV infection are largely unknown. Adults developing IM may have an exaggerated, pathologic T-cell response to primary EBV infection. The degree of viremia does not appear to be related to symptomatology, with EBV viral loads in blood from symptomatic subjects being comparable to those undergoing silent EBV infection.[453]

Prodrome

In most persons with IM, a prodrome of 2 to 5 days develops during the end of the incubation period. Prodromal symptoms typically are mild and may consist of malaise, fatigue, and possibly fever. At this stage, differentiating IM from other viral infections is difficult.

Acute Phase

The prodrome is followed by the classic clinical features of IM (i.e., fever, sore throat, malaise, and fatigue), and physical examination reveals lymphadenopathy and tonsillopharyngitis (Table 172–1). The fever usually begins rather abruptly, ranges from 38° C to 40.5° C (usually <39° C), is more prominent in the afternoon and evening, and persists for 1 to 2 weeks. Occasionally, the fever may last 4 to 5 weeks. Lymphadenopathy occurs in more than 90 percent of children and adults and typically involves the anterior and posterior cervical lymph nodes (Fig. 172–1). Affected nodes are moderately enlarged in a symmetric manner. However, generalized lymphadenopathy also is characteristic and involves the occipital, supraclavicular, axillary, epitrochlear, and inguinal chains. Like other causes of viral lymphadenitis, the lymph nodes in patients with IM may be slightly tender, but they generally are nontender, nonerythematous, and discrete. Lymphadenopathy is most prominent during weeks 2 to 4 of the illness. Tonsillopharyngitis develops during the first week of illness and usually resolves rather abruptly the next week. Although mild symptoms occur in some patients, most have substantial symptomatology. Exudative pharyngitis, similar to that found with *Streptococcus pyogenes* pharyngitis, occurs in approximately half of patients (Fig. 172–2). *S. pyogenes* is present in the posterior pharyngeal region of 5 percent of patients with IM and probably represents carriage rather than simultaneous bacterial tonsillopharyngitis.

Splenomegaly occurs in approximately 50 percent of patients with IM, but more frequently in younger children. Usually only the tip of the spleen is palpable, with maximal size developing by the end of the second week of illness. The splenomegaly typically resolves by the third or fourth week. Hepatomegaly occurs in approximately 60 percent of young children with IM and less commonly in older age groups. However, silent inflammation of the liver is a common finding.[221] Cough and rhinitis are noted frequently in young children with IM, perhaps as a result of other concurrent viral infections. Rash (unassociated with antibiotic administration) develops in less than 15 percent of adults with IM but occurs more commonly in children and adolescents (18-34%).[478] The strong correlation in young adults between the administration of ampicillin and the subsequent development of a rash is not observed in children with IM, possibly overshadowed by the overall increased incidence of cutaneous manifestations in children with IM (see "Complications of Infectious Mononucleosis" for a detailed discussion of rashes associated with IM). Children are more likely than are adults to have abdominal pain, failure to thrive, otitis media, and recurrent tonsillopharyngitis preceding or following IM.[478] A palatal enanthem is present in approximately a third of adults, but it is a nonspecific finding. Eyelid edema also is described in up to a third of adults but occurs less commonly (15%) in children.[478]

TABLE 172–1 Clinical Manifestations of Infectious Mononucleosis in Children and Adults

	Frequency (%)		
Sign or Symptom	**Age <4 yr***	**Age 4-16 yr***	**Adults (Range)***
Lymphadenopathy	94	95	93-100
Fever	92	100	63-100
Sore throat or tonsillopharyngitis	67	75	70-91
Exudative tonsillopharyngitis	45	59	40-74
Splenomegaly	82	53	32-51
Hepatomegaly	63	30	6-24
Cough or rhinitis	51	15	5-31
Rash	34	17	0-15
Abdominal pain or discomfort	17	0	2-14
Eyelid edema	14	14	5-34

Resolution Phase

The acute phase of IM lasts several days to 3 to 4 weeks, with gradual and uneventful resolution. Occasionally, biphasic illness is observed, with recrudescence of acute symptoms after significant improvement. Organomegaly may persist for 1 to 3 months. The severe fatigue usually resolves within 3 to 4 weeks, but several months may be required for persons with IM to fully resume their pre-illness activity levels. There is evidence, albeit minimal, suggesting that subsequent fatigue-like syndromes in patients with IM may be related to (or predicted by) the presence of preexisting lower physical fitness or prolonged bed rest during convalescence, whereas mood disorders are more related to premorbid psychiatric history.[524]

DISSEMINATED EBV INFECTION IN X-LINKED LYMPHOPROLIFERATIVE DISEASE

Overwhelming primary EBV infection, seen rarely in immunocompetent patients, occurs more commonly in children with certain primary immunodeficiency disorders, most notably, boys with x-linked lymphoproliferative disease (XLP).[406,472] These patients typically first present with features consistent with IM, but fulminant disease leading to death subsequently develops. Widespread, uncontrolled lymphoproliferation is found at autopsy, and causes of death include acute hemorrhage, meningoencephalitis, secondary bacterial infection, and liver failure.[355] Survivors usually have hypogammaglobulinemia, and B-cell lymphomas may develop later. XLP is associated with the deletion or mutation of a specific gene (SLAM-associated protein) located in the chromosomal Xq25 region, which is involved in key cellular signaling pathways for immune responses[78,363,443]; absence of this functional protein permits overwhelming and usually fatal infection from a primary EBV infection.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

Hemophagocytosis, first described in 1939, is a pathologic condition demonstrating engulfment of bone marrow cellular elements (erythrocytes, leukocytes, platelets, and their precursors) by activated macrophages (Fig. 172–3) Hemophagocytic lymphohistiocytosis (HLH, also called *hemophagocytic syndrome*) is characterized primarily by fever, pancytopenia, splenomegaly, and hemophagocytosis in lymphoreticular tissue (bone marrow, spleen, and lymph nodes). Since the initial description of its association with viral infections in 1979,[420] numerous viral infections, including EBV, have been linked with HLH.[379,413] Hereditary forms of HLH exist, most prominently those occurring in children with XLP (see previous section).[355] A disseminated form of EBV infection with features of HLH may develop in these patients; most other cases are sporadic. In contrast to IM, which involves infection of B cells, primary infection in patients with sporadic HLH results in an EBV-driven T-cell proliferation with proinflammatory cytokines playing a central pathogenetic role.[242] Untreated EBV-associated HLH carries a high mortality rate.

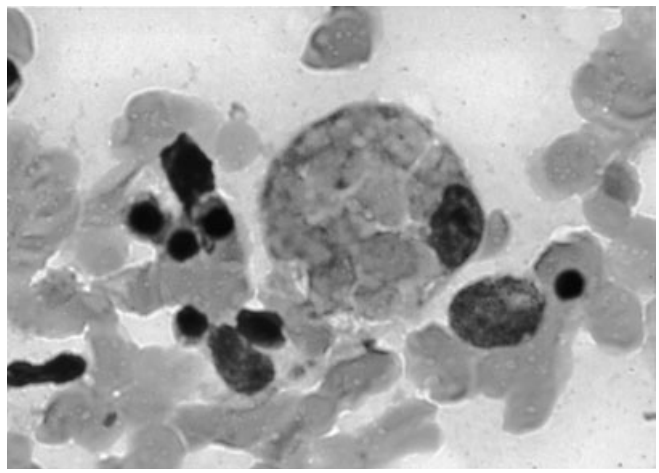

Figure 172–3 Bone marrow from an 18-year-old woman with Epstein-Barr virus–associated hemophagocytic lymphohistiocytosis revealing a macrophage (center) filled with phagocytosed red blood cells. *(From Blood 93:1991, 1999. CHRONIC ACTIVE DISEASE

Although first described in 1978,[511] chronic active Epstein-Barr virus (CAEBV) infection is not as well-characterized as are other

EBV-associated diseases. It shares with HLH the central theme of infection and proliferation of non-B cells. CAEBV occurs more commonly in Japan,[273] with children affected more frequently than adults. Two forms of the disease have been described, one involving EBV-infected T cells and the other affecting NK cells.[274] Patients with the more severe form can be considered as having a chronic version of HLH, with similar symptoms and a uniformly poor prognosis. After having a typical IM-like illness, these patients develop persistent infection of their peripheral T cells ($CD4^+$, $CD8^+$, or both) and do not recover fully. Continuous or intermittent signs and symptoms, persisting for 3 months or longer, typically include fever, hepatosplenomegaly, lymphadenopathy, headache, malaise, and fatigue.[450,526,527] More severe cases display neurologic disease (e.g., encephalitis), malignancy (e.g., lymphoma or leukemia), hepatic failure, hematologic disease (e.g., hemophagocytosis), and disease localized to other organs (e.g., myocarditis, pneumonitis).[273] One distinctive characteristic of these patients is the extremely high antibody titers against EBV replicative antigens, including VCA and EA, and low or absent responses to EBNA. Poor prognostic factors include older age and high EBV viral loads.[273] Some cases may be related to mutations in the perforin gene.[262] Clonal expansion of EBV-infected T cells probably plays a central role in disease pathogenesis.[273] A second form of the disease, described principally in Japanese patients, is characterized by milder IM symptoms, less extreme EBV serologic abnormalities, granular lymphocytosis, and high IgE levels.[274] Interestingly, these patients also typically develop pronounced skin reactions in response to mosquito bites. Large expansions of EBV-infected, CD56-positive NK cells are observed in peripheral blood and in the skin reactions. CAEBV infection should not be confused with chronic fatigue disorder, which has no clear association with EBV.

OTHER DISEASES

EBV has been linked with various autoimmune disorders in children and adults, based primarily on seroepidemiologic information. These disorders include rheumatoid arthritis,[56] systemic lupus erythematosus,[240,340] and multiple sclerosis.[5] Further careful studies must be conducted in order to substantiate these early reports of an etiologic relationship with EBV.

COMPLICATIONS OF INFECTIOUS MONONUCLEOSIS

Acute EBV infection in a healthy child or adolescent, regardless of whether it is associated with typical IM, rarely is complicated by serious illness. The most frequent complications, exanthems and mild hepatitis, more appropriately are considered part of the normal spectrum of disease. More serious complications involving major organs have been reported regularly since IM first was described as a distinct clinical entity, but they remain rare (for review, see elsewhere).[6,245,392,478] Most complications, including the more severe ones, are transient.

In one prospective study,[478] significant complications involving mainly the pulmonary, neurologic, and hematologic systems were noted in approximately 20 percent of children with IM. Thrombocytopenia with hemorrhagic manifestations, severe airway obstruction, and neurologic complications developed in children with IM more frequently than in adults; jaundice occurred less frequently.

EXANTHEMS

Ampicillin Rash. Historically, patients with IM were treated frequently with antibiotics, primarily for suspected streptococcal pharyngitis or bacterial lymphadenitis. Soon after the release of ampicillin, reports linked the antibiotic with the occurrence of exanthems in patients with IM. Two large case series have indicated that administration of ampicillin (or amoxicillin) precipitates an exanthem in most (95-100%) adolescents and adults with EBV-associated IM[382,405]; it is less common in children with IM.[478] This phenomenon has become known as the "ampicillin rash" associated with IM. The rash usually develops 5 to 10 days after treatment is initiated and resolves within a few days of discontinuation. Characteristically, the cutaneous lesions are maculopapular and pruritic and involve the trunk, face, and extremities (Fig. 172–4).[382] A rash also may develop in patients with IM

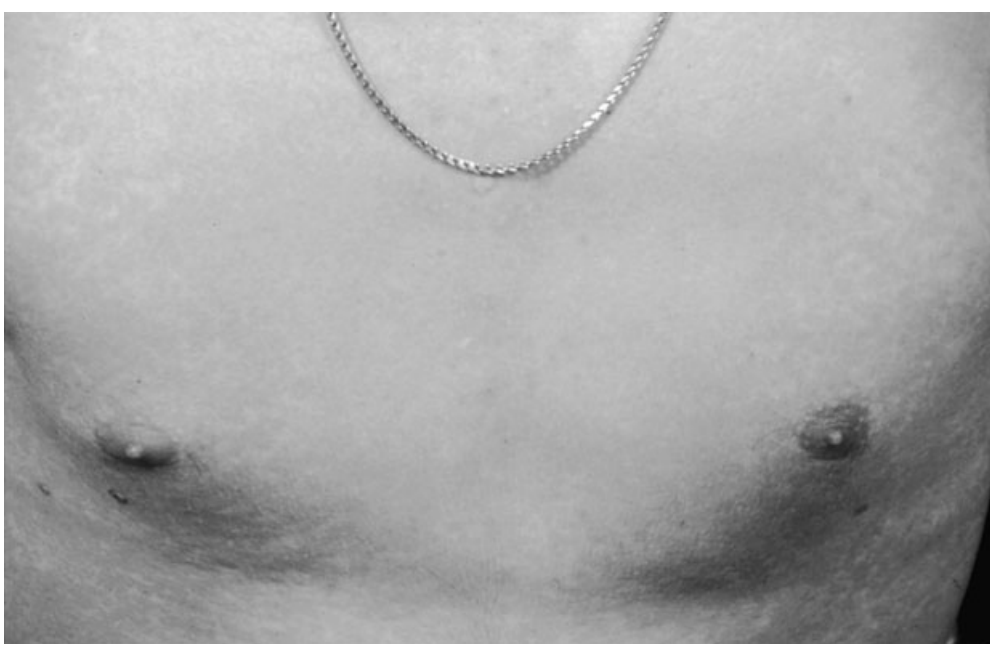

Figure 172–4 "Ampicillin rash" occurring in an adolescent with infectious mononucleosis after the administration of amoxicillin. *(Courtesy Dr. James Brien, Scott and White Hospital, Temple, Tex.)*

treated with other β-lactam antibiotics, but such rashes do not represent hypersensitivity reactions.

Other Exanthems. An exanthem will develop in approximately 3 to 15 percent of persons with IM not treated with β-lactam antibiotics.[27,213,251,334,410,478] These rashes are maculopapular but can be urticarial, scarlatiniform, or erythema multiforme–like. Erythema nodosum also has been noted.[43] Although most commonly associated with hepatitis B, some cases of Gianotti-Crosti syndrome (papular acrodermatitis of childhood) also have been related to primary EBV infection.[217]

CARDIAC

Mild electrocardiographic abnormalities (mostly nonspecific ST and T wave changes) have been observed in 6 to 16 percent of adults with IM.[110,214] Abnormalities usually are noted during the second or third week of illness and disappear by the fourth week, but they may persist longer. A case of myocarditis heralding typical IM has been noted in a young adult.[513] Serious cardiac complications occur extremely rarely.[142]

HEMATOLOGIC

Hemolytic Anemia. Hemolytic anemia occurs in 1 to 3 percent of patients with IM,[215,478] and many cases have been reported in children with previously unrecognized hemoglobinopathies. The anemia typically develops during the second or third week of illness and resolves in 1 to 2 weeks. Corticosteroid therapy may hasten resolution.[151]

Aplastic Anemia. This anemia is a rare complication of IM, with only scattered case reports in the literature.[169,293,507] Steroids have been beneficial,[169] but bone marrow transplantation has been necessary in some cases.[309] Fatalities have been recorded, usually in association with pancytopenia.[1,507]

Thrombocytopenia. Thrombocytopenia occurs in 25 to 50 percent of patients with IM[58,59] and probably is immune-mediated. Platelet counts usually return to normal levels 4 to 6 weeks after the onset of illness. Severe thrombocytopenia (platelet counts $<20 \times 10^3/mm^3$) occurs rarely, with fewer than 40 cases identified in one review.[395] These authors noted a complication rate of 27 percent and a mortality rate of 5 percent associated with severe thrombocytopenia. Case reports have suggested beneficial effects of corticosteroids[313,488] or intravenous immunoglobulin[109] for severe, life-threatening thrombocytopenia.

Neutropenia. Mild to moderate neutropenia occurs frequently during IM.[57,60] Neutrophil counts typically reach their lowest values during the third and fourth weeks of illness but may persist for another month or more. Although severe neutropenia (absolute neutrophil count <200) and agranulocytosis are rare events, with patients recovering uneventfully, death from overwhelming bacterial infection has been reported.[361] Antineutrophil antibodies elicited during EBV-induced polyclonal antibody stimulation probably are the source.[444]

Pancytopenia. Pancytopenia has been reported to develop in a small number of children and adults with IM.[293] Fatalities attributable to overwhelming bacterial infection have occurred.[239,507]

SPLEEN

Detectable splenomegaly develops in up to 50 percent of patients with IM, with one study demonstrating splenic enlargement by ultrasound in 100 percent of patients hospitalized with IM.[105] Patients with a palpable spleen are at risk for having spontaneous rupture. In the United States, spontaneous rupture of the spleen occurs in an estimated one in every 1000 adults with IM[127,328]; the rate of splenic rupture in children is unknown but probably is lower. Rupture typically occurs during the first to third week of illness and is heralded by abdominal pain. Signs of hypovolemia occur frequently and include orthostasis, tachycardia, and syncope. Pain in the left shoulder (Kehr sign),[322] caused by diaphragmatic irritation from blood, is observed in approximately 50 percent of patients with splenic rupture; right shoulder and subscapular pain may develop as well.[440] Splenic abscess has been described in a child with IM.[73]

To reduce the risk of splenic rupture, physicians customarily caution patients against engaging in strenuous physical activity and contact sports during recovery from the acute illness and for the period of significant organomegaly.[436,516] Recommendations for reduced activity vary between 3 weeks and 6 months. In a recent review, the lack of evidence-based information regarding the timing of return to activity for athletes is acknowledged, and physicians are discouraged from making decisions on the basis of a single parameter.[516] Instead, individualized decisions must be made. In general, if the patient is asymptomatic without a palpable liver or spleen, a gradual return to pre-IM levels of activity probably is safe. Imaging procedures (e.g., computed tomography [CT] or ultrasound) generally are not cost effective or accurate in determining the timing for normal activity, but they may be considered for athletes desiring to return to play early and for those with ambivalent examination findings.

Most cases of splenic rupture require emergency splenectomy.[127] However, in an effort to maintain the patient's hematologic and immunologic competence, practical management of splenic rupture is evolving. At some institutions, selected patients with splenic rupture who meet certain requirements, including hemodynamic stability with low transfusion requirements and a normal level of consciousness, may be managed with medical therapy,[22] or endovascular interventional methodologies,[47] instead of traditional splenectomy.

GASTROINTESTINAL TRACT

Liver. Mild to moderate, subclinical inflammation of the liver occurs in more than 90 percent of patients with IM.[221] Rarely, more serious cases of hepatic disease, including children with fulminant hepatic failure, have been described.[101,145,191,281,321,325,332] Chronic hepatitis also has been reported.[490]

Other. Other gastrointestinal diseases purportedly associated with IM include pancreatitis, gastritis, typhlitis, and cholecystitis.[193,281,312,452,548]

NEUROLOGIC

Acute neurologic disorders[83,454] develop in 1 to 5 percent of persons with IM.[36,213,454] Neurologic complications usually occur at the height of the typical manifestations of IM, but they also may develop during the resolution phase. In addition, some reports document neurologic disease as a heralding event, before the development of typical IM, or even as the sole manifestation of EBV infection, especially in children.[44,104,118,354] The most common neurologic complications include those occurring in the CNS, such as aseptic meningitis, meningoencephalitis, and encephalitis; however, other central and peripheral neurologic complications have been described. The pathophysiology of CNS manifestations is not well established. Possible mechanisms

include direct viral invasion, immunologic mechanisms, and inflammation.

Encephalitis and Aseptic Meningitis. EBV frequently affects the CNS, causing cerebrospinal fluid (CSF) abnormalities and electroencephalographic abnormalities, yet most patients exhibit no symptoms.[390] In two large series of patients with encephalitis, EBV was responsible for 2 to 5 percent of cases,[266,279] and EBV caused 8 percent of cases of focal encephalitis.[525] Clinical findings in EBV encephalitis include fever, headache, vomiting, seizures, alteration in mental status, irritability, disorientation, lethargy, and, occasionally, a comatose state. Symptoms suggestive of schizophrenia, such as delusions, hallucinations, and extreme agitation, are seen occasionally. Patients with aseptic meningitis typically complain of a stiff neck, headache, fever, and vomiting. Symptoms of IM occur uncommonly in children developing EBV encephalitis. Typical CSF findings in children with EBV encephalitis include mild to moderate pleocytosis (lymphocytic predominance) in 50 percent, mildly elevated protein levels in half of cases, and normal glucose.[104] EBV antibodies, EBV DNA, and even EBV itself have been identified in the CSF or brain tissue of persons with EBV-associated neurologic complications.[185,230,252,388] Some reports suggest that the immune dysregulation caused by primary EBV infection may act as a triggering mechanism for the development of measles-associated subacute sclerosing panencephalitis.[129,216] Because typical IM symptoms seldom occur in children with EBV encephalitis, and clinical findings are not specific, EBV should be considered a possible etiology for any child with acute encephalitis.

Other CNS Manifestations. EBV-associated cerebellitis is a rare occurrence that develops primarily in children and young adults.[76,83,118,157] Full recovery occurs within weeks to months. Cranial nerve palsies, singly or in combination, also occur rarely; the facial nerve is involved most commonly.[344,546] Other manifestations of cranial nerve involvement include optic neuritis,[140] deafness,[118,528] and ophthalmoplegia.[438] Some cases of brain stem encephalitis[372,449] and recurrent aseptic (Mollaret) meningitis[163] have been reported.

Non-CNS Neurologic Complications. Outside the CNS, Guillain-Barré syndrome (ascending polyradiculoneuritis) is the most common complication of EBV infection.[170,171,415] Other non-CNS neurologic complications of IM include peripheral neuropathy,[112] autonomic dysfunction,[536] hemiplegia,[29] and transverse myelitis.[503]

RENAL

Silent abnormalities of the urine sediment, including proteinuria and microscopic hematuria, occur commonly in patients with IM.[213,299] However, clinically significant renal disease is an extremely rare event. Tubulointerstitial disease and nephrotic syndrome have been observed most commonly.[42,510] Acute renal failure with and without rhabdomyolysis has been reported.[141,302,510] Some children and adolescents have developed hemolytic uremic syndrome related to acute EBV infection.[447,455]

RESPIRATORY TRACT

Airway Obstruction. Severe airway obstruction occurs in 1 to 5 percent of children and adults with IM. Alpert and Fleisher[6] observed severe airway obstruction in a fourth of children admitted for complications of IM. Patients typically have severe tonsillopharyngitis with progressive symptoms of airway obstruction, usually in association with dysphagia and odynophagia. Airway obstruction may occur at any of several levels, including inflammation and hypertrophy in the Waldeyer ring, edema of the epiglottis and pharynx, and development of pseudomembranes in large airways.[156,178] Management of airway obstruction has included systemic corticosteroids, tonsillectomy, tracheostomy, and nasopharyngeal airway placement, as well as general supportive measures such as humidification and elevation of the head of the bed.[462,530] Nonsurgical management, including the administration of systemic steroids, usually is beneficial, although tonsillectomy may be necessary in refractory cases.[462,469,530] With the widespread availability of intensive care and mechanical ventilation, mortality from this complication is much lower than previously observed.

Neck Abscesses. Cervical and peritonsillar abscesses have been described in association with IM.[54,187,249,522] This uncommon complication follows severe tonsillopharyngitis in patients with IM and typically is caused by bacteria found in the oral cavity, including alpha-hemolytic streptococci and anaerobes. Appropriate management includes administration of antibiotics and surgical drainage. Some concern exists that corticosteroid therapy of incipient airway obstruction may predispose to the development of an abscess.[54,187] On the other hand, abscesses may develop in the absence of previous corticosteroid therapy.[149,400]

Pulmonary Disease. Radiographic evidence of pulmonary infiltrates occurs in 0 to 5 percent of patients with IM,[110,289] yet significant symptomatology rarely is present.[110,213,289] Some cases of IM with pulmonary disease may represent co-infection with other etiologic agents.[15,131] However, several immunocompetent adults (but few children) with acute EBV infection have been described with pulmonary disease seemingly unrelated to other organisms.[77,184,373] Typically, unilateral or bilateral interstitial infiltrates are observed, and pleural effusions may be present.[113,280] In some cases, EBV has been detected in lung tissues.[467,508] Recovery is the rule, although mechanical ventilation may be necessary.

PSYCHIATRIC

Chronic Fatigue. In the early 1980s, a chronic debilitating disorder (now designated *chronic fatigue syndrome*) began receiving increased publicity and purportedly was linked etiologically to EBV.[255,471] The syndrome occurs more commonly in middle-aged women and is characterized primarily by chronic debilitating fatigue, as well as low-grade fever, mild lymphadenopathy, pharyngitis, neuropsychological problems, and other symptoms. The association with EBV was drawn mainly from epidemiologic features and some abnormal EBV-specific immune responses. Variable general immunologic abnormalities have been described in some cases. However, no consistency exists in these findings, and a plausible pathogenetic association has not been demonstrated. Most experts today do not regard EBV as a major etiologic agent in the development of this syndrome, although it may play a contributory role along with other viruses (e.g., human herpesvirus 6, CMV).

"Alice-in-Wonderland" Syndrome. This unusual syndrome, technically termed *metamorphopsia*, is a visual illusion manifested as a distortion in size, form, movement, or color, and it is associated most commonly with migraine headaches, epilepsy, and hallucinogenic drugs. Copperman[85] first described its association with IM in 1977, and other similar cases also have been described.[74,119,286,287] Onset may occur during or soon after resolution of the clinical IM symptoms, and it may resolve within 4 to

6 weeks. Visual-evoked potentials suggest diminished cerebral perfusion in affected cases.[287]

MISCELLANEOUS COMPLICATIONS

Other complications purportedly associated with IM or primary EBV infection include recurrent tonsillitis,[509] sinusitis,[475] periorbital cellulitis,[475] ocular disease,[335] rhabdomyolysis,[377] genital ulcers,[401] and orchitis.[409]

MALIGNANT DISEASES ASSOCIATED WITH EPSTEIN-BARR VIRUS

BURKITT LYMPHOMA

Endemic BL is a rapidly progressive and fatal tumor that predominantly affects young children in central Africa and Papua New Guinea (Fig. 172–5).[53] Approximately 60 percent of African patients with BL present with jaw masses, with abdominal masses being second most common.[550] Less common sites include the CNS and the eye. Non-African patients with BL are most likely to have abdominal masses initially. In some patients with BL and some with congenital or acquired immunodeficiencies (including AIDS), CNS involvement is present or eventually develops and is characterized by intracranial mass lesions of lymphomatous cells or a CSF pleocytosis consisting of malignant cells, or both.[14,550,551]

HODGKIN DISEASE

The association of EBV with HD is based primarily on serologic studies[306,356] and identification of EBV DNA in H-RS cells (the malignant cells characteristic of HD).[267,520] The differential incidence distribution of HD in children throughout the world corresponds with the age at first EBV infection: It increases in adolescence in developed countries and increases in early childhood in developing countries.[177,248] Virtually all cases of HD in developing countries are associated with the presence of EBV, whereas the virus is present in approximately 40 percent of patients with HD in developed countries.[268] However, in developed countries, EBV is strongly associated with HD in children younger than 10 years old and in tumors displaying the mixed cellularity variant.[20,205,380] HD rarely occurs in children younger than 5 years old in Western countries, but it is seen more commonly at younger ages in developing countries. The precise pathogenetic mechanisms for EBV-associated HD are being unraveled, but evidence indicates that HD is primarily a result of chronic inflammation, with EBV contributing to the overproduction of various cytokines and chemokines by H-RS cells and the surrounding inflammatory cells.[268] Patients typically have cervical or supraclavicular lymphadenopathy, as well as mediastinal adenopathy (occasionally with obstructive symptoms).[225] Constitutional symptoms such as fever, nightsweats, and weight loss develop in approximately a fourth of patients with HD, and these symptoms worsen the prognosis.

NASOPHARYNGEAL CARCINOMA

NPC occurs primarily among adults in southern China, but it may be seen in Greenland, Alaska, and the Mediterranean region as well; the tumor is extremely rare in Western countries.[125] In endemic regions, children younger than 16 years old account for only 1 to 2 percent of all cases of NPC, whereas this proportion is higher (10%) in the United States.[232] Children with NPC most commonly present with a painless unilateral neck mass, nasal symptoms (congestion, epistaxis, discharge), auditory symptoms (otalgia, otitis media, hearing loss), and cranial nerve abnormalities.[24,247] At initial evaluation, children with NPC are more likely than are adults to have locoregional disease.[24,232]

POST-TRANSPLANT LYMPHOPROLIFERATIVE DISEASE

Children immunosuppressed for organ transplantation have an increased risk for developing EBV-related lymphoproliferative syndromes and B-cell lymphomas (collectively termed *PTLD*).[211,283,464] Ho and colleagues[211] reported a greater frequency of lymphoproliferative lesions in pediatric transplant recipients (4%) than in adult transplant recipients (0.8%). Pediatric organ transplant recipients are thought to have an increased risk for development of EBV-related PTLDs because, when compared with adult transplant recipients, they are more likely to be seronegative for EBV at transplantation, and primary infection is more likely to progress to PTLD and other severe EBV-associated disorders.[210,211] Some variability exists in the incidence of PTLD according to the specific organ transplanted: The incidence is highest in children receiving intestinal transplants (31%),[470] probably attributable to more profound immunosuppressive regimens and greater loads of lymphatic tissue in the grafts; generally lower PTLD incidences are noted in other pediatric organ transplant populations (liver: 7-13%; thoracic organs: 4-12%; kidney: 1-9%).[470] After human stem cell transplantation, the 10-year cumulative incidence rate for PTLD is approximately 1 percent overall.[89] Rates of PTLD are substantially higher if benign, hyperplastic cases of PTLD are included.[547]

The clinical history, physical examination findings, and confirmatory virologic laboratory testing are required in order to establish a diagnosis of PTLD. Symptoms may be quite nonspecific, especially early in the course, and include fever, malaise, weight loss, abdominal symptoms (bleeding, nausea, vomiting), sore throat, swollen lymph nodes, headache, focal neurologic symptoms, and indications of graft dysfunction.[165] On examination, signs may include lymphadenopathy, large tonsils, hepatosplenomegaly, pallor, subcutaneous nodules, and focal neurologic findings.[165]

Subsequent EBV-associated, smooth-muscle tumors (e.g., leiomyosarcomas) have been found to develop in some adolescent and young adult patients undergoing organ transplantation.[298,426]

LYMPHOPROLIFERATIVE DISEASE IN OTHER IMMUNODEFICIENT PATIENTS

Patients with a wide variety of congenital immunodeficiencies (e.g., severe combined immunodeficiency syndrome, Wiskott-

Aldrich syndrome, ataxia telangiectasia, Chédiak-Higashi syndrome, common variable immunodeficiency), as well as iatrogenically immunosuppressed patients (e.g., patients receiving cancer chemotherapy or antitumor necrosis factor alpha monoclonal antibodies), also are at risk for developing various EBV-associated lymphoproliferative diseases and severe atypical EBV infections. One should keep in mind, however, that IM and other forms of EBV infections in immunocompromised children and adults usually run a course similar to that in immunocompetent persons; actually, even in immunosuppressed patients (and post-transplantation subjects), the majority of EBV infections are clinically silent.[202,211]

OTHER MALIGNANCIES

Other rare lymphoproliferative diseases (B cell and T cell), as well as carcinomas, have putative associations with EBV. The strength of these associations is quite variable. Pyothorax-associated lymphomas, occurring at sites of long-standing inflammation (e.g., tuberculosis), are quite strongly associated with EBV, with EBV identified in tumor cells in 70 to 100 percent of cases.[147] Lymphomatoid granulomatosis, seen predominantly in immunosuppressed patients, has the distinctive histopathologic finding of malignant cells surrounding blood vessels (angiocentricity). This malignancy is considered to have a pathogenesis similar to that of PTLD, with diminished T-cell surveillance probably allowing proliferation of EBV-transformed B cells.[414] Lymphomatoid granulomatosis occurs primarily in the lung but may be found at other sites including lymph nodes of children.[108] Plasmablastic lymphomas (extraordinarily rare in children) are unusual tumors typically found in the oral cavity of adult patients with AIDS, but they also sometimes are found in immunocompetent patients.[61] They have a strong association with EBV.

Several T-cell lymphomas are associated with EBV.[414] They include (1) angioblastic lymphadenopathy (or AILT)[521]; (2) enteropathy-type T-cell lymphoma (often associated with celiac disease)[535]; (3) extranodal nasal T/NK-cell lymphoma, an aggressive tumor involving the nasal or midline facial area, or other non-nasal, extranodal sites[237]; and (4) aggressive NK-cell leukemia, a rapidly fatal disease heralded by an acute symptom complex that includes fever and multiorgan system failure.[237]

Gastric carcinomas are more common in Asia, but they are extremely rare in children. In adults, two types of gastric tumors are noted to be associated with EBV. Gastric adenocarcinoma is a more common tumor, but EBV is found in only approximately 10 percent of tissues. In contrast, EBV can be found in the majority of tissues from patients with gastric tumors displaying an undifferentiated (lymphoepithelioma-like) histopathology.[270] Also in Asian populations, EBV is detectable within most lymphoepithelioma-like salivary gland tumors[448] and could play an etiologic role. Considerable ongoing debate continues regarding the etiologic relationship of EBV with breast cancer.[292]

EPSTEIN-BARR VIRUS AND HUMAN IMMUNODEFICIENCY VIRUS

Several studies have indicated that underlying HIV infection is responsible for abnormal responses to EBV infections. These findings probably are attributable to the relative ineffectiveness of T cells from patients with AIDS in controlling EBV-infected lymphocytes.[41] In HIV-infected adults, these unusual reactions include exaggerated antibody responses to certain EBV antigens, including VCA and EA,[408] and enhanced oropharyngeal shedding of EBV.[7,243] Oropharyngeal shedding of EBV occurs more commonly in younger HIV-infected children, and children whose HIV disease progressed more rapidly had a substantially higher rate of excretion.[243] In another study, EBV infection developed in HIV-infected children at an earlier age and was more likely to involve hepatosplenomegaly.[389] Whether EBV contributes directly to the progression of immune deficiency in these patients continues to be a matter of conjecture, although in vitro studies do indicate that some EBV proteins (e.g., LMP, BZLF1) are able to transactivate HIV-1.[186,329]

Studies clearly have revealed that certain lymphoproliferative and other diseases develop in HIV-infected patients at rates higher than those in healthy persons. These diseases include NHL, HD, body-cavity lymphoma, smooth muscle tumors, lymphocytic interstitial pneumonitis (LIP), and oral hairy leukoplakia.

NHL has remained the most common malignancy occurring in children with AIDS[39] and is an AIDS-defining condition.[84] In the present era of highly active antiretroviral therapy (HAART), NHL also has surpassed Kaposi sarcoma as the most common malignancy in adults.[114] In one pediatric study, approximately one third of NHL tumors contained EBV DNA.[339] Primary CNS lymphomas are extremely rare occurrences in healthy children, but they have accounted for 8 percent[339] to 23 percent[39] of NHLs in children with AIDS. Primary CNS lymphomas are linked very strongly to EBV, with the virus present in virtually every case.[324] NHL invariably occurs in patients with AIDS who have profound immune suppression (e.g., $CD4^+$ concentration <200 cells/μL). Pediatric patients with AIDS and NHL typically have systemic symptoms of fever and weight loss. Signs of extranodal disease include hepatosplenomegaly, abdominal distention, jaundice, bone marrow involvement, and, rarely, CNS symptoms.[338]

Although not an AIDS-defining condition, HD in adults with AIDS historically has occurred at rates 5 to 15 times higher than the general population. HD is an uncommon occurrence in children with AIDS, but it has been described.[339,403] HIV-infected patients, including children,[403] appear more likely than non–HIV-infected patients to present with disseminated disease, sometimes without obvious nodal involvement on physical examination.[396] In adults with AIDS, the incidence of HD has increased significantly in the HAART era.[114] Interestingly, HD incidence rates are higher in patients with AIDS and moderate compared with severe immune suppression, and the increased incidence is postulated possibly to be related to the inability of EBV-infected H-RS cells to recruit sufficient lymphocytes and histiocytes for their survival.[40]

Body cavity lymphoma (or primary effusion lymphoma) is a rare malignancy that occurs almost exclusively in adult patients with AIDS, but it has been reported in children.[296] Patients typically have immunoblastic lymphomatous effusions without solid tumors in body cavities such as the peritoneum or pleura.[358] More than 75 percent of these nonsolid tumors are associated with human herpesvirus 8; however, EBV also is identified frequently in tumor cells. EBV may play a cofactorial role in the pathogenesis of these unusual tumors.[414]

Leiomyosarcoma is an extremely rare occurrence in healthy patients,[540] but it is the second most common malignancy in children with AIDS[337] and is an AIDS-defining condition (Category B).[84] It also has developed in solid organ transplant recipients[298] and in patients with other types of immunodeficiency.[345] EBV may be responsible for the unusually high incidence of these smooth-muscle tumors found in children with AIDS.[244,339] Leiomyosarcoma tissues from patients with AIDS have high concentrations of EBV (CD21) receptors, contain clonal (or oligoclonal) EBV DNA, and express EBERs and EBNA-1.[244,339] Leiomyosarcoma may develop in any smooth muscle tissue in patients with AIDS, but more typically it is noted first in the gastrointestinal tract and lungs.

LIP is a lymphoproliferative disease that occurs primarily in children with AIDS.[16] In the era prior to HAART, the incidence of LIP was 12 percent among children enrolled in a large longi-

tudinal natural history study[161]; in the HAART era, this incidence has dropped to less than one case of LIP per 1000 person-years. Previous serologic and virologic evidence pointed to an association with EBV,[16,264,411,435] but the exact role that EBV plays in this lymphoid proliferation is unclear at present. LIP is associated with an improved prognosis for survival.[435] Radiographically, diffuse interstitial infiltrates are noted. The course of disease is variable: Many infections in infants are asymptomatic, and whereas some children remain stable for long periods, others may exhibit a slow, but relentless progression to chronic lung disease typified by tachypnea, cough, wheezing, and hypoxemia. Advanced disease is characterized by clubbing, wasting, cor pulmonale, and bronchiectasis.

Oral hairy leukoplakia is a nonmalignant squamous cell proliferation that develops in the oropharynx of patients with AIDS. Although a common occurrence in adults with AIDS, it occurs in less than 5 percent of HIV-infected children.[326] EBV DNA and virus replication can be detected within epithelial cells,[167,461] with defective variants possible.[148] Oral hairy leukoplakia lesions are manifested as nonremovable gray or white plaques on the lateral surface of the tongue; they often have vertical corrugations and a shaggy or "hairy" appearance when dry.[446]

DIAGNOSIS OF INFECTIOUS MONONUCLEOSIS

GENERAL LABORATORY FINDINGS

Patients with IM typically have an absolute lymphocytosis (>50% lymphocytes, with total leukocytes >5000/μL), prominent atypical lymphocytes (usually >10% of total leukocytes), and a positive test result for Paul-Bunnell heterophile antibodies (positive "differential heterophile"). The atypical lymphocytes observed in the blood of patients with mononucleosis (Fig. 172–6) predominantly consist of activated T lymphocytes responding to the B-cell infection.[385] Although often considered a hallmark of IM, atypical lymphocytes also may be observed in association with CMV infection, toxoplasmosis, measles, mumps, roseola, rubella, drug reactions, and other conditions.[72,534]

For a typical uncomplicated case of IM, establishing a specific diagnosis of EBV infection is unnecessary, with a complete blood count, differential, and heterophile antibody test being sufficient for diagnostic testing. These tests are uncommonly normal early in the course of disease and thus may need to be repeated during the first 3 to 4 weeks before diagnostic results are achieved. The clinician should be aware that very young (<4 years) patients with primary EBV infection frequently have a negative heterophile test.[477] Some recent studies suggest that a higher ratio (>0.35) of lymphocytes to white blood cell counts,[531] or the detection of lymphatic tissue with fibrinous membranes observed via nasopharyngeal endoscopy,[517] may distinguish between IM and acute bacterial tonsillitis.

Heterophile antibodies classically were measured as sheep erythrocyte agglutinins.[386] Beef, ox, and horse red blood cells (RBCs) also are agglutinated by the heterophile antibodies found in the serum of patients with IM, but these heterophile antibodies do not bind to guinea pig kidney antigen extracts. These properties of mononucleosis heterophile antibodies distinguish them from the naturally occurring Forssmann heterophile antibodies and from the heterophile antibodies found in serum sickness and other conditions. Thus, traditional tests for Paul-Bunnell heterophile antibodies involve absorption of the test serum with beef or ox RBCs (which remove Paul-Bunnell heterophile antibodies) and guinea pig extract (which does not remove them). Tests in current use (e.g., Mono-Test, Mono-Diff, Mono-Spot) typically use horse RBCs, which provide a more sensitive assay than do sheep erythrocytes. However, when horse erythrocyte agglutination tests are performed, the specificity of a positive result always should be confirmed by absorption of the serum with at least guinea pig kidney extract or, preferably, with both guinea pig kidney extract and beef (or ox) RBCs. Materials for the absorption steps are included in many, but not all, of the kits available commercially. Another heterophile antibody test, the beef (or ox) erythrocyte hemolysin assay, does not require absorption of the test sera but is somewhat less sensitive than is horse erythrocyte agglutination testing. Other tests[139,181,303,428] using purified forms of heterophile antigen do not seem to offer any significant advantage over the rapid slide test using horse erythrocyte agglutination.

Other laboratory tests in patients with severe mononucleosis syndromes or in those with atypical clinical manifestations may indicate involvement of major organs, but such involvement rarely is associated with severe complications (see the previous section "Complications of Infectious Mononucleosis"). These laboratory abnormalities include elevated transaminase levels, mild hemolytic anemia, and neutropenia.

EBV-specific laboratory testing should be reserved for patients with an EBV-suspected disease (1) lacking a heterophile antibody response; (2) exhibiting atypical, severe manifestations; or (3) associated with significant lymphoproliferative, oncogenic, or chronic findings. In most cases of EBV-associated IM episodes in immunocompetent patients, EBV-specific serology (i.e., antibody determination) is sufficient to affirm the viral-specific diagnosis. Isolation of virus from body secretions, fluids, and tissues (see "Virus Isolation," later) is labor intensive and not widely available. Quantitation or semiquantitation of EBV-specific viral load provides some measure of activity or putative influence of the virus in a variety of EBV-associated diseases. Other laboratory methods demonstrating high concentrations of actively replicating virus or latent antigens (such as immunohistochemical methods for antigen testing or quantitative PCR) may be more useful in associating EBV infection with disease, particularly in immunocompromised patients (Table 172–2).

EPSTEIN-BARR VIRUS ANTIBODIES

The viral-specific diagnosis of EBV-associated primary infections as IM in immunocompetent individuals (and commonly in immunocompromised patients) usually requires three types of antibody analysis on acute serum: IgG to EB VCA (VCA IgG), IgM to EB VCA (VCA IgM), and IgG to EBNA (EBNA IgG). (The EBNA complex is composed of six nuclear antigen or proteins, principally EBNA-1; the antibody response to the complex will herein

TABLE 172–2 Summary of Laboratory Tests for Epstein-Barr Virus (EBV)–Associated Diseases

Detection of	Test	Purpose
Antibodies	Heterophile antibody	Detect heterophile antibodies indicating infectious mononucleosis (more reliable in patients older than 4 yr of age)
	EBV antibodies	Measure antibody response to viral proteins in serum samples; distinguish acute from remote infection
EBV DNA and RNA	Southern blot	Assess clonality of lesions with respect to EBV DNA structure; distinguish latent from replicative infection
	In situ hybridization	
	RNA (EBERs)	Identify EBER transcripts in specific cell types within histologic lesions
	DNA	Identify EBV DNA in specific cell types within histologic lesions
	PCR	Detect and quantitate EBV DNA in blood or CSF to diagnose and monitor disease
EBV proteins	Immunohistochemistry	Identify EBV protein expression in specific cell types within histologic lesions; distinguish latent from replicative infection on the basis of expression profiles
EBV	Virus culture	Detect infectious virions or latently infected B cells; impractical for routine clinical use
	Electron microscopy	Identify whole virions representing replicative infection; impractical for routine clinical use

CSF, cerebrospinal fluid; EBER, EBV-encoded RNA.
Modified from Gulley, M. L.: Molecular diagnosis of Epstein-Barr virus–related diseases. J. Mol. Diagn. 3:1-10, 2001.

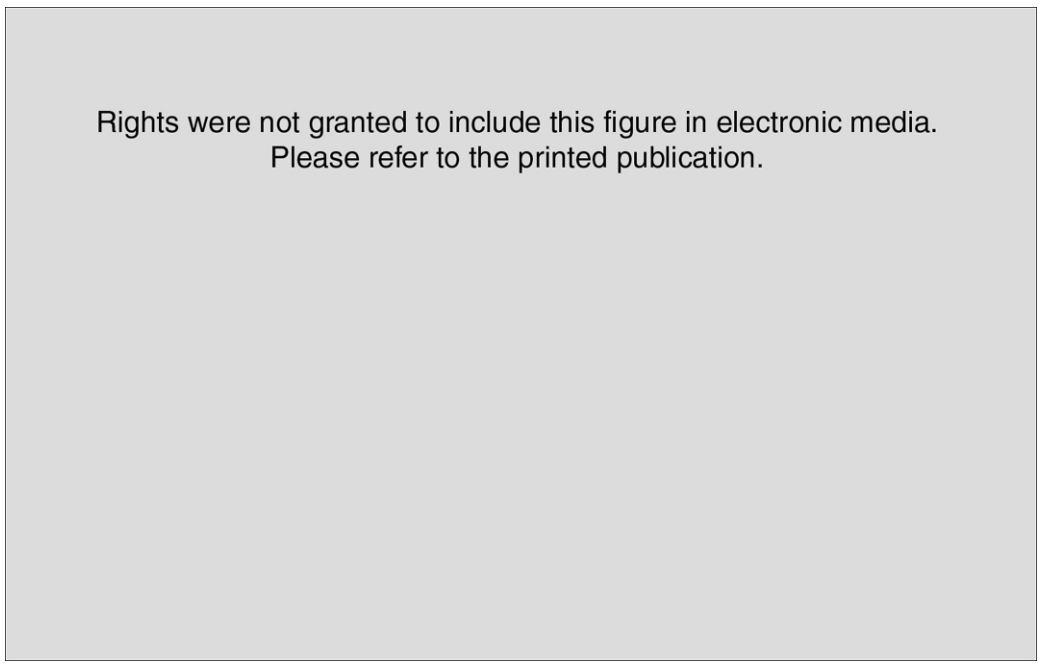

Figure 172–7 Schematic representation of the evolution of antibodies to various Epstein-Barr virus antigens in patients with infectious mononucleosis. The titers are geometric mean values expressed as reciprocals of the serum dilution. The minimal titer tested for viral capsid antigen (VCA) and early antigen (EA) antibodies was 1:10, and for Epstein-Barr nuclear antigen (EBNA) it was 1:2.5. The IgM response to capsid antigen was divided because of the significant differences noted according to age. *(From Jenson, H.B., Ench, Y., and Symaya, C.V.: Epstein-Barr virus.* In *Rose, N.R., de Macario, E.C., Folds, J.D., et al. [eds.]: Manual of Clinical Laboratory Immunology. 5th ed. Washington, D.C., American Society for Microbiology, 1997, pp. 634-643.)*

be referred to as IgG to EBNA, or EBNA IgG.) The three EBV antibodies can be detected by commercially available immunofluorescent techniques or by various enzyme immunoassays. The need to add the determination of IgG to EB early antigen, a serologic response commonly found early in the primary infection, usually is not necessary for IM-like episodes.

Evolution of the serologic response to EBV antigens after a prototypic EBV-associated IM episode is depicted in Figure 172–7. By the time clinical evaluation for IM and probably other forms of primary EBV infection is performed, an appreciable antibody response to EBV VCA has developed in most persons.[201,477] In the case of primary infections (e.g., IM), the initial serum sample often contains both IgG and IgM antibodies to VCA. Most children also have (or they will develop shortly) antibodies to the EA complex, which can be measured separately as antibodies to the restricted (R) or diffuse (D) components.[135,477] During the early phase of primary infection, most persons do not have detectable IgG antibodies to EBNA; a few have marginally detectable anti-EBNA titers. Thus, the serologic diagnosis of a recent or current primary EBV infection typically consists of a positive IgG and IgM anti-VCA response and negative anti-EBNA, with positive results in the anti-EA assay, if performed.

Following the acute primary EBV infection (reflected in IM), IgM antibodies to VCA typically disappear within 2 to 3 months, and IgG antibodies to EA usually disappear within 6 to 12 months after infection (see Fig. 172–7).[477] IgG anti-VCA and anti-EBNA

antibodies persist for life and are indicative of a typical, chronic virus-carrying state.[477] Some studies also have shown the persistence of anti-EA antibodies for several years after an acute EBV infection and the occasional appearance of anti-EA antibodies in healthy seropositive persons; however, the clinical or virologic importance of this finding is not clear. Heterophile antibodies may persist for months and sometimes for a year or more in persons who have recovered from IM; they remain detectable longer (usually more than a year) when the more sensitive horse erythrocyte agglutination and a quantitative method for determining the antibody response are used.

The antibody profile for an acute primary EBV infection, particularly that associated with an IM episode, is relatively clear in comparison with the variability of serologic or antibody profiles found in persons with other EBV-related disorders (Table 172–3). When a disease is not a consequence of primary infection but may be related to persistent or reactivated EBV infection (e.g., BL, NPC, some lymphomas of immunocompromised hosts, some chronic or atypical illnesses), the following serologic profile may be observed: positive IgG anti-VCA, often in high titer; usually negative IgM anti-VCA; often elevated anti-EA titer; and a positive anti-EBNA assay (though sometimes at low titer and occasionally undetectable).[187,202,203,246,406,472] Of note is that males with XLP frequently have no or low levels of EBV antibodies in response to EBV infection.[437]

Some studies[333,418,429] suggest that monitoring for decreases in anti-EBNA antibodies, or identification of increased immunologic mediators as IL-4 and soluble CD23 and increased circulating EBV (see later, "EBV Antigens"), may be useful in providing early serologic signs of EBV-associated tumor development in organ and bone marrow transplant recipients. Further, testing for IgA antibody responses to EBV antigens may be helpful in establishing a diagnosis and evaluating the response to therapy for nasopharyngeal carcinoma.[258]

Molecular cloning of subregions of the EBV genome into high-expression plasmid vectors can generate large amounts of pure proteins containing EBV-encoded polypeptide sequences for use in immunoblot and enzyme-linked immunosorbent assay (ELISA)-based tests.[52,63,126,207,333,418,429] These methods have extended the availability and utilization of EBV laboratory diagnosis and follow-up. There is a growing number of commercially available EBV serologic tests, particularly enzyme immunoassays.[51,206] Yet after several decades of use, immunofluorescent techniques still remain the "gold standard" in EBV-specific serologic testing because of their overall excellent specificity and sensitivity. However, they require more expensive equipment, time, effort, and experience in interpretation. ELISAs are important alternates for serologic testing because of their ease in performance and enhanced sensitivity. However, their specificity may be inferior to that of immunofluorescent techniques.[305] It is noteworthy that there is insufficient standardization of antigen preparation, antigen and substrate selection, and cross-comparability of serologic techniques and manufacturers involved with commercially available EBV serologic tests. Therefore, interpretations should be drawn carefully, particularly with serum of young children, an age group that has been less well evaluated.[304]

Improvements in standardization, as well as specificity and sensitivity, of commercially available serologic testing would benefit the laboratory diagnosis of primary EBV infections. Current EBV-specific serologic testing for nonprimary infections, particularly in immunocompromised patients, provides more limited diagnostic interpretations. The expanding capacity in the detection and quantitation of EBV viral load in body compartments and lesions (see next section) is of growing diagnostic importance in the latter circumstances.

EPSTEIN-BARR VIRUS NUCLEIC ACID (DNA OR RNA)

In young patients, EBV serologic testing may reveal false-positive results owing to retained maternal antibodies from the placenta, or from excessive blood product infusions, or from asymptomatic seroconversion. In patients treated with immunosuppressants, a false-negative serologic response to EBV antigens may occur. In such situations, demonstrating EBV nucleic acid in tissue sections or in blood may be necessary for diagnostic purposes.[8] Methods include Southern blotting, in situ hybridization, and detection of EBV DNA by PCR. Besides their utility as diagnostic aids, these tests also are useful for epidemiologic and pathogenetic purposes relevant to EBV infections.

Southern blot hybridization has been very useful in demonstrating the association of EBV with disease.[14,519] Although it is not as sensitive as PCR, Southern blotting has the advantage of providing additional information regarding the monoclonality of EBV-associated lesions, detection of lytic EBV processes, and recognition of viral integration into the genome.[166,175,179,407]

Because of their ubiquity in EBV-infected cells (up to 10^7 copies per cell), detection of EBERs in tissues by in situ RNA

TABLE 172–3 Correlation of Clinical Status and Characteristic Serologic Responses to Epstein-Barr Virus (EBV) Infection*

Clinical Status	Heterophile Antibodies (Quantiatitive Test)	Response EBV-Specific Antibodies				
		IgM-VCA	IgG-VCA	EA-D	EA-R	EBNA
Susceptible	—	—	—	—	—	—
Infectious mononucleosis

Burkitt lymphoma	—	—	+++/++++	–[§]	++/+++	+/++
Nasopharyngeal carcinoma	—	—	+++/++++	++/+++	–[¶]	++/+++

**Antibody response scale is none or negative (–), low (+), average (++), above average (+++), and very high (++++). A scale is used for application to various antibody tests and techniques. This table is modified from numerous studies. Individual responses outside the characteristic range may occur.*

[†]Children younger than 4 years of age may have weak or undetectable heterophile antibody responses as determined by qualitative rapid slide tests.

[‡]In some young children and in adults with asymptomatic seroconversion, the anti-EA response may be mainly to the EA-R component.

[§]A minority of individuals will have the anti-EA response mainly to the EA-D component.

[¶]A minority of individuals will have the anti-EA response mainly to the EA-R component.

hybridization has become a standard method for detecting and localizing latent EBV in tissues.[32,176,324] Probes for detection of EBERs ("riboprobes") are labeled conveniently by immunoperoxidase methods. Detection of EBV DNA by in situ hybridization also can be performed,[48] although DNA detection is less sensitive because of the lower copy numbers per cell in comparison with EBERs.

Amplification of EBV DNA by PCR has emerged as an important test for establishing the diagnosis and treatment of several EBV-associated diseases. In adult patients with AIDS and primary CNS lymphomas, detection of EBV DNA in CSF has high sensitivity and specificity in most studies.[18,75,91,324] PCR for EBV in CSF, possibly in combination with certain imaging studies,[18] may be sufficient for establishing the diagnosis of CNS lymphoma and could preclude performing brain biopsy, which can be associated with complications. On the other hand, lumbar puncture in patients with cerebral lesions also must be considered carefully because of the risk for cerebral herniation.

In stem cell and solid organ transplant recipients, quantitative PCR for EBV DNA in peripheral blood serves as a useful tool for the diagnosis of PTLD and as a marker during follow-up.[165,300,512,539] Levels of EBV DNA in blood typically are low in healthy control subjects, high in those with PTLD or other EBV-associated diseases, and intermediate in asymptomatic organ transplant patients. A high EBV load in the blood has a clear relationship with development of PTLD,[164] and with successful management, EBV DNA concentrations typically diminish to baseline levels.[164,222,427] Although negative predictive values for these tests are higher than 90 percent, positive predictive values are substantially lower. Healthy subjects with IM, asymptomatic seroconvertors, and transplant recipients with PTLD may have comparably high levels of EBV detected in the blood, thus making it difficult to separate out true PTLD from increases unassociated with PTLD. Detection of EBV within cellular specimens such as whole blood or PBMCs appears to be more reproducible and accurate than are tests measuring cell-free EBV in plasma or serum. Further studies clearly are necessary to establish quantitative laboratory standards for diagnosing and monitoring EBV-associated PTLD. Histopathology of a suspicious tumor site is much more informative and less controversial regarding diagnostic utility.

Quantitative PCR also may be useful for diagnosing and monitoring other EBV-associated malignancies, including NPC,[295] HD,[301] and NHL.[468] Larger studies are necessary to define better the role of EBV viral load testing in these diseases.

EPSTEIN-BARR VIRUS PROTEINS

Immunofluorescent techniques may be used to detect the presence of cells carrying EBV proteins in touch imprints of biopsy material or in frozen sections of cryopreserved tissue.[166,324,398,542] Most commonly, tissues are examined for VCA, EBNA-1, and LMP-1 proteins with the use of mouse monoclonal antibodies.

VIRUS ISOLATION

EBV from blood or oropharyngeal specimens (rarely, other specimens) can be isolated in tissue culture with a transformation assay.[246] For oropharyngeal specimens, the test requires incubation with fresh cord blood mononuclear cells for as long as 6 weeks. Transforming virus can be identified in peripheral blood by incubating mononuclear cells in the presence of cyclosporine (for inhibition of cytotoxic T cells, which can suppress the growth of EBV-positive B cells). An end-point dilution assay may be used to quantitate the amount of EBV within blood specimens.[425] Virus isolation tests are used primarily for research purposes and are not widely available.

ELECTRON MICROSCOPY

EBV virions also may be detected by electron microscopy, which has been used in patients with oral hairy leukoplakia,[236] NPC,[21] and other EBV-associated lesions. The ultrastructural features of EBV virions, however, are indistinguishable from those of other herpesviruses, and confirmatory tests usually are necessary. Electron microscopy generally is available only at larger research centers and, therefore, is impractical for routine diagnostic testing.

IMAGING STUDIES

Imaging studies seldom are necessary in typical patients with IM. In one study of patients hospitalized with IM, the most common findings on chest radiography were splenomegaly (47%), hilar adenopathy (13%), and interstitial infiltrates (5%).[289] Imaging studies are used more commonly for evaluation of EBV-associated neurologic disease, especially in immunocompromised patients. Children with EBV-associated encephalitis usually have normal neuroimaging results.[104] However, some patients may display diffuse swelling or patchy low-density lesions by CT, and magnetic resonance imaging (MRI) may reveal increased signal on T2-weighted images, as well as atrophy.[104,449] Contrast CT scans of primary cerebral lymphoma in patients with AIDS typically reveal large (2-6 mm) lesions occurring anywhere in the cerebrum with diffuse and homogeneous enhancement[486]; however, some overlap exists with findings observed in other diseases such as cerebral toxoplasmosis. Thallium 201 single-photon emission CT (SPECT), in conjunction with MRI and PCR testing of CSF for EBV DNA, may be useful in distinguishing CNS lymphomas from toxoplasmosis in adult patients with AIDS.[18]

DIFFERENTIAL DIAGNOSIS

Infectious Mononucleosis. EBV causes an estimated 80 to 95 percent of IM syndromes.[481] Numerous agents have been associated with heterophile-negative IM. CMV is responsible for most cases of heterophile-negative IM with typical clinical and hematologic findings.[220] Certain features of CMV mononucleosis may help distinguish it from EBV (e.g., less common sore throat and lymphadenopathy, less intense atypical lymphocytosis, and prominent splenomegaly), but these characteristics have considerable overlap with EBV-associated IM. Serologic testing consistent with acute CMV infection in the absence of characteristic EBV serologic findings confirms the diagnosis. The remainder of cases may be attributable to infection with *Toxoplasma gondii*, adenoviruses, rubella virus, and hepatitis A virus. Acute HIV syndrome also may mimic IM. However, in children with non-EBV IM, the etiology frequently remains elusive. In heterophile-negative children with mononucleosis and both the clinical and hematologic characteristics of the syndrome, the most likely known agents are EBV and CMV.

Other EBV-Associated Disorders. EBV-associated HLH may be confused with IM, systemic connective tissue disorders, septicemia, and certain hematologic malignancies.[231] EBV–associated CNS lymphomas in adults with AIDS are difficult to distinguish from cerebral toxoplasmosis on the basis of clinical findings and imaging studies. Historically, a negative *Toxoplasma gondii* serum antibody test eliminates toxoplasmosis, whereas a

positive test may necessitate a trial of antitoxoplasmic therapy. Response within a week suggests toxoplasmosis, but a nonresponse indicates the need for stereotactic brain biopsy to establish a diagnosis. Identification of EBV DNA in CSF by PCR may help confirm the diagnosis of lymphoma. Because PTLDs may affect the graft, a high EBV viral load in conjunction with graft abnormalities (e.g., elevated liver enzyme values in a liver transplant recipient) may be confused with graft rejection; histologic evaluation of biopsy tissue from the graft should differentiate PTLD from acute graft rejection.

TREATMENT: NONMALIGNANT EPSTEIN-BARR VIRUS–ASSOCIATED DISEASES

INFECTIOUS MONONUCLEOSIS

Supportive Care. Support, including rest, fluids, and antipyretics, is all that is required for uncomplicated IM. Although clinical trials and case reports dating back to the 1950s generally have demonstrated a beneficial effect of corticosteroids in reducing the symptoms associated with IM (e.g., fever, pharyngitis, lymphadenitis), current guidelines suggest that physicians use corticosteroids cautiously, if at all.[341] This decision is based partly on the unknown long-term consequences of such therapy, including a potential deleterious effect on the immune system. Nonetheless, small series and anecdotal reports suggest that some severely symptomatic patients (e.g., those with high fever, severe pharyngitis) may benefit from short-term courses of corticosteroids.[13,35,46] Though little controversy exists regarding the use of corticosteroids for patients with complicated illnesses (e.g., with stridor from massively enlarged tonsils or paratracheal adenopathy, or for those with hematologic or neurologic complications) (see "Complications of Infectious Mononucleosis" earlier), personal experience and clinical judgment largely dictate the use of corticosteroids in practice.[103,497] For example, in a recent report of patients with IM evaluated as outpatients and inpatients, 45 percent received systemic corticosteroids, with only a small proportion (less than 10%) of these patients having airway concerns.[497]

Antiviral Treatment. Numerous antiviral agents inhibit replication of EBV in vitro. Such agents include acyclovir, famciclovir, penciclovir, ganciclovir, and other nucleoside analogues.[26,81,94,158,317] None of these agents is capable of eliminating latent EBV present as episomes in infected cells. Five randomized, placebo-controlled trials of acyclovir (with or without corticosteroids) in adolescents and adults with IM demonstrated no beneficial effect in resolving the clinical signs and symptoms associated with illness, as well as no reduced rate of complications.[11,12,378,505,506] Moreover, a meta-analysis substantiated these findings.[502] Acyclovir did significantly reduce the rate of EBV shedding in the oropharynx, albeit temporarily.[502]

EPSTEIN-BARR VIRUS–ASSOCIATED MALIGNANCIES

Providing details regarding treatment of EBV-associated lymphoproliferative diseases, including lymphomas, is beyond the scope of this chapter. Pediatric oncologists must be involved in the care of children with these malignancies. A brief overview of treatment of the principal diseases is provided.

Post-transplant Lymphoproliferative Disease

The most effective therapy for PTLD in transplant recipients is reduction (or complete elimination)[228] of immunosuppression to allow more effective control of rampant EBV infection by the cell-mediated immune system. This measure halts progression of PTLD in approximately two thirds of pediatric solid organ transplant recipients developing polymorphic PTLD in the first year after undergoing transplantation.[165] Decisions concerning reduction of immunosuppression must be weighed against the risk of graft rejection, and careful follow-up with frequent EBV viral load measurements must be assured. If no improvement occurs after a trial of reduced immune suppression, then other therapeutic modalities must be considered singly or in combination.

Although antiviral agents (acyclovir, ganciclovir, valganciclovir) are used frequently for PTLD, based largely on an anecdotal report published in 1982,[188] no clinical trials have confirmed their efficacy. Because these agents treat lytic EBV infections, yet PTLD primarily involves latent virus, the consensus has been that these agents should have minimal impact on PTLD. However, this view has been challenged by recent reports in experimental animals, suggesting that the small proportion of lytically infected cells within these tumors may contribute to the growth of EBV-associated malignancies by enhancing angiogenesis and inducing paracrine B cell growth factors.[218,219]

There is now considerable experience with the use of rituximab, a chimeric monoclonal antibody directed at CD20, against PTLD.[155] Although no randomized controlled clinical trials have been conducted to date in children, data from cohort studies and case reports indicate that rituximab is safe and effective.[155] Most adverse events are mild or moderate and usually are related to the first infusion of the antibody. Despite a profound reduction of circulating B cells in peripheral blood, hypogammaglobulinemia is an uncommon occurrence with rituximab treatment (although more likely in young children), and patients are not at higher risk for development of infectious complications. Most centers now use rituximab as a primary therapeutic agent for PTLD, if reduction of immune suppression is unsuccessful.

IFN-α has induced complete remissions in some studies,[95,311] but relapses and graft rejections have occurred. Conventional NHL chemotherapy (CHOP regimen) consisting of cyclophosphamide, daunorubicin, vincristine, and prednisone may be associated with increased toxicity and mortality associated with infection when standard doses are used,[359,484] thus leading to investigation of low-dose CHOP regimens consisting of cyclophosphamide and prednisone.[30,172]

Experimental therapy using EBV-specific cytotoxic T-lymphocytes (CTLs) has been successful for PTLD in human stem cell transplant recipients,[430] but it is more complicated for solid organ transplant recipients with PTLD. In contrast to stem cell transplant recipients, whose EBV-associated PTLD tumors are derived from the donor, tumors in solid organ transplant recipients are invariably derived from the recipient. Therefore, EBV-specific CTLs must be prepared by ex vivo EBV transformation of either the recipient's B cells[269] or at least partially HLA-matched banked B cells.[190] Surgery and radiation therapy generally are reserved for local complications of tumors, including compression of an airway or gastrointestinal bleeding,[165] but they have been used more widely at some institutions.[82] A multifaceted approach, such as that used by Comoli and colleagues,[82] ultimately may yield the highest response rates against the most aggressive forms of PTLD.

B-Cell Lymphoma

Endemic (African) BLs, which are highly associated with EBV,[284] are treated primarily with cyclophosphamide-based chemotherapy.[285,549] Favorable responses were observed by Labrecque and coworkers[285] in patients with tumors expressing lytic genes. Treatment of sporadic BL also is based primarily on multiagent chemotherapy that includes cyclophosphamide.[314] Case reports have indicated positive responses to rituximab, and Children's

Oncology Group protocols now include rituximab as first-line treatment for BL.[155]

B-cell lymphomas in patients with AIDS are extremely difficult to treat, primarily because of the underlying severe host immune deficiency. Early regimens using standard chemotherapeutic regimens were largely failures, with survival rates lower than those of untreated patients; most patients died of opportunistic infections, drug toxicity, and resistant tumors. Alternative therapeutic strategies have improved outcomes for this malignancy, yet mortality rates remain substantial.[320] These strategies have included lower doses of standard drugs,[259] continuous infusion of chemotherapy,[465] hematopoietic growth factors,[291] novel immunotherapies (e.g., IL-2),[37] and adoptive immunotherapy,[523] as well as improved management of opportunistic infections and HIV. Recent in vitro data indicate the effectiveness of anti-NFκB treatments, including bortezomib[552] and certain statin drugs,[263] and the hope is that human studies will follow. An exciting new area of therapy is termed *lytic induction* and involves treatment of EBV-positive lymphoma cells with certain agents that induce a transition from latent to lytic infection, thus rendering them susceptible to antiviral therapy (e.g., ganciclovir).[92]

AIDS-related primary CNS lymphomas are extremely difficult to treat. Historically, palliative whole brain radiation therapy in conjunction with corticosteroids was used for treatment, but with disappointing survival rates of only a few months. Combined-modality therapy with whole brain radiation and chemotherapy has been investigated but generally also produces poor outcomes.[260] However, most studies were conducted prior to wide availability of HAART. A minority of healthier patients with AIDS may respond better to combined-modality regimens.[260] For patients not already on HAART, initiation of an appropriate regimen is recommended because case reports have described improvement.

Hodgkin Disease

Historically, children with HD were treated with high-dose radiation. However, high rates of skeletal growth inhibition and secondary malignancies were noted in survivors, so new trials using lower involved-field radiation in conjunction with multiagent chemotherapy were conducted. These trials form the basis for combination treatment regimens used currently in growing children.[226,402] Although the presence of EBV in tumor (more likely in mixed-cellularity types) currently plays no role in pretherapy staging, some studies suggest improved outcomes for patients with EBV-positive tumors.[351,357]

Nasopharyngeal Carcinoma

NPCs are sensitive to radiotherapy, as well as chemotherapy. Surgery usually is not an option because of the location of the primary tumor, although it may be necessary for persistent or recurrent lymph node disease. For early localized disease, radiotherapy generally is indicated, whereas combined-modality treatment (radiation and chemotherapy) may be considered for more advanced disease.[3] Children failing treatment have a high rate of distant metastases, principally to bone.[23,232]

NONMALIGNANT EPSTEIN-BARR VIRUS–ASSOCIATED DISEASES

XLP. In an effort to prevent fulminant IM, intravenous immunoglobulin is recommended for patients with XLP who display hypogammaglobulinemia, although such therapy is not fully effective.[150] Traditional therapy with antivirals and IFN-α has been very disappointing for fulminant IM, but recently reported success with rituximab (in combination with corticosteroids and other agents) has provided some enthusiasm.[348] Males with XLP also can develop lymphomas, which may respond to traditional chemotherapy regimens. Presently, the only definitive cure for XLP is allogeneic hematopoietic stem cell transplantation. Fifteen such transplants were reported between 1986 and 2005, with 10 survivors.[290] Younger age appears to be associated with improved survival in this limited population. Administration of rituximab may be considered as a bridge between the diagnosis of XLP and a transplantation.[290] Now that the gene defect in XLP has been identified, consideration may be given to a gene therapeutic approach.

HLH. Early studies using non–etoposide-containing regimens were largely unsuccessful in significantly reducing the high mortality rate associated with HLH.[19] Recently, chemotherapeutic regimens including etoposide (toxic to macrophages) have reduced the mortality rate significantly. Results of a standardized protocol (HLH-94) developed by the Histiocyte Society were published recently.[204] Agents in this protocol included etoposide and corticosteroids for initial therapy, followed by etoposide, corticosteroids, and cyclosporine A (continuation therapy), leading to bone marrow transplantation. A similar standardized protocol (HLH-2004), but including cyclosporine A at initiation, currently is being evaluated.[242] Little data are available on salvage therapy for those children unresponsive to the HLH-94 protocol, but Janka[242] has summarized anecdotal successes with standard NHL or HD treatment protocols, some monoclonal antibodies (e.g., anti-CD25 and anti-CD52), and one child treated with fludarabine (an antiviral agent) who survived until bone marrow transplantation could be performed.

CAEBV. Treatment modalities for chronic active EBV infection have varied widely because the rarity of this disease precludes performing proper clinical trials. Resolution of symptoms has been reported in case reports using antiviral drugs (e.g., acyclovir, ganciclovir),[234] etoposide,[375] immunomodulatory agents (e.g., corticosteroids, intravenous immune globulin, cytokines),[146,265] adoptive transfer of cytotoxic T cells,[442] or combinations thereof. For the most severe forms of disease, stem cell transplantation may be considered.[374]

HIV-Associated Diseases. Oral hairy leukoplakia generally does not require therapy because patients typically are asymptomatic and the lesions have no malignant potential. However, therapy may be required for troubling symptoms or cosmetic or psychological reasons. Small lesions may be treated topically,[352] but large lesions require systemic oral antiherpesviral agents.[381] Treatment strategies for LIP are not defined well. Supportive care, including supplemental oxygen, may be necessary. Suppression of HIV with effective antiretroviral agents also is logical to improve immune function and minimize the potential direct effect of HIV. Although no controlled studies have documented the value of antiretrovirals, benefit is suggested by the declining prevalence of LIP in children during the HAART era.[161] Corticosteroids also may be of benefit.[17,343] No controlled studies have evaluated antiherpesviral drugs (e.g., acyclovir) for LIP.

PROGNOSIS

The prognosis for healthy persons with IM is extremely good, with mortality considered a rare occurrence. In a series of 30 fatal cases of IM from the 1950s, Lukes and Cox[323] found splenic rupture, Guillain-Barré syndrome, hemorrhage, and secondary infection to be the most common causes of death. In Penman's[392] later study of 20 documented deaths, predominantly of young adults, the causes of death (in order of frequency) were neurologic complications, splenic rupture, secondary infection, hepatic

failure, and myocarditis. EBV-induced aplastic anemia, a rare but dreaded hematologic complication, now is thought to have a better prognosis for eventual recovery if the patient can be supported successfully through the acute stages.[31,293]

The prognosis for patients with EBV-associated lymphoproliferative diseases is variable and depends on the immunologic status of the patient and the type of lymphoproliferation. A registry of 161 males with XLP indicated a mortality rate of 70 percent by the age of 10 years, and 100 percent by the age of 40.[168] HLH has a greater than 90 percent fatality rate without treatment; most deaths are caused by hemorrhage, overwhelming infection, disseminated intravascular coagulation, or multiorgan failure.[71,241] Etoposide-based treatment has improved outcomes considerably.[242] The largest case series of CAEBV (from Japan), which includes 21 children age younger than 18 years old, reports a mortality rate of approximately 30 percent despite various forms of therapy.[272] Historically, PTLD that develops after solid organ transplantation has carried a relatively high mortality rate (50-80%), with higher mortality rates in bone marrow transplant recipients.[128] Presently, the mortality rate is probably much lower, but further time is necessary to assess the impact of newer therapeutic modalities. The prognosis for healthy children with NHL generally is good, with 5-year relative survival rates of 80 percent.[419] However, the prognosis for patients with AIDS and NHL is poor. In adults with AIDS, median survival is 2 to 4 months for CNS lymphomas (virtually all of which are EBV-associated), with only slightly longer survival noted in patients on HAART.[260] Childhood HD generally has a very good prognosis, with 5-year survival rates of approximately 95 percent.[419] Using combined modality therapy, children with NPC have long-term survival rates in the range of 70 to 90 percent.[24]

PREVENTION

EBV is shed regularly in saliva, and, therefore, infection control policies are difficult to develop. In addition, mechanisms for EBV transmission are not well understood, and EBV outbreaks occur rarely, if at all. For these reasons, no more than standard infection control precautions are recommended for patients hospitalized with EBV infections, including IM.[387] Although transfusion-associated EBV infection occurs rarely, persons with recent EBV infection of mononucleosis-like illnesses are urged to refrain from donating blood or organs.[387]

VACCINE

Efforts continue in the development of an EBV vaccine. Because of concern over the administration of a vaccine with unknown long-term consequences, including malignancy, most efforts have been focused on development of subunit EBV vaccines. A subunit vaccine containing the EBV gp350 protein has proved effective in preventing EBV infection in an experimental animal model.[117] A vaccinia virus-based gp350 vaccine has been evaluated in a small number of Chinese patients, eliciting good antibody responses and providing some protection from EBV infection;[174] however, these findings were not corroborated, and this vaccine was not developed further. A recombinant gp350 vaccine with adjuvant has been evaluated in Belgium, with phase I and phase II data published recently.[353,464a] The vaccine was immunogenic, safe, and well tolerated. Although vaccine recipients were not protected from EBV infection, symptoms of IM were reduced compared with controls.[417,464a] An effective vaccine could be considered for persons at high risk for developing EBV-associated lymphoproliferative disease and cancer, such as patients with AIDS, those with XLP, and organ transplant recipients. Before such a vaccine is approved, further research must be conducted to address issues such as protection against exogenous superinfection from wild type EBV strains.[514] Therapeutic vaccines, aimed primarily at latent antigens expressed in EBV-associated malignancies such as NPC, also are under investigation.[111,315]

PREVENTION OF POST-TRANSPLANT LYMPHOPROLIFERATIVE DISEASE

Strategies for preventing PTLD reflect many of those used for treatment of established PTLD (see earlier section on Treatment of PTLD). Children at high risk for developing PTLD (e.g., EBV seronegative children and infants age younger than 12 months) typically are given prophylactic anti-CMV IG and an antiviral following transplantation. A recent retrospective analysis of a large renal transplant database covering Europe and North America (96% adults) has suggested a beneficial effect of anti-CMV IG (e.g., Cytogam) in the prevention of B-cell lymphomas.[376]

After undergoing transplantation, these children should have frequent EBV viral load testing. If EBV viral loads persist above a significant cutoff value established by the laboratory, preemptive measures should be considered. Although real-time PCR tests are quite sensitive in predicting development of PTLD, they are not highly specific and lack standardization. Cutoff values for "significant" concentrations of EBV DNA vary from laboratory to laboratory. Once a decision is made that preemptive therapy is warranted, reduction or elimination of immunosuppressive medication(s) should be performed.

CHAPTER 173

Human Herpesviruses 6, 7, and 8

Charles Grose

Before 1986, five human herpesviruses (HHVs) were known. They were herpes simplex virus (HSV) type 1 (oral) and type 2 (genital), cytomegalovirus (CMV), varicella-zoster virus (VZV), and Epstein-Barr virus (EBV). The herpesviruses are important pathogens causing a variety of childhood diseases that are described in other chapters of this textbook. An inherent characteristic of herpesviruses is their ability to form a latent infection, in which the viral genome continues to reside within the host. When the virus reactivates, it often causes further symptoms and signs. Thus, herpesviruses cause a

spectrum of illnesses during the lifetime of the infected human host.

During the last decades of the 20th century, three novel herpesviruses were discovered. Two of them have been designated HHV-6 and HHV-7, whereas the newest member of the family has been called either Kaposi sarcoma–associated herpesvirus or HHV-8. These three viruses and the diseases they cause are described in this chapter.

HUMAN HERPESVIRUSES 6 AND 7

One unexpected consequence of the epidemic of acquired immunodeficiency syndrome (AIDS) was the discovery of a new human DNA virus. The virus was isolated first from the white blood cells of six patients with lymphoproliferative disorders, two of whom had AIDS.[27] Further electron-microscopic characterization of the virus demonstrated properties of a herpesvirus, including (1) an icosahedral capsid composed of 162 capsomers covered by a lipid membrane and (2) an enveloped particle with a diameter of 200 nm (Fig. 173–1). Because the virus was isolated originally from B lymphocytes, the agent was designated human B-lymphotropic virus. However, this apparent tropism for B lymphocytes was not confirmed by other investigators, who found that the virus preferentially infected $CD4^+$ T lymphocytes and not B lymphocytes.[20,30] Thus, the initial designation of human B-lymphotropic virus was changed to HHV-6.

The DNA sequence and the deduced amino acid sequence of the HHV-6 genome have been published.[6] Calculation of the percentage of amino acid identity shared by HHV-6 proteins with those in other herpesviruses revealed that HHV-6 proteins most closely resembled those of human CMV. The strains of HHV-6 have been divided into group A and group B. The HHV-6 isolates related to prototype strain U1102 have been called group A, whereas those related to strain Z29 have been designated group B. In 1990, while searching for additional strains of HHV-6, Frenkel and coworkers[14] isolated a new T-lymphotropic herpesvirus that was designated HHV-7. HHV-7 is related closely at a genetic level to HHV-6 and to a lesser degree to CMV.[6] All three of these agents are subclassified as beta-herpesviruses.

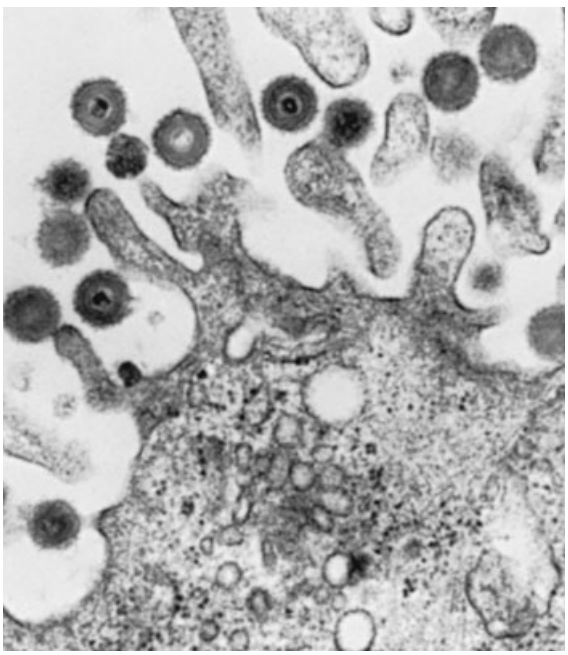

Figure 173–1 Electron micrograph of cultured mononuclear cells infected with HHV-6. Several enveloped viral particles are visible in the extracellular area. *(Courtesy of Dr. Y. Asano.)*

Most persons contract their primary HHV-6 infection before reaching the age of 5 years.[3] In the United States, primary HHV-6 infection occurred in 40 percent of children by the time they reached 12 months of age and in 77 percent by the age of 24 months.[41] In these young children, group B strains of HHV-6 appear to be a major cause of the disease roseola (exanthem subitum). Roseola is discussed at greater length in Chapter 65. Children also may contract a primary HHV-6 infection without manifesting a rash. After acute infection, HHV-6 forms a latent infection, probably in T lymphocytes. Endogenous virus reactivates in adults with immunosuppressive disorders, such as AIDS, although reactivation has not been associated with a specific disease entity. Seronegative recipients of organ transplants may acquire a primary HHV-6 infection from latent virus in the donor organ. In a small number of infants, acute HHV-7 infection appears to cause a roseola illness much like that of acute HHV-6 infection.[17]

DISEASES CAUSED BY HHV-6 AND HHV-7

Studies in Japan first delineated the nature of the illness associated with acute HHV-6 infection in young children.[37] HHV-6 was cultured from the peripheral blood leukocytes of four infants with roseola (exanthem subitum); each subject was 6 months old and had an acute febrile illness followed by a concurrent fall in temperature and the onset of a rash. The blood samples were collected during the febrile stage of the disease. In a subsequent paper by the same group, two infants (6 and 7 months of age) were described who developed HHV-6 infection *without* a rash.[29] Both infants had been seen by physicians because of a 2- to 3-day history of high temperature (38.5° C to 39.5° C). The only abnormal clinical finding was congestion of the throat. In both cases, the temperature rapidly returned to normal around day 3 of illness, but no rash was ever observed. Cultures of peripheral blood cells from both infants were positive for HHV-6.[29] Further seroprevalence studies performed in Japan showed that most Japanese children (86%) contracted HHV-6 infection by the time they were 24 months of age.[38] Thereafter, the increase in seropositivity among the childhood populations was small. These statistics suggest that HHV-6 infection goes unrecognized in most children.

Primary HHV-6 infection has been implicated in a few cases of severe hepatitis. The first case was that of a 21-year-old patient with cystic fibrosis who received a liver transplant.[34] The recipient lacked antibodies to HHV-6, and the organ donor was seropositive. Two weeks after undergoing transplantation, the recipient developed fever and grand mal seizures; her hepatic function deteriorated. HHV-6 was cultured from her peripheral blood cells, and herpesviral particles were seen by electron-microscopic examination of a liver biopsy specimen. The patient also developed antibodies to HHV-6 by day 16 after transplantation. The apparent source of infection was the donor liver, from which HHV-6 presumably was reactivated after transplantation. She gradually recovered her hepatic function during the course of several weeks.

A fatal case of fulminant HHV-6 hepatitis has been reported in a 3-month-old boy.[4] The infant was admitted to a hospital because of fever, jaundice, convulsions, and loss of consciousness. His serum bilirubin concentration, liver transaminases, and blood ammonia level were elevated markedly. Within 7 days, he became comatose and died. As part of the diagnostic evaluation, HHV-6 was cultured from his mononuclear cells. Furthermore, HHV-6 DNA was detected in biopsy samples of liver and brain, which were obtained immediately after death. A serum sample drawn

TABLE 173–1 Selected Features in Roseola Associated with Infection in Children

Clinical Findings	%
Temperature above 37.5° C	98
Rash	98
Diarrhea	68
Nagayama spots	65
Cervical adenopathy	31
Edematous eyelids	30
Bulging fontanelle	26
Prodromal symptoms	14
Convulsions	8
Cough	0

Data modified from Asano, Y., and Grose, C.: Human herpesvirus type 6 infections. In *Glaser, R., and Jones, J. (eds.): Herpesvirus Infections. New York, Marcel Dekker, 1994, pp. 227-244.*

before death showed reactivity to HHV-6. On the other hand, the child had no serologic evidence of acute infection with hepatitis A, B, or C virus or with any other HHV.

In a large retrospective review of roseola in association with acute HHV-6 infection, the signs and symptoms were tabulated.[3] The study population included 94 boys and 82 girls, who ranged in age from 3 weeks to 18 months (Table 173–1). As would be predicted, the two most common clinical findings were fever and rash. The temperature often rose to 39° C, and fever persisted for 2 to 4 days. The rash usually appeared when the fever lessened; the rash was papular in 54 percent, macular in 40 percent, and maculopapular in the remainder of the children. The exanthem typically persisted for 3 to 4 days and was not followed by desquamation. Diarrhea was a surprisingly frequent occurrence, but it was not severe. An enanthem called *Nagayama spots* in Japan consisted of papules on the mucosa of the soft palate and uvula. Of the total study group, 8 percent developed febrile seizures. More severe central nervous system (CNS) complications have been documented in children not enrolled in this study. A few children with HHV-6 encephalitis have had abnormal electroencephalographic recordings. Some children with encephalitis have had permanent neurologic sequelae. In the United States in particular, acute HHV-6 infection also appears to be associated with concurrent acute otitis media.[24]

Reactivation of previous HHV-6 infection has been demonstrated in some healthy children and adults who contracted a second herpes-type infection, such as primary EBV infection (infectious mononucleosis) or primary CMV infection.[3] A similar serologic survey was performed in 10 renal transplant recipients who initially were HHV-6 seropositive.[3] After transplantation, all 10 showed greater than fourfold rises in antibody to HHV-6. Only two of the ten developed a febrile illness, and both of them also had primary CMV infection. More recent evidence suggests that HHV-6 infection in combination with CMV infection may worsen post-transplantation pneumonitis previously thought to be associated solely with CMV infection. HHV-6 does not appear to be related causally to Kawasaki disease,[22] nor does HHV-6 infection appear to alter the course of human immunodeficiency virus (HIV) infection.[28]

Whether HHV-7 causes a distinct illness has been the subject of many medical investigations since 1990. In general, HHV-7 antibody is acquired by mid-childhood, but there appears to be no corresponding sentinel illness. However, in two infants with roseola, both isolation of HHV-7 and seroconversion to HHV-7 were documented; in addition, another five children with roseola were found to have undergone seroconversion to HHV-7.[32] HHV-7 also has been isolated from one infant with an acute febrile illness.[25] Therefore, in a small number of young children, acute HHV-7 infection may be associated with fever and sometimes a roseola-like rash.

Finally, congenital infections also can occur in pregnant women already infected with HHV-6. In a survey of 5638 cord blood samples, HHV-6 DNA was detected in 57 samples (1%), but the congenital infections did not cause an identifiable disease in the newborn.[16] In contrast to HHV-6, HHV-7 DNA was not detected in any cord blood sample.

NEUROLOGIC COMPLICATIONS

In the preceding paragraphs, CNS symptoms were mentioned briefly. In a large series of clinical studies performed in Japan, seizures were a common feature of acute HHV-6 infection.[3,40] In one series of 105 young children with acute febrile convulsions, 21 had evidence of primary HHV-6 infection, as assayed by either isolation of virus from blood or seroconversion of HHV-6 antibodies. When the age of the patient was assessed, HHV-6 infection was found in 13 of 23 seizure patients younger than 1 year; thus, the seizure group with HHV-6 infection was significantly younger than the seizure group without HHV-6 infection. In addition, the frequency of clustering seizures, long-lasting seizures, partial seizures, and postictal paralysis in children having their first febrile convulsion episode was significantly higher in those with primary HHV-6 infection than in those without HHV-6 infection. One child with fatal acute necrotizing encephalitis and concurrent HHV-6 infection also has been described.[21]

In studies from Japan, assays for HHV-6 and HHV-7 DNA were performed on cerebrospinal fluid samples from 43 children with CNS symptoms.[39] All children had symptoms compatible with aseptic meningitis. HHV-6 DNA was detected in the peripheral blood cells of 15 and in the cerebrospinal fluid of 7 children; all were HHV-6 variant B. HHV-7 DNA was detected in the peripheral blood cells of 28 and in the cerebrospinal fluid of 6 patients. Thus, the clinical study demonstrated that both HHV-6 and HHV-7 can invade the CNS or, alternatively, frequently reactivate within the CNS during childhood neurologic disease. The results from Japan have been confirmed in a similar large analysis of young children with seizures in Britain and Ireland.[36] Among 156 children hospitalized with febrile seizures, 26 (17%) were associated with acute HHV-6 or HHV-7 infection. The median age for hospitalization in the HHV-6 group was 53 weeks, and the median age for the HHV-7 group was 60 weeks. In one study in the United States, however, an association between acute HHV-6 infection and seizures was not found.[41]

PATHOGENESIS OF HHV-6 AND HHV-7 INFECTION

The pathogenesis of HHV-6 infection certainly includes a viremia while the child is asymptomatic; the total duration of the incubation period is not well defined but may be approximately 10 days. The prodrome, which signals the end of the incubation period, includes 2 to 4 days of fever, which precedes the onset of the rash.[3,26] During this period, virtually 100 percent of peripheral blood cell cultures are positive for HHV-6. By day 3 or 4, when the rash first appears, the viremia is abating. Between 5 and 7 days after the onset of the fever (or 2 to 4 days after appearance of exanthem), viremia persists in less than 20 percent of the children. Viremia is absent later in convalescence, when the antibody response is detectable. HHV-6 occasionally reactivates from latency throughout the lifetime of an infected human, but usually no apparent illness is present.[7]

The mothers of infants with HHV-6 infection have been studied to determine whether they are the source of the infectious agent.[16] Because most mothers are seropositive, the possibility

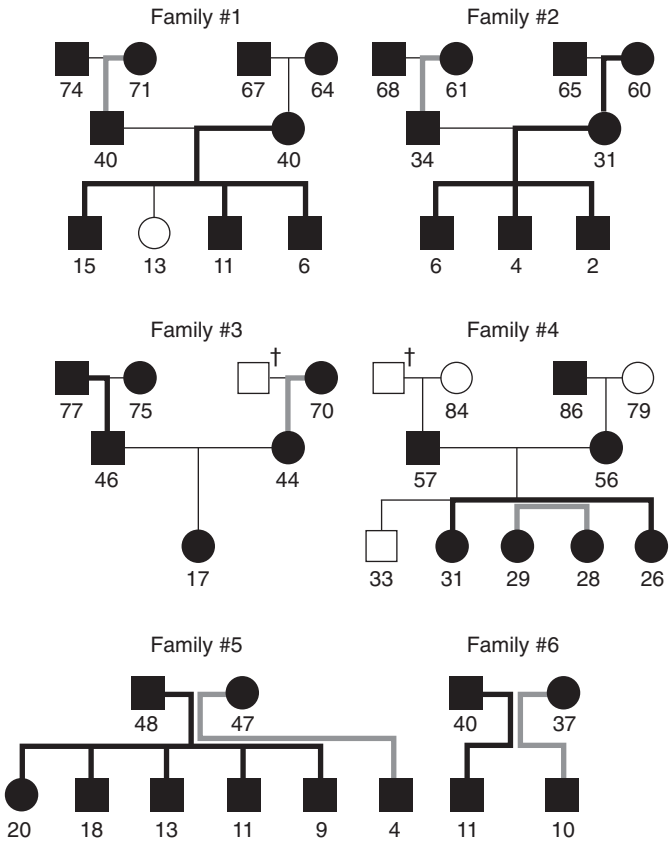

Figure 173–2 Pedigrees of six families with HHV-7 infection. All families resided in Okayama, Japan. Males and females are indicated as boxes and circles, respectively. Persons from whom HHV-7 was isolated are shaded. A person who was already deceased is marked†. Members who have similar HHV-7 DNA restriction patterns are connected with bold lines. Numbers under the boxes and circles indicate ages. *(From Takahashi, Y., Yamada, M., Nakamura, J., et al.: Transmission of human herpesvirus 7 through multigenerational families in the same household. Pediatr. Infect. Dis. J. 16:975-978, 1997.)*

exists that HHV-6 infection could reactivate in the mother, who would then transmit the infection to her child, possibly through exchange of saliva. Cultures of peripheral blood mononuclear cells and saliva specimens of 14 mothers of infected infants failed to yield conclusive results. However, in another study, HHV-6 DNA was detected in the vaginal secretions of young adult women, so perinatal HHV-6 transmission remains a possibility. Older siblings are another possible source of infection within a household.[41]

In contrast with HHV-6, HHV-7 seropositivity occurs in children but often after the first 2 years of life. HHV-7 transmission has been investigated in large multigenerational Japanese families living in the same household.[31] The results indicated that HHV-7 is transmitted gradually from older generation to younger generation (Fig. 173–2). Transmission often occurs in children before the child enters a traditional primary school at the age of 6 years. Either parent or presumably an older sibling can transmit the virus. A reasonable explanation for this pattern of transmission is repeated exchange of infectious saliva among family members living in the same household during the course of many years.

DIAGNOSIS

Infection with HHV-6 can be diagnosed by several means, including (1) measurement of antibody, (2) isolation of virus, (3) detection of viral antigen, and (4) detection of viral DNA. The first method (i.e., the traditional approach for diagnosis of virus infection) usually requires acute and convalescent serum samples for determination of a fourfold or greater rise in titer of virus-specific IgG antibody. The finding of IgM specific for HHV-6 in a single serum sample also would indicate an acute infection in a young child. The titer of IgG antibody rises during reactivation of the virus in adults, but whether IgM antibody to HHV-6 appears regularly at the same time is not known. HHV-6 antibodies usually have been measured by an indirect immunofluorescence method, although neutralization tests also have been performed.[3,4,35]

Isolation of HHV-6 was the original technique for identification of this herpesvirus.[27] The method is more difficult to perform than are those methods commonly used for most herpesviruses (e.g., HSV, CMV, VZV) but is similar to that required for isolation of another herpesvirus, EBV. HHV-6 usually is isolated in a cell substrate consisting of mononuclear cells obtained from cord blood of a newborn infant. The source of virus in the patient also is the peripheral blood mononuclear cell population.[35]

Viral genome can be detected in infected tissues by DNA hybridization techniques.[35] Viral DNA also can be detected in tissue samples by polymerase chain reaction (PCR). In one fatal case of HHV-6 infection,[4] DNA was extracted from postmortem liver and brain samples and amplified by the PCR test. On direct gel electrophoresis, HHV-6–specific DNA was detected in both the liver and the brain specimens. These studies indicate that HHV-6 infection can be diagnosed by both traditional and newer molecular techniques. Likewise, HHV-7 infection usually is diagnosed by isolation of virus or detection of viral DNA by PCR testing in samples from patients.

TREATMENT OF HHV-6 INFECTION

In most instances of HHV-6 infection in healthy children, treatment with an antiviral medication is not indicated. Recovery is complete within a few days after onset of the rash, and sequelae rarely occur. However, HHV-6 disease in immunocompromised persons may be more persistent or severe (e.g., encephalitis). Several groups have analyzed the in vitro sensitivity of HHV-6 to four antiviral drugs: acyclovir, ganciclovir, phosphonoformic acid, and cidofovir.[1,3] All four compounds have been used in treatment of other herpesvirus infections. Multiplication of HHV-6 in cell culture is inhibited readily by ganciclovir at a concentration of 2 to 10 μg/mL, easily achievable levels in humans. This effect is of interest because ganciclovir inhibits human CMV to a similar degree; as mentioned earlier, CMV and HHV-6 are related closely at a genomic level. Phosphonoformic acid (foscarnet) at a concentration of 6 μg/mL also is effective against HHV-6 infection. On the other hand, HHV-6 is affected by acyclovir only at concentrations of 50 μg/mL, considerably higher levels than those required for treatment of HSV-1, HSV-2, and VZV infections and probably toxic in humans. Likewise, cidofovir is more toxic than is ganciclovir and would not be recommended for HHV-6 treatment. At present, none of these antiviral drugs has been approved specifically for treatment of HHV-6 infections.

KAPOSI SARCOMA HERPESVIRUS (HUMAN HERPESVIRUS 8)

Yet another consequence of the HIV epidemic in the 1980s was the appearance of Kaposi sarcoma in many people with AIDS. The increase in Kaposi sarcoma was especially puzzling because the tumor occurred more frequently in people who acquired HIV by sexual transmission rather than by infusion of infected blood

products, such as factor VIII in hemophiliac patients. The question often arose whether a second infectious agent was involved in the etiology of Kaposi sarcoma. The answer to that question was provided by a report published in late 1994. The authors announced the identification of a previously unknown herpesvirus-like DNA sequence collected from patients with AIDS in New York.[9] The viral DNA was called *Kaposi sarcoma–associated herpesvirus* (KSHV). Other virologists prefer that the agent be called *human herpesvirus 8* (HHV-8).

DISEASES CAUSED BY KAPOSI SARCOMA–ASSOCIATED HERPESVIRUS

The authors of the original KSHV report were investigating patients with Kaposi sarcoma. They discovered the herpesvirus-like DNA sequences by using a combination of genetic techniques, including amplification of DNA by PCR and subsequent representational difference analysis.[9] Thereby, they were able to identify and to characterize unique DNA sequences in Kaposi sarcoma that were absent from nonmalignant tissue from the same patient. One such sequence showed close homology to regions of the genome of *Herpesvirus saimiri*, a simian herpesvirus, and to a lesser degree to EBV, the agent that causes infectious mononucleosis. A second DNA fragment was homologous to another region in the *H. saimiri* genome. In their study, the authors located one or both of these herpesvirus-like DNA sequences in 20 of 27 different samples of Kaposi sarcoma tissue. The investigators concluded that they had discovered DNA of a previously unknown herpesvirus within Kaposi sarcoma tissues.

Their results were confirmed quickly by other groups. In one study from California, investigators detected identical viral sequences in 13 of 13 biopsy specimens of Kaposi sarcoma from patients with AIDS.[2] This study also found the same sequence in the peripheral blood cells collected from 10 of the 13 patients but not in the blood samples of 20 patients with no history of Kaposi sarcoma. A third study from France found the herpesvirus-like DNA in biopsy specimens from five patients with Mediterranean-type Kaposi sarcoma; all five patients were HIV seronegative.[11] In subsequent studies, HHV-8 DNA has been detected in most Kaposi sarcomas (classic) in HIV-seronegative individuals, often men residing in the Mediterranean area.

The authors of the original KSHV report subsequently found the herpesvirus-like DNA sequences in body cavity–based lymphomas from patients with AIDS.[8] HHV-8 DNA also has been found in the B-cell lymphoproliferative disorder known as *multicentric Castleman disease*.[5] Of equal importance, KSHV sequences were not found in several other lymphomas or leukemias (e.g., small-lymphocyte lymphoma, monocytoid B-cell lymphoma, follicular lymphoma, diffuse large-cell lymphoma, Burkitt lymphoma, lymphoblastic lymphoma, anaplastic large-cell lymphoma, multiple myeloma, hairy-cell leukemia, acute lymphoblastic leukemia, or cutaneous T-cell lymphoma).

TRANSMISSION OF HHV-8 AMONG CHILDREN

One of the most perplexing aspects of HHV-8 epidemiology is the mode of transmission. That the seroprevalence is high among a population of adult men who have sex with men is well known.[23] Yet, the question remains whether larger segments of the population are infected on a worldwide basis and, in particular, whether children are infected. To answer this question, several HHV-8 seroepidemiology studies were surveyed. Two studies provide partial answers to the question of childhood infection.

The first study was performed in a village in French Guiana, South America, among 1337 individuals of African origin.[24] They ranged in age from 2 to 91 years. The serologic data indicated that HHV-8 seropositivity was strongly age dependent. Among 14 children aged 2 to 14 years, 3 of 146 were positive; aged 5 to 9 years, 14 of 278 were positive; aged 10 to 14 years, 31 of 232 were positive; aged 15 to 19 years, 24 of 149 were positive; aged 20 to 29 years, 38 of 236 were positive; aged 30 to 39 years, 16 of 120 were positive; aged 40 to 49 years, 19 of 70 were positive; and older than 50 years, 32 of 106 were positive. These seroprevalence data clearly show a gradual acquisition of infection during early childhood, with a stepwise increment from approximately 5 to 12 percent at age 10 years.

HIV infection did not play a role in the likelihood of transmission because HIV infection is not a common occurrence in this village. Instead, extensive analyses of intrafamilial relationships demonstrated a highly significant familial correlation in HHV-8 seropositivity between mother and child (especially when children were younger than 10 years) and between siblings. The correlation was highest when the siblings had an age difference of less than 5 years. Of interest, a similarity in transmission appears to exist between HHV-8 and HHV-7, when HHV-7 was studied in multigenerational Japanese households (see Fig. 173–2).

A second large HHV-8 seroepidemiology analysis was performed in Israel.[10] The incidence of classic Kaposi sarcoma in Israel is among the highest in the developed world. Because of this statistic, the investigators undertook a study to ascertain the HHV-8 seroprevalence in Israel and also to investigate HHV-8 intrafamilial transmission. The study population included 1648 healthy blood donors determined to be positive for hepatitis B antigen and 2403 family members.

The seroprevalence data showed that 9 percent of children aged 2 to 14 years and 9 percent of adolescents and young adults aged 15 to 24 years were HHV-8 seropositive. Seroprevalence in older adults ranged from 12 to 18 percent. HHV-8 positivity was more likely to occur in children when at least one of the parents was positive compared with children with neither parent positive. The most important predictor of a child's HHV-8 seropositivity status was maternal seropositivity.

These two large seroepidemiologic studies demonstrate that HHV-8 is spread by nonsexual means in children in many countries around the world. In these same countries, HHV-8 seropositivity rises throughout adolescence and adulthood, regardless of HIV infection status.[33] However, in North America and western Europe, the seropositivity rate among HIV-seronegative adults is considered to be low, approximately 3 to 5 percent. The reasons for these differences between continents are not resolved. Nonetheless, the most reasonable hypothesis for transmission is exchange of saliva within family groups. Studies have proved that the virus is present in saliva, in particular in epithelial cells contained within saliva.[12] An alternative mode of infection, described next, is transmission by blood transfusion.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

Hemophagocytic lymphohistiocytosis (HLH) is a rare and sometimes fatal disorder of immune regulation, often associated with mutations in the perforin gene. Even carriers of the mutated gene may require an acute infection to trigger HLH. HHV-8 is one of the triggers. HLH in association with HHV-8 infection has occurred in adults with severe HIV infection or with a recent kidney transplant.[13,19]

HLH has been diagnosed in two identical siblings from Iowa during the first 6 months of life.[15] The siblings were born prematurely and spent several months in intensive care. Both siblings had mutations in the perforin gene. Both siblings had HHV-8 infection. Because the mother of the two was negative for HHV-8 infection, one possible route of transmission was a blood transfusion given while they were in the nursery. In fact, in a large

study in East Africa, blood transfusions were shown to transmit HHV-8 infection.[18] Therefore, children who have had multiple blood transfusions may be at risk for acquiring HHV-8 infection.[11]

DIAGNOSIS AND TREATMENT OF HHV-8 INFECTION

Diagnosis of prior HHV-8 infection can be made by serology. Diagnosis of acute HHV-8 infection requires a scraping of cells from the mouth for testing by PCR amplification of HHV-8–specific DNA.[9,11,12] Mononuclear blood cells also may be tested by HHV-8–specific PCR. These PCR protocols are becoming more widely available.

Treatment is not necessary in most healthy hosts because the virus quickly enters latency after the primary infection. No disease has been associated with a latent infection in children, except those with defects in the perforin gene. However, acute HHV-8 infection in recent transplant recipients or HIV-seropositive children could be an indication for treatment.[13,19] Some of the same antiviral drugs described for HHV-6 treatment also inhibit HHV-8 replication (e.g., ganciclovir), but currently there are too few clinical data on which to base a standard regimen, so treatment would need to be individualized for each infected patient.

CHAPTER 174

Varicella-Zoster Virus

Anne A. Gershon

Varicella-zoster virus (VZV) causes two diseases, varicella (chickenpox) and zoster (shingles). Varicella, the primary infection, usually occurs in childhood and is manifested as a pruritic rash accompanied by fever and other systemic signs and symptoms that usually are of a mild to moderate nature. Zoster is primarily a disease of adults, although it can occur in children. It develops in a setting of low cell-mediated immunity to VZV, such as occurs with normal aging or after disease or the use of various therapies, such as steroids, cancer chemotherapy, organ transplantation, and irradiation. During varicella, VZV establishes a latent infection in sensory nerve ganglia; zoster results when latent VZV reactivates and returns from the ganglion to infect the skin and produce a unilateral dermatomal eruption.

The origin of the nomenclature "chickenpox" is uncertain, but it may have come from the French *pois chiche* (chickpea) or from the domestic fowl (in Old English, *cicen*, and in Middle High German, *kuchen*).[39] *Herpes* is the Greek word meaning "to creep," and *zoster* comes from the Greek and Latin word meaning "girdle" or "belt."

THE ORGANISM

VZV is an alpha-herpesvirus. It has a DNA core surrounded by a nucleocapsid composed of 162 hexagonal capsomers that form an icosahedron with a diameter of approximately 100 nm. A tegument surrounds this structure, which in turn is surrounded by a lipid-containing envelope. Enveloped virions have a diameter of approximately 200 nm.[46]

The genome of VZV has been sequenced; it contains 71 open-reading frames.[47] The linear, double-stranded DNA consists of a long unique segment, U_L, and a short unique sequence, U_S, flanked by internal and terminal repeats.[48,51,173] The genome of the Oka vaccine strain also has been sequenced, and the molecular basis for attenuation of the strain is being investigated.[4,79,124]

At least six open-reading frames (genes 4, 21, 29, 62, 63, and 66) have been detected in human sensory ganglia during latent VZV infection. VZV is synthesized by an orderly cascade of gene expression consisting of immediate-early (IE), early (E), and, finally, late (L) lytic genes that encode structural proteins. The genes detectable during latent infection are IE and E genes; L genes are not expressed. One hypothesis is that cellular immunity to VZV normally can control early replication of the virus so that productive or lytic infection does not occur.[34,41-43,92,106,107,131,132,133]

During productive infection, VZV synthesizes[41-44] more than 30 polypeptides; the function of most of these polypeptides remains unknown, but some are structural and others are nonstructural and presumably have regulatory action. VZV synthesizes at least seven glycoproteins (g) termed gB, gC, gE, gH, gI, gK, and gL.[45,82,109] These glycoproteins correspond somewhat to those of herpes simplex virus (HSV), but unlike HSV, VZV has no equivalent of gD, which is the major glycoprotein of HSV. The major glycoprotein of VZV is gE. The VZV glycoproteins not only provide structures for the virion but also play roles in infectivity, such as mediating adhesion and promoting entry of VZV from an infected cell into another uninfected cell. The glycoproteins also are antigenic, as is the tegument, and immune responses are directed toward these structures.

Just one antigenic type of VZV has been identified. Three major genotypes of wild-type VZV have been described, usually referred to as European (E), Japanese (J, for strains homologous to the Oka parental vaccine strain), and Mosaic (M, for strains displaying a combination of European and Japanese genotype-like mutations).[17,128,162,182] In 2001-2002, an analysis of 130 clinical specimens from varicella cases in the United States showed that 81.5, 3, and 15.5 percent were genotypes E, J, and M, respectively.[162]

Wild-type VZV DNA can be distinguished from that of vaccine-type virus by restriction enzyme analysis of DNA from cultured virus or by polymerase chain reaction (PCR).[4,79,116,127,135,140]

VZV replicates in the nuclei of infected cells, where the DNA core and capsid are synthesized. The capsid is enveloped by a complex process, after which it traverses the cell in cytoplasmic vesicles.[70] In vitro, VZV grows rather slowly and is highly cell associated; its synthetic pathway entraps it in endosomic vesicles, where it is inactivated before it can be released from cells in infectious form. In vivo, however, infectious VZV is released from cells of the superficial epidermis and is highly contagious; VZV avoids the endosomal route in this particular tissue because of the loss of its receptor and thereby exits cells by the secretory pathway.[36]

VZV has an extremely limited host range and infects mostly primates. Hairless guinea pigs may be infected with VZV; the illness produced is extremely mild, and latent infection occurs only infrequently, but specific immune responses can be demonstrated.[141] Rodent models of latent VZV infection have been described.[95,107,137,195] An in vitro model of latency and reactivation of VZV in intestinal neurons from guinea pigs also has been developed.[35]

TRANSMISSION

VZV is spread by the airborne route[119] and requires face-to-face contact with an infected individual for transmission to occur. In varicella, VZV is transmitted mainly from the skin[35]; the respiratory tract cannot be excluded but is not likely to be the usual method of spread. VZV is isolated readily from skin lesions, but isolation of the virus from the respiratory tract is extremely difficult.[78,145,176] Spread of VZV from varicella patients before the onset of rash in closed communities has been reported, however, thus implicating respiratory spread.[80] VZV DNA has been detected by PCR in the nasopharynx of children during the preeruptive and early stages of varicella.[108,146,160] Investigations of leukemic recipients of live attenuated varicella vaccine have implicated spread of VZV from skin. No transmission to siblings from vaccinees who did not have a rash was found, but a 14 percent transmission rate occurred when siblings were exposed to a recently immunized child who had a vaccine-associated rash.[177] The chance of transmission occurring was directly proportional to the number of skin lesions present.[177] Recent observations in children with wild-type varicella despite their having been immunized indicated that higher transmission rates are associated with greater numbers of skin lesions.[164] Finally, an attack rate of more than 20 percent occurred after medical students were exposed to VZV during an autopsy of a patient with disseminated varicella; clearly, this transmission could not have occurred by the respiratory route.[147] Taken together, these observations suggest that VZV spreads mainly from skin lesions rather

than from the respiratory tract. Epidemiologic studies suggest that transmission is most likely to take place in the early stages of varicella.[139]

Zoster is not transmissible per se, but the vesicular lesions of zoster contain infectious VZV and can transmit varicella to other individuals.[26,113] Zoster is less contagious than is varicella,[161] and whether VZV is spread from the respiratory tract of patients with zoster is unknown.

EPIDEMIOLOGY

VZV infections occur worldwide, and both sexes are affected equally. The virus spreads less efficiently in countries with tropical climates than in those with temperate climates,[110] thereby resulting in a high rate of susceptibility in adults reared in tropical countries. In the pre-vaccine era, approximately 3.8 million cases of chickenpox, an entire birth cohort, occurred annually in the United States. In the United States in the pre-vaccine era, 8 to 9 percent of children between the ages of 1 and 9 years contracted the illness annually.[153] These data were collected before the time that many children began to attend daycare facilities; exposure to VZV in the daycare setting may lead to earlier acquisition of disease.

The link between varicella and zoster was recognized first about 100 years ago when Bokay[22] appreciated that cases of varicella often occurred after exposure to a patient with zoster. Early in the 20th century, medical investigators inoculated vesicular fluid from zoster patients into varicella-susceptible children, who then contracted chickenpox.[26,113] Weller[186] first successfully isolated VZV in vitro, gave the virus its name, and demonstrated that the viruses isolated from patients with varicella and zoster are identical. Garland[58] proposed that zoster is the result of reactivation of latent VZV. Hope-Simpson[96] presciently recognized the importance of the immune system in preventing reactivation of VZV; he postulated that zoster results when immunity to VZV wanes with age. Declining cell-mediated immunity to VZV has been identified as contributing to the development of zoster.[9,90] With the use of molecular techniques for DNA analysis, researchers have established that the DNA of the viruses causing varicella and zoster is the same, and autopsies have revealed that latent VZV is detectable in neurons of the sensory ganglia of individuals with a past history of varicella.[44,130,133] Zoster is not acquired by contact with patients who have zoster or chickenpox.[63] Zoster develops in approximately 20 percent of the varicella-immune population during their lifetimes.[96]

Varicella is highly contagious; clinical infection develops in 80 to 90 percent of susceptible individuals exposed in a household.[156] Secondary varicella cases in a family usually are more severe than are the primary cases, probably because of intensity of exposure.[150,156] Approximately 75 percent of American adults with no past history of varicella have detectable antibodies to VZV,[118] thus indicating that subclinical varicella can occur. One epidemiologic study suggests that its incidence is approximately 5 percent.[156]

Subclinical zoster also may occur, and zoster with dermatomal pain and no rash has been described (zoster sine herpete). Increases in VZV immune responses and episodes of viremia shown by PCR in asymptomatic individuals suggest that silent reactivation occurs.[66,83,193] Asymptomatic shedding of VZV is not known to occur.

Second attacks of varicella are uncommon but may occur more frequently in the immunocompromised than in immunologically normal individuals.[71,103] Immunologic boosting to VZV occurs commonly on re-exposure to the virus.[7,71] Whether boosting is necessary for long-term maintenance of immunity to VZV is not known for certain.

Adults and children older than 2 years with zoster usually have a history of a previous attack of varicella.[96] Zoster is an unusual event in children, but the incidence is increased in young children who had varicella either in utero or before reaching their second birthday.[50] Chickenpox in the first year of life increases the risk for development of childhood zoster by a relative factor between roughly 3 and 21,[86] possibly because of immaturity of the immune response to VZV in young infants. Infants with the congenital varicella syndrome are at greatly increased risk, as high as 18 percent in the first few years of life, for the development of zoster.[59]

The incidence of zoster in a population begins to increase sharply at approximately 50 years of age.[96] The loss of cell-mediated immunity to VZV that occurs naturally with normal aging contributes to the increased incidence of zoster,[18,27] and investigators recently have shown that zoster can be prevented by immunization. In a double-blind, placebo-controlled study involving more than 38,000 healthy individuals older than 60 years, immunization with a live attenuated zoster vaccine (Oka strain) reduced the burden of illness of zoster by 61 percent.[144] Zoster also develops with increased frequency in patients with neoplasms and organ transplants[126]; in severely immunocompromised patients with zoster, disseminated infection with viremia also may occur.[53] Spinal trauma, irradiation, and corticosteroid therapy may be additional precipitating factors. Children who are infected with human immunodeficiency virus (HIV) and have $CD4^+$ levels less than 15 percent when varicella develops are at great risk for the development of zoster; in one published series, the incidence was 70 percent.[64]

On occasion, however, zoster may develop in healthy children or young adults who are not immunocompromised, presumably the result of a transient fall in cell-mediated immunity to VZV caused by a stimulus such as another viral infection or stress. Zoster does not develop in all immunocompromised persons; the deficiency of cell-mediated immunity to VZV is a necessary but not sufficient requirement for this illness. The distribution of lesions in chickenpox, which primarily involves the trunk and head, is reflected in a proportionately greater representation of these regions in the dermatomal lesions of zoster.[171] Zoster may recur, in either the same or a different dermatome; the chance of developing recurrent zoster is similar to the chance of having a first attack for a particular age group and is reported as occurring in 2 to 5 percent of adults.[96,154]

Varicella occurs most commonly in the winter and early spring. In contrast, zoster occurs at equal rates during all seasons of the year.

PATHOGENESIS

The incubation period of varicella ranges from 10 to 23 days (average, 14 days).[80] During the incubation period, VZV is thought to spread to regional lymph nodes, undergo multiplication, and cause a primary low-grade viremic phase after approximately 5 days that spreads the virus to the viscera, where further multiplication of VZV occurs. This process results in the second and greater viremic phase, which delivers the virus to the skin, where it causes the characteristic rash.[84] VZV can be isolated from blood cultures either a few days before the onset of rash or within 1 to 2 days after onset in immunocompetent children.[11] An alternative pathogenic mechanism, recently proposed, is that VZV reaches keratinocytes soon after infection occurs, by virus-infected $CD4^+$ memory T cells. These memory cells, when uninfected, normally circulate through the skin. In this model, overcoming of innate immunity in skin accounts for the 2- to 3-week incubation period that follows infection.[111,112]

The skin lesions of VZV infection begin as macules and progress rapidly to papules, vesicles, pustules, and scabs. Histologic changes in the skin lesions are similar for chickenpox and zoster. The hallmarks of each disease are multinucleated giant cells and intranuclear inclusions. In varicella, they are localized primarily in the dermis and epidermis, where ballooning degeneration of cells in the deeper layers is accompanied by intercellular edema. As the edema progresses, the cornified layers and basal layers separate to form a thin-roofed vesicle. An exudate of mononuclear cells is seen in the dermis.[2,186] In zoster, in addition to skin lesions that resemble those of varicella, a mononuclear inflammatory infiltrate is present in the dorsal root ganglion of the affected dermatome. Hemorrhagic necrosis of ganglion cells and demyelination of the corresponding axon also may be present.[52,93,130]

Both humoral and cell-mediated immune responses to VZV develop within a few days after the onset of varicella. Peak antibody levels are attained 4 to 8 weeks after onset, remain high for approximately 6 months, and then decline. IgG VZV antibody titers are detectable in healthy adults for decades after recovery from varicella.[74,170,192] After active immunization against varicella develops, antibody titers are lower than after natural infection occurs but persist for as long as 20 years in healthy vaccinees immunized as children.[12,187] Serum IgG, IgA, and IgM develop after both varicella and zoster. Zoster occurs despite high levels of specific antibodies, but significantly higher titers develop during convalescence and are indicative of an anamnestic response to VZV in this secondary infection.[24,179]

Cell-mediated immune responses are thought to play the major role in host defense against the virus. Cell-mediated immunity to VZV can be demonstrated in vitro by stimulation of lymphocytes with VZV antigens,[89,196] by an intradermal skin test,[118] by specific lysis of histocompatible target cells by cytotoxic T cells,[8] and by an enzyme-linked immunosorbent spot assay.[123] Natural killer cell and antibody-dependent cellular toxicity to VZV also has been described.[99] Immune responses of normal subjects with remote clinical evidence of varicella are characterized by occasional high activity in the absence of symptoms, thus suggesting either exposure to VZV with boosting of the immune response or subclinical reactivation of the virus. Cell-mediated immune reactions remain positive for years after a case of varicella, although this response may wane in many individuals older than 50 years.[18,27] The predominant cell in vesicular lesions is the polymorphonuclear leukocyte. Polymorphonuclear leukocytes may play a role in generating interferon in vesicular lesions, which may be a factor in recovery.[172]

Exactly how immunity to varicella and zoster is mediated is unclear. Because patients with isolated agammaglobulinemia do not experience either severe or recurrent varicella, researchers long presumed that cell-mediated immunity is more important in host defense than is humoral immunity. We now recognize that T-cell cytotoxicity is crucial in recovery from VZV infection.[6] The response or responses that prevent clinical illness after reinfection with VZV are presumed to be those of cytotoxic T lymphocytes, but antibodies also may play a role. Elderly individuals with poor cell-mediated immune responses to VZV are not subject to recurrent chickenpox. In addition, specific antibodies must have some importance because passive immunization is used successfully to prevent or to modify varicella in exposed susceptible persons, perhaps by neutralization of cell-free VZV early in the infection. However, the issues are not straightforward. Varicella may develop in young infants after exposure despite detectable transplacental antibody titers,[14] and modified cases of breakthrough varicella have developed in vaccinated leukemic children despite the presence of humoral or cell-mediated immune responses at exposure to VZV.[72,75] Still, clinical illness is far less likely to develop in individuals with detectable antibody titers or positive cell-mediated immune responses (or both) at exposure to VZV than in those without positive immune responses. Thus, some forms of cell-mediated immunity and specific antibodies each probably play roles in host defense against VZV, and there may be some redundancy in the system.

NOSOCOMIAL VARICELLA

Although it is probably less of a problem since licensure of varicella vaccine, nosocomial varicella is a potentially serious and expensive problem in hospitals, where both patients and employees may be susceptible to chickenpox.[81,88,184] Because varicella-susceptible hospital employees may serve as vectors for the spread of VZV to susceptible patients, serologic testing of employees for immunity to chickenpox if they have no past history of having had clinical varicella and offering vaccine to those who are susceptible are now standard measures in many hospitals.

The risk of horizontal transmission in maternity wards or the newborn nursery after hospital exposure to an adult or child is surprisingly low.[59] A few episodes of nursery transmission of varicella have been reported,[56,65,87] but the low incidence of such transmission may be, at least partly, a result of the fact that many infants are in isolettes. Furthermore, most hospital employees and most mothers and their newborn infants have antibodies to VZV and are at low risk for the development of clinical illness. Even in low-birth-weight infants, antibodies to VZV may be detectable.[136,155]

CLINICAL MANIFESTATIONS

VARICELLA

Varicella is a highly contagious, usually self-limited systemic infection characterized by fever and a generalized pruritic rash lasting approximately 5 days. A prodromal phase in children is unusual, but malaise and fever for 1 to 2 days before the onset of rash is a common manifestation in adults.[39] The rash is more intense on the trunk and head than on the extremities, and it typically evolves as a series of "crops" during the course of 1 to 2 days in normal hosts. Most children with varicella have 250 to 500 superficial skin lesions, many of which are vesicular (Fig. 174–1).[156] Not uncommonly, a few lesions may develop in the mouth, conjunctiva, or other mucosal sites. Residual scarring is exceptional but can occur, and depigmented areas of skin may occur in dark-skinned patients. A self-limited increase in hepatic transaminase levels without jaundice is not an uncommon occurrence during varicella.[149] Rarely, thrombocytopenia and neutropenia may transiently occur. Severe infections are more likely to develop in adults than in children, presumably because of less robust cell-mediated immune responses to VZV in adults than in children.[60,142] Newborn infants who acquire varicella from their mothers in the few days before delivery also are at risk for acquisition of severe varicella because of immaturity of the cell-mediated immune response.[59]

Complications of Varicella

The most frequent complication of varicella in normal hosts is bacterial superinfection of the skin, lungs, or bones, most often by *Staphylococcus aureus* or group A beta-hemolytic streptococci.[25,194] Central nervous system complications, which may precede or follow varicella, include transient cerebellar ataxia, severe cerebral encephalitis, aseptic meningitis, and transverse myelitis.[101,102] Encephalopathy as a sequela of Reye syndrome has become a rare complication because aspirin no longer is recom-

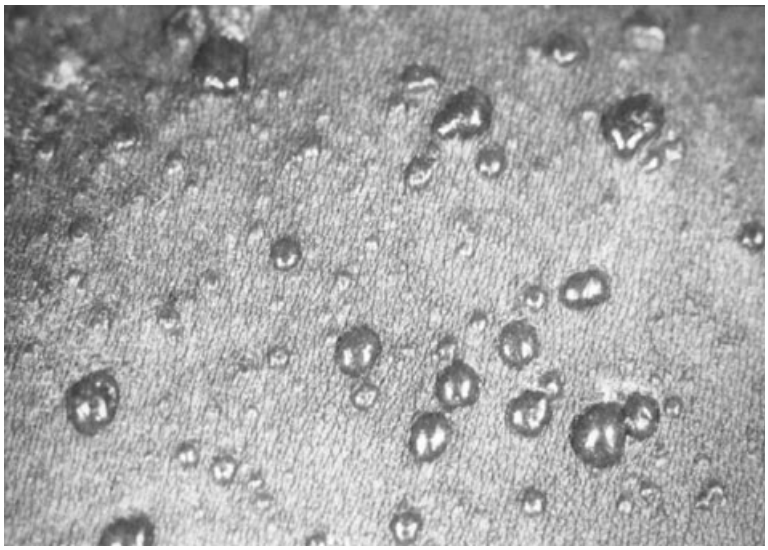

Figure 174–1 Typical skin lesions of varicella.

Figure 174–2 Progressive varicella in a 9-year-old child with underlying leukemia.

mended for children with varicella. Other complications of chickenpox encountered less commonly include arthritis, glomerulonephritis, myocarditis, and purpura fulminans.[186]

Varicella may be severe and even fatal in immunocompromised patients, including those with an underlying malignant neoplasm or congenital or acquired deficits in cell-mediated immunity, such as patients who have undergone organ transplantation or have underlying HIV infection, and in children receiving high doses of corticosteroids for any reason (Fig. 174–2).[55] These patients may be susceptible to progressive varicella, with continuing fever and the development of new vesicular lesions for 2 weeks or longer. Their skin lesions characteristically are large, umbilicated, and hemorrhagic, and primary varicella pneumonia is a frequent complication. Alternatively, in some immunocompromised patients, an acute form of varicella with disseminated intravascular coagulation develops and is rapidly fatal, at times before antiviral therapy can be instituted. A 30 percent rate of dissemination with a 7 percent fatality rate was reported in leukemic children in whom chickenpox developed in the pre–antiviral drug era.[54] Severe varicella has been observed in children with underlying HIV infection, especially those classified as having acquired immunodeficiency syndrome (AIDS).[104] In most HIV-infected children, however, mild to moderate forms of varicella develop, although the illness generally is more severe than that in otherwise healthy children.[64] Varicella does not seem to be a cofactor for clinical progression of HIV infection to

AIDS, but in approximately 5 percent of these children, chronic wartlike hyperkeratotic VZV lesions may develop, presumably being a chronic form of zoster in which the infection is low grade but persistent.[5]

Primary varicella pneumonia accounts for many of the fatalities ascribed to varicella, particularly in immunocompromised patients, adults, and neonates.[148] In male military recruits with varicella, radiographic evidence of pneumonia was found in 16 percent.[185] Symptoms include fever, cough, and dyspnea. Other common symptoms and signs are cyanosis, rales, hemoptysis, and chest pain. The chest radiograph typically reveals a diffuse nodular or miliary pattern, most pronounced in the perihilar region.[175] Blood gas analyses and pulmonary function tests indicate a diffusion defect that may persist in some cases for months after recovery.[21] The availability of antiviral chemotherapy has improved greatly the outcome of this complication.

Congenital Varicella Syndrome

LaForet and Lynch[115] in 1947 were the first to describe an infant with multiple congenital anomalies after contraction of maternal chickenpox. The infant had hypoplasia of the right lower extremity, clubfoot, absent deep tendon reflexes on the right, cerebral cortical atrophy, cerebellar aplasia, chorioretinitis, torticollis, insufficiency of the anal and vesical sphincters, and cicatricial cutaneous lesions on the left lower extremity, which are now recognized to be typical. In 1974, Srabstein and colleagues[169] rediscovered this syndrome. Their report of another case and review of the literature concluded that although the virus could not be isolated from affected infants, the congenital syndrome consisted of a typical constellation of birth defects as originally described by LaForet and Lynch. This syndrome occurs after maternal VZV infection develops in the first or second trimester of pregnancy; approximately 2 percent of the offspring of pregnancies complicated by varicella are affected. Approximately 100 affected infants have been described in the literature; 95 percent occurred after maternal varicella and 5 percent after maternal zoster. In the pre-vaccine era, approximately 40 affected infants were thought to be born annually in the United States.[59]

Cicatricial scars of the skin, the most prominent stigmata, are reported in more than 60 percent of cases.[59] Other frequent abnormalities include chorioretinitis, microphthalmos, Horner syndrome, cataract, nystagmus, hypoplastic limbs, cortical atrophy or mental retardation (or both), and early death. Many of these children develop zoster (in which VZV can be identified) in the early months of life.

ZOSTER

Zoster usually begins as a localized unilateral vesicular skin eruption involving one to three dermatomal segments (Fig. 174–3). The skin lesions resemble those of varicella but tend more toward confluence and are likely to be painful or pruritic, especially in adults. Zoster generally is a milder disease in children than in adults.

Complications of Zoster

Between 25 and 50 percent of persons older than 50 years in whom zoster develops may experience protracted pain, or postherpetic neuralgia, after healing of the rash. Postherpetic

Figure 174–3 Zoster in an otherwise healthy 10-year-old boy.

neuralgia also develops frequently in immunocompromised patients. Pain may persist for months to years and is described as aching, jabbing, or boring. The cause of postherpetic neuralgia is unknown. Children rarely experience postherpetic neuralgia; both the incidence and duration are related directly to increasing age.[76,77] Zoster may be particularly severe and common after bone marrow transplantation; in the first year after undergoing transplantation, 20 to 70 percent of recipients develop zoster.[61]

DIAGNOSIS

CLINICAL DIAGNOSIS OF VARICELLA AND ZOSTER

It usually is not difficult to establish a clinical diagnosis of VZV infection because the vesicular rash is so characteristic. In questionable cases of varicella, epidemiologic information, such as a history of recent exposure to varicella or zoster and subsequent transmission of varicella to another person, may be useful. The differential diagnosis of varicella includes generalized HSV infection, rickettsialpox, impetigo, allergic reactions including Stevens-Johnson syndrome and poison ivy, and insect bites.

In one study of zoster, 13 percent of clinically diagnosed cases were proved by culture to be caused by HSV infection.[105] The unilateral rash of zoster most frequently appears on the trunk or face. The trigeminal nerve, most commonly the ophthalmic branch, is an especially significant site because the eye may be involved.

LABORATORY DIAGNOSIS

Laboratory diagnosis of VZV infection is facilitated by the presence of VZV in superficial skin lesions, where it is easily accessible for testing. The diagnosis is made best by the demonstration of specific viral antigens in skin scrapings by immunofluorescence with a commercial monoclonal antibody to VZV that is conjugated to fluorescein.[62] This diagnostic method is highly sensitive and rapid and can be completed within approximately an hour.

The diagnosis also may be made by isolation of virus from skin lesions. Vesicular fluid for culture should be obtained as early in the course of illness as possible for successful virus isolation. Within several days after the onset of varicella, vesicular fluid no longer is likely to be infectious, although viable VZV may be present in zoster lesions for a longer period, especially in immunocompromised patients. VZV cannot be isolated from skin lesions that have become pustular or dry. Isolation of VZV is a slow method because approximately 48 hours is required before the first signs of a viral cytopathic effect are seen. Virus isolation is less sensitive than is immunofluorescence staining because infectious virus persists for a shorter time in vesicles and is more labile than are viral antigens. VZV rarely is isolated from infected cerebrospinal fluid and respiratory secretions. Isolation of VZV or demonstration of viral antigen in material obtained from skin or other lesions or autopsy tissue is diagnostic of a current infection with VZV because, unlike other herpesviruses, no known carrier state or shedding of VZV by asymptomatic individuals exists.

PCR testing of skin scrapings, vesicular fluid, respiratory secretions, and cerebrospinal fluid has been used successfully to establish the diagnosis of VZV infection.[62] In many virology laboratories, PCR is supplanting culture for diagnosis of VZV infection because it is both more rapid and sensitive. PCR also may be used to distinguish between vaccine (Oka strain) and wild-type VZV infections.[62]

Numerous serologic tests, including the fluorescent antibody to membrane antigen method, latex agglutination, and enzyme-linked immunosorbent assay, are useful for measuring antibodies to VZV.[62] Antibody to VZV develops within a few days after the onset of varicella, persists for many years, and is present before the onset of zoster. VZV infections may be documented by a fourfold or greater rise in VZV antibody titer in acute and convalescent serum specimens. Specific IgM in one serum specimen suggests recent VZV infection. Persistence of VZV antibody beyond 8 months of age is highly suggestive of intrauterine varicella. Immunity to varicella is very likely to be present if an antibody titer to VZV is demonstrated on a single serum sample. However, serologic methods, particularly commercial enzyme-linked immunosorbent assays, may fail to identify individuals who have been immunized.[62,170]

The value of serologic procedures for the diagnosis of zoster is limited. Heterologous increases in antibody titer against VZV in patients with HSV infection who previously had varicella may occur and has been ascribed to antigens common to the two viruses.[62]

TREATMENT

Traditionally, nonspecific measures, such as frequent bathing to discourage bacterial skin infection, antihistamines given orally, calamine lotion applied locally, oatmeal baths to decrease itching, and cutting fingernails short to discourage scratching, have been used to treat varicella. Fever is controlled best with acetaminophen rather than aspirin, which may predispose to Reye syndrome.[91] The issue of whether treatment with ibuprofen is associated with group A streptococcal superinfection in varicella has not been resolved, and, therefore, avoidance of its use for symptomatic treatment of this disease seems to be the best approach.[28,38,121,198]

Useful specific antiviral therapy for VZV became available in the mid-1980s with the introduction of acyclovir, an inhibitor of DNA polymerase and a DNA chain terminator. The antiviral effect of acyclovir depends on its being phosphorylated in the body by virus-induced thymidine kinases, which accounts for its relative lack of toxicity.[190]

Patients with severe or potentially severe VZV infections should be treated with intravenous acyclovir (30 mg/kg/day for adults and adolescents and 1500 mg/m^2/day for children, both given in three divided doses). Orally administered acyclovir is less reliable for immunocompromised patients because only approximately 20 percent of this formulation is absorbed from the gastrointestinal tract, and no data on its efficacy in high-risk patients have been published. Because acyclovir is excreted by the kidneys, patients with a creatinine clearance of less than 50 mL/min/1.73 m^2 should receive one half to one third of this dosage. Intravenous acyclovir is infused for at least 1 hour, with maintenance fluids given both before and during the infusion. Providing adequate hydration is important to prevent renal damage from precipitation of the drug in the renal tubules. Other adverse effects of acyclovir include phlebitis, rash, nausea, and neurologic manifestations such as headache and tremor. In general, however, acyclovir is extremely well tolerated.[190]

Early intravenous therapy should be instituted for patients at high risk for development of severe VZV infection, such as leukemic children and those who have undergone organ or bone marrow transplantation, to prevent the dissemination of VZV.[166,189] Not only may this therapy be potentially lifesaving in immunocompromised patients, but it also prevents considerable morbidity from VZV infection. Children thought to be somewhat less immunocompromised, such as those with HIV infection but without AIDS, may be given a treatment trial with oral acyclovir under close medical supervision. For such patients who are not doing well, intravenous therapy should be started promptly. In zoster patients, the use of intravenous acyclovir is

associated with more rapid healing of skin lesions and resolution of acute pain than if no specific treatment is given.[191]

Considerable controversy has ensued about the role of orally administered acyclovir for the treatment of varicella and zoster in otherwise healthy children because most of these infections are self-limited. Customarily, however, adults, who are at greater risk for development of severe infection, are treated. Oral dosages used are 80 mg/kg/day (in four divided doses) for children and 4 g/day (in five divided doses) for adults. Double-blind, placebo-controlled studies in healthy children given oral acyclovir at 80 mg/kg/day for 5 days or placebo beginning within 24 hours of the onset of varicella rash have revealed that the number of chickenpox skin lesions is reduced significantly by acyclovir. A modest benefit was derived from acyclovir; children who received it had fever for approximately 1 day less, but they did not return to school any more rapidly, nor did they have fewer complications of chickenpox.[16,49]

Some evidence indicates that early administration of oral acyclovir may decrease the acute pain associated with zoster.[98] However, the need to administer specific therapy for zoster in otherwise healthy children for whom pain is not a particular problem rarely occurs.

A newer drug, penciclovir, has an action similar to that of acyclovir.[94] It is administered as famciclovir, a prodrug that when given orally is converted rapidly to penciclovir in the body. A major advantage of famciclovir is that it is administered only three times a day (1500 mg/day for an adult), whereas acyclovir is given four or five times daily. Penciclovir has an antiviral action similar to that of acyclovir. One study suggests that famciclovir given to elderly patients with zoster early in the course of infection decreases the duration of postherpetic neuralgia, although not its incidence.[178] No data regarding whether varicella may be treated successfully with famciclovir have been published, nor have any data on the use of famciclovir in immunocompromised patients or in children.

The prodrug of acyclovir, valacyclovir, also is given orally, reaches blood levels that are approximately three to four times higher than those of acyclovir, and has been shown in one study to be superior to acyclovir for treatment of zoster.[19] Neither valacyclovir nor famciclovir is licensed in the United States for use in children.

Of concern about the potential widespread use of acyclovir is that drug resistance may develop. At present, resistance is less a problem with VZV than with HSV, but VZV resistant to acyclovir has been reported in a few patients with underlying AIDS.[100] A vaccinated child with neuroblastoma and zoster caused by the Oka strain that became resistant to acyclovir after prolonged treatment has been described.[122] Foscarnet was licensed by the Food and Drug Administration for the treatment of VZV infections that are resistant to acyclovir and famciclovir. Foscarnet inhibits the synthesis of VZV DNA polymerase.[157,158,168] Intravenous foscarnet is given at a dosage of 180 mg/kg/day in two divided doses, adjusted according to renal function. The main toxicity of foscarnet is renal damage and electrolyte imbalance.[61]

PROGNOSIS

The prognosis of varicella and zoster is excellent in children without underlying health problems. The outlook for immunocompromised patients receiving antiviral chemotherapy also is good, especially if treatment is begun at an early stage of the illness. In general, zoster carries a better prognosis than varicella does, possibly because it is a secondary infection. If the disease is diagnosed promptly, complications such as bacterial superinfections usually can be treated successfully with antimicrobials. In the pre-vaccine era, despite the availability of antiviral therapy and passive immunization, the Centers for Disease Control and Prevention (CDC) estimated that approximately 100 deaths from varicella occurred annually in the United States, mostly in children with no previous health problems. An epidemiologic study of more than 250,000 health maintenance organization records indicated that the rates of varicella in adolescents and young adults and the complication and hospitalization rates had increased in recent years by a factor of approximately 5.[37]

The widespread use of varicella vaccine in the United States has decreased the morbidity and mortality rates from chickenpox sharply. By 2000, in the three sentinel communities in the United States, vaccine coverage among children 19 to 35 months was more than 80 percent, and reported varicella cases had declined roughly from 70 to 80 percent, compared with the pre-vaccine era. Hospitalizations for varicella also declined by approximately 80 percent. The greatest declines occurred in young children.[143]

PREVENTION

VZV is such an infectious agent that general measures are not useful for prevention of varicella in susceptible individuals. Some protection, however, can be achieved by isolation of hospitalized patients, particularly in rooms with negative-pressure ventilation. Hospitalized patients with active VZV infection should be admitted to a private room, and hospital personnel and visitors should wash their hands before and after entering the room and wear masks, gowns, and gloves while in it. The CDC now recommends postexposure vaccination for healthy varicella-susceptible exposed individuals.[31]

PASSIVE IMMUNIZATION AGAINST VARICELLA

Varicella-susceptible children at high risk for development of severe chickenpox should be passively immunized if they are closely exposed to VZV. Passive immunization may be lifesaving; it may modify varicella or prevent it.

Passive immunization is indicated for varicella-susceptible individuals who have been closely exposed to varicella or zoster and are at high risk for development of severe chickenpox. This population includes immunocompromised children and adults, pregnant women, newborn infants whose mothers have active varicella at the time of delivery, and premature infants of less than 28 weeks' gestation or who weighed less than 1000 g at birth. Children at high risk should be considered to be susceptible to varicella if they have no history of having had chickenpox. False-positive antibody test results may occur in immunocompromised individuals, and, therefore, susceptible children may be identified serologically as immune; hence, a history of illness is a preferred indication of these patients' immune status. Passive immunization usually is reserved for VZV-exposed adults only if they have been proved serologically to be susceptible to chickenpox because most adults with a negative history of varicella raised in the continental United States are immune.

Patients with HIV infection, especially those with AIDS, have some increased risk for development of severe varicella, and their management should be similar to that of immunocompromised children with regard to passive immunization. Even children who are receiving intravenous globulin for treatment of HIV infection should receive passive immunization if they have no past history of varicella and close exposure has occurred.

Infants whose mothers have an onset of chickenpox 5 days or less before delivery or within 48 hours after delivery should be given passive immunization as soon as possible after birth.[59] The transplacental route of infection and the immaturity of the immune system probably account for the severity of varicella in

these infants.[59] Attack rates for varicella as high as 50 percent in infants exposed to mothers who have varicella have been reported, despite their having passive immunization.[59,152] Passively immunized infants should be observed closely, but usually they can be managed as outpatients. Intravenous acyclovir should be reserved for the rare, passively immunized infant with varicella in whom an extensive rash (more than 200 vesicles) or possible pneumonia develops.[15]

Passive immunization need not be given to full-term infants who are exposed to VZV after they are 48 hours old. Passive immunization is optional for newborn infants (<1 week old) if their siblings at home have active varicella. Infants exposed to VZV after birth almost always have mild varicella. Although the reported mortality rate from varicella in children younger than 1 year is four times that in older children, both rates are exceedingly low, 8 per 100,000 cases and 2 per 100,000 cases, respectively.[151] The mortality rate for adults and for leukemic children receiving chemotherapy, in contrast, is 20 and 1000 times higher, respectively.[153] Passive immunization is not useful to treat or to prevent zoster, and whether it is useful for pregnant varicella-susceptible women who have been exposed to VZV to protect the fetus from congenital varicella syndrome is not known.

Until recently, varicella-zoster immune globulin (VZIG), distributed by the Massachusetts Public Health Biological Laboratory and the American Red Cross, was used for passive immunization. Because of limited requests for VZIG since licensure of varicella vaccine in the United States, however, VZIG no longer is being produced. A new product, varicella immune globulin (human), VariZIG, manufactured in Canada, is now available under an investigational new drug application expanded-access protocol.[29] VariZIG can be obtained in the United States, but central institutional review board approval is required, and local institutional review board approval also may be necessary. The sole distributor of VariZIG is FFF Enterprises (800-843-7477), in Temecula, California. An alternative to VariZIG is intravenous immune globulin, 400 mg/kg.

Although passive immunization has been shown to be effective when it is given within 4 days and perhaps as long as 5 days, it should be administered as soon as possible after an exposure to VZV.[29] The dose is 1 vial or 125 units for every 10 kg of body weight, with a maximal dosage of 5 vials or 625 units, intramuscularly. VariZIG should be readministered to high-risk susceptible individuals who are closely re-exposed 3 weeks after a first exposure.[3]

ACTIVE IMMUNIZATION AGAINST VARICELLA

Live attenuated varicella vaccine was developed in Japan more than 30 years ago. It was licensed in the United States in 1995 for universal immunization of healthy children and adults who are susceptible to varicella[32] and has proved to be extremely safe and well tolerated.[20,165] The most frequent adverse reaction is a mild rash that develops several weeks after vaccination in approximately 5 percent of healthy children.[73,74,165,187] These rashes can be serious in immunocompromised children who are vaccinated inadvertently[68,165] but usually respond to antiviral therapy. When healthy vaccinees develop rash from the Oka strain, the potential for transmission of the vaccine virus exists, but transmission is rare, with fewer than 10 known instances from healthy vaccinated individuals after more than 10 years of routine immunization of as many as 40 million American children.[25,85,117,165] In contrast, the rate of transmission of the Oka strain was 14 percent after household exposure from vaccinees with underlying leukemia who had rash and exposed their susceptible healthy siblings.[177] Serious neurologic events have not been causally demonstrated to be connected to varicella vaccine.

Live attenuated varicella vaccine is highly effective in healthy children and adults, but not all vaccinees are completely protected. Approximately 10 to 20 percent of children given one dose may develop a modified breakthrough illness after intimate exposure to VZV. Varicella vaccine has, however, been 97 percent effective in preventing severe varicella.[180,181] The vaccine is also highly effective in adults; after two doses, more than 75 percent of adults are completely protected from varicella after household exposure to the virus.[1,69,73,159] Severe wild-type varicella in vaccinated adults is rare.

Originally, it was observed that approximately 85 percent of healthy children are protected after only one dose of vaccine,[114,180,181,187,188] and there was little concern about breakthrough varicella because it is almost always a modified illness. Loss of VZV antibodies, furthermore, occurs rarely in healthy vaccinated children, some of whom have been monitored for as long as 20 years after immunization.[10,12,40,114,167,183,197]

Beginning in approximately 2000, however, breakthrough varicella became a growing concern in the United States, and investigators suspected that primary or secondary immune failure occurred in some vaccinees. The incidence of varicella in sentinel geographic areas where active surveillance was being carried out revealed that although the incidence of disease fell after 1995, it leveled off at a low rate in about 2000.[163,164] Moreover, the number of reports of outbreaks of varicella among vaccinated children was increasing; some of these studies indicated vaccine effectiveness as low as 44 and 56 percent, although most showed 80 to 85 percent effectiveness.[33,57,120] Also recognized was that children with breakthrough infections could spread wild-type VZV to contacts almost as efficiently as could unvaccinated children.[164] Attempts at outbreak control with second doses of varicella vaccine proved to be expensive and complicated.[134] Finally, one study suggested that the seroconversion rate could be as low as 76 percent, indicating an unexpectedly high rate of primary vaccine failure after one dose of vaccine.[138] The fear was that without a second routine dose, a gradual accumulation of young adult susceptibles would develop as a result of primary vaccine failure and would be at risk to develop severe chickenpox.

In the light of all these problems, a second dose of varicella vaccine was recommended for all children, not just those older than 12 years, by the CDC in June 2006. Early studies exploring immune responses to two doses had indicated the safety of a second dose and a marked boost in immunity and the seroconversion rate afterward. Interestingly, this marked booster effect (by a factor of 10) was observed for the varicella component of measles-mumps-rubella-varicella (MMRV) only. MMRV was approved by the Food and Drug Administration in 2005 for use in children; thus, today, many infants and children are immunized with two doses of MMRV, depends on its availability. Catch-up immunization also is recommended for children who received only one dose of varicella vaccine.

Because the risk from wild-type VZV is greater than is the risk from vaccine-type VZV, immunization is recommended for health care workers and persons whose varicella-susceptible family members are immunocompromised or pregnant.[31] Varicella vaccine is recommended only for healthy persons. Vaccinees in whom an extensive VZV rash develops within 2 to 3 weeks after immunization are likely to have wild-type infection.[165] In such situations, PCR and restriction fragment length polymorphism analysis can be used to differentiate between wild-type and vaccine-type VZV.[79,116,129] Passive immunization could be considered for immunocompromised individuals inadvertently exposed to a vaccinee with rash resembling chickenpox that might be caused by wild-type VZV.

Most states now require varicella vaccination for children to attend daycare or school. In geographic areas where vaccine use in children younger than 3 years is 70 percent or more, the incidence of varicella has decreased sharply, not only in the

vaccinated but in all age groups, a process indicative of herd immunity.[163] Zoster appears to be less of a problem after immunization than after natural infection in vaccinated immunocompromised individuals,[63,67] which suggests that it also will be less of a problem in healthy vaccinees.

DRUG PROPHYLAXIS

Prophylaxis of varicella in exposed persons may be achieved by the administration of acyclovir.[13,97,125,174] This approach is not recommended often, however, because the optimal dosage and timing of administration have not been studied in large groups of children, nor is it known whether long-term maintenance of immunity exists in all children. In the United States, prevention of varicella by vaccination is a preferable approach. Long-term acyclovir therapy may be used to prevent the development of zoster in patients who have undergone bone marrow transplantation; however, its value is questionable because zoster commonly develops after administration of acyclovir is stopped.[30]

CHAPTER 175

SMALLPOX (VARIOLA VIRUS)

James D. Cherry ✪ Samantha Johnston

Smallpox was a dreaded febrile exanthematous disease caused by the orthopoxvirus variola virus.[4,6,8,23,25,37] After an extensive decade-long World Health Organization (WHO) program to eradicate smallpox, the world was certified free of smallpox in 1979.[16,104] Increased concern relating to biologic terrorism occurred during the 1990s, and the events of September 11, 2001, and immediately thereafter brought home the potential reality of this threat for the present and future.[3,23,52,53,56,73,77,94,104]

HISTORY*

Evidence suggests that endemic smallpox was occurring before 1500 BCE. Three mummies dating from the 18th to the 20th dynasties in Egypt had pustular lesions all over their bodies.[37] Reliable written accounts of smallpox first appeared during the fourth century. Smallpox was differentiated from measles in 340 CE by Ko Hung in China. At that time in China, smallpox was an established endemic disease that had come from the west 300 years earlier. During the period from 340 to 1000 CE, the disease was described in Egypt, India, Korea, Japan, southern Europe, and North Africa. A major contributor to the spread of smallpox was the great Islamic expansion across North Africa and into Spain in the seventh and eighth centuries.

By the year 1000 CE, smallpox probably was endemic in populated areas of Europe, Asia, and the African Mediterranean countries. Smallpox was established further in northern Europe by the population movements related to the Crusades. By the 16th century, smallpox was a serious disease in Europe, as indicated by death statistics in Geneva, London, and Sweden. In London during the 17th century, approximately 10 percent of the yearly deaths were attributed to smallpox.

The disease was introduced into the American colonies in 1507 and into Mexico soon thereafter. Epidemics of smallpox posed serious problems for the colonists, as well as for the Native Americans. These epidemics also may have been important in certain stages of the American Revolution.[6,39] Smallpox persisted in the United States and Mexico until the 1940s and 1950s, respectively, despite concerted efforts to eliminate the problem.

Soon after this disease was recognized, the Chinese are reported to have made efforts to prevent it. The technique used presumably was variolation, the intentional intranasal or intracutaneous inoculation of susceptible persons with vesicular fluid or crusts from patients with smallpox. This technique apparently originated in China and subsequently was used in many countries, including the United States. As recently as 1968 and 1969, isolated instances of the use of variolation were noted in remote areas of Africa and Asia.[39,58]

After making his observations in 1796 on the immunity against smallpox that was conferred by inoculation with material obtained from cowpox lesions, Jenner extended his research to include intentional and deliberate exposure of some of those persons immunized with cowpox. This strategy provided convincing evidence of solid protection against smallpox.[62] Encouraged by the results, Jenner predicted in 1801 the ultimate eradication of smallpox, a remarkable prediction indeed.[39,51]

The Intensified Smallpox Eradication Program of the WHO, established in 1967, initiated remarkable progress toward total global eradication of this disease.[55] Several factors responsible for this rapid progress included the following: emphasis on surveillance of disease, with containment rather than routine vaccination; improved vaccines and vaccination technology; and sound administrative and fiscal support.[39,40,54,55,68] Of the more than 30 countries in 1967 in which smallpox was endemic, the disease persisted in only 5 in 1975 and in 2 in 1977. The world's last case of endemic smallpox occurred on October 31, 1977, in Merca, Somalia.[29] A year later, in 1978, a photographer working at the University of Birmingham in England was infected with a laboratory strain of smallpox virus and died.[100]

After the worldwide eradication of smallpox was achieved, the World Health Assembly in 1980 recommended that all countries cease vaccination.[104] Subsequently, a WHO expert committee recommended that all laboratories throughout the world destroy their stocks of variola virus or transfer them into either of two WHO reference laboratories.[56] The laboratories were the Russian State Research Center on Virology and Biotechnology, Koltsovo, Novosibirsk Region, and the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia.[5] Reportedly, all countries complied with this recommendation.

The WHO committee at a later date recommended that all variola virus stocks be destroyed by 1999, and the World Health Assembly concurred with this recommendation.[8] In 1998, a committee of the Institute of Medicine reviewed the possible importance of retaining variola virus for research purposes.[61] In May 1999, the World Health Assembly agreed to postpone the destruction of all variola stocks until 2002.[42] No further date has been set for the destruction of variola stocks.[33,93] At the present time, research using the virus is being conducted in the United States and Russia. This research is related to the development of safer vaccines and to antiviral agents.

In the early 1990s, evidence revealed that during the previous 10 years, the Soviet government apparently had developed a successful program to produce variola virus for use as a biologic weapon.[56,90] In the late 1990s, concern increased with regard to bioterrorism and, in particular, with the possibility that Russian expertise and equipment could have fallen into non-Russian hands because financial support for laboratories and workers had declined.

Smallpox has the dubious distinction of being used as a biologic weapon almost 250 years ago.[30] In the French and Indian Wars (1754 to 1767), British forces sent smallpox-contaminated blankets and handkerchiefs to the Native Americans surrounding Fort Pitt in the summer of 1763.

ETIOLOGY

Smallpox is caused by variola virus, an orthopoxvirus.[38,55,80] The virus particles are brick shaped and measure 250 to 300 × 200 to

*See references 25, 30, 34, 37, 38, 48, 55, 58, 59, 88, 89, 102.

250 × 100 nm; the size and shape are similar for all orthopoxviruses. The distinctive appearance is helpful in rapidly identifying members of this virus group by electron microscopy of vesicular fluid or crusts. The virus is stable when dried and may remain viable for long periods of time in dried crusts and indefinitely under freeze-drying techniques in the laboratory. It is propagated readily on the chorioallantoic membrane of embryonated eggs and in a variety of mammalian cell cultures.

EPIDEMIOLOGY

In infected patients, variola virus was found in respiratory secretions and in vesicular fluid from skin lesions. Transmission usually occurred after close personal contact, but airborne spread also could occur.[7,55,56,101] Patients with smallpox were most infectious from the onset through the first 7 to 10 days of rash.

All persons were susceptible to smallpox unless they previously had been infected with variola virus itself or with cowpox or vaccinia virus. Thus, the occurrence of smallpox depended entirely on the presence of a source of infection and effective exposure of susceptible persons. The age distribution of cases varied in individual countries, depending largely on vaccination practices. Preschool-aged children often were not vaccinated and thus had the greatest prevalence of disease.

The seasonal influence was substantial and perhaps is shown best by the spread of disease after the winter and spring introduction of smallpox into Europe; spread of infection was more than 30 times as great after the introduction of infection into European nations between December and May, in contrast to substantially less frequent spread after introduction between June and November.[60]

Substantial contrast in case-fatality rates was recognized in different geographic areas; these differences did not seem to depend on the supportive care available and did not appear to be related to ethnic or specific resistance factors. The only logical explanation for these different rates was substantial differences in the virulence of the virus prevalent in the regions. The mildest form of smallpox, described as *variola minor*, or *alastrim*, was prevalent in Brazil, Ethiopia, and adjacent countries. Case-fatality rates of 1 percent or less were customary, and permanent residual scarring and blindness were most unusual occurrences. In other areas of Africa and Indonesia, the disease appeared to be of intermediate severity, whereas on the Indian subcontinent, case-fatality rates were as high as 30 percent, with residual permanent scarring, blindness, and other sequelae occurring frequently in those who survived the acute illness.[39]

PATHOLOGY

The characteristic pathologic lesions affected the skin and mucous membranes. They involved the deeper layers of the skin and progressed through macular, papular, vesicular, and pustular stages, with the subsequent formation of crusts. Lesions similar to those on the skin also were found in the lower respiratory and gastrointestinal tracts.

Secondary bacterial infection occurred frequently and often affected the skin and lungs. Hemorrhagic complications (hemorrhagic smallpox) were not uncommon events.

CLINICAL MANIFESTATIONS[34,55,67,79]

After an incubation period of between 7 and 17 days, the disease began abruptly with fever (temperatures between 38.9° C and 40.5° C [102° F and 105° F]), headache, and marked malaise.[9] Backache and muscle pain were prominent symptoms. Nausea, vomiting, and abdominal pain also were present.

After these prodromal signs and symptoms were present for 2 to 4 days, the fever usually decreased, and the characteristic cutaneous eruption appeared. The rash was most extensive on the face and extremities, and the individual lesions passed through the stages of macules and papules; by the third or fourth day, they clearly were vesicular. Lesions in a single area of the body were characteristically at the same stage of development.

By the sixth day, the vesicular fluid usually was cloudy, and the individual pustules frequently were umbilicated. Pustules often converged and become confluent. By the 10th day, the individual lesions began to dry and formed characteristic crusts that remained intact for several days before they were shed. The patient's temperature customarily fell during the early appearance of the rash, although the fever usually returned. Significant fever that persisted after the 10th or 12th day of disease suggested the presence of bacterial superinfection.

Although most cases were similar to this description, which was characteristic of the ordinary type of smallpox, other clinical variations were described. The hemorrhagic type was the most severe form, with a case-fatality rate that approached 100 percent. In this form, hemorrhagic manifestations appeared during the prodromal stage, with extensive cutaneous extravasation of blood and bleeding from the various body orifices. Death usually occurred within the first week of illness, and frequently, few typical diagnostic lesions appeared on the skin surfaces before death ensued. Fortunately, this form of disease occurred in only 2 or 3 percent of the total cases of variola major in Asia, and it rarely was seen elsewhere.

A flat variety had been reported in approximately 6 percent of cases observed in India. In this variety, the cutaneous lesions remained flat and soft to the touch, in contrast to the ordinary variety; these lesions characteristically resolved without pustulation. This form was associated with case-fatality rates of 75 to 96 percent.[39]

A modified form of disease occurred almost exclusively in previously vaccinated persons. Although the prodromal illness often was severe, skin lesions were few, evolved rapidly, and were more superficial. The prognosis was excellent.

The mildest form of the disease, alastrim or variola minor, was caused by a specific variola virus having less pathogenicity in humans. Serious forms of the illness, as with variola major, were unusual occurrences. The skin lesions tended to be superficial, and the clinical course resembled that of varicella, with the exception of the distribution of cutaneous lesions. These lesions involved the face and extremities, in contrast to the characteristic central body distribution of varicella. Residual scarring, if it occurred at all, usually reflected secondary bacterial infection of individual lesions.

In recently vaccinated persons, asymptomatic infection with variola virus after exposure had been demonstrated by increases in antibody titer against the virus when acute and convalescent sera were tested. This uncommon event was of neither clinical nor epidemiologic significance.

Complications included hemorrhagic events and various secondary bacterial infections, including impetigo, pneumonia, empyema, and otitis media. Nephritis and arthritis with permanent joint changes were described.

DIFFERENTIAL DIAGNOSIS

The typical course, the characteristic cutaneous lesions, and the presence of other cases after contact 7 to 17 days earlier left little doubt about the etiologic agent. Varicella presented the greatest problem in differential diagnosis, particularly from the variola minor or alastrim form of the disease, but the distribution of

cutaneous lesions for each condition was characteristic. Generalized vaccinia or eczema vaccinatum was distinguished by a history of exposure to vaccinia virus, previous skin lesions, and the distribution of the rash. Impetigo (especially the bullous variety caused by staphylococcal infection), scabies, secondary syphilis, and yaws were other considerations. Usually, little difficulty was encountered clinically in distinguishing among these infections.

Monkeypox can be clinically similar to smallpox, and, therefore, specific laboratory procedures are required for diagnosis (see Chapter 176). Other conditions included in the differential diagnosis were erythema multiforme, pityriasis rosea, measles, rickettsialpox, disseminated herpes simplex infection, syphilis, enteroviral exanthems, and bacterial, viral, and rickettsial petechial and purpuric rashes.

SPECIFIC DIAGNOSIS

Several laboratory procedures are available to provide specific and accurate diagnosis. Vesicular fluid, crusts, or scrapings from skin lesions reveal the characteristic brick-shaped viral particles of the variola-vaccinia virus group when examined by electron microscopy. These orthopoxviruses differ in appearance from the herpesviruses, which in the past were the agents most frequently confused with smallpox. Electron microscopy is precise and rapid and is preferred when facilities for this examination are available.[26] Smallpox virus DNA also can be identified rapidly by polymerase chain reaction (PCR).[34,35,66,84] PCR has an advantage over electron microscopy in that it can specifically distinguish smallpox virus from the orthopoxviruses.

Orthopoxviruses may be recovered and propagated on the chorioallantoic membrane of embryonated eggs or in tissue culture.[34] Recovery of the virus requires more time (3 to 7 days) than the direct antigen-detection tests do, but it provides the specific active virus required for differentiation among the various orthopoxvirus types.[81,83] Infection also can be determined serologically by using acute-phase and convalescent-phase sera in enzyme-linked immunosorbent assays (ELISA), Western blotting, or virus neutralization assays.[34]

The specific diagnosis of a disease that does not currently exist anywhere in the world presents unique challenges. Recognizing these challenges, the CDC during the last few years developed an overall *Smallpox Response Plan and Guidelines*, available at www.bt.cdc.gov/agent/smallpox/response-plan. Presented in Figure 175–1 is an algorithm that lists the symptoms associated with acute, generalized vesicular or pustular rash illness and categorizes the risk of smallpox according to the patient's signs and symptoms. Figure 175–2 presents a flow chart for laboratory testing of specimens from patients presenting with acute generalized vesicular or pustular rash illness. A two-armed algorithm is presented to reduce the time to receive results and to ensure that testing of high-risk specimens is confined to laboratories with appropriate biosafety levels and expertise. The two arms of the testing algorithm are for (1) specimens from individuals with low- and moderate-risk symptoms and (2) specimens from individuals with high-risk symptoms.

TREATMENT

Therapy primarily was supportive and symptomatic. The skin was kept clean, the bed linen was changed at regular intervals, and local or systemic therapy was provided for the frequent bacterial complications. Attention given to appropriate fluid and nutritional support was required.

Methisazone, convalescent smallpox serum, and vaccinia immune globulin (VIG) were effective in preventing the disease after exposure, but no evidence showed that these agents altered the course of the disease once symptoms occurred.[63] Idoxuridine was used for corneal lesions.[6]

At the present time, methisazone is not available. Stockpiling of VIG is under way in the United States, and intravenous formulations of VIG are being manufactured.[103] Studies with the antiviral cidofovir indicate that this agent may be useful for the treatment of smallpox.[23,79]

PREVENTION

ACTIVE IMMUNIZATION

In the 20th century, many strains of vaccinia virus were used in the effective prophylaxis of smallpox. In 1967, at least 15 strains were in use in various countries.[1] In the late 1960s and 1970s, most vaccinations were performed with the New York City Board of Health (NYCBOH) strain or the Lister (Elstree) strain, which were similar. They were prepared by the freeze-drying (lyophilization) process, and inoculation was performed best with use of a bifurcated needle, with 5 (for primary immunization) to 15 (for re-vaccination) punctures within a small (5-mm diameter) area of the skin of the upper left deltoid region. The vaccination site was not to be covered tightly, although a loose, dry dressing was applied during the height of the reaction for decreasing the possibility of transferring the vaccinia virus by fingers to the eye or to skin lesions, such as insect bites or impetigo lesions. A small but definite risk of developing complications, both local and neurologic, was associated with vaccination.[69,82]

In the late 1990s, concerns arose that smallpox could be used as a weapon of bioterrorism. The events of September 11, 2001 and immediately thereafter highlighted the potential reality of this threat.[3,23,52,53,56,77,94] Estimates were that probably less than 20 percent of the U.S. population had any immunity.[53] These concerns led to recommendations by the Advisory Committee on Immunization Practices (ACIP) for the use of smallpox vaccine to protect persons who may need to work with orthopoxviruses and to prepare for a possible bioterrorism attack.[15] The government took steps to prepare the country in the event of a bioterrorist attack involving smallpox. These measures included building an adequate supply of vaccine and bifurcated needles, enhancing the laboratory capacity for diagnosis of variola and vaccinia virus infection, and training health care and public health personnel.[45]

The current stockpile of vaccine is enough to immunize the entire U.S. population. Studies have shown that the current supply of vaccine is viable and in good titer, although dilution to titers of less than 10^7 may result in a reduced rate of successful vaccination.[43,44]

The primary strategy used to control an outbreak of smallpox and to interdict the transmission of virus has been known as a surveillance and containment (ring vaccination) strategy. This strategy identifies infected persons through intensive surveillance and subsequently both isolates the individuals with the disease and vaccinates household and close contacts of the infected patient. Vaccination also would be recommended under these conditions for contacts of the primary contact with the patient (so-called secondary contacts). This strategy was instrumental in the eradication of smallpox as a naturally occurring disease. Depending on the size of any smallpox outbreak and the availability of resources for rapid and thorough contact tracing, ring vaccination was supplemented previously in areas with identified smallpox cases to include voluntary vaccination of all those individuals without vaccine contraindications. This strategy was pursued to expand the ring of immune individuals within an outbreak area and to reduce further the chance of any secondary transmission of smallpox to patients before they could be identified and isolated.

Available at http://www.bt.cdc.gov/agent/smallpox/diagnosis/rashtestingprotocol.asp.)*

Most recently, the ACIP reconsidered its recommendations for the use of smallpox vaccine. In so doing, the ACIP considered the following factors: the level of disease risk or threat, the expected severe adverse reactions to vaccination, the supply of VIG that may be available, the supply of vaccine, the deployment of vaccine, and the vaccination capacity at state and local levels. In addition to these factors, the following additional assumptions were made: (1) vaccine currently is available only under an investigational new drug protocol and requires appropriate informed consent, patient follow-up, and oversight administratively by federal, state, and local public health officials; (2) based on the information available at the time of the ACIP meeting, the risk of smallpox as a result of deliberate release by terrorists was considered low but not zero; (3) the epidemiology of person-to-person transmission after bioterrorism release of smallpox would be consistent with prior experience; (4) vaccinia vaccine and vaccine immune globulin would be available for use in sufficient supply and would be handled and administered appropriately; and (5) appropriate screening for contraindications to vaccination would be implemented and would include both vaccinated persons and their contacts, and recommended precautions would be taken to minimize the risks of adverse events among vaccinees as well as among their close contacts; (6) healthcare workers and others would be afforded protection from infection through

implementation of appropriate infection control measures, including use of appropriate personal protective equipment; and (7) surveillance and containment would be considered the strategy for control and containment of smallpox, and, furthermore, state and local health departments were presumed to have the capacity to vaccinate the entire population of their areas within a period of several weeks if so indicated.

The CDC developed protocols to permit rapid, simultaneous delivery of smallpox vaccine to every state in U.S. territory within 12 to 24 hours. Smallpox response planning at the federal level

has been conveyed to state and local health departments to address the rapid distribution of the vaccine if vaccination programs are suggested.

The CDC currently recommends that cases of febrile rash illnesses for which smallpox is considered in the differential diagnosis be reported immediately to local or state health departments, or both. After evaluation is performed by local or state health departments, if smallpox laboratory diagnostics are considered necessary, the CDC Rash Illness Evaluation Team should be consulted at 770-488-7100 or 404-639-2888. At this time, laboratory confirmation for smallpox is available routinely only at the CDC. Both a clinical consultation and a preliminary laboratory diagnosis can be completed within a period of 8 to 24 hours.

To assist public health and other medical personnel in evaluating the possibility of smallpox in patients who present with febrile rash illnesses, the CDC developed a rash illness assessment algorithm. Copies of this algorithm are available from state health departments and may be viewed on the CDC Web site at http://www.cdc.gov/agent/smallpox/diagnosis/nskalgorithm. Updated additional information can be found on the CDC interim smallpox response plan and guidelines at the following Web site: http://www.bt.cdc.gov/agent/smallpox.

Medical evaluation of the current risks of acquiring smallpox under current conditions and in the absence of a case of smallpox or a confirmed smallpox bioterrorism threat compared with the potential risks of developing vaccine complications was such that the ACIP concluded that vaccination of the general population was not recommended because the potential benefits of vaccination did not outweigh the risks of vaccine complications. In 2001, the ACIP recommended smallpox vaccine for laboratory workers who directly handle (1) cultures or (2) animals contaminated or infected with vaccinia, recombinant vaccinia viruses, or other orthopoxviruses that infect humans (e.g., monkeypox, cowpox).[15] Other health care workers (e.g., physicians, nurses) whose contact with these viruses is limited to contaminated material (e.g., dressings) but who adhere to appropriate infection control measures are at lower risk of inadvertently acquiring infection than are laboratory workers. However, because a theoretical risk of developing infection does exist, vaccination may be considered for this group. Because of the low risk of developing infection, vaccination is not recommended for persons who do not handle virus cultures or materials directly or who do not work with animals contaminated or infected with these viruses. According to available data on the persistence of neutralizing antibody after vaccination, persons working with vaccinia, recombinant vaccinia viruses, or other non-variola orthopoxviruses should be re-vaccinated every 10 years.

In 2003, the ACIP and the Healthcare Infection Control Practices Advisory Committee (HICPAC) published supplemental recommendations for using smallpox vaccine in a pre-event vaccination program.[17] A summary of these recommendations is presented here:

To facilitate preparedness and response, smallpox vaccination is recommended for persons designated by public health authorities to conduct investigation and follow-up of initial smallpox cases that could necessitate direct patient contact. The ACIP recommends that each state and territory establish and maintain more than one smallpox response team. The ACIP and the HICPAC recommend that each acute-care hospital identify health care workers who can be vaccinated and trained to provide direct medical care for the first smallpox patients requiring hospital admission and to evaluate and manage patients who are suspected as having smallpox. When feasible, the first-stage vaccination program should include previously vaccinated health care personnel, to decrease the potential for adverse events. Additionally, persons administering smallpox vaccine in this pre-event vaccination program should be vaccinated.

Smallpox vaccine is administered by using the multiple-puncture technique with a bifurcated needle, packaged with the vaccine and diluents. According to the product labeling, two to three punctures are recommended for primary vaccination and 15 punctures for re-vaccination. A trace of blood should appear at the vaccination site after 15 to 20 seconds; if no trace of blood is visible, an additional three insertions should be made by using the same bifurcated needle without reinserting the needle into the vaccine vial. If no evidence of vaccine take is apparent after 7 days, the person can be vaccinated again.

Optimal infection control practices and appropriate site care should prevent transmission of vaccinia virus from vaccinated health care workers to patients. Health care personnel providing direct patient care should keep their vaccination sites covered with gauze in combination with a semipermeable membrane dressing to absorb exudates and to provide a barrier for containment of vaccinia virus to minimize the risk of transmission; the dressing should also be covered by a layer of clothing. Dressings used to cover the site should be changed frequently to prevent accumulation of exudates and consequent maceration. The most critical measure in preventing contact transmission is consistent hand hygiene. Hospitals should designate staff to assess dressings for all vaccinated health care workers. When feasible, staff responsible for dressing changes for smallpox health care teams should be vaccinated; all persons handling dressings should observe contact precautions. Administrative leave is not required routinely for newly vaccinated health care personnel, unless they are physically unable to work as a result of systemic signs and symptoms of illness, have extensive skin lesions that cannot be adequately covered, or are unable to adhere to the recommended infection control precautions. Persons outside the patient care setting can keep their vaccination sites covered with a porous dressing; hand hygiene remains key to preventing inadvertent inoculation.

The U.S. Food and Drug Administration recommended that recipients of smallpox vaccine be deferred from donating blood for 21 days or until the scab has separated. Contacts of vaccinees, who have inadvertently contracted vaccinia, also should be deferred from donating blood for 14 days after complete resolution of their complication.

CURRENT SMALLPOX VACCINE

The smallpox vaccine currently licensed and used in the recent vaccination efforts in the United States is a lyophilized preparation of infectious vaccinia virus produced in the 1970s (Dryvax; Wyeth Laboratories; available from the CDC). The vaccine was prepared from calf lymph with a seed virus derived from the NYCBOH strain of vaccinia; it has a concentration of 10^8 pock-forming units (pfu) per milliliter. Vaccine is administered by using the multiple-puncture technique with a bifurcated needle.[17] The CDC is holding three other formulations in reserve: another previously manufactured vaccine from Sanofi Pasteur, as well as two newly developed vaccines: ACAM1000, which is grown in human embryonic lung cell culture (MRC-5), and ACAM2000, which is grown in African green monkey cells (VERO).[18]

After percutaneous administration of a standard dose of smallpox vaccine, neutralizing or hemagglutination-inhibition antibody develops in more than 95 percent of primary vaccines (i.e., persons receiving their first dose of vaccine) at a titer of 1:10 or higher.[21] Neutralizing antibody titers of 1:10 or higher are found in 75 percent of persons for 10 years after receipt of two doses and for up to 30 years after receipt of three doses of vaccine.[32,74] The level of antibody required for protection against vaccinia infection is not known. However, when the response to re-vaccination is used as an indication of immunity, fewer than 10 percent of persons with neutralizing titers of 1:10 or higher exhibit a primary-type response at re-vaccination as compared

with more than 30 percent of persons with titers of less than 1:10.[76]

In the present era with concerns relating to smallpox as a bioterrorism agent, more precise knowledge about the duration of immunity in previously vaccinated persons is critical.[22] In this regard, a study performed in Liverpool, England, in 1902 to 1903 is of interest. In this study, researchers found that the smallpox case-fatality rate in adults older than 50 years who had been vaccinated in infancy was 5.5 percent, whereas it was 50 percent in adults of similar age who had not been vaccinated. Similar, but better, protection was noted in younger adults, and in general, adults who had been vaccinated as infants had less severe disease than did those who had not been vaccinated.

Since concerns were first raised over the country's preparedness in the event of a bioterrorism attack involving smallpox, interest has developed in producing smallpox vaccines that have fewer complications than those associated with Dryvax, that can be generated in tissue culture, and that can be used in patients who are immune-compromised and/or have atopic dermatitis.

Since October, 2002, tissue culture cell vaccines are being prepared by Acambis/Baxter Laboratories. Vero monkey kidney cells and a human fibroblast cell line (MRC5) are used to prepare the vaccine. The NYCBOH strain is the seed virus for both vaccines. Phase II studies of ACAM2000 (prepared in VERO cells) have shown non-inferiority of the 6.8×10^7 pfu/mL concentration when compared with Dryvax in previously unimmunized subjects.[2,78] No significant difference in adverse events between Dryvax and ACAM2000 has been reported. If cell culture vaccines are successful in clinical trials, one will supplant the calf-lymph vaccine.

Alternatives to NYCBOH strains also have received attention. German scientists in the 1950s developed the modified vaccinia Ankara (MVA) strain that had been used in vaccine studies in the 1970s. At that time, attenuated vaccine with MVA was studied with children, adult, and elderly subjects, as well as in subjects with skin conditions, and it demonstrated decreased neurologic virulence as compared with Dryvax and no serious adverse events.[75] Although MVA was never tested in field conditions with naturally occurring smallpox, experts suggested exploring the use of MVA as an alternative to vaccines based on NYCBOH strain because of its decreased virulence in older studies. More recently, phase I trials using an attenuated clone derived from MVA strain 571 (IMVAMUNE) at different titers demonstrated good antibody response as well as few side effects, although the sample size of 86 subjects was small.[97]

Studies also are under way to evaluate recombinant envelope protein subunit vaccines. Several groups[36,41,47,57,85] explored vaccination with recombinant variola virus proteins (intracellular mature virion L1R and A27L and extracellular enveloped virions A33R and B5R). These groups achieved protection against lethal doses of various orthopoxviruses in mice and rhesus macaques.

Response to Vaccination (Fig. 175–3)

A papule develops at the site of vaccination 2 to 5 days after percutaneous administration of vaccinia vaccine to a nonimmune person (i.e., primary vaccination).[18,45] The papule becomes vesicular, then pustular, and reaches its maximum size in 8 to 10 days. The pustule dries and forms a scab that separates within 14 to 21 days after vaccination, and then it leaves a typical scar. Primary vaccination can produce swelling and tenderness of regional lymph nodes, beginning 3 to10 days after vaccination and persisting for 2 to 4 weeks after the skin lesion has healed. Maximum viral shedding occurs 4 to14 days after vaccination, but vaccinia can be recovered from the site of vaccination until the scab separates from the skin.[68,104]

Formation by day 6 to 8 of a papule, vesicle, ulcer, or crusted lesion, surrounded by an area of induration, is referred to as a *major reaction* or a *take*, and it signifies a response to vaccination. It usually results in formation of a scar. Before the eradication of smallpox, persons who had scar formation had lower attack rates when they were exposed to smallpox than did those who had no scar formation. A "take," then, has become a surrogate of smallpox immunity. All other reactions are considered equivocal and raise concern for lack of immunity to smallpox. On the other end of the spectrum of vaccine reactions, 10 percent of first-time vaccinees experience large reactions (>10 cm). These reactions generally do not signify an adverse event and rarely result in secondary bacterial infection.[18]

Side Effects and Adverse Events

The risk of adverse events resulting from smallpox vaccine is presumed potentially to be at least as great, in terms of severity and frequency of events, as during the era when universal vaccinia vaccination was performed[18,46] (Figs. 175–4 through 175–7). One

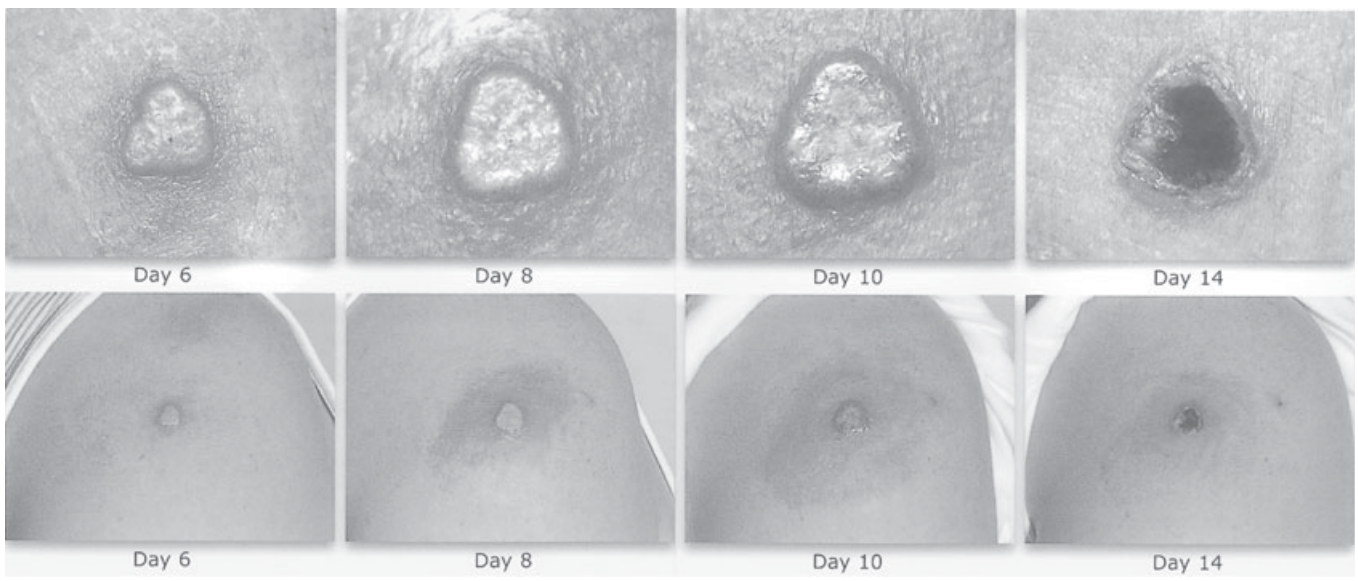

Figure 175–3 **A** to **D**, Typical sequential appearance of the response ("take") following primary smallpox vaccination in a child.

Figure 175–4 Accidental implantation of vaccinia virus, after primary vaccination, by autoinoculation or contact transfer.

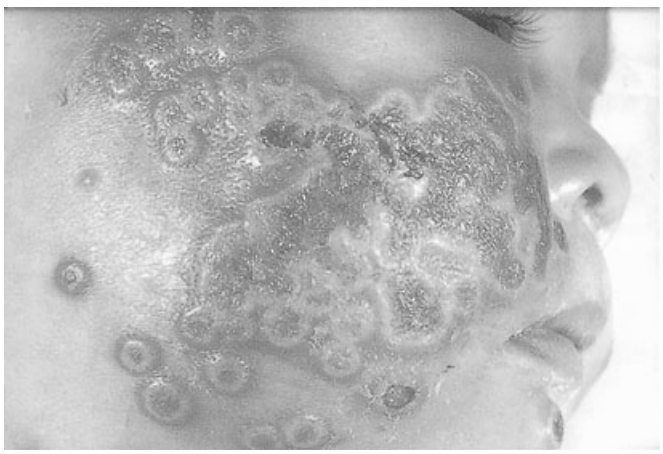

Figure 175–6 Eczema vaccinatum. Accidental implantation of vaccinia virus in a child with eczema.

can suspect that the number of adverse reactions may be increased in frequency in the current era compared with the 1960s and 1970s because a larger proportion of the population of the United States and the world may have an inherited or acquired a form of immunodeficiency or may be receiving a variety of agents that suppress the immune system. Factors thought to predispose to development of adverse events include pregnancy or breast-feeding, extensive skin eruptions, atopic dermatitis, T-cell immune defect, immunosuppressive therapy, inflammatory or disruptive diseases of the cornea, and age younger than 1 year.[18]

Fever occurs commonly after smallpox vaccination. As many as 70 percent of children have 1 or more days with a temperature of 37.8° C (100° F) or higher 4 to 14 days after receiving primary vaccination,[21,76] and 15 to 20 percent have temperatures of 38.9° C (102° F) or higher. After receiving re-vaccination, 35 percent of children have temperatures of 37.8° C (100° F) or higher, and 5 percent have temperatures of 38.9° C (102° F) or higher.[76] Fever after vaccination or re-vaccination occurs less commonly in adults than in children.

An erythematous or urticarial rash may occur approximately 10 days after receipt of primary vaccination. The vaccinee usually is afebrile, and the rash resolves spontaneously within 2 to 4 days. Rarely, bullous erythema multiforme (Stevens-Johnson syndrome) occurs.[67]

Inadvertent inoculation at other sites, the most frequent complication of vaccinia vaccination, accounts for approximately half of all complications of primary vaccination and re-vaccination. Inadvertent inoculation usually results from autoinoculation of

vaccine virus transferred from the site of vaccination. The most common sites involved are the face, eyelid, nose, mouth, genitalia, and rectum. Most lesions heal without specific therapy, but VIG may be useful for cases of ocular implantation (see "Treatment of Complications of Smallpox Vaccine").

Generalized vaccinia in persons who have no underlying illness is characterized by a vesicular rash of varying extent. The rash generally is self-limited and requires little or no therapy, except in patients whose conditions appear to be toxic or in those who have a serious underlying illness.

Other expected systemic symptoms associated with smallpox vaccination include malaise, myalgia, headache, chills, nausea, and fatigue (0.3-37%).[43,44] Soreness at the site of the vaccination is a very common development, as are local lymphadenopathy and erythema surrounding the vaccination site.[45]

Expected local events occurring relatively infrequently require symptomatic treatment. They include satellite lesions within 2.5 cm of the primary lesion, viral lymphangitis, local edema, and intense inflammation surrounding the papule.[43-45]

More severe complications of vaccinia vaccination include eczema vaccinatum, progressive vaccinia, myopericarditis, and post-vaccinial encephalitis. These complications, with the exception of myopericarditis, occur at least 10 times more often among primary vaccinees than among re-vaccinees and more frequently among infants than among older children and adults.[70-72]

The number of adverse events per million doses of primary smallpox vaccination and re-vaccination is reported in Table 175–1. The rates described are based on surveys of vaccination-associated complications that occurred in the late 1960s in the United States. Whether the growth of vaccine in tissue culture rather than on calf skin will change the neurotropism of vaccinia virus is not known. The high prevalence of immunosuppression in the United States today as compared with the late 1960s may render the rates of vaccinia necrosum higher than in 1968. The rate of post-vaccinial encephalitis in adults was difficult to document in the 1960s because very few adults were primary vaccinees. Studies performed in Europe showed higher rates of post-vaccinial encephalitis in adults than in young children. Studies performed since 2002, when efforts were made to vaccinate members of the military and civilians, have shown similar rates of adverse reactions, although cardiac side effects have been more notable (Table 175–2).

Eczema vaccinatum is a localized or systemic dissemination of vaccinia virus in persons who have eczema or a history of eczema and other chronic or exfoliative skin conditions (e.g., atopic dermatitis). The illness often is mild and self-limited but may be severe and occasionally fatal. The most serious cases in vaccine recipients occur in primary vaccinees and appear to be independent of the activity of the underlying eczema.[98] Severe cases also have been observed after contact infection has occurred.

TABLE 175–2 Number of Reported Events Associated with Smallpox Vaccination in the Military: 2002 to 2007

Event Type	Department of Defense Experience*	Grabenstein and Winkenwerder†
Inadvertent inoculation	61	Self: 48 Transfer to contact: 21
Generalized vaccinia	43	36
Eczema vaccinatum	1	0
Progressive vaccinia	0	0
Myopericarditis	140	37
Ischemic heart disease	16	N/A
Encephalitis	N/A	1
Treated with VIG	6	N/A
Death‡	8	0

**Department of Defense experience: December, 2002 to May, 2007, 1,200,000 million vaccinees.[28]*
†Experience of U.S. military: December, 2002 to May, 2003, 450,293 vaccinees.[50]
‡After review, one death was the result of an acute lupus-like illness that may have been caused by the vaccine, and others were thought to result from other causes.[28]
NA, not applicable; VIG, vaccinia immune globulin.

Progressive vaccinia (vaccinia necrosum) is a severe, potentially fatal illness characterized by progressive necrosis in the area of vaccination, often with metastatic lesions. It occurs almost exclusively in persons with cellular immunodeficiency.

More recent experience with vaccination highlights how rare the incidence of eczema vaccinatum and progressive vaccinia are when a population is screened for susceptible individuals. Among more than 1,200,000 persons vaccinated through the U.S. Department of Defense, only a single case of eczema vaccinatum occurred, and no cases of progressive vaccinia were reported.[28,50,96]

In the 1960s, cardiac complications were reported but were not considered significant. Myopericarditis now is thought to be a true adverse event related to smallpox vaccine, although most cases resolve without further complications.[10,31] Cases of ischemic heart disease occurring after receipt of smallpox vaccination also have been reported. Although this association has not been shown to be causal, the ACIP recommended excluding persons with

cardiac disease from participation in current smallpox vaccination programs.[17] The incidence of cardiac events in children is not known because the recent vaccination program has targeted adults.

The most serious complication is post-vaccinial encephalitis. Usually, it affects primary vaccinees younger than 1 year of age. Fifteen to 25 percent of affected vaccinees with this complication die, and 25 percent have permanent neurologic sequelae.[49,71,72]

Death rarely occurs after receipt of vaccinia vaccination; reports note approximately one to two deaths per million primary vaccinations and 0.1 death per million revaccinations. Death most often is the result of post-vaccinial encephalitis or progressive vaccinia.

Vaccinia may be transmitted when a recently vaccinated person has contact with a susceptible person. In the CDC's 10-state survey of complications of smallpox vaccination, the risk of transmission to contacts was 27 infections per million total vaccinations; 44 percent of these contact cases occurred in children 5 years of age or younger.[72] Since 1980, several cases of contact transmission of vaccinia from vaccinated military recruits have been reported and include six cases transmitted by a single vaccine recipient.[11,13,14]

Since 2001, among 1,200,000 vaccinated military personnel, 61 suspected instances of transfer of vaccinia occurred, 36 of which were laboratory confirmed.[28] This number included two cases of tertiary transfer, one from a service member to his wife and then to their breast-feeding baby, and another among male sports partners.[19,45] Fetal vaccinia occurs rarely (<40 reported cases), but usually it is fatal.[46]

More than 60 percent of cases of contact transmission result in uncomplicated inadvertent inoculation. Approximately 30 percent of these cases result in eczema vaccinatum, which may be fatal.[72] Eczema vaccinatum may be more severe in contacts than in vaccinated persons, possibly because of simultaneous multiple inoculation at several sites.[24,71] Contact transmission rarely results in post-vaccinial encephalitis or vaccinia necrosum.

Precautions and Contraindications

Before administering smallpox vaccine, the physician should obtain a careful history to document the absence of contraindications to vaccination among both vaccinees and household contacts of vaccinees. Special efforts should be made to identify vaccinees and household contacts who have eczema, a history of eczema, or immunodeficiencies. Vaccinia vaccine should not be administered if these conditions are present in a possible recipient or, in most instances, if they are present in household contacts.

Specific precautions and contraindications include a history or the presence of eczema, pregnancy, altered immunocompetence, infection with human immunodeficiency virus (HIV), allergies to vaccine components, underlying heart disease, or three or more major known cardiac risk factors. The reader is referred to the CDC for more complete information on contraindications.[17,18]

Prevention of Contact Transmission of Vaccinia

Vaccinia virus may be cultured from the site of primary vaccination beginning at the time that a papule develops (2 to 5 days after vaccination) until the scab separates from the skin lesion (14 to 21 days after vaccination). During this time, care must be taken to prevent spread of the virus to another area of the body or to another person. Present recommendations state that the vaccination site should be covered at all times with a porous bandage until the scab has separated and the underlying skin has healed.[15] An occlusive bandage should not be used. The vaccination site should be kept dry. When the vaccinee bathes, the site should be covered with an impermeable bandage. Vaccinated health care workers may continue to have contact with patients, including those with immunodeficiencies, as long as the vaccination site is covered and good handwashing technique is maintained.

Semipermeable polyurethane dressings (e.g., Op-Site) are effective barriers to vaccinia and recombinant vaccinia viruses.[42] However, exudate may accumulate beneath the dressing, so care must be taken to prevent viral contamination when the dressing is removed. In addition, accumulation of fluid beneath the dressing may increase the maceration of the vaccination site. Accumulation of exudate may be decreased by first covering the vaccination with dry gauze, then applying the dressing over the gauze.

Studies have shown variable results with respect to vaccinia recovery from dressings. A 2004 study found no difference in the percentage of positive PCR results from bandage site among self-adhesive dressing, gauze with tape, or gauze with porous dressing.[99] However, a similar study by the same researchers found higher rates of vaccinia recovery by culture from gauze dressings versus occlusive semipermeable bandage or foam hydrocellular bandage, although foam dressing resulted in more maceration of the site.[91] One case of autoinoculation occurred in a patient with gauze dressings. Another analysis of vaccination sites covered with adsorbent base with an overlying semipermeable layer saw no cases of secondary vaccinia or autoinoculation, a finding suggesting that this combination may decrease the rates of these events.[92]
